Mites

Susan E. Little, Roberto Cortinas

KEY POINTS

Cheyletiella spp. ('Walking Dandruff')

- First Described: *Cheyletiella parasitovorax* was first described from the fur of rabbits by Megnin in 1878 as the genus *"Cheyletus."* In 1885, Canestrini erected the genus *Cheyletiella.* Robert Smiley described *Cheyletiella yasguri* as a primary infestation on dogs in 1965, and *Cheyletiella blakei* as a new species from cats in 1970.
- Cause: *Cheyletiella yasguri, Cheyletiella blakei* (family Cheyletidae, order Actinedida).
- Affected Hosts: Dogs *(C. yasguri)*, cats *(C. blakei).*
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Direct contact with infested animals or with mites in the environment.
- Major Clinical Signs: Mild to moderate dermatitis, excessive scaling, and alopecia usually along the dorsal aspect of the head, neck, and back. Pruritus may be the primary presenting complaint or, in subclinical carriers of mites, absent.
- Differential Diagnoses: Flea allergy dermatitis, other mite infestations *(Demodex* spp.*, Notoedres cati*, *Otodectes cynotis, Sarcoptes scabiei)*, lice, mosquito allergy, dermatophytosis, bacterial pyoderma, *Malassezia* dermatitis, atopic dermatitis, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: Humans, especially those in frequent contact with infested animals through shared households or animal care teams, are very susceptible to infestation with *Cheyletiella* spp. and may develop pruritus and a papular, erythematous dermatitis, particularly on regions of the body in direct contact while holding infested animals, such as the forearms or abdomen.

Demodex spp. (Hair Follicle Mites, Red Mange, Demodicosis, Demodectic Mange)

- First Described: *Demodex canis* was first described by Leydig in 1859. *Demodex cati* was first described by Megnin in 1877 as *Demodex folliculorum* var. *cati*, and then later as *D. cati* by Hirst in 1919. In 1997, Hillier and Desch described *Demodex injai*, and in 1999, *Demodex gatoi* was described from a cat in Louisiana, United States, by Desch and Stewart. Morphologic variants (e.g., "*Demodex cornei*") have occasionally been described but later synonymized with existing species. Skin lesions and otitis externa caused by unnamed *Demodex* spp. have also been reported.
- Cause: *Demodex canis, Demodex injai, Demodex cati, Demodex gatoi*, *Demodex* sp. (family Demodicidae, suborder Prostigmata, order Trombidiformes).
- Affected Hosts: Dogs (*D. canis*, *D. injai*); cats (*D. cati*, *D. gatoi*, *Demodex* sp.).
- Geographic Distribution: Worldwide, with *D. canis* and *D. cati* reported more commonly and in a wider distribution than the other species.
- Primary Mode of Transmission: Most *Demodex* species are thought to be transferred from dam to offspring early in the neonatal period upon close contact during nursing. Some species (e.g., *D. gatoi*) are contagious and can be transmitted via direct contact among co-housed young or adult animals.
- Major Clinical Signs: Localized demodicosis: focal regions of mild to moderate alopecia and hyperkeratosis, often on the face and usually not pruritic. Generalized demodicosis (juvenile or adult onset): moderate to severe alopecia, erythema, and alopecia with folliculitis and furunculosis; pustules and crusts are often present and secondary pyoderma, which may be pruritic, can lead to sepsis. Lesions develop anywhere on the body, including periorbital, pedal, or associated with otitis externa.
- Differential Diagnoses: Flea allergy dermatitis, other mite infestations (*N. cati*, *O. cynotis, S. scabiei*), lice, mosquito allergy, dermatophytosis, bacterial pyoderma (often present with demodicosis), *Malassezia* dermatitis, atopic dermatitis, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: None known. *Demodex* spp. of dogs and cats are not transmitted to humans.

Sarcoptes scabiei (Itch Mite, Scabies, Sarcoptic Mange)

- First Described: *Sarcoptes scabiei* was first described in 1689 by Bonomo and Cestoni, and is widely considered to be the first known human disease with a confirmed microscopic etiology (Arlian and Morgan, 2017). Mites infesting different hosts are generally regarded as somewhat host-specific varieties of the larger *S. scabiei* species group.
- Cause: *Sarcoptes scabiei* var. *canis* (family Sarcoptidae, order Sarcoptiformes).
- Affected Hosts: Dogs, wild canids, especially coyotes, wolves, and red fox (*Vulpes vulpes*); rarely cats.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Highly contagious through direct contact with infested animals.
- Major Clinical Signs: Intense pruritus, hyperkeratosis, alopecia, self-excoriations. If chronic, weight loss and decreased body condition. Lesions are often most pronounced on the margins of pinnae, lateral elbows, and lateral tarsi. If immunocompromised, profound hyperkeratosis may develop in a condition referred to as "crusted scabies."
- Differential Diagnoses: Flea allergy dermatitis, other mite infestations (*Demodex* spp., *O. cynotis*), lice, mosquito allergy, dermatophytosis, bacterial pyoderma, *Malassezia* dermatitis, atopic dermatitis, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: Humans, especially those in frequent contact with infested animals through shared households or animal care teams, are very susceptible to infestation with *S. scabiei* var. *canis* from dogs and may develop pruritus and a papular, erythematous dermatitis, particularly on regions of the body in direct contact while holding infested animals, such as the forearms or abdomen. However, outbreaks of human scabies that occur in

shared housing (e.g., nursing homes, prisons, dormitories) are caused by *Sarcoptes scabiei* var. *hominis* and are of human origin.

Notoedres cati (Feline Head and Neck Mange)

- First Described: *Notoedres cati* was first described as a small feline *Sarcoptes* sp. by Hering in 1838, and then as a distinct genus and species by Railliet in 1893.
- Cause: *Notoedres cati* (family Sarcoptidae, order Sarcoptiformes).
- Affected Hosts: Cats, wild felids.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Highly contagious through direct contact with infested animals.
- Major Clinical Signs: Intense pruritus, alopecia, and hyperkeratotic crusts, particularly on the pinnae, head, and feet, often presenting with self-excoriation which can be severe.
- Differential Diagnoses: Flea allergy dermatitis, other mite infestations (*Demodex* spp., *O. cynotis*), lice, mosquito allergy, dermatophytosis, bacterial pyoderma, *Malassezia* dermatitis, atopic dermatitis, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: Humans, especially those in frequent contact with infested cats through shared households or animal care teams, are very susceptible to infestation with *N. cati* and may develop pruritus and a papular, erythematous dermatitis, particularly on regions of the body in direct contact while holding infested animals, such as the forearms or abdomen.

Otodectes cynotis (Ear Mites)

- First Described: Ear mites were originally described as *Sarcoptes cynotis* by Hering in 1838 and reclassified as *Otodectes cynotis* by Neveu-Lemaire in 1938.
- Cause: *Otodectes cynotis* (family Psoroptidae, order Sarcoptiformes).
- Affected Hosts: Cats, dogs.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Direct contact with infested animals; transfer particularly common during neonatal period.
- Major Clinical Signs: Otitis externa characterized by otic pruritus, excessive dark cerumen, head shaking, and, in some cases, bloody discharge; mites usually confined to ear canal.
- Differential Diagnoses: Other otic mite infestations (*Demodex* spp.), mosquito allergy, dermatophytosis, otitis externa caused by bacteria or *Malassezia*, atopic dermatitis, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: Although rare, there are a few isolated anecdotal case reports of human infestation with *O. cynotis*.

INTRODUCTION

The term "mites" refers to a large, diverse group of arthropods in the class Arachnida, subclass Acari, and include free-living, commensal, and parasitic species. Closely related to ticks, parasitic mites can cause considerable disease in infested hosts. Knowledge of their preferred hosts, location, collection strategies, and identifying features can assist in diagnosis and selection of effective treatment and control strategies. Most parasitic mites are difficult to observe without a light microscope. As obligate parasites, most common mites remain on the host for the entirety of their life cycle and are transmitted among animals by direct contact; because of this, large populations can develop on susceptible animals. Chiggers (trombiculid mites) are a notable exception and are acquired as larvae from the environment.

CHEYLETIELLA SPP.

ETIOLOGY AND EPIDEMIOLOGY

Cheyletiella spp. are prostigmatid mites that infest the fur and skin of cats, dogs, and rabbits worldwide. The genus is easily recognizable by its distinct, large palpal claws (Fig. 110.1). Identifying *Cheyletiella* to the species level can be challenging. Individual species are not host-specific but have strong host associations, with *Cheyletiella yasguri* most commonly associated with dogs, *Cheyletiella blakei* with cats, and *Cheyletiella parasitovorax* with rabbits. All three species have been reported in human *Cheyletiella* infestations.[1–3]

The mites are intimate ectoparasites, spending their entire life cycle on the host. They have six developmental stages: egg, prelarva, larva, a first and second nymphal stage, and adult.[4] All motile stages are parasitic. Adult females deposit single, elliptical eggs that range in size 190–260 μm by 110–140 μm.[1,5] Eggs are wrapped in finely woven threads attached to the hair shaft approximately 2–3 mm above the base.[5]

The prelarva and larva develop within the egg. The prelarva is a legless, inactive, nonfeeding stage. The larva hatches from the egg and molts through the first (protonymph) and second (deutonymph) nymphal stages before developing in to adults. Adult *Cheyletiella* spp. are yellowish and large, barely visible to the unaided eye. Adult females measure approximately 500 × 315 μm and males measure approximately 350 × 225 μm.[1,5] All parasitic stages have large palpal claws that lie lateral to the mouthparts (gnathostoma) and feather-like appendages (empodia) at the distal extremities of the legs (tarsi) (see Fig. 110.1). The life cycle varies in duration from 21 to 35 days.[3,6–10]

Cheyletiella spp. mites live in the hair of the host and travel to the epidermis to feed on the keratin layer.[4] The mites do not burrow in the epidermis.[3,9] Instead, they pierce the epidermis with their chelicerae to feed on tissue fluids.[3,5] Regardless of humidity or temperature, immature stages and males die within 48 hours of leaving the host, whereas females may be hardier and can live off the host for 10 days if kept in cool conditions.[5]

Transmission of mites is by direct and indirect contact; mites may also be acquired from the environment. Humans are transiently infested and human-mediated transfer among animals is possible. Infestations are contagious among young animals and can spread quickly in multiple-animal situations, such as kennels and catteries. The introduction of a new cat or dog, even if apparently healthy, is a risk factor for infestation of other animals in the household.[11,12] Transmission is likely on fomites, such as brushes and collars. "Phoresy," whereby *Cheyletiella* spp. mites attach themselves to other arthropods for the purpose of travel, has been suggested, including *C. blakei* and *C. parasitovorax* with fleas, and *C. yasguri* with the dog louse fly, *Hippobosca longipennis*.[13-16]

PATHOGENESIS

The feeding of mites on the keratin layer of the epidermis results in a subacute, nonsuppurative dermatitis with slight hyperkeratosis and vacuolization of epidermal cells. Varying degrees of superficial perivascular dermatitis may be observed with nonspecific inflammatory cell infiltrate.[5,12,17] Occasionally, lymphoplasmacytic dermatitis develops. Eosinophils vary from few to many. Mite segments may be present in hyperkeratotic stratum corneum.[10,12]

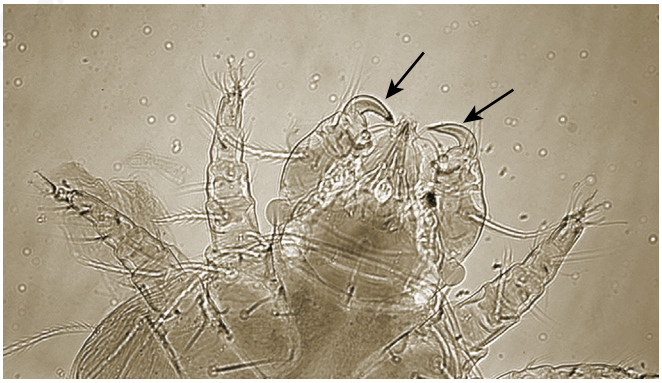

Fig. 110.1 Adult *Cheyletiella* sp., causative agent of "walking dandruff" on dogs, cats, and rabbits, are usually found in superficial hyperkeratotic flakes shed from infested animals. The large palpal claws *(arrows)* confirm the identification. (Courtesy of National Center for Veterinary Parasitology.)

CLINICAL FEATURES

Clinical signs associated with *Cheyletiella* sp. infestation include scaling, crusting, and dermatitis; infestations may not cause clinical signs in some individuals. Skin scaling, characterized by powdery, meal-like scurf or dandruff, is usually observed on the dorsum, particularly in the sacral region.[5,6,18] Scaling may not be obvious in animals that aggressively groom; self-trauma commonly occurs. In severe cases, scaling and mites may be present over most of the body surface. Pruritus can vary from absent to severe.[6,18] The intensity of clinical signs may not be proportionate to the mite density and is thought to be related to a hypersensitivity reaction.[9,12] Infestations on young dogs may be more severe, with older dogs more likely to be subclinical carriers.[3,5]

DIAGNOSIS

Direct Microscopic Examination

Diagnosis of cheyletiellosis is performed by directly visualizing the mites or by microscopic examination of material collected from the infested animal. Evidence of mites moving among debris, often with adherent scales, has given cheyletiellosis the common name of "walking dandruff." Combing is a recommended diagnostic technique but fails to confirm mites in 15% of infested dogs and 58% of cats.[9,19–21] To examine by combing, the haircoat on the back, especially over the sacral area, is parted and a flea comb or brush used to collect scurf; scales and other material are placed on dark paper and examined for movement among the debris. Material can also be transferred to a microscope slide with a few drops of mineral oil, a coverslip applied, and examined microscopically.[19] Other collection methods include using clear tape to examine scurf, superficial skin scrapes, and hair plucks to evaluate for eggs; clipping the hair in long-haired animals may facilitate examination.[22] A modified vacuum technique with in-line filters has been described and was demonstrated to be more efficient than tape preparations, skin scraping, or hair plucking but is not widely available.[9] Fecal flotation may also demonstrate mites and their eggs, particularly in cats that frequently groom.[8]

Regardless of the method employed, finding mites may be difficult.[8,12,21] The number of mites present may be highly variable and low, particularly if the animal is over-grooming or if the area being sampled is small.[8,9,12,21] Combing in combination with other diagnostic tests may yield better results.[9,23] In some cases in which mites are not demonstrated but there is considerable suspicion, empiric treatment may be warranted; in these circumstances, other animals in the household should also be treated.[23]

Comparatively speaking, *Cheyletiella* spp. are one of the larger mites encountered. Adults are yellowish, have a waist-like appearance (more pronounced in females), and very large palps that end with prehensile claws, giving the appearance of an extra pair of legs. An M-shaped peritreme can be observed in the gnathostome, just posterior to the chelicerae. The legs terminate with comb-like appendages (empodia). In addition to the number and arrangement of setae, the shape of the sensory organs (solenidia) on genu I of the legs has been used to identify *Cheyletiella* to species—the organs on *C. yasguri* are heart-shaped, those on *C. blakei* are conical, and *C. parasitovorax* has spherical organs.[4] However, there is much variation in solenidia shape in immature stages, and variation can even sometimes be observed on an individual adult.[4]

Serology

Serologic assays have not been developed to detect *Cheyletiella* spp. antibodies. In one study, protein electrophoresis was used to assess infested dogs, but gammopathy was not demonstrated.[12] Immunologic cross-reactions between *Cheyletiella* spp. and the dust mites *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus* have been documented, a phenomenon also observed with other parasitic mites.[12]

Laboratory Abnormalities

CBCs and chemistry panels from infested animals are generally unremarkable. In one study, mild peripheral eosinophilia was observed in 2 of 23 infested dogs that resolved after treatment.[12]

Gross Pathologic Findings

Scaling, crusting, and dermatitis are commonly seen in animals with cheyletiellosis, although subclinical infestations also occur. Lesions are most evident on the back, particularly over the sacral region. Desquamation results in bran-like exfoliative debris in affected areas. In an uncomplicated case, very little dermatitis or pruritus is observed and alopecia is mild or absent. However, papular, crusting eruptions, scabies-like lesions, alopecia, and severe pruritus can develop due to hypersensitivity reactions.[10,12,24]

TREATMENT AND PROGNOSIS

No products are FDA label-approved for use against *Cheyletiella* mites, but several efficacious off-label treatments have been described. Treatments reported to be effective include transdermal selamectin applied for 3 consecutive months to cats, or every 2 weeks to dogs for four treatments;[8,23] two treatments of transdermal moxidectin (applied in combination with imidacloprid) administered 4 weeks apart also cleared *Cheyletiella* sp. infestations in a group of dogs.[25] Sarolaner was reported to be effective in treating cheyletiellosis in four dogs; other systemic isoxazolines are also expected to be effective.[26] Milbemycin oxime was also effective in treating dogs (2 mg/kg, PO, q7d for 3 to 9 weeks).[12] Although effective when given PO or SC, high-dose, off-label large animal preparations of ivermectin or other macrocyclic lactones are not recommended due to safety concerns; if used, treatment must be continued weekly for as long as 6 to 8 weeks.[19–21]

Topical fipronil has been used with success to treat canine cheyletiellosis using a 0.25% spray, and a 10% (w/v) spot-on was effective for cats.[27,28] Other topical therapies include lime sulfur dips and pyrethroid sprays and shampoos.[22] Amitraz topically at 250 ppm has been

used to treat canine cheyletiellosis but is contraindicated in cats and is not considered the treatment of choice for dogs and canine amitraz products are not available in many areas.[19,29] An alternative topical treatment for cats and dogs is 3-weekly baths with 1.0% selenium sulfide shampoo.[22]

Regardless of the treatment used, continuing to treat for a sufficient period of time is of particular importance. The treatment period may be adjusted to address the severity of infestation, number of animals involved, the product being used, housing conditions, and the possibility of environmental contamination.[20] Because the mites are not highly host-specific and some animals remain subclinical, all animals in a household or facility should be treated simultaneously. Reinfestation from off-host females and eggs is considered possible; accordingly, the environment should be cleaned and treated with products that have acaricidal activity. Bedding and grooming tools should be discarded, washed using hot temperatures, or treated with an acaricide. Diagnostic procedures should be repeated to ensure treatment success, but due to the difficulty of isolating mites and the hardiness of eggs to treatment, therapy should continue for at least 2 to 4 weeks after signs have resolved regardless of the results of examination for mites.[19] Hypersensitivity reactions and accompanying pruritus may be alleviated if miticidal treatment is accompanied by a short course of anti-inflammatory glucocorticoid treatment if not contraindicated. Treatment of cheyletiellosis usually has a good prognosis when all animals can be treated and reinfestation prevented.

IMMUNITY

Studies investigating the immune response during cheyletiellosis have not been reported. Observations that young animals appear predisposed to infestation and that infestations can be self-limiting suggests that immunity develops.[1,3] Severe cases are in all probability the result of hypersensitivity reactions.[12]

PREVENTION

Prevention of cheyletiellosis entails that there is no direct or indirect transmission of the mite. When new pets are introduced to a household, they should be checked for mites and treated. Previously used grooming tools and other fomites should be avoided. Routine use of products effective against *Cheyletiella* spp. (e.g., transdermal macrocyclic lactones, oral or transdermal isoxazolines) would also be expected to limit infestations. Anecdotal observations have been made that in warmer areas where year-round flea control is practiced, the prevalence of *Cheyletiella* spp. mites has substantially decreased.[30]

PUBLIC HEALTH ASPECTS

Pet owners, animal care teams, and others who are in frequent contact with infested animals are susceptible to developing dermatitis associated with *Cheyletiella* spp. Approximately 20%–40% of owners of infested animals are affected.[1–4,7–9,18] Small, pruritic, erythematous papules are most frequently observed on areas of the body that are in contact while holding infested animals, such as the arms, abdomen, or legs.[2,3,7] The lesions develop into vesicles or pustules, and eventually demonstrate central necrosis.[3] Arthralgia and peripheral eosinophilia have been reported in some affected individuals.[31] In some cases, the first indication that a pet is infested may be the owners' dermatitis if the pet is apparently healthy. Mites are rarely recovered from people and do not reproduce on humans; treatment of all animals in the household prevents further lesions from developing.[8]

DEMODEX SPP.

ETIOLOGY AND EPIDEMIOLOGY

Demodex spp. are prostigmatid mites that live primarily in the pilosebaceous unit or the stratum corneum of mammals; mites occasionally venture to the surface and can be transferred between hosts of the same species by direct contact. At present, two species infest dogs and three are reported from cats although additional variants have been described.[32] *Demodex* spp. mites have elongated bodies (Fig. 110.2) that consist of a cranial gnathosoma where the mouthparts are located, a podosoma bearing short, stubby legs, and a caudal opisthosoma; an anus is absent. *Demodex canis* and *Demodex cati* are considered normal commensal fauna ubiquitous on dogs and cats, respectively, live in the hair follicles and sebaceous glands, and are transmitted early in

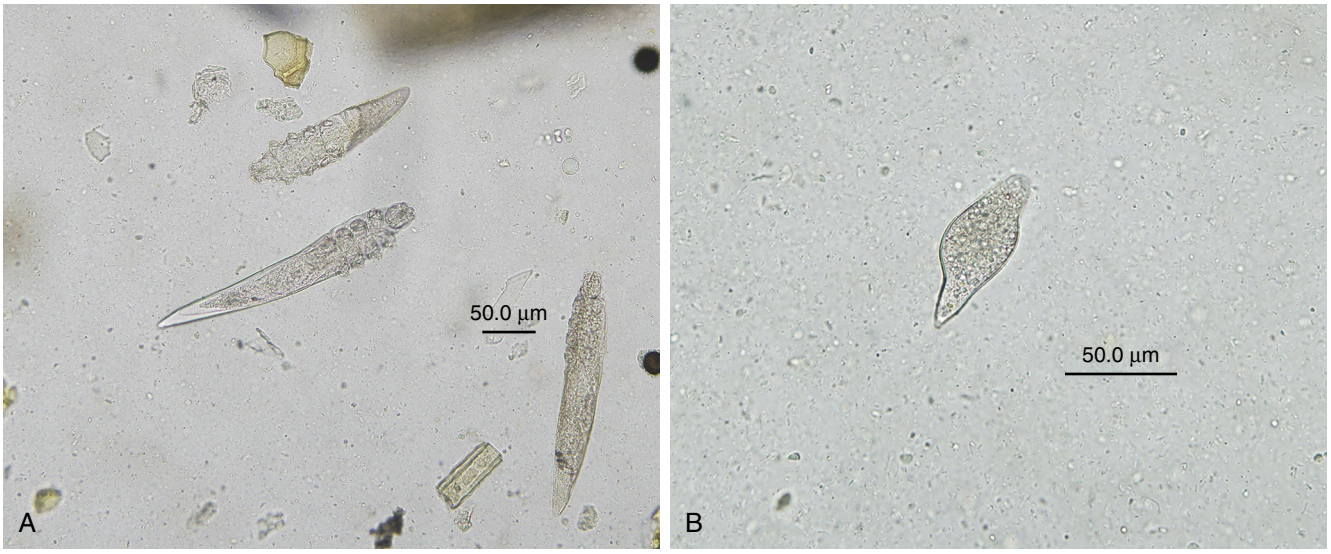

Fig. 110.2 Elongated adults (A) and spindle-shaped egg (B) of *Demodex canis* are readily found on skin scrapes from dogs with generalized demodicosis. (Courtesy of Megan Lineberry, National Center for Veterinary Parasitology.)

life by direct contact from dams to nursing neonates.[33,34] Dogs may also harbor *Demodex injai*, which has a long, thin opisthosoma and is associated with hyperplasia of sebaceous glands and excess sebum production.[32] Cats can be infested with a shorter, unnamed *Demodex* sp., or with *Demodex gatoi*, which is very short and stubby; both primarily infest the stratum corneum.[30]

Demodex spp. females deposit eggs in the infested hair follicles. Larvae hatch from eggs, feed, and molt, developing through two nymphal stages before becoming adults. Comprehensive life history studies on *Demodex* spp. of pets are lacking, but the life cycle is thought to be completed in 14 to 21 days. Females are diploid and males haploid. Infestations with *D. canis* and *D. cati* are considered universal and treatment of contact animals is not required to effectively address cases. In contrast, *D. gatoi* can be transferred between individual cats, and thus this mite should be considered contagious and managed accordingly.[30,32]

PATHOGENESIS

Most *Demodex* spp. mites are commensal organisms, and populations are kept in check by the host immune system; contagious feline *D. gatoi* infestations that spread in multi-cat facilities are the exception.[32] Immune restriction occasionally fails in young, otherwise healthy dogs, and in adult, immunocompromised dogs or cats, allowing mite populations to increase dramatically and leading to clinical disease. In dogs, localized demodicosis and juvenile-onset generalized demodicosis are thought to develop following temporary alterations in CMI; the tendency to develop the condition has a genetic basis.[32] Although the pathogenesis is not fully understood, specific DLA haplotypes have been associated with juvenile-onset generalized demodicosis in some predisposed breeds.[35]

Risk factors associated with juvenile-onset (<1.5 years old) generalized demodicosis in dogs include coccidiosis, hookworm infection, pyoderma, short haircoat, and pit bull-type breed.[36] Although any breed of dog may be affected, including mixed breeds, increased risk of disease has been reported for the American Staffordshire terrier, Staffordshire bull terrier, Chinese shar-pei, French bulldog, English bulldog, pit bull-type dog, boxer, Argentinian mastiff, and Sealyham terrier.[35–37]

Immunocompromising conditions and the use of immunosuppressive therapies are thought to be responsible for adult-onset (>4 years old) canine demodicosis, and for feline demodicosis caused by *D. cati*.[32,33] Conditions associated with adult-onset canine demodicosis include hyperadrenocorticism, hypothyroidism, leishmaniosis, and other vector-borne infections (babesiosis, ehrlichiosis). A history of neoplasia or atopic dermatitis has also been associated with generalized demodicosis but may be related to chemotherapy or glucocorticoid treatment.[32] Wire-haired fox terriers and other terrier breeds are more often reported with disease due to *D. injai* infestation and associated hyperplastic sebaceous glands; affected dogs are older (average age of 8 years) and often have a history of allergy, endocrine disease, neoplasia, or immunosuppression.[38–40]

Predisposing conditions for feline demodicosis caused by *D. cati* include FIV or FeLV infection, hyperadrenocorticism, systemic lupus erythematosus, diabetes mellitus, and xanthoma.[32,33] Localized *D. cati*–associated feline demodicosis has been described with squamous cell carcinoma.[41] Clear breed predispositions have not been identified for feline demodicosis although some consider the condition more common in Siamese and Burmese cats.[30] Infestations with *D. gatoi* can result in pruritis although not all infested cats develop clinical signs.[42] Clusters of feline *D. gatoi* infestations have been reported in multi-cat households involving several breeds and all ages of cats.[42]

CLINICAL FEATURES

Dogs

Dogs with localized demodicosis due to *D. canis* typically exhibit few (1 to 4), small (≤2.5 cm diameter), nonpruritic areas of alopecia and scaling. When localized, the condition is of only minor cosmetic concern. In contrast, dogs with generalized demodicosis can have moderate to severe disseminated skin lesions, deep pyoderma, and systemic illness.[10,32] Juvenile-onset generalized demodicosis develops in dogs less than 1.5 years of age and is considered due to an underlying genetic defect, whereas adult-onset (>4 years of age) is thought to be associated with immunocompromising disease state or administration of immunosuppressive drugs.[43] Mite proliferation in the hair follicles and sebaceous glands leads to large focal or multifocal areas of alopecia, comedone formation, and erythema, with lesions often coalescing over time. Severe pododemodicosis may develop and, when present on at least two feet, is considered indicative of generalized demodicosis even if feet are the only area affected. Follicular hyperpigmentation can be evident. In dogs with mild to moderate demodicosis due to *D. canis* infection but without secondary bacterial infection, pruritus is usually absent. As disease progresses and secondary bacterial or fungal infections establish, associated pruritus may become evident. Over time, deep, pustular pyoderma can develop with draining tracts, lymphadenomegaly, fever, and lethargy; in the absent of treatment, fatality from sepsis can occur.[32] Dogs with demodicosis due to *D. injai* also present with alopecia and an erythematous dermatitis as well as characteristic excessive sebum production dorsally and hyperplastic sebaceous glands.[39]

Cats

Cats with demodicosis due to *D. cati* infection develop localized or generalized areas of alopecia, scale, crusting, and erythema; pruritus is variable and pyoderma is rare.[30] Lesions most commonly appear first on the face and can be associated with otitis externa either as the primary focus of the infestation or as part of a generalized demodicosis.[44] Mite proliferation can also be localized to carcinoma *in situ* lesions. In cats with clinical signs due to *D. gatoi*, pruritus is often the primary owner complaint and other clinical signs (e.g., alopecia) associated with excessive grooming secondary to intense pruritus are often found on the abdomen and thorax. Hypersensitivity appears to develop in some cats infested with *D. gatoi*, while others remain subclinically infected.[32,33,42,44] Due to the contagious nature of *D. gatoi* infestations, many animals in a cattery or multi-cat household may harbor mites or experience clinical disease.[42,45,46]

DIAGNOSIS

Direct Microscopic Examination

Demodex spp. mites are readily recovered from dogs with localized or generalized demodectic mange. Although considered normal fauna, when present together with characteristic pathology and in high enough numbers to readily detect using light microscopic examination of skin scrapings, treatment is indicated. To collect material for microscopic examination, a scalpel blade with a small amount of mineral oil is used to scrape affected areas of skin in the direction of hair growth; application of lateral pressure to a skin fold while scraping increases the recovery of mites. Scrapes should be collected from multiple affected areas, when present. Primary lesions with pustules or alopecia are more likely to have mites than ulcerated areas. Collected material is transferred to microscope slides, coverslips applied, and examined for mites. When

infestations are active, eggs may be numerous and all stages of mites (larvae, nymphs, adults) present; mites are often active in fresh mineral oil preparations.[32]

Other methods useful to examine for mites include clear tape preparations from patients with seborrheic dermatitis; direct examination of purulent material expressed from pustules or draining tracts in dogs with deep pyoderma; and trichograms or hair plucks, which may be preferred for collecting specimens from areas of the face and feet that are difficult to scrape. If using trichograms, many (50–100) plucked hairs should be collected, transferred to a microscope slide with mineral oil, and applied to a coverslip to facilitate examination. When lymphadenomegaly is present, mites may be identified in lymph node aspirates. Otic swabs allow identification of *Demodex* sp. mites associated with otitis externa. Mites ingested by dogs that chew affected skin can also be found on fecal flotation; however, this method alone is not considered a sensitive means of diagnosis.[32,34] In general, recovery of *Demodex* sp. mites is more challenging in cats, and especially from cats infested with *D. gatoi,* which is superficial and may elicit hypersensitivity leading to excessive grooming.[44] Cats that are active groomers reduce mite populations on the skin and may only have mites detected in feces.[46]

To allow mites to be easily visualized, the microscope lighting should be adjusted to optimize contrast by closing the condenser. *Demodex* spp. mites are readily identified by their characteristic shape (Fig. 110.2A); measurements that allow identification of different species are provided in Table 110.1. Eggs are spindle-shaped (Fig. 110.2B) and often recovered on fecal flotation or skin scraping at initial diagnosis before treatment is instituted.[34] The number and stage of mites present in skin scrapings can be used to monitor progress during treatment. As lesions resolve, mite populations will be reduced; only a small number of adults may be found, eggs are rare if present at all, and many mites are dead.[10]

Serology

Serologic assays to confirm demodicosis are not available. Common *Demodex* spp. mites (e.g., *D. canis*, *D. cati*) are considered part of normal flora and infestations universal.

Laboratory Abnormalities

Dogs with generalized demodicosis and deep pyoderma may have anemia of inflammatory disease or an inflammatory leukogram; an elevated concentration of C-reactive protein and haptoglobin, reduced butyrylcholinesterase activity, and reduced paraoxonase-1 activity that normalize with treatment.[47] Cats may have normal hemograms or changes associated with co-morbidities.[33]

TREATMENT AND PROGNOSIS

Dogs

Localized demodicosis usually resolves without treatment within 2 months.[32] If topical treatment is desired, benzoyl peroxide shampoo or gel or rotenone ointment can be used.[32,43] Progression to generalized demodicosis is considered rare and prognosis is excellent. Prescribing transdermal moxidectin and imidacloprid for heartworm, intestinal parasite, and flea control, or an isoxazoline for flea and tick control, would be expected to protect against progression although this approach has not been evaluated experimentally. Dogs with only demodectic otitis externa or pododermatits benefit from acaricidal treatment even though mites and lesions are localized.[32,43]

Dogs with juvenile-onset generalized demodicosis can usually be treated with acaricides and, if indicated, antibiotics for secondary bacterial pyoderma. Underlying conditions are not considered common; further diagnostic testing is not considered necessary and the prognosis for recovery is good.[32] In contrast, adult-onset generalized demodicosis is a more serious condition and successful treatment requires long-term commitment; although most dogs recover with treatment, lifelong therapy may be required in some patients to restrict mite proliferation, particularly if the underlying condition cannot be identified and addressed. Without treatment, fatalities can result, and relapse following treatment is common, particularly when therapy is terminated early.[32]

Successful treatment of adult-onset generalized demodicosis involves a thorough diagnostic evaluation to identify and address any underlying conditions, management of pyoderma when present, and acaricidal treatment of mites. Although recurrence with estrus is considered anecdotal, intact females should be spayed once the skin has healed to allow surgery to both limit recurrence and breeding of susceptible animals. Topical antimicrobial shampoos (e.g., benzoyl peroxide, chlorhexidine) are adequate to manage secondary bacterial infections in most cases; occasionally the severity of pyoderma and risk of sepsis necessitates use of systemic antibiotics. Symptomatic relief may result from acaricidal therapy alone, but recurrence is likely if underlying conditions are not identified and addressed. Continued regular monitoring of the overall health of dogs with adult-onset generalized demodicosis is recommended as underlying conditions not evident at initial presentation may become apparent over time.[10,32,43]

Widely available miticidal treatments include systemic isoxazolines and macrocyclic lactones; all are off-label in the United States. Systemic isoxazolines (afoxolaner, fluralaner, lotilaner, sarolaner) approved in dogs for flea and tick control are effective against generalized demodicosis when administered according to label directions,

TABLE 110.1 Morphology and Preferred Location of *Demodex* spp. Mites from Dogs and Cats

Species	Host	Length (μm)	Approximate Ratio Opisthosoma: Total Length (%)	Description	Preferred Location
Demodex canis	D	150–250	50–60	Long tail	Hair follicles and sebaceous glands
Demodex injai	D	270–390	60–70	Long, thin, sharply tapered tail	Hair follicles and sebaceous glands
Demodex cati	C	180–220	60–70	Long, slender, 5:1 length-to-width ratio of opisthosoma	Hair follicles and sebaceous glands
Demodex gatoi	C	90–110	40–50	Stubby, 2:1 length-to-width ratio of opisthosoma	Stratum corneum
Demodex sp.	C	140–175	50–60	Shorter, rounder than *D. cati*, 2:1 length-to-width ratio of opisthosoma	Stratum corneum

C, cat; *D,* dog.

every 4 to 12 weeks depending on product used.[32,48–57] Most (afoxolaner, fluralaner, lotilaner) are available for use in dogs > 8 weeks of age and all should be used with caution in dogs with a history of seizures. Transdermal moxidectin/imidacloprid administered weekly is effective against demodicosis and labeled for this purpose in Europe; use of weekly transdermal moxidectin/imidacloprid is recommended only for mild to moderate cases.[32,58,59] Milbemycin oxime (1 to 2 mg/kg/day PO) is also safe and effective although cost of daily use may be prohibitive.[56,60] Reports evaluating efficacy of milbemycin oxime/afoxolaner combination products are not yet available.[32] Response to treatment should be monitored with monthly skin scrapes and miticidal therapy continued for at least 8 weeks past first negative skin scrape.[32]

Historically, large animal formulations of macrocyclic lactones or amitraz rinses were used to treat generalized demodicosis. Daily, high-dose, off-label use of large animal formulations of ivermectin (0.3 to 0.6 mg/kg/day PO) or moxidectin (0.2 to 0.5 mg/kg/day), or weekly administration of doramectin (0.6 mg/kg/week PO or SC) is effective. However, neurologic toxicity may occur and these approaches are no longer necessary or recommended as the first-choice therapy.[56] Amitraz is a well-established treatment for generalized demodicosis and FDA label-approved for use at 0.025% concentration every 2 weeks; efficacy improves when amitraz is used off-label weekly and at higher concentrations (0.05%) although toxicity risk also increases.[32,59] Long-haired animals should be clipped prior to applying the dip. Sale of the approved canine formulation of amitraz (Mitaban, Zoetis, USA) was discontinued in the United States in 2018.

Although management is involved and the treatment course may be long and expensive, most dogs with generalized demodicosis can recover and euthanasia is no longer a common consideration. The prognosis for recovery from generalized demodicosis is better in young dogs (<1.5 years) than in older dogs. Spontaneous resolution from generalized demodicosis has been reported in younger dogs although the incidence is unknown and likely varies with breed and underlying condition.[32,43,59] Spontaneous resolution is not thought to occur in older dogs; without treatment, the condition can be fatal.

Cats

Demodicosis in cats may be treated with topical dips, systemic macrocyclic lactones, or systemic isoxazolines. Weekly lime sulfur dips (2%) have long been a mainstay of feline demodicosis treatment; weekly amitraz rinses (0.0125%) have also been used.[32] However, feline patients often do not tolerate both approaches well, and when several individual cats in a multi-cat household are affected, application of topical, body-wide rinses weekly can be challenging. Weekly administration of transdermal moxidectin/imidacloprid is also effective and more easily achieved.[32,60] Fluralaner and sarolaner are also effective for treatment of feline demodicosis[61–63]; other isoxazolines approved for cats (i.e., lotilaner) may also be effective. Combination macrocyclic lactone/isoxazoline products (e.g., moxidectin/fluralaner, selamectin/sarolaner) are available for cats; inclusion of both drug classes in treatment likely supports efficacy.

IMMUNITY

An underlying immune deficit is considered responsible for development of localized and generalized demodicosis; addressing stress caused by poor nutrition or presence of other infections improves patient health and supports treatment of demodicosis. A comparison of pit bull terrier-type dogs with juvenile-onset generalized demodicosis with healthy age- and breed-matched controls revealed significantly higher serum concentrations of IL-2, IL-18, and monocyte chemoattractant protein-1 in dogs with generalized demodicosis, a finding interpreted to reflect an appropriate immune response.[64]

The beneficial effects of immunostimulants in demodicosis treatment are not clear, and most studies evaluating potential adjunctive therapies are small.[32] Inactivated *Parapoxvirus ovis* administered subcutaneously together with amitraz dips decreased time to remission (85 days) when compared with amitraz dips alone (104 days).[65] Insufficient evidence is available to support use of vitamin E, muramyl dipeptide, or herbal and homeopathic products in treatment of demodicosis.[43]

PREVENTION

Judicious breeding can limit the number of litters that develop demodicosis.[10] The American Academy of Veterinary Dermatology and the consensus guidelines from the World Association for Veterinary Dermatology have consistently recommended neutering all dogs with generalized demodicosis and state that both dogs with demodicosis and their parents should not be used for breeding.[32] Although more research is needed, administering fluralaner 10 days before breeding reduced the number of puppies that developed disease.[66] Monthly administration of moxidectin/imidacloprid may prevent relapse in dogs with generalized demodectic mange.[67] Administering isoxazolines reduces but does not eliminate populations of *Demodex* sp. mites from treated dogs.[68] Routine administration of isoxazolines would also be expected to support remission for dogs with generalized demodicosis. Quarantine and prophylactic treatment of newly acquired cats should limit introduction of *D. gatoi* into a facility.

Underlying conditions should be identified and addressed whenever possible. Improving nutrition, identifying and eliminating intestinal parasites, and reducing environmental stress in stray or rescued dogs supports recovery. Co-morbidities and other inciting causes are not always identified, but one review of 41 cases of adult-onset demodicosis identified exogenous glucocorticoid use in allergy patients (24%), hyperadrenocorticism (19%), chemotherapy (15%), and hypothyroidism (12%) as common potential underlying problems.[69] Relapse after treatment occurs in 10% to 45% of canine patients due to stress (including during estrus, pregnancy, or lactation), as well as when systemic diseases are not well controlled.[10,43] Avoiding immunosuppressive drugs (e.g., glucocorticoids, oclacitinib maleate, cyclosporine) in patients with a history of generalized demodicosis is also recommended to reduce incidence of relapse.[43]

PUBLIC HEALTH ASPECTS

Canine and feline demodicosis are not zoonotic. Humans develop disease due to overgrowth of *Demodex* spp. mites that only infest humans (*Demodex folliculorum* and *Demodex brevis*) and that are normal commensals of hair follicles and sebaceous glands. Lesions most commonly appear on the face and include acne, rosacea, pityriasis folliculorum, and blepharitis. A meta-analysis found that prevalence and density of *Demodex* spp. mites were significantly higher in patients with rosacea than in controls.[70,71]

SARCOPTES SCABIEI VAR. *CANIS*

ETIOLOGY AND EPIDEMIOLOGY

Sarcoptes scabiei var. *canis* is a burrowing mite in the order Sarcoptiformes, family Sarcoptidae. Sarcoptid mites have a distinctly rounded morphology with short legs that scarcely project beyond the

body margin. The anterior pretarsi of *S. scabiei* consist of long, unsegmented pedicels, also referred to as stalks, that terminate in caruncles (suckers); females have these structures on the first and second pairs of legs, and males have them on the first, second, and fourth pair of legs.[34] The dorsum has numerous transverse ridges and triangular scales or spines and the anus is located at the posterior edge of the body. The *S. scabiei* species complex is found worldwide and has been reported from more than 100 species of mammals.[72,73] However, infestations are generally regarded as caused by host-adapted strains or "varieties" of the same core species, with host varieties spread more readily among species to which each has adapted. *Sarcoptes scabiei* var. *canis* is the strain reported from domestic dogs and wild canids. Although *S. scabiei* var. *canis* will transfer to and cause dermatitis on other hosts, including humans, these infestations are generally considered self-limiting.[22,72] Sarcoptic mange is rare in cats but occasionally reported.[22,74] Mites from cats suspected to be *S. scabiei* may be *Notoedres cati* (see below) and should be submitted to a parasitologist with appropriate diagnostic expertise for accurate diagnosis.

Sarcoptic mange has been described from domestic dogs and wild canids worldwide. Sex and breed predilections have not been reported, but younger dogs are overrepresented in case series.[75,76] Mites are found in 1% or fewer of dogs in surveys and are not recovered from many infested, clinically affected dogs even when pruritus is severe.[77–79] Accordingly, the true prevalence of *S. scabiei* var. *canis* is not known. In areas where infestations are common in dogs, antibodies may be present in a majority of animals tested. One survey in Nigeria found antibodies to *S. scabiei* in 67% of dogs.[78] A survey that utilized a remote camera in Texas, United States, found lesions consistent with sarcoptic mange in 72% of coyotes.[73] Sarcoptic mange is considered a major mortality factor for red fox in the southeastern United States, and mites are more readily recovered from wild canids or domestic dogs with crusted scabies.[10,80]

After mating, fertilized female mites burrow into the stratum corneum, creating horizontal tunnels. The mites feed on fluids leaking from damaged tissues. While in tunnels, females oviposit 2 to 3 eggs per day over a lifespan of 2 months. The eggs hatch in 3 to 5 days. The larvae then crawl out onto the skin surface and make shallow superficial burrows termed "molting pockets" wherein they feed and molt. After 2 to 3 days, larvae molt to the nymphal stage and after 3 to 4 days, nymphs undergo two subsequent molts to the adult stage. Males make their way to the skin surface where they seek immature females. Mating may take place on the skin surface or in molting pockets depending on the location of the immature female. Immature and adult mites are transmitted by direct contact to other hosts and *S. scabiei* is considered highly contagious; all dogs with known contact with an infested dog should be treated. Infestation following indirect contact via fomites (e.g., clippers, bedding) has also been reported although off-host survival is limited. The entire life cycle usually takes 17 to 21 days to complete, but generation times as short as 10 days have been described.[22]

PATHOGENESIS

The burrowing activity of the fertilized female and its destructive feeding behavior, as well as the deposition of eggs, molted cuticles, and mite feces within the upper layers of the epidermis, lead to varying levels of dermatitis characterized by intense pruritus, alopecia, and hyperkeratotic lesions. Pruritus is observed early after infestation and may be evident as early as 1 week prior to development of lesions. A hypersensitivity reaction to mite antigens, including mite feces, contributes to the pruritus. Mites also release immunomodulating substances that shift immune responses, including upregulation of IL-20 which may promote hyperkeratosis.[72,81] Initial lesions consist of erythematous maculopapular eruptions with alopecia and often first appear in areas where hair is sparse. Predilection sites include the ears, particularly the margins of the pinnae, periocular region, face, lateral elbows, and lateral hocks. As infestation spreads, the ventral thorax and ventral abdomen may be affected and lesions can eventually cover the majority of the body. Extensive alopecia and generalized lymphadenomegaly may be evident.[3,76] When untreated, fatalities can result.

Biopsy of affected areas reveals acanthosis, spongiosis, hyperkeratosis, and prominent rete ridge formation; intracorneal pustules may be present.[82] Biopsy lesions contain mixed cellular infiltrates comprising mononuclear cells, neutrophils, plasma cells, and mast cells.[83] Direct evidence of infestation (e.g., mites, eggs, mite feces) confirms infestation but may not be consistently evident. In chronic infestations, lichenification and hyperpigmentation may be apparent and associated with self-excoriation. Secondary bacterial infections are common and may be promoted by mite-mediated inhibition of host complement.[84,85] In some individuals, crusted scabies develops with profound hyperkeratosis and an enormous number of mites present. In humans, patients with crusted scabies develop a more pronounced IgE response than patients with routine scabies.[86]

CLINICAL FEATURES

Intense pruritus is the most common clinical sign reported in dogs with sarcoptic mange. In some case series, pruritus is reported in only 56% to 74% of cases although severe hypersensitivity reactions responsible for pruritus may limit mite populations, precluding confirmation of infestation and inclusion in case series reports.[76,87] Other common signs include alopecia (43%), crusts (41%–78%), lesions on the pinnae (41%), and scaling (24%–44%).[76,87] In one study evaluating treatment of naturally infested dogs, pruritus, alopecia, and crusts or scales were reported in virtually all cases.[88] Lesions may occur anywhere but are most pronounced on the margins of the pinnae, lateral elbows, and lateral tarsi.[3,10] However, sarcoptic mange should be considered in any dog with a history of pruritus. Young or immunocompromised animals may develop "crusted scabies" characterized by marked, profound hyperkeratosis associated with extremely large numbers of mites; patients with crusted scabies are usually not pruritic. This condition is common in red fox in the southeastern United States and has been reported in young, malnourished dogs, dogs co-infected with *Leishmania* sp., and, rarely, in cats.[80,89,90]

DIAGNOSIS

Direct Microscopic Examination

Although mites are not recovered from approximately 50% of canine patients, sarcoptic mange can be confirmed directly by identifying *S. scabiei* mites using microscopic examination of multiple skin scrapes from the margin of affected areas. To perform skin scrapes, a small amount of mineral oil is applied to a scalpel blade used to gently abrade affected areas; the scurf thus collected is transferred to a microscope slide, a coverslip applied, and the material examined for characteristic mites. Females are 300–400 μm long and males are ~250 μm long. Pretarsi on the first two pairs of legs have long, unsegmented pedicels each bearing a caruncle; males also have these structures on the fourth pair of legs. Numerous transverse ridges and triangular scales are present on the dorsum and the anus is located at the posterior edge of the body (Fig. 110.3). Because skin scraping is relatively insensitive for confirming a diagnosis of sarcoptic mange, multiple areas should be examined and failure to detect mites should not be used to eliminate *S. scabiei* var. *canis* as a potential etiology.[10,22]

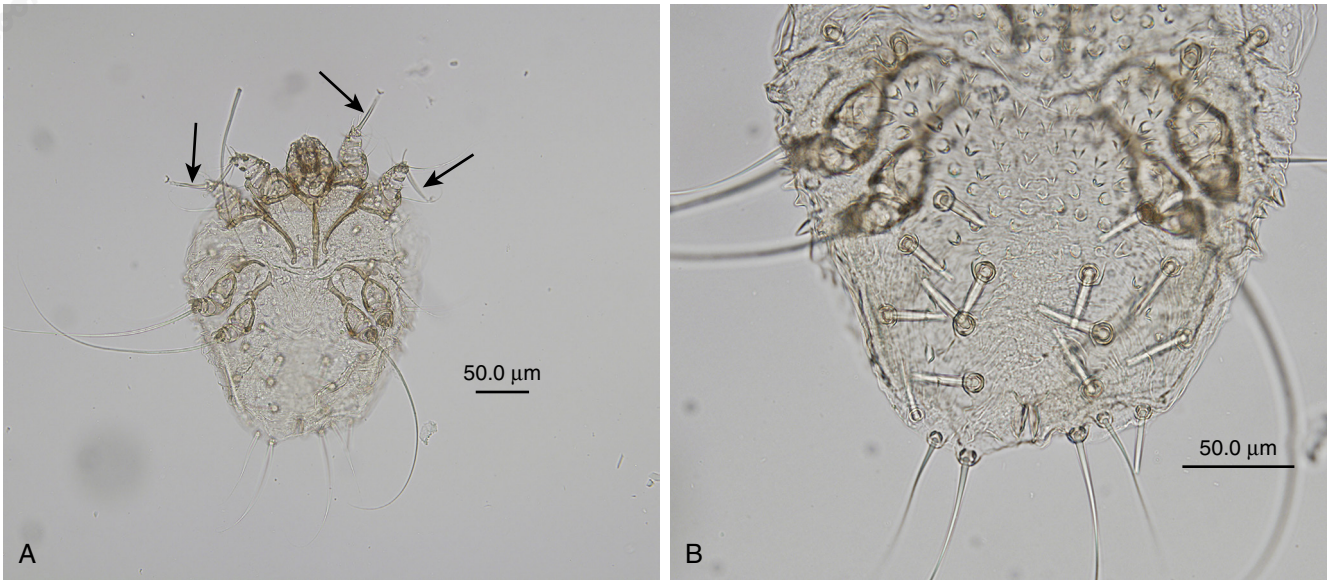

Fig. 110.3 Adult *Sarcoptes scabiei* var. *canis* showing unjointed pedicles bearing suckers *(arrows)* on first and second pairs of legs (A). Magnified view of dorsum with characteristic spines (B). Mites of *S. scabiei* var. *canis* are often present in low numbers making them difficult to find on some infested dogs, even when pruritus is intense. (Courtesy of Megan Lineberry, National Center for Veterinary Parasitology.)

Serology

Although not widely available, ELISAs have been developed to support the diagnosis of *S. scabiei* in dogs. In field evaluations using microscopic detection of mites as the comparator, ELISA has had 84%–96% sensitivity and 90% specificity.[78,91] Antibodies are not detected until 4 weeks after infestation. Specificity can be compromised by cross-reactivity with antibodies to common dust mites (*Dermatophagoides* spp.) and false positives have been reported in dogs with documented atopy associated with dust mites.[92,93] Values on serum chemistry profiles are usually unchanged.[94]

Laboratory Abnormalities

Blood values in dogs with sarcoptic mange are largely unremarkable. Hemoglobin and hematocrit concentrations decrease with infestation, and neutrophil counts increase, but in the absence of sepsis secondary to pyoderma, all remain within normal limits. Eosinophilia is reported in some individual dogs but is not consistently evident.[94]

Gross Pathologic Findings

Dogs with sarcoptic mange develop erythematous, follicular, papular dermatitis that is initially focal but spreads to become multifocal and then generalized. Alopecia, hyperkeratosis, and self-excoriations are common, and abundant crusts are often noted. In the absence of treatment, secondary pyoderma commonly develops. Mites are not easily recovered particularly early in the course of disease; a high index of suspicion and response to treatment can support a clinical diagnosis.[10,22]

TREATMENT AND PROGNOSIS

Transdermal moxidectin and selamectin are FDA label-approved for treatment of sarcoptic mange in dogs. In some countries, amitraz dips or oral milbemycin oxime may also be approved.[95] Isoxazolines (e.g., afoxolaner, fluralaner, lotilaner, sarolaner) have been shown to be effective; multiple doses may be necessary depending on the product used.[87,88,95–97] Fipronil is label-approved to aid in the control of sarcoptic mange and may help limit infestations but is not recommended as a stand-alone treatment. Older therapies, including high-dose, off-label macrocyclic lactones intended for use in large animals or phosmet dips are no longer recommended due to safety concerns and the wide availability of safer, label-approved choices. Most dogs with sarcoptic mange respond well to treatment. Pruritus is relieved within a few days of instituting effective acaricidal therapy, and lesions resolve so long as treatment course is completed and immunocompromise, malnutrition, or other co-morbidities can be addressed.

IMMUNITY

Both field and experimental data indicate that dogs develop immunity to *S. scabiei* var. *canis*. The preponderance of young dogs in case series of clinical sarcoptic mange has been interpreted as older dogs becoming less susceptible to infestation, presumably due to prior exposure.[76] In experimental infestation trials, seven of eight dogs developed immunity to *S. scabiei* var. *canis*; although reinfested, immune dogs self-cleared mites within 1 to 2 months of reinfestation and some dogs eliminated reinfestation in 3 to 4 weeks.[83] Biopsy specimens from immune dogs documented that monocytes and neutrophils predominated in challenge infestations and appeared more rapidly in sensitized dogs than in naïve dogs undergoing a primary infestation; immune dogs also had a more rapid antibody response that decreased as mite populations decreased.[83]

PREVENTION

Vaccines for *S. scabiei* are not available. Prevention requires avoiding direct contact with dogs or wild canids that are likely to harbor mites, limiting roaming, and routine use of control products effective against *S. scabiei*.[10] Dogs diagnosed with sarcoptic mange should be confined and all shared animal facilities (e.g., dog parks, groomers, boarding kennels, dog day care) avoided until treatment is completed and lesions are fully resolved. All dogs in the same household or that have had direct contact with an infested dog should be presumed infested and treated simultaneously, including dogs that are not showing evidence of clinical disease; subclinical carriers of mites contribute to

perpetuating infestations.[98] Routine use of products effective against *S. scabiei* (e.g., transdermal macrocyclic lactones, oral or transdermal isoxazolines) would also be expected to limit infestations.

PUBLIC HEALTH ASPECTS

Sarcoptes scabiei var. *hominis* is a human parasite that affects approximately 200 to 300 million people worldwide each year and infests as many as 10% of children in developing countries.[99] Scabies is recognized as a neglected tropical disease by the WHO, and cases appear to be increasing in developed countries.[100,101] Patients with primary scabies due to *S. scabiei* var. *hominis*, the variety responsible for direct human-to-human transmission, develop an erythematous, papular rash characterized by intense pruritus; serpiginous burrows where mites have tunneled are often apparent. Lesions associated with *S. scabiei* var. *hominis* most commonly appear in the interdigital region, wrists, elbows, knees, abdomen, and groin, and mites are transmitted between humans by prolonged, intimate contact. Institutional outbreaks are frequently reported in nursing homes, dormitories, and prisons; transmission among family members is also common but *S. scabiei* var. *hominis* is not known to infest pets.[98,101] People are most often treated with topical permethrin or oral ivermectin.[99]

While zoonotic, cases of *S. scabiei* var. *canis* infestation are only a concern in individuals that have direct contact with infested dogs or wild canids. The rash usually develops within 1 to 4 days after contact with an infested dog. Mites are rarely present and history is key to reaching a diagnosis.[102] Although intensely pruritic, once acquired by a person, *S. scabiei* var. *canis* mites do not transfer to other humans. Preventing dermatitis associated with zoonotic infestations requires use of appropriate preventives in dogs to avoid development of infestations, prompt diagnosis and treatment of infested dogs, and careful handling of dogs with skin conditions consistent with mange or known to harbor mites.[98] Dogs or red fox with crusted scabies harbor a huge number of mites and thus present an elevated zoonotic risk. Zoonotic infestations may be managed symptomatically with topical hydrocortisone creams or, if severe, treated systemically.[3,98]

NOTOEDRES CATI

ETIOLOGY AND EPIDEMIOLOGY

Notoedres cati is a burrowing sarcoptid mite (order Sarcoptiformes, family Sarcoptidae) of domestic cats and wild felids. Infestations with *N. cati* have been reported in at least 18 different host species, including rabbits, and, rarely, dogs.[103,104] The parasite is most commonly described from domestic cats and bobcats (*Lynx rufus*). Although the rounded appearance and pretarsi (long, unjointed pedicels ending in caruncles) are morphologically similar to *S. scabiei*, *N. cati* is smaller (150–225 µm) than *S. scabiei*, lacks dorsal spines, and the anus is dorsal rather than terminal (Fig. 110.4).[34] Other species of *Notoedres* infest rodents, procyonids, and bats.[103]

The life cycle of *N. cati* is similar to that of *S. scabiei*, with larvae, nymphs, and adults burrowing in the host skin, and requires approximately 2 weeks. Females deposit eggs in burrows in the skin of the face, ears, and, occasionally, legs of the host. Mites are transferred between cats by direct contact. Cats infested with *N. cati* are reported worldwide albeit less commonly than dogs with *S. scabiei* var. *canis*. In North America, reports are more common in the southern United States and Mexico.[30,103]

A survey of feline parasites in pet cats from several countries in Europe identified *N. cati* in only 3 of 1,519 cats but infestations are considered more common in some countries, including Greece (where prevalence in stray cats in a survey was 2.4%) and Brazil.[105–107] Local epizootics have also been reported and long-haired cats are predisposed.[105,108] Infestations with *N. cati* are highly contagious and may be seen as entire litters affected, in multi-cat facilities, and in free-ranging felid populations.[10,108–110]

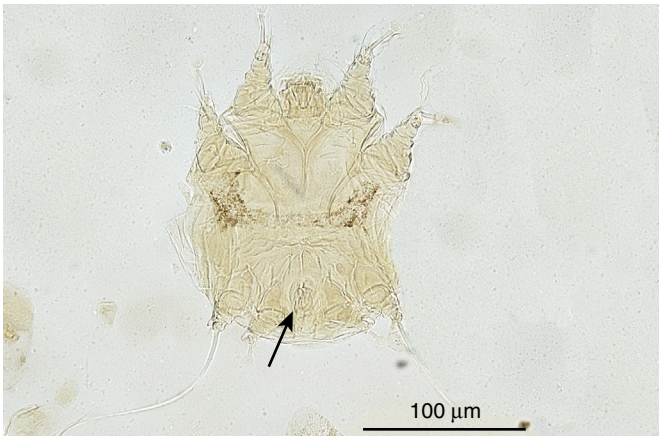

Fig. 110.4 Adult *Notoedres cati* showing dorsal anus *(arrow)* that distinguishes it from *Sarcoptes scabiei*. (Courtesy of National Center for Veterinary Parasitology.)

PATHOGENESIS

Similar to *S. scabiei*, *N. cati* activity elicits inflammation. Mites burrowing in the stratum corneum lead to an erythematous, papular dermatitis that progresses to thickened skin covered with crusts. Alopecia and intense pruritus are common, and secondary infections occur, particularly with self-excoriation.[10]

CLINICAL FEATURES

Notoedric mange is characterized by intense pruritus and development of hyperkeratotic crusts and alopecia on the dorsal pinnae. Hypersensitivity contributes to pruritus and leads to intense grooming which can result in secondary excoriations. In chronically infested cats with advanced disease, anorexia, weight loss, and poor condition may be evident.[10]

DIAGNOSIS

Direct Microscopic Examination

Mites are present in high numbers and are readily recovered in skin scrapings from affected areas. Although rare, *S. scabiei* has been reported in cats; feline sarcoptiform mites must be carefully examined to distinguish *N. cati* from those of *S. scabiei*. Use of clear tape to collect material for microscopic examination from affected areas may be less stressful for feline patients and appears to be of equal diagnostic sensitivity for *N. cati*.[107] Like other mites (e.g., *Demodex* sp., *Lynxacarus* sp.), *N. cati* is occasionally detected on fecal flotation of infested cats due to ingestion during grooming.[111] Fecal PCR has been developed for survey of wild felid populations but is not commercially available for testing domestic cats.[112]

Serology

Serologic assays to detect antibodies to *N. cati* have not been described, and *S. scabiei* ELISA is not validated for use in cats with notoedric mange.

Laboratory Abnormalities

Clinical pathology values have not been described in cats with *N. cati* infestations. Bobcats with notoedric mange have had low serum creatinine concentrations, hypoglycemia, and electrolyte abnormalities (hyperphosphatemia, hypernatremia, and hyperchloremia), as well as decreased serum cholesterol, albumin, globulin, and total protein concentrations, presumably due to protein loss across the affected skin.[113]

Gross Pathologic Findings

Notoedric mange most commonly presents as facial dermatitis, often initially involving the anterior edge and dorsal surface of the pinnae. As the infestation progresses, the head, neck, and dorsal thorax may become affected, and the skin becomes profoundly thickened, wrinkled, and lichenified. Lesions may also appear on the feet, tail, and perineum following contact with affected areas during grooming. In chronic infestations, most of the body surface can be affected, peripheral lymphadopathy develops, and fatality may occur.[10]

TREATMENT AND PROGNOSIS

Although FDA label-approved options to treat *N. cati* are not available, treatment is similar to that recommended for *S. scabiei*, with transdermal eprinomectin, moxidectin, or selamectin recommended; combination products in which both active ingredients have efficacy against mites (e.g., eprinomectin/fipronil, selamectin/sarolaner, moxidectin/fluralaner) are likely of even greater efficacy.[114–116] Isoxazolines approved for cats (i.e., fluralaner, lotilaner, sarolaner) would also be considered effective. High-dose off-label cattle preparations of macrocyclic lactones have been used historically but are not recommended due to safety concerns; repeating the treatment at 14-day or monthly intervals may be necessary to remove mites that hatch from eggs which remain after treatment and eliminate the infestation. If a dip is preferred, a 2% to 3% warm lime sulfur solution can be applied topically and allowed to dry on the skin every 7 days for at least 6 weeks and until lesions resolve.[10] Because some cats may be subclinical carriers, all cats in the household should be treated for *N. cati* infestation regardless of clinical appearance. Cats with notoedric mange respond well to treatment so long as all cats in the household can be treated, re-exposure is prevented, and treatment can be repeated, if necessary, until infestations completely resolve.[10]

IMMUNITY

The extent to which cats develop immunity to *N. cati* has not been investigated. The occurrence of epizootics in wild felid populations that stabilize over time suggests that, although notoedric mange can be responsible for population declines, immunity may develop similar to what has been described for *S. scabiei* in some wild canid populations.[103]

PREVENTION

Vaccines are not available for prevention of *N. cati* infections. Prevention involves keeping cats indoors, avoiding contact with other cats likely to be infested, and, for multi-cat households, treating new arrivals during initial quarantine to prevent introduction. Although not evaluated experimentally, routine use of control products effective against mites, including macrocyclic lactones and isoxazolines, would also be expected to prevent infestation.[30,117] Cats with notoedric mange should be isolated until cleared of the infestation. All littermates or adult cats in the same household should be treated regardless of clinical appearance as subclinical infestations may be present in some cats, creating a reservoir for future infestations.[10]

PUBLIC HEALTH ASPECTS

People in direct contact with infested cats often develop self-limiting dermatitis characterized by intense pruritus and an erythematous papular rash; lesions are common on areas in contact with infested cats including the hands, wrists, forearms, and abdomen.[108,118] As with pruritus due to zoonotic *S. scabiei* varieties, *N. cati* mites create a transient infestation in humans and are not transmitted to other humans.[10]

OTODECTES CYNOTIS

ETIOLOGY AND EPIDEMIOLOGY

Otodectes cynotis (order Sarcoptiformes, family Psoroptidae) is the common ear mite of domestic cats, dogs, and ferrets; infestations have been reported in many other mammals.[30] Although most commonly reported from domestic and free-roaming cats, *O. cynotis* is well recognized as a parasite of ferrets and dogs. Adults of *O. cynotis* are approximately the same size (300–450 µm) as *S. scabiei*; at 350–450 µm, females may be grossly visible to the unaided eye. The pretarsi consist of a caruncle (sucker) attached to a very short pedicel (stalk) on the first two pairs of legs of the female and all four pairs of legs on the male; males also have distinct copulatory structures on the ventral surface.[34] *Otodectes cynotis* is the only member of the genus.

Completion of the life cycle of *O. cynotis* requires approximately 3 weeks, with larvae, nymphs, and adults developing in the ear canal and feeding on superficial epidermal debris; under warmer conditions, the life cycle is completed more rapidly.[30] Females adhere eggs to the epidermal surface of the ear canal; larvae hatch from eggs in approximately 4 days and then develop through two nymphal stages (protonymph, deutonymph) to the adults. Motile stages largely remain in the ceruminous exudate and cellular material that accumulates in infested ears, occasionally venturing to the surface. Mites are transferred between animals by direct contact, including from dams to nursing young, and off-host survival is limited. However, experimentally mites can survive for 5 to 17 days off host depending on temperature and relative humidity.[119,120] Cats and, less commonly, dogs, infested with *O. cynotis* are reported worldwide; ear mites are also very common in ferrets and both wild and farmed foxes.

The prevalence of *O. cynotis* infestation in cats ranges from 0.9% of pet cats in the United Kingdom to 37% of free-roaming cats in the United States (Florida) (Table 110.2).[120–122] Failure to microscopically examine otic exudate from every cat underestimates prevalence and may explain some of the variation seen.[121,122] In a multi-institutional survey of 1,519 cats in seven different countries in Europe, *O. cynotis* was present in 17.4% of pet cats and was more commonly recovered from cats than any other ectoparasite, including fleas (15.5%).[106] Although infestations are frequently found in kittens and in cats with outdoor access, age-related differences in prevalence have not been clearly established in all feline populations and ear mite infestations also occur in adult cats.[22,123–125] Prevalence in dogs has ranged from 2.8% (Albania) to 6% (Brazil); age, sex, and breed have not been associated with risk of infestation in dogs.[126,127] *Otodectes cynotis* is also commonly identified in pet ferrets and wild canids.[128–131] In wild canid populations, *O. cynotis* infestations tend to be focused in certain geographic areas. For example, 4% of Arctic foxes across Iceland were infested, but all were from a single county where the prevalence of infestation was 38%.[132]

PATHOGENESIS

Infestation with *O. cynotis* is an important inciting cause of otitis externa in cats and, less commonly, dogs. Ear mites do not burrow

TABLE 110.2 Prevalence of *Otodectes cynotis* in Pet and Free-Roaming Cats and Dogs

Location	Host	Lifestyle	Prevalence	Reference
Europe (Austria, Belgium, France, Hungary, Italy, Romania, and Spain)	Cat	Pet	17.4%	106
Greece (Thessaloniki area)	Cat	Pet kittens (0 – 6 months), first exam	14%	125
Greece (northern)	Cat	Pet cats, clinically normal	25.5%	123
United States	Cat	Pet	7.4%	155
Japan	Cat	Pet	9.4%	124
United Kingdom (England, Wales)	Cat	Pet and rescue cats	0.9%	122
Greece (Thessaloniki area)	Cat	Free roaming	15.8%	105
Spain (Murcia)	Cat	Free-roaming	30%	156
Spain (central)	Cat	Free-roaming	10.6%	157
United States (Oklahoma, Arkansas)	Cat	Free-roaming	19.3%	158
United States (Florida)	Cat	Free-roaming	37%	121
Albania	Dog	Pet	2.8%	126
Albania	Dog	Pet	6.7%	159
Brazil	Dog	Pet	6.0%	127
Iran (Ahvaz)	Dog	Pet	4.8%	160
Korea (Gwang-Ju City)	Dog	Free-roaming	22.3%	161
Mexico (Yucatán)	Dog	Free-roaming	3.5%	162

but instead feed on superficial epithelial cells and associated exudate; occasionally tissue fluid is imbibed.[10] The inflammatory response leads to erythema of the ear canal and development of dark brown, granular, ceruminous exudate. As mite populations expand, miliary dermatitis may develop on adjacent areas of the head and, less commonly, on the feet or tail following transfer during grooming.[3] Some estimate that as many as 85% of feline otitis externa cases and 50% of canine otitis externa cases are caused by ear mites.[133] In a survey of free-roaming cats in northern Italy, 55% had evidence of otitis externa with *O. cynotis* found in a majority (53.3%) of affected cats.[134] When treatment is delayed, secondary bacterial and fungal infections can develop.[135] In some infested pets, diffuse hypersensitivity resembling flea allergy dermatitis and associated with ectopic mites has been described.[10] The chronic ceruminous gland hyperplasia resulting from untreated *O. cynotis* infestations has been associated with development of ceruminous gland tumors.[131]

CLINICAL FEATURES

Ear mite infestations lead to a wide variety of clinical presentations. Some infested animals appear normal, whereas others develop intense otic pruritus accompanied by head shaking and frequent, persistent scratching of the ears. Acne-like lesions on the face have been described.[123] Affected ears may contain copious amounts of dark, granular discharge described as resembling coffee grounds. In severe cases, self-excoriation leads to traumatic injury of the skin, bleeding, development of aural hematomas, and secondary infections. Purulent otitis externa may develop. Dermatitis may also be seen, particularly when mites are present outside the ear canals; common sites for ectopic mites and associated alopecia and pruritus include the neck, back, feet, and tail.[10,30] However, some animals will have large numbers of mites with minimal discharge or pruritus evident. In cats, there is not a clear correlation between the number of mites and the severity of lesions that develop, or the amount of otic discharge and the relative degree of pruritus. Dogs are usually pruritic with only minimal discharge evident.[10]

DIAGNOSIS

Direct Microscopic Examination

Ear mites can be visualized directly during otoscopic examination or by microscopic examination of exudate collected on a swab; mineral oil aids in collection of material for examination and transfer to a microscope slide. Direct microscopic examination of material collected from the ear canal is key to reaching an accurate diagnosis. In one study, otoscopic examination alone failed to identify *O. cynotis* in 39% of infested cats, including eight cats with an ear canal that appeared normal and had only mild ceruminous exudate.[121] Another study showed that otoscopic examination identified only 67% of infestations and that sensitivity was increased by use of curettage to collect the cerumen.[136] Flushing the external ear canal with a small amount of mineral oil further enhances recovery and increases prevalence of infestation when used for surveys of clinically normal pet cats but is likely impractical in a clinical setting.[123] Immature and adult *O. cynotis* are motile when collected and are readily identified by their large size (200–450 µm), characteristic rounded appearance, and presence in the ear canal (Fig. 110.5). The other mite occasionally found associated with otitis externa is *Demodex* spp., which has a distinct elongated morphology. Males and deutonymphs (pre-females) of *O. cynotis* are often found in copulation; eggs are commonly seen within females or in collected exudate.[34] Ectopic *O. cynotis* may occasionally be recovered on skin scrape of the neck or tail.[10]

Serology

Serologic tests for ear mites are not available. Cross-reactions with dust mites can occur on intradermal skin tests similar to that seen with *S. scabiei* and *Cheyletiella* spp.[137]

Laboratory Abnormalities

Blood values in cats and dogs with *O. cynotis* infestations are largely unremarkable. Significant changes on CBCs, including eosinophilia, have not been demonstrated.[138]

Gross Pathologic Findings

Classically, *O. cynotis* induces erythematous hyperplasia and hyperkeratosis in the ear canal epithelium. Pronounced hyperplasia of the sebaceous and ceruminous glands is commonly seen together with dilated blood vessels and increased numbers of macrophages

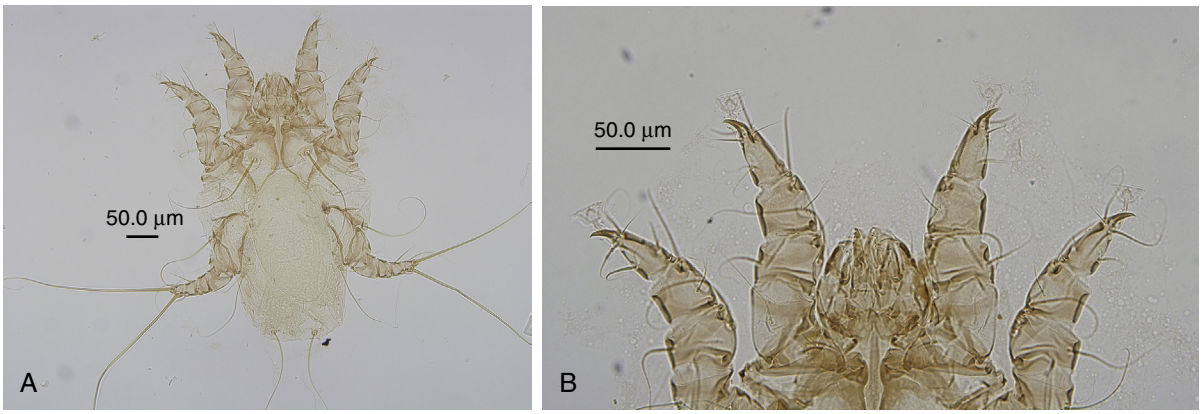

Fig. 110.5 (A) Adult *Otodectes cynotis*. (B) Magnified view showing suckers at the end of short pedicels on the first and second pair of legs. (Courtesy of Megan Lineberry, National Center for Veterinary Parasitology.)

and mast cells.[10,30] Copious dark, ceruminous otic discharge often packs the ear canal and must be removed to allow complete examination. However, many cats and dogs confirmed to be infested as documented by the presence of mites on ear swabs do not develop significant pathology and otoscopic examination is unremarkable.[121]

TREATMENT AND PROGNOSIS

Otodectes cynotis is readily treated with macrocyclic lactones, including otic preparations of ivermectin or milbemycin oxime developed for treating ear mites, or transdermal, systemic formulations of eprinomectin, moxidectin, or selamectin with broad-spectrum efficacy against many internal and external parasites.[22,139,140] Otic preparations may lead to more rapid clearance of mites.[141] Systemic isoxazolines (afoxolaner, fluralaner, lotilaner, sarolaner) are also effective against ear mites and may be given alone or in combination with macrocyclic lactones to further support efficacy.[142–148] In one study, a single administration of a label-approved formulation of fluralaner plus moxidectin eliminated ear mites from treated cats.[147] Historically, ear mites have been treated with otic preparations of pyrethrin, rotenone, fipronil, or lindane, or by using high-dose large animal preparations of macrocyclic lactones off-label; toxicities have been reported and these strategies are no longer recommended.[149] Mineral oil alone is effective although repeated treatments are needed, an overly aggressive approach can exacerbate otitis, and an oily residue is left on the cats.[30,150]

Otic cytology should be evaluated prior to cleaning; when present, secondary bacterial or fungal infections should also be treated. If debris is present, ear canals can be gently cleaned with ceruminolytics to provide symptomatic relief to the patient and to remove mites, taking care not to irritate the epidermal lining.[150] When otic acaricides are to be used, cleaning should occur before application. Eliminating ectopic mites with systemic macrocyclic lactones or isoxazolines should resolve traumatic alopecia associated with excessive grooming due to pruritus from a diffuse hypersensitivity reaction. If pruritus is severe, symptomatic care may be indicated while infestations resolve. All dogs and cats in contact with the patient should also be treated with acaricides; subclinical infestations are common, and these animals may serve as reservoirs to perpetuate the cycle of infestation. When the primary patient and any direct contacts (e.g., other cats or dogs in the household) can be treated, and any secondary infections addressed, animals routinely recover.[10]

IMMUNITY

The negative association between age and intensity of *O. cynotis* infestation suggests immunity may develop, and this reaction could limit mite populations in older animals.[123,151] However, ear mites are still present in many adult cats and dogs, and reinfestation following treatment has been described.[137]

PREVENTION

Preventing *O. cynotis* infestation can be achieved by avoiding contact with other cats and dogs likely to be infested, including keeping cats indoors and preventing roaming in dogs. Young animals are particularly susceptible to acquiring infestations from dams in the neonatal period due to prolonged, intimate contact while nursing; treating breeding females before or during pregnancy, prior to parturition, would be expected to eliminate mites and reduce risk of transmission to kittens and puppies. In addition, routine use of products known to have efficacy against *O. cynotis*, including macrocyclic lactones and isoxazolines used to control heartworm, intestinal parasites, fleas, and ticks, would also limit infestations with ear mites.[142–148] A combination fipronil, S-methoprene, eprinomectin, and praziquantel product has been shown to protect cats from *O. cynotis* infestation.[152]

PUBLIC HEALTH ASPECTS

Although a few isolated cases of human infestation or dermatitis associated with *O. cynotis* in pets have been reported, transmission from pets to people appears quite rare.[153,154] Ear mites pose minimal, if any, zoonotic risk.

PNEUMONYSSOIDES CANINUM (NASAL MITE)

Nasal mites (*Pneumonyssoides caninum*, also *Pneumonyssus caninum*) are an uncommon finding in pet dogs in most of the world. The large (1.0–1.5 mm) mites live in paranasal sinuses and nasal cavity, and transmission occurs with direct or indirect contact between dogs. Nasal mites appear more common in Scandinavia, with prevalence estimated to be 7% in Norway and 23% in Sweden.[163,164] One survey in Uppsala, Sweden documented *P. caninum* in 20% of dogs surveyed; infestations were more common in older (>3 years) and large-breed dogs, and dolichocephalic breeds may be more commonly infested.[165] Cases have also been described

in North America and the United Kingdom, but the true prevalence is not known.[166–169]

Clinical signs vary from nasal irritation, nasal discharge, sneezing, nasal pruritus, and stertorous breathing, to epistaxis, hyposmia, and head shaking.[169] Diagnosis can be made by visualizing mites with rhinoscopy or by retrograde saline nasal flush.[163] Nasal biopsy may reveal an eosinophilic inflammatory response, and transient peripheral eosinophilia has been described.[169,170] Selamectin applied every 2 weeks for three treatments is effective and clinical signs resolve within a few days of initial treatment.[169,171] Milbemycin oxime (1 mg/kg, PO, q10d × 3 doses) is also effective.[163] All dogs in the home should be treated. Nasal mites are not known to be zoonotic.

LYNXACARUS RADOVSKYI (FUR MITE, HAIR CLASPING MITE)

The fur mite, *Lynxacarus radovskyi*, is laterally compressed and primarily found infesting cats in tropical areas. Mites attach eggs to the hairs of cats. Larvae, nymphs, and adults clasp the hairs with the anterior end oriented toward the hair shaft (Fig. 110.6). The complete life cycle has not been described, but off-host survival is considered limited.[30] Mite populations are higher on the caudal area of the body, including the base of the tail, tail tip, and perianal region.[172,173] *Lynxacarus radovskyi* may be found on more than 70% of pet cats in Malaysia and free-roaming cats in the Caribbean.[172,173] Many infested cats are subclinically infested, with pruritus, presumably due to a hypersensitivity reaction, only occasionally observed.[174]

Infested cats develop a dry, dull hair coat, alopecia, and, occasionally, pruritus; the stippled appearance to the fur is often described as "peppered." Excessive grooming leads to alopecia that is most pronounced in the perianal region, caudolateral hind legs, base of tail, and abdomen.[173] An association between fur mite infestation and feline eosinophilic granuloma complex has been suggested.[175] Diagnosis can be made by identifying mites grasping hairs plucked from affected areas. Clear tape applied to the fur also recovers mites and identifies more infested animals.[172] Effective treatments include moxidectin/imidacloprid or selamectin applied every 2 weeks, fluralaner once, or sarolaner.[173,173,176,177] All cats in the home should be treated. Humans in contact with infested cats may develop a papular rash that resolves with treatment of the pet.[178]

TROMBICULID MITES (CHIGGERS, RED BUGS, BERRY BUGS, HARVEST MITES, SCRUB ITCH OR GRASS ITCH MITES)

ETIOLOGY AND EPIDEMIOLOGY

Chiggers (family Trombiculidae, order Trombidiformes) are minute, larval mites that cause chigger dermatitis (trombiculosis). They are found in many tropical and temperate terrestrial habitats. Although usually parasites of wildlife, trombiculids occasionally found on dogs and cats include *Eutrombicula* spp. (North, Central, and South America), *Neotrombicula* spp. and *Ericotrombidium* spp. (Europe), and *Leptotrombidium* spp. (Asia, Australia).[179–186] Over 1,200 species of trombiculid mites have been identified, but many only as larvae. More than 50 species have been recorded infesting humans and approximately 20 are recognized as capable of causing animal and human disease. Specific identification is often not pursued, and the full diversity of species involved is likely under-recognized.[183] *Eutrombicula alfredugessi* is the most common and widespread chigger in the Western Hemisphere and is found from Canada to Argentina and the Caribbean.[187] In the United States, *E. alfreddugesi* is more common east of the Rocky Mountains, *Eutrombicula splendens* is found in the eastern United States, and *Eutrombicula lipovskyi* is encountered in the southern United States from Arkansas, Oklahoma and Kansas to Alabama and Tennessee.[187] *Walchia americana*, a mite in the family Walchiidae and in the same superfamily as the trombiculids (Trombiculoidea), is found in the southwest and eastern United States, and commonly infests squirrels and other rodents although larvae can infest cats.[180] *Neotrombicula autumnalis*, the harvest mite, is the most common chigger in Europe, found throughout the continent and the British Isles.[187] *Neotrombicula inopinata* is found in England, Spain and France, and portions of central and Eastern Europe, from Germany and Poland to Ukraine and the Northern Caucasus region of Russia.[188] A related trombidioid mite of foxes, *Straelensia cynotis* (family Leeuwenhoekiidae), parasitizes dogs in Portugal, Spain, France, Italy, and Israel.[189–193] *Leptotrombidium* spp., the vectors for scrub typhus, are found in Southeast Asia, the southwestern Pacific Islands, and northern Australia.[194]

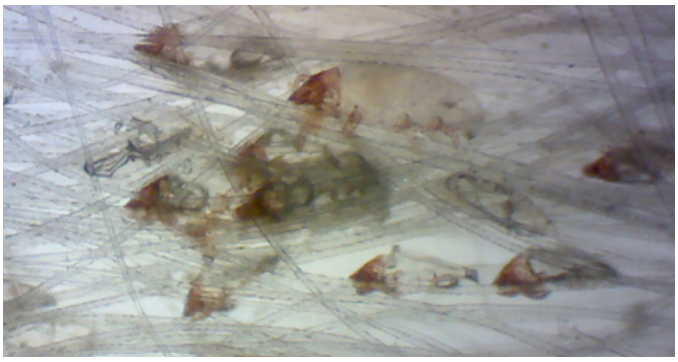

Fig. 110.6 Adult *Lynxacarus radovsky* in hairs collected from an infested cat. (Courtesy of National Center for Veterinary Parasitology.)

The life history of trombiculid mites encompasses the egg, prelarva, larva, prenymph, nymph, tritonymph, and adult stages. The female adult oviposits on the ground and larvae hatch and begin to search for new hosts in 12 days. The larvae, which are obligate parasites, have little host specificity and will feed on a wide variety of terrestrial vertebrates, including domestic animals and humans. Larvae feed for 1 to 5 days, but generally, most will complete feeding by the second day. Engorged larvae then drop to the ground where they molt into the prenymph stage. Following another molt, nymphs prey on invertebrates and, following two more molts, become adults. Nymphal and adult stages are either predatory on invertebrates or scavengers; they are usually found in soil. The adults are typically bright red or yellow, and about 1 mm in length. Covered in plumose setae, adults appear to be covered in velvet and are sometimes referred to as red velvet or true velvet mites.

Pets become infested when they encounter larval stages in the environment, often in brushy areas frequented by wildlife. In temperate regions, larvae usually begin to appear in the mid-summer and their populations peak in the late summer and early fall, and in tropical and subtropical areas, larval populations may be host-seeking throughout the year.[187,195,196] The harvest mite, *N. autumnalis*, is active on warm, sunny days[187] and *E. alfreddugesi* larvae are most active at dawn and late afternoon–early evening, with low levels of activity during the midday and night.[197]

CLINICAL FEATURES

Larvae are round, 0.2 to 0.5 mm long, often orange or red in color, and have six legs. The mouthparts (gnathostoma) include the chelicerae, or cutting plates, that are used for piercing and holding onto the host. Attached larvae eject saliva into the epidermis through a buccal aperture. The saliva digests host tissue and aids in formation of a stylostome, or feeding tube, through which the larva can imbibe fluid. After feeding, or if dislodged by the host, the larva falls to the ground and the stylostome is left behind, resulting in persistent, intense pruritus; chiggers do not burrow.[187] Irritation reactions appear to become more severe with repeated feeding episodes, likely due to a hypersensitivity reaction. In cats, the ears are most frequently infested, but clusters of orange-red trombiculid larvae may be visible on margins of pinnae, periorbital region, ventrum, or interdigital skin; alopecia is often evident, and associated lesions are dry and crusted. Papules, measuring 0.1 to 0.3 cm, may be observed with mild wheals, crusting, and yellow exudate. Involvement of the feet may present with swollen paws and cracked claws.[180] Pruritus was the most common clinical sign although a majority (57%) of infested cats in one study did not have clinical signs.[198] Neurologic signs have been reported in dogs heavily infested with *Neotrombicula* spp.[199,200]

In contrast, larvae of *S. cynotis* infest hair follicles of dogs and cause a nonpruritic nodular dermatitis on the dorsal head and trunk; when severe, nodules may be painful and dogs lethargic and anorexic. Infestations with *S. cynotis* are associated with contact with fox dens where the nymph and adult mites live and have been reported in dogs and, occasionally, cats, in Spain, Portugal, France, and Israel.[189–191,193,201] Histologically, the cysts comprise large, dilated hair follicles containing a larva; the follicular epithelium is hyperplastic and infiltrates of plasma cells and mast cells are evident.[190] Inflammatory infiltrates are usually mild and eosinophils are rarely observed.

DIAGNOSIS

When there is an abundant and recent infestation, clumps of reddish- to orange-colored larvae can be observed on the skin. Diagnosis of chiggers can be made by close inspection of lesions, gently scraping mites from affected areas or collecting with clear tape, or, in the case of *S. cynotis*, examining biopsy specimens of the nodular dermatitis.

TREATMENT AND PREVENTION

Treatments for trombiculid mites reported to be effective in cats include transdermal selamectin or fipronil.[202–205] Dogs have been treated successfully with topical fipronil, permethrin-pyriproxyfen, and permethrin-fipronil combinations.[202,206,207] *Straelensia cynotis* infestations do not consistently respond to systemic treatment with ivermectin.[190,191] Treatment failures may relate to the mite's endofollicular location. Topical or systemic antibiotics may be indicated to treat secondary infections, and glucocorticoids would provide relief. Anecdotally, isoxazolines may also have good efficacy, eliminating chiggers on dogs within 6–8 hours.[200]

Modifying chigger habitat so as to make it inhospitable for mite survival can reduce the likelihood of exposure. Routinely mowing grassy areas, clearing brush, and raking leaves can decrease chigger exposure. Reinfestation in cats (and dogs and humans, as well) is very likely after treatment if there are no changes in lifestyle.[198] Avoidance of sites where chiggers are active, especially during the times of the year when larvae are active, is useful in minimizing chigger exposure. Limiting activity in those areas to the midday hours during chigger season may also minimize exposure as the larvae are less likely to be seeking hosts during the warmest and driest part of the day.

PUBLIC HEALTH ASPECTS

Although humans are considered accidental hosts, about 20 mite species are considered medically relevant because their bites can elicit dermatitis and hypersensitivity reactions, as well as being vector pathogens.[194] In addition, scrub typhus (tsutsugamushi disease), caused by the bacterium *Orientia tsutsugamushi*, is transmitted by chiggers of *Leptotrombidium* spp. in far eastern Russia, the Korean Peninsula, Japan, South east Asia, India, and northern coastal Australia.[194] Larvae are efficient vectors because the bacterium is transovarially transmitted.

In humans, chigger bites usually occur on the lower limbs. Small (1–2 mm) papules appear approximately 3 to 24 hours post-exposure, which can develop into pustules. Intense pruritus begins to subside after 1 week and accompanying skin lesions may last 3 weeks.

People are advised to prevent mite exposure by avoiding known and suspected chigger areas, wearing protective clothing, and using repellents. Although direct contact with host-seeking larvae on vegetation is the likeliest route of transmission, there are two suspected cases of animal-to-human transmission in the literature.[208,209]

CASE EXAMPLE

Signalment

"Ginger," a 5-year-old female spayed domestic shorthair cat from Muscogee, Oklahoma, United States.

History

Ginger was evaluated in July for alopecia and mild to moderate pruritus on the head, pinnae, and shoulder. Her owner reported excessive grooming over the past month when the lesions first appeared; this included pawing at the ears, scratching, and occasionally chewing the affected area on the shoulder. Ginger was an indoor-only cat that had been housed in a long-term, limited access private shelter. Ginger joined the shelter population in April (3 months ago) following the death of a previous owner. The owner's impression was that Ginger was removing her own hair with the excessive grooming, perhaps due to stress, but she had not observed any difficult interactions with other cats in the facility. The current owner managed the shelter and had not noted pruritus or similar skin lesions in any of the other 14 cats in residence.

Current Medications: Topical monthly flea control (imidacloprid).

Other Medical History: No medical problems or skin lesions were noted at intake. Ginger was negative for feline retroviruses and feline heartworm antigen. *Giardia* sp. cysts were present on fecal flotation in April; 3 days of fenbendazole (50 mg/kg) was administered to avoid introducing *Giardia* sp. into the shelter population. For the past 3 weeks, the owner had fed Ginger a commercial hydrolyzed protein dry kibble diet; pruritus and skin lesions persisted.

Physical Examination

Body weight: 6.4 kg; BCS 6/9.

General: Bright, alert, hydrated, responsive. Mucous membranes pink, HR = 170 beats/minute, RR = 50 breaths/minute, T = 100.8°F (38.2°C).

Continued

CASE EXAMPLE—cont'd

Integument: Alopecia, scaling, and broken hairs were evident on the dorsal neck, right shoulder and right lateral thorax (Fig. 110.7). Alopecia and scaling were present on the dorsal surface of the head and the external pinnae; excoriations were noted on the left pinna. Flea frass, fleas, or other grossly apparent ectoparasites were not recovered by combing. Fluorescence was not noted with ultraviolet illumination of affected areas; culture of plucked hairs in dermatophyte test medium did not reveal color change or fungal growth.

Eyes, ears, nose, and throat: Mild amount of light tan cerumen in both ears. No other clinically significant findings were found on physical examination.

Skin Cytology and Skin Biopsy Findings

Mites were not evident on multiple (n = 6) skin scrapings collected from affected areas. Cytologic examinations of skin scrapings revealed no significant findings. Skin biopsy revealed mild hyperkeratosis and mild to moderate perivascular dermatitis.

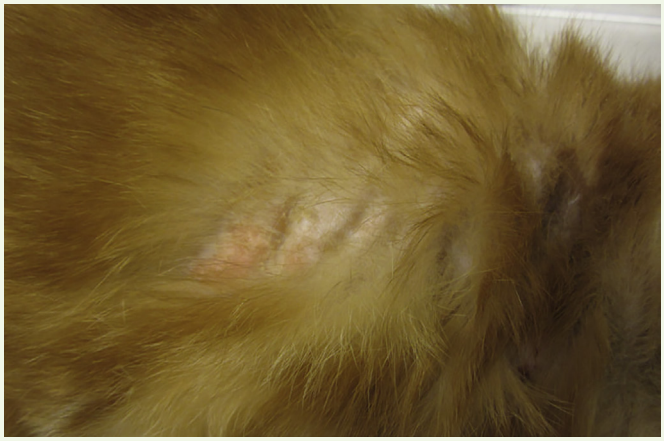

Fig. 110.7 Alopecia, mild erythema, and mild to moderate scaling on the dorsal neck, shoulder, and lateral thorax of a cat with demodicosis.

Fecal Flotation Findings

Demodex gatoi mites, with characteristic stubby appearance and each approximately 90–110 μm long, were recovered on centrifugal fecal flotation using 33% zinc sulfate (Fig. 110.8).[45]

Diagnosis

Demodex gatoi infestation.

Treatment

Ginger was treated with transdermal moxidectin/imidacloprid administered weekly for three consecutive treatments and monthly thereafter. Clavulanic acid-amoxicillin (10 mg/kg, q12h, PO) was also administered; antibiotics were discontinued after 7 days. The pruritus and associated lesions began to resolve in the first week of treatment. Mites were detected on fecal flotation 7 days after treatment but not at 14 days or 21 days. At 1-month follow-up examination, the skin appeared normal.

Comments

Mites are not consistently recovered in skin scrapings from cats with demodicosis, including those with *D. gatoi* infestation. Examination of material collected with tape strips may be more successful for confirmation of diagnosis.[42] However, because the pruritus associated with demodicosis causes cats to groom excessively, mites are ingested and frequently identified on fecal flotation.[46] Fecal examination should be requested for cats seen for pruritus. Skin biopsy was not necessary in this case and could have been avoided if fecal flotation had been performed initially. Although this cat was treated with transdermal moxidectin, isoxazolines (lotilaner, fluralaner, sarolaner) are available for cats, and sometimes in combination with macrocyclic lactones (selamectin, moxidectin) and would also be expected to be effective. Unlike most other *Demodex* spp., *D. gatoi* causes contagious pruritus and when co-housed, multiple cats are often infested.[42] Ginger should be isolated until treatment has been completed and other in-contact cats closely evaluated for skin lesions. Prophylactic treatment of all cats in the facility with selamectin/sarolaner or moxidectin/fluralaner may be warranted.

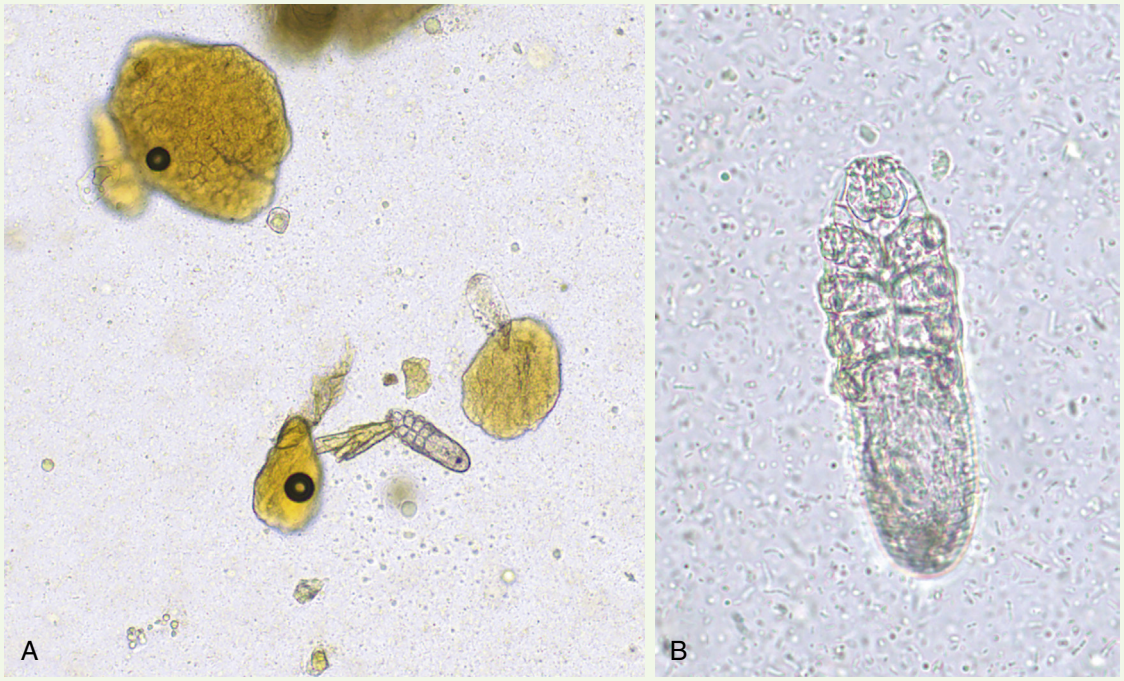

Fig. 110.8 *Demodex gatoi* mites recovered on fecal flotation as viewed with 10× (A) and 40× (B) objectives (100× and 400× magnification, respectively).

Heartworm and Related Nematodes

C. Thomas Nelson

KEY POINTS

- First Described: Heartworm was first described in dogs in Italy in 1626[1] and in the United States in 1847.[2]
- Cause: *Dirofilaria immitis*, belonging to the superfamily Filarioidea and family Onchocercidae. A related nematode, *Dirofilaria repens,* is found in southern and central Europe, Africa, and Asia but is not currently endemic in North America.
- Affected Hosts: Although canids (domestic dogs, coyotes, foxes, wolves, and other wild canids) are the definitive hosts for heartworms, the parasite has been found in more than 30 species of animals, including domestic cats and wild felids, bears, ferrets, seals, sea lions, and humans.
- Intermediate Hosts: There are multiple mosquito vectors in every region of the United States. More than 70 species of mosquitoes have been shown to be capable of transmitting heartworms; 25 species have been proven to be significant vectors.
- Geographic Distribution: Heartworm is endemic in North, Central, and South America; the Caribbean Islands; the coastal regions of Africa, southern Europe, and Asia; Japan; Indonesia; and Australia.
- Route of Transmission: Female mosquitoes feeding on a microfilaremic canine host ingest microfilariae. The ingested microfilariae undergo a transformation and two molts over a 2- to 4-week period to become infective third-stage larvae (L_3). The L_3 are then deposited on a dog's skin in a droplet of hemolymph by a feeding female mosquito. The L_3 enter through the bite wound into the subcutaneous tissue.
- Major Clinical Signs: Signs of heartworm disease can range from a cough and exercise intolerance to dyspnea, abnormal heart and lung sounds, hepatomegaly, syncope, ascites, and death.
- Differential Diagnoses: These include primary pulmonary diseases (pneumonia, chronic bronchitis, allergic lung disease), pulmonary thromboembolism, pulmonary hypertension, and right-sided heart failure.
- Human Health Significance: *Dirofilaria immitis* is of public health concern even though the number of reports of infection in humans is relatively small. The most common clinical syndrome reported in human infections is the formation of a pulmonary nodule or nodules within the lung parenchyma.

CANINE HEARTWORM DISEASE

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Heartworm disease is caused by the parasitic filarial nematode *Dirofilaria immitis*, belonging to the superfamily Filarioidea and family Onchocercidae. Nine filarial nematode species infect dogs worldwide, and three have been diagnosed in the United States: *D. immitis, Dirofilaria repens,* and *Acanthocheilonema reconditum* (formerly *Dipetalonema reconditum*). Only *D. immitis* and *A. reconditum* are considered endemic, but conditions exist for *D. repens* to become established. Heartworm was first described in dogs in Italy in 1626[1] and in the United States in 1847.[2] Although canids (domestic dogs, coyotes, foxes, wolves, and other wild canids) are the definitive hosts for heartworms, the parasite has been found in more than 30 species of animals, including domestic cats and wild felids, bears, ferrets, seals, sea lions, and humans. There has even been one confirmed case in a bird.[3] Information specific to the cat is presented in the second part of this chapter.

Heartworms are endemic in North, Central, and South America; the Caribbean Islands; the coastal regions of Africa, southern Europe, and Asia; Japan; Indonesia; and Australia.[4,5] In the United States, heartworm has progressed from being a parasitic disease primarily in the southeast to being diagnosed in all 50 states (Fig. 111.1). Alaska is the only state in which transmission has not been documented; however, there are mosquito vectors and climatic conditions present in regions of central Alaska to support the transmission of heartworms for brief periods.[6] The yearly incidence of identified cases of canine heartworm infection continues to rise despite the availability of many chemoprophylactic drugs. The increased incidence has been prominent in the western half of the United States over the past 30 years. Two factors are likely responsible: (1) heartworm-infected dogs have been relocated to western regions as humans have moved from endemic areas, thus establishing a reservoir of infection, and (2) mosquito habitats have been created as a result of irrigation of newly developed areas and the subsequent influx of suitable vector mosquitoes. A sylvatic cycle has developed in the coyote population, as the rate of heartworm infection is over 90% in many western areas.[7] The prevalence of infection elsewhere in the United States varies by region with over 90% of unprotected dogs along the Gulf Coast, lower Atlantic Coast, and Mississippi River valley being infected.[8] The severity of clinical illness also varies by region. The worm biomass in an infected dog is typically higher in dogs coming from the high-prevalence areas just listed. However, there are isolated pockets of infection with high prevalence and severity of infection throughout the United States.

The natural cycle and transmission of heartworms requires a reservoir of infection, a competent mosquito vector, and favorable climatic conditions. Unprotected domestic and feral dogs as well as wild canids serve as the reservoir hosts. Relocation of heartworm-infected dogs and expansion of the territories of microfilaremic wild canids into other areas continue to precipitate the spread of heartworms.

There are multiple mosquito vectors in every region of the United States.[9] More than 70 species of mosquitoes have been shown to be capable of transmitting heartworms; 25 species have been proven to be significant vectors. Importation of new mosquito species into an area, environmental changes created by humans, and natural climatic conditions can affect heartworm transmission. *Aedes albopictus* (Asian tiger mosquito), originally introduced into southeast Texas in 1985, has increased the exposure rate of dogs in many regions of the United States.[10] This mosquito can now be found in 35 states primarily in the Southeast, the Midwest, and the Atlantic seaboard as far north as New Jersey, southern New York, and Pennsylvania.[11] This large urban-dwelling mosquito can reproduce in small water-containing vessels such as flower pots. It voraciously feeds throughout the day, not just at dusk and dawn. The female lives for 3 months and is capable of overwintering. *Aedes albopictus* was introduced into Italy in 1990 and has spread over much of southern Europe, becoming a major vector of *D. immitis* and *D. repens*. *Aedes sierrensis* (western tree-hole mosquito) has had its geographic range extended in the western United States as a result of the continuing development of previously semiarid areas by the installation of irrigation systems and the planting of trees in new urban home sites.

Laboratory studies have determined that a minimum temperature of 57°F is necessary for the development of heartworm larvae to the infective third-stage larva (L_3).[12] This has led to the common practice of seasonal, rather than year-round, heartworm prevention in states north of the 37th parallel. Unfortunately, the heat island effect (Fig. 111.2) in urban areas can create microenvironments that are capable of supporting heartworm larva development even during winter months in northern states.[13] Furthermore, *Culex* spp. mosquitoes are competent vectors that are frequently found indoors. Therefore, transmission can continue even during cooler months in large indoor kennels. These factors along with the northward spread of *A. albopictus* have prompted the American Heartworm Society (AHS) to recommend year-round administration of heartworm preventive to dogs and cats in the continental United States and Hawaii.[14]

A knowledge of the heartworm life cycle is important for development and implementation of prevention and treatment strategies (Fig. 111.3). The life cycle of *D. immitis* is 7 to 9 months (210 to 270 days). Female mosquitoes feeding on a microfilaremic canine host ingest microfilariae. The ingested microfilariae then undergo a transformation into first-stage larvae (L_1) after entering a mosquito.[15] The L_1 will undergo two molts over the next 2 to 4 weeks, depending on the average ambient temperature, at which time they become infective L_3. The L_3 are then deposited on the dog's skin in a droplet of hemolymph by a feeding female mosquito (Fig. 111.3A). The L_3 enter through the bite wound into the subcutaneous tissue, where most L_3 molt to fourth-stage larvae (L_4) within a couple of days. The L_4 migrates in the subcutaneous tissue and muscle toward the thorax, and from approximately 50 to 70 days after initial infection L_4 undergo a final molt to juvenile worms. These juvenile worms subsequently penetrate the muscle tissue and eventually enter the circulation. Historically, the juvenile worm has been referred to as a fifth-stage larva (L_5). Because this stage does not undergo another molt, it should not be considered a larval stage. It is an immature or juvenile worm that matures into an adult over the next several months. After entering a peripheral vein, the blood then carries immature worms to and through the heart and into the

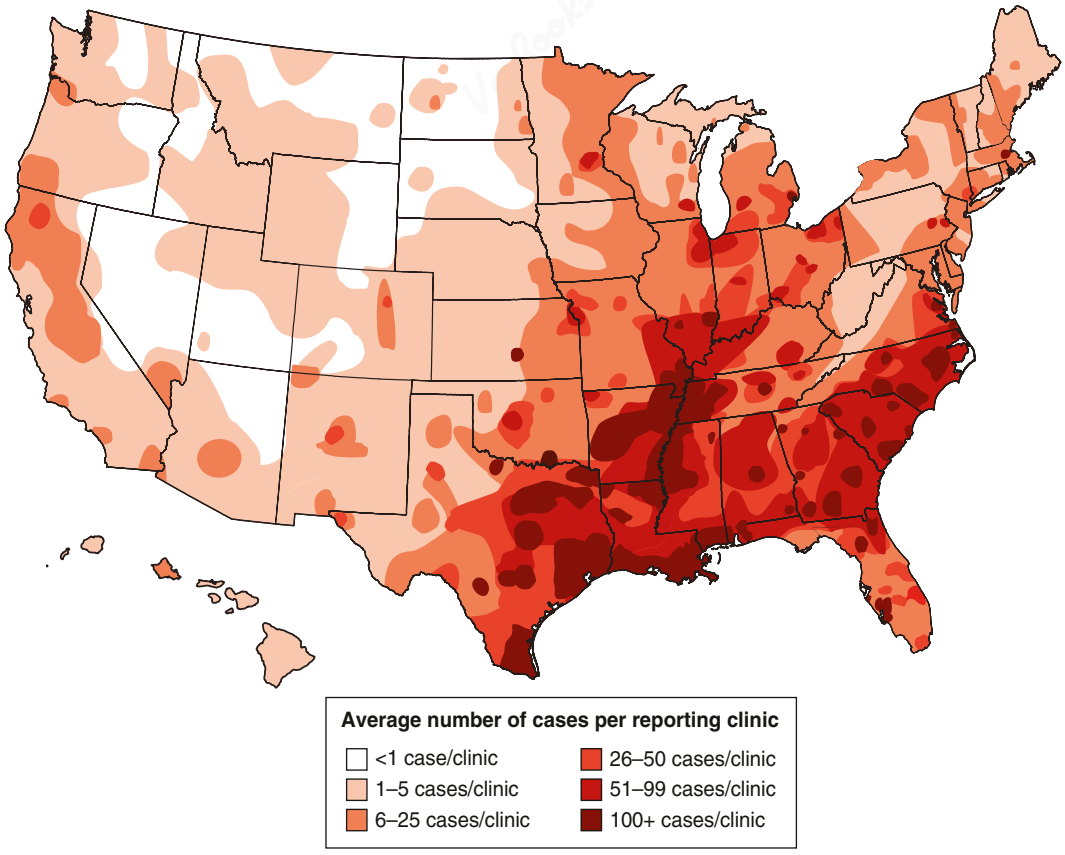

Fig. 111.1 Heartworm incidence in the United States, 2019. The severity of heartworm incidence as shown in this map is based on the average number of cases per reporting clinic. Some remote regions of the United States lack veterinary clinics; therefore, we have no reported cases from these areas. (Courtesy The American Heartworm Society.)

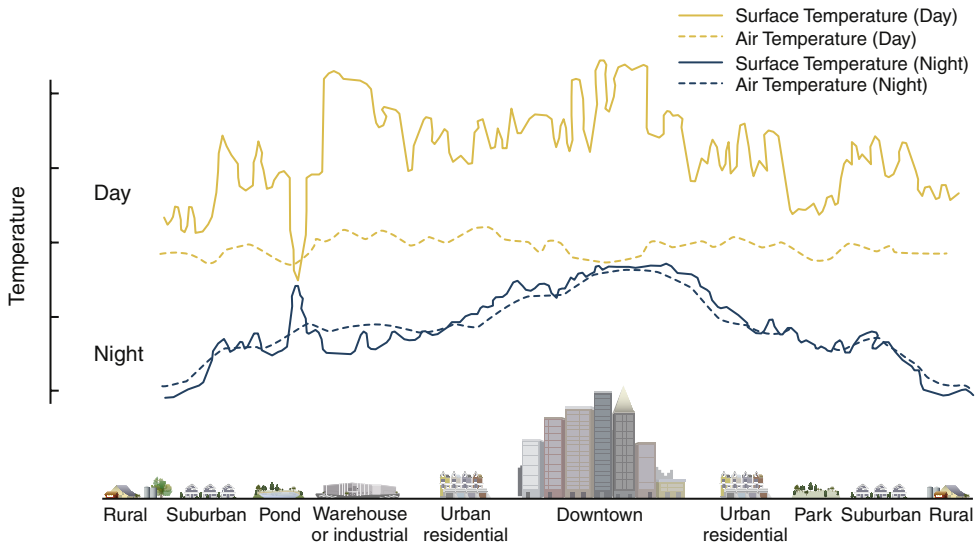

Fig. 111.2 The heat island effect in urban environments keeps urban temperatures relatively high compared to suburban and rural areas.

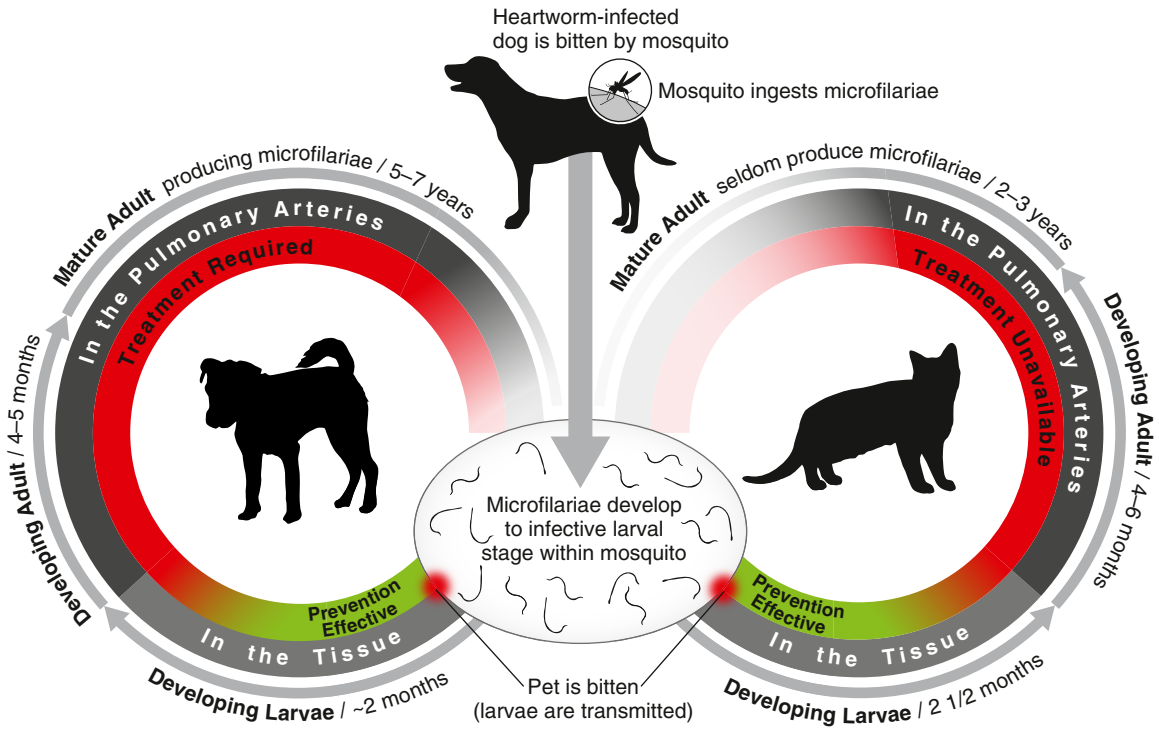
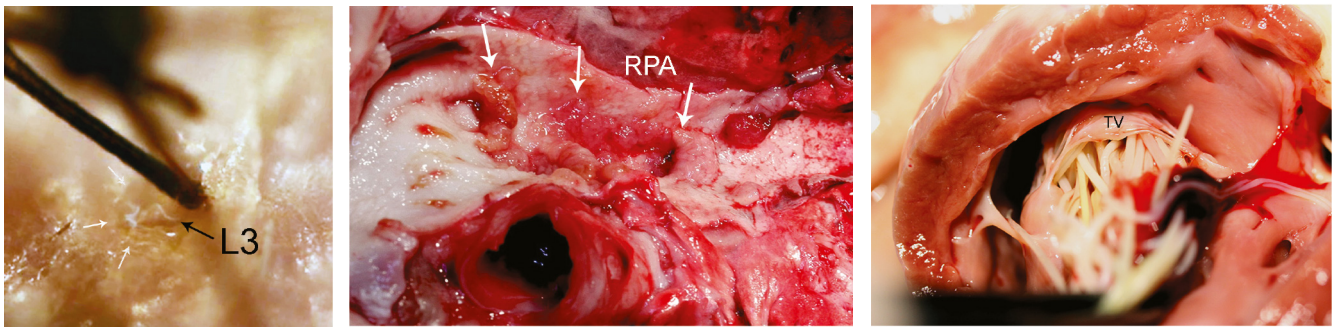
pulmonary arteries, arriving as early as 70 days PI.[16] By 120 days PI, virtually all juvenile worms have entered the pulmonary vasculature. Final maturation to adult worms and mating occurs in the pulmonary vessels. Microfilariae are then produced, typically around 180 to 210 days (but up to 270 days) PI, completing the life cycle. Mature adult males range from 15 to 18 cm in length and females from 25 to 30 cm with a life expectancy of 5 to 7 years.[17]

CLINICAL FEATURES



Pathogenesis and Clinical Signs



Heartworm infections primarily cause damage to the pulmonary arteries and lungs. Juvenile worms entering the pulmonary vasculature 3 months PI initiate an eosinophilia and eosinophilic pneumonitis.[18] Mature worms cause endothelial damage to pulmonary vessels, villous proliferation, and neutrophilic infiltrates in the vessel walls (Fig. 111.3B). Heartworms harbor the rickettsial endosymbiont *Wolbachia pipientis* that produces *Wolbachia* surface proteins (WSPs). These WSPs activate IL-8 transcription and stimulate chemokinesis in canine neutrophils.[19] In dogs infected with *D. immitis*, neutrophils accumulate in the pulmonary arterial walls and may help incite the pulmonary vasculature changes that develop. WSPs can be detected using IHC in glomerular capillaries from heartworm-infected dogs (Fig. 111.4) which suggests that glomerulonephropathy associated with heartworm disease may be the direct result of *D. immitis* that harbor *Wolbachia*.[20] The WSP also stimulates IL-10 and prostaglandin E_2 responses and IFN-γ production and IgG1 antibody responses in humans infected with *Onchocerca volvulus*, another filarial nematode that harbors *Wolbachia*.[21]

The severity of disease can be affected by the number of worms and the duration of the infection; but of equal importance, if not greater, is the activity level of the dog. Dogs in which 50 worms were surgically implanted and that were exercise-restricted took longer to develop clinical disease, and developed less pulmonary vascular resistance, than dogs infected with 14 heartworms that were allowed moderate activity.[22] This is also evident in naturally infected dogs in which there is no correlation between the number of heartworms and pulmonary vascular resistance, indicating that the individual host-parasite interaction plays an important role in the severity of disease.[22] Results of a subsequent study included similar findings in dogs being treated with melarsomine.[23] Whereas live heartworms can cause endarteritis and muscular hypertrophy of arteriole walls, primarily of the caudal pulmonary arteries, the pathologic changes seen in clinical disease are primarily the result of the effects of dying heartworms. As worms die from either natural causes or as a result of administration of adulticidal drugs, they decompose. Small worm fragments lodge in the distal pulmonary arteriole and capillary beds in the caudal lung lobes, blocking blood flow. These worm fragments, along with the inflammation that they elicit and platelet aggregation, result in pulmonary thromboembolism. During periods of increased activity or exercise, the increased blood flow to these blocked vessels can cause fragile capillaries to rupture with resultant pulmonary hemorrhage and subsequent fibrosis.[24] This fibrosis, along with the release of vasoactive substances by heartworms, leads to increased pulmonary vascular resistance and subsequent pulmonary hypertension.[25] The sequelae to these pulmonary vascular events is cor pulmonale and potential right-sided heart failure.

Ectopic lesions, due to aberrant migration of worms into the eye, CNS, abdominal cavity, and systemic circulation, can occur.[15] "Caval syndrome," which occurs in a small percentage of cases, results from heartworms located in the posterior vena cava and right atrium causing interference with tricuspid valve function (see Fig. 111.3C). Luminal obstruction, which can result in a peracute hemolytic crisis from traumatic injury to erythrocytes, contributes to the development of overt right-sided heart failure. "Caval syndrome" is usually associated with excessively large worm burdens in the right ventricle and atrium and may result from a combination of cardiac insufficiency and increased pulmonary vascular resistance, which allows the heartworms in the pulmonary artery to move back into the right heart. Glomerulonephropathy may also occur as a result of antigen-antibody complexes leading to proteinuria, and anemia, hemoglobinemia, and hemoglobinuria are often present (Table 111.1).

Many dogs infected with heartworms have no clinical signs, because dogs can tolerate live heartworms very well, especially if they are not very active. Factors that can affect the onset of clinical signs are the number of worms present in relationship to the size of the dog; the duration of infection; the individual host response to the parasite; and, most importantly, the activity level of the dog. Clinical signs usually develop gradually, with a mild cough being the most common sign noticed. This will be followed by exercise intolerance and an unthrifty appearance. Clinical signs associated with more advanced disease can

A B C

Fig. 111.3 Life cycle of heartworm infection. Microfilaria are ingested by the mosquito. After undergoing transformation to first-stage larvae (L_1), they undergo two molts over a period that can span 10 to 28 days, depending on ambient temperature. During this transformation, they first enter the malpighian tubules, then the body cavity, finally migrating toward the head and into the labium. (A) During feeding, the third-stage larvae (L_3) are deposited in a droplet of hemolymph (*white arrows*) on the animal's skin surface and migrate into subcutaneous tissue. In dogs, they molt into fourth-stage larvae (L_4) within 3 to 4 days post-infection (PI), and migrate in the subcutaneous tissue and muscle moving toward the thorax. L_4 molt into juvenile worms (sexually immature adult stage) within 50 to 70 days PI. Juvenile worms enter the venous circulation within the muscle tissue and between 70 and 120 days PI have migrated to the heart and pulmonary vasculature. The juvenile worm grows to a sexually mature adult during the range of 120 to 210 days PI, and female worms release increasing levels of antigen. *In dogs*, pulmonary vascular changes include blunting of the arteries, intraluminal thrombi and pulmonary hypertension (B). Adult worms usually reside in the pulmonary arteries and in severe infections, in the right side of the heart including the cranial and caudal vena cava (arrows indicate right pulmonary artery [RPA]). (C) A heart from a dog with caval syndrome as viewed from the right ventricle toward the tricuspid valve (*TV*). A mass of heartworms completely occludes the valve preventing it from closing. Right atrial, ventricular, and pulmonary artery enlargement are apparent. *In cats*, 90% to 95% of infections do not go past the juvenile stage, and 50% of cats have negative antibody titer results by 8 months. Dying immature worms produce heartworm-associated respiratory disease (HARD) syndrome consisting of occlusive hypertrophy of pulmonary arterioles, peribronchial infiltrates, and alveolar inflammatory infiltrates and consolidation. (A, Courtesy Boehringer Ingleheim; B, Photographic images courtesy of Stephen Jones, DVM.)

also develop acutely as a result of the natural death and disintegration of a heartworm that leads to sudden pulmonary thromboembolism. As the disease progresses and pulmonary pathology worsens, signs associated with right-sided heart involvement such as abnormal heart sounds and ascites appear.[15] Dogs that have experienced pulmonary thromboembolism from dead worms may be febrile and have hemoptysis. Those with caval syndrome present with acute, often profound, lethargy and weakness. Four classes of heartworm disease have been described with associated clinical signs (see Table 111.1). Classification of disease based on clinical severity has been used to determine

treatment strategies and prognosis. However, although class 3 patients are statistically at a greater risk for severe complications and death after treatment, class 1 and 2 patients can experience the same levels of complications.[14] Dogs with caval syndrome (class 4) are severely ill and require surgery to survive.

Physical Examination Findings

Physical examination findings in dogs with heartworm disease may be normal in mild or early infections. Dogs may exhibit a thin body condition, tachypnea, dyspnea, a right-sided heart murmur from tricuspid insufficiency, cardiac gallop, and jugular distension with pulsation. Auscultation of lung fields could reveal pulmonary crackles primarily in the caudal lung lobes. Dogs with caval syndrome are severely lethargic, have pale mucous membranes and delayed capillary refill time, weak peripheral pulses, and often have dark urine due to hemoglobinuria.

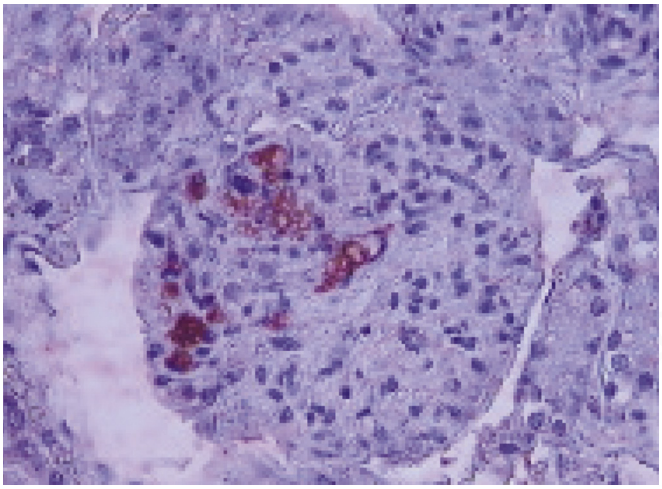


Fig. 111.4 Immunohistochemical staining for *Wolbachia* surface protein in a dog with natural *Dirofilaria immitis* infection showing a positive reaction in a renal glomerulus (×40). (From Kramer LH, Tamarozzi F, Morchon R, et al. Immune response to and tissue localization of the *Wolbachia* surface protein (WSP) in dogs with natural heartworm (*Dirofilaria immitis*) infection. *Vet Immunol Immunopathol.* 2005;106:303–308, with permission.)

TABLE 111.1 Classification of Canine Heartworm Disease Based on Clinical Severity

Severity	Class	Clinical Signs
Early infection	Class 1	No signs
Mild disease	Class 1	Cough
Moderate disease	Class 2	Cough, exercise intolerance, abnormal lung sounds
Severe disease	Class 3	Cough, exercise intolerance, dyspnea, abnormal heart and lung sounds, hepatomegaly, syncope, ascites, hemoptysis and death
Caval syndrome	Class 4	Sudden onset of severe lethargy and weakness accompanied by hemoglobinemia and hemoglobinuria

DIAGNOSIS

The diagnosis of heartworm disease is primarily done using serum immunoassays, but other testing modalities are useful in determining the severity of disease present.

Laboratory Abnormalities

Abnormal clinical laboratory results occur but are not uniquely diagnostic for heartworm infection. Hemogram abnormalities may include eosinophilia, basophilia, neutrophilia, nonregenerative anemia, and thrombocytopenia. Elevated liver enzyme activities,

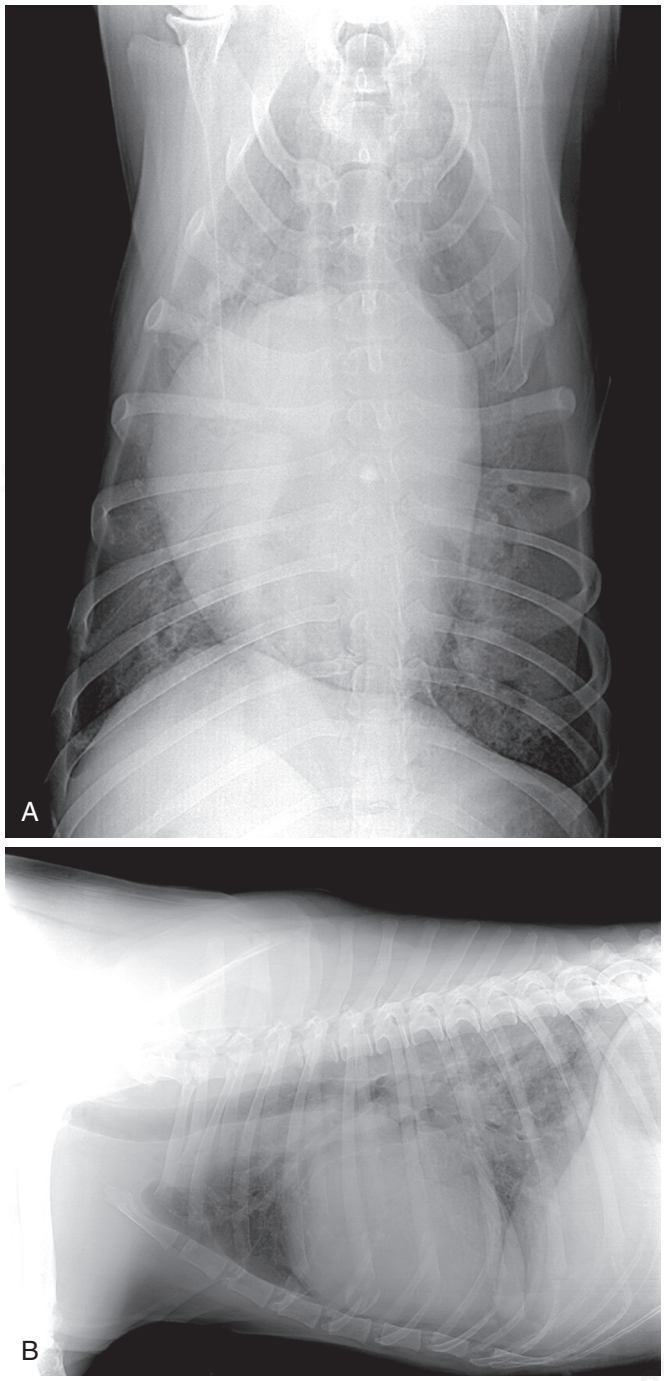

Fig. 111.5 (A) Ventrodorsal and (B) lateral thoracic radiographs of a dog with class 3 heartworm infection.

azotemia, and hyperbilirubinemia may be noted in results of serum chemistries, and proteinuria may be detected on urinalysis.

Diagnostic Imaging

Plain Radiography

Radiography is an effective way of evaluating the severity of cardiopulmonary disease, and before the availability of serologic testing, it was the method used to diagnose occult (nonmicrofilaremic) heartworm disease. The heart silhouette appears as a reversed "D" and caudal lobar pulmonary arteries are enlarged, tortuous, and often truncated. These vascular changes are accompanied by varying degrees of pulmonary parenchymal disease (Fig. 111.5).[26]

Parasitologic Tests

The AHS recommends annual screening using both a microfilariae and an antigen test for all dogs over 7 months of age; and testing is indicated 6 months after starting prophylaxis in dogs over 8 weeks of age; before starting prophylaxis in dogs over 7 months of age; and on days 0, 180, and 360 when there has been noncompliance or a change in prophylactic treatment product.

Detection of Microfilaria

Microfilaria can be identified microscopically by direct examination of a drop of anticoagulated blood, with concentration techniques using a Millipore filter, or centrifugation using the modified Knott's procedure (see Chapter 5). Microfilariae may not be detected in as many as 20% of heartworm-infected dogs. These "occult" infections may occur as a result of single-sex infections, host immune responses suppressing reproduction, and if the dog has been on a heartworm preventive.[15] For various reasons, microfilariae may be present in dogs with negative blood antigen result. It is possible for puppies to acquire microfilariae *in utero* when the bitch has a high microfilaria count. Because microfilariae can survive in the dog's bloodstream for over 2 years, dogs treated with an adulticide or dogs whose infection has cleared naturally can have microfilariae and have negative antigen test results. Heartworm microfilariae must be differentiated from those of *A. reconditum* (Fig. 111.6 and Table 111.2).

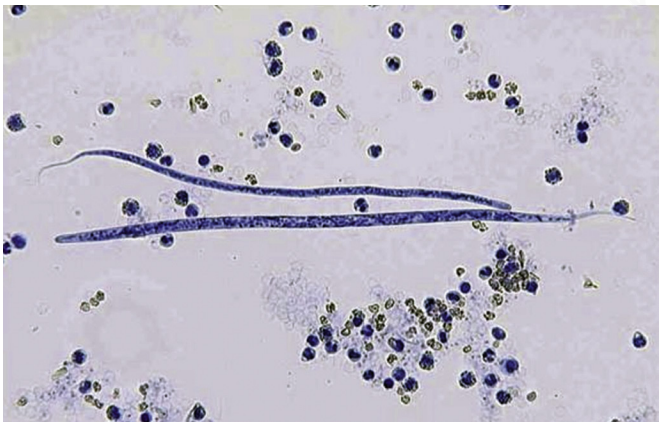

Fig. 111.6 *Acanthocheilonema reconditum* (top) and *Dirofilaria immitis* (bottom). (Courtesy Byron Blagburn, Auburn University, Auburn, AL.)

Serologic Testing

Antigen detection, which, together with microfilaria testing is the recommended method for diagnostic screening in dogs, is accomplished by using one of several commercially available antigen tests kits. These are available as POC tests or well-based tests that are used by reference laboratories to process large numbers of specimens. These tests detect a glycoprotein secreted mainly by adult female heartworms and are the most sensitive diagnostic method currently available.

Commercially available antigen test systems are based on enzyme immunoassay methods that have been adapted to laboratory or POC kits. The sensitivity (95% to 100%) and specificity (100%) of these test systems are excellent in infections when three or more female worms are present. Most POC test kit systems have low sensitivity in dogs with fewer than three female worms. In dogs with one female worm, the sensitivity ranged from 65% to 85%, and with two female worms, it ranged from 85% to 95%.[27] However, when comparing the presence or absence of female worms at necropsy, the sensitivity of one in-clinic instrument-based agglutination immunoassay test system ranged between 50% and 72% compared with 92% and 99.6% for a kit-based enzyme immunoassay.[28] False-positive results are rare, and, therefore, it is better to accept rather than reject a positive test result. However, it is prudent to repeat a test when positive results are found for dogs residing in hypoendemic areas, and in animals that receive heartworm preventive. Confirmation of the positive test result can be obtained if circulating microfilaria are identified, or if another positive result is generated using a different type of antigen test. An animal with clinical signs of heartworm disease that has a negative test result should also be retested. The amount of antigen present in the circulation can be quantitated and does have a relationship to the number of female worms, but this is not an accurate determination of the total worm burden. Male and immature female worms could be present but not producing detectable antigen. Likewise, shortly after the death of a female worm, large amounts of antigen are released into the circulation, giving the appearance of a heavy worm burden in quantitative test results.[14]

False-negative test results occur most commonly when infections are light, female worms are still immature, only male worms are present, and/or the test kit instructions have not been followed. There are also documented cases of antigen blocking, presumably from antigen-antibody complexes, interfering with antigen testing, resulting in false-negative test results. Laboratory studies have shown that heating the sample test-tube to 104°C for 10 minutes degrades the complexes, which releases antigen, yielding more accurate results.[29,30] The routine

TABLE 111.2 Comparison of Microfilariae of *Acanthocheilonema reconditum* and *Dirofilaria immitis*

	Number in Blood	Motion	Shape	Length (Modified Knott Test)
A. reconditum	Usually few	Progressive	Curved body Blunt head Curved or "button-hook" tail	250–288 μm
D. immitis	Usually many	Stationary	Straight body and tail Tapered head	307–322 μm

TABLE 111.3 Treatment for Canine Heartworm Disease

Drug[a]	Dose	Route	Interval	Duration (Days)
Melarsomine	2.5 mg/kg[b]	Deep IM	Once; repeat in 4 weeks followed by third dose 24 hours later	3 doses
Macrocyclic lactones[c]	Varies	PO, topical	30 days	Indefinite[c]
Doxycycline	10 mg/kg; 5 mg/kg in cases of severe gastrointestinal signs	PO	q12h	28
Prednisolone	0.5 mg/kg	PO	q12h	7[d]

[a]See Chapter 13 for specific information on each anti-infective drug.
[b]This drug has a low margin of safety: three times the single dose indicated (7.5 mg/kg) can result in severe pulmonary inflammation, edema, and death. Dose calculations must be very accurate and given over the extended period specified.
[c]Ivermectin, milbemycin, moxidectin, selamectin: See manufacturers' dosage recommendations.
[d]Dosage is reduced to 0.5 mg/kg every 24 hours for the next 7 days and 0.5 mg/kg every other day for 1 to 2 weeks thereafter.

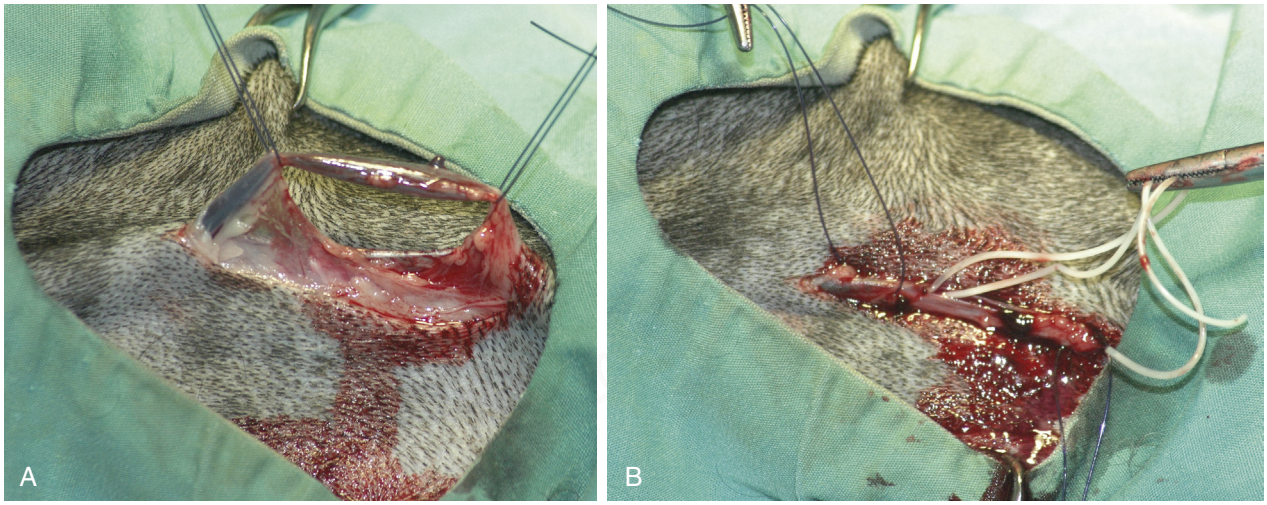

Fig. 111.7 Surgical removal of *Dirofilaria immitis* from a dog with caval syndrome. (A) Isolation of the right jugular vein. (B) Extraction of worms. (Courtesy of C. Thomas Nelson.)

heating of all blood samples is not recommended at this time as this is contrary to the label instructions for these tests and could interfere with the results of combination tests that include an antibody test for detection of other infectious agents. Due to this, and other mentioned considerations, heartworm test results should only be recorded as positive or no antigen detected (NAD) and should not be written as "negative." Antigen test results should be interpreted carefully, taking other relevant clinical information into consideration.

Antigen may be detected as early as 5 months PI and consistently by 7 months PI. Antigenemia may be delayed until 9 months PI in some infected dogs that receive preventives. Microfilaria can be detected microscopically 6 months PI, by examining fresh blood, or with concentration techniques. Screening dogs for the presence of microfilaria is complementary to antigen testing, because it adds sensitivity without compromising specificity,[31] confirms the infection and alerts the veterinarian of a potential adverse reaction that may occur after administration of microfilaricidal doses of macrocyclic lactones. Because of the prepatent period, dogs should not be tested with either microfilariae or antigen tests until they are at least 7 months old.[14]

Molecular diagnostic methods are occasionally used in research for diagnosis of heartworm infection. A multiplex PCR assay has been developed that can detect and discriminate *D. immitis* from *D. repens*.[32]

TREATMENT

Successful management and treatment of heartworm disease requires a thorough understanding of the life cycle of *D. immitis*, the host-parasite relationship, and the susceptibility of the various life stages to microfilaricidal and adulticidal drugs. The goals of any heartworm treatment are to improve the clinical condition of the animal and to eliminate all adult heartworms and developmental stages with minimal post-treatment complications. Before initiation of therapy, a thorough physical examination, clinical laboratory testing, and thoracic radiographs should be performed. Clinical or laboratory problems of concern should be controlled or stabilized before the dog receives adulticidal therapy. This may involve the administration of glucocorticoids to reduce pulmonary inflammation as well as angiotensin-converting enzyme inhibitors to improve cardiac function. In severe cases of right-sided heart failure, abdominal drainage may be necessary to remove ascitic fluid to initially reduce diaphragmatic pressure followed by maintenance therapy with furosemide and sildenafil (see Table 111.3 for doses of drugs used to treat canine heartworm disease).

Caval syndrome is an often fatal manifestation of heartworm disease in dogs that have a high worm burden that obstructs blood flow. Severe pulmonary arteriolar hypertension and decreased cardiac output occur. Heartworms can be surgically extracted via a right jugular venotomy and

introduction of alligator forceps, a flexible snare, or brush (Fig. 111.7).[33] The use of a C-arm imaging device is useful but not imperative. This procedure is done as an emergency measure that is reserved for dogs with this syndrome. Medical management of heartworm disease is used in all other patients as discussed in the following sections.

Melarsomine

Melarsomine is an arsenic-based drug and is the only adulticidal drug approved by the FDA for heartworm treatment in the United States. It is administered by deep intramuscular injection into the epaxial lumbar muscles. The two-dose protocol recommended on the package insert for treating class 1 and 2 heartworm infections (see Table 111.1) kills 90% of adult worms present. The "alternate" or three-dose protocol recommended for treating class 3 heartworm infections kills 98% of the adult worms. Approximately 50% of adult worms are killed by the first dose, and most of the remaining worms are killed by the second and third injection administered 4 to 8 weeks later. The three-dose protocol is recommended by the AHS as the adulticidal treatment of choice because of its increased safety margin and efficacy.

Macrocyclic Lactones

The heartworm preventive products belonging to the macrocyclic lactones contain ivermectin, milbemycin, moxidectin, or selamectin.

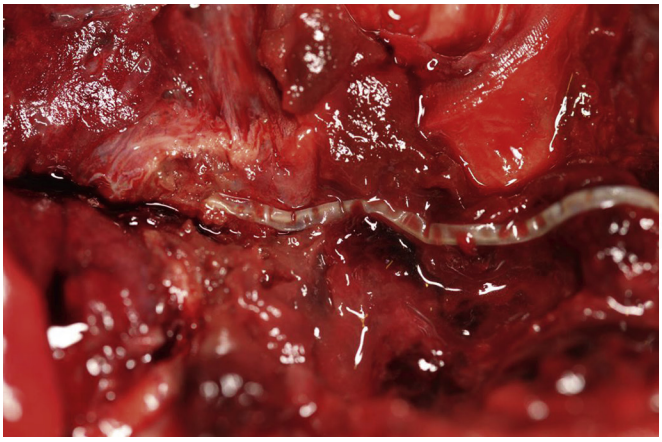

Fig. 111.8 Heartworm cuticle after 3 years of ivermectin preventive administration. (Courtesy of Stephen Jones, DVM.)

In the past, long-term administration of heartworm preventives has been advocated to prevent reinfection while waiting for existing adult heartworms to die. This approach is not recommended because it can take 2 to 3 years to completely clear the infection, during which time pulmonary and cardiovascular abnormalities can progress (Fig. 111.8). There is also the chance of selection for resistant strains of *D. immitis*.

Doxycycline

Because the metabolites (WSP) of *Wolbachia* contribute to the disease process, doxycycline has been the subject of several studies in heartworm treatment, and is now being used in the treatment of several human filarial diseases. Results of two studies were compared: heartworm test–positive dogs treated with ivermectin and doxycycline before melarsomine injections versus those with melarsomine alone had fewer gross pulmonary pathologic changes associated with the death of the heartworms.[34,35] In one study, there was a 78% reduction in heartworm numbers using ivermectin and doxycycline only after 36 weeks of therapy.[34] Other studies have shown similar results.[36] Histopathologic changes in the lung tissue included an intense inflammatory reaction and positive staining for WSP in the dogs treated with melarsomine. The inflammation was significantly reduced and staining for WSP was virtually absent in dogs receiving doxycycline-ivermectin-melarsomine combination therapy (Fig. 111.9).[37] Doxycycline administered at 10 mg/kg q12h for 4 weeks eliminates the presence of *Wolbachia* DNA. The dose can be reduced to 5 mg/kg q12h if GI adverse effects occur. In one study, 40% of heartworm-infected dogs receiving doxycycline developed elevated serum liver enzyme activities. This does not appear to be clinically significant in dogs with normal liver function. The elevated activities are transient and they typically return to pretreatment values without intervention.[38] Microfilariae from dogs treated with doxycycline developed into L_3 after ingestion by mosquitoes, but those L_3 did not develop into adult worms when inoculated into a new canid host. This impaired maturation of L_3 would result in decreased transmission and reduces the potential for selection of resistant strains of *D. immitis*.[39,40]

Macrocyclic Lactones/Doxycycline Combinations

Select macrocyclic lactones (ivermectin and moxidectin) coupled with doxycycline individually suppress embryogenesis and weaken adult heartworms. Administration of doxycycline in combination with ivermectin provided more rapid adulticidal activity than

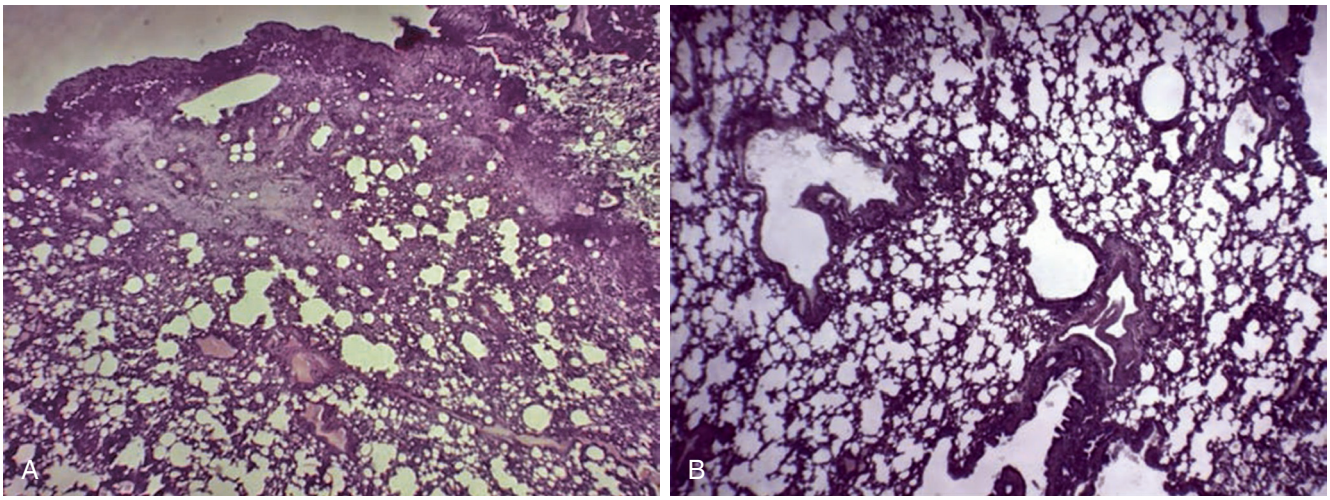

Fig. 111.9 Histopathologic appearance of the lung tissue from dogs experimentally infected with heartworms. (A) Treatment with melarsomine only. (B) Combined treatment with ivermectin, doxycycline, and melarsomine. (Courtesy Laura Kramer, University of Parma Veterinary School, Parma, Italy.)

ivermectin alone, and reduced *Wolbachia* burden to a greater extent than doxycycline alone.[41] Topical moxidectin in combination with doxycycline had 95.9% efficacy in killing adult worms after 10 months of treatment.[42] In cases where arsenic therapy is not possible or is contraindicated, the use of a monthly heartworm preventive containing ivermectin or topical moxidectin along with doxycycline at 10 mg/kg q12h for a 4-week period might be considered. This protocol is not recommended by the AHS as a standard first-line treatment but instead as a salvage procedure. The safety and long-term effects of these protocols have not been evaluated. An antigen test should be performed every 6 months and the dog not considered cleared until two consecutive negative heartworm antigen tests have been obtained. Heat treatment of samples from dogs being treated with only preventive and doxycycline prior to antigen testing is necessary because false-negative antigen tests are common in such patients.[43] If a dog treated this way is still antigen positive after 1 year, doxycycline therapy should be repeated. Exercise should be rigidly restricted for the duration of the treatment process.

Prednisone

Thromboembolism is an unavoidable sequela of any heartworm treatment protocol. Emboli primarily consist of worm fragments with associated perivascular inflammation; grossly visible clots are not usually present. The treatment of choice to help reduce the inflammatory response is prednisone. The dosage is 0.5 mg/kg q12h for the first week, 0.5 mg/kg q24h for the second week, and 0.5 mg/kg q48h for 1 to 2 weeks. Aspirin had been advocated in years past, but has been shown to be contraindicated in heartworm treatments because it leads to greater pulmonary vascular extravasation of blood. Prednisone reduces parenchymal and arterial wall damage resulting in less reparative fibrosis. Arterial elasticity is better preserved, which leads to reduced pulmonary vascular resistance, and subsequently fewer right-sided heart complications.[44] In dogs experimentally infected with heartworms, efficacy of therapy with melarsomine and prednisone was the same as that in dogs treated only with melarsomine, in either two- or three-dose protocols.[45]

AHS-Recommended Treatment Protocol

The treatment protocol outlined in Table 111.4 is designed to eliminate *Wolbachia* organisms and allows time for clearance of *Wolbachia*-associated metabolites such as WSP. Pretreatment with a macrocyclic lactone heartworm preventive and doxycycline halts embryogenesis and makes the adult worms unthrifty and smaller. This is followed by the three-dose melarsomine protocol, which provides a 99% kill rate of adult worms. Results of a retrospective study of naturally infected dogs treated with the AHS protocol compared with an identical protocol with the exception of doxycycline showed a decrease in overall post-treatment complications and mortality with the AHS protocol.[46] A second study that compared cardiopulmonary biomarkers between a classic melarsomine two-injection protocol and the AHS approach showed higher levels of D-dimer in the melarsomine treatment group.[47]

PROGNOSIS

Most heartworm infections can be cleared successfully, but there is usually residual damage to the pulmonary vasculature and parenchyma. The extent of the damage depends on the number of worms, activity level of the dog before and after treatment, and the host-parasite relationship. Strict exercise restriction during and after treatment along with utilizing the AHS treatment protocol provides the best opportunity to minimize permanent lung damage.[46]

TABLE 111.4 Example of Treatment Protocols for Canine Heartworm Disease

Day	Treatment
0	Dog diagnosed and verified as heartworm positive
	If the dog has clinical signs, attempt to stabilize the dog with angiotensin-converting enzyme inhibitor and furosemide. If dog is severely ascitic, also perform abdominal drainage.
	Administer heartworm preventive. (If microfilariae are present, pretreat with antihistamine and glucocorticosteroid if not already on prednisone.)
	Apply topical mosquito repellant approved for use in dogs
	Begin exercise restriction. The more pronounced the clinical signs, the stricter the exercise restriction.
1–7	Prednisone: 0.5 mg/kg PO q12h (only if clinical signs are present)
1–28	Doxycycline: 10 mg/kg PO for 4 weeks
8–14	Prednisone: 0.5 mg/kg PO q24h
15–28	Prednisone: 0.5 mg/kg PO q48h
30	Administer heartworm preventive Apply topical mosquito repellant approved for use in dogs
60	Administer heartworm preventive Apply topical mosquito repellant approved for use in dogs
61	Melarsomine: 2.5 mg/kg IM
61–67	Prednisone: 0.5 mg/kg PO q12h; further decrease activity level; cage rest in severe cases
68–74	Prednisone: 0.5 mg/kg PO q24h
75–88	Prednisone: 0.5 mg/kg PO q48h
90	Administer heartworm preventive and second melarsomine injection 2.5 mg/kg IM
91	Administer heartworm preventive and third melarsomine injection 2.5 mg/kg IM
91–97	Prednisone: 0.5 mg/kg PO q12h
98–104	Prednisone: 0.5 mg/kg PO q24h
105–118	Prednisone: 0.5 mg/kg PO q48h; continue exercise restriction for 6–8 weeks after last melarsomine injection
120	Test for microfilaria and if positive treat with a microfilaricide and retest in 4 weeks. Continue a year-round heartworm prevention program as described in prevention section.
365	Antigen test 9 months after last melarsomine injection. If still positive, re-treat with doxycycline followed by two doses of melarsomine 24 hours apart.

IMMUNITY AND VACCINATION

Attempts to produce a vaccine, while successful, have not been commercially marketed as vaccine efficacy was less than the current preventives on the market.

PREVENTION

Dirofilaria immitis infection can be prevented with commercially available macrocyclic lactone heartworm preventives (see Table 13.2), which should be recommended no later than 8 weeks of age. These products vary in their claims of efficacy against other internal and external parasites and are offered as orally administered flavored or

chewable tablets (ivermectin, milbemycin oxime, and moxidectin), as topically applied liquids (moxidectin and selamectin), or as a slow-release formulation of subcutaneously injected drug (moxidectin). The oral and topical forms are administered once monthly, and the injectable product licensed in the United States is available in a 6-month and 12-month formulation.[14] The macrocyclic lactones are formulated to kill the tissue stages (L_3 and L_4) of *D. immitis*. The final molt from L_4 to juvenile worm can occur as early as 50 days PI, so it is imperative that the product be given at a 30-day interval, because late L_4 stages have reduced susceptibility.[48] These preparations also help to control other internal and external parasites.[49]

There have been increased reports of lack of efficacy (LOE) according to the Center for Veterinary Medicine of the FDA.[50] Evidence of LOE is defined by the FDA as having positive heartworm test results in the face of consistent heartworm preventive use. Unless the injectable form is given, it is very difficult to assess client compliance with regard to product administration. Other reasons for LOE are possible. Underdosing may occur in animals that have gained weight. Dosing intervals may be prolonged beyond efficacy, because doses may be inadvertently skipped or animals may fail to retain a dose because they spit out or vomit tablets shortly after administration. There is also the possibility of biological variation in how an individual animal metabolizes a drug or whether or not a strain of *D. immitis* has developed drug resistance.

In experimental studies that have evaluated these products against apparently resistant strains of *D. immitis*, dogs being given preventives developed adult worms.[51,52] Therefore, the drugs generally cannot be assumed to be 100% effective and clients should be so informed. Furthermore, genetic variations associated with decreased susceptibility to macrocyclic lactones occur among *D. immitis* isolates, indicating resistant strains exist.[53,54] Because drug resistance is selected for and does not randomly develop, it is imperative that any dog suspected of harboring a more tolerant or resistant strain be treated immediately with an adulticidal protocol that incorporates doxycycline and melarsomine. Doxycycline will eliminate *Wolbachia* and reduce the potential for transmission of the resistant strain. A three-injection melarsomine treatment protocol will eliminate 98% of the total worm burden. With this protocol, usually 100% of the male worms needed for sexual reproduction will be eliminated, thus impairing microfilaria production. This approach, along with the extensive refugia of wild-type genes, may limit resistance from becoming widespread.

Addition of topical products that repel and kill mosquitoes will also enhance the efficacy of the macrocyclic lactones. Use of a topical dinotefuran-permethrin-pyriproxyfen product in conjunction with a macrocyclic lactone heartworm preventive was able to prevent experimental heartworm infection by a known resistant strain.[55] Reduction of exposure to mosquitoes through standard environmental control of mosquitoes and their breeding environments, and when possible, reducing outdoor exposure during key mosquito feeding periods is also recommended.

Diethylcarbamazine citrate is an older medication that is no longer marketed in the United States but is still available for heartworm prevention in other parts of the world. Its effect is at the molt between L_3 and L_4 and, therefore, it must be given every day to be effective.

PUBLIC HEALTH ASPECTS

Dirofilaria immitis is of public health concern, even though the number of reports of infection in humans is relatively small. However, there is no serologic test to detect infection, so invasive procedures that involve biopsy of lesions is usually necessary.[56] The most common clinical syndrome reported in human infections is the formation of a pulmonary nodule or nodules within the lung parenchyma.[57,58] This lesion appears on radiographs as circular density and has been described as a "coin lesion." These lesions resemble those of pulmonary adenocarcinomas and often are not diagnosed until after a person has undergone a thoracotomy for the removal of a lung lobe. Histopathologic findings are granulomatous inflammation surrounding the remnants of an immature heartworm. Granulomatous lesions have also been recorded in the eye, skin, testicle, and other tissues.[58] Infected dogs or blood with microfilaria do not present a direct risk of infection to humans because the parasite can only be transmitted by mosquitoes. Prevention is best accomplished through mosquito-abatement programs and by using mosquito repellents, wearing protective clothing, and remaining indoors during mosquito feeding periods. See Chapter 13 for further information on insect control measures.

FELINE HEARTWORM DISEASE

ETIOLOGY AND EPIDEMIOLOGY

Heartworm disease was first discovered in cats in Brazil in 1921[59] and in the United States in 1922.[60] Its geographic distribution mirrors that of canine heartworm infections, as long as there is a competent mosquito vector present that will feed on both dogs and cats.[61] The means of transmission and life cycle are identical in the cat and dog until the juvenile heartworm (also referred to as an immature adult or fifth stage) reaches the pulmonary arteries (see Fig. 111.3). Most juvenile worms in dogs mature to adults over 3 to 4 months, after which they mate and produce microfilariae. However, in the cat, most of the juvenile worms die 3 to 4 months PI, resulting in an abbreviated infection.[62] In a small percentage of cats, a few worms mature to be adults and live for 2 to 4 years.[63] Microfilaria will be produced and may be found 8 months PI in 20% of mature worm infections. They will be removed from the circulation by the cat's immune response within 2 months and not found again.[62]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

There are three stages of heartworm disease in cats. The first stage begins shortly after the arrival of the juvenile worms in the caudal pulmonary arteries 75 days PI. There is an acute vascular and parenchymal inflammatory response to the presence and subsequent death of most of these immature worms approximately 90 days PI. Light and electron microscopic lesions can be detected in the lungs of experimentally infected cats as early as 42 days PI.[64] Vascular disease can be found in the caudal lung lobes by day 75 PI, followed by interstitial and alveolar disease by day 90 PI.[65,66] The vascular lesions are described as severe muscular hypertrophy of the medium- and small-sized arteries. These same types of lesions are found in cats that have positive results for anti-heartworm antibodies but have no adult heartworms at necropsy.[66] Therefore, cats do not have to have fully mature adult worms to have pulmonary disease.

A study of experimentally infected cats compared the pulmonary pathologic changes between cats receiving heartworm prevention, cats with abbreviated juvenile worm infections, and cats with adult heartworms. Vascular lesions were found in both cats that had mature heartworms and cats with abbreviated infections (Fig. 111.10). The lesions in the bronchioles and alveoli of the abbreviated juvenile worm were almost identical to those found in cats with adult worm infections (Figs. 111.11 and 111.12).[68] Thus, pulmonary disease occurs in cats as a result of juvenile worm infections even if they do not progress to the mature adult worm stage. Because heartworm disease in the cat is primarily a pulmonary disease, the term "heartworm-associated respiratory disease" (HARD) has been adopted to describe heartworm infections in cats.[68,69]

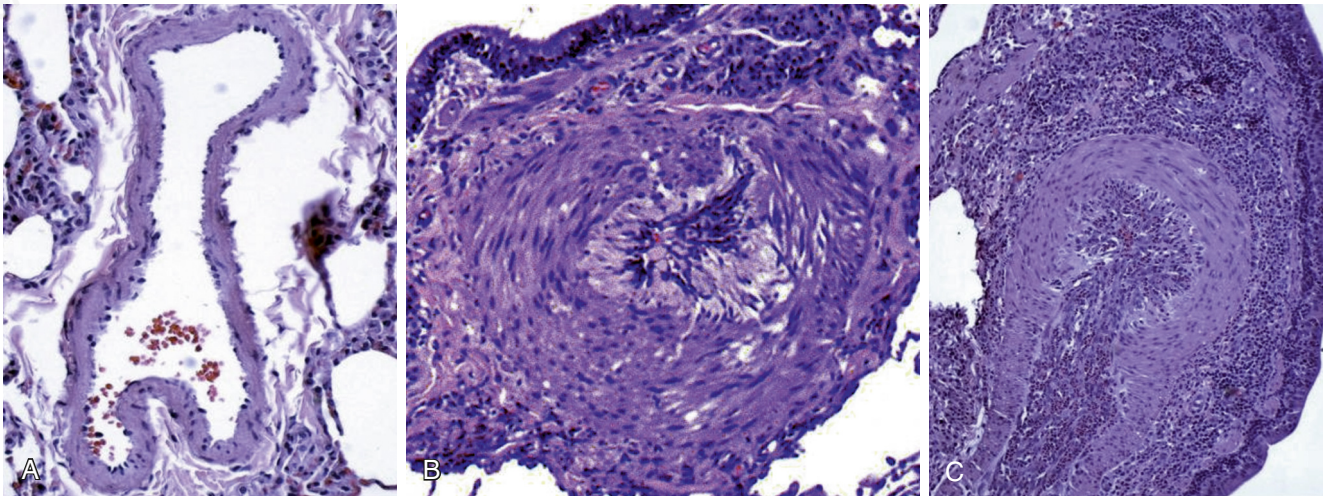

Fig. 111.10 Histopathologic view of arterioles from heartworm-challenged cats. (A) Cat receiving monthly heartworm preventive. (B) Cat with abbreviated juvenile worm infection. (C) Adult heartworm infection (hematoxylin and eosin stain, ×40). (Courtesy Drs. Ray Dillon and Byron Blagburn, Auburn University, Auburn, AL.)

(C) Adult heartworm infection (hematoxylin and eosin stain, ×20). (Courtesy Drs. Ray Dillon and Byron Blagburn, Auburn University, Auburn, AL.)

Adult heartworms have the ability to suppress the activity of the pulmonary intravascular macrophage, the main component of the cat's reticuloendothelial system.[70,71] Therefore, if the juvenile worm matures to the adult worm, suppression of the host immune response occurs and there may be some resolution of clinical signs. However, when heartworms die, this downregulation of the immune system ceases and the degenerating parasite causes an intense inflammatory reaction and thromboembolism, which can lead to a catastrophic acute lung injury and sudden death. Sudden death has been reported to occur in 10% to 20% of cats with mature adult heartworm infections.[63,72] If the cat survives this insult, there is hyperplasia of type II alveolar cells, which replace the normal type I cell, and may cause permanent pulmonary dysfunction.[24,71] This can lead to chronic respiratory disease, the third manifestation of heartworm disease in cats.

Arterial intimal proliferation of the pulmonary arteries, resembling the characteristic heartworm arteritis found in dogs, can occur in cats. These lesions are localized and ordinarily fail to cause sufficient obstruction to produce clinically significant pulmonary hypertension in cats. Consequently, right ventricular hypertrophy and right heart failure are less common in cats than in dogs. Ectopic migration of worms, however, appears more common in cats.

Proteinuria occurs as a consistent complication in experimentally infected cats.[73] Naturally infected cats also have a greater prevalence of proteinuria (90% versus 35%) than do age- and gender-matched control cats.[73] The mechanism for the proteinuria is presumed to be renal in origin; however, further investigation is needed to determine its cause and significance.

The most common clinical signs observed in cats are cough or dyspnea (64%) and intermittent vomiting unrelated to eating (38%); 28% of infected cats are clinically healthy.[72] The large proportion of subclinically affected cats is probably a result of the sedentary lifestyle of many cats, because exercise is a major factor in precipitating

TABLE 111.5 Comparison of Diagnostic Tests for Feline Heartworm Disease[a]

Test	Brief Description	Result	Interpretation	Limitations
Antibody test	Detects antibodies produced by the cat in response to presence of heartworm larvae, immature adults, or adult worms. May detect infections as early as 8 weeks post-transmission by the mosquito	Negative	Does not rule out heartworms	Antibodies confirm infection with heartworm larvae, immature adults, or mature adults. Studies have shown significant false-negative results
		Positive	Indicates a current or recent infection; 50% or more cats will have pulmonary arterial disease	
Antigen test	Detects antigen produced by the adult female heartworm or from the dying male (>5) or female heartworms	Negative	Does not rule out heartworms	Immature or male-only worm infections are rarely detected. Does not detect larvae or immature worm infections
		Positive	Confirms presence of heartworms	
Thoracic radiography	Detects vascular enlargement (inflammation caused by immature worms and, later, hypertrophy), pulmonary parenchymal inflammation, and edema (the latter only in ARDS-like reaction)	Normal	Lower index of suspicion	Radiographic signs subjective and affected by clinical interpretation
		Signs consistent with FHWD	Enlarged arteries greatly increases index of suspicion	
Echocardiography	Detects echogenic walls of the immature or mature heartworm residing in the lumen of the pulmonary arterial tree, if within the visual window of the ultrasound	No worms seen	No change to index of suspicion	Ultrasonographer experience with heartworm detection appears to influence accuracy rate
		Worms seen	Confirms presence of heartworms in the structure	

[a]Courtesy of the American Heartworm Society.
Note: In cats, a combination of test results is usually required to determine the likelihood of heartworm disease. While antigen tests are highly specific for detecting adult heartworm antigen, they will not detect infections with only live male worms.
ARDS, acute respiratory distress syndrome; *FHWD,* feline heartworm disease.

cardiopulmonary manifestations of heartworm disease in dogs. Ascites, hydrothorax, chylothorax, pneumothorax, ataxia, seizures, and syncope have been reported in cats, but are uncommon. A peracute syndrome consisting of some combination of signs including respiratory distress, ataxia, collapse, seizures, hemoptysis, or sometimes sudden death may arise without warning.

DIAGNOSIS

Diagnosis of heartworm disease in cats can be challenging because there is no test that can reliably detect all stages of disease (Table 111.5). Running multiple tests increases the chances of making a diagnosis. It is difficult to make a diagnosis using a single method unless there is a positive antigen test result or a worm is found on ultrasound. Additional testing must be considered if results do not support clinical suspicion. In a study of 22 heartworm-infected cats, where thoracic radiography, echocardiography, and antigen and antibody testing were performed, pulmonary enlargement was detected using radiography in 64%; worms were visualized by echocardiography in 64%; 55% had antigen-positive results; and 82% had antibody-positive results.[74] In a multicenter study of 215 cats when clinical signs were correlated to serologic and radiographic findings, 44% of cats with coughing or dyspnea and intermittent vomiting unrelated to eating had positive antibody test results.[75] This was twice the positive antibody result rate for clinically healthy cats in the same geographic area. Of cats with radiographic signs consistent with heartworm disease, 58% had positive antibody test results.[76]

Diagnostic Imaging

Radiology

A bronchointerstitial lung pattern (Fig. 111.13A) can also be found in cats with heartworm disease but is not specific. The most common radiographic

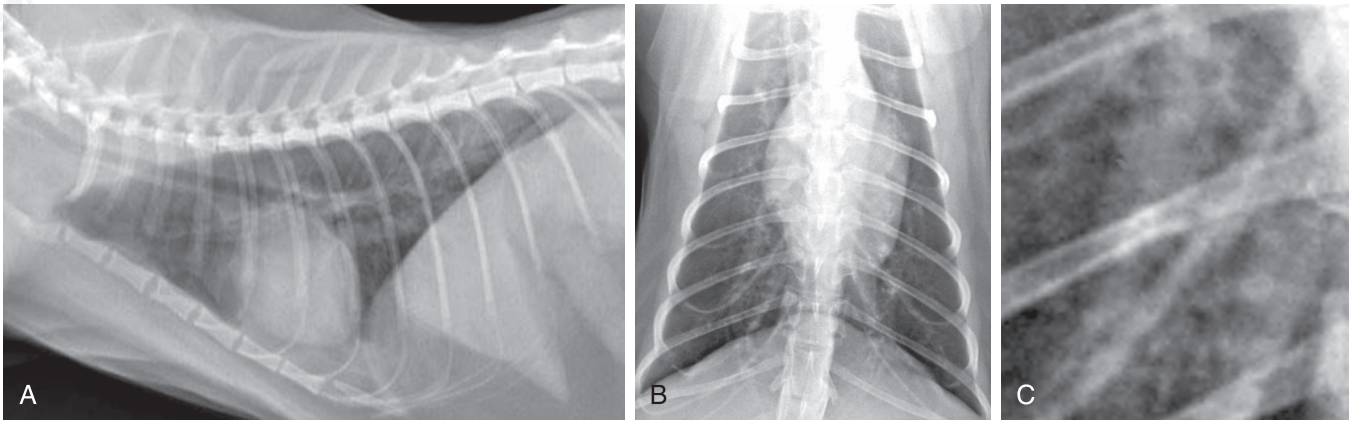

Fig. 111.13 Thoracic radiographs from a cat with heartworm infection and bronchointerstitial lung pattern. (A) Lateral view. (B) Dorsoventral view. (C) Closer view of enlarged right caudal lobar pulmonary artery.

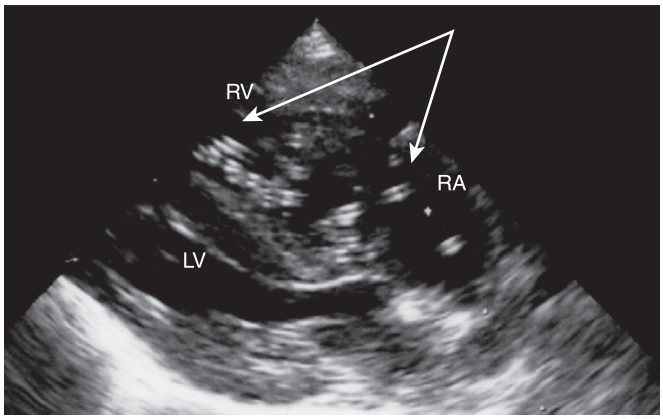

Fig. 111.14 Echocardiogram of a heartworm-infected cat. Arrows point to heartworm signatures. *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Courtesy Dr. Clarke Atkins, North Carolina State University, Raleigh, NC.)

abnormality is an enlargement of what appears to be the right caudal lobar pulmonary artery, which is best seen in a ventrodorsal view (Fig. 111.13B and C). This apparent enlargement is a result of inflammatory infiltrates surrounding the vessel and producing a radiographic shadow. Cats with these lesions may be misdiagnosed as having allergic bronchitis or asthma, and if treated with glucocorticoids, the radiographic signs improve, further supporting the misdiagnosis. Other less commonly seen findings are hyperinflation of the lungs with flattening of the diaphragm, focal parenchymal radiodensities, consolidated lung lobes, pleural effusion, and pneumothorax. The use of radiography does have limitations, as found in one study where only 6 of 10 cats with heartworm antigen-positive test results had radiographic signs consistent with heartworm disease.[76]

Echocardiography

Ultrasound examination can detect adult heartworm infections, but the caudal pulmonary arteries must be examined up to the bifurcation within the lung fields, because this is where most adult heartworms are found. The cuticle of the adult heartworm is strongly echogenic and produces short, segmented, parallel lines ("heartworm signatures") where the imaging plane crosses the worm (Fig. 111.14). Heartworm signatures on echocardiography have been described as "equal signs" (=). Because the imaging beam may cross the worm multiple times, quantification of the number of worms is difficult. Reports cite echocardiography as detecting heartworms in 68% of naturally infected cats[77] and 88% of experimentally infected cats.[78]

Microfilarial Detection

Microfilaremia in the cat is rare for multiple reasons. More than 90% of infections in cats are abbreviated and do not reach the adult stage. When adult worms are present, the infections are frequently single sex, and if microfilariae are produced, their presence is transient because the cat's immune response will eliminate them from circulation.

Serologic Testing

Antigen Detection

Both antigen and antibody testing are available for cats, but a thorough understanding of their limitations is essential for interpretation of results. Antigen tests are considered the gold standard for diagnosis of heartworm disease in dogs. Because the available antigen tests detect a glycoprotein primarily produced by the uterus of the mature female worm, these tests will not detect early or male-only worm infections as readily. The most common form of heartworm disease in cats results from the death of juvenile worms at 3 to 4 months PI and will not be detected by an antigen test. If mature adult heartworms do develop, most cats have only one or two adult worms. Single-sex infections are common, and these are frequently male-only infections. Multiple studies have reported the sensitivity of antigen test in mature heartworm infections to be 50% to 86%.[79–81] Antigen-antibody complexes, as described earlier in this chapter for dogs, also occur in cats further decreasing sensitivity.[82] Blocked antigen is particularly common early in feline infection, and multiple testing modalities may be needed to reach a diagnosis.[83] Blocked antigen was identified in 5.3% of shelter and free-roaming cats in the southern United States and a majority (77%) were also antibody positive.[84] As a result, a negative antigen test result cannot be used to rule out heartworm infections in cats.

Antibody Detection

Tests that measure serum antibody detect infection with late L_4, juvenile and adult worm infections. They have been reported to be 93% to 100% sensitive in experimental models[85,86] but are less sensitive in naturally infected cats. A retrospective study involving 50 cats with heartworms had a 14% false-negative antibody test result rate.[72] Results of a necropsy study of shelter cats in Texas revealed 50% false-negative antibody test results.[80] In a similar necropsy study of shelter cats in Florida, 11% to 68% had false-negative test results using eight different antibody test methods.[81] In this study, 21 of 31 cats with heartworms had negative test results on at least one of six antibody methods that were evaluated. A number of the assays described in these references are no longer available. Clearly however, a negative antibody test result cannot be used to

TABLE 111.6 Treatment for Feline Heartworm Disease

Drug[a]	Dose	Route	Interval	Duration (Days)
Macrocyclic lactones[b]	Varies	PO	30 days	Indefinite[b]
Doxycycline[c]	5 mg/kg	PO	q12h	28
Prednisolone				
Anti-inflammatory	1–2 mg/kg	PO	q12h	7[d]
Shock, pulmonary	50–100 mg/cat	IV	q24h	prn
Dexamethasone (shock, pulmonary)	1–2 mg/kg	IM, IV	q24h	prn
Aminophylline (respiratory distress)	6.6 mg/kg	IV	q24h	prn

[a]See Chapter 13 for specific information on antiparasitics.
[b]Eprinomectin, ivermectin, milbemycin, moxidectin, selamectin; see manufacturers' dosage recommendations.
[c]Give as suspension or else round up and use whole tablets, or use monohydrate salt. Damaged or cracked tablets in the esophagus can cause esophagitis and esophageal strictures.
[d]Dosage is reduced to 0.5 mg/kg q12h for the next 7 days and 0.5 mg/kg q48h for 1 to 2 weeks thereafter.

rule out heartworm infection in cats, and more sensitive and specific assays are badly needed for diagnosis of heartworm infection in cats.

TREATMENT AND PROGNOSIS

Table 111.6 summarizes the drug dosages used to treat cats with heartworm disease. Cats with clinical or radiographic signs of heartworm disease should be treated with daily anti-inflammatory doses of glucocorticoids (prednisolone 1 to 2 mg/kg PO). This dosage should be reduced on a weekly basis, over a 3- to 4-week period. If clinical signs recur or persist, then alternate-day glucocorticoid therapy is given at the lowest dose effective for control of clinical signs. Radiographic evaluation and serologic testing are repeated periodically to monitor the course of the disease. Infected cats can be started on a once-monthly heartworm preventive, because cats are rarely microfilaremic, and even when microfilaria are present, their numbers are low, so reactions do not occur.

Cats with acute respiratory distress should be given oxygen and "shock doses" of glucocorticoids (dexamethasone sodium phosphate, 1 to 2 mg/kg, IM or IV; or prednisolone sodium succinate, 50 to 100 mg/cat, IV) and bronchodilators (such as theophylline or terbutaline). Supportive therapy (IV fluids and external thermal regulation) is maintained until the cat's clinical condition is stabilized.

Results of retrospective studies are that between 10% to 20% of cats with adult heartworm infections will die within 4 years.[63] If cats are diagnosed with adult heartworms by antigen test or echocardiography, their owners must be made aware of this risk and instructed to seek prompt medical attention at any sign of respiratory distress, because timely treatment is critical. It may be prudent to send home dexamethasone sodium phosphate (10 mg), with instruction to administer it IM in case of a respiratory emergency, to initiate treatment. This is not in lieu of, but before, seeking emergency veterinary care.

There is no form of adulticidal therapy proven to improve the survival rate of heartworm-infected cats. Theoretically, the use of antileukotrienes might help because cytokines contribute to the disease process. IL-8 is produced in response to *Wolbachia*, an intracellular rickettsial endosymbiont found in all stages of heartworms and IL-4 can be found in the secretions recovered by bronchoalveolar lavage from heartworm-infected cats. There is anecdotal evidence that antileukotrienes such as montelukast (2 mg, PO, q24h) may be beneficial in thwarting a respiratory crisis in heartworm-infected cats.[87]

Doxycycline therapy is another theoretical treatment option. Elimination of *Wolbachia* reduces the pathologic changes associated with worm death in dogs.[34,35] Doxycycline is now being used to treat some filarial nematode infections in humans.[88,89] Although this form of therapy in cats is unproven, considering the 20% chance of a heartworm-related death in cats with adult worms, its use could be considered in cases where the owner wants to pursue all options. The recommended protocol would be to administer doxycycline 5 mg/kg q12h for 1 month with once-monthly administration of a macrocyclic lactone heartworm preventive. If doxycycline hyclate is used, a suspension is preferred to prevent esophagitis and potential esophageal strictures. If tablets are used, follow with a minimum of 6 mL of water.

Although not shown to improve outcomes or survival, heartworms can be surgically extracted via a right jugular venotomy and introduction of a flexible snare or brush that is guided into the pulmonary artery using a C-arm imaging device. During removal, care must be taken to keep the worms intact, because partial or complete traumatic transection of a worm may result in acute circulatory collapse and death.[90]

PREVENTION

All cats in endemic areas, whether residing indoors or outdoors, should receive heartworm preventives. Indoor cats are at similar risk of exposure as outdoor cats. There are many commercially available products on the market labeled for cats that are safe and virtually 100% effective (see Chapter 13). Ivermectin is available as a chewable treat, milbemycin as a flavored tablet, and selamectin, eprinomectin, and moxidectin as topical applications. All products have activity against *D. immitis* as well as a variety of other internal and external parasites.[69] Of 400 animal sheltering agencies in the southeastern United States, only 23% performed heartworm testing and 31% provided preventive medication for cats for cats.[91] Expense and the perception that the risk of feline infection in the region was low were reasons for these low prevalences. Further financial support and education are required concerning this disease in cats.

PUBLIC HEALTH ASPECTS

CASE EXAMPLE

Signalment
"Possum," a 2-year-old female spayed blue heeler from Roanoke, AL.

History
Possum's owner reported that Possum had shown signs of lethargy, cough, and inappetence for several days. When abdominal distention was noted and she vomited a few times, Possum was taken to her regular veterinarian where a rectal temperature of 105°F and harsh lung sounds were documented. A presumptive diagnosis of pneumonia was made, as well as possible intestinal obstruction, as the dog had a history of chewing and swallowing foreign objects. Possum was discharged with a course of antibiotics and instructions to return the following day for abdominal radiographs if vomiting continued. That evening the abdominal distention became more pronounced and labored respirations developed, so Possum was taken to a 24-hour facility where she was admitted to the critical care unit. Possum was up to date on core vaccines and was given monthly ivermectin-based heartworm preventive. Upon further questioning, the owner admitted to missing an occasional dose and that the preventive had not been started until the dog was 6 months old.

Current Medications
Ivermectin 136 μg/pyrantel 114 mg PO q30d for monthly heartworm prevention and intestinal parasite control.

Physical Examination
Body weight: 15 kg.
General: Quiet, alert and responsive. Ambulatory on all four limbs. Temperature = 102.1°F (38.9°C), HR = 132 beats/minute, respiratory rate = 148 breaths/minute, mucous membranes pale pink, CRT = 2 seconds.
Integument: No clinically significant abnormalities.
Eyes, ears, nose, and throat: No significant abnormalities.
Musculoskeletal: BCS of 5/9; no clinically significant abnormalities.
Cardiovascular: Grade 3/6 systolic murmur loudest at sternum.
Respiratory: Breath sounds harsh with labored breathing.
GI and genitourinary: Abdomen distended and firm but not painful. Urinary tract appears normal.
Lymph nodes: Within normal limits.

Laboratory Findings
CBC: HCT 42.8% (37%–55%), MCV 74.3 fL (60–77 fL), MCHC 33.6 g/dL (30–37.5 g/dL), WBC 23,680 cells/μL (5,500–16,900 cells/μL), neutrophils 20,550 cells/μL (2,000–12,000 cells/μL), lymphocytes 900 cells/μL (500–4,900 cells/μL), monocytes 1,900 cells/μL (300–2,000 cells/μL), platelets 264,000 platelets/μL (175,000-500,000 platelets/μL).
Serum chemistry profile: Sodium 147 mmol/L (144–160 mmol/L), potassium 4.0 mmol/L (3.5–5.8 mmol/L), chloride 111 mmol/L (109–122 mmol/L), BUN 22 mg/dL (7–27 mg/dL), creatinine 1.0 mg/dL (0.5–1.8 mg/dL), glucose 101 mg/dL (74–143 mg/dL), total protein 7.9 g/dL (5.2–8.2 g/dL), albumin 3.2 g/dL (3.0–4.4 g/dL), globulin 4.7 g/dL (1.8–3.9 g/dL), ALT 49 U/L (10–100 U/L), ALP 76 U/L (23–212 U/L).

Imaging Findings
Thoracic radiographs: Enlarged reversed D cardiac silhouette with large, tortuous caudal lobar arteries and areas of consolidation consistent with heartworm disease. Evidence of pulmonary embolism of the left caudal lobar artery was identified (Fig. 111.15).
Abdominal radiographs: No evidence of GI foreign body obstruction. Loss of abdominal detail suggesting ascites (Fig. 111.16).
Abdominal ultrasound: Hepatic congestion, distended caudal vena cava, and free abdominal fluid. Abdominocentesis was performed and yielded serosanguineous fluid.
Fluid analysis: Color – serosanguineous; total solids 2.8 g/dL, few mesothelial cells and RBCs noted on microscopic review, no bacteria. Consistent with a modified transudate.
Fecal examination: No parasite ova seen.
Heartworm test: Antigen strong positive, no microfilariae on Knott's test.

Diagnosis
Class 3 heartworm disease.

Treatment
Possum was placed on flow-by oxygen and 450 mL of serosanguineous fluid was removed from the abdominal cavity to relieve severe abdominal distension, which was considered to be impacting respiration. The dog was also started on prednisone 10 mg

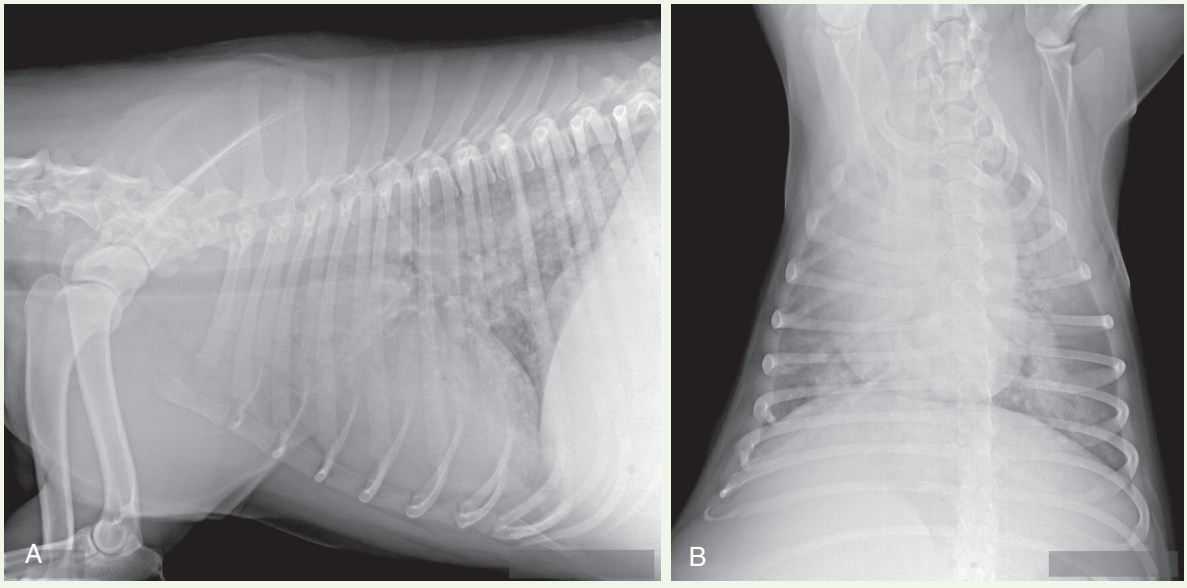

Fig. 111.15 Lateral (A) and ventrodorsal (B) radiographs of the thorax of a 2-year-old female spayed blue heeler with heartworm disease before treatment (day 0). Enlarged reversed D cardiac silhouette is evident with large, tortuous caudal lobar arteries and areas of consolidation consistent with heartworm disease.

Continued

CASE EXAMPLE—cont'd

q24h for 2 weeks then reduced to 10 mg q48h, doxycycline 150 mg q12h for 30 days, enalapril 5 mg q12h, and furosemide 12.5 mg. Possum responded favorably to therapy and was weaned off oxygen within 24 hours and released from the hospital the following day with instructions for strict exercise restriction for the duration of treatment.

Possum returned for a recheck examination 2 weeks later. Her appetite had returned, her lung sounds were greatly improved and the heart murmur was no longer noted. Radiographs showed significant improvement, and the dog was scheduled to start melarsomine therapy in 6 weeks.

Possum continued to do well clinically although significant abnormalities persisted on thoracic radiography (Fig. 111.17A). The first melarsomine injection was given on day 62. The dose of prednisone was increased to 10 mg q24h for 2 weeks, then the dosage interval was reduced to q48h. The furosemide dosage interval was decreased to q48h. The owners were reminded of the importance of exercise restriction. The second and third melarsomine injections were given on days 97 and 98. Again, the prednisone dosage interval was increased to q24h for 2 weeks then reduced to q48h. Possum returned on day 128 for a recheck. No abnormalities were detected on physical examination, and the furosemide, enalapril, and prednisone doses were reduced by 50%. On day 160, thoracic radiographs revealed reduction in the size of the right heart and pulmonary arteries (Fig. 111.17B). The owner perceived that Possum had a normal appetite and activity level. The enalapril, furosemide, and prednisone were discontinued and Possum was allowed to resume normal activity. Follow-up radiographs taken 7 years later revealed persistent cardiac, vascular and pulmonary parenchymal changes that resulted from worm death (Fig. 111.17C).

Comments

This dog was not treated with preventives until 6 months of age. When preventive treatment was initiated, she was not tested 6 months later and was likely infected during the first few months of life. By starting a dog in a highly endemic region on preventives after 6 months of age (i.e., after infection), a "slow kill" form of heartworm treatment was essentially implemented, which is not recommended. Death of worms lead to pulmonary thromboembolism and right-sided heart failure at an early age, and was likely exacerbated by the fact that she was a very active dog. Puppies should be started on heartworm preventives no later than 8 weeks of age, and if started after 8 weeks of age, they should be tested 6 months later.

Possum was treated with the protocol described in this chapter. Although the heartworm infection was cleared and the dog survived, the radiographs taken 7 years later revealed how permanent damage to cardiopulmonary structures can occur.

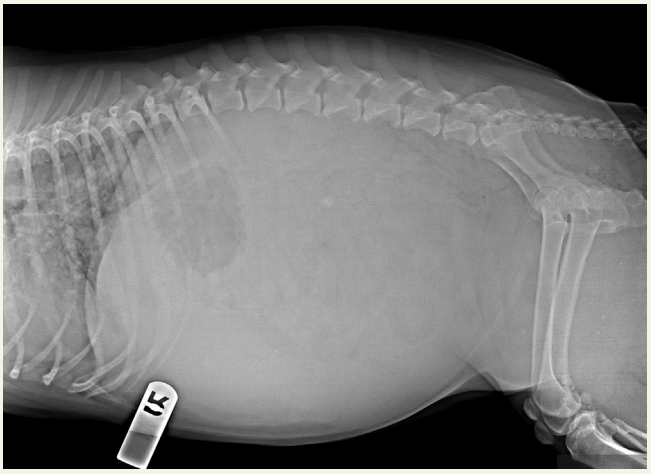

Fig. 111.16 Lateral radiograph of the abdomen of a 2-year-old female spayed blue heeler with heartworm disease before treatment showing marked abdominal distention and evidence of ascites.

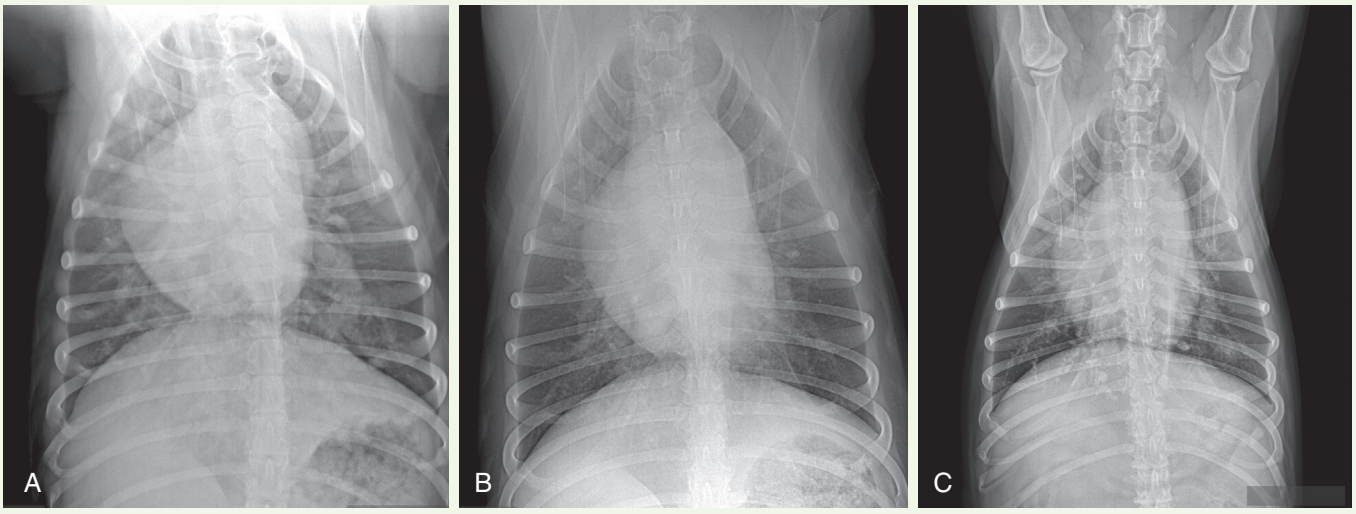

Fig. 111.17 Ventrodorsal radiographs of the thorax of the same dog in 110-15 after 62 days (A), 160 days (B) and 7 years (C) of treatment as described in the case report. There is progressive radiographic improvement but even at 7 years after treatment, persistent abnormalities remain.

Ascarids

Michael J. Yabsley, Sarah G.H. Sapp

KEY POINTS

- First Described: *Toxocara canis* and *Toxocara cati* have been recognized since the late 1700s. *Toxascaris leonina* was first described in 1902. *Baylisascaris procyonis* was first described in raccoons (*Procyon lotor*) in Poland in 1951, and first reported in dogs in 1988 (Michigan, United States).
- Cause: Ascarids (order Ascaridida) are large robust nematodes that primarily infect the small intestine of their definitive hosts. The anterior end of this group of nematodes has three prominent lips and males lack copulatory bursa. Representatives of this group include important pathogens of several domestic animals, wildlife species, and humans. This chapter will focus on the four primary ascarid species that infect dogs and cats: *Toxocara canis* and *Toxascaris leonina* in dogs, *Toxocara cati* and *T. leonina* in cats, and *Baylisascaris procyonis* (raccoon roundworm), which rarely occurs in dogs.
- Affected Hosts: Domestic dogs and wild canids can become infected with *T. canis* and *T. leonina,* whereas domestic cats and wild felids are the hosts of *T. cati* and *T. leonina*. Although the raccoon is the primary host of *B. procyonis*, domestic dogs can develop patent infections.
- Paratenic Hosts: An intermediate host is not required for ascarids, but many species utilize paratenic hosts. Rodents are the primary paratenic host species, although birds can also become infected with *Toxocara* spp. and *B. procyonis*.
- Geographic Distribution: *Toxocara canis, T. cati*, and *T. leonina* have cosmopolitan distributions. *Baylisascaris procyonis* is native to many regions of the United States and Canada but has been introduced to parts of Asia and Europe through translocation of raccoons.
- Route of Transmission: *Toxocara canis* can be transmitted to canids by ingestion of embryonated eggs or paratenic hosts or by transplacental or transmammary routes. *Toxocara cati* can be transmitted to felids by ingestion of embryonated eggs or paratenic hosts and through the transmammary route. *Toxascaris leonina* is transmitted to canids or felids by ingestion of embryonated eggs or paratenic hosts. *Baylisascaris procyonis* is transmitted to canids by ingestion of embryonated eggs or paratenic hosts.
- Major Clinical Signs: Young dogs and cats are more likely to develop signs which may include unthriftiness, lethargy, abdominal tenderness, rough haircoat, poor body condition and potbellied appearance, cough, and mucoid diarrhea. Adult animals are less likely to develop signs, as are those animals with low parasite burdens.
- Differential Diagnoses: Parasitic ova of other GI helminths must be differentiated from ascarid eggs. In dogs and cats, other large parasitic helminths or pseudoparasites (e.g., *Physaloptera* spp., free-living planarian *Bipalium,* horsehair worms/nematomorpha) may be passed in feces or vomitus and must be differentiated from ascarids.
- Human Health Significance: *Toxocara* spp. and *B. procyonis* are zoonotic. Infections are acquired by ingestion of embryonated eggs in the environment.

TOXOCARA CANIS

ETIOLOGIC AGENT

The common dog roundworm *Toxocara canis* is one of three ascarids that occur in the small intestine of domestic dogs. The other two ascarids are *Toxascaris leonina* and *Baylisascaris procyonis* (raccoon roundworm); the latter rarely occurs in dogs. *Toxocara canis* is transmitted to dogs by ingestion of embryonated eggs or paratenic hosts, or by transplacental or transmammary routes (see Transmission, later in this section). Infection is of zoonotic importance because of the potential for *T. canis* to cause ocular larva migrans (OLM) and visceral larva migrans (VLM) in humans.

Toxocara canis can most readily be distinguished from *T. leonina* by the presence of cervical alae in *T. leonina* which are absent or inconspicuous in *T. canis* (Table 112.1; Fig. 112.1). In addition, the eggs of these two species are easily distinguished based on morphology but not size (see Table 112.1; Fig. 112.2). Eggs of *T. canis* are pitted, whereas *T. leonina* are smooth with an undulating, prominent vitelline membrane on the inner boundary of the shell (which is not apparent in *T. canis*). Therefore, if there is any doubt to identity of adult worms, female worms can be teased open and egg morphology examined. Eggs of *T. canis* are most similar to those of *B. procyonis*; eggs of the latter tend to be smaller in diameter with a zygote that usually does not fill the shell, and possess a darker coat that is less distinctly pitted (see Fig. 112.2).[1] Another species, *Toxocara tanuki*, has been described from the raccoon dog (*Nyctereutes procyonoides*) in South Korea and Japan, but it has not been reported in domestic dogs.[2] Morphologically, *T. tanuki* is similar to *T. canis* (similar width of cervical alae and egg size) but the two can be distinguished based on spicule length (*T. tanuki* spicules are longer than those of *T. canis* and *T. cati*) and by sequence analysis of several gene targets.

EPIDEMIOLOGY

Toxocara canis is ubiquitous in canine populations worldwide and the prevalence varies among regions.[3–14] In the United States, prevalence varies considerably among studies in different regions or among different populations of dogs (e.g., owned dogs with low risk of infection

TABLE 112.1 Morphologic Characteristics of the Four Primary Ascarid Species Found in Domestic Dogs and Cats

	Toxocara canis	*Toxocara cati*	*Toxascaris leonina*	*Baylisascaris procyonis*
Authority	Werner 1782	Schrank 1788	Von Linstow 1902	Stefanski and Zarnowski 1951
Historical Synonyms	*Ascaris marginata* *Belascaris marginata*	*Ascaris teres* *Ascaris cati* *Ascaris felis* *Belascaris mystax* *Belascaris cati* *Toxocara mystax*	*Ascaris leptoptera* *Ascaris leonina*	*Ascaris columnaris* *Ascaris procyonis*
Adult size				
Female	6.5–10 cm	4–10 cm	6–10 cm	5–33 cm
Male	4–6 cm	3–7 cm	3–7 cm	4–11 cm
Cervical alae	Somewhat inconspicuous	Very prominent, arrow shaped	Prominent, spear shaped	Inconspicuous
Maximal L_3 size				
Length	400–500 μm	400–450 μm	650–750 μm	1,400–1,800 μm
Diameter	18–20 μm	15–16 μm	32–43 μm	60–75 μm
Average egg size	75 × 65 μm	75 × 65 μm	65 × 80 μm	70 × 60 μm
Egg morphology	Yellow to amber, round to slightly pear-shaped, pitted surface, zygote usually fills shell	Very similar to *T. canis*, pits may be smaller	Translucent to pale yellow, slightly ellipsoid, smooth surface	Amber, slightly ellipsoid, granular, irregularly pitted surface
Definitive hosts	Mostly dogs, infrequently cats	Cats only	Both dogs and cats	Raccoons, dogs
Zoonotic	Yes; common	Yes; relative frequency not known	Unlikely	Yes; rare

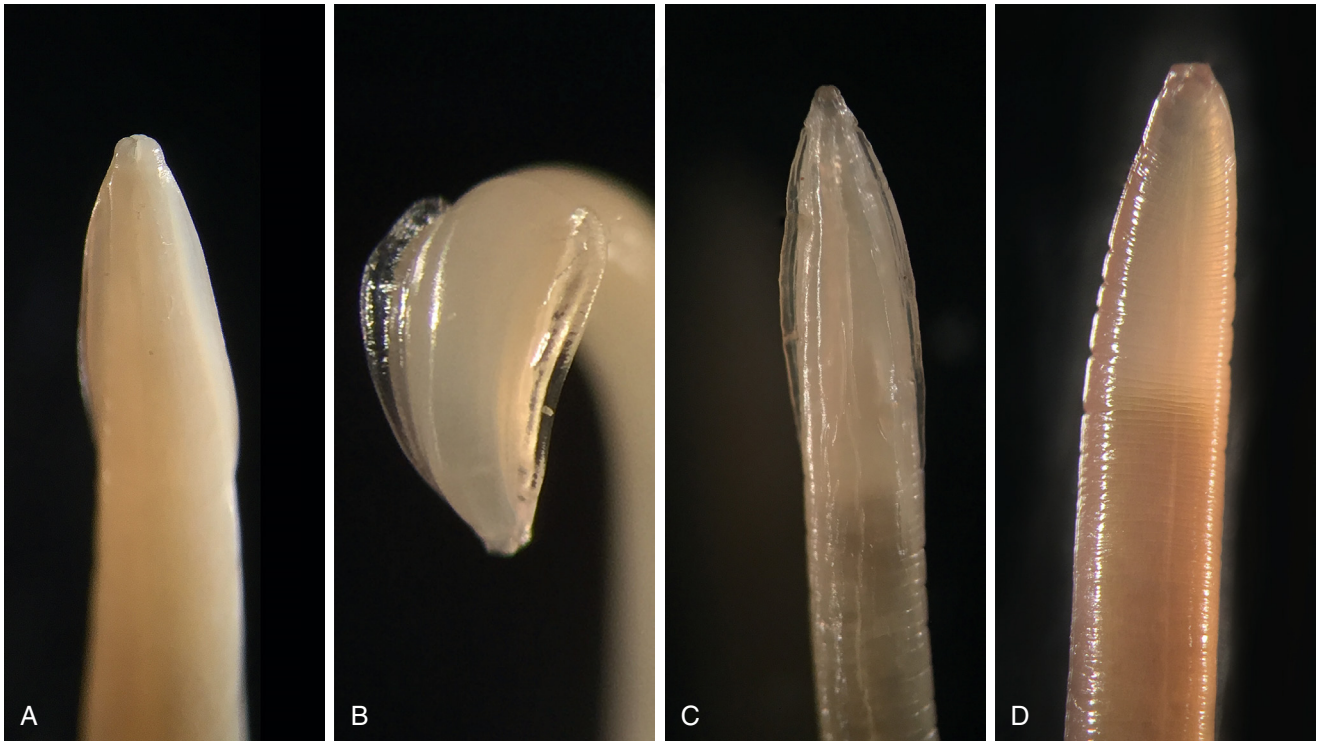

Fig. 112.1 Anterior end of four ascarid species found in domestic dogs and cats: (A) *Toxocara canis*, (B) *Toxocara cati*, (C) *Toxascaris leonina*, and (D) *Baylisascaris procyonis*.

versus stray/shelter dogs). However, even in areas where infection is believed to be infrequent, prevalence can change. For example, using a long-term dataset (capcvet.org), the prevalence of *T. canis* in dogs in Colorado was shown to have increased nearly 36% between 2013 and 2017.[15] Although lower in prevalence, *T. leonina* is considered widespread in canid populations.

Age resistance to *T. canis* is well documented but not absolute. Puppies spontaneously lose many adult worms after 6–8 weeks and patent infections are less likely to develop in dogs older than 6 months following ingestion of eggs.[16] In subsequent exposures, larvae are more likely to undergo somatic migration than to successfully complete the tracheal migration necessary for development. However, patent

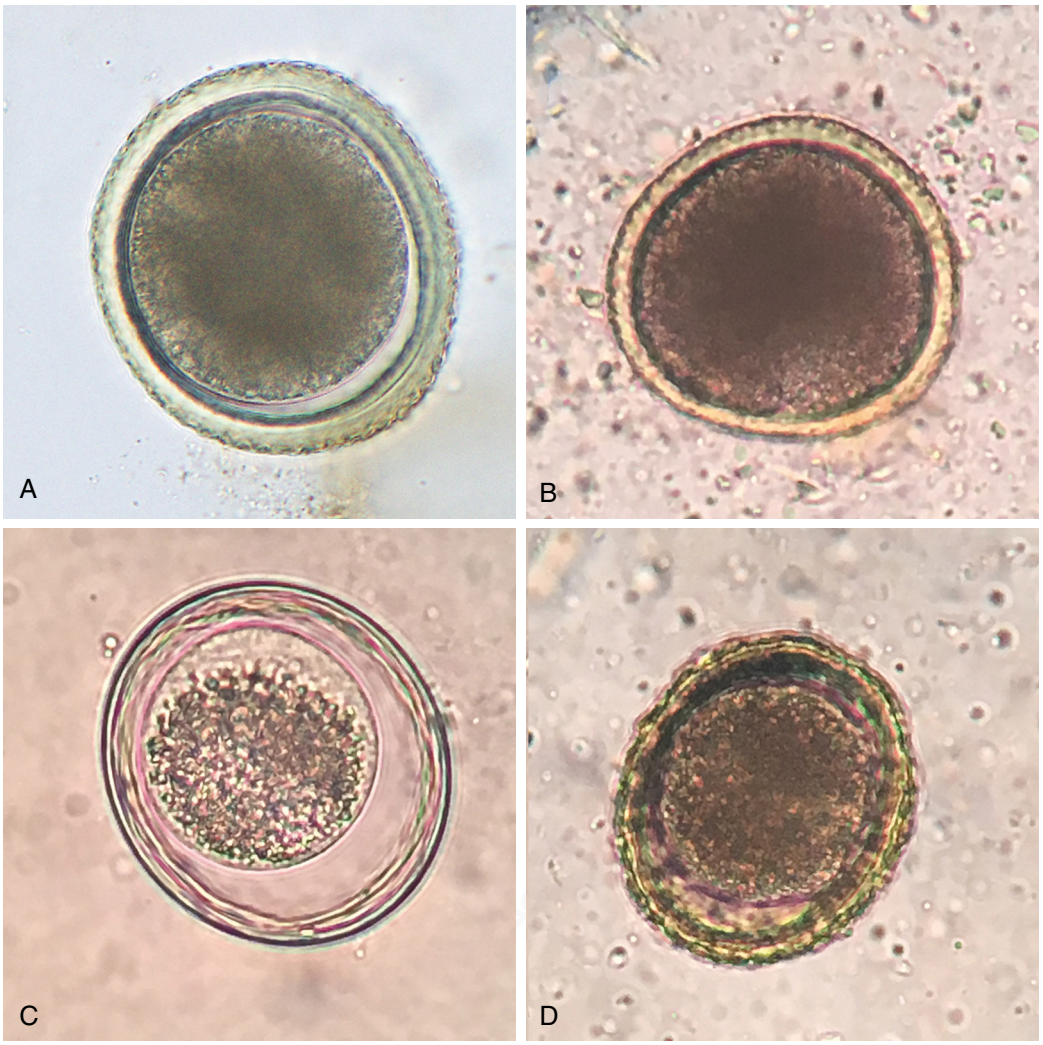

Fig. 112.2 Eggs of four ascarid species found in domestic dogs and cats: (A) *Toxocara canis*, (B) *Toxocara cati*, (C) *Toxascaris leonina*, and (D) *Baylisascaris procyonis*.

infections are still capable of developing in adult dogs and are detected occasionally; these dogs, even with low worm burdens, are sufficient to provide substantial environmental contamination; transmission.[17,18] Male dogs are somewhat more frequently infected than female dogs, although it is not clear if this is due to biological or epidemiologic factors,[19–21] and the opposite has also been noted.[22] Among owned dogs, prevalence is generally greater in dogs used for hunting or pastoral purposes than in companion dogs.[20,23–25]

Similar to most ascarids, large numbers of eggs are passed by infected dogs. Each female worm can release thousands of eggs, so a single puppy could excrete 10,000 to more than 100,000 eggs per gram of feces (EPG).[26–28] Eggs passed by dogs are unembryonated and require at least 2–4 weeks under ideal conditions to become infectious. Larval development ceases below 10°C and most larvae die if frozen (–15°C).[29] Once embryonated, eggs retain infectivity for a considerable period of time, up to 14 months in experimental settings, and are generally resistant to freezing.[30,31]

Seasonality has been noted for identification of *T. canis* in dogs in the United States.[32–34] Evaluation of more than 39 million fecal float test results at national service laboratories from 2012 to 2018 compiled by the CAPC (capcvet.org) revealed monthly prevalence of detection was consistent among years but highest (2.4%–2.7%) in the winter (December–January) and lowest (1.2%–1.5%) in the summer (May–June).[35] Similar seasonality was noted for whipworms, but the opposite seasonality was noted for hookworms, indicating that year-round control of intestinal parasites is important. On Prince Edward Island, Canada, the highest prevalence of *T. canis* infections in dogs occurred in the autumn (September–December) and winter (December–March).[22]

Numerous studies have shown that *T. canis* eggs may adhere to the haircoat of dogs and possibly present a risk, if a small one, for transmission to humans or other animals with direct contact to pet dogs.[36–39] In one study, 100% of stray puppies and over half of stray adult dogs had *Toxocara* spp. eggs adhering to perianal hair. Puppies also had a significantly higher mean concentration of eggs on hair (1,499 EPG) versus adult dogs (mean 42 EPG).[40] Among owned dogs, 8.8% were positive for *Toxocara* spp. eggs on hair on the head, neck, back, and/or perianal areas. Concentrations were very low compared to stray dogs (mean 4.4 EPG).[41] Despite the frequency of contamination, the risk of transmission is negligible unless these adherent eggs are embryonated. Eggs are capable of developing on hair in a laboratory environment, although dogs would likely groom away this fecal contamination before embryonation could occur.[42] While most studies have recovered predominately nonviable or unembryonated eggs, some dogs acquire embryonated eggs on fur from contaminated environments.[36] Appropriate hand hygiene after contact with dog fur should be observed to reduce risk of zoonotic transmission, particularly for dog groomers and individuals caring for stray dogs, especially young puppies.

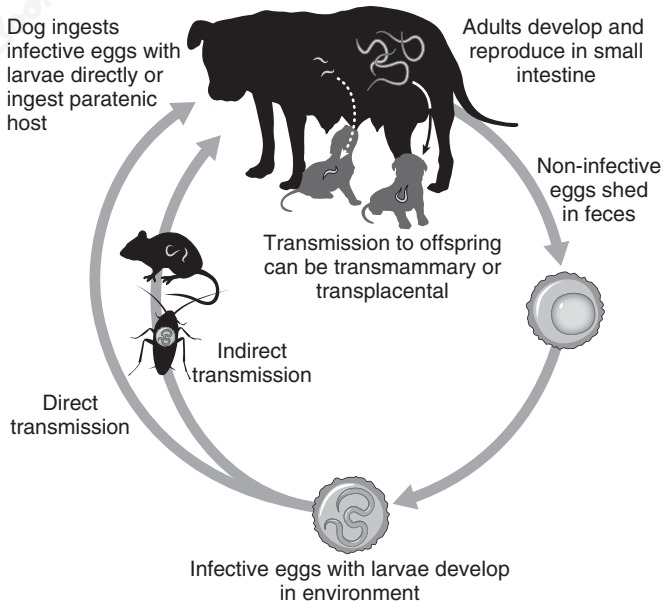

Fig. 112.3 Life cycle and transmission routes of *Toxocara canis*.

There is growing interest in the canine and public health risks associated with contamination of the environment with *T. canis* eggs. Numerous studies have shown that soil and/or dog feces in dog parks, city parks, children's playgrounds, etc. can contain *Toxocara* spp. eggs.[43–46] In a 2020 study from the United States, 9% of 3,006 fecal specimens from dogs that were using off-leash parks were positive for at least one intestinal nematode, 17 of which were ascarids.[47] Overall, intestinal parasites were detected in over 20% of dogs and at 85% of dog parks across the study areas.

CLINICAL FEATURES

Pathogenesis

Toxocara canis is transmitted to canid hosts by numerous routes including the ingestion of embryonated eggs from the environment or ingestion of paratenic hosts (Fig. 112.3). However, transplacental, and to a lesser extent transmammary, routes of transmission are very common, which is why nearly all puppies are born infected or become infected early in life. The migration of larvae in the canine host is complex and influenced by age, route of infection, and host immunity.

Transmission by Egg Ingestion

When eggs with infectious third-stage larvae (L_3) are ingested by young dogs, the eggs hatch in the duodenum and the L_3 penetrate the small intestinal wall to enter circulation. Within approximately 24 hours, circulating larvae are transported to the liver via the portal vein where they exit via the vena cava and are carried to the lungs. Larvae exit the circulation through the alveoli, then are coughed up and swallowed, reentering the GI tract in what is referred to as *hepatotracheal migration*. Once in the stomach, the L_3 molt to L_4; another molt to the L_5 (subadult) stage occurs in the small intestine. It takes approximately 1 to 2 weeks for this migration to be completed. Completion of maturation and patency typically occurs after 4 to 6 weeks, tending towards longer periods in older experimentally inoculated animals.[17,19] Some larvae do not complete the hepatotracheal migration; instead they reenter circulation after exiting the lungs. These larvae then undergo somatic migration and cause VLM. When larvae become trapped in capillaries during migration, they become encapsulated in granulomas produced by host immune mechanisms and arrest at the L_3 stage.

An interesting observation regarding infection via ingestion of eggs is the effect of dose on infection success. Ascarid-naïve puppies inoculated with 10 to 1,000 eggs developed intestinal infections, but no infections were detected in those inoculated with 10,000 eggs, suggesting this resistance is not a result of pre-existing immunity.[48] Similar results have been observed with 3-week-old puppies inoculated with 3,000 eggs.[49]

Transmission by Paratenic Host Ingestion

When a susceptible paratenic host, such as a rodent or bird, ingests infectious eggs, the larvae hatch in the GI tract and enter the circulation. Larvae in paratenic hosts do not undergo hepatotracheal migration, but instead undergo somatic migration and accumulate in the liver, lung, kidney, skeletal muscle, and nervous tissues.[50] Invasion of the CNS by larvae is referred to as neural larva migrans (NLM), and these migrating larvae may produce neurologic disease which can be fatal. Larvae can also invade the eye (OLM) and cause vision damage or blindness. Larvae can remain viable in tissues of paratenic hosts for months to years.[50–54] Experimentally, cockroaches and earthworms can ingest eggs and serve as paratenic hosts.[53–56] Reviews of the ecology and impacts of *Toxocara* spp. infections in paratenic hosts have been published.[50,54]

These larvae, regardless of location in the paratenic host, are infectious to the canine definitive host or other paratenic hosts.[57] When a dog ingests larvae in paratenic host tissues, tracheal migration may not always occur, presumably because larvae have developed sufficiently during migration within the paratenic host.[58] In experimental inoculations of dogs with *T. canis* larvae within mouse tissues, infection develops, in some instances, without breaching the GI tract as few to no larvae are recovered from sites other than the GI wall/lumen.[49,58] When development proceeds without tracheal migration, prepatent periods (PPPs) tend to be short (as early as 33 days in one experimental infection study).[57]

Transplacental and Transmammary Transmission

The majority of, if not all, infections of very young puppies with *T. canis* are acquired through the transplacental (intrauterine, prenatal) route. Infection of the dam either during gestation or prior to conception can result in vertical transmission. Hypobiotic larvae in tissues of the dam can become reactivated during gestation, but it is unknown how long these larvae can persist. The mechanism by which hypobiotic larvae become activated is also not understood, although it is likely mediated by complex hormonal changes (e.g., estradiol, progestin, prolactin) and immunosuppression that occur during pregnancy.[59] The timing of infection of a dam during gestation can impact transplacental transmission, with more frequent transmission occurring when dams become infected later in gestation.[60] For example, inoculation at 35 days post-conception did not result in transmission, whereas five of six pups from a dam inoculated at 56 days post-conception had larvae within their tissues.[60] In another study, larvae were first noted in a single fetus in a dam infected 43 days post-conception, and the infection of dams after 47 days post-conception resulted in the presence of larvae within fetuses.[61]

In puppies born to experimentally inoculated pregnant dams, L_3 were present in the heart and lungs of the puppies at parturition. Larvae had migrated to the GI tract within 3 days and molted to the L_4 stage with in ~1 week. In these puppies, mature *T. canis* were detected as early as 3 weeks post-parturition.[49,61]

Larvae that fail to establish infection in the intestine in young puppies may be passed in the feces. Dams may become reinfected postpartum by swallowing these expelled larvae during grooming of pups.[62] Also, adult worms are frequently expelled in large numbers by older puppies, especially around 9 to 10 weeks or age.

Lactogenic (transmammary) transmission can also occur, but this is considered a minor route of infection in dogs compared with the transplacental route.[63] As with larvae acquired through ingestion of paratenic hosts, the ingested L_3 do not undergo hepatotracheal migration.

Transplacental transmission has also been demonstrated in paratenic hosts. Experimental infections in mice revealed the presence of larvae in the placenta and fetal tissues after inoculation at mid-gestation. This process is generally thought to be prolactin-mediated.[59,64]

Clinical Signs and Physical Examination Abnormalities

Clinical signs of *T. canis* infestation are most severe and most likely to occur in young puppies. Most adult dogs with intestinal *T. canis* infections are subclinically infected. Heavy burdens can cause unthriftiness, abdominal tenderness, poor body condition, lethargy, vomiting, diarrhea, and cough. Puppies will often present with a "potbellied" appearance. Extremely high worm burdens can cause intestinal obstructions or intussusception. Larval migration though the lungs creates hemorrhage, but respiratory distress is not usually evident unless infections are particularly intense. In rare cases, very young puppies may die acutely due to the migration of large numbers of prenatally acquired larvae out of the lungs after birth. In some cases, puppies vomit developing mature worms when worm burdens are high.

Rarely, migrating larvae may become encapsulated in granulomas and, if numbers of larvae are high, cause morbidity or mortality.[65,66] A few unusual cases of retinitis attributed to ocular toxocariasis in puppies have been reported. In one case, four puppies developed retinopathy leading to blindness, and *T. canis* larvae were recovered from the eye of the one puppy that was necropsied. These puppies had been fed raw pork liver, which may have contained a large number of encysted larvae.[67]

Toxocara canis is capable of causing VLM in cats following experimental inoculation. Cats inoculated with *T. canis* eggs developed granulomatous lesions in the liver, lungs, and kidneys accompanied with peripheral eosinophilia, but clinical signs were mild to absent.[68] However, a naturally infected cat that was evaluated for pyrexia and eosinophilic pulmonary endarteritis had disseminated lesions containing *T. canis* larvae, suggesting that migrating *T. canis* larvae are capable of causing disease in cats in the field.[69]

DIAGNOSIS

Laboratory Abnormalities and Diagnostic Imaging

Laboratory abnormalities in dogs with *T. canis* infections are nonspecific; peripheral eosinophilia may be present, and increased serum liver enzyme activities have been documented as a result of hepatic migration.[58] Radiographs may reveal diffuse mixed pulmonary opacities as a result of larval migration. Ascarids may be visible as linear foreign objects within the GI tract following barium administration; they may also be seen on ultrasound examination as two non-shadowing parallel hyperechoic lines ("train tracks") on longitudinal section and ring-shaped hyperechoic structures on transverse section (Fig. 112.4). In one study from Sardinia, Italy, ascarids were visible in the intestinal tract of newborn puppies using ultrasonography on days 10, 15, 20, and 25 after birth, even before eggs were visible on zinc sulfate fecal flotation.[70]

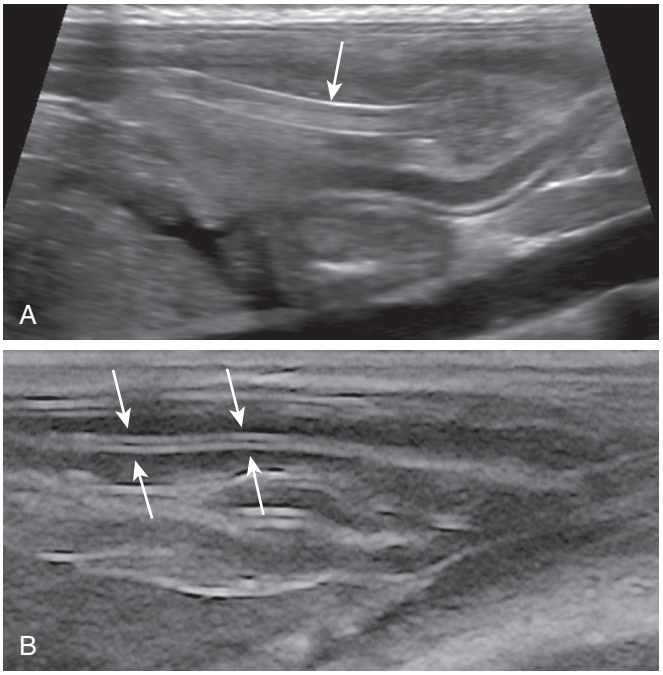

Fig. 112.4 (A) Abdominal ultrasound of a 9-week-old golden retriever puppy. Within a loop of jejunum, an ascarid is recognized as long thin parallel hyperechoic lines *(arrow)*. (B) Ultrasound of a 15-day-old dachshund puppy showing an intraluminal ascarid *(arrows)*. (A, Courtesy of K. Gendron DACVR, The University of Georgia, USA. B, Courtesy of A. Corda, University of Sassari, Italy.)

Microbiologic Tests

Diagnosis Using Fecal Examination

All dogs should be tested for ascarid infections by fecal flotation with centrifugation (see Chapter 5), although all puppies should be assumed infected and thus dewormed. Recently, a commercial test that detects antigens shed by developing and adult ascarids has become available.[71] Puppies should be tested more frequently than adult dogs; testing at least four times a year for puppies and at least 1 to 2 times a year for adults is recommended.

Ascarid eggs float in most salt- and sugar-based flotation solutions (e.g., $ZnSO_4$ SpG 1.18; sugar SpG 1.25). Although ascarids produce large numbers of eggs, increased sensitivity is gained from using centrifugation of fecal floats. This is especially important because not all parasites in dogs may produce large numbers of ova. *Toxocara* spp. eggs must be differentiated from those of *T. leonina* and *B. procyonis* (see Table 112.1; Fig. 112.2; see also section on Etiology, earlier). Coprophagy is an important consideration when examining fecal floats, especially if the dog has access to cat feces, as eggs of *T. canis* and *T. cati* are morphologically similar. If a dog tests positive for *Toxocara* spp. eggs but the history suggests a patent infection is unlikely (e.g., owner compliance regarding monthly preventive use is not in question or dog has had recent treatment), additional fecal specimens should be evaluated after the dog has been leash-confined to prevent coprophagy.

An ELISA that detects antigens produced by immature and adult ascarids is available (IDEXX Laboratories, Inc., Westbrook, ME, USA).[72] Because this test can detect antigens released by immature worms, detection of infection can occur before patency. Experimentally, the ELISA detected *T. canis* coproantigen 31 to 38 days PI.[71] Single-sex infections can also be detected. However, the assay does not differentiate between the ascarid species, so microscopic examination of feces is still recommended (e.g., patent infections with either *T. canis* or *B. procyonis* can result in a positive ELISA result).[73] As noted earlier, coprophagy may confuse interpretation of coproantigen test results; if a dog is coproantigen negative but fecal float positive, one should consider coprophagy. Several studies have noted that a high number of canine fecal specimens with *Toxocara* spp. eggs actually harbor *T. cati* eggs.[74,75] Additionally, older dogs are more likely to have discordant results (antigen negative, fecal egg positive).[72] Retesting of specimens after prevention of coprophagy should be recommended.

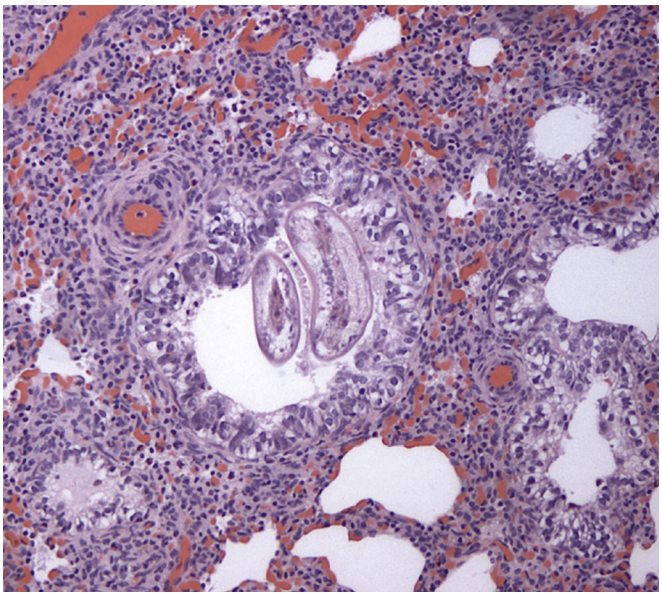

Fig. 112.5 Histopathology image showing severe, diffuse, acute, eosinophilic interstitial pneumonia with intralesional migrating ascarid larvae in a 36-hour-old great Pyrenees puppy that died acutely together with three other puppies. Severe perivascular eosinophilic hepatitis was also present, consistent with hepatopulmonary migration of larvae that were most likely obtained by transplacental infection, given the young age of the puppy. The puppy also had spina bifida and an associated acute suppurative meningitis. (Courtesy Jane E. Sykes, University of California-Davis.)

Sometimes adult worms will be detected in the vomitus of dogs. Ascarids can be differentiated from *Physaloptera* spp. by their large size and the three prominent lips on the anterior end. In contrast, *Physaloptera* spp. are smaller, are frequently more coiled, and have a triangle-shaped anterior end that often has a swelling of the cuticle (cervical collar); male *Physaloptera* spp. have large caudal alae (see Chapter 116).

Pathologic Findings

Gross pathologic findings in puppies that die as a result of large numbers of migrating ascarids include pulmonary congestion and hemorrhages, as well as hepatic congestion (which may be secondary to shock). On histopathology, eosinophilic enteritis, hepatitis, and interstitial pneumonia may be identified with intralesional ascarid larvae (Fig. 112.5).

TREATMENT AND PREVENTION

Treatment for *T. canis* is necessary for several reasons: (1) treatment of clinically ill dogs, (2) to prevent contamination of the environment with environmentally resistant eggs, (3) to prevent transmission from the dam to puppies, and (4) to reduce the risk of human disease. All dogs should be on a monthly product with efficacy against *T. canis* to limit reinfections. Also, limiting the ability of dogs to ingest possible paratenic hosts will minimize infection risk. Another final consideration for prevention of infection in dogs is to avoid raw diets; raw animal tissues (e.g., liver) can be a source of infection if tissues include *Toxocara* spp. larvae, as has been noted in humans.

Currently, numerous anthelmintics are approved for the treatment of *T. canis* including fenbendazole, milbemycin oxime, moxidectin, and pyrantel pamoate. In addition, pyrantel in combination with ivermectin, pyrantel in combination with ivermectin and praziquantel, and febantel in combination with pyrantel and praziquantel are approved for treatment of *T. canis* infections (see https://capcvet.org/parasite-product-applications/). All are effective when administered at the label-approved dose; repeated treatment may be necessary to eliminate all stages.

To prevent excretion of eggs into the environment, all pups should be routinely treated at 2, 4, 6, and 8 weeks of age and then placed on a monthly preventive with activity against *T. canis*. Nursing dams should be treated for ascarids on the same schedule as the puppies. If possible, pregnant dams should be treated during pregnancy to prevent vertical transmission to the pups. Daily fenbendazole (50 mg/kg, PO, q24h), selamectin (6–12 mg/kg applied topically), and monthly topical moxidectin/imidacloprid have been shown to prevent infection from dam to pups when administered late in pregnancy.[76–78]

PUBLIC HEALTH ASPECTS

VLM in humans can likely occur with both *T. canis* and *T. cati* infections, although most cases are thought to be associated with *T. canis* infection. Most cases are reported in children due to geophagia/pica. Signs and symptoms are generally nonspecific and variable depending on which tissues larvae migrate through, which can complicate diagnosis. Common manifestations of acute infection include fever, cough, abdominal pain, eosinophilia, and sometimes respiratory signs; diagnosis is confirmed with case history and serologic testing (typically, a *T. canis* excretory-secretory ELISA to detect specific IgG).[79] *Toxocara canis* larvae rarely invade the brain, but there are a few documented cases of cerebral toxocariasis.[80] Children should be encouraged to practice hand hygiene and be prevented from engaging in geophagia to prevent exposure to *T. canis* eggs.

OLM causes diffuse unilateral subacute retinitis (DUSN) involving unilateral vision loss and strabismus, again more in children than adults (Fig. 112.6). Symptoms can wax and wane, or it may be an incidental finding on routine ocular examination. Granuloma formation may be misdiagnosed as retinoblastoma and result in unnecessary enucleation, so awareness of ocular toxocariasis is critical for physicians.[81] Unlike VLM, OLM is thought to be associated with exposure to a low number of eggs, which would not generate a sufficient immune response to prevent larvae from invading the eye.[82] Furthermore, this low degree of immunologic activation complicates diagnosis as antibody levels may be minimal to undetectable.[83]

Antibodies to *Toxocara* spp. have been detected in people throughout the world, but seroprevalence varies regionally and with socioeconomic development.[84] In the United States, three large nationally representative surveys revealed that 5.1% to 13.9% of individuals were seropositive, with the greatest prevalence among lower socioeconomic strata.[85–88] The presence of antibodies in otherwise asymptomatic individuals is sometimes referred to as *covert toxocariasis*. Multiple epidemiologic studies have found statistical associations between covert toxocariasis and other health conditions such as urticaria, allergies, diminished lung capacity, occult seizures, and cognitive delay in children, although the role of *Toxocara* as the causative agent is not always clear.[89]

TOXOCARA CATI

ETIOLOGIC AGENT

The cat roundworm, *T. cati,* is the most common ascarid detected in domestic cats. Unlike *T. leonina*, the other ascarid likely to be found in domestic cats, adult *T. cati* have very prominent, broad, "arrow-shaped" cervical alae which are less prominent and more spear-shaped in *T. leonina* (see Table 112.1; Fig. 112.1). In addition, the eggs

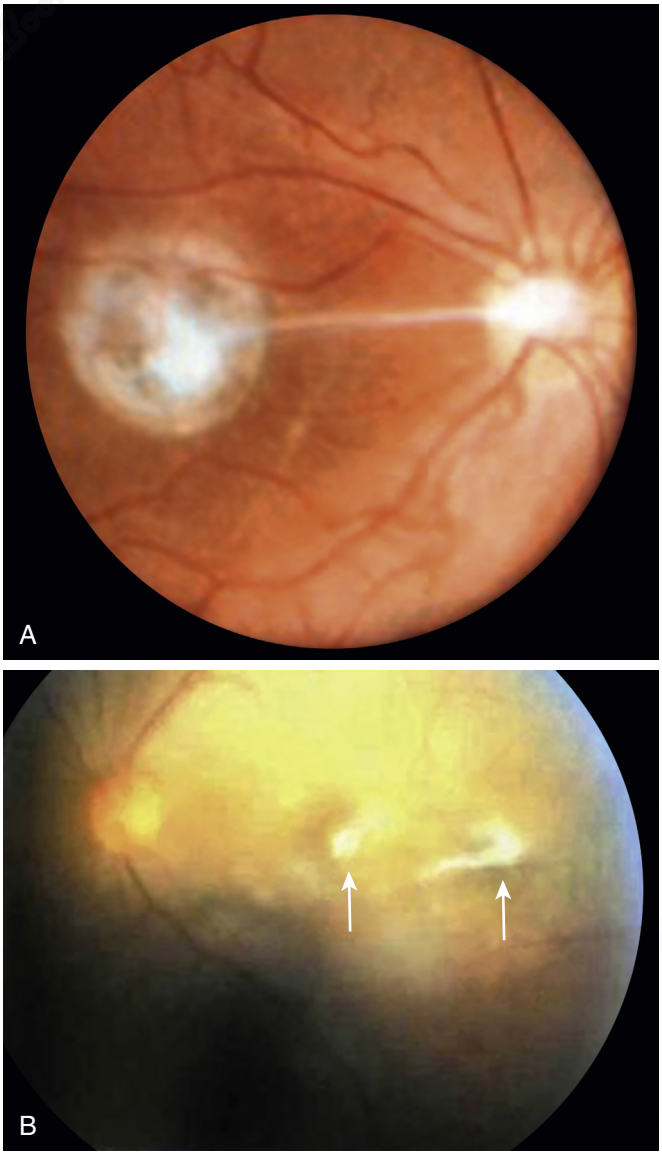

Fig. 112.6 Fundoscopic lesions in humans with ocular toxocariasis (ocular larva migrans). (A) Peripheral retinal and vitreous lesion with a localized mass of whitish tissue ("snow bank") involving the retina and peripheral vitreous. There is also a fibrocellular band that runs from the peripheral lesion toward the optic nerve or posterior retina. (B) White retinal lesions *(arrows)* caused by the migration of *Toxocara cati*. (A, From Rubinsky-Elefant G, Hirata CE, Yamamoto JH, et al. Human toxocariasis: diagnosis, worldwide seroprevalences and clinical expression of the systemic and ocular forms. *Ann Trop Med Parasitol*. 2010;104:3–23. B, From ZibaeiM, Sadijadi SM, Jahadi-Hosseini SH. Toxocara cati larvae in the eye of a child: a case report. *Asian Pacific J Trop Biomed*. 2014;4:S53–S55.)

of these two species are easily distinguished based on morphology, but not size (see Table 112.1; Fig. 112.2). Eggs of *T. cati* are pitted, whereas *T. leonina* are smooth, and *T. leonina* eggs contain prominent vitelline membranes which are absent in *T. cati*. Therefore, if there is any doubt to identity of adult worms, female worms can be teased open and egg morphology examined. In a geographically limited area of Asia, a third ascarid (*Toxocara malayasiensis*) has been reported from domestic cats. Morphologically, *T. malayasiensis* lacks the prominent broad cervical alae of *T. cati* (thus is morphologically most similar to *T. canis*).

EPIDEMIOLOGY

Toxocara cati is widespread in felid populations worldwide, although the prevalence varies among regions.[5–9,11–13,90] Its prevalence tends to be highest in shelter/unowned cats or cats without veterinary care; prevalence in these groups is often > 20%. This high prevalence in free-roaming cats likely explains the frequently detected contamination of outdoor spaces (e.g., parks, children's playgrounds).[46,91,92] In many of these environmental studies, more *T. cati* eggs were detected than *T. canis* eggs. Similar to *T. canis* in dogs, *T. cati* prevalence varies seasonally in cats (highest prevalence in winter) and in the environment.[34,91]

The PPP can be as early as 21 days if infections develop from ingestion of paratenic hosts but can take approximately 38 to 55 days if infections follow egg ingestion. As for *T. canis*, large numbers of eggs can be passed in the feces of infected cats, although egg numbers are more variable and generally range from 200 to 23,000 EPG. Eggs require about 3 weeks in an oxygenated environment to become infective. No development occurs below 10°C.[29]

Dogs may develop VLM following ingestion of *T. cati* eggs, with larvae recovered from the skeletal muscle and lung tissue, but patent intestinal infections have never been successfully established in dogs.[93]

Toxocara cati has been reported in cats worldwide. It has also been reported in wild felids.[94] Prevalence varies greatly based on location and host factors.[5–9,11–13,90] Young cats (<1 year) are more commonly infected than older cats.[14,16,95,96] Stray cats have a much greater prevalence of *T. cati* infection versus owned cats, and among owned cats, those with outdoor access are at increased risk of infection.[97–100] Cats receiving more than three anthelmintic treatments per year had a significantly reduced prevalence compared with those receiving fewer, although prevalence was still 10.4% in this group.[97]

Toxocara cati is frequently detected in soil specimens, particularly in urban areas. For example, in Poland, *T. cati* was more prevalent in soil in urban regions than *T. canis*, presumably due to the presence of feral cats.[101] However, the majority of surveys do not distinguish between the *Toxocara* species, so data on individual *Toxocara* species and environmental contamination is limited.[102]

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Similar to *T. canis* infection in dogs, transmission of *T. cati* to cats can occur after ingestion of either infectious eggs or paratenic host tissues containing larvae (Fig. 112.7). Transmammary transmission from dam to offspring occurs but is less important than the other two routes. Currently there is no evidence to suggest that prenatal or transplacental transmission occurs in cats even though it is a major transmission route for *T. canis* in dogs.[93,103,104]

Transmission by Egg Ingestion

As with *T. canis* infections, ingestion of *T. cati* eggs is followed by hepatotracheal migration. During the first 5 to 10 days after infection, the larvae migrate through the liver and lungs; some of the larvae migrate up the trachea, where they are swallowed. Other larvae migrate to muscle tissues. Those that return to the stomach enter the stomach wall and begin to grow from about 0.3–0.4 mm in length to approximately 1.0 mm, at which point they molt to the L_4 stage and enter the intestinal lumen.[93] L_4 stages proceed to develop to adults after passage into the lumen.

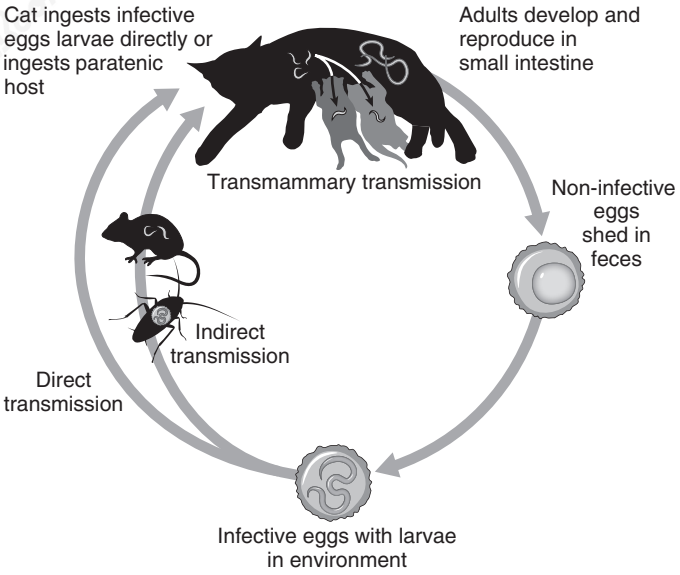

Fig. 112.7 Life cycle and transmission routes of *Toxocara cati*.

Transmission by Paratenic Host Ingestion

Predation of paratenic hosts such as rodents, birds, and some invertebrates (earthworms, beetles) is likely the most important transmission route for *T. cati* infections. When vertebrate hosts ingest eggs, the larvae migrate through the liver, lungs, skeletal muscle, and other tissues where they can remain infectious for several months.[54,105] In general, fewer *T. cati* larvae migrate to the CNS or eyes compared with *T. canis*; however, should they migrate into these tissues, they can cause clinical disease.[106–108] In a mouse model, *T. cati* appeared to have a preference for the cerebellum, whereas *T. canis* localized primarily in the cerebrum.[109] These differences may explain observed behavioral differences in neurologic manifestations between *T. canis*– and *T. cati*–induced neurotoxocariasis.[110] Although most work on paratenic hosts revolves around understanding transmission to cats, disease due to larval migrans can be important for vulnerable or endangered species (e.g., North Island brown kiwi (*Apteryx mantelli*)).[111] Reviews of the ecology and impacts of *T. cati* infections on paratenic hosts have been published.[50,54] Within paratenic hosts, larval width differentiates *T. cati* (maximum 18 μm) from *T. canis* (generally ≥ 18 μm). Several PCR assays have also been developed for detection and distinction of ascarid larvae in tissues and other specimens.[112,113] When larvae in paratenic host tissues are ingested by cats, they generally do not undergo hepatotracheal migration, although a few larvae may be recovered from the lungs or liver.

Transmammary Transmission

Transmammary transmission is most likely to occur following acute infection during pregnancy or soon after birth, after which the larvae migrate to mammary glands and infect nursing kittens. However, transmammary transmission also has been documented from chronically infected queens. Larvae are abundant in mammary glands and appear in milk throughout lactation.[95] Larvae acquired by kittens via this route do not undergo hepatotracheal migration.

Larva migrans can follow egg ingestion in cats. When large numbers of eggs are ingested, early migration of larvae in lungs can produce focal hemorrhages, pulmonary arterial lesions, and inflammation, resulting in dyspnea and cough. Complete vessel occlusion can occur as a result of arterial wall hyperplasia.[114,115] In cats that were experimentally infected with 6,000 eggs, treatment with a commercial preventive (topical moxidectin/imidacloprid) prior to inoculation did not prevent larval migration through the lungs, although it did ameliorate

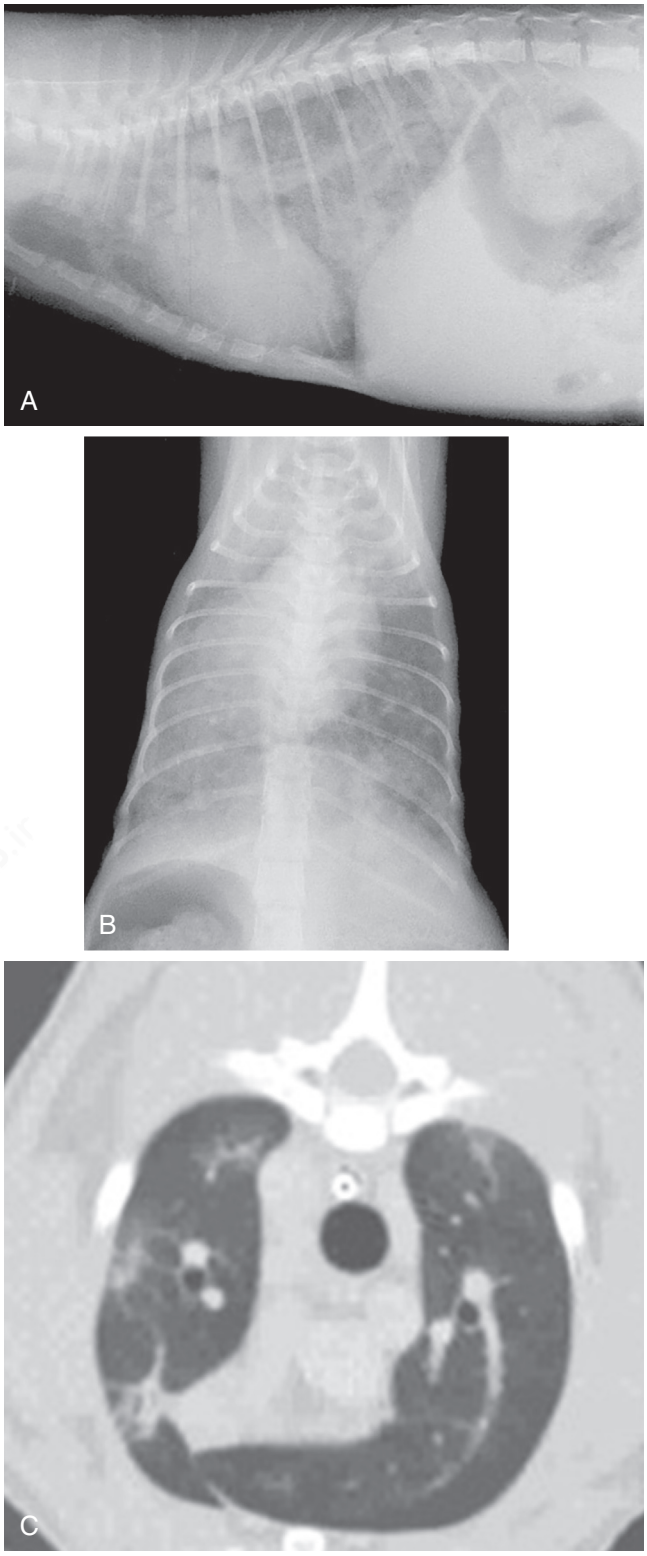

Fig. 112.8 (A) Lateral and (B) ventrodorsal radiograph showing evidence of diffuse pneumonia secondary to ascarid migration in a kitten. (C) Computed tomography scan of a cat 11 days after experimental inoculation with 3,000 *Toxocara cati* eggs. Patchy pulmonary densities are present throughout the lung parenchyma. (A,B Courtesy University of California-Davis Diagnostic Imaging Service. C, From Dillon AR, Tillson DM, Hathcock J, et al. Lung histopathology, radiography, high-resolution computed tomography, and bronchio-alveolar lavage cytology are altered by *Toxocara cati* infection in cats and is independent of development of adult intestinal parasites. *Vet Parasitol.* 2013;193:413–426.)

pathologic changes to some degree and prevented maturation in the intestine.[116] Therefore *T. cati* larva migrans should be considered as a differential diagnosis in cases of acute and chronic lung disease in cats even if a preventive is being utilized.

Intestinal infections with mature *T. cati* are nearly always subclinical. Occasionally worms may migrate in a retrograde manner to the stomach and incite vomiting (see Case Example). Unthriftiness may occur in heavy infections in young kittens or older cats with other underlying health conditions. Heavily infected kittens may present with a potbellied appearance, poor haircoat, vomiting, anorexia, and weakness.

DIAGNOSIS

Laboratory Abnormalities and Diagnostic Imaging

Cats infected with *T. cati* may have peripheral eosinophilia. Radiographic and CT findings due to pulmonary migration in experimentally inoculated cats have been described and include a patchy to diffuse bronchointerstitial pattern and enlarged pulmonary arteries, which appeared similar to changes associated with *Dirofilaria immitis* and *Aelurostrongylus abstrusus* infection (Fig. 112.8).[116]

Microbiologic Tests

Diagnosis Using Fecal Examination

As for dogs, cats should be tested for ascarid infections by fecal flotation with centrifugation. Kittens should be tested at least four times during their first year and then one to two times annually as adults. Cats can be infected with *T. cati* and/or *T. leonina* but, as described earlier, their eggs are readily differentiated (see Table 112.1; Fig. 112.2). A commercial ELISA that detects antigens produced by immature and adult ascarids has become available and can be used to detect *T. cati* antigens in fecal specimens.[71]

Migration of *T. cati* adults into the stomach can cause vomiting, so adult worms are commonly detected in the vomitus of cats (Fig. 112.9). These worms must be differentiated from *Physaloptera* spp. nematodes which are also commonly present in vomitus of cats. Ascarids are larger and have three prominent lips, whereas *Physaloptera* are smaller and have a triangle-shaped anterior end that often has a swelling of the cuticle (see Chapter 116). Nonparasitic free-living planarians (*Bipalium*) can also be found in the vomitus of cats and are identified by their large triangle-shaped anterior end.

Pathologic Findings

Kittens that were experimentally inoculated with larvated *T. cati* eggs had multifocal depressed lesions on the surface of their lungs at necropsy. Histopathologic findings included pulmonary artery intimal and smooth muscle hyperplasia that was associated with bronchial inflammation as well as inflammatory infiltrates within the alveolar interstitium (Fig. 112.10).

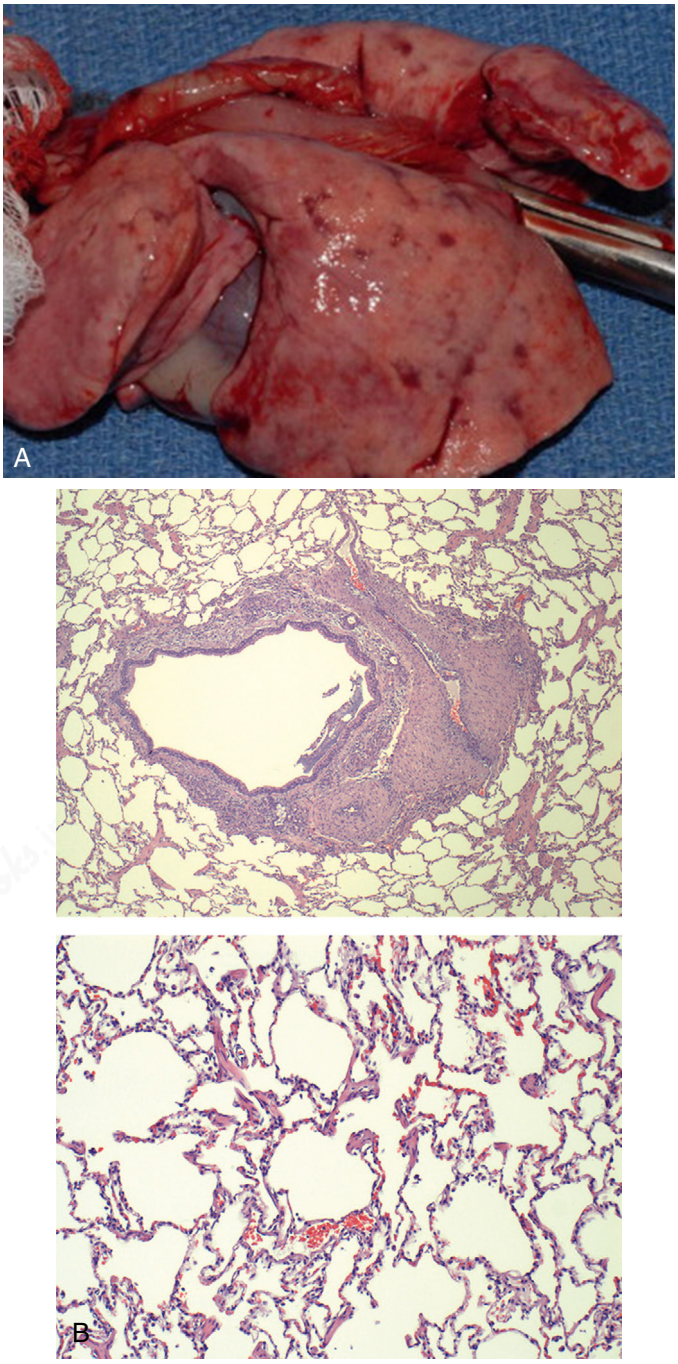

Fig. 112.10 (A) Lungs of a cat that was experimentally inoculated with *Toxocara cati* eggs following hepatotracheal migration. There are multifocal depressions on the lung surface. (B) Histopathology showing arterial smooth muscle and intimal hypertrophy in association with bronchi *(top)* and alveolar interstitium *(bottom)*. (From Dillon AR, Tillson DM, Hathcock J, et al. Lung histopathology, radiography, high-resolution computed tomography, and bronchio-alveolar lavage cytology are altered by *Toxocara cati* infection in cats and is independent of development of adult intestinal parasites. *Vet Parasitol*. 2013;193:413–426.)

TREATMENT

There are numerous commercially available products for the treatment of ascarids in cats and many of these products, when used regularly, limit

reinfection (e.g., fenbendazole, milbemycin oxime, eprinomectin, moxidectin, selamectin, emodepside, pyrantel pamoate, and combinations thereof; see Chapter 13). An interactive quick product reference guide that lists all of the currently approved drugs for treatment of *T. cati* and other parasites can be found on the CAPC website (https://capcvet.org/parasite-product-applications/). Treatment of larva migrans in the cat may also be needed, especially since disease can be associated with migration through the lung and other tissues. Topical emodepside/praziquantel (Profender; Elanco) is approved for the treatment of larvae, and efficacy was 98.5% when used to treat kittens 5 days after inoculation with *T. cati*. However, oral milbemycin oxime/praziquantel was not efficacious.[117]

Vertical transmission may be prevented by treatment of pregnant queens before parturition. Application of topical emodepside/praziquantel 5–6 days before parturition in experimentally inoculated queens resulted in negative fecal egg counts in both the queen and litter, where untreated queens and their kittens were coproscopically positive.[118] When queens were inoculated with eggs daily from 50 to 60 days after conception, then treated with the same topical medication, treatment was 98.7% efficacious in preventing vertical transmission to kittens.[119]

PUBLIC HEALTH ASPECTS

Most reports of human toxocariasis (VLM or OLM) are presumed to be due to *T. canis*, but a few reports of confirmed *T. cati* larva migrans have been detected by biopsy.[120,121] Additional cases of *T. cati* larva migrans likely exist given the global distribution of the parasite, but current serologic diagnostic techniques cannot distinguish between the two species.[83,122] A high antibody titer to *T. cati* antigen but a low titer to *T. canis* antigen may be suggestive of *T. cati* infection.

Rarely, adult *T. cati* are recovered from vomit or feces of humans, typically children. Given the lack of seroconversion and consistent clinical signs, and the low likelihood that *T. cati* could mature in the human intestine, these cases may have been the result of children consuming adult *T. cati* possibly passed by pet cats.[123,124]

TOXASCARIS LEONINA

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Toxascaris leonina can be found in both wild and domestic canids and felids, although in most locations, the prevalence in domestic animals is lower compared with *Toxocara* spp.[3,96] As noted earlier, the anterior end of the worm and egg morphology can be used to differentiate *T. leonina* from *Toxocara* spp. (see Table 112.1; Figs. 112.1 and 112.2).

Worldwide, *T. leonina* is a common parasite of many wild felids and canids. Wild felid hosts include nearly all extant species across subfamilies Pantherinae (e.g., lions, tigers, ocelots) and Felinae (e.g., bobcats, wildcats, pumas, leopards). Within Canidae, infection has been reported in foxes, wolves, jackals, and coyotes, among others. Molecular studies have suggested that *T. leonina* is a species complex consisting of three phylogenetically distinct clades; a canid clade (domestic dogs, wolf), a felid clade (cheetah, lynx, tigers), and parasites from foxes. However, additional work is needed to determine if the canid and felid parasites are genetic variants or separate species.[125,126] Interestingly, *T. leonina* was recently molecularly confirmed in an ~17,000-year-old coprolite from a cougar (*Puma concolor)* from Argentina.[127]

Younger dogs are more likely to be infected; however, prevalence does not drop off as sharply with age as it does for *Toxocara* spp.[128,129] Patent infections have been detected in weaning-age puppies, presumably from contamination of the whelping environment by the dam.[130] The rapid development of *T. leonina* eggs relative to *Toxocara* spp. necessitates rigorous sanitation of facilities to prevent reinfections after treatment. Because of the wide host range and persistence of eggs, *T. leonina* infection is common among captive wildlife species that do not receive regular preventives.[131]

Unlike *Toxocara* spp., *T. leonina* does not undergo liver-lung-tracheal migration in the host and completes development solely within the GI tract. After ingestion of larvated eggs or tissues from infected paratenic hosts, larvae penetrate into the intestinal mucosa and emerge into the lumen after 3 to 4 weeks of development as either L_4 stage or small adults. The PPPs range from 45 to 80 days (average, ~50 days).[132,133] Eggs of *T. leonina* reach infectivity more rapidly than those of *Toxocara* spp. or *Baylisascaris* spp., capable of becoming embryonated as soon as 4 days to 1 week under ideal conditions. Also, *T. leonina* eggs can develop at low temperatures (6°C–8°C).[134] Vertical transmission of *T. leonina* does not occur due to lack of somatic migration.[132]

Although *T. leonina* infects both dogs and cats, some studies suggest there may be some host-adapted strains. Cats inoculated with eggs of *T. leonina* derived from a dog did not develop patent infections; either no larvae were recovered or arrested L_3 were found months after inoculation. However, cats were successfully infected when fed mice infected with canine-strain larvae.[132,133] Some dogs inoculated with "feline-strain" eggs became infected, whereas others did not develop patent infections.[133] In addition, morphologic variation (esophageal length differences) has been noted among canine- and feline-derived isolates.[133,135]

Occasionally, larvae persist in the intestinal wall or lumen as L_4 stage in developmental arrest. In a cat experimentally co-infected with *T. leonina* and *T. cati*, the PPP of *T. leonina* was prolonged to 22 weeks, and at necropsy 1 year after inoculation, many immature L_4 and few adult *T. leonina* were found, suggesting that competition may occur.[133]

In paratenic hosts, *T. leonina* undergoes somatic migration; the majority of larvae become encapsulated in the mesentery and intestinal wall. A smaller proportion are recovered from other organs (liver, lung, skeletal muscle).[133,136] Migration to the brain has not been observed.[136] Some evidence suggests that host-adapted strains (i.e., canine and feline isolates) may have differential growth characteristics in the paratenic host.[133]

Overall, *T. leonina* infection is associated with few or no clinical signs. Very heavy infections may cause unthriftiness and GI distress.

DIAGNOSIS, TREATMENT AND PREVENTION

See sections earlier on *Toxocara* spp. infections.

PUBLIC HEALTH ASPECTS

There are no confirmed cases of *T. leonina* larva migrans in humans. One unusual report of infection with adult worms exists in which nematodes were purportedly extracted from a subcutaneous abscess[137]; however, this could represent a misidentification with other large nematodes that would be more likely to cause such signs (e.g., *Eustrongylides*, *Dirofilaria, Onchocerca*). *Toxascaris leonina* can cause VLM in paratenic hosts, so it is possible that some human VLM cases that are assumed to be *Toxocara* spp. infections may be due to *T. leonina* infection. However, there appears to be little or no serologic cross-reaction between these genera based on the excretory-secretory antigen fractions commonly used for diagnosis of *Toxocara* spp. VLM in humans.[138,139]

BAYLISASCARIS PROCYONIS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Baylisascaris procyonis, a common zoonotic ascarid of raccoons (*Procyon lotor*), is widespread in North America. Domestic dogs can serve as alternative definitive hosts and excrete eggs into the

TABLE 112.2 Published Reports of *Baylisacaris procyonis* Infections in Dogs (Patent Infections and Larva Migrans)

Number Of Dogs	Age	Natural/ Experimental	Route	Signs/Outcome	Diagnosis	Source
1	10 months	Natural	Likely larvated egg[a]	Encephalomyelitis; acute onset ataxia, deterioration, euthanized within 48 hours.	Histopathology	178
2	5–6 months	Natural	Unknown	Patent intestinal infection in one dog which passed 3 adults; 2 adult females passed by other dog which did not reach patency	Fecal flotation, recovery of worms after treatment	150
2	NS	Natural	Unknown	Patent intestinal infection; 7 male and 19 females from both dogs recovered.	Fecal flotation, necropsy	1
1	12 weeks	Natural	Likely larvated egg[a]	Progressive weakness, ataxia, imbalance deteriorating to severe CNS disease within 24 hours; euthanized.	Histopathology	179
1	NS	Natural	Unknown	Vomiting, anorexia, eosinophilia (peripheral and CSF), sublumbar lymphadenopathy, progressive neurologic deterioration, euthanized within 24 hours.	MRI and histopathology	180
7	NS	Experimental	Larvae[a]	Patent intestinal infection in 4/7 dogs after 42–80 days.	Fecal flotation, necropsy	146
7	NS	Experimental	Larvated eggs	Unthriftiness and abdominal tenderness followed by severe CNS signs within 10 days in 2 dogs fed 100,000 and 200,000 eggs, dead at 14 days. Ataxia and incoordination in one dog fed 10,000 eggs by day 19.	Necropsy	151
4	10 months	Experimental	Larvae[b]	Patent intestinal infection in 3/4 dogs	Fecal flotation; recovery of worms after treatment followed by necropsy	141
12	6 months	Experimental	Larvae or larvated eggs	Patent intestinal infection in 2/6 dogs inoculated with larvae (low dose group)	Fecal flotation and fecal antigen ELISA (IDEXX Laboratories)	72

[a]Had access to a cage that had previously housed a raccoon suggesting ingestion of larvated eggs as the likely route of exposure; however, only one of three puppies in the litter became ill.

CNS, central nervous system; *CSF,* cer ebrospinal fluid; *ELISA,* enzyme-linked immunosorbent assay; *NS,* not specified.

environment or can act as paratenic hosts and develop clinical disease due to larva migration.[73,140] Morphologically, adults resemble *T. canis* and differ from *T. leonina* by the presence of inconspicuous cervical alae (see Table 112.1; Fig. 112.1). The males of *B. procyonis* can be differentiated from those of *T. canis* by the presence of a roughened anal patch. Eggs of *B. procyonis* can be differentiated from those of *T. leonina* by their smooth egg shells and polar filaments (see Fig. 112.2). As noted previously, *T. canis* and *B. procyonis* eggs can be difficult to distinguish, but the latter tend to be darker amber and are more ellipsoid.

Although there are numerous other *Baylisascaris* spp. in North America (e.g., *B. columnaris* in skunks, *B. transfuga* in bears), none have been reported from domestic dogs. However, diagnosis of infection in dogs is generally by fecal examination and the eggs of most *Baylisascaris* spp. cannot be reliably distinguished based on morphology.[141]

Sporadic patent infections have been reported in the United States and Canada and a 2017 report of reference laboratory data described *Baylisascaris* spp. eggs in 504/9,486,672 (0.005%) fecal specimens.[140,142] Prevalence was also low in a study on Prince Edward Island, Canada (7/242 dogs; 0.36%).[143] However, prevalence in stray dogs or dogs not receiving regular veterinary care is likely higher. Also, unreported infections may be detected during POC fecal examinations or as a result of misidentification of eggs as *Toxocara* spp. eggs. In the United States, prevalence in dogs was lower in the southern and central regions, which corresponds with the known prevalence and distribution of the parasite in raccoons.[142] Most of these positive dogs were large breeds in the sporting and working groups (AKC breed classifications). These dogs may be more likely to be kept outdoors unsupervised where they have access to raccoon feces and/or infected paratenic hosts, such as rodents. Like the eggs of other ascarids, *B. procyonis* eggs are extremely hardy and are resistant to low and freezing temperatures, desiccation, and disinfectants.[144,145] Only temperatures > 60°C will destroy eggs[145] although bleach removes their mammilated outer layer, making them easier to remove from surfaces.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

The life cycle of *B. procyonis* is similar to that of other ascarids. Like raccoons, dogs can develop patent infections (i.e., act as definitive hosts) but unlike raccoons, some infected dogs, particularly puppies, can develop VLM. Definitive hosts are infected when they ingest embryonated eggs or tissues of infected paratenic hosts. Depending on the route of infection, the PPP for dogs can range from 42 to 48 days after ingestion of paratenic hosts to ~60 days after infection with eggs, although data are limited.[146,147] Some PPPs may be longer.[73] It is unknown if *B. procyonis* larvae undergo hepatotracheal migration in the

definitive host after egg ingestion as reported for *Toxocara* infections, although this has been reported for *Baylisascaris laevis* in rodents.[148] Eggs excreted in feces require 2 to 3 weeks under ideal conditions to embryonate.

When eggs are ingested by paratenic hosts (including dogs), they hatch and larvae exit the GI tract and migrate through tissues. After an initial liver-lung migration, larvae migrate throughout the somatic tissues of the host, including the CNS and eyes, causing NLM and OLM, respectively. As with *Toxocara* spp., VLM can also produce disease if significant numbers of larvae are present. The paratenic host range is remarkably broad and encompasses over 150 species of mammals and birds.[140]

Some evidence exists for vertical transmission of *Baylisascaris* spp. in definitive and paratenic hosts. *Baylisascaris procyonis* eggs have been detected in the feces of puppies as young as 2 months of age[140,142] and *Baylisascaris* sp. larvae were detected in a neonatal lamb with neurologic disease suggesting infection via the transplacental or transmammary route.[149] Additionally, *B. transfuga* (a parasite of bears) was found in the cerebrum of two newborn sibling moose calves with neurologic disease who were born to a dam shot for aggressive behavior.[150]

Migration of larvae in susceptible paratenic hosts can lead to VLM, NLM, and/or OLM; these can be severe or fatal. When larvae hatch from eggs, they are ~300 µm in length but within 10–15 days grow to ~1,500–1,800 µm. Histologically, these larvae are ~60–80 µm in diameter and have distinct lateral alae visible in cross-section. In contrast, larvae of *Toxocara* spp. and *T. leonina* are significantly shorter and have smaller diameters (see Table 112.1). The larger size of *Baylisascaris* spp. larvae compared with *Toxocara* spp. larvae and the growth of larvae during migration leads to more significant inflammation and tissue damage.

In raccoons, intestinal infections with *B. procyonis* are nearly always subclinical and the same is likely true for dogs when they act as definitive hosts. Very high worm burdens could theoretically cause signs that are similar to heavy *T. canis* infections. However, because dogs are not the normal definitive host for *B. procyonis*, such high worm burdens may not develop. In the few case reports that exist, burdens ranged from only 2 to 13 worms.[1,151] Also, not all dogs experimentally exposed to *B. procyonis* develop infections, which is further indication that they are not an ideal host for the parasite (Table 112.2).[73,146,147]

Cerebral baylisascariasis in paratenic hosts can result in behavioral changes, agitation, ataxia, lethargy, and confusion that deteriorates into paralysis, seizures, coma, and death. Eosinophilic meningitis or encephalomyelitis with moderate to high peripheral eosinophilia are common outcomes of CNS infection. Although ocular manifestations are poorly studied in animals, *Baylisascaris*-associated OLM in humans is often associated with DUSN which can lead to diminished vision or blindness.[140] Although most natural paratenic hosts are rodents or birds, there have been cases in numerous species of lagomorphs, and carnivores, as well as domestic animals (e.g., sheep, chickens) and captive exotics (e.g., primates, prosimians, marsupials, flying fox, parrots).[140]

Several cases of larva migrans in puppies have been reported (see Table 112.2). Puppies generally showed neurologic signs, and larvae morphologically consistent with *B. procyonis* were found in association with inflammatory lesions. However, not all puppies develop disease; there have been several instances of puppies (<2 months) passing eggs in feces which were presumed to be early patent infections.[140,142] NLM has also been experimentally induced in adult dogs inoculated with high doses of *B. procyonis* eggs (see Table 112.2). Two dogs given > 100,000 embryonated eggs developed clinical signs by 2–3 days PI, including lethargy, pale mucosa, anorexia, ataxia, and reduced activity (which was likely due to VLM). By 10 days PI, their condition deteriorated and severe neurologic signs (inability to stand or right self, extensor rigidity, repetitive limb movements) developed and both dogs died by 14 days PI. Both dogs had large, ulcerated, hemorrhagic foci in the pyloric stomach presumably due to larvae migration out of the GI tract.[152] Two additional dogs were given 10,000 eggs and although one remained clinically normal, the other developed ataxia and incoordination by 19 days PI. However, this dog never developed signs as severe as the other two dogs given a higher dose. Some behavioral changes and agitation were noted in a dog inoculated with 50,000 eggs, but no neurologic disease developed. No major histologic lesions were noted in the dogs receiving 10,000 to 50,000 eggs.[152] In another study, a single dog given 5,000 eggs orally did not develop any clinical disease and no larvae were recovered from tissues.[153]

DIAGNOSIS

Centrifugal fecal flotation to recover eggs is the primary method for diagnosis of patent *Baylisascaris* spp. infections in dogs. Given their morphologic similarities, care should be taken to distinguish *Baylisascaris* spp. eggs from those of *T. canis* (see Fig. 112.2). Coprophagy has the potential to contribute to diagnostic confusion in domestic dogs. For example, oocysts of *Eimieria* spp., common raccoon parasites, were detected in 15% of canine fecal specimens positive for *Baylisascaris* spp. eggs.[142] The finding of embryonated *Baylisascaris* spp. eggs or *Eimeria* spp. oocysts indicates that coprophagy has occurred.

PCR-based protocols can be used to confirm the presence of *Baylisascaris* spp. eggs in fecal specimens.[154] Also, a commercial coproantigen ELISA (IDEXX Laboratories Inc., Westbrook, ME), developed for the detection of more common roundworm genera (*Toxocara, Toxascaris*), can also detect antigen shed from *B. procyonis* in the intestine.[73]

A diagnosis of *B. procyonis* larva migrans cannot be confirmed antemortem as serologic tests are not available for dogs. A history of exposure to raccoon feces can suggest a risk. Larvae recovered from tissues by artificial digestion or in histologic sections can be identified morphologically and/or with molecular tools. It is possible that *B. procyonis* NLM in dogs is under-recognized given these diagnostic challenges and the variable nature of disease progression and clinical signs.

TREATMENT AND PREVENTION

There are no anthelmintics approved for the treatment of *B. procyonis* in dogs. However, anthelmintics labeled for treatment of *T. canis* appear effective for the elimination of intestinal *B. procyonis* infections. Single doses of pyrantel (20 mg/kg) and moxidectin (1 mg/kg) were efficacious in experimentally infected raccoons.[155] Three daily doses of fenbendazole (50 mg/kg) and flubendazole (22 mg/kg) were also effective.[155] High-burden infections may require re-treatment to eliminate all worms. For example, in a study of *B. procyonis*–infected dogs, a single oral dose of milbemycin oxime was effective for dogs infected with 25 worms; but in two dogs with more than 25 nematodes, infection was not eliminated using this protocol.[142]

Treatment of *Baylisascaris* spp. larva migrans in dogs has not been investigated. In some recent human cases, early intervention with anthelmintics (typically albendazole, use of which should be

avoided in dogs and cats) and glucocorticoids to control inflammation resulted in favorable clinical outcomes with full or nearly full recoveries.[156,157]

Use of monthly products labeled for prevention of other ascarids should control *B. procyonis* infection. Prevention of coprophagy is important for two reasons: it prevents exposure and the subsequent development of a patent infection and/or larva migrans and also prevents passive excretion of *B. procyonis* eggs by dogs into a domestic environment.

Preventing contact with captive raccoons and any structures/substrates that may be contaminated is also important. Raccoons should not be kept as pets, and any raccoons in captivity should be routinely examined for *B. procyonis* infection and treated if necessary.

PUBLIC HEALTH ASPECTS

Over 50 human cerebral and ocular baylisascariasis cases have been reported. Case fatality rates for NLM are ~40%; however, treatment is more successful now given improved diagnostic tests as well as increased awareness.[140,157] However, NLM survivors are still frequently left with permanent sequelae, and OLM can cause permanent vision defects.[140] While human infections are rare, the potentially severe consequences warrant awareness and prevention efforts. Some infections may occur covertly as with toxocariasis; however, the implications of seropositivity in asymptomatic individuals are not well understood.[158]

Although prevalence is very low in dogs, infected dogs may represent a greater risk for human and other companion animal exposure due to their indiscriminate defecation habits (versus raccoons that utilize defined latrine sites). No human cases have been linked to contact with infected dogs, but veterinarians should provide information to clients about the risks of *B. procyonis* infection and prevention strategies, especially in areas where raccoons are ubiquitous and the parasite occurs at a high prevalence.

OTHER ASCARIDS

TOXOCARA MALAYASIENSIS INFECTION

A relatively recently described species, *Toxocara malayasiensis*, has been detected in domestic cats in Southeast Asia. *Toxocara malayasiensis* shares many morphologic characteristics with *T. canis* but can be differentiated based on appearance of cervical alae in transverse section (curved versus straight in *T. canis*), shorter spicule length, and lip morphology.[159] Molecular analysis also supports the validity of this species.[160]

Little is known about the distribution and epidemiology of *T. malayasiensis* in cats. Worms collected from domestic cats in China and Malaysia were confirmed to be *T. malayasiensis* using nucleic acid–based methods.[161] In stray cats from Malaysia, the prevalence of *T. malayasiensis* infection was higher than that of *T. cati* infection.[162] This emphasizes the need for further investigation into potential cryptic *Toxocara* species globally.

LAGOCHILASCARIS SPP. INFECTION

The genus *Lagochilascaris* includes zoonotic ascarids of domestic and wild felids from Mexico south to Argentina. This genus is distinguished from other Ascarididae based on unique lip and anterior end morphology; involutions in each lip create a "hare-lipped" appearance (for which the genus is named), and the lips are of equal width to or wider than the cuticular collar. The two primary species that infect domestic cats are *Lagochilascaris minor* and *Lagochilascaris major.* The females of both species are 18 to 22 mm long, while males are 17 to 20 mm.[163] The lips of *L. major* protrude over the collar more compared with *L. minor*. Eggs of both species are similarly sized, ~60 µm wide and generally spherical, with a prominently pitted surface, but the species differ in the number of pits on the surface of the eggs (*L. minor* 15 to 25; *L. major* 33 to 45).

The life cycle of *L. minor* has been elucidated in experimental infections.[164] The adult nematodes form tumor-like masses and fistulous lesions in the larynx, pharynx, tongue, and palate, and occasionally in the esophagus and stomach of cats, although this is not always observed (especially in wild felids, presumably the "natural" host). Clinical signs became apparent within 10 days of inoculation, including dyspnea, poor body condition, decreased vocalization, decreased activity, and frequent sneezing.[164] One study observed mild to moderate neurologic impairment in some experimentally infected cats, such as imbalance, mild ataxia, and torticollis, although other cats appeared normal in behavior.[165]

Infections became patent ~2 weeks PI and eggs were excreted in feces.[164] Some lesions contained adults at variable stages, larvae, and embryonated eggs, suggesting that autoinfection may occur.[164,165] *Lagochilascaris* spp. are believed to be obligatory heteroxenous (requiring at least two host species to complete their life cycle) as no cats inoculated with eggs of *L. minor* became infected, but all mice inoculated with eggs developed VLM.[164] It is possible that young cats could become infected through egg ingestion, but this has not been evaluated. Natural infections of *L. minor* in domestic cats are variable in presentation, ranging from benign subcutaneous nodules around the head and neck to large, fistulated abscesses in the upper respiratory tract.[166–169] Both young (<1 year) and adult cats are susceptible.

The life cycle of *L. major* has not been demonstrated experimentally, but is presumably similar; reports of natural infections in cats exist and resemble those of *L. minor*. The adults of *L. major* may cause fistulated, purulent pharyngeal abscesses that result in cough, dyspnea, and difficulty swallowing.[163] Abscesses may contain 50 or more adult worms.

In humans, larvae migrate to subcutaneous sites of the head, neck, throat and particularly the submandibular area, where large nodules may develop. If these form in proximity to the eyes, severe, persistent ocular disease may result.[170] At least one human case has been associated with fatal NLM.[171] More than 60 cases have been reported in Mexico, Trinidad, Suriname, Venezuela, Colombia, Bolivia, Brazil, and Argentina.[172] The transmission route to humans is unknown, although in some communities it may be due to the practice of eating wild intermediate hosts such as capybara, agouti, and opossums.[165,173] One suspected *L. major* larva migrans case has been reported from a dog and involved a purulent abscess.[174]

Treatment in humans and felids typically involves surgical excision of the nodules, followed by lavage of the area and anthelmintic therapy to remove any remaining larvae. Levamisole and ivermectin appear to be the drugs of choice; diethylcarbamazine and benzimidazoles appear to lack efficacy in some human cases and experimental infections.[175–177] Prolonged or multiple rounds of anthelmintic therapy may be required to prevent recrudescence via autoinfection.[170] Antibiotic treatment may be necessary if secondary bacterial infection of subcutaneous abscesses has occurred.

CASE EXAMPLE

Signalment

"Chloe," a 4-year-old female spayed domestic shorthair cat from Edmond, Oklahoma, United States.

History

Chloe was evaluated in April for a recent episode of acute vomiting. Her owners reported finding motile nematodes in the vomitus; one was brought for examination (see Fig. 112.9). Chloe was an indoor/outdoor cat that lived in a wooded subdivision. She was current on vaccinations and wore a flumethrin/imidacloprid collar for flea and tick control. Her owners denied that she hunted often but reported occasionally finding dead, eviscerated mice and birds around their home.

Current medications: No treatments other than the flumethrin/imidacloprid collar. Owners reported applying a new collar each March.

Other medical history: Previous medical problems included flea infestation and ear mites as a kitten, both of which resolved with treatment. Owners declined earlier recommendations for comprehensive monthly internal parasite control (selamectin), opting instead to only protect Chloe from fleas and ticks.

Physical Examination

Body weight: 3.7 kg; BCS: 4/9.

General: Bright, alert, hydrated, responsive. Mucous membranes pink, HR = 180 beats/minute, RR = 40 beats/minute, T = 101.2°F (38.4°C).

GI and genitourinary: Normal palpation. No abdominal mass, pain, or other abnormalities detected.

Integument: Normal haircoat. No ectoparasites were evident.

Eyes, ears, nose, and throat; musculoskeletal; respiratory; cardiovascular; lymph nodes: No clinically significant findings were noted.

Fecal flotation, fecal antigen test, and parasite identification results: Numerous eggs of *T. cati* were present on examination of zinc sulfate centrifugal fecal flotation, and fecal specimen was positive for antigen of *Toxocara* spp. (FecalDx®, IDEXX Laboratories, Inc.). The adult nematode (see Fig. 112.9) was morphologically identified as a female *T. cati* ascarid.

Serology

A feline heartworm antibody test and antigen test were negative.

Diagnosis

Toxocara cati infection.

Treatment

Chloe was treated with a single transdermal dose of emodepside/praziquantel. Topical moxidectin/fluralaner administered every 8 weeks was commenced and the owners were advised to discontinue the flumethrin/imidacloprid collar. No further incidents of vomiting were reported.

Comments

A definitive diagnosis of *T. cati* infection was made based on identification of adult worms in vomitus, eggs on fecal flotation, and antigen detected in feces. Although normally present in the small intestine, ascarids often migrate in a retrograde manner to the stomach, irritate the gastric mucosa, and are expelled through vomiting. The distinct arrowhead-shaped anterior end allows adults of *T. cati* to be distinguished from those of *Physaloptera* spp., another nematode found in cat vomit us that requires a different treatment (see Chapter 116). Treatment with emodepside/praziquantel was recommended to address potential co-infection with *Taenia* sp. tapeworms which are difficult to detect on fecal examination and commonly found together with ascarid infections in cats with access to prey species.[178] Treating only with moxidectin/fluralaner every 2 months would eliminate the *T. cati* infection and address the need for ongoing flea and tick control but would not provide efficacy against tapeworms.

Hookworms

Dwight D. Bowman, Araceli Lucio-Forster, Alice C.Y. Lee

KEY POINTS

- First Described: The canine hookworm, now known as *Ancylostoma caninum*, was first described by Ercolani in a veterinary textbook in Italy in 1859, and in 1911, the species was moved to the genus *Ancylostoma.*[1] *Ancylostoma tubaeforme* was first described by Zeder in 1800 as a hookworm of the cat; it was later considered the same as the dog hookworm until 1962 when Burrows showed it was a distinct species.[2] *Ancylostoma braziliense* was described as a new species by de Faria in 1910 from specimens collected from dogs and cats in Brazil. It was then synonymized with *Ancylostoma ceylanicum* until 1951 when Biocca showed they were distinct species.[3] *Ancylostoma ceylanicum* was first described by Looss in 1911[1] based on specimens from a civet and then in three people in India.[4] *Uncinaria stenocephala* was initially named *Dochmoides stenocephala* in France in 1884 by Railliet and then later transferred to the genus *Uncinaria.*
- Cause: Five members of the hookworm family Ancylostomatidae: *Ancylostoma caninum* (canine ancylostomiasis), *Ancylostoma tubaeforme* (feline ancylostomiasis), *Ancylostoma braziliense* (the creeping eruption hookworm of people), *Uncinaria stenocephala* (canine uncinariasis), and in tropical areas of Australasia, *Ancylostoma ceylanicum* (causing ancylostomiasis in dogs, cats, and humans).
- Affected Hosts: *Ancylostoma caninum* is a parasite of dogs and other canids; *A. tubaeforme* is a parasite of the domestic cat and other felids; *A. braziliense* is a parasite of canids and felids; adults of *A. ceylanicum* can be found in canids, felids, and people; and *U. stenocephala* is found in dogs, foxes, and other canids. There are no intermediate hosts; however, all these hookworms can utilize some invertebrates and mammals as paratenic hosts.
- Geographic Distribution: *Ancylostoma caninum* and *A. tubaeforme* have a cosmopolitan distribution. *Ancylostoma braziliense* tends to be restricted to the southeastern United States and the coastal areas of the Atlantic, through the Caribbean, the eastern coastal areas of Mexico, Central and South America, southeast Asia, and the northern coast of Australia. *Ancylostoma ceylanicum* occurs in India, Taiwan, central Thailand, Malaysia, Indonesia, Borneo, and likely New Guinea; it is also in Surinam in South America. *Uncinaria stenocephala* is found in the northern United States and Canada, as well as the EU, Africa, and it has been reported from Australia.
- Primary Mode of Transmission: Hookworms infect their final hosts through either oral or percutaneous routes. *Ancylostoma caninum* is the only species capable of infecting offspring through transmammary transmission. Relative to transmission into their carnivorous final hosts, all four species of *Ancylostoma* persist in the tissues of murine paratenic hosts for extended periods, with the exception being *A. ceylanicum* where a very small percentage of larvae (<1%) survive in mice one month PI. It has been reported that the larvae of *U. stenocephala* can also persist in the tissues of mice after either oral or percutaneous infection; however, others consider *U. stenocephala* to have strictly a direct life cycle.
- Major Clinical Signs: When present in sufficient numbers, hookworms can cause anemia, leading to pale mucous membranes, tachycardia, and lethargy. Inappetence, emaciation or failure to gain weight, and poor haircoat are often evident. During acute infections, feces can contain blood and mucus. Dark, tarry feces may be produced when there is significant blood loss into the intestinal lumen.
- Differential Diagnoses: Other parasitisms (e.g., fleas, ticks, coccidia, *Babesia* spp.), bacterial or viral enteritis (e.g., parvovirus, feline panleukopenia virus, *Salmonella*, enterohemorrhagic *Escherichia coli*), IMHA, hemotropic *Mycoplasma* infections, FeLV or FIV infections, portosystemic shunt, hereditary hemophilia, toxicity (e.g., rodenticide, NSAID, garlic, onion), and neoplasia.
- Human Health Significance: *Ancylostoma braziliense* and, to a lesser extent, *A. caninum* cause cutaneous larva migrans in humans ("creeping eruption"). *Ancylostoma caninum* can mature to the adult stage in the human intestine on rare occasions, eliciting an eosinophilic enteritis.

ETIOLOGY AND EPIDEMIOLOGY

Hookworm infections in cats and dogs are caused by species of nematodes in the genera *Ancylostoma* and *Uncinaria*. The species of *Ancylostoma* infecting companion animals in the Americas include: *Ancylostoma caninum* in dogs, *Ancylostoma tubaeforme* in cats, and *Ancylostoma braziliense* in both hosts. *Uncinaria stenocephala* infects dogs and other canids, and although the nematode has been previously reported in cats, infections in feline hosts are rare. In companion animals, these parasites are important because of the anemia they induce as they feed from the mucosa of the small intestine. The major differences in the pathology induced in their hosts are related to: (1) the modes of infection utilized by each species, and (2) the amount of blood loss induced by individual worms within the intestinal tract, which varies with the species of hookworm involved. Aside from the exotic *Ancylostoma ceylanicum* that routinely develops to the adult stage in humans, the zoonotic importance of canine and feline hookworms stems from the ability of the larvae to penetrate skin and produce cutaneous lesions in humans.

The general life cycle of hookworms requires that the feces from an infected host be deposited at a site where it will be mixed with porous soil that remains moist; in this manner, the eggs will be protected from being overly heated, frozen, or dried. Then, in about a week, larvae develop within the egg, hatch as first-stage larvae, feed and grow, molt twice, and become non-feeding infective third-stage larvae. The larvae of *A. caninum*

develop optimally at 25°C to 30°C, taking only 3 days to become infective at 30°C compared to 22 days if maintained at 15°C.[5] *Ancylostoma tubaeforme* and *U. stenocephala* develop optimally at 20°C.[5,6] Fecal cultures harboring both *A. caninum* and *U. stenocephala* eggs, if held at 15°C, will produce only *U. stenocephala* larvae 8 days after the cultures are initiated; the eggs and larvae of *U. stenocephala* are tolerant to cold and can survive temperatures near freezing, for days to weeks, while the same conditions will kill *A. caninum* eggs and larvae in a few days.[5] There have been no similar studies on the development of *A. braziliense*, but its presence only in warmer climes would suggest that it develops most successfully at warmer temperatures and may not develop in soils of colder climates.

Infective-stage hookworm larvae that develop in the soil can enter their final canine or feline hosts in three different ways. One means of infection is to penetrate the skin, be carried to the lungs via the circulatory system, and then enter the intestine after migrating up the trachea and being swallowed. Second, they can be ingested as free larvae from the soil or on contaminated plants or fomites. Third, they can be ingested as infective-stage larvae in the tissues of prey paratenic hosts. All four species of *Ancylostoma* persist in tissues of rodent paratenic hosts for extended periods, with the exception of *A. ceylanicum* where a small percentage of larvae (< 1%) survive in mice a month PI.[7–9] Additional work with *A. caninum* has shown that it will persist in the tissues of cockroaches, rodents, cats, sheep, and goats.[10] Chickens appear refractory to *A. caninum* larval infection with < 1% of the inoculum being recovered from muscle after 2 months,[11] and no larvae were recovered from chickens 20 days after infection with *A. tubaeforme*.[7] *Uncinaria stenocephala* can also persist in the tissues of mice after oral or percutaneous infection[12]; however, others consider *U. stenocephala* to have strictly a direct life cycle.[13] *Ancylostoma caninum* of dogs is the only species discussed herein that infects neonates through transmammary transmission (Fig. 113.1).[14] In this case, larvae that have been sequestered in the tissues of the dam will enter the mammary gland and make their way into the milk after the female begins lactation. Thus, very young pups can be infected with a large number of *A. caninum* relative to their body size, which can lead to severe and even fatal anemia. The pre-patent and patent periods for *A. caninum*, *A. tubaeforme, A. braziliense*, and *U. stenocephala*, respectively, are: 15–26, 18–28, 14–16, and 15–17 days before eggs are produced; and about 6, 18–24, 4–8, and 6–12 months of egg excretion.[15–18]

Ancylostoma caninum and *A. tubaeforme* have a cosmopolitan geographic distribution. *Uncinaria stenocephala*, the most cold tolerant of the species,[19] is found in the northern United States and Canada, as well as in the EU, Africa, and has been reported from Australia.[20] The CAPC prevalence maps for the United States show the results for over 10 million dog fecal examinations; in 2021, about 2.9% contained hookworm eggs. The CAPC maps for cats, representing almost 1.8 million fecal specimens, show that 0.8% contained hookworm eggs. Much higher infection rates were reported in animals not receiving routine veterinary care or endoparasitic treatments, and those having access to prey and contaminated environments.[21–23] The areas with the highest prevalence rates were in the southeastern and southcentral states, and the areas with the lowest rates of infection were the southwestern states. *Ancylostoma braziliense,* based on reported cases of "creeping eruption" in humans and surveys of dogs and cats in the United States, is located mainly in the southeastern and southcentral states bordering the shores of the Atlantic and the Gulf of Mexico.[24–26] Globally, cutaneous larva migrans (CLM) occurs in warmer climates, is endemic in many countries in the developing world, and has increasingly been a problem in southern Europe. The disease has been a problem among travelers returning to North America from the Caribbean[27]; a study that included over 17,000 travelers consulting specialized travel or tropical medicine clinics on six continents after holidays identified the disease in 2%–3% of patients.[28] Sites of exposure, in decreasing order of frequency, were the Caribbean, Southeast Asia, Central America and South America, and the northern coast of Australia.[15,29] (see Public Health Significance). *Ancylostoma ceylanicum* occurs in India, Taiwan, central Thailand, Malaysia, Indonesia, Borneo, and likely New Guinea; it is also in Surinam in South America.[15,29]

CLINICAL FEATURES

Pathogenesis

The disease produced by adult hookworms is anemia. In 1992, Dr. Jay Georgi, who for years studied blood loss from hookworm infection and haemonchosis, described the blood lost due to *A. caninum* as follows: "The amount of blood removed is directly proportional to the weight of adult hookworms in the small intestine and amounts to a daily loss of about 30 µL of erythrocytes per mg of worm. An adult female *A. caninum* weighs 2.0 to 2.6 mg and a male, about 0.8 mg. Therefore, a population of only 50 females and 25 males would exact a toll of about 4 mL of erythrocytes each day, a substantial drain on the hemopoietic resources of any puppy. The imposition of such a burden during the nursing period could prove fatal. To make matters worse, peak blood loss is experienced even before eggs appear in the feces. This not only renders diagnosis difficult but constitutes a sudden hemorrhagic shock that very young puppies are ill-equipped to compensate. The other species of *Ancylostoma* remove less blood than *A. caninum*, and *U. stenocephala* least of all."[30–32]

It has also been estimated that amount of blood lost in dogs per worm is 10–200 µL for *A. caninum*, 14 µL for *A. ceylanicum*, 1 µL for *A. braziliense*, and 0.3 µL for *U. stenocephala*.[31] Thus, *A. caninum* causes far greater blood loss than the other species. In the case of puppies, not only do they have a markedly lower total blood volume than adults but also they do not receive large amounts of iron in the milk from the dam, limiting their ability to regenerate red blood cells. By the end of the third week postpartum, a heavily infected pup can lose 25% of its circulating erythrocyte volume; this can be fatal.[33]

The same number of worms will cause as much blood loss in an adult dog as they do in puppies, however, a well-nourished adult dog can compensate for the blood loss. "Compensated" and "decompensated" hookworm disease has been described.[30] In compensated disease, well-maintained dogs will have no signs other than fecal egg excretion or reductions in erythrocyte parameters. In decompensated hookworm disease, animals that are malnourished or emaciated may require supportive protein and iron supplements along with treatment for intestinal hookworms.

Hookworms secrete a family of anticoagulative proteins into the host blood that prevents fibrin clot formation and also enhances the dissolution of formed clots. They act by several mechanisms, including inhibition of platelet aggregation and clotting factor activity (Xa, VIIa/tissue factor complex), as well as degradation of fibrinogen into nonfunctional components.[34,35] Consequently, hemorrhage can continue from hookworm-abandoned feeding sites within the intestine until hemostasis is re-established (Fig. 113.2). This intestinal hemorrhage, in combination with that lost through direct feeding by the worms, contributes to anemia and hypoproteinemia in heavily infected animals.

Dogs and cats infected with hookworm species other than *A. caninum* can have large numbers of worms without significant clinical signs, because these other species are not passed directly from the mother to offspring, they cause less blood loss per worm, and they are less pathogenic. However, all hookworm infections cause blood loss, and signs are commensurate with the number of worms present. Thus, a high egg count in adult animals indicates a larger number of adult female worms, and greater blood loss than an animal with low egg counts, in most cases. Though anemia is uncommon with *U. stenocephala* and *A. braziliense* infections, hypoproteinemia may still develop as a result of villous atrophy with associated malabsorption and protein loss.[36] Additionally, intestinal mucosal thickening can be observed when *U. stenocephala* worm numbers reach 1,000 or more.[36]

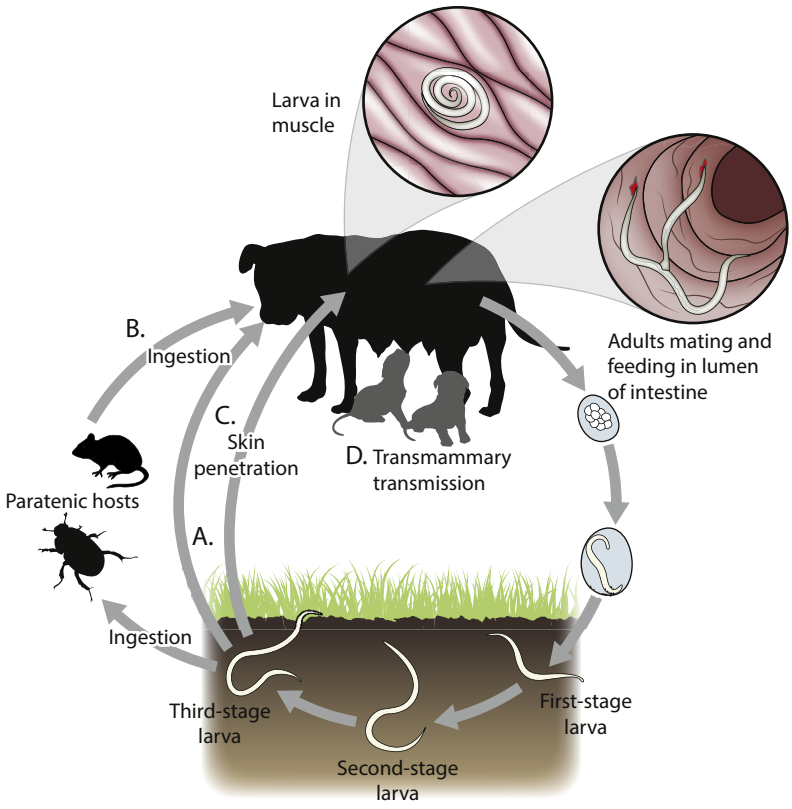

Fig. 113.1 Life cycle of *Ancylostoma caninum*, the most common hookworm in dogs in the United States. The nematode can infect dogs in the same manner as the other hookworms of cats and dogs (i.e., ingestion of free larvae from the environment, ingestion of larvae in prey tissues, and through skin penetration), but it is the only hookworm species in these hosts that is capable of transmammary transmission through the reactivation of hypobiotic larvae from the tissues of the dam.

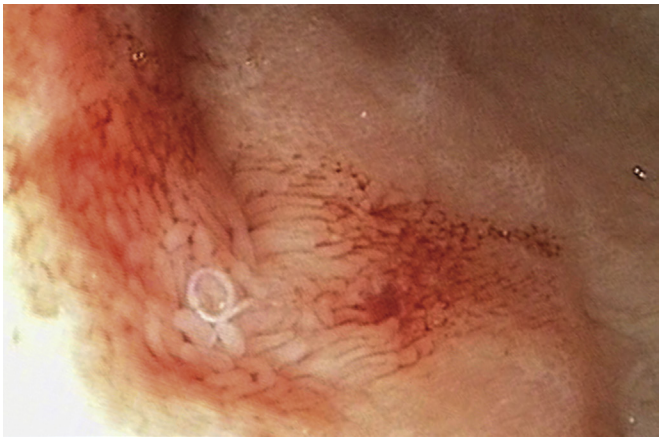

Fig. 113.2 Endoscopic evidence of hemorrhage associated with an immature worm feeding in the small intestine of a dog experimentally infected with *Ancylostoma caninum* (11 days post-infection).

Clinical Signs and Physical Examination Findings

Peracute clinical disease is seen in neonatal pups infected by *A. caninum* through transmammary transmission. Pups often appear healthy in the first week of life, then rapidly deteriorate and die at 2–3 weeks of age. Acute disease affects older pups and kittens, and even adult animals exposed to overwhelming numbers of infectious larvae. Clinical signs include diarrhea with melena and/or mucus, mucosal pallor, lethargy, inappetence, emaciation or failure to gain weight, and poor haircoat. Tachycardia, tachypnea, and weak pulses may be present on physical examination in severely anemic and hypoproteinemic animals. In peracute—and sometimes acute—hookworm disease, clinical signs may occur before eggs appear in the feces, so an accurate diagnosis relies on a good history and physical examination findings. Animals with chronic, compensated hookworm infections are subclinically infected, though decreases in hematologic parameters such as erythrocyte count and hemoglobin concentration may be evident.

Uncinaria stenocephala infection is most commonly associated with dermatitis, though *Ancylostoma* spp. are also capable. These cutaneous manifestations typically occur in kenneled greyhounds.[37] There is typically dermatitis with keratitis of the paw pads, but associated lesions can also often be observed on the ventral thorax and abdomen as well as the limbs. Thickened intestinal loops may also be palpable on physical examination in heavy infections of *U. stenocephala*.

DIAGNOSIS

Fecal Analysis

Fecal Flotation

Patent hookworm infections may be diagnosed by recovery of eggs from fresh or refrigerated fecal specimens examined by routine fecal centrifugal flotation; stationary (noncentrifuged) flotations will recover a markedly lower percentage of hookworm eggs from any given fecal specimens. Hookworm eggs are thin-shelled, smooth and oval, containing an embryo in a morula (generally 4–8 cells) stage.

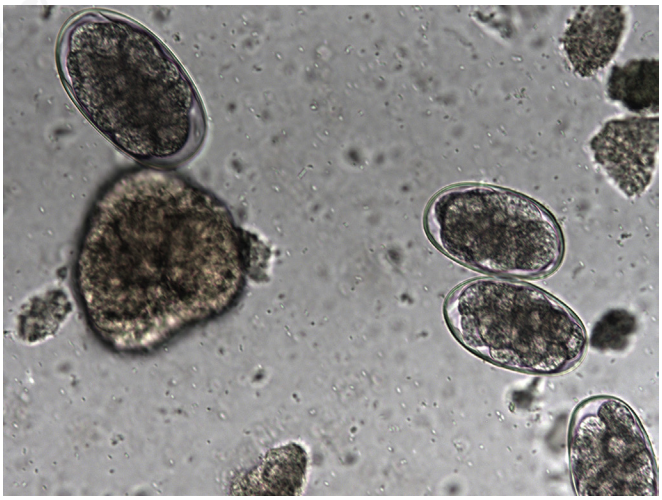

Fig. 113.3 A single egg of *Uncinaria stenocephala (top left corner)* and three eggs of *Ancylostoma caninum* recovered by centrifugal flotation of a fecal specimen from a naturally infected dog.

Careful measurement of length and width, and consideration of the host species, can aid identification of the species of hookworm involved. The eggs of *A. caninum* and *A. tubaeforme* are similarly sized, but can be distinguished based upon the host specificity of the parasite. Dogs and cats can both be infected with *A. braziliense*, but the smaller egg of this species allows it to be distinguished from the dog- and cat-specific hookworms. *Uncinaria stenocephala* eggs are larger than any of the *Ancylostoma* spp. (Fig. 113.3). The egg measurements (length by width) of the four hookworm species in micrometers are: 48–57 × 34–39 µm for *A. braziliense*, 58–66 × 38–42 µm for *A. tubaeforme*, 58–76 × 36–41 µm for *A. caninum*, and 71–92 × 35–58 µm for *U. stenocephala*.[38,39] Mixed infections are possible. In the case of *U. stenocephala*, the major confounder in fecal examinations is the presence of strongyle or trichostrongyle eggs in the feces of a dog that has ingested either prey or the feces of ruminants, equids, or other animals.

Fecal Antigen Detection

Coproantigen detection of hookworms via a fecal ELISA is commercially available (IDEXX Laboratories, Inc., Westbrook, ME, USA). This test can detect a protein excreted by *Ancylostoma* spp. and *U. stenocephala* worms in the intestine of cats and dogs, but cannot differentiate species. This test detects both patent and nonpatent infections, i.e., young and adult nematodes of either sex in the intestine.[40] It is recommended that coproantigen testing be paired with fecal centrifugal flotation tests to optimize detection of concurrent infections and to provide information on egg excretion (and hence environmental contamination).

Adult Nematode Morphology

Adult worms recovered from the feces or during necropsy may be identified to species level by examination of the buccal capsule and the teeth present on its anterior margin. *Ancylostoma* species can be differentiated by the number of teeth present: one large tooth on either side of the midline in *A. braziliense,* and three lateral teeth on either side for *A. caninum* and *A. tubaeforme*. *Uncinaria stenocephala*, on the other hand, is armed with a cutting plate on each side rather than teeth (Fig. 113.4). Although adult *A. caninum* resemble *A. tubaeforme*, they can be differentiated based on the length of the spicules of the males. However, cats and dogs are refractory to infections with *A. caninum* and *A. tubaeforme*, respectively, so such efforts for differentiation are seldom warranted.

Molecular Identification

Molecular identification of hookworm eggs, larvae, or adults to the species level is possible by performing PCR amplification-sequencing. In early 2022, a real-time PCR assay was released in North America that detects the DNA of *Ancylostoma* spp. and *U. stenocephala* as part of a panel designed to detect the DNA of 20 different parasites (KeyScreen GI Parasite PCR, Antech, CA, USA). The assay also detects a genetic marker for benzimidazole (fenbendazole) resistance in *A. caninum* (see Treatment, below). Additional peer-reviewed studies are required to assess the performance of this panel.

Laboratory Abnormalities

In animals with hookworm infections, the CBC may reveal acute normocytic, normochromic anemia progressing to microcytic, hypochromic anemia. Eosinophilia may also be observed. Hypoalbuminemia is present in severe cases, and increased BUN concentration may be evident as a result of intestinal bleeding.

Diagnostic Imaging

Although not practical or economical as a primary means of diagnosing hookworm infection, intestinal hookworms in both dogs and cats can be detected using conventional flexible endoscopy (see Fig. 113.2).[41] Capsule endoscopy is another option in dogs.[42]

Pathologic Findings

Grossly, translucent, white, or red-colored nematodes up to 2 cm long are found attached to the intestinal mucosa in hookworm infections. Pinpoint red lesions are visible in the mucosa at sites where hookworms previously fed. The contents of the intestinal lumen are dark red in color due to waste produced by the hookworms and ongoing hemorrhage. In severely anemic animals, extreme pallor of the intestines, liver, and other internal organs is observed. Serous effusion may be found in the abdominal and thoracic cavities as a consequence of hypoproteinemia. Intestinal thickening may be apparent in animals heavily infected with *U. stenocephala*.

TREATMENT AND PROGNOSIS

Products approved for *A. caninum* treatment in dogs include fenbendazole, milbemycin, moxidectin, pyrantel, and a pyrantel/febantel/praziquantel combination. All of these, aside from milbemycin, are also labeled for treatment of *U. stenocephala* infections. The ivermectin-based heartworm preventives that contain a pyrantel component also are labeled for the treatment of *A. braziliense* infections. Approved products for the treatment of *A. tubaeforme* infection in cats include emodepside, ivermectin, milbemycin, moxidectin, pyrantel, and selamectin; in cats, the ivermectin dose used for heartworm prophylaxis is also approved for treatment of *A. braziliense* infections.

The prognosis for recovery from acute and chronic hookworm disease is good to excellent after effective anthelmintic treatment. Unfortunately, in recent years, veterinarians have observed an increase in the number of cases where *A. caninum* infections have not been successfully cleared by treatment with multiple doses or even multiple classes of anthelmintics approved for this purpose. Initially the "larval leak" phenomenon was suspected to be largely responsible (see Prevention, below), but subsequently, emergence of anthelmintic resistance has been documented in *A. caninum* in the United States. Resistance of *A. caninum* to pyrantel was first reported in pet dogs in Australia in 2007.[43] In the United States, resistance was first suspected in pet greyhounds that failed to stop excreting hookworm eggs despite aggressive treatment with a combination of topical moxidectin, oral

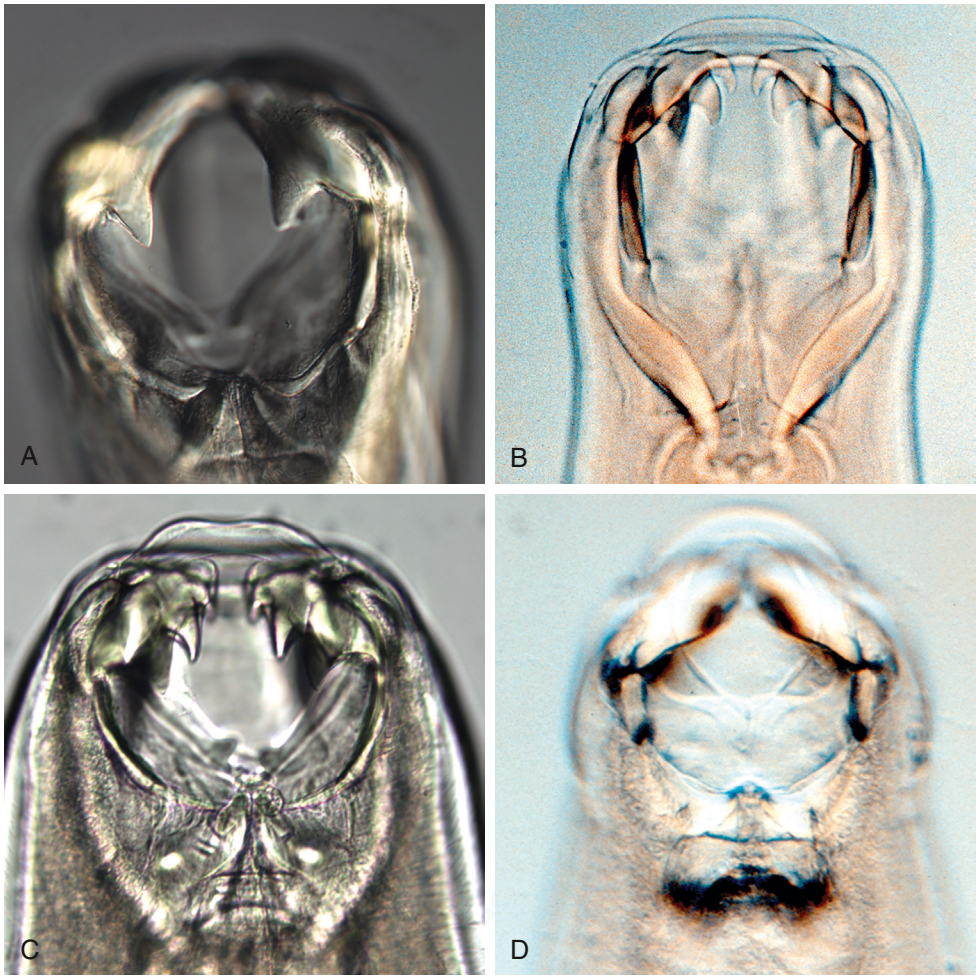

Fig. 113.4 Dorsoventral view of the buccal cavity of adult worms: (A) *Ancylostoma braziliense*, (B) *Ancylostoma caninum*, (C) *Ancylostoma tubaeforme*, and (D) *Uncinaria stenocephala*.

pyrantel, and oral febantel. However, uncertainty about client compliance limited full interpretation.[44] Subsequent work with hookworm isolates from pet greyhounds and pet dogs of other breeds confirmed infection with multidrug resistant *A. caninum* through poor reduction in fecal egg counts and elevated resistance ratios.[45,46] The problem appears to have initially developed in greyhound kennels, and although resistance is also described from other breeds, greyhounds are overrepresented in reports of *A. caninum* resistance.[47] Initial data indicate that canine hookworms resistant to pyrantel, benzimidazoles, and macrocyclic lactones can be cleared with emodepside treatment.[48] An oral product containing emodepside is available for dogs in Europe (but not in the United States) and is effective for treating *A. caninum* infections.[49] A topical feline emodepside product is available in the United States and appears effective against multidrug resistant hookworm infections when administered to dogs orally. However, due to toxicity concerns, the topical feline formulation should only be administered orally to dogs by a veterinarian and care must be taken to avoid severe reactions in heartworm-infected dogs.[50] The geographic distribution of multidrug resistant hookworm populations in the United States has not been fully defined but appears widespread. It is strongly recommended that veterinarians follow up with suspected resistant cases post-treatment to confirm that egg excretion has ceased. If egg clearance cannot be accomplished, owners must be careful to promptly dispose of feces to prevent larval development that may lead to reinfection of the dog or infection risk for humans. Emodepside treatment under the close supervision of a veterinarian may also be considered.[50]

The prognosis for recovery from peracute hookworm disease due to *A. caninum* is guarded to poor, even when effective treatment is instituted. Whole blood transfusion and other colloid therapy are often necessary for supportive care and to allow time for worms to be killed by anthelmintics. Supplemental oxygen may be required. Additional ongoing support in the form of iron supplementation and a high-protein diet is warranted.

IMMUNITY AND VACCINATION

Greyhounds appear to develop immunity to infections with *U. stenocephala*.[51] A vaccine for hookworms was previously available that utilized irradiated larvae, similar to the commercial vaccine for the bovine lungworm, *Dictyocaulus viviparus*.[52] Thus, dogs do develop immunity to hookworm infections, but it does not appear to be sterile immunity. Also, work has shown that when dogs receive less than adequate nutrition, their immunity wanes and they can be reinfected with hookworms.[53]

PREVENTION

With current heartworm prevention products that are effective against hookworm infections, along with the other excellent anthelmintics labeled for treatment of hookworms, there is every reason to believe that hookworm infections can be controlled through routine prevention. Dogs and cats receiving broad-spectrum heartworm prevention should in most instances remain relatively hookworm-free (caveat: dormant larvae present in the tissues are not removed until they reactivate, migrate to the

intestines, and are killed when the next dose of anthelmintic is administered). If they are not receiving such prevention, cats and dogs should have two to four fecal examinations each year to insure that any worms detected at that time are removed through proper treatment. Some intact females, especially rescue dogs, may have large numbers of sequestered larvae in their tissues that can reactivate and infect nursing pups, and there is currently no approved means of preventing transmammary infection in these dogs. Thus, veterinarians need to remain aware that post-natal hookworm infections are likely to occur and can prove fatal to pups. For all puppies, the recommendation is to deworm with pyrantel every 2 weeks beginning at 2 weeks of age until they can be transitioned to a monthly heartworm preventive product with activity against hookworms. For a dam with a history of *A. caninum*-related peracute disease in a previous litter, decreased transmission to subsequent litters can be achieved by the off-label use of one of the following: daily fenbendazole (50 mg/kg, PO, given from the 40th day of gestation to the 14th day postpartum; this regimen can be costly), ivermectin (0.5 mg/kg, SC, given 4–9 days before parturition and then again 10 days later), transdermal moxidectin (4–4.6 mg/kg given on the 56th day of gestation), or injectable moxidectin (1 mg/kg, SC, on the 55th day of gestation).[54]

Some dogs persistently excrete eggs in spite of treatment. Even when treatment successfully removes the population of worms in the intestine, sequestered larvae in the dog's tissues—the same ones that awaken to infect pups—constantly reactivate to repopulate the intestine and mature to egg-producing adults.[55–57] This "larval leak" phenomenon was a common occurrence before monthly control products became available. Some dogs on monthly preventives, especially those coming from heavily contaminated environments, continue to shed eggs despite many months of repeated hookworm treatments. In these dogs, the goal should be to use the monthly preventives to remove any worms reactivated since the last dose in order to maintain low populations of feeding worms in the intestine, and preclude disease in the animal as well as egg excretion into the environment.

PUBLIC HEALTH ASPECTS

The hookworms of dogs and cats in the United States can all penetrate the skin of mammals. At the same time, the vast majority of reports of creeping eruption from hookworms occur in areas where the species *A. braziliense* is found. *Ancylostoma braziliense* is also the species for which larvae have been recovered from human skin and identified using molecular methods.[58] Migrating larvae cause pruritic, serpiginous tracks in the skin that can persist for weeks if not treated (Fig. 113.5).

Fig. 113.5 Serpiginous tracts secondary to cutaneous larva migrans. (Reprinted from Kinkaid L, Klowak M, Klowak S, et al. Management of imported cutaneous larva migrans: A case series and mini-review. *Travel Med Infect Dis.* 2015;13:382–387.)

An often overlooked aspect of canine and feline hookworm infections is that these parasites utilize mammalian paratenic hosts as part of their life cycles. All four of these hookworms persist for long periods in the tissues of rodents, and a hookworm larva was identified in a muscle biopsy from a person 3 months after diagnosis of CLM.[59] *Ancylostoma caninum* larvae can persist in the muscles of sheep after percutaneous infection.[10] Thus, it seems likely that in patients with CLM, larvae will migrate into the musculature where they will begin a long-term residence.

Among the hookworm species found in the United States, only *A. caninum* is known to develop to the adult stage in humans. The worms have been found in the intestine and cause eosinophilic enteritis with abdominal pain as the main symptom.[21]

CASE EXAMPLE

Signalment

"Tonka," a 13-week-old intact male basset hound from Ithaca, NY, USA.

History

Tonka's owner reported a 24-hour history of lethargy and inappetence, with one episode of a small amount of bile being vomited. Tonka had had diarrhea with intermittently black and tarry feces since he was acquired from a local breeder 1 week ago. He had been eating, drinking, and urinating normally up until the previous day. According to the owner, Tonka had been vaccinated by the breeder at 8 and 12 weeks of age with a "9-way" vaccine, and had also been dewormed. He was not on any current medications.

Physical Examination Findings

Body weight: 7.6 kg.

General: Quiet, alert, and responsive. Temperature = 100.5°F (38.1°C), HR = 188 beats/minute, RR = 24 breaths/minute, pale mucous membranes, CRT < 2 seconds.

Integument: Normal haircoat. No petechiation and no evidence of ectoparasites.

Eyes, ears, nose, and throat: Mild waxy debris within both ear canals. No other abnormalities noted.

Cardiovascular: Sinus tachycardia. Femoral pulses strong and synchronous. No murmurs were detected on auscultation. Mucous membranes were pale and tacky.

GI and genitourinary: The abdomen was large and distended, with fluid-filled intestinal loops. No pain was elicited upon palpation. No other abnormalities noted.

Musculoskeletal, respiratory, lymph nodes: No clinically significant abnormalities noted.

Laboratory Findings

Rapid assessment tests: PCV 17%, TP 5.1 g/dL, BUN 15–26 mg/dL.

Coagulation panels: PT and aPTT within normal limits.

Parvovirus fecal antigen ELISA test: Negative.

Blood smear: Normal RBC morphology with no spherocytes observed. WBCs (lymphocytes, neutrophils, eosinophils) were subjectively increased. Approximately 15 platelets/HPF were observed.

Continued

CASE EXAMPLE—cont'd

Fecal Examination Results

Fecal flotation: *Ancylostoma caninum* eggs, >100 per 10× field.

Diagnosis

Anemia due to ancylostomiasis.

Treatment

Tonka was given an IV bolus of 20 mL/kg of Plasmalyte for cardiovascular support, followed by 175 mL of packed RBCs. Anthelmintic treatment was initiated with fenbendazole (50 mg/kg, PO, q24h for 3 days). Famotidine (0.5 mg/kg, q12h) and sucralfate (0.5 g slurry, q8h) for 5 days were also prescribed for gastroprotection.

Comments

This puppy was evaluated by a veterinary emergency service. It was unclear from the history provided by the owners what drug and protocol the breeder used for deworming. Based on the severity of the clinical signs, the large numbers of eggs in the feces, and the large numbers of *A. caninum* worms passed in the feces a day after the initiation of anthelmintic treatment (Fig. 113.6), it seemed likely that whatever parasite protocol the breeder utilized was insufficient for hookworm control. Adherence to the recommendation for deworming every 2 weeks starting at 2 weeks of age until puppies can be placed on a broad-spectrum heartworm preventive should prevent this condition.

Fig. 113.6 *Ancylostoma caninum* worms recovered from the feces of the 13-week-old intact male basset hound pup with severe anemia described in the case example. Hookworms were passed after treatment with fenbendazole.

114

Whipworms

David A. Elsemore, Jennifer K. Ketzis

KEY POINTS

- First Described: *Trichuris vulpis* was first described in 1789 by von Frölich, who isolated it from a dog in Europe. *Trichuris serrata* and *Trichuris campanula*, described in 1879 and 1888, respectively, were first isolated from cats in Brazil by von Linstow.[1,2] It has been proposed that these are the same species and should be renamed *Trichuris felis*.[3]
- Cause: *Trichuris vulpis*, which occurs in dogs, and *Trichuris felis* (*Trichuris serrata* and *Trichuris campanula*), which occurs in cats, are commonly referred to as whipworms (family Trichuridae).
- Affected Hosts: *Trichuris vulpis* infects dogs and wild canids. *Trichuris felis* infects domestic cats and wild felids.
- Geographic Distribution: The distribution of *T. vulpis* is worldwide, although prevalence is reportedly lower in extremely cold and extremely hot arid climatic zones.[1] *Trichuris felis* is considered a more exotic infection except in tropical and subtropical zones with infection being common in South America and the Caribbean. Less frequent reports of infection have come from the USA, Australia, and Europe.
- Route of Transmission: Dogs and cats become infected with whipworms by ingestion of eggs with infective first-stage larvae.
- Major Clinical Signs: In general, *T. vulpis* infections are of low pathogenicity. However, infections can be associated with intermittent diarrhea and, with heavy infections, chronic and/or severe diarrhea, dehydration, lethargy, anorexia, and anemia. Little is known regarding feline disease. Theoretically, cats could have similar clinical signs as dogs, although there are no published case studies suggesting infection results in clinical signs.
- Differential Diagnoses: The clinical signs are representative of many large bowel disorders (gastroenteritis, dietary indiscretion, gastrointestinal foreign body, inflammatory bowel disease, and other nematode infections). In some cases, infection can be associated with pseudo-hypoadrenocorticism. Presence of *Trichuris* eggs does not necessarily indicate that whipworms are the cause of the clinical signs, given the general low pathogenicity of infection.
- Human Health Significance: *Trichuris vulpis* has been proposed as a zoonotic pathogen. While there have been a few reported human infections, genetic sequencing to confirm the *Trichuris* sp. has been limited. There are no reports of *T. felis* infecting humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Dogs

Trichuris spp. belong to the superfamily Trichinelloidea and the family Trichuridae. While the name of this genus can be translated as "hair-tail," it is actually the anterior portion (forming up to ¾ of the body) that is filamentous and the posterior portion that is thick, resulting in the typical whip-like appearance.[4] *Trichuris vulpis* adults range from 4.5 to 7.5 cm in length (Fig. 114.1).[5] They have a stichosome esophagus and a bacillary band in the esophageal region. The male adults have a single spicule and a coiled posterior while the females have a straight uterus and straight posterior.[6] The eggs range from 70 to 90 µm long by 30 to 50 µm wide, are lemon shaped with symmetrical bipolar plugs, and contain a single cell in fresh feces (Fig. 114.2).[5,7,8]

Several experimental infections have been conducted to determine the life cycle of *T. vulpis* (Fig. 114.3).[7,9–11] Infection occurs via ingestion of an egg with an infective first-stage larva. On arrival in the small intestine, the plugs are digested and the larvae are released primarily in the duodenum and upper portion of the jejunum with some delayed until the upper portion of the ileum.[9,11] The larvae enter the mucosa via the crypts of Lieberkühn where they remain tightly coiled for 6 to 15 days.[9,11] Some minor destruction of the host tissue cells surrounding the larvae can occur. By 15 days PI, the larvae enter the lumen and travel to the cecum or colon where they enter the mucosa, molt three times, and then mature to adults. As the larvae molt from an immature stage (which are not whip-shaped and more uniform in diameter) to an adult, the anterior end remains in the epithelium and the posterior end begins to protrude into the lumen. The final adult worm lives with the anterior esophagus in a "tunnel" in the mucosa, formed by the destruction of the lateral membranes while the apical and basal surfaces remain intact.[12] The embedded portion of the adult worm is normally limited to the superficial tunica propria although some individual nematodes penetrate more deeply into lymph follicles resulting in focal coagulative necrosis surrounding the region.[7,9–11]

In low-burden infections, *T. vulpis* can be found crowded together in the cecum. However, in heavier infections, the worms also can be found in the colon and, rarely, near the rectum. The prepatent period is long (70 to 112 days) with the single-cell eggs excreted in the feces.[7,9–11,13] Adult worms can live for several months to over a year with female worms having the capability of excreting 1000 to 5000 eggs per day, with potentially fewer eggs per female with high burden infections.[7,9,13,14] While the impact of crowding has not been well studied in dogs, *Trichuris* spp. in other hosts have been shown to decrease in size and fecundity with higher burden infections.[15–18] Also, egg excretion can vary significantly on a daily basis. The eggs require <2 weeks to 1.5 months to develop to the infective stage, depending on the soil temperature and moisture level (e.g., 1.5 months at 20°C, 1 month at 25 to 30°C).[7,19,20] Infective eggs contain a first-stage larvae and have a slightly rounder appearance. At cool temperatures (e.g., 4°C), development can be delayed but resumes when temperatures increase, while long periods of freezing temperatures and direct sunlight can destroy eggs. Though generally considered relatively hardy, *Trichuris* eggs do not survive desiccation and heat as well as ascarid eggs do.[7,10,11,19–21]

Given the susceptibility of eggs to freezing temperatures and arid conditions, it is not surprising that prevalence of infections in dogs is lower in hot arid regions and regions with long cold winters. While

challenging to compare prevalence studies due to differences in the diagnostic methods used and source of dogs, it appears that prevalence in well-cared-for pet dogs is decreased in many regions, likely attributable to regular anthelmintic treatment. Data from CAPC indicate that prevalence in pet dogs is <1% in the United States (vs. 8 to 81% in the US in the 1930s to 1950s) and <0.5% in Canada.[7,21] Other United States–based studies have found prevalence to range from <1% to 10%.[22,23] In Australia, a study from 1975 showed a prevalence of 60.6% in shelter dogs, whereas a study from 2004–2005 found only 3.1% to be infected, with <1% of owned dogs infected.[24] In Europe, more contemporary studies have also indicated that prevalence is generally low among owned dogs (0.1 to <4%) although it is higher in regions of Greece, Hungary, and Italy (9.6 to 23.3%).[4,25,26] Higher prevalences (14 to >50%) have been documented in dogs from rural areas, kennels, shelters, and stray dogs as well as other regions of the world, which is likely reflective of parasite control and dog ownership practices.[27–32]

In addition to occurring worldwide in domestic dogs, *T. vulpis* has been documented in red foxes (*Vulpes vulpes*), coyotes (*Canis latrans*), and wolves (*Canis lupus*) in the United States, Europe, Asia, and Africa with prevalences ranging from 0.5 to 33%, and an indication that in the Netherlands, it might be increasing in prevalence.[33–39] These canids could serve as a source of environmental contamination and hence domestic dog infection.

Cats

Much less is known about the whipworm species that infect cats and their epidemiology when compared with dog whipworm species. While two separate species, *Trichuris serrata* and *Trichuris campanula*, were described, it has been proposed that they are one species and should be renamed *Trichuris felis*.[3] In the original descriptions, the presence of a vulva appendage in *T. serrata* and differences in the size of the adults, spicule, and eggs were used as differing characteristics.[1,2] *Trichuris serrata* adult females range from 14.7 to 49.5 mm in length; males from 12.8 to 40 mm; and their eggs are 54 to 60 µm long by 35 to 40 µm wide. *Trichuris campanula* adult females range from 22.5 to 31.5 mm in length; males from 21.5 to 36 mm; and their eggs are 63 to 72 µm long by 34 to 39 µm wide.[40–43] Given that adult worm size can vary based on infection intensity and variation in egg size has been demonstrated with other *Trichuris* spp., size is an unreliable characteristic for species differentiation.[15,16] Twenty-two females (with the vulva appendage and classified as *T. serrata*) and 12 males harvested from 12 cats and eggs from the feces of nine of these cats were measured and shown to overlap with the measurements for *T. serrata* and *T. campanula*, supporting the theory that there is just one species.[43] While the 18S rRNA gene of these "*T. serrata*" were sequenced, at the time of writing, sequences are not available from *Trichuris* spp. from cats that lack the vulva appendage.[44] Therefore it remains to be determined if cats host two *Trichuris* species or one. Given the lack of information on the separate species, these are, herein, referred to as *T. felis* (Figs. 114.4–114.6).

Based on one experimental study, the prepatent period of *T. felis* is believed to range from 62 to 91 days.[42] The life cycle is the same as that of *T. vulpis*. However, since it has not been as extensively studied as *T. vulpis*, less is known about the timeframe for each stage of development. Less also is known about the factors that influence egg development, although they are likely similar to *T. vulpis* and other *Trichuris* species.

Trichuris felis are generally present in low prevalence in much of the world with most reported infections occurring in the Caribbean and South America.[3] In a study from Argentina, 16% of cats were infected.[45] On St. Kitts, 71% of feral cats and 22% of owned cats were

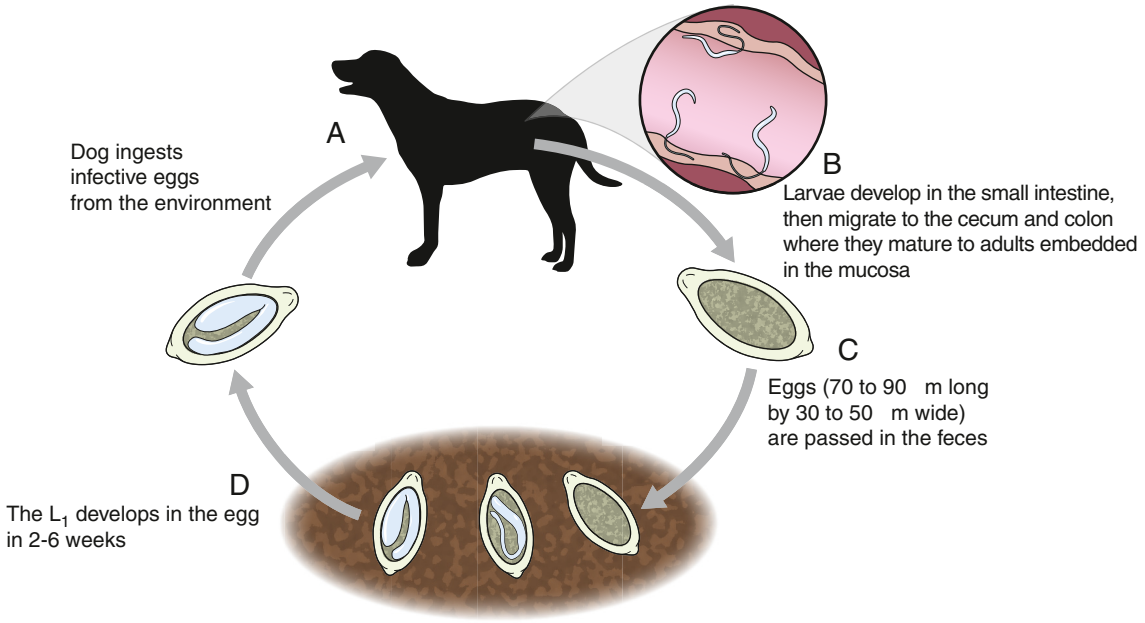

Fig. 114.3 Life cycle of *Trichuris vulpis*.

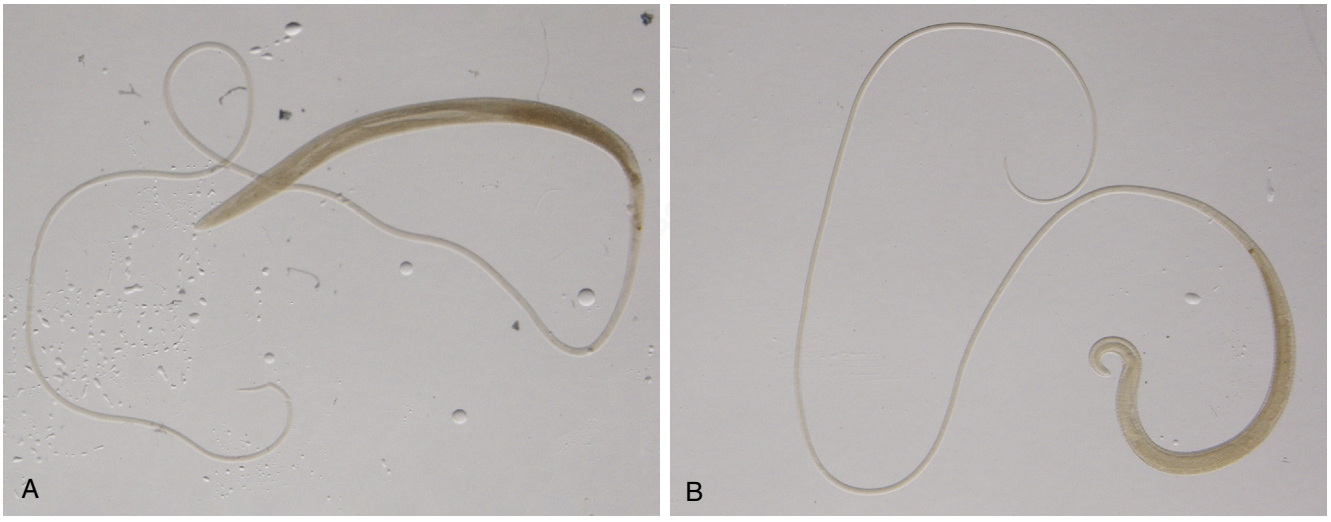

Fig. 114.4 Adult *Trichuris felis* worms. (A) Female; length ranges from 14.7 to 49.5 mm. (B) Male; length ranges from 12.8 to 40.0 mm. (Courtesy of Jennifer K. Ketzis, Ross University School of Veterinary Medicine, St. Kitts, West Indies.)

positive.[46,47] In a 1975 study from Australia, 1.5% of cats were infected, although infections have not been reported in more recent studies.[24,48] In the United States there have been infrequent reports of infection in cats from the Midwest, Southeast, and Northeast. A study from 2003 reported a prevalence of 0.03% in owned cats.[3,42,49] A 2015 study of a shelter in Miami, Florida, however, found 25 (38%) of 65 cats to be infected, suggesting that prevalence can be higher among certain regional populations.[50] In Europe, most prevalence studies have not detected *Trichuris* sp. in cats.[51,52] However, two studies from Italy (one with owned and the other stray cats) and a study from Serbia (owned cats) found 0.9 to 2.9% to be infected; these infections were referred to as *T. vulpis*.[26,53] Based on a small study in Nigeria where 5.8% of cats were positive, feline *Trichuris* sp. infection also occurs in Africa.[54]

Trichuris felis infections have been reported in two oncillas (*Leopardus tigrinus*, 1851 in Brazil and 1963 in Venezuela) and from ocelots (*Leopardus pardalis*, 1937 in Trinidad; *Oncifelis geoffroyi*, 2005 in Argentina).[3,40,55]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

During the prepatent stage of infection, the embedding of larvae in the mucosa of the small intestine can cause mechanical damage resulting in localized inflammation, mucosal hyperemia, and hemorrhage.[7,9–11,56] Immature and adult worms in the cecum (and colon in heavy infections) also cause mechanical damage to the mucosa due to the penetration and movement of the embedded anterior end and mouth stylet. Hemorrhage and inflammatory cell infiltration of the mucosa and submucosa are localized around worms.[7,9–11,56] *Trichuris* spp. release cytolytic and hemolytic enzymes, believed to enable them to consume tissue fluids that contribute to the localized reactions.[9,11,56] *Trichuris* also consume blood (at a low level compared to hookworms) and mucosal epithelium.[57]

In many cases, *T. vulpis* infection is of low pathogenicity and there are no or limited clinical signs. The most common clinical sign is

BOX 114.1 Clinical Signs and Physical Examination Results in Dogs with *Trichuris*-associated Pseudo-hypoadrenocorticism

Clinical Sign	Number of Dogs with Sign/Total Examined
Diarrhea	20/20
Dehydration	20/20 (2 mild, remainder moderate to severe)
Vomiting	8/20
Lethargy, weakness, and/or depression	11/13
Anorexia or inappetence	5/13
Weight loss	3/13
Polydipsia and polyuria	3/13
Episodes of collapse/acute collapse	2/13
Trembling/muscle twitching	2/13
Hypothermia	3/7
Pale mucus membranes	2/7
Bradycardia	1/7
Abdominal pain	1/7

intermittent diarrhea with variable hematochezia and mucus secondary to the mechanical damage being caused by the worms. These signs can begin during the prepatent period. In heavy infections, diarrhea can be severe and chronic leading to dehydration.[5,8] Weight loss, anorexia, and lethargy also can occur in severe infections, especially those associated with pseudo-hypoadrenocorticism (pseudo-Addison's disease) (Box 114.1).[58–64] Anemia is listed in many references as a clinical sign; however, few experimental infections have been able to induce anemia, and in other hosts (e.g., children with *Trichuris trichiura* infestation) there has not been a strong association of infection with anemia.[65] Studies with *Trichuris muris* and *Trichuris suis* have demonstrated a parasite-microbiota interaction which could increase the pathology and clinical signs; however, the changes in microbiota have not been consistent.[66–68] While not studied with *T. vulpis*, this variable interaction with the microbiota has the potential to explain the occurrence of pseudo-hypoadrenocorticism.

No clinical signs have been associated with *T. felis* infections in cats. This apparent lack of clinical disease has been attributed to most infections being low intensity (1 to 10 adult worms).[3] However, cats can harbor >100 adult worms, so more studies are required to ascertain whether infections in cats can be associated with signs of disease.[43,45]

Physical Examination Findings

Most dogs have no abnormal findings on physical examination except in high-intensity infections.[5,8] Infections with a large number of whipworms may result in chronic or severe diarrhea, with dehydration, lethargy, weight loss, pale mucus membranes, and even hypothermia noted on physical examination. Dehydration may be severe and can lead to acute collapse, bradycardia, and weak pulses.[58–64] Rectal examination may indicate the presence of diarrheic feces with blood flecks and mucus. Rectal prolapse has not been associated with *T. vulpis* infection in dogs as it has in humans and pigs.

No abnormal physical examination findings have been reported in cats with *T. felis* infections.

DIAGNOSIS

The most common method used to identify *T. vulpis* and *T. felis* infection is fecal examination for the identification of eggs. A commercial fecal antigen test (IDEXX Laboratories, Inc., Westbrook, ME USA) became available in 2015 but is not in a POC format. Adult *T. vulpis* worms can be seen at necropsy, and the stichosome esophagus and bacillary bands can be used for identification in histology. Because of the long prepatent period, clinical signs can appear before eggs can be detected in the feces. Intermittent shedding can also lead to failure to detect infection on a single fecal flotation. In these situations, failure to treat dogs with chronic diarrhea can result in the somewhat unfortunate occasional diagnosis with colonoscopy, a significantly more costly procedure than assessment of response to treatment (Fig. 114.7).

Laboratory Abnormalities

In cases of pseudo-hypoadrenocorticism, hyponatremia, metabolic acidosis, and hyperkalemia are present. An adrenocorticotropic hormone (ACTH) stimulation test can be used to rule out true hypoadrenocorticism. Basal and poststimulation cortisol levels will be normal and aldosterone normal or high (Table 114.1).[58–64]

Microbiologic Tests

Isolation and Identification

Trichuris vulpis and *T. felis* eggs can be identified by fecal examination with the preferred method being centrifugation with Sheather's sugar flotation solution. While other solutions can be used, the solution should have a specific gravity of at least 1.2, given that *T. vulpis* eggs have a specific gravity of 1.15.[66] Eggs can be intermittently shed and therefore multiple fecal examinations over a one-week period might be required. Centrifugation with Sheather's sugar flotation solution can be used to detect many other GI parasites, and co-infections with other parasites and whipworms are common. The presence of intestinal parasite co-infection can make it more complicated to determine the cause of the clinical signs.

While the eggs of *Trichuris* spp. are distinct (oval, yellowish-brown, and thick-shelled, with two polar plugs), they can be confused with *Eucoleus aerophilus* (syn. *Capillaria aerophila*), *Eucoleus boehmi*, and *Aoncotheca putorii* (Table 114.2). Also, if fecal material is contaminated with urine, *Trichuris* eggs must be distinguished from *Pearsonema plica* (*Capillaria plica*).[69–71] Misdiagnosis is more likely to occur with *T. felis* infections, due to the similarity in size with *Eucoleus* spp. eggs. Because of this, some cases of *T. felis* diagnosed in the United States may have represented *Eucoleus* infections and vice versa.[3,71] However, in regions where *T. felis* is uncommon, it is reasonable to presumptively identify eggs with bipolar plugs as *Eucoleus* eggs, provided there is no travel history. Bipolar plugged eggs also may be found in cat feces following consumption of rodents or other wildlife harboring infection with *Trichuris* spp. or *Capillaria* spp.[69] Confining the pet to prevent additional predation or coprophagy and repeating fecal flotation 2 to 3 days later should facilitate differentiation of these pseudoinfections.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Specific PCR assays have been used to detect nucleic acid of *Trichuris* spp. in feces. However, this approach is not used for clinical specimens, is not effective for eggs (unless eggs are first crushed to release nucleic acid), and sequencing is required to differentiate the species.[72–74]

Fecal Antigen Testing

A fecal antigen test (IDEXX Laboratories, Inc., Westbrook, ME, USA) became available in 2015 and was offered at some commercial veterinary diagnostic laboratories. This test has been validated for detection of *T. vulpis* and *T. felis* antigen and can detect infections not identifiable on fecal examination including single-sex infections (male or female) and prepatent infections. Antigen tests also have been demonstrated to differentiate between true infection and eggs in feces from coprophagy.[50,75,76]

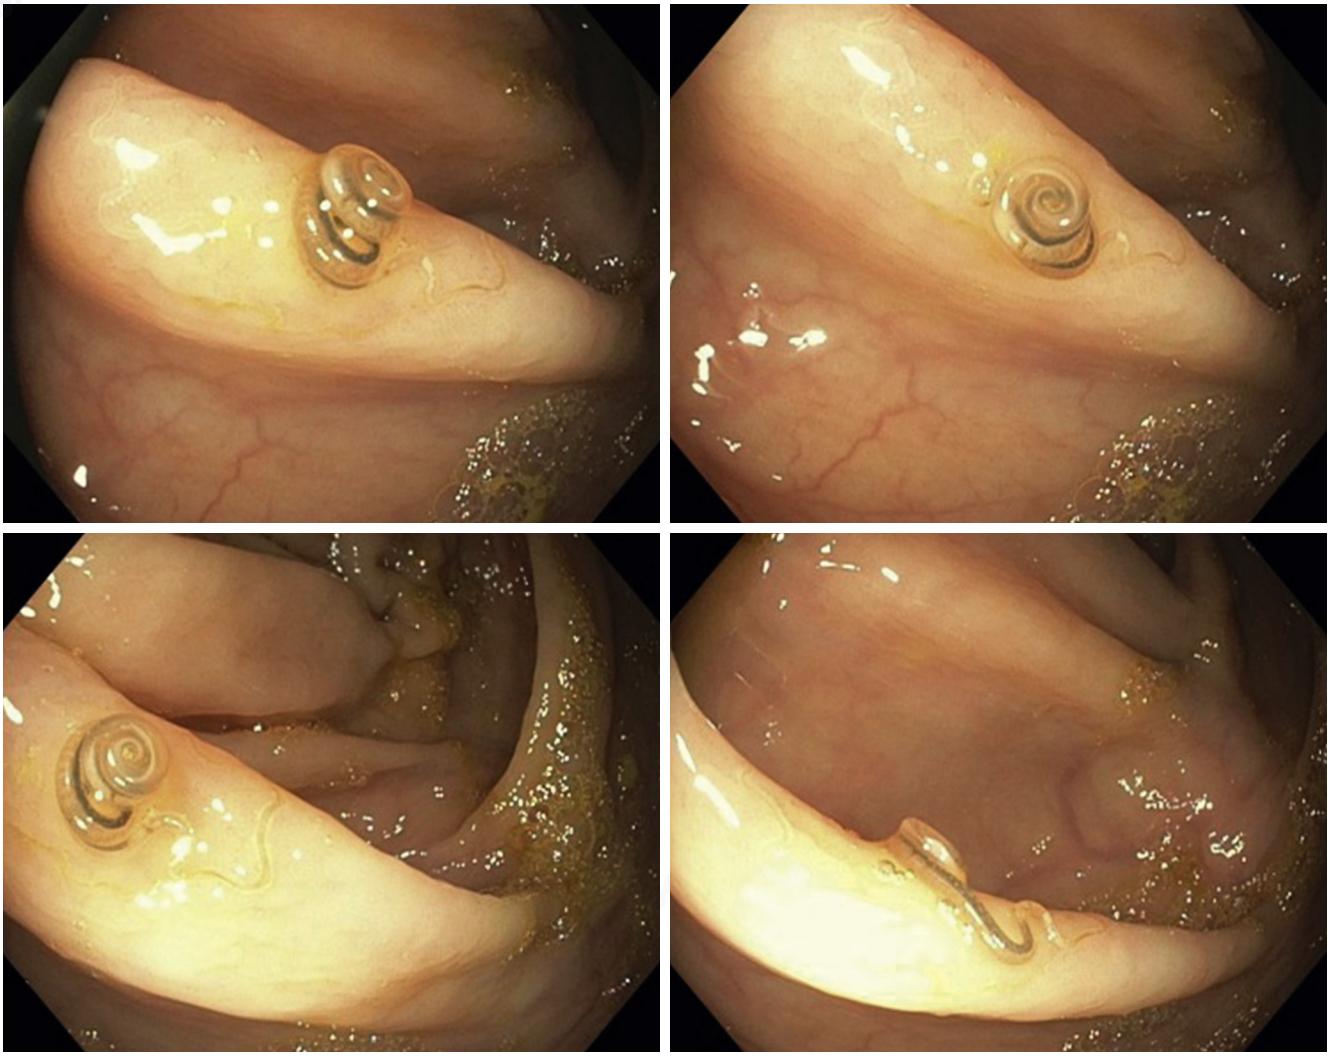

Fig. 114.7 Image obtained at the level of the ileocecal valve using colonoscopy from a 50-year-old woman infested with *Trichuris trichiura*. She was referred for a 20-pound weight loss over 2 months and had immigrated to New York, USA from Bangladesh 15 years previously. (From Sunkara T, Sharma SR, Ofosu A. *Trichuris trichiura*—an unwelcome surprise during colonoscopy. *Am J Trop Med Hyg.* 2018;99:555–556.)

Aldosterone	NR	NR	NR	High	High 3 dogs	NR	NR

[a]Cortisol: basal and response to ACTH stimulation.
[b]There were five dogs with one dog having two episodes (e.g., six cases); only the first episode for this dog is reported here. In addition, for one dog, Na, K, and the Na:K ratio were not reported although the dog's records indicated that it was hyponatremic and hyperkalemic.
[c]Results were mixed: one dog normal; one low with a normal response; four elevated (3 to >10 times normal) of which two had a normal response and two did not; one not tested.
NR, not reported or not determined.

TABLE 114.2 Egg Size, Plug, and Shell Wall Comparison for *Trichuris, Eucoleus,* and *Aonchotheca*[70,71]

	Trichuris vulpis	*Trichuris felis*	*Eucoleus aerophilus (Capillaria aerophilia)*	*Eucoleus boehmi*	*Aonchotheca putorii*
Length (μm)	70–90	54–72	58–85	50–60	56–72
Width (μm)	30–50	34–40	25–40	30–35	23–32
Bipolar plugs	Symmetrical Ringed	Symmetrical	Asymmetrical	Asymmetrical	Asymmetrical
Shell wall	Smooth	Smooth	Striated Anastomosing ridges	Pitted	Sides parallel Anastomosing ridges

Note: The symmetry of the bipolar plugs listed is the most common form; however, those that are typically symmetrical can occasionally be asymmetrical and vice versa.

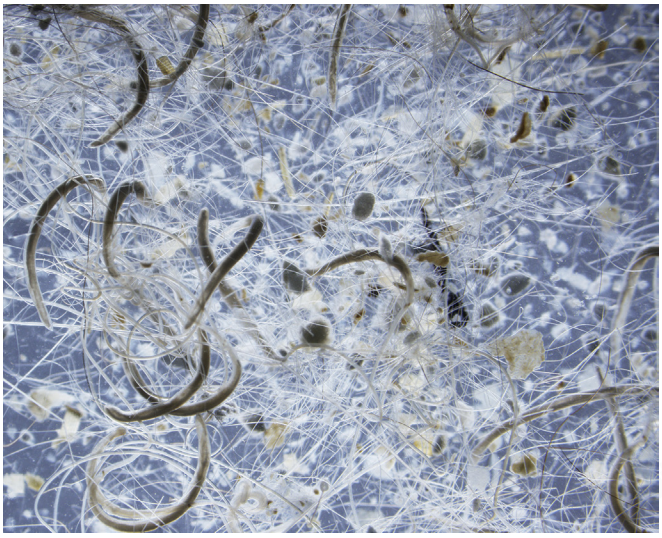

Fig. 114.8 "Medusa's head" appearance of large numbers of *T. felis.* (Courtesy of Jennifer K. Ketzis, Ross University School of Veterinary Medicine, St. Kitts, West Indies.)

Pathologic Findings

Adult *Trichuris* spp. can be seen grossly at necropsy with either only the posterior end visible in the lumen or whole worms with the classic whip shape in the lumen of the cecum and colon. In heavy infections, if the adult whipworms have released from the mucosa, they will be tangled together forming a "Medusa's head" (Fig. 114.8). Occasionally, the worms contain a reddish or pinkish fluid due to blood consumption. In histopathologic sections, the stichosome esophagus and the bacillary band(s) are key characteristics for differentiation from other nematodes.

Histologic changes that can be observed include pyknotic nuclei in cells of the lamina propria, coagulative necrosis, hyperemia, and lymphocytic invasion. Immediately after infection, hyperemia in the duodenal and jejunal mucosa and desquamation of the epithelium can be seen. Larvae in the lamina muscularis of the duodenum and jejunum are surrounded with clusters of eosinophils. Larvae and adults in the cecum and colon are associated with diffuse lymphohistiocytic infiltration of the submucosa and mucosa. Mucoid dystrophy and vascular hyperemia also are present.[56,77]

TREATMENT AND PROGNOSIS

Several anthelmintics are approved for the treatment of *T. vulpis* (Table 114.3). Repeat treatments (e.g., 3 monthly treatments) are usually recommended since few anthelmintics have efficacy against the immature stages and reinfection from a contaminated environment is common. *Trichuris* spp. can be dose-limiting parasites for some anthelmintics and the best treatment and control are achieved with consistent use of monthly broad-spectrum anthelmintics. When infection is associated with pseudo-hypoadrenocorticism, complete recovery is possible with prompt treatment for the infection and supportive therapy for the dehydration. As with all cases of severe dehydration and electrolyte imbalance, slow correction of the serum sodium concentration is required to prevent CNS disorders and death. Hypokalemia can develop in these pseudo-hypoadrenocorticism–associated cases if mineralocorticoids for hypoadrenocorticism are administered; however, the hypokalemia will resolve when steroid administration is stopped.[60]

No anthelmintics are registered for the treatment of *T. felis* and few studies have been conducted to assess efficacy of the available anthelmintics. Compounds effective against *T. vulpis* are considered likely effective against *T. felis*. In one case report, fenbendazole (Panacur 10% oral suspension, Merck Animal Health) at 50 mg/kg administered for 5 days was effective at treating a cat infected with *T. felis*.[78] In a small study, emodepside (Profender Topical Solution, Elanco) at 3 to 15 mg/kg also was effective.[79]

IMMUNITY AND VACCINATION

Dogs and cats do not develop strong immunity and are susceptible to reinfection. Self-curing and some resistance to reinfection has been noted in a few dogs that were experimentally infected. However, dogs and cats of all ages, regardless of previous exposure, have been identified with *Trichuris* spp. infestations. Therefore, any immunity that develops appears to be of a limited nature. Vaccination is not available.

PREVENTION

Given the hardiness of whipworm eggs, the key to prevention is removal of feces from the environment. This recommendation applies to gardens, yards, public parks, and other locations where dogs and cats roam. Once soil contamination has occurred, removing eggs is not feasible. In kennels and shelters, thorough cleaning is important. Regular fecal examinations using centrifugation and antigen testing, especially in adult dogs and cats (in areas where feline infections are prevalent), with prompt treatment of all positive animals, can assist in decreasing environmental contamination. Given the long prepatent period and the lower efficacy of treatments against immature stages, multiple treatments may be required. Alternatively, use of treatments

TABLE 114.3 Treatments for *Trichuris vulpis* Infections

Active Compound Product[a] (Additional Compounds in the Product)	Dose[b] (mg/kg)	Route	Interval/Duration
Emodepside Procox Oral Suspension (toltrazuril)[c] Profender Tablet (praziquantel)[c]	0.45, 1	PO	Once
Febantel Drontal Plus (pyrantel pamoate, praziquantel)	25	PO	Once[d]
Fenbendazole Panacur	50	PO	24h/3 days[d]
Milbemycin oxime Interceptor Interceptor Plus (praziquantel) Sentinel (lufenuron) Sentinel Spectrum (lufenuron, praziquantel) Trifexis (spinosad) Nexgard Spectra (afoxolaner)	0.5	PO	Once[e]
Moxidectin Advantage Multi (imidacloprid) (Advocate in Europe)	2.5	Topical	Once[e]
Oxantel embonate Dolpac (praziquantel, pyrantel embonate)[c]	20	PO	Once

[a]Products listed were available as of December 2020 and registered with the U.S. Food and Drug Administration unless otherwise indicated. Generics (e.g., products with the same active compound, same combination of actives, and same indication but different brand names) are not listed. Instead, only the original registered product is listed.
[b]All doses have activity against adults only, except the higher dose of emodepside, which also has activity against L_4 and immature adults
[c]These products were not available in the USA as of December 2020 but were available in Europe and registered with the European Medical Agency.
[d]Three monthly administrations are recommended.
[e]Monthly use is approved (for heartworm prevention), which can be used to treat and control *T. vulpis* infection.

with efficacy against immature stages of whipworms or the use of monthly broad-spectrum anthelmintics with efficacy against whipworms can be used to control and prevent infections.

For *T. felis*, given the lack of information regarding the optimal conditions for egg development, it is unclear if the prevalence of this parasite could increase outside the Caribbean and South America. It is possible that the distribution of this parasite could extend with global climate change and translocation of cats. Given increased travel of pet cats with owners, measures should be implemented to prevent transport of *T. felis* to nonendemic locations. Treatment should be administered before departure from endemic areas with follow-up fecal examinations and treatment as needed upon arrival in nonendemic areas.

PUBLIC HEALTH ASPECTS

There have been no reports of *T. felis* infecting humans. Zoonotic transmission of *T. vulpis* has been proposed with reports of *T. vulpis* completing its development in humans. Reported incidence has ranged from <0.2% to >7% with infections primarily in children.[80,81] These infections have been asymptomatic or caused clinical signs ranging from abdominal upset, diarrhea, nausea, vomiting, and eosinophilia. Humans have their own species of *Trichuris*, *T. trichiura*, which can be misidentified as *T. vulpis*; disease caused by *T. trichiura* primarily occurs in children living in poverty in the tropics and subtropics. Adult worms (excreted post treatment) can be distinguished based on spicule length and cloaca of the males and the vagina and uterus of the females, with *T. trichiura* convoluted and *T. vulpis* straight.[16] Traditionally, however, egg size has been used to distinguish *T. vulpis* from *T. trichiura* infections in humans. *Trichuris trichiura* eggs (50–56 μm by 21–26 μm) are normally half the size of *T. vulpis* (72–90 μm by 32–40 μm); however, a small percentage of *T. trichiura* eggs overlap in size with *T. vulpis*. Therefore, when egg size is used to determine the species infecting people, misidentification can occur.[16,78,80] *Trichuris vulpis* has rarely been reported to cause visceral larva migrans in people[82]; however, none of these reports have been confirmed and the evidence more strongly suggests that these were not *T. vulpis* infections, particularly since there is no evidence of larval migration with *T. vulpis*.

CASE EXAMPLE

Signalment

"Rusty," an 8-year-old female spayed boxer mix from Tennessee, USA.

History

The owner reported that Rusty had a history of weight loss, lethargy, and anorexia. The last recorded body weight (4 years previously) was 34 kg. Vaccinations were not current and the dog was not on any medications, including heartworm preventive.

Physical Examination

Ambulatory on all four limbs. Body weight: 23.4 kg. Temperature = 99.5°F (37.5°C).

Faint/muffled heart sounds, strong pulses, and slightly increased respiratory noise. No significant abnormalities were noted in examination of the eyes, ears, nose, and throat. Mucous membranes pink and tacky; decreased skin turgor. Lymph nodes were normal. Abdominal palpation was unremarkable. No evidence

Continued

CASE EXAMPLE—cont'd

of ectoparasites. After hospitalization, Rusty had an episode of voluminous diarrhea, which was liquid in consistency and without obvious blood or mucus.

Laboratory Findings

CBC: WBC 35,820 cells/μL (6000–17,000 cells/μL), neutrophils 32,550 cells/μL (3000–12,000 cells/μL), HCT 60% (37–55%); all other parameters were within the normal range.

Serum chemistry profile: BUN 118 mg/dL (7–25 mg/dL), creatinine 2.5 mg/dL (0.3–1.4 mg/dL), phosphorus 11.3 mg/dL (2.9–6.6 mg/dL), glucose 267 mg/dL (60–110 mg/dL), potassium 6.4 mmol/L (3.7–5.8 mmol/L), sodium 109 mmol/L (138–160 mmol/L); all other parameters were within the normal range.

ACTH stimulation test (cosyntropin, 125 mg, IV) with samples taken at times 0 (<1.0 μg/dL; normal range 1.0–5.0 μg/dL) and 1 hour (6.1 μg/dL; normal range 8–17 μg/dL).

Imaging Findings

Thoracic radiographs revealed decreased cardiac size, clear lung fields, and no pleural effusion or masses.

Microbiologic Testing

Fecal flotation revealed large numbers of hookworm and whipworm eggs.

Diagnosis

Pseudo-hypoadrenocorticism secondary to whipworm and hookworm infestation. The initial differential diagnoses were hypoadrenocorticism (Addison's disease), whipworm infestation, neoplasia, and renal failure.

Treatment

After initial examination, Rusty was hospitalized for IV fluid administration; dexamethasone sodium phosphate was also administered (4 mg, once, IV). On the following day, when the fecal and ACTH stimulation results became available, IV fluids were continued and the following medications were started: sucralfate 1 g PO q12h and fenbendazole PO q24h for 3 days.

Comments

Rusty's condition rapidly improved and he began eating and drinking by the evening after the first dose of fenbendazole. Stools were firm within 2 days of instituting treatment and electrolyte and renal values were normal when retested 3 days after treatment commenced. The fenbendazole treatment was repeated 3 weeks and 3 months later.

Tapeworms

Christopher B. Adolph, Andrew S. Peregrine

KEY POINTS

Dipylidium caninum

- First Described: *Dipylidium caninum* has been known to infect pets since ancient times. Linnaeus named this parasite *Taenia cania* in 1758; Leuckart created the genus *Dipylidium* in 1863.
- Cause: *Dipylidium caninum* (order Cyclophyllidea).
- Geographic Distribution: Worldwide.
- Affected Hosts: Dogs and cats, as well as other canids and felids, serve as definitive hosts for adult *D. caninum.*
- Primary Mode of Transmission: Infected definitive hosts intermittently shed segments that contain egg packets which break down in the environment. When a suitable arthropod intermediate host (e.g., *Ctenocephalides felis felis* [flea], *Trichodectes canis* [biting louse]) ingests the eggs, a metacestode stage (a cysticercoid) develops within the arthropod. Final hosts become infected and develop patent intestinal infections upon ingestion of an infected intermediate host.
- Major Clinical Signs: Heavy infections in dogs and cats may cause constipation and diarrhea. However, the most common clinical situation arises when an owner discovers segments in the hair coat, bedding, or recently passed feces, of a healthy animal.
- Differential Diagnoses: Other GI parasites, dietary indiscretion, pancreatitis, intestinal bacterial overgrowth, IBD, GI neoplasia, exocrine pancreatic insufficiency, hepatobiliary disease, GI foreign body, and intestinal perforation. When segments are present, these need to be differentiated from other tapeworms that shed segments.
- Human Health Significance: *Dipylidium caninum* occasionally infects people that accidentally ingest infected fleas.

Taenia spp.

- First Described: *Taenia* was first described by Linnaeus in 1758.
- Cause: Multiple cyclophyllidean species that belong to the family Taeniidae. The family contains two generally accepted genera: *Taenia* and *Echinococcus.*
- Geographic Distribution: Essentially worldwide. However, the importance of different *Taenia* species varies depending on the geographic region.
- Affected Hosts*: Taenia pisiformis, Taenia crassiceps, Taenia hydatigena, Taenia ovis, Taenia serialis,* and *Taenia multiceps* all infect dogs as the definitive host. The predominant *Taenia* species infecting cats globally is *Taenia taeniaeformis.*
- Primary Mode of Transmission: Infected dogs and cats intermittently pass egg-laden segments into the environment. Eggs are then consumed by a suitable mammalian intermediate host (e.g., rabbit, sheep, mice, rats) resulting in the formation of the metacestode, larval, tapeworm in that host's tissues; the type of metacestode varies with the *Taenia* spp. involved. Dogs and cats develop patent intestinal infections after consuming an infected intermediate host.
- Major Clinical Signs: Intestinal infections with *Taenia* spp. in dogs and cats have long been thought to be well tolerated with no associated clinical signs. When clinical signs occur, they are relatively non-specific and may include vomiting and diarrhea. Rarely, cats require an enterotomy to relieve a cestode impaction.
- Differential Diagnoses: Differentials include other GI parasites, dietary indiscretion, pancreatitis, intestinal bacterial overgrowth, IBD, GI neoplasia, exocrine pancreatic insufficiency, hepatobiliary disease, GI foreign body, and intestinal perforation. When segments are present, these need to be differentiated microscopically from segments of other tapeworms.
- Human Health Significance: In general, zoonotic *Taenia* spp. are limited to species that utilize cattle and pigs as intermediate hosts (e.g., *T. saginata*, *T. solium*); dogs and cats are not involved in the life cycles. However, adult *T. taeniaeformis* have been recovered from the intestinal tract of humans. Humans may also occasionally be infected with the metacestode stage of *T. multiceps* or *T. serialis*, which utilize dogs as a definitive host. When eggs are accidentally ingested by humans, they hatch in the GI tract; oncospheres are released and circulate in the bloodstream until they lodge in organs where coenuri develop. For *T. multiceps*, coenuri may be found in the brain and eyes, while those of *T. serialis* are found in subcutaneous tissue.

Echinococcus spp.

- First Described: *Echinococcus granulosus* s.l. was first described by Batsch in 1786, and *Echinococcus multilocularis* was first described by Leuckart in 1863.
- Causes: *Echinococcus granulosus* sensu lato (s.l.) and *Echinococcus multilocularis* (family Taeniidae).
- Geographic Distribution: *Echinococcus granulosus* s.l. comprises multiple genotypes/species that differ in their geographic distribution due to differences in host specificity. The genotype most important for human disease is *E. granulosus* sensu stricto (s.s.), which is primarily associated with sheep and found worldwide. *Echinococcus multilocularis* occurs throughout much of the northern hemisphere (Europe, Asia, and North America).
- Affected Hosts: Adult stages of both cestodes are a few millimeters in length and occur in the small intestine of carnivores. Definitive hosts for *E. granulosus* s.l. are primarily dogs and, to a lesser extent, wild canids, which excrete infective eggs into the environment in feces. *Echinococcus multilocularis* occurs primarily in a wildlife cycle with wild canids (arctic/red fox, coyote, raccoon dog, wolf) as definitive hosts. Dogs, and to a lesser extent cats, may also be definitive hosts. Dogs occasionally may also be accidental hosts that develop metacestodes.
- Primary Mode of Transmission: Ingestion of *E. granulosus* s.l. eggs by intermediate hosts (e.g., sheep, cattle, goats, pigs, horses)

and accidental hosts (e.g., people) results in the development of a hydatid cyst within the liver, lungs, or other internal organs. The resultant disease is termed *cystic echinococcosis* (CE). After ingestion of *E. multilocularis* eggs by rodents, the typical intermediate host, the metacestode stage develops most commonly within the liver, behaves like an invasive tumor, and produces *alveolar echinococcosis* (AE). Ingestion of eggs by accidental hosts (e.g., people, dogs) also results in AE. Thus, dogs can be both definitive and accidental hosts for *E. multilocularis.* Dogs, cats, and wild canids develop intestinal infections following ingestion of metacestode-infected rodents.

- Major Clinical Signs: Intestinal infections are rarely clinical. AE in dogs is typically associated with hepatic injury; clinical signs include abdominal pain and/or distension, lethargy, anorexia, and vomiting.
- Differential Diagnoses: Both cats and dogs excrete eggs morphologically identical to those of *Taenia* spp. and require DNA analysis to determine the genus/species. Differential diagnoses for hepatic AE in dogs include tumors, abscesses, and cysts (sterile, congenital).
- Human Health Significance: Most species of *E. granulosus* s.l. can infect people. However, globally, most human cases of CE are due to *E. granulosus* s.s. (sheep strain). This strain occurs in both domestic and wildlife cycles. However, the domestic cycle is of particular zoonotic significance as human infections are typically associated with ingestion of eggs in the feces of dogs. The resultant hydatid cysts are usually large, fluid-filled structures that behave like a space-occupying lesion. While often clinically silent, they may cause CE, a potentially severe disease of the liver, lungs, bone, brain, or other organs. While *E. multilocularis* occurs in wild and domestic life cycles, most human infections are associated with ingestion of eggs in the feces of dogs. In humans, AE is typically associated with development of the metacestode stage in the liver and has a high case fatality rate when left untreated; the metacestode behaves like an invasive tumor and often metastasizes to other organs. The clinical incubation period is 5 to 15 years. Both AE and, to a lesser extent, CE, have high pathogenic potential and are considered two of the most important helminthic zoonoses. In a veterinary environment, infection risk in people when handling dogs and cats can essentially be eliminated by strict attention to hand hygiene.

Mesocestoides spp.

- First Described: Valliant described *Mesocestoides ambiguous* in 1863.
- Causes: Cestodes that belong to the *Mesocestoides* genus. Questions remain as to how to define the species because the life cycle has not been fully defined for any species.
- Geographic Distribution: Worldwide.
- Affected Hosts: Dogs, cats, and raccoons are definitive hosts for *Mesocestoides* spp.; there are a variety of intermediate hosts (e.g., mammals, amphibians, birds, reptiles). Peritoneal larval cestodiasis occasionally occurs in dogs or cats following ingestion of an infected intermediate host.
- Primary Mode of Transmission: Definitive hosts become infected by ingesting intermediate hosts that contain the second metacestode stage, a tetrathyridium, located in the peritoneal cavity. The first intermediate stage is thought to be a cysticercoid that develops from an oncosphere in a coprophagic insect, but this has yet to be proven. Tetrathyridia develop into adult tapeworms in the intestinal tract of the definitive host. Subsequently, sections of the strobila, or body, are excreted in feces, rather than individual segments like *D. caninum* or *Taenia* spp. Segments contain eggs that vary in maturity. Peritoneal larval cestodiasis occurs when dogs and cats ingest an infected intermediate host and larval parasites migrate through the intestinal wall and multiply as the tetrathyridial stage within the peritoneal cavity by asexually dividing or budding.
- Major Clinical Signs: Dogs and cats infected with *Mesocestoides* spp. typically have subclinical intestinal infections. Dogs with peritoneal larval cestodiasis may show abdominal distention with or without systemic signs of anorexia, weight loss, vomiting, diarrhea, lethargy, ascites, and tachypnea. Clinical signs in one cat from Sicily, Italy included anorexia, moderate abdominal swelling, cough, and dyspnea.
- Differential Diagnoses: *Mesocestoides* spp. segments are significantly smaller than those of more common cestodes (i.e., *D. caninum* and *Taenia* spp.) and may be confused with those of *Echinococcus* spp. Differentials for peritoneal larval cestodiasis include other causes of ascites, such as right-sided heart failure, neoplasia, pancreatitis, GI foreign body, and intestinal perforation.
- Human Health Significance: Rarely, humans can become infected with adult *Mesocestoides* spp. by ingestion of undercooked organs (e.g., raw snake liver, chicken viscera) containing tetrathyridia leading to abdominal pain and passage of segments in the stool. Infected dogs and cats are not a direct zoonotic risk to people.

Diphyllobothrium spp.

- First Described: Linnaeus, 1758.
- Causes: Cestodes of the *Diphyllobothrium* genus (family Diphyllobothriidae). Globally, *Diphyllobothrium latum* (*Dibothriocephalus latus*) is the most important species.
- Geographic Distribution: *Diphyllobothrium latum* has a circumboreal distribution involving Alaska, the Great Lakes region of the USA/Canada, northern Europe, Russia, and parts of Asia and South America.
- Affected Hosts: Adult tapeworms occur in the small intestine of dogs, cats, people, pigs, foxes, mink, and other fish-eating animals.
- Primary Mode of Transmission: Ingestion of the plerocercoid stage in raw or undercooked freshwater fish.
- Major Clinical Signs: Infections in both dogs and cats are typically subclinical.
- Differential Diagnoses: Segments of *D. latum* within feces are typically larger in size than those of *Spirometra* spp., *Taenia* spp., and *D. caninum.* Unlike *Taenia* spp. and *D. caninum*, segments of *D. latum* and *Spirometra* spp. have a medial uterine pore.
- Human Health Significance: Humans acquire *D. latum* infection by ingestion of raw or undercooked fish; infections are most commonly asymptomatic. Dogs and cats infected with *D. latum* are not a direct risk to human health.

Spirometra spp.

- First Described: Rudolphi first described *Spirometra erinaceieuropaei* (syn. *Diphyllobothrium erinaceieuropaei*) in 1819. In 1882, Mason described *Spirometra mansoni.* In 1935, Mueller described *Spirometra mansonoides.*
- Causes: *Spirometra* spp. (family Diphyllobothriidae); a cestode closely related to *Diphyllobothrium* spp.
- Geographic Distribution: *Spirometra erinaceieuropaei* occurs in Asia, Australia, and Europe. *Spirometra mansonoides* occurs in North and South America. *Spirometra mansoni* is predominantly found in Asia.
- Affected Hosts: Adult *Spirometra* spp. occur in the small intestine of dogs, cats, wild felids, wild canids, raccoons, and other carnivores. Proliferative sparganosis (proliferation of plerocercoids) occasionally occurs in the abdominal or thoracic cavity, or connective tissue, of dogs and cats.
- Primary Mode of Transmission: Infected definitive hosts shed eggs in feces that hatch in water to release a coracidium. When ingested

by freshwater copepods (e.g., *Cyclops* spp.), the coracidium develops into a procercoid. Following ingestion of infected copepods by a second intermediate host (e.g., amphibians, reptiles, birds, mammals), the procercoid develops into a plerocercoid (or spargana). Definitive hosts become infected following ingestion of muscle or connective tissue of second intermediate hosts or paratenic hosts containing a plerocercoid. The plerocercoid then attaches to the intestinal wall and develops into an adult tapeworm. Proliferative sparganosis occurs following ingestion of water containing copepods infected with procercoids, or plerocercoids in second intermediate hosts or paratenic hosts.

- Major Clinical Signs: Dogs and cats infected with adult *Spirometra* spp. often have subclinical infections. However, enteritis, diarrhea, weight loss, and vomiting have been associated with infection, particularly in cats. Occasionally, the only evidence of infection is the presentation of chains of segments by owners to a veterinarian. Clinical signs associated with proliferative sparganosis depend on the location of the plerocercoids.
- Differential Diagnoses (Intestinal Infections): Other GI parasites, dietary indiscretion, pancreatitis, intestinal bacterial overgrowth, IBD, GI neoplasia, exocrine pancreatic insufficiency, hepatobiliary disease, and GI foreign body.
- Human Health Significance: *Spirometra* spp. cause sparganosis in people. This occurs when the plerocercoid stage (spargana) is transferred to humans following ingestion of raw or undercooked meat (e.g., frog) or when copepods infected with the procercoid larval stage are consumed by drinking untreated water. This condition is rare, and usually presents as a subcutaneous nodule containing a plerocercoid. However, in some cases, proliferative sparganosis involving the CNS or other organs has been reported.

INTRODUCTION

Cestodes are flatworms that are divided into two orders of veterinary significance, Cyclophyllidea and Diphyllobothriidea (formerly Pseudophyllidea).[1] The Cyclophyllidea comprise *Dipylidium caninum, Echinococcus* spp., *Mesocestoides* spp., and *Taenia* spp. The Diphyllobothriidea, or primitive tapeworms, contain *Diphyllobothrium* spp. and *Spirometra* spp.. Definitions that are related to cestode infections are shown in Box 115.1.

DIPYLIDIUM CANINUM

ETIOLOGY AND EPIDEMIOLOGY

Dipylidium caninum is the only *Dipylidium* species of veterinary importance and commonly infects dogs, cats, and other canids and felids. Molecular characterization of *D. caninum* isolates obtained from infected fleas and proglottids of both dogs and cats has demonstrated the existence of two distinct genotypes, suggesting the possibility of two separate species within *D. caninum*. Extensive evaluation of infected fleas from the United States and Europe as well as adult tapeworms from South Africa, France, and China has demonstrated that the two genotypes (dog and cat) generally appear to be species specific around the world.[2] The success of this tapeworm can partially be attributed to the global distribution of flea intermediate hosts. However, multiple additional factors are involved including societal attitudes toward dogs and cats as pets, ability and willingness to institute proper flea control, and the low sensitivity of current detection methods. Thus, *D. caninum* has been documented in North America,[3] South America (e.g., Brazil),[4] Europe,[5] the Middle East (e.g., Iran),[6] Russia,[7] Asia (e.g., China),[8] and Africa (e.g., Nigeria).[9]

Dogs and cats become infected when they ingest arthropod intermediate hosts that include fleas (*Ctenocephalides felis, Ctenocephalides canis,* and *Pulex irritans*) and chewing lice (*Trichodectes canis*) (Fig. 115.1).[3] Dogs and cats pass gravid segments intermittently in feces. Pre-adult stages of the intermediate host (e.g., flea larvae) ingest eggs of the cestode once the segment breaks down in the environment. As the intermediate host develops to adulthood, the oncosphere (tapeworm embryo) develops to the metacestode stage, a cysticercoid, within the intermediate host. Dogs and cats become infected when infected arthropods are ingested. The cysticercoid then develops to an adult tapeworm within the lumen of the small intestine and attaches to the small intestine wall via muscular suckers on the scolex and small hooks on the rostellum. The body of the tapeworm (strobila) elongates and the most mature (gravid) segments on the distal end detach and are passed in feces. Gravid segments may be shed by dogs and cats as soon as 2 to 3 weeks after being infected with cysticercoids.[10,11]

Proglottids do not have an opening for eggs to escape and each segment is packed with eggs. The oncospheres are contained within

BOX 115.1 Definitions Used in Reference to Cestodes

Alveolar echinococcosis	Disease due to the metacestode stage of *E. multilocularis*
Brood capsule	Fluid-filled bladder found within hydatid cyst that contains multiple protoscolices
Calcareous corpuscle	Ovoid mineral structures, 2–30 μm in size, found in all tapeworms
Cestode	Tapeworm; a parasitic flatworm of the class Cestoda
Cystic echinococcosis	Disease due to the metacestode stage of *E. granulosus* s.l.
Hydatid cyst	Metacestode stage of *E. granulosus* s.l.
Intermediate host	Animal species in which development of the metacestode stage occurs
Metacestode	Immature stage that occurs in the intermediate host
Oncosphere	Immature stage that hatches from egg
Patent infection	Shedding of eggs in feces or presence of proglottids in feces or perianal region
Prepatent period	Time from ingestion of metacestode stage to development of adult parasites and shedding of eggs or proglottids in feces
Protoscolices	Juvenile scolices (plural of scolex) formed from germinal layer of a metacestode
Scolex	Adult tapeworm holdfast organ that attaches to the host intestinal wall
Strobila	Chain of individual adult tapeworm segments that progressively mature as the tapeworm elongates

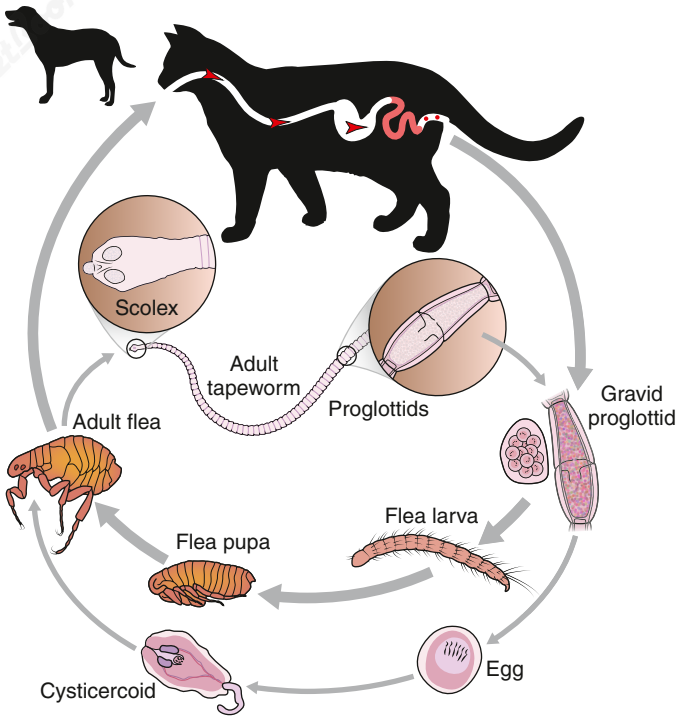

Fig. 115.1 Life cycle of *Dipylidium caninum*.

a packet and each packet may contain 25 to 30 oncospheres (Fig. 115.2A).[3] Evidence of the longevity of *D. caninum* is unclear; estimates vary widely, from as short as 3 months to 3 years.[12]

Previous surveys in New Jersey and Wisconsin, USA, reported *D. caninum* prevalences of 10.4% and 13.0% in cats, respectively. The same two surveys also reported prevalences for dogs of 0.4% and 4.0%, respectively.[13,14] In the New Jersey survey, 318 feral cats were examined by both fecal flotation and necropsy; 33 were infected with *D. caninum* at necropsy (10.4%); none tested positive by zinc sulfate fecal flotation. In a more recent survey in Oklahoma, USA, 40 of 116 (34.5%) cats were positive for *D. caninum* at necropsy; however, 0 of 40 of these infections were detected utilizing two different flotation methods (passive and centrifugal).[15] These data indicate that prevalence determinations based solely on fecal examination underestimate the true prevalence of infection. This finding is consistent with the biological characteristic of proglottids passing singly in feces without release of eggs in the intestinal tract.[16]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Adult *D. caninum* cause little pathology and are well tolerated by the host. Dogs and cats with tapeworm proglottids visible on the perineal area, or detected in freshly passed feces, have been observed to drag their anus on the ground. However, such behavior can also happen in the absence of infection.[11] Occasionally, cats infected with *D. caninum* have developed convulsions and seizures.[10] More commonly,

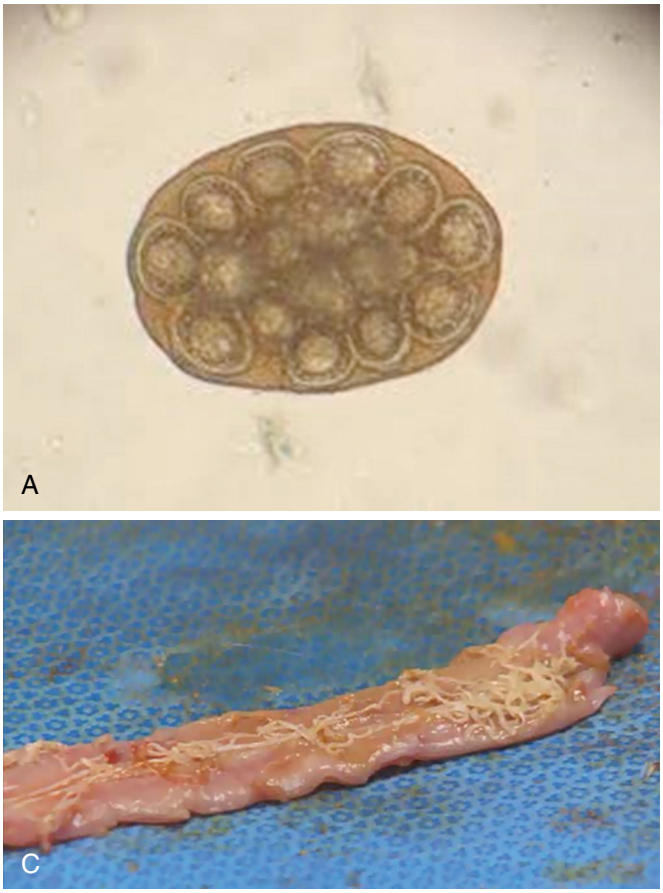

Fig. 115.2 Morphologic features of *Dipylidium caninum*. (A) Egg packet from a proglottid. Eggs containing a hexacanth embryo are visible inside the egg packet. (B) Scolex. The rostellum is retractable and armed with small hooks and four suckers. (C) Strobila in the small intestine of a cat. (B, courtesy of Megan Lineberry, National Center for Veterinary Parasitology, Oklahoma State University). *Continued*

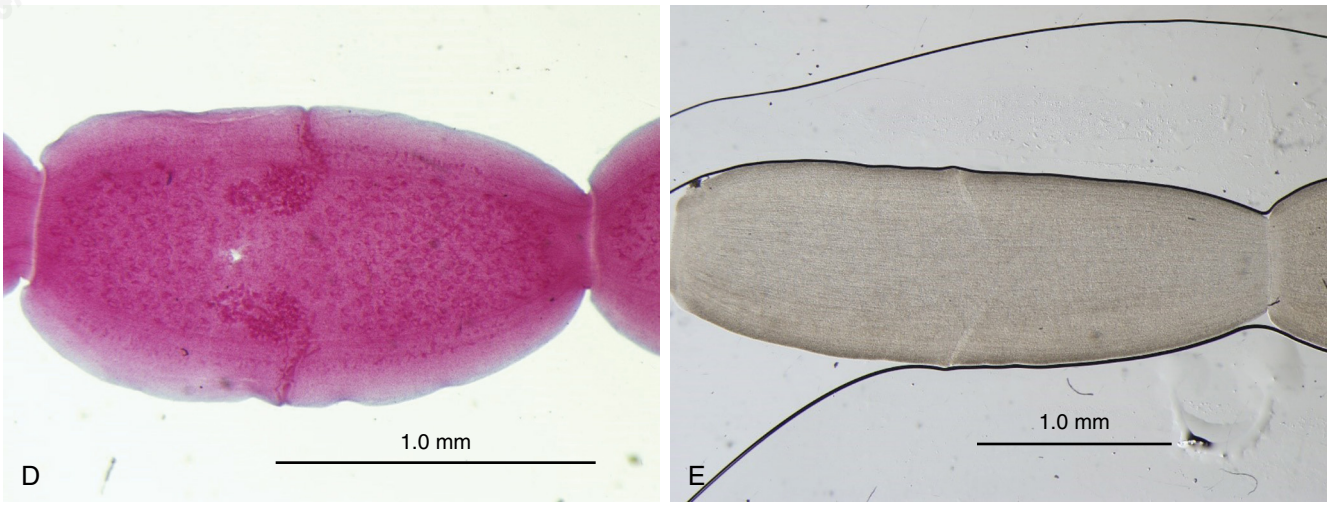

Fig. 115.2 cont'd (D) Stained and (E) unstained segment showing bilateral genital pores. (D, E courtesy of Megan Lineberry, National Center for Veterinary Parasitology, Oklahoma State University.)

young animals with clinical signs exhibit an unthrifty, potbellied appearance.[17]

In a 2015 survey in Oklahoma, cats infected with *D. caninum* had gross intestinal lesions, including distension of the small intestine, mural thickening, hemorrhage, and ulceration in association with the presence of tapeworms. Because of this, it appears that the current understanding of pathology associated with intestinal tapeworm infections requires more study.[15]

Most clients have strong emotional reactions to detecting a proglottid in their pet's feces or on the pet's perianal region and will often contact their veterinarian for assistance. Differentiating proglottids of *D. caninum* from other cestodes will allow the clinician to appropriately treat the current infection, because certain tapeworms require higher dosages of anticestodal medications and for longer periods of time, and to address the risk of reinfection.

DIAGNOSIS

Adult *D. caninum* tapeworms may be detected at necropsy and are usually 15 to 30 cm in length (Fig. 115.2C).[10] The scolex has a retractable rostellum with 30 to 150 small thorn-like hooks arranged in circles and four muscular suckers (Fig. 115.2B). Gravid segments are 10 to 12 mm in length, narrowed at both ends, and contain two genital pores. The common name, "cucumber seed" tapeworm, is based on the appearance of the gravid segment (Fig. 115.2D and E).[3] Diagnosis of *D. caninum* antemortem typically relies on detection of the characteristic proglottid on the host or in the feces, as well as detection of the characteristic egg packet on fecal flotation. However, egg packets can be difficult to float and astute veterinary team members are more likely to detect proglottids on gross examination than egg packets on flotation.[15] Occasionally, the egg packet may be disrupted during specimen preparation and individual eggs observed in feces. Generally, high specific gravity solutions (e.g., Sheather's sucrose solution, SpG 1.27) have a higher probability of floating heavier helminth eggs than lower specific gravity solutions.[18]

Tapeworm proglottids should be definitively identified prior to initiating anticestodal therapy. Environmental structures may be confused for proglottids, and determining the genus of the tapeworm and addressing risk factors is important to prevent reinfection. Rehydrating suspected proglottids in water or saline for 10 to 30 minutes prior to microscopic examination often aids identification of the bilateral genital pores characteristic of *D. caninum* (see Fig. 115.2D and E). Eggs can be observed by adding a drop of saline and crushing the proglottid between two glass slides. Occasionally, proglottids are sterile and one may only observe calcareous corpuscles (ovoid mineral concentrations that contain calcium carbonite) that vary in size from 2 to 30 µm.[19] However, these are typical of all cestodes. Regardless of the detection method (flotation or proglottid preparation), egg packets are 120 to 200 µm long and contain 25 to 30 individual ova. Each egg measures 35 to 60 µm and contains a hexacanth embryo (see Fig. 115.2A).[20] Copro-antigen and PCR detection methods are not yet commercially available for detection of *D. caninum* infections but would be expected to dramatically improve diagnosis. These strategies have been used on a research basis to detect *D. caninum* in fleas and to differentiate *D. caninum* from other cestode species.[21,22]

TREATMENT AND PROGNOSIS

Effective treatment of *D. caninum* infections requires both treatment for tapeworms and for the flea intermediate host. To avoid reinfection, every dog and cat on the premise must be treated for fleas. Treatment with appropriate anticestodal medication at both the time of the initial diagnosis and at conclusion of environmental flea elimination (2 to 4 months is a reasonable expectation with proper flea control of all pets) will eliminate all current and newly acquired tapeworms.

Praziquantel is available as both oral and injectable formulations for both dogs and cats. Dogs and cats are dosed at 5 mg/kg PO or 5.7 mg/kg when administered either SC or IM (Table 115.1). These dosages eliminate 100% of the adult and immature stages.[23] Praziquantel (12 mg/kg) is also available as a topical formulation in combination with emodepside or eprinomectin, and as a standalone formulation (8 mg/kg) for cats. Epsiprantel is an oral medication with efficacy against adult stages of *D. caninum* and is dosed at 5.5 mg/kg in dogs and 2.75 mg/kg in cats.[11] Nitroscanate is approved for use in dogs in some countries. A dosage of 25 mg/kg eliminated natural infections with *D. caninum*.[24] However, nitroscanate is approved in Canada for treatment of *D. caninum* infections in dogs at a dosage of 50 mg/kg. Nitazoxanide has been given to dogs and cats infected with *D. caninum* and was 100% effective at a single dosage of 100 mg/kg.[25] Over the last few years, there have been reports of *D. caninum* infections in dogs in the USA that could not be eliminated despite effective flea control and therapeutic dosages of either praziquantel or epsiprantel.

TABLE 115.1 Recommended Drugs for Treating *Dipylidium caninum* Infections in Dogs and Cats

Drug	Species	Dose (mg/kg)	Route	Interval
Praziquantel	B	5.0	PO	Once
	B	5.7	IM/SC	Once
	C	8.0	TD	Once
Epsiprantel	D	5.5	PO	Once
	C	2.75	PO	Once
Nitroscanate	D	50	PO	Once
Nitazoxanide	B	100	PO	Once

B, both dog and cat; *C*, cat; *D*, dog; *TD*, transdermal.

Cases were resolved following treatment with either nitroscanate or a compounded pyrantel/praziquantel/oxantel formulation.[26]

PREVENTION

With proper flea control and use of an effective anticestodal medication, *D. caninum* infections should be eliminated and the risk of reinfection minimized.

PUBLIC HEALTH ASPECTS

Dipylidium caninum can infect people. Young children are at greatest risk due to their propensity to sample their environment orally leading to ingestion of flea intermediate hosts.[27] Human infections have been reported worldwide. A recent publication described 349 human cases of dipylidiasis, distributed among 24 countries; more than 100 cases were reported in Italy, followed by the USA (86 cases), Japan (81 cases), China (30 cases), Chile (18 cases), Poland (6 cases), India (5 cases), and Mexico, Brazil, Canada, Sri Lanka, and Uruguay (each had 2). Individual cases were reported in other countries. More than two-thirds of the cases were in small children.[28] Most humans with dipylidiasis are asymptomatic; however, anal pruritus, diarrhea, or mild abdominal pain may occur. Flea control in pets should eliminate environmental infestations and minimize the risk of human infection.

TAENIA SPP. INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

The *Taenia* genus belongs to the cyclophyllidean group of tapeworms and has multiple species that utilize dogs, and one that utilizes cats, as definitive hosts. Like *D. caninum*, definitive hosts are infected by ingestion of the metacestode (immature or larval) stage within the tissues of an intermediate host (Fig. 115.3). *Taenia* species typically form one of three different kinds of metacestode: a cysticercus, strobilocercus, or coenurus (Table 115.2). A cysticercus is composed of a single bladder within which is a single immature parasite with a protoscolex. A strobilocercus also consists of a single bladder that contains a single immature parasite; however, unlike a cysticercus, the strobilocercus contains a protoscolex with a long segmented body. Thus, elongation and segmentation has begun in the intermediate host. A coenurus is composed of a single bladder, within which are many protoscolices; each protoscolex has the potential to develop into a mature tapeworm. Dogs are infected with *Taenia pisiformis* when the cysticercus is consumed in the viscera of rabbits or rodents (see Table 115.2). For *Taenia crassiceps*, dogs are infected when the cysticercus is consumed in the viscera of rodents. Dogs are infected with *Taenia hydatigena* when the cysticercus is consumed in the viscera of ruminants, horses, and pigs. *Taenia ovis* infects dogs when the cysticercus is ingested in the muscle of sheep or goats (see Table 115.2). The metacestode stage of *Taenia multiceps* is a coenurus and infects dogs following consumption of the brain or spine of sheep or cattle. The metacestode of *Taenia serialis* is also a coenurus and infects dogs following consumption of connective tissue of rabbits or rodents. Cats are infected with *T. taeniaeformis* by ingesting rodents containing a strobilocercus, typically within the liver (see Table 115.2).[3]

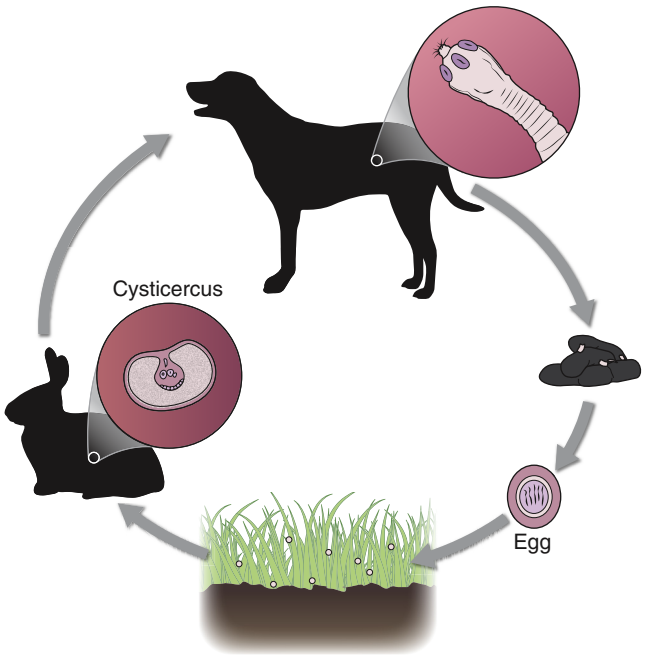

Fig. 115.3 Life cycle of *Taenia pisiformis*.

Once the metacestode stage is consumed by a dog or cat, it develops into an adult tapeworm in the lumen of the small intestine. Gravid tapeworm segments containing eggs detach and are excreted in feces. *Taenia pisiformis* reaches patency in approximately 56 days, *T. crassiceps* in 27 to 31 days, *T. hydatigena* in 51 days, *T. ovis* in 42 to 63 days, *T. multiceps* in 30 days, *T. serialis* in 1 to 2 months, and *T. taeniaeformis* in 40 days.[11,29] If a suitable intermediate host ingests the eggs, which are immediately infective in fresh feces, the oncosphere hatches, penetrates the intestinal wall, and migrates to the preferred organ. Here the embryo grows, cavitates, and forms the metacestode stage that is infective to the definitive host.[11]

Necropsy surveys indicate that *Taenia* spp. infections are common in dogs and cats; prevalences in North America have been reported between 25.0% and 29.7% for dogs (*T. pisiformis*), and between 25.9 and 33.0% in cats (*T. taeniaeformis*).[13–15] In Iran, 90 dogs were necropsied; *T. hydatigena* was recovered in 43%, *T. multiceps* in 11%, and *T. ovis* in 3%.[6] In Albania, 111 dogs were necropsied; *T. hydatigena* was recovered in 2.7%.[30]

When fecal flotation is utilized as the sole detection method, the observed prevalence of infection is typically much lower than that observed by necropsy.[13,15,31] However, the sensitivity of fecal flotation depends on the flotation method used. For example, in a 2015 study from Oklahoma, 30/116 (25.9%) cats were detected as infected with *T. taeniaeformis* by necropsy. Fecal flotation was performed on all the cats utilizing two flotation methods: passive flotation with $NaNO_3$ and centrifugal flotation with Sheather's sucrose solution.

TABLE 115.2 *Taenia* Species that Infect Dogs and Cats

Species	Definitive Host	Prepatent Period (Days)	Intermediate Host	INFECTIVE METACESTODE	
				Type	Location
Taenia pisiformis	Dog, wild canids	56	Rabbit, rodents	Cysticercus	Abdominal cavity, liver
Taenia crassiceps	Dog, wild canids	27–31	Rodents	Cysticercus	Abdominal or thoracic cavity
Taenia hydatigena	Dog, wild canids	51	Ruminants, horses, pigs	Cysticercus	Abdominal cavity, liver
Taenia ovis	Dog, wild canids	42–63	Sheep, goat	Cysticercus	Muscle
Taenia multiceps	Dog, wild canids	30	Sheep, cattle	Coenurus	Brain, spinal cord
Taenia serialis	Dog, wild canids	30–60	Rabbit, rodents	Coenurus	Connective tissue
Taenia taeniaeformis	Cat, wild felids	40	Rodents	Strobilocercus	Liver

Centrifugal flotation detected 8/30 infected cats (26.7%); passive flotation detected only 3/30 infected cats (10.0%).[15] In fecal flotations, *Taenia* species eggs are morphologically indistinguishable from one another and from *Echinococcus* spp.; a diagnosis to species level requires identification of adults procured at necropsy or the use of molecular techniques. For example, a recent study in Turkey demonstrated that 27 of 100 dogs were positive for taeniid eggs by centrifugal flotation and sedimentation. *Echinococcus granulosus*-specific PCR products were obtained in 14/27 (51.9%) taeniid specimens. Since additional PCR analysis was not conducted, the remaining 13/27 positive taeniid specimens can be presumed to be other *Echinococcus* or *Taenia* spp.[32]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The current dogma is that *Taenia* spp. infections in dogs and cats are generally not associated with clinical signs. As for dipylidiasis, some infected animals will exhibit scooting behavior associated with anal pruritus, but other conditions such as impacted anal glands will lead to the same behavior. Several case reports describe cats with *Taenia* sp. impactions.[33,34]

Dogs and cats are rarely infected with the metacestode stages of *Taenia* spp. However, disseminated abdominal, thoracic, or subcutaneous cysticercosis due to *T. crassiceps* has been reported in dogs;[35–37] a compromised immune system may have played a role in the pathogenesis. Occasional cases of feline cerebral coenurosis due to *T. serialis* have been described in Australia and North America. In all cases the diagnosis was made at necropsy following morphological identification of cerebral coenuri (i.e., fluid-filled cysts containing characteristic protosolices). *Taenia serialis* normally utilizes a dog as the definitive host and a lagomorph or rodent as the intermediate host. The rare cat that develops cerebral coenurosis presumably is infected by ingesting eggs passed by an infected dog; the larvae then aberrantly migrate to the cat's cerebrum.[38] Neurocysticercosis due to *T. crassiceps* has been rarely described in cats.[39]

DIAGNOSIS

When fully intact *Taenia* spp. are grossly identified, characteristic features include a scolex with four suckers and a non-retractable rostellum armed with two rows of hooks (Fig. 115.4A). Depending on the maturity of the specimen, the length of the tapeworm can range from tens to hundreds of centimeters. The segments are rectangular with alternating unilateral genital pores (Fig. 115.4B and C). Typical taeniid eggs are usually observed in gravid segments (Fig. 115.4D). Morphologic identification is based on the number and size of rostellar hooks and the morphology of mature segments.[40] It is recommended that fresh (in saline) specimens be submitted to a reference laboratory for speciation efforts; fixation in formalin may preclude proper identification.

Diagnosis of *Taenia* spp. infection in dogs and cats is most commonly based on detection of segments on the haircoat or skin of the host or in freshly passed feces, as well as detection of eggs by fecal flotation. As for *D. caninum*, both methods are very insensitive;[15,31] segments are excreted intermittently and eggs are only present in feces if the segment is damaged in the GI tract or during preparation of the fecal specimen for examination. However, segments should be examined when present as identification informs advice on prevention of reinfection. A single lateral genital pore may be observed (see Fig. 115.4B) which differentiates *Taenia* spp. from *D. caninum*. Furthermore, segments can be differentiated from those of *Echinococcus* spp. as *Taenia* spp. segments are more rectangular and much larger (Fig. 115.5). As with other tapeworms, the presence of calcareous corpuscles allows one to distinguish between a cestode segment and a pseudoparasite (e.g., small foreign body).[41] Molecular techniques allow identification of adult parasites or segments to the species level.[42]

Eggs may be identified in segments or free in feces. They have a thick shell wall with radial striations, are brown, and 25 to 40 µm in diameter. *Taenia* spp. eggs are morphologically indistinguishable from those of *Echinococcus* spp. (Fig. 115.4D).

Two methods for characterization of taeniid eggs in fecal specimens have been developed: PCR and copro-antigen detection by ELISA. In a study from Iran, 450 canine fecal specimens were evaluated; taeniid eggs were observed in 25 specimens (5.6%) by microscopic examination using formalin-ethyl acetate sedimentation. Use of a multiplex PCR assay identified *E. granulosus* in 2/25 (8.0%), *Taenia* spp. in 17/25 (68.0 %), and co-infection with *E. granulosus* and *Taenia* spp. in 6/25 (24.0%) of the positive specimens. *Echinococcus multilocularis* DNA was not detected in any of the specimens.[42] Multiplex PCR has also been utilized to distinguish individual *Taenia* spp.; an Australian study identified *T. ovis, T. hydatigena, T. serialis,* and *T. pisiformis* in the feces of red foxes (*Vulpes vulpes*) and wild dogs.[43] Detection of parasite antigen in feces is another promising area of focus for detection of *Taenia* spp. and *Echinococcus* spp. However, while these tests typically have high sensitivity, they are generally genus specific. Even so, this approach offers several advantages, namely: antigen can be detected in feces weeks before patency, the levels of antigen in feces are independent of egg production, copro-antigen is stable in feces for days at a range of temperatures and for several months in formalin-fixed feces, and copro-antigen levels drop rapidly, in 1 to 5 days, following successful treatment.[44]

(B) Stained and (C) unstained segment showing alternating unilateral genital pore. (D) Egg. Note the thick shell wall and two of the six hooks visible in the embryo. (A, B, and C courtesy of Megan Lineberry, National Center for Veterinary Parasitology, Oklahoma State University.)

TREATMENT AND PROGNOSIS

Praziquantel or epsiprantel are effective for treatment of *Taenia* spp. infections using the same dosages as used for *D. caninum* (Table 115.3).[23] In the USA, fenbendazole is approved at 50 mg/kg q24h for 3 consecutive days for *T. pisiformis* in dogs; in the UK, the same drug dosage is approved for use in dogs and cats for *Taenia* spp.. Nitroscanate is approved in some countries for use in dogs; a dosage of 50 mg/kg was 98% effective against *T. hydatigena, T. ovis,* and *T. pisiformis*.[24] Nitazoxanide has been used to treat dogs and cats infected with *T. pisiformis* and *T. taeniaeformis*, respectively. The drug was 100% effective against both cestodes at a single dose of 100 mg/kg.[25]

PREVENTION

Prevention of *Taenia* spp. infections is essentially limited to minimizing the risk of ingestion of infected intermediate hosts, which requires confinement. Ideally, the *Taenia* species infecting a dog or cat should be identified as this will allow one to determine the most likely source of infection. Pets can then be administered an effective anticestodal medication periodically based on risk factors for exposure. Depending on the *Taenia* spp. involved, *Taenia* spp. that infect dogs and cats have PPPs of 27 to 63 days (see Table 115.2). If limiting predation of intermediate hosts is not possible, anticestodal medication could be considered every 6 to 12 weeks; preventive treatment at intervals slightly greater than the PPP typically provides adequate control because not all intermediate hosts are infected with the metacestode.

PUBLIC HEALTH ASPECTS

Occasionally, the metacestode stages of *T. crassiceps, T. multiceps, T. serialis,* and *T. taeniaeformis* have been described in people. However, overall, the risk of zoonotic infection by these *Taenia* spp. is very low and often associated with immunosuppression;[45] infections are likely

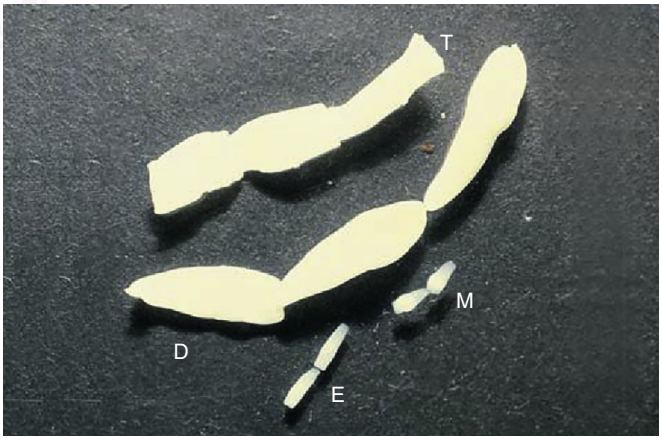

Fig. 115.5 Mature tapeworm segments passed in the feces may be observed by owners and presented for identification. *Taenia* segments *(T)* are square to rectangular in shape, *Dipylidium* segments *(D)* are more barrel shaped, and *Mesocestoides (M)* has club-shaped segments. Both *Mesocestoides* and *Echinococcus (E)* segments are small and are often overlooked. Identification can be confirmed by examining eggs from the segments. TABLE 115.3 Recommended Drugs for Treatment of *Taenia* spp. in Dogs and Cats

Drug	Species	Indication	Dosage (mg/kg)[d]	Route
Praziquantel	B	*T. pisiformis*[a,b], *T. multiceps*[b], *T. hydatigena*[b], *T. ovis*[b] *T. taeniaeformis*[a]	5.0	PO
	B	*T. pisiformis*[a] *T. taeniaeformis*[a]	5.7	IM/SC
Epsiprantel	C	*Taenia* spp.[b]	8.0	TD
	D	*T. pisiformis*[a]	5.5	PO
	C	*T. taeniaeformis*[a]	2.75	PO
Fenbendazole	D	*T. pisiformis*[a]	50	PO
	B	*Taenia* spp.[b]	50	PO
Nitroscanate	D	*Taenia* spp.[c]	50	PO
Nitazoxanide	D	*T. pisiformis*	100	PO
	C	*T. taeniaeformis*	100	PO

[a]USA; [b]United Kingdom; [c]Canada.
[d]All doses are for one time administration, with the exception of fenbendazole, which is given q24h for 3 days.
B, both dog and cat; *C*, cat; *D*, dog; *TD*, transdermal.

acquired via ingestion of eggs in the feces of dogs or cats. Dogs and cats are not involved in the life cycle of *T. saginata* (beef tapeworm) and *T. solium* (pork tapeworm).

ECHINOCOCCUS SPP. INFECTIONS (ECHINOCOCCOSIS)

ETIOLOGY AND EPIDEMIOLOGY

All species in the genus *Echinococcus* have a predator-prey, indirect life cycle that commonly involves wildlife. However, some occur in significant domestic life cycles. The adult tapeworms of all species are only a few millimeters in length and reside within the small intestine of carnivores, especially canids. Intermediate hosts range from livestock to rodents. Most species are infective for people. However, globally, the two most important species are *E. granulosus* sensu lato (s.l.) and *Echinococcus multilocularis*.

Echinococcus granulosus sensu lato Infections

Echinococcus granulosus s.l. occurs in animals and people and is found worldwide, except for Greenland and Iceland which are considered free of the parasite.[46] This etiologic agent is composed of multiple genotypes/species that differ in host specificity, morphology, geographical distribution, and human pathogenicity (Table 115.4).[47–49] Dogs are the definitive host for most genotypes/species. However, wild canids can also be definitive hosts for some. Following ingestion of eggs, the intermediate stage, a hydatid cyst, develops within internal organs of intermediate hosts (primarily ruminants, horses, pigs) and accidental hosts (people and other mammals). The resultant disease is termed cystic echinococcosis (CE). Furthermore, while most species/strains of *E. granulosus* s.l. have been associated with CE in people, the majority of human cases are due to *E. granulosus* sensu stricto (s.s.) (sheep strain) (dangerous dog tapeworm, dwarf dog tapeworm).[48,50] This genotype is therefore the primary focus of the rest of this section.

Dogs are the primary definitive host for *E. granulosus* s.s. However, wild canids such as foxes, coyotes, and dingoes may also serve as definitive hosts. Domestic herbivores and omnivores (e.g., sheep, cattle, buffalo, goat, camel, pig) are the predominant intermediate hosts. Furthermore, while sheep are the primary intermediate host in many regions, reindeer constitute the primary intermediate host in parts of northern Europe and northern Russia; camels are the main reservoir in parts of the Middle East.[51]

Adult tapeworms develop within the small intestine of definitive hosts and live for approximately 6 months. Once segments are fully mature, they usually disintegrate within the intestine to release eggs that are shed in feces and are immediately infective. Both intermediate hosts and accidental hosts, including people, are infected by ingestion of eggs. Subsequently, oncospheres hatch from eggs within the small intestine, penetrate blood vessels, and travel primarily to the liver where they develop into hydatid cysts, the metacestode stage. Hydatid cysts are composed of an outer acellular laminated layer and an inner germinal layer. Weeks to months following infection, the germinal layer may generate brood capsules, 0.25 to 1.5 mm in diameter, that each contain up to approximately 40 protoscolices. Brood capsule walls may subsequently rupture. Thus, hydatid cysts occur either as a single, fluid-filled, cyst or one large cyst containing multiple smaller cysts; hydatid fluid is composed of protoscolices, calcareous corpuscles, and potentially brood capsules that collectively are referred to as "hydatid sand". Cysts may take 6 to 12 months to mature and, depending on the host species, age of the animal, and organ involved, may vary in diameter from 1 mm to 20 cm. In intermediate hosts and people, the liver and lungs are the primary organs involved. Less commonly, cysts develop in body cavities, the CNS, eye, kidney, muscle, or spleen. Cysts may remain viable for lengthy periods (Fig. 115.6). The life cycle is completed when fertile hydatid cysts are eaten by dogs and wild canids. In dogs, the PPP is 34 to 58 days.[52,53]

Although *E. granulosus* s.s. occurs in wildlife species, it is the domestic life cycle that is of particular zoonotic concern. Thus, CE in people is especially common in parts of Africa, Asia, Australia, Europe, the Middle East, and South America where the following condition(s) occur that facilitate establishment of the domestic cycle: (1) large sheep and dog populations, (2) dogs that have access to dead livestock or offal, (3) cestocide treatment of dogs is lacking, (4) communities have a low socioeconomic status. Prevalences of hydatid cyst detection in sheep in excess of 40% have been demonstrated in parts of China,

TABLE 115.4 Species, Strains, and Genotypes of *Echinococcus granulosus* sensu lato

Species/Strain/Genotype	Distribution	Definitive Host	Intermediate Host	Occurrence of Cystic Echinococcosis in People
Echinococcus granulosus s.s. sheep (and buffalo) strains G1-G3	Worldwide	Dog Wild canids	Sheep, cattle, buffalo, goat, camel, yak	Yes
Echinococcus equinus horse strain G4	Africa, Europe, Middle East, USA	Dog	Horse, donkey, zebra	Not reported
Echinococcus ortleppi cattle strain G5	Africa, Asia, Central & South America, Europe	Dog	Cattle, buffalo, goat, sheep	Yes
Echinococcus canadensis cluster Camel strain G6	Africa, Asia, South America	Dog	Camel, cattle, goat, sheep	Yes
Pig strain G7	Worldwide focally	Dog	Pig, wild boar, (cattle)	Yes
Cervid strains G8, G10	Eurasia, North America	Dog Wild canids	Moose, reindeer, wapiti	Yes
Echinococcus felidis lion strain	Africa	Lion	Warthog	Not reported

Fig. 115.6 Large burden of hydatid cysts throughout the abdomen of a cow in Kosovo. (Courtesy of Dr. Naim Zeqiri and Dr. Arsim Ademi, Kosovo.)

Ethiopia, Iran, Italy, and Kyrgystan.[51] While few studies have evaluated the prevalence of *E. granuosus* s.l. in dogs in many of these regions, in some areas of Italy the prevalence of hydatid cysts in sheep has been 23.5% to 27.9%; in the same areas, 24.6% of dogs were copro-antigen-positive for *E. granulosus* s.l.; significant levels of CE have been identified in people in the same region.[54]

Human infections only occur following ingestion of eggs, which primarily occur in feces or an environment contaminated with feces, or on the skin and coat, of dogs. Unfortunately, little information is available on the typical prevalence of infection in dogs in endemic areas. *Echinococcus granulosus* s.l. infection prevalences of 3.8% were reported for farm dogs in Lithuania[55] and 10.6% for farm dogs in Wales.[56]

In moist environments, eggs can remain viable for weeks to months. However, the duration of viability is greatly reduced in low humidity. At temperatures of 75 to 100°C, eggs are destroyed within minutes; at −80°C this takes approximately 48 hours. Commonly used chemical disinfectants do not destroy eggs.[53]

While cats are not definitive hosts for *E. granulosus* s.l., a few cases of CE have been reported in cats. CE due to *E. granulosus* s.s. (genotype 1) has been described in cats from Russia and Uruguay;[57,58] and CE due to *E. granulosus* s.l. was reported in a cat in Turkey.[59] One of the cats was co-infected with FIV;[58] the other two cats were not tested for retrovirus infection.

Echinococcus multilocularis (Dwarf Fox Tapeworm)

Echinococcus multilocularis is a zoonotic tapeworm that occurs throughout the northern hemisphere, primarily in a wildlife-associated life cycle. Across its distribution, only minor genetic variation has been observed.[60] In North America, *E. multilocularis* has historically been considered to occur in two distinct geographic regions: the Northern Tundra Zone that extends from the west coast of Alaska to parts of the Canadian arctic,[61] and the North Central Region that includes the southern parts of three Canadian provinces (Alberta, Saskatchewan, Manitoba) and 13 midwestern US states (North Dakota, South Dakota, Iowa, Minnesota, Montana, Wyoming, Nebraska, Illinois, Wisconsin, Indiana, Ohio, Missouri, Michigan).[61–63] However, the geographical range has been expanding into parts of British Columbia and Ontario, Canada.[64,65] In Europe, the parasite has historically occurred in Austria, France, Germany, and Switzerland. However, over the last two decades the distribution of the parasite has extended into western, northern, and eastern parts of Europe, involving a total of 21 countries; those with the highest prevalence of infection in definitive hosts (>10%) include the Czech Republic, Estonia, France, Germany, Latvia, Liechtenstein, Lithuania, Poland, Slovakia, and Switzerland. European countries currently free of *E. multilocularis* in wild canids are Finland, Ireland, the United Kingdom, and mainland Norway.[66,67] The parasite also occurs throughout much of the Middle East (e.g., Turkey, Iran) and Asia (e.g., Russia, China, Japan).[68,69]

Adult *E. multilocularis* reside within the distal small intestine of definitive hosts, which are primarily wild canids. In Europe, the red fox is the primary definitive host. In North America, coyotes, wolves, and arctic foxes also harbor adult parasites and may play a significant role in the epidemiology. Domestic dogs may also be definitive hosts. Dogs also can play an important role in the epidemiology in parts of Alaska and Asia (e.g., China).[53,70] Domestic cats and wild felids occasionally develop intestinal infections but are of minor importance in the epidemiology due to the short duration, and low levels, of fecal egg excretion.[71]

Like *E. granulosus* s.l. eggs, eggs of *E. multilocularis* are morphologically indistinguishable from eggs of *Taenia* spp. and are immediately infective for intermediate and accidental hosts. Intermediate hosts for *E. multilocularis* are primarily wild rodents.[72] Accidental hosts include humans, non-human primates, pigs, horses, and dogs. Both intermediate and accidental hosts become infected by ingestion of eggs (Fig. 115.7). Subsequently, an oncosphere hatches from the egg, typically travels to the liver via the hepatic portal circulation, and develops into

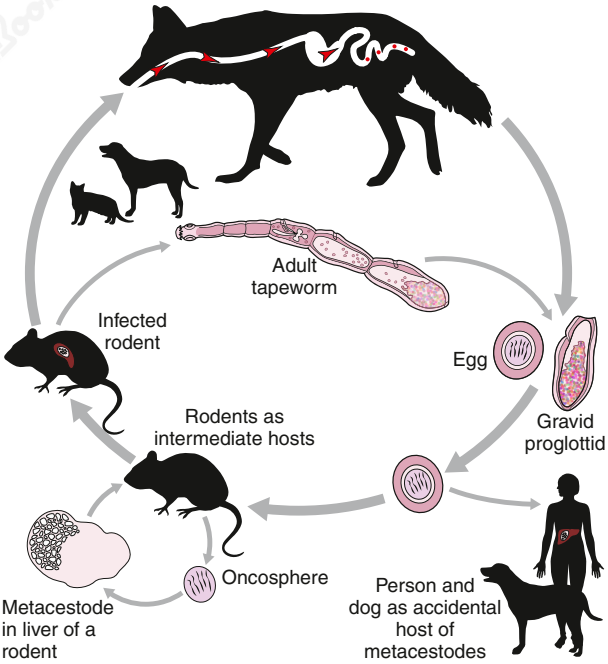

Fig. 115.7 Life cycle of *Echinococcus multilocularis*.

the metacestode. This stage comprises numerous small vesicles that vary in size from <1 mm to 3 cm in diameter; the wall is composed of an outer laminated layer and an inner germinal epithelium from which multiple protoscolices may develop. In intermediate hosts that are highly susceptible to infection, protoscolices develop in 2 to 4 months. In less susceptible hosts, the rate of development is slower or the number of protoscolices that develop is reduced or absent. Unlike hydatid cysts caused by *E. granulosus* s.l., the metacestode of *E. multilocularis* undergoes exogenous budding. During this process, the metacestode buds smaller portions of its cystic-like structure that invade neighboring tissue and may spread to distant organs, mimicking an invasive tumor.[46] By the time clinical signs develop, there is usually substantive involvement of the liver. The resultant disease, alveolar echinococcosis (AE), is usually associated with extensive hepatic damage and occasionally spreads to other locations (e.g., lungs, brain, bone). The life cycle is completed when an infected intermediate host is ingested by a definitive host; development of adult tapeworms takes approximately 4 to 5 weeks.[71] Thereafter, egg excretion usually lasts a few weeks. However, some parasites persist for up to 12 months. In experimental work, the duration and level of egg excretion in cats has been substantively less than in dogs.[73,74]

Across Europe, pooled prevalence estimates of infection in red foxes range from <1% to >50%.[67] Furthermore, within endemic areas the focal prevalence of infection in red foxes shows regional variability.[75,76] High prevalences have been observed in fox populations that have established in multiple European cities over the last two decades. For example, in Geneva, Stuttgart, and Zurich in Switzerland, the prevalence of infection in red foxes ranges from 17% to 44%.[77] This, in turn, has been associated with the establishment of urban parasite life cycles. For example, fecal analysis of 660 randomly selected, privately owned dogs in a densely populated part of eastern Switzerland demonstrated an *E. multilocularis* prevalence of 0.3%; in the same area, 0.4% of 263 cats were infected.[78] Among dogs in endemic European countries, a pooled estimate for the prevalence of intestinal infections was 0.3%.[67] However, among dogs that roam freely and have access to rodents, a prevalence as high as 8.1% has been described.[79]

Infected dogs, particularly in urban environments, constitute a significant risk for human infection. For example, in central Europe, 4% to 19% of environmental contamination with *E. multilocularis* eggs is associated with domestic dogs. The contribution of cats is considered insignificant (<0.3%).[80] Within North America, there are very few reports of intestinal infections in dogs or cats in either the USA or Canada. Historically, prevalences of infection up to 12% have been observed in some dog populations on St. Lawrence Island, Alaska.[81] However, outside Alaska, intestinal infections in dogs appear to have been evaluated only three times; using molecular methods, *E. multilocularis* was identified in feces of 1/218 (0.5%) dogs in Alberta[63] and 0/477 (0%) dogs in Ontario[82]; an intestinal infection has recently been described in a dog in Missouri.[83] Similarly, only five cats have been reported with intestinal infections (three in Saskatchewan;[84] two in North Dakota).[85] Under central European summer conditions, with adequate moisture, eggs of *E. multilocularis* survive in the environment for 2 to 3 months. Under cooler conditions and at −20°C, eggs may remain viable for months. However, as with *E. granulosus* s.l., eggs are susceptible to desiccation. Temperatures in excess of 70°C inactivate eggs. At −80°C, infectivity is lost after 48 hours.[53]

Alveolar Echinococcosis in Dogs

Since the late 1980s, cases of AE, primarily involving the liver, have been described in domestic dogs in Switzerland, Germany, France, and Belgium.[72,86] These cases are thought to occur either as a result of ingestion of large numbers of infective eggs (e.g., in the feces of foxes) or by autoinfection in association with the presence of adult *E. multilocularis* in the small intestine.[87,88] Of the cases seen in Switzerland, the median age at diagnosis is 3.1 years (range = 1.1–10.7 years), with no significant breed predilection.[88]

Prior to 2009, AE had not been diagnosed in a dog in North America. However, in 2009, hepatic AE was diagnosed in a 3-year-old dog that had lived permanently in British Columbia,[64] a Canadian province previously considered free of *E. multilocularis*. Subsequently, examination of wild canids in the area where the dog resided indicated that 11/33 (33%) were infected with *E. multilocularis*.[89] Between 2009 and 2020, at least 25 dogs have been described with AE in Canada: in British Columbia, Alberta, Saskatchewan, Manitoba, and southern Ontario.[19,65,69,90,91] Furthermore, the Ontario dogs were generally from an area where the prevalence of *E. multilocularis* in wild canids is >30%.[92] In 2020, AE was described in an 8-year-old Labrador retriever that was acquired as a puppy from Mississippi and brought to Virginia,[93] which is the first case reported in the United States.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Echinococcus granulosus s.l. Infection

Dogs (definitive host). Parasites are typically found in the proximal small intestine, deeply embedded within crypts and attached to the mucosa via the scolex. This usually results in minimal damage, even when substantive parasite burdens are present (similar to Fig. 115.8); minor damage to the epithelium and mild cellular infiltration of the mucosa may be observed. Thus, intestinal infections are typically subclinical, even when large numbers of parasites are present. When parasite burdens are heavy, segments of *Echinococcus* spp. are occasionally found on the perianal region or in feces; they are white and 0.5 to 3.0 mm long.

Cats (accidental hosts). In all three cats described in the literature, large numbers (>150) of fluid-filled, transparent-white, hydatid cysts,

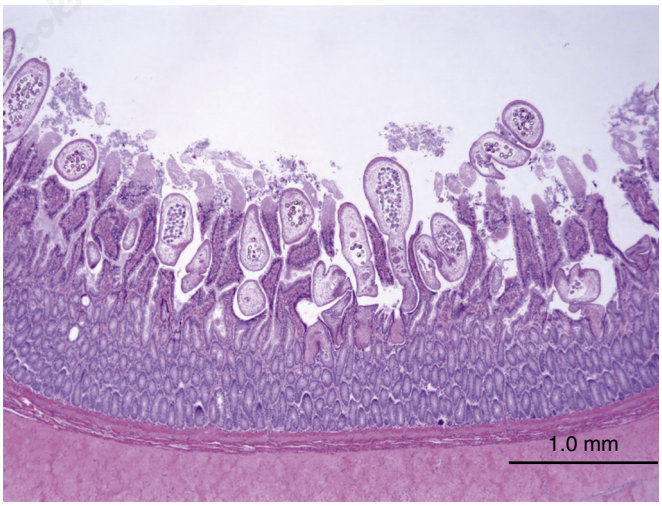

Fig. 115.8 Histopathology of the small intestine of a coyote (*Canis latrans*) infected with *Echinococcus multilocularis*. Multiple cross and longitudinal sections of *E. multilocularis* are present between villi. Note the presence of eggs within segments. There is no associated tissue response or inflammation. (Courtesy of Dr. Jamie L. Rothenburger, Faculty of Veterinary Medicine, University of Calgary, and Canadian Wildlife Health Cooperative.)

0.1 to 5.0 cm in diameter, were found free in the abdomen and attached to serosal surfaces. In one cat, multiple cysts were also present within hepatic parenchyma.[57–59] However, despite substantive cyst burdens, minimal pathology was described. Signs were primarily associated with a progressive space-occupying lesion within the abdomen; all cats had a history of progressive abdominal enlargement. Additional clinical signs included anorexia, dull mentation, polydipsia, dyspnea, and constipation.[57–59] One of the three cats was co-infected with FIV;[58] immunosuppression has been associated with an increased risk of AE in people.[94]

Echinococcus multilocularis Infection

Dogs and cats (definitive hosts). Adult parasites are found attached to the small intestinal mucosa via the scolex, typically deep within intestinal crypts (see Fig. 115.8). Intestinal burdens in dogs are much greater than in cats.[71] However, even when large numbers of parasites are present, lesions are minimal and infections are rarely clinical.

Dogs (accidental hosts). Cases of AE in dogs are typically associated with lesions in the liver; usually, there is significant involvement by the time a diagnosis is made, with lesions up to 10 to 15 cm in diameter. Furthermore, because of the ability of the metacestode to metastasize, secondary lesions may be found elsewhere in the body, both within and outside the abdomen.[95] Dogs with AE usually have signs of abdominal distention, lethargy, anorexia, and vomiting.[87,88] Other, less common, signs include abdominal pain, diarrhea, weight loss, polypnea, fever, and polyphagia.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, and Urinalysis

In dogs and cats with *Echinococcus* spp. intestinal infections, the CBC, serum biochemical tests, and urinalysis are typically unremarkable. In a European study on 11 dogs with AE, the most common serum chemistry abnormalities were hypoalbuminemia (10/11), hyperproteinemia (9/11), increased serum amylase (7/11), and hyperglobulinemia (3/11). Increased liver enzyme activities were only observed in 2/11 dogs. The most significant CBC abnormality was a decreased PCV (3/11).[96]

Diagnostic Imaging

Sonographic Findings

In dogs with AE, abdominal ultrasound typically reveals the presence of one or more large, heterogeneous, poorly limited, cavitated hepatic masses, with or without wall mineralization. Usually, there is a thick hyperechoic outer surface, an irregular inner surface, and a centrally located cavity filled with echogenic fluid.[88,96] Non-cavitated ultrasound patterns are thought to represent early infiltration prior to central liquefaction or cavity formation. A lack of vascularity of masses is evident.[96] Extension to neighboring organs is observed in approximately one-third of cases. Free abdominal fluid is present in a similar proportion and is generally attributed to rupture of cystic structures.[88]

Advanced Imaging

CT of dogs with AE usually reveals cystic to cavitated, or granular, masses within liver lobes; cavitated masses have a hypoattenuating center and a distinct hyperattenuating wall (Fig. 115.9).[96,97] Mineralization may be observed in walls of cavitated masses. The absence of enhancement within masses has been observed and is a characteristic CT feature of AE in people.[98] Progressive mineralization over time is considered a sign of chronic disease and of dystrophic tissue metaplasia because of medical therapy.[99] A lack of vascularity of masses is evident.[96]

Microbiologic Tests

Cytologic Diagnosis

In many dogs, ultrasound-guided fine-needle aspirates of intralesional or peritoneal fluid generates specimens with cytologic morphology consistent with AE, namely, calcareous corpuscles and folded membranous structures (Fig. 115.10).[19] While the former may be associated with any cestode, the folded membranes have only been described in AE cases.

Isolation and Identification

In heavy parasite burdens, a presumptive diagnosis of intestinal infection may be made if segments are found in feces or on the perianal region. However, *Echinococcus* spp. segments are much smaller than those of *Taenia* spp. and *Dipylidium caninum* (see Fig. 115.5) and usually disintegrate before being passed in feces. Eggs of *Echinococcus* spp. may be found in feces using flotation methods. However, this is insensitive and the eggs are indistinguishable from *Taenia* spp. eggs (see *Taenia* earlier in this chapter).[20,53] Eggs of both species are immediately infective for people and appropriate biosecurity practices must be followed when handling intestinal contents and feces.

At necropsy, adult parasites are most likely to be found by: (1) stereoscopic examination of the small intestine, (2) intestinal scraping, and (3) examination of small intestine wash fluid using the sedimentation and counting technique (SCT).[100] The latter method has the highest sensitivity. *Echinococcus granulosus* s.l. are generally located within the proximal small intestine. Adult parasites are 1 to 7 mm in length with a scolex containing two rows of hooks and four suckers. Typically, three (two to six) segments are present. The genital pore is located approximately equidistant from either end of the segment. *Echinococcus multilocularis* are generally located within the distal small intestine.[101] Adult parasites are 2 to 4 mm in length with a scolex containing two rows of hooks and four suckers. Typically, five (two to six) segments are present. The genital pore is located within the anterior half of the segment.

The sensitivity of necropsy examination for diagnosis of intestinal echinococcosis is high (>97%). However, when low parasite burdens are present (<6 parasites), false-negative results may occur, particularly

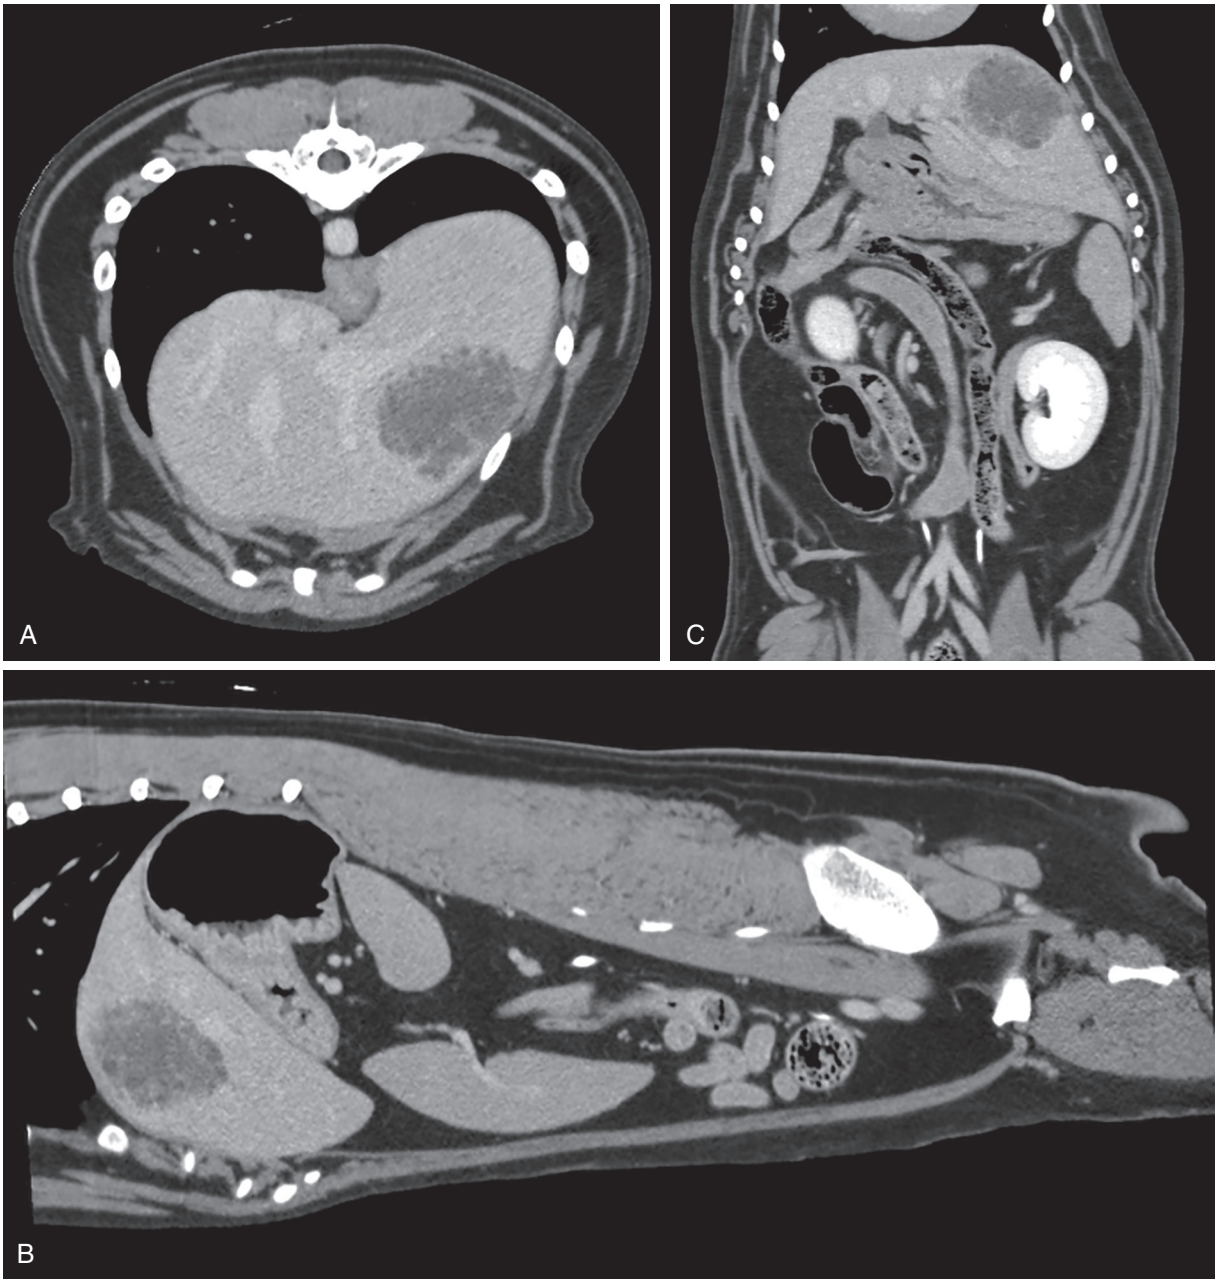

Fig. 115.9 Computed tomography images of a dog with hepatic alveolar echinococcosis. (A) Transverse. (B) Sagittal. (C) Dorsal. (Courtesy of Dr. Taizha Ciasca, Dr. Chris Warren-Smoth, and VetCT.)

if SCT is not performed.[102] Confirmation of the parasite species recovered can be carried out by DNA analysis.[103]

Serologic Diagnosis (Fecal Antigen Detection)

Multiple copro-antigen-detection ELISAs have been developed for examining fecal specimens from dogs for *Echinococcus* spp. but are generally genus specific. Sensitivities of these tests range from 60% to 92%; specificities range from 70% to 96%. Copro-antigen ELISA sensitivity is influenced by parasite burden.[53,102] Cross-reactions are generally associated with infection with *T. hydatigena* but likely also occur with other *Taenia* spp.. Thus, when used on dogs or cats, copro-antigen ELISA-positive results should ideally be confirmed with nucleic acid–based testing.[53]

Serology

Most dogs with AE develop antibodies to an *E. multilocularis*-specific antigen.[88,104] At the time of writing, this diagnostic tool is only available at the Universities of Bern and Zurich, Switzerland. Due to abortive infections, some dogs will seroconvert but not develop AE.[105,106]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Multiple PCR-based assays have been described for detection of *E. granulosus* s.l.[102] and *E. multilocularis*, some of which require isolation of eggs. While most assays have high specificity, sensitivity has been variable; some methods have low sensitivity, presumably due to PCR inhibitors in feces or intermittent shedding of eggs. One *E. multilocularis* PCR assay had an overall sensitivity of 88%; in animals with more than 100 parasites, sensitivity was 95.7%; specificity was at least 99.9%. This assay was selected for use in national surveillance programs of wild canids in Europe and has been used to detect infection in fecal specimens from dogs and cats.[107]

Multiple *Echinococcus* species-specific assays also have been developed for use on tissue specimens. For example, DNA sequence data for

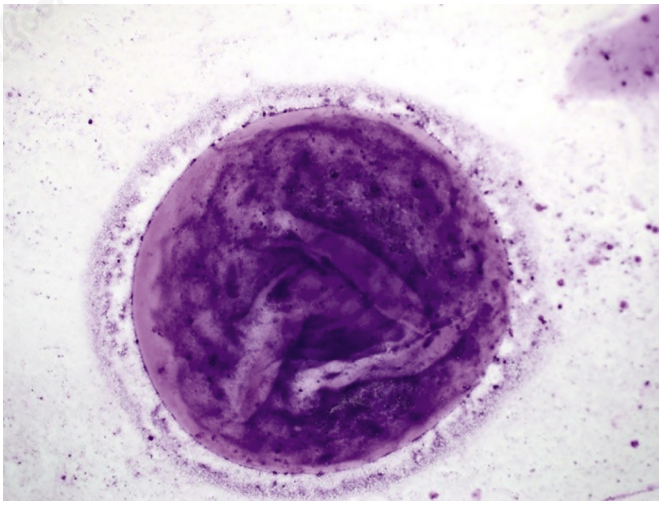

Fig. 115.10 Sediment smear of an aspirate from an abdominal mass in a dog with alveolar echinococcosis showing folded membrane structure. Wright stain, 200× magnification.

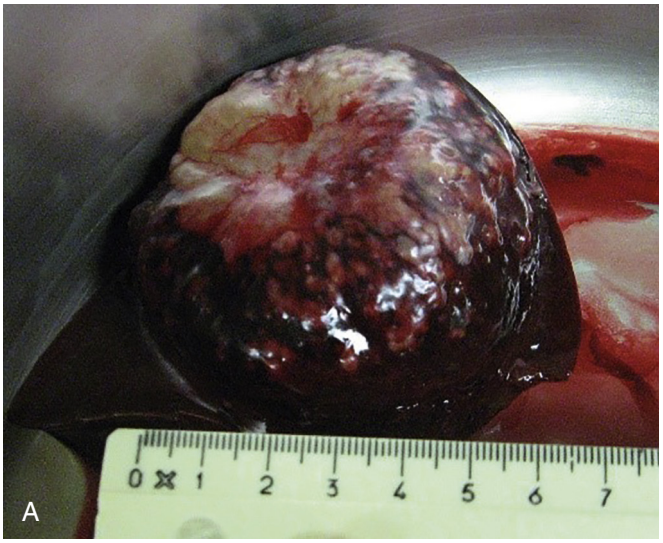
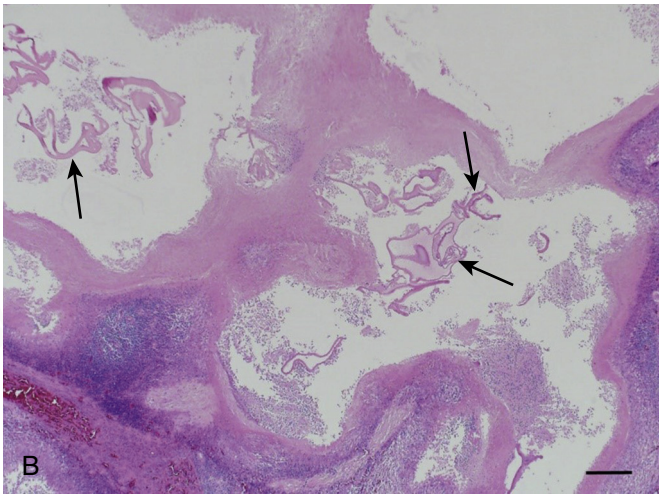
PCR-generated fragments of the mitochondrial *12S rRNA* gene[108] and restriction fragment length polymorphism analysis of the *12S rRNA* gene and *NADH dehydrogenase 1* gene[109] can be used to confirm the presence of *E. multilocularis*. Similar methods are available for detection and identification of *E. granulosus* s.l.[48,102]



Pathologic Findings



Gross Pathologic Findings

In dogs with hepatic AE, multiple nodular firm pale-tan masses are typically present that can be readily mistaken for neoplasia, or sometimes abscesses, without histologic examination (Fig. 115.11A). Furthermore, while the liver is the most common organ affected, extension(s) into neighboring organs such as the omentum, peritoneum, and diaphragm may occur.[88] Exogenous budding of the metacestode has also been associated with lesions in the lungs, spleen, vertebral bodies, brain, and prostate of dogs.[87,97]

Histopathologic Findings

Histological examination of tissue biopsies is extremely helpful for diagnosis of AE as morphology is characteristic for *E. multilocularis*;[64,72] hepatic architecture is replaced by multi-loculated coalescing cystic structures surrounded by fibrosis.[88] Lining individual cysts is an eosinophilic hyaline membrane ("laminated layer") that stains with PAS (Fig. 115.11B and C). The inner lining of the hyaline membrane is typically composed of a germinal epithelial layer and a basophilic matrix that contains occasional calcareous corpuscles. Intraluminal protoscolices are sometimes observed. A prominent chronic eosinophilic and granulomatous inflammation is also usually present. The combination of histopathology and a positive *E. multilocularis* species-specific PCR assay is the gold standard for diagnosis of AE.[88,109]

TREATMENT AND PROGNOSIS

E. granulosus s.l. and *E. multilocularis* Intestinal Infections

Praziquantel is most commonly used and typically recommended as a single treatment as it kills both adult and immature parasites in the intestine (see Table 115.5).[110] However, two treatments 24 hours apart

TABLE 115.5 Recommended Drugs for Treating *Echinococcus* spp. Infections in Dogs and Cats

Parasite/Drug (Indication)	Species	Dosage (mg/kg)	Route
E. granulosus s.l.			
Praziquantel (intestinal infection)	D	5.0	PO
		5.7	IM
Epsiprantel (intestinal infection)	D	5.5	PO
E. multilocularis			
Praziquantel[a] (intestinal infection)	B	5.0	PO
	B	5.7	IM
	C	8.0	TD
Epsiprantel[a,b] (intestinal infection)	B	5.5	PO
Albendazole[c] (alveolar echinococcosis)	D	10	PO

[a]In order to ensure adequate dosing, retreat 24 hours after the first treatment.
[b]At least one repeat treatment is required as the efficacy is less than praziquantel; in contrast to praziquantel, which kills adult and immature *E. multilocularis*, epsiprantel only kills adult parasites. Epsiprantel is not approved for treatment of *E. multilocularis* in the USA. However, the drug has been used in Finland for this purpose.
[c]Administer q24h for life.
B, both dog and cat; *C,* cat; *D,* dog; *TD,* transdermal.
From Domingo M, Boue F, Conraths F, et al. Assessment of the risk of echinococcosis introduction into the UK, Ireland, Sweden, Malta and Finland as a consequence of abandoning national rules. *The EFSA Journal.* 2006;441:1–54.

are recommended for *E. multilocularis* infections to ensure adequate dosing. Epsiprantel may also be used but efficacy is typically less than that of praziquantel.[111] Neither praziquantel nor epsiprantel are ovicidal, and infective eggs may be shed in feces for up to 3 days following treatment. As a result, when treating infected dogs and cats, animals should be maintained in an environment that is easy to clean, feces should be safely disposed of for 3 days following treatment, animals should be washed entirely after treatment using a shampoo to remove eggs from the coat, and people should ideally wear mouth protection (e.g., surgical mask or cloth face covering), gloves, and protective clothing.[3]

Alveolar Echinococcosis

The metacestode of *E. multilocularis* in the abdomen of dogs does not constitute a direct risk to human health. However, some dogs with hepatic AE may also have patent intestinal infections[112] and therefore may constitute a zoonotic risk. Thus, as soon as a presumptive diagnosis of hepatic AE is made, dogs should be treated with praziquantel to eliminate intestinal infection;[110] treatment should be repeated 24 hours later. Praziquantel has little efficacy against the metacestode.

Once a definitive diagnosis of AE is made, treatment should be initiated with albendazole at 10 mg/kg PO q24h for life.[96] In some dogs, albendazole can cause bone marrow toxicity leading to aplastic anemia.[113] Therefore dogs receiving albendazole should be monitored weekly for 1 month, then every 3 to 4 months thereafter, with a CBC. This treatment regimen is recommended whether or not surgical excision is pursued. As in people, surgery is only recommended if complete removal of the metacestode can be achieved.[88] Dogs with any type of intervention (albendazole, surgery, or both) live significantly longer than those that have no intervention.[88] At present, there is no evidence that debulking surgery (cytoreduction) followed by treatment with albendazole results in a superior outcome compared to treatment with albendazole alone.[88]

Historically, it has been assumed that medical management of dogs with AE is associated with short-term survival. However, four of six dogs managed with only daily albendazole were in remission 0.5, 0.5, 2.6, and 9.5 years after the initial diagnosis.[88]

IMMUNITY AND VACCINATION

A recombinant vaccine (EG95) for *E. granulosus* s.l. has been developed for use in sheep and cattle intermediate hosts which results in a substantive reduction (>95%) in hydatid cyst burdens. As such, this vaccine is approved for use in a number of countries (e.g., Argentina, China)[53,114,115] and constitutes a useful tool in *E. granulosus* s.l. control programs. A similar vaccine is currently being developed for AE in people.[68] Although vaccines are not available for dogs, they have been considered desirable, and vaccine trials in dogs have yielded promising results.[115]

PREVENTION

E. granulosus s.l. Infections

In some countries with high prevalence of infection in dogs and high incidence of CE in people, control programs have been implemented (e.g., Argentina, Chile, Cyprus, New Zealand, Uruguay) that include: (1) strict regulation of animal slaughter and disposal of offal, (2) control of dog populations, (3) treatment of all dogs every 6 weeks with a cestocide, and (4) education of the public about transmission of *E. granulosus* s.l. and the importance of cooking raw offal or freezing it at −18°C for a minimum of 3 days prior to feeding it to dogs.[3,116,117] Such programs are costly and take >10 years before the prevalence of infection in dogs and intermediate hosts declines to low levels. Incorporation of (EG95) vaccination of both intermediate and definitive hosts into these control programs will likely have a more rapid and sustainable impact on the prevalence of infection in different hosts.[53,115]

E. multilocularis Infections

In areas endemic for *E. multilocularis*, administration of praziquantel at 5.0 mg/kg PO every 4 weeks is recommended for dogs with access to rodents.[88] In such areas, a risk assessment should be carried out on a regular basis to determine if such preventive treatment is necessary. Since AE in dogs may be associated with autoinfection, such a protocol may also reduce the risk of AE in dogs.

In order to reduce the risk of importation of *E. multilocularis* into countries free of this parasite, some countries require dogs from endemic areas to be treated with a cestocide at the time of entry, for example, Finland, Iceland, Ireland, mainland Norway, Malta, and the United Kingdom.[118,119]

PUBLIC HEALTH ASPECTS

People only become infected with *E. granulosus* s.l. and *E. multilocularis* by ingestion of eggs. Thus, in a veterinary environment, this will typically only occur by contamination of hands. Since the eggs of both parasites are immediately infective in fresh feces of dogs or cats, strict attention to hand hygiene whenever handling feces, materials contaminated by

feces, or a potentially infected animal will effectively eliminate the risk of infection. When performing a necropsy on a dog potentially infected with *Echinococcus* spp., masks, gloves, and protective clothing should be used if the intestine is opened.

Cystic Echinococcosis

While many genotypes/species of *E. granulosus* s.l. infect people, >88% of human infections that have been typed are *E. granulosus* s.s. genotype G1,[48] indicating that sheep are the intermediate hosts. Many infections in people remain clinically inapparent for lengthy periods, even when large hydatid cyst(s) are present.[120] Disease ranges from mild to fatal and is associated with the space-occupying nature of cysts that usually occur in the liver and lungs and, less commonly, in the bone, CNS, or spleen. Liver involvement is typically associated with abdominal pain. With lung involvement, patients may present with chest pain, cough, dyspnea, and hemoptysis.[121] Diagnosis is based on detection of cysts by imaging (ultrasound, CT, MRI) combined with *Echinococcus* spp. serology.[120] Surgical excision is the preferred management as this is the only approach likely to result in cure.[122] When surgery is not an option, prolonged treatment with albendazole or mebendazole is carried out which, while usually not curative, reduces the cyst size and the associated clinical signs.[122]

Alveolar Echinococcosis

Only approximately 1% to 10% of people that are exposed to eggs of *E. multilocularis* and seroconvert develop disease.[68,98] When infections are not eliminated, the clinical incubation period is 5 to 15 years. People usually present with symptoms associated with hepatic neoplasia, such as epigastric pain, fatigue, jaundice, and weight loss.[122,123] Disease has been reported in all ages, but is most commonly diagnosed in people aged 50 to 55 years.[124,125] AE is usually diagnosed by imaging (ultrasound, CT, MRI) followed by *Echinococcus* spp. serology. However, imaging is usually suggestive of a neoplasm; suspicion of AE typically only occurs after histological examination of a biopsy.[120]

AE in people often presents in an advanced stage[124] and mortality rates are typically much greater than CE. When left untreated, AE has a chronic course that lasts weeks to years. Surgical excision of the entire lesion, followed by treatment with a benzimidazole (albendazole or mebendazole), is the only intervention that can result in cure, but is an option for only approximately one-third of cases. For individuals with non-resectable lesions, long-term treatment with a benzimidazole is recommended.[68] Since this treatment is parasitostatic rather than parasitocidal, regular imaging (e.g., PET scan) is required to determine the duration of therapy; in some individuals, life-long treatment may be required.[123] Data from Europe indicate that the 10-year survival rate in untreated individuals is 6% to 25%. However, this increases to 80% to 89% in people on long-term benzimidazole treatment.[126]

In a recent systematic review and meta-analysis of the literature, risk factors associated with AE in people included dog-related factors (e.g., playing with dogs, dog ownership), gender (being female), vocational factors (e.g., being a farmer, handling foxes), sociocultural factors (e.g., low income), and human habits (e.g., chewing grass). However, these potential risk factors likely vary in importance in different endemic areas of the world.[127] For example, strong associations between AE in people and dogs have been observed in parts of Alaska and China.[81,128] If exposure of people to *E. multilocularis* eggs is a concern, serological testing for up to 12 months following exposure is recommended.[129–131]

In North America, despite the large geographic distribution of *E. multilocularis* in wildlife, only a small number of cases of autochthonous alveolar echinococcosis in people had been described before 2013—one from Manitoba in 1937,[132] and one from Minnesota in 1977.[133] This low number of cases led some to conclude that the genetic variants of *E. multilocularis* occurring in North America are of lower infectivity or pathogenicity for people than those in Europe.[134] However, since 2013, reports of disease in humans associated with a European-type strain began to emerge, including seventeen cases from Alberta, one from Saskatechewan, and one from Vermont, USA.[135,136] The case from Vermont was a 36-year-old woman who owned a dog and had grown up fox-hunting in Maryland; she had traveled extensively throughout the USA, Costa Rica, Rome/Naples, and Montreal, but not to regions in Europe or Canada where the majority of European haplotype strain cases have been described.

MESOCESTOIDES SPP. INFECTION

ETIOLOGY AND EPIDEMIOLOGY

There is still much to learn about *Mesocestoides* spp., including the number of species and the identity of the first intermediate hosts.[137,138] At present, there are no accepted specific criteria that can be used to define a species, so numerous species appear in the literature. In 1932, Witenberg recognized one species, *Mesocestoides lineatus* in dogs, foxes, jackals, and cats, and synonymized or discounted 24 described species.[17,139] In 1980, Loos-Frank created the name *Mesocestoides leptothylacus* for the species commonly found in foxes in Europe.[140] In 1991, Etges proposed the name *Mesocestoides vogae* to replace the species *Mesocestoides corti* first described by Hoeppi in 1925, utilizing specimens collected from a mouse in Colorado, USA.[141] The most common European species are *M. vogae*, *M. leptothylacus*, and *M. lineatus*. However, some authors believe the name of the latter is taxonomically incorrect; the first descriptions were based on specimens that were not available for future authors to compare and none of the descriptions matched the original description. Therefore it has been proposed that all descriptions under the name *M. lineatus* be revised.[140]

Mesocestoides spp. occasionally infect dogs and cats, and essentially have a worldwide distribution. In Europe, the adult stage of *Mesocestoides* spp. occurs mainly in foxes, with a prevalence in some areas of up to 70%.[142] The prevalence in dogs and cats is considerably less. For example, the prevalence of *Mesocestoides* spp. in feral cats in Denmark at necropsy was 3.0%.[143] The prevalence of *Mesocestoides* spp. in owned cats in central Italy was 1.2% by fecal flotation.[144] In Iran, *M. lineatus* was reported in 19% of stray dogs at necropsy.[145] In Russia, *M. lineatus* was found in 1.7% to 23.5% of dogs at necropsy.[146] *Mesocestoides* spp. have also been reported in North and South America.[147,148] In North American dogs and cats, both fecal examination and necropsy studies have revealed a low prevalence (0%–1%); infections are more commonly detected in the southeastern and western United States.[14,15,148,149]

Adult *Mesocestoides* spp. develop in the intestine of dogs and cats following ingestion of the infective metacestode stage (tetrathyridium) within the abdominal cavity of various intermediate hosts, which include over 200 species of reptiles, amphibians, mammals, and birds (Fig. 115.12).[150] However, strangely, despite this breadth of information, the first stage and first intermediate host for *Mesocestoides* spp. remain a mystery. It is currently believed that a cysticercoid stage occurs in an arthropod such as an ant, and that this precedes

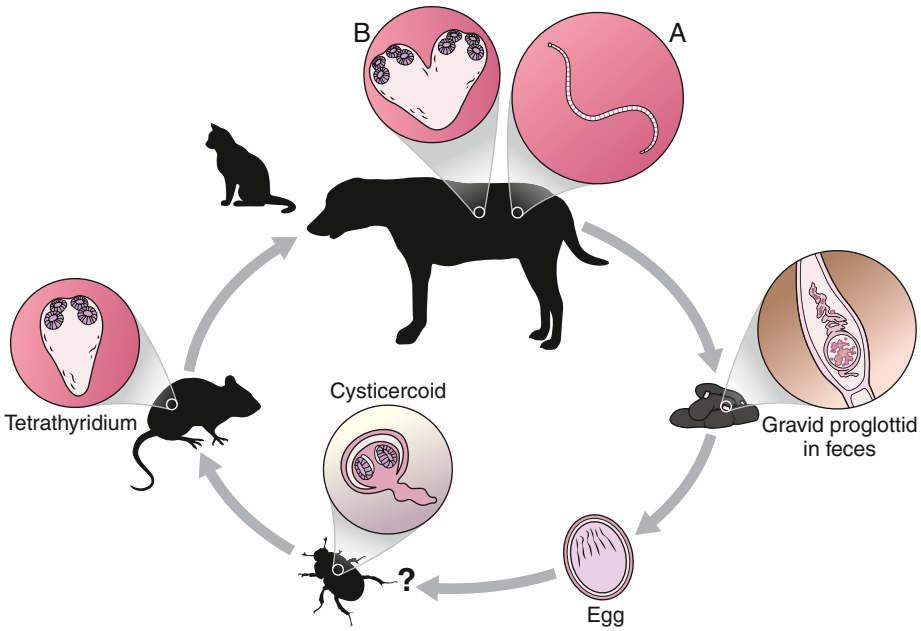

Fig. 115.12 Life cycle of *Mesocestoides* sp. A, within the intestine. B, peritoneal infection.

the tetrathyridial stage. However, experimental infections have yet to confirm this.[137,151] One study examined thousands of soil-inhabiting invertebrates from areas heavily contaminated with *Mesocestoides* spp. gravid segments shed by experimentally infected foxes, but cysticercoids were not found.[137]

Once infected with *Mesocestoides* spp., gravid segments may be detected in the feces of dogs and cats 20 to 30 days later.[11] Peritoneal tetrathyridial infection in dogs and cats may follow ingestion of a first-stage larva in the still-unidentified first intermediate host or a tetrathyridium in a second intermediate host.[152] In *M. vogae* (syn. *M. corti*), both the tetrathyridium and adult tapeworm can undergo asexual reproduction.[153] Thus, this species can repopulate the intestinal tract without further exposure if not eliminated by anthelmintic treatment.[154] Chronic glucocorticoid treatment may be a risk factor for peritoneal disease in dogs; Welsh Corgis appeared to be overrepresented in a study of 60 dogs from the United States, comprising 10% of the affected dogs.[155]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Intestinal infection appears to be subclinical in dogs and cats. Most reported cases of peritoneal infections have been dogs from North America. Of 60 dogs in the United States with peritoneal infections, most (50) were from California, with three cases from Oregon, and single cases from Washington, Arizona, Florida, and Oklahoma.[155] Single cases have also been reported in dogs from New Mexico and Washington state, and British Columbia, Canada.[138,156,157] Additional affected dogs have been reported in other countries (e.g., Germany, Japan).[142,158] Disease is associated with asexual division or budding of the parasite and development of large numbers in the peritoneal cavity; viable tetrathyridial or non-viable acephalic metacestodes may be produced. Infected dogs and cats may appear clinically normal, especially if infected with relatively few metacestodes; subclinical infections may be an incidental finding during abdominal surgery. Clinically affected dogs may have abdominal distension secondary to ascites, anorexia, weight loss, vomiting, diarrhea, and tachypnea.[155] Some affected cats have abdominal pain and vomiting.[152,159,160]

DIAGNOSIS

Laboratory Abnormalities

In dogs with peritoneal larval cestodiasis, leukocytosis, eosinophilia, and thrombocytopenia have been demonstrated on CBC. Serum chemistry analysis may show azotemia, hyperphosphatemia, hyponatremia, panhypoproteinemia, and hyperbilirubinemia.[142,158]

Diagnostic Imaging

Abdominal radiographs typically show a general loss of detail secondary to ascites. Abdominal ultrasound may reveal round, thin-walled, anechoic cysts. Some may contain a 1-mm to 5-mm rounded structure compatible with a tetrathyridium.[142,158,159] Large quantities of hyperechoic free peritoneal fluid is often present that is highly suggestive of the disease (Fig. 115.13).

Microbiologic Tests

Diagnosis Using Fecal Examination

Diagnosis of intestinal infections is by detection of segments in feces (Fig. 115.14A and B) or, rarely, detection of eggs via fecal flotation (Fig. 115.14C). Gravid segments are 3 to 4 mm in size and club shaped; they are similar in size to segments of *Echinococcus* spp. but smaller than those of *Taenia* spp. and *D. caninum* (see Fig. 115.5). For definitive identification, segments should be flattened between two glass slides after adding water or saline to the segment; the genital pore is positioned mid-ventrally. Furthermore, *Mesocestoides* spp. possess a thick-walled parauterine organ in mature segments where eggs accumulate; this is rarely found in other cyclophyllideans.[11,161] Segments can also be disrupted to release eggs (if present). As for other cestodes, calcareous corpuscles also may be seen.[41]

Although fecal flotation is insensitive (as for other cestode infections), *Mesocestoides* eggs are unique; they are 30 to 40 µm in diameter and possess a thin, clear, smooth shell wall. Hooks of the hexacanth embryo can help distinguish the egg from a pseudoparasite.[3]

Cytologic Diagnosis

Peritoneal larval cestodiasis is diagnosed by detection of either tetrathyridia or calcareous corpuscles in abdominal fluid; abdominal

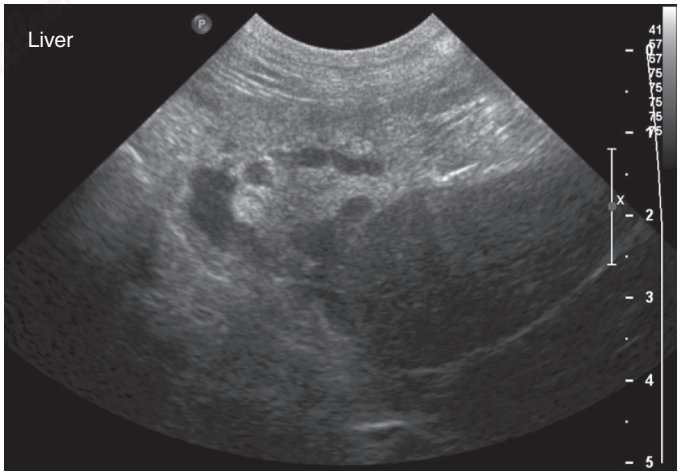

Fig. 115.13 Abdominal ultrasound image of a 4-year-old male neutered beagle mix with peritoneal larval cestodiasis. Clinical signs were chronic weight loss in the face of polyphagia. (Courtesy University of California-Davis Veterinary Diagnostic Imaging Service.)

fluid is collected via centesis or during an exploratory laparotomy.[153] Grossly, free fragments of white, flocculated material that vary in size from less than 1 mm to 5 mm may be seen in abdominal fluid that appears clear to serosanguinous (Fig. 115.15). Microscopically, tetrathyridia of *Mesocestoides* spp. have four suckers, calcareous corpuscles, and the absence of hooks or a rostellum (Fig. 115.16).[142,158,159]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Molecular methods can be used to definitively identify acephalic metacestodes.[138] PCR-DNA analysis targeting the mitochondrial (mt) *12S rRNA* gene and mt cytochrome *c* oxidase subunit 1 gene has been used to identify *M. vogae* (syn. *M. corti*),[158] as well as the mt *12S rRNA* gene of *M. lineatus*.[142]

TREATMENT AND PROGNOSIS

A single dose of praziquantel (5 mg/kg PO or 5.7 mg/kg SC or IM) can eliminate intestinal *Mesocestoides* spp. infections in dogs and cats (Table 115.6).[11,162] However, dogs with peritoneal infections require long-term use of high dosages of fenbendazole (100 mg/kg q12h for 28 days) along with peritoneal lavage following laparotomy to remove tetrathyridia (see Table 115.6).[138] One case report concluded that praziquantel was more effective than fenbendazole at treating canine peritoneal cestodiasis; however, this was only in one dog that had previously been treated with fenbendazole. In this case, praziquantel was dosed at 5.0 mg/kg and repeated 15 days later.[163] Long-term follow-up is indicated as some dogs will experience recurrence of clinical disease even after 28 days of high dosages of fenbendazole.[155] Dogs that fail fenbendazole treatment or have adverse effects of high-dose fenbendazole (typically gastrointestinal or neurologic signs in the editor's experience) after peritoneal lavage may respond to 8 mg/kg praziquantel q24h for 2 weeks (Sykes JE, personal observations).

In the 60 dogs from California, Oregon, Washington, Arizona, Florida, and Oklahoma, dogs received one, two, or three of the following treatment options: surgery/lavage, fenbendazole at any dosage, or fenbendazole at 100 mg/kg for >28 days (termed high dose). Overall, survival was 72.3% at 6 months and 60.5% at 1 year. Both clinical severity at the time of diagnosis and treatment regimen significantly influenced the treatment outcome; dogs treated with high-dose fenbendazole, or both peritoneal lavage/surgery and any dosage

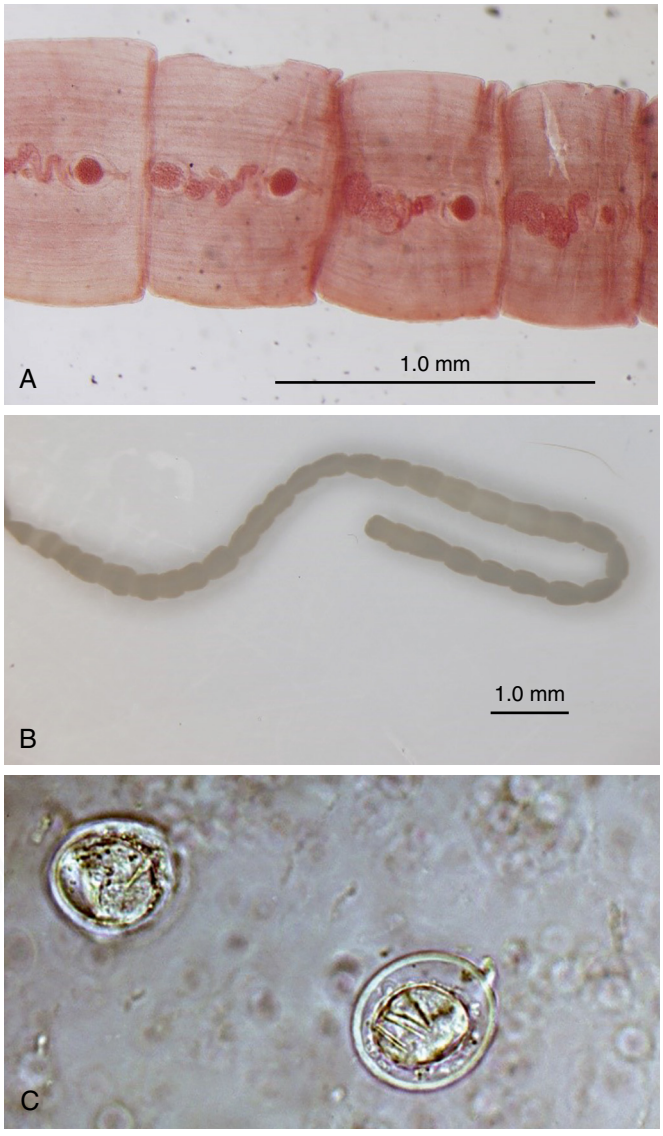

Fig. 115.14 Features of *Mesocestoides* sp. cestodes. (A) Mature segments. Note eggs contained within the medially located parauterine organ. (B) Strobila (body). (C) Egg. Note the hooks visible in the embryo. (A and B, courtesy of Megan Lineberry, Oklahoma State University. C, courtesy of National Center for Veterinary Parasitology, Oklahoma State University.)

of fenbendazole, had less than one-fifth the risk of dying compared to dogs that were not treated in this manner.[155] If there is a history of chronic treatment with glucocorticoids or other immunosuppressive medications, these should be tapered and discontinued if possible.

When parasites are present in pockets or cysts, ultrasound guidance may be needed to locate and drain these areas when lavage is impractical (e.g., invasion of tissue by parasites, substantive fibrous adhesions); surgery may be required to remove parasites and affected tissues.[155] Dogs that remain persistently infected should be treated with fenbendazole at 50 to 100 mg/kg daily for life (if tolerated).[155] Nitazoxanide (100 mg/kg) was found to be 100% effective against adult *M. lineatus* infections in cats.[25]

PREVENTION

The only preventive measure available is minimizing the risk of consumption of intermediate hosts by dogs and cats. Since the tetrathyridium stage (the stage infective to dogs and cats) has been reported in

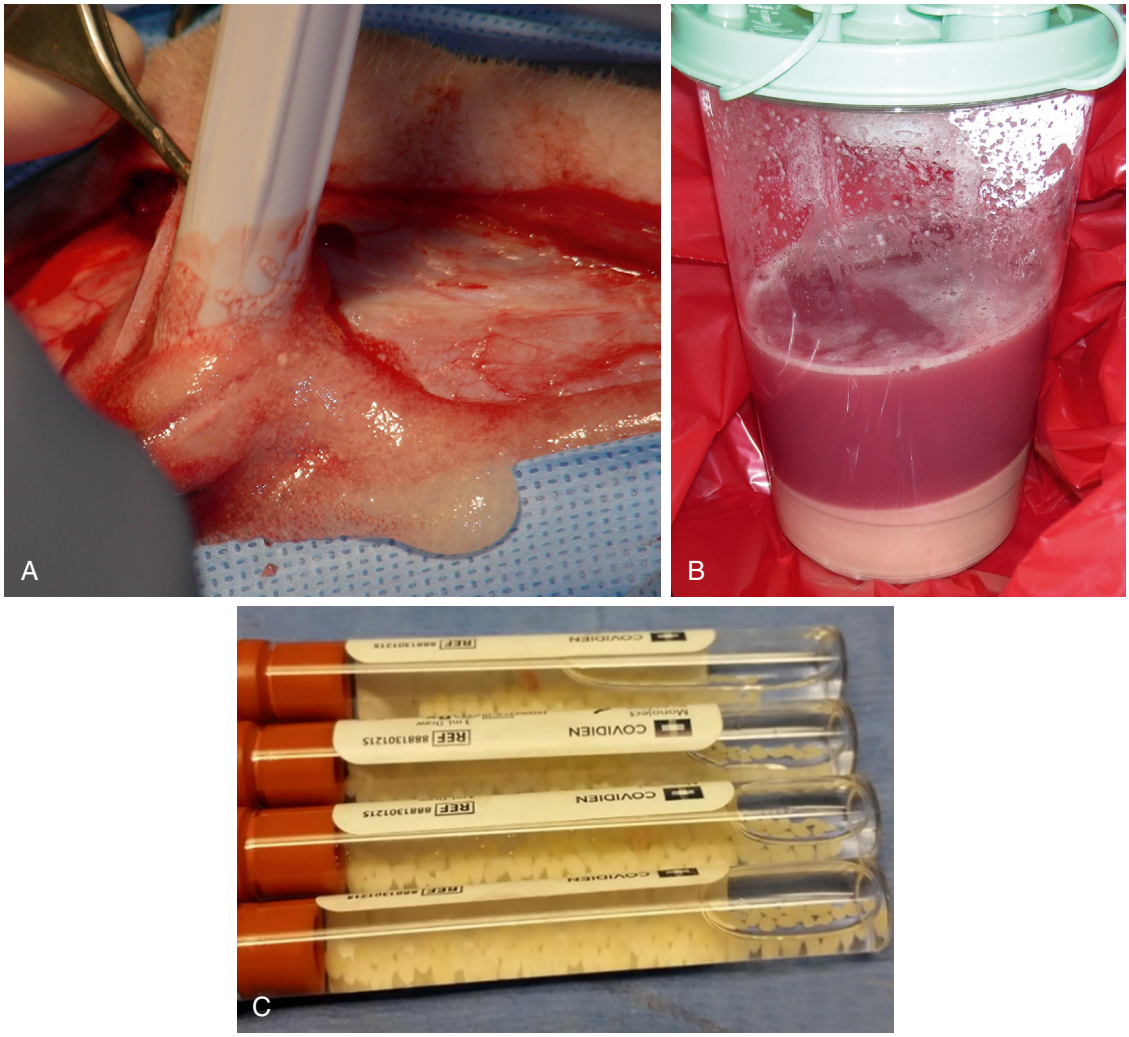

Fig. 115.15 (A) Peritoneal fluid containing *Mesocestoides* sp. tetrathyridia oozing from an initial laparotomy incision in the dog in Fig. 115.13. (B) Suction canister after surgery that contained serosanguineous fluid and what was estimated to be 11,500,000 tetrathyridia. (C) *Mesocestoides* sp. tetrathyridia lavaged from the peritoneal cavity of a 1.5-year-old German shepherd. (A and B, courtesy of Dr. Jane E. Sykes, University of California-Davis. C, courtesy of Dr. Joe Dubois, Mountain View Animal Clinic, Poteau, Oklahoma and Dr. Mason Reichard, National Center for Veterinary Parasitology, Oklahoma State University.)

over 200 species of reptiles, amphibians, mammals, and birds, the best recommendation is to limit unsupervised roaming outdoors.[150]

PUBLIC HEALTH ASPECTS

Humans have very rarely been reported to develop intestinal adult *Mesocestoides* spp. infections, but infected dogs and cats are not a direct risk to humans. The first report of a human infection was in Texas, USA (1942), where a girl was diagnosed with an *M. lineatus* infection.[164] Other cases include a 19-month-old boy from Louisiana diagnosed with an *M. variabilis* infection; the proposed origin of infection was food-borne.[165] Six other human cases of *M. lineatus* or *Mesocestoides* spp. have been reported in the USA in Texas, Missouri, New Jersey, Ohio, Mississippi, and California.[166] In Japan, a 35-year-old man was diagnosed with *M. lineatus* infection and thought most likely to have acquired the infection by eating raw snake liver.[167] These infections all appeared to be well tolerated and were diagnosed by finding segments in the feces. Treatment with praziquantel is typically effective. In addition, niclosamide and paromomycin sulfate have been used.[166,167]

DIPHYLLOBOTHRIUM SPP. INFECTION

ETIOLOGY AND EPIDEMIOLOGY

The *Diphyllobothrium* genus contains approximately 50 species of which 14 have been reported in humans.[168] All occur as adult parasites within the intestinal tract of fish-eating mammals and birds. Globally, *Diphyllobothrium latum* (*Dibothriocephalus latus*)[169] is the most important species. Regionally important species include *Diphyllobothrium dendriticum* (Russia, Argentina, Chile) and *Diphyllobothrium nihonkaiense* (Pacific Coast of Asia and North America).[168,170]

Diphyllobothrium latum (the fish tapeworm, broad tapeworm) infects both dogs and cats; other definitive hosts include humans, bears, foxes, pigs, mink, and seals. The parasite occurs in North America (Alaska and the Great Lakes region of Canada and the USA), northern Europe (Estonia, Finland, Hungary, Lithuania, Poland, Sweden and sub-Alpine lakes in France, Italy, Switzerland), and Russia. However, cases have also been reported in South America (Argentina, Brazil, Chile, Peru) and occasionally in parts of Asia (Japan, Korea, Philippines, Taiwan).[171–173]

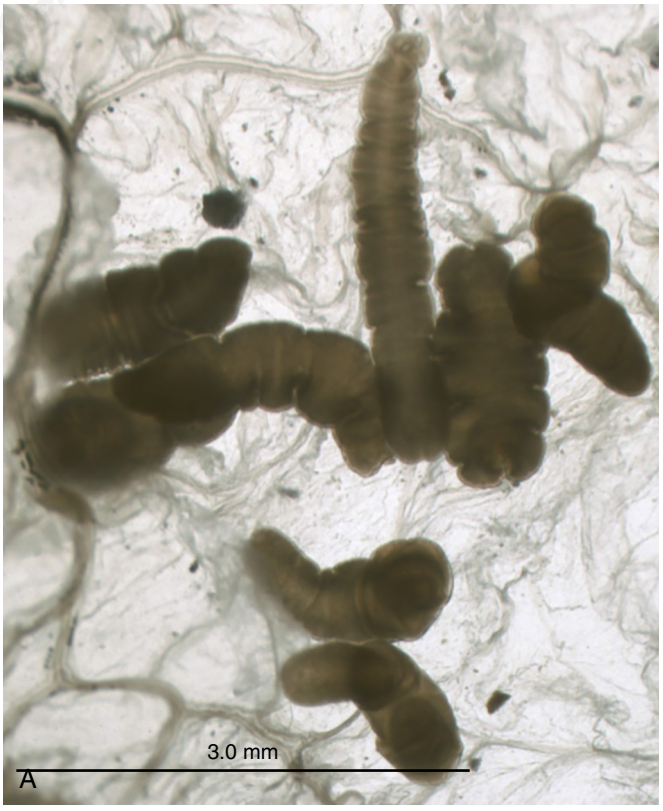

Fig. 115.16 (A) Light microscopic appearance of unstained tetrathyridia of *Mesocestoides* sp. in a specimen from the abdomen of a cat. Note the lack of hooks or a rostellum and the presence of suckers and an elongated body. (B) Romanowsky-stained cytospin specimen of peritoneal fluid from an adult mixed-breed dog with *Mesocestoides* sp. peritonitis. Note the tetrathyridium *(arrow)* and calcareous corpuscles *(arrowhead)*. (A, courtesy of Dr. Mason Reichard, Oklahoma State University. B, courtesy Dr. William Vernau, University of California-Davis Veterinary Clinical Pathology Service.)

TABLE 115.6 Recommended Drugs for Treating *Mesocestoides* spp. Infections in Dogs and Cats

Drug (Indication)	Species	Dosage (mg/kg)[a]	Route
Praziquantel (intestinal infection)	B	5.0 5.7	PO IM/SC
Nitazoxanide (intestinal infection)	C	100	PO
Fenbendazole (peritoneal larval cestodiasis)[b,c]	D	100	PO
Praziquantel (peritoneal larval cestodiasis)	D	5–8	PO

[a]Doses are for one time administration with the exception of fenbendazole, which should be given q12h for 28 days; and praziquantel (peritoneal larval cestodiasis), which should be given twice, 15 days apart, or q24h for 14 days (based on limited anecdotal evidence).
[b]Combine with peritoneal lavage and debridement to remove as many tetrathyridia as possible.
[c]Long-term follow-up is necessary. Neurologic signs and GI signs (twitching, vomiting, inappetence) have been observed using such high doses.
B, both dog and cat; *C*, cat; *D*, dog.

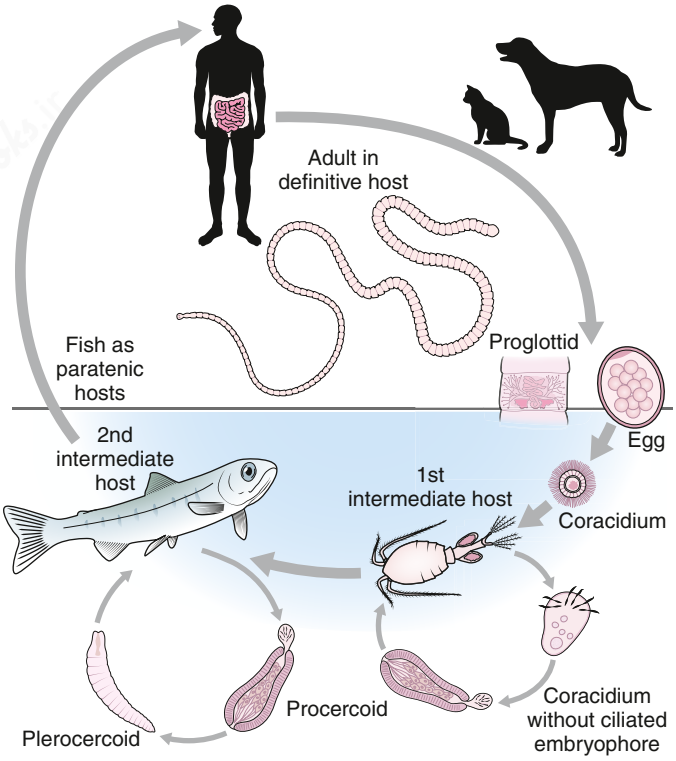

Fig. 115.17 Life cycle of *Diphyllobothrium latum*.

Diphyllobothrium latum has a three-host life cycle (Fig. 115.17). Adult parasites occur within the small intestine of dogs, cats, people, and other definitive hosts. Each parasite releases up to 1,000,000 eggs per day in to the intestinal contents via a single uterine pore that is present in each segment.[174] Eggs are then shed into the environment in feces. In fresh water, a ciliated coracidium hatches from the egg[174] and is ingested by the first intermediate host, aquatic copepods (*Cyclops* and *Diaptomus* species).[175] The coracidium matures into a procercoid within the body cavity of the copepod. When ingested by the second intermediate host, fresh water fish, the procercoid invades the peritoneal cavity, internal organs, or muscles and matures to a 1- to 3-cm long pleroceroid that resembles a small tapeworm. Plerocercoids can survive for extended periods in these locations.[176] If a fish infected with a plerocercoid is ingested by another fish, the plerocercoid can transfer to the new fish, that is, fish may be paratenic hosts. Dogs, cats, and other definitive hosts develop intestinal infections after consuming fish infected with a plerocercoid. In dogs and cats, the prepatent period is 5 to 6 weeks.[11]

Fish intermediate hosts for *D. latum* are primarily non-salmonids.[172] Plerocercoids are most commonly found in perch, pike, burbot (Europe), and walleye (North America).[177] Prevalence of infection in these species is highly variable. However, in Lake Geneva, France/Switzerland, the prevalence of plerocercoids in perch in 2003–2005 was 4% to 10%.[178] By contrast, in Lake Como, Italy, the prevalence of infection from 2013 to 2014 in perch and pike was 25.4% and 84.2%, respectively.[179]

Little information is available on the prevalence of *D. latum* in dogs and cats. In North America, most infections are diagnosed in dogs.[3] In Europe, *D. latum* infections are generally rare. Thus, in dog populations examined in both Finland and Switzerland, *D. latum* infections were detected in 0.4% of dogs.[180,181] By contrast, in parts of Russia, up to 90% of cats have been shown to be infected.[182,183]

One of the most important components of the epidemiology of *D. latum* is contamination of freshwater environments by untreated human sewage, although dogs can also be an important source of environmental contamination.[184,185]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Intestinal infections in both dogs and cats are usually subclinical. While anemia has been associated with *D. latum* intestinal infections in people, this phenomenon has not been described in naturally infected dogs or cats. Experimental *D. latum* infections in dogs have been associated with decreased red cell numbers and decreased total hemoglobin levels.[186] The possibility of infection is generally only considered after owners report the presence of chains of segments (typically empty of eggs) in feces.[3]

DIAGNOSIS

Laboratory Abnormalities

Laboratory abnormalities are generally unremarkable in dogs and cats with *D. latum* infections.

Microbiologic Tests

Isolation and Identification

Adult *D. latum* are found in the small intestine and measure 1 to 12 m in length. As with other pseudophyllidean tapeworms, the scolex lacks hooks and suckers. Instead, it contains two shallow longitudinal grooves (bothria). The strobila contains up to 3000 segments. Anterior segments are broader than long (width = 12–20 mm); posterior segments are approximately square shaped (Fig. 115.18). Segments have a number of characteristic features that include a medioventral uterine pore and a centrally located, rosette-shaped uterus. Unlike the more common tapeworms of dogs and cats (i.e., *Taenia* spp. and *D. caninum*), segments of *D. latum* continuously release eggs until the uterine contents are exhausted. Thus, terminal segments are typically not gravid, that is, do not contain eggs. Furthermore, they usually detach in chains, not individually.

Eggs of *D. latum* are oval, light brown, have an operculum at one pole, and measure 58 to 76 µm × 40 to 51 µm. They resemble eggs produced by *Spirometra* spp. and digenetic trematodes. However, a pore is often visible in the shell wall at the pole opposite the operculum in association with a small amount of material that protrudes from it (Fig. 115.18C). Eggs may be recovered by fecal flotation but are most readily detected using sedimentation.[20,176] Precise identification of different *Diphyllobothrium* species is most reliably achieved by PCR sequencing.[187]

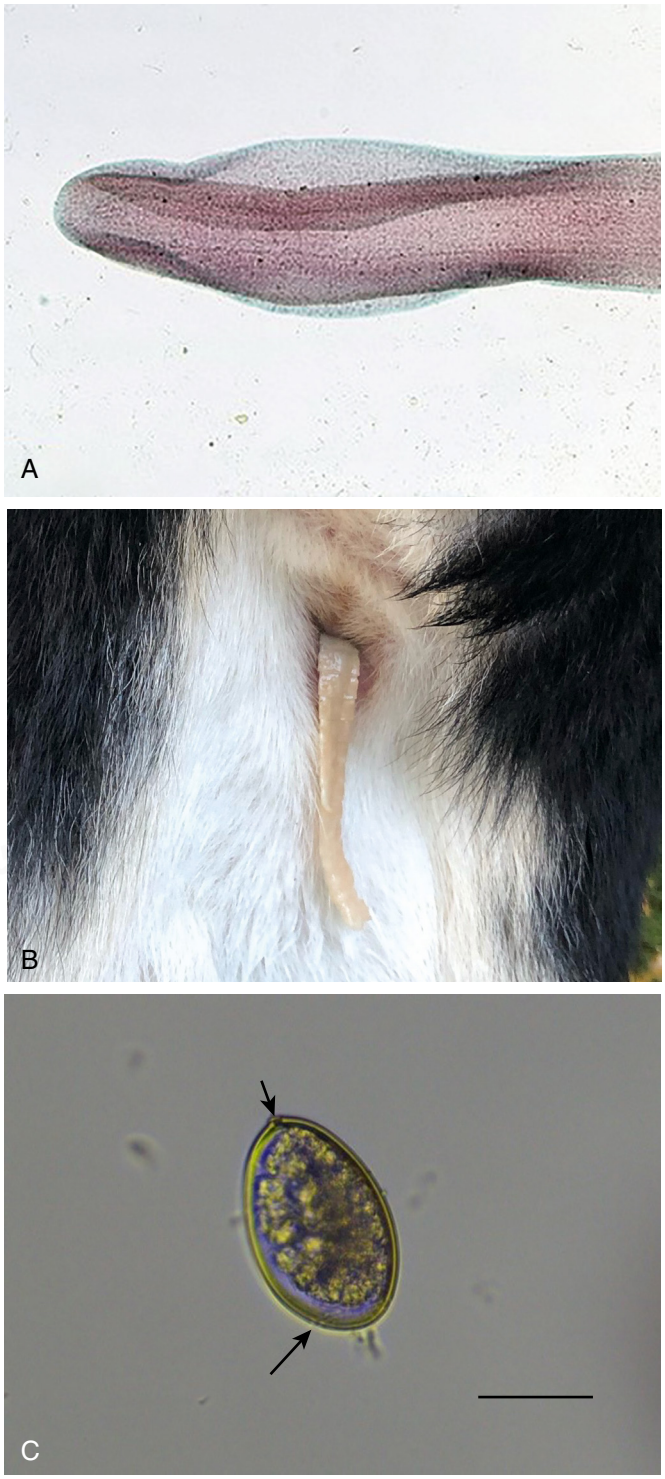

Fig. 115.18 Morphologic features of *Diphyllobothrium* sp. Anterior end (A) and chain (B) of *Diphyllobothrium* segments (proglottids) protruding from the anus of a 6-month old shepherd mix dog. (C) Egg. Note the operculum *(long arrow)* and pore in shell wall *(short arrow)*. Bar = 30 µm. (A, courtesy of National Center for Veterinary Parasitology, Oklahoma State University. TREATMENT AND PROGNOSIS

Praziquantel has been reported to be efficacious for treatment of *D. latum* infections in dogs and cats, but increased dosages are required beyond label recommendations (Table 115.7). Some authors have reported efficacy in dogs at 7.5 mg/kg, PO, either singly or for 2 consecutive days.[11,188] However, both the authors of this chapter and others have observed infections in dogs that have not been eliminated by these dosage regimens. A single dose of 35 mg/kg eliminated *D. latum* from infected cats[189]

TABLE 115.7 Recommended Drugs for Treating *Diphyllobothrium latum* Infections in Dogs and Cats

Drug	Species	Dose (mg/kg)	Route
Praziquantel	D	7.5[a]	PO
	C	35	PO

[a]Some authors recommend a second treatment, 24 hours after the first. In some dogs, a higher dose (35 mg/kg) is required.
C, cat; *D*, dog.

and has eliminated infections in dogs (Andrew Peregrine, unpublished observations).

PREVENTION

Diphyllobothrium latum infections in dogs and cats are acquired by ingestion of raw or undercooked fish. However, freezing fish for over 48 hours at −18°C, or cooking fish (core temperature ≥ 50°C) for ≥ 5 minutes, will eliminate infection risk.[178] Preventing animals from roaming freely or scavenging dead fish will also prevent infection.[190]

PUBLIC HEALTH ASPECTS

Diphyllobothrium latum infection is an important fish-borne zoonosis,[172] but dogs and cats infected with *D. latum* are not a direct risk to humans. Worldwide, approximately 20 million people are infected with *Diphyllobothrium* spp., of which *D. latum* and *D. nihonkaiense* are the most common.[172,178] As with dogs and cats, human infections are acquired by ingestion of raw or undercooked fish that contains plerocercoids. Smoking or marinating fish typically does not kill the plerocercoid.[191] Increased consumption of carpaccio, ceviche, sushi, sashimi, and other dishes made from raw fish has been associated with increased risk of *D. latum* infection in people.[172,184] Intestinal infections in people are typically clinically silent. However, some individuals experience poorly defined symptoms that may include mild abdominal discomfort, nausea, diarrhea, constipation, and weakness. Occasionally, heavy, prolonged *D. latum* infections may result in a megaloblastic anemia due to absorption of vitamin B_{12} by tapeworms.[192] Infections are readily eliminated by treatment with praziquantel or niclosamide.[178]

SPIROMETRA SPP. INFECTION

ETIOLOGY AND EPIDEMIOLOGY

Spirometra spp. are diphyllobothridean tapeworms and infect wild and domestic carnivores, including cats and occasionally dogs. The most important species appear to be *Spirometra erinaceieuropaei/Spirometra erinacei* (Asia, Australia, Europe), *Spirometra mansonoides* (North and South America), and *Spirometra mansoni* (Asia). Adult parasites are found in the small intestine of cats, dogs, and wild carnivores.[193] In the USA, infection is most common in cats in the Gulf Coast and southeastern states, with additional reports from Hawaii, New Jersey, New York, and Pennsylvania.[194] In stray cat populations from Syracuse, New York and New Jersey, the prevalence was 3% and 1%, respectively.[13,195] *Spirometra* sp. was detected in 7.9% of shelter cats in Florida.[196] Typically, higher prevalences have been detected in the Gulf Coast states of southeastern United States (e.g., Florida) where aquatic ecosystems support the life cycle of *Spirometra* spp. In a necropsy study

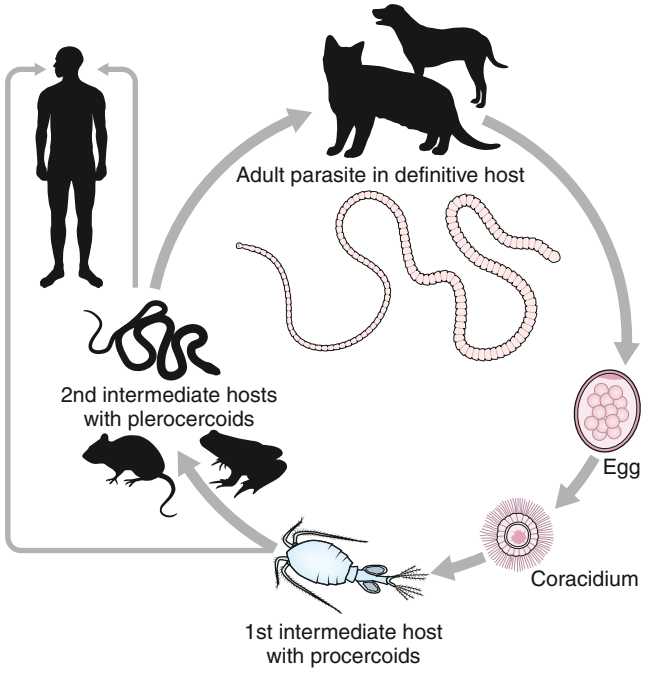

Fig. 115.19 Life cycle of *Spirometra* sp.

in Brazil, 4.1% of cats were infected with *S. mansonoides*.[4] In northern Portugal, 0.3% of dogs living on farms were positive for *Spirometra* sp. using fecal flotation and sedimentation.[197] In Iran, *Spirometra* spp. were found in 7.4% of dogs and 33.3% of cats at necropsy.[198] In Japan, 1.7% of owned cats were infected with *S. erinacei* as determined using fecal sedimentation.[199] In China, 40.5% of cats and 27.5% of dogs from 23 villages had eggs of *S. mansoni* detected in feces using the Kato-Katz technique.[200] In Malaysia, 9.2% of stray cats and 3.5% of stray dogs were positive for *Spirometra* sp. by fecal sedimentation.[201] In Thailand, 4.0% of cats and 0.6% of dogs from an animal refuge were infected with *S. mansoni* by fecal sedimentation.[202]

Like *Diphyllobothrium* spp., *Spirometra* spp. differ from the more common cyclophyllidean tapeworms in several aspects of their life cycle (Fig. 115.19). Firstly, they shed individual eggs into the intestinal tract through a mid-ventral uterine pore of individual segments, rather than detach an egg-laden segment from the strobila. Secondly, the egg is operculated, hatches once it reaches water, and releases a ciliated coracidium that is free-swimming. The coracidium is then ingested by the first intermediate host, a copepod (e.g., *Cyclops* spp.) and matures into a procercoid. Thereafter, infected copepods are consumed accidentally by the second intermediate host (i.e., amphibians, reptiles, birds, rodents) while drinking water. In the second intermediate host, the procercoid develops into a plerocercoid, also referred to as a *spargana*, in the muscle or connective tissue. The plerocercoid stage is highly paratenic, meaning it can remain in this stage through a series of paratenic hosts. For example, if a tadpole is infected with plerocercoids and is consumed by a water snake, the plerocercoids will migrate through the snake's tissues but remain as plerocercoids in this new paratenic host. The parasite will survive this way until an infected paratenic host is ultimately consumed by a carnivore definitive host (e.g., cat or dog). This increases the odds that *Spirometra* spp. cestodes find their way into a definitive host. When an infected second intermediate host, or paratenic host, is consumed by a definitive host, the plerocercoid attaches to the small intestine wall and develops into an adult tapeworm. The prepatent period is 10 to 60 days in dogs and cats.

Furthermore, infection can persist up to 3.5 years in cats.[194,195,203] The duration of infection in dogs is unclear.

When plerocercoids are ingested by accidental hosts (e.g., rodents, pigs, humans), they may penetrate the intestinal wall and invade serous cavities, connective tissue, or internal organs (proliferative sparganosis). Such infections occasionally also occur in dogs, cats, and other definitive hosts.[195,204–206]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Infection with adult *Spirometra* spp. appears to be well tolerated by cats and dogs; however, vomiting, diarrhea, and weight loss have been reported.[13,195] The mechanism underlying disease has not been fully elucidated. Selective uptake of vitamin B_{12} by the adult and plerocercoid stage has been demonstrated,[207] but the significance of this phenomenon in cats and dogs is unknown. Clinical signs usually resolve quickly following treatment.

In sparganosis, spargana proliferate in abdominal and thoracic cavities, affecting the stomach, lungs, liver, and spleen, as well as in subcutaneous tissues. This is associated with chronic inflammation and fibrosis. Proliferative sparganosis is rare, but has been reported in dogs from Australia,[205] and cats and dogs from the USA.[204,206] Probable exposure routes include ingestion of copepods infected with procercoids in contaminated drinking water, and ingestion of plerocercoids in second intermediate or paratenic hosts.[3] Clinical signs vary depending on the tissue involved and disease can range from mild to severe. In Gainesville, Florida, USA, a 6-year-old cat was evaluated for abdominal pain; physical examination revealed a palpable abdominal mass. Proliferative sparganosis was diagnosed at necropsy; the liver and spleen and wall of the cat's stomach contained numerous spargana.[204] Two cats from southern Georgia were described that had subcutaneous cystlike masses.[208] In Tampa, Florida, a 21-month-old border collie was evaluated for progressive right thoracic limb lameness and subcutaneous edema. The subcutaneous tissue and intermuscular fascia contained multiple cavities filled with spargana. Septic pleuritis and peritonitis were detected later in the course of the disease. At necropsy, multiple spargana were found in the pleural and peritoneal cavities.[206] In Australia, five dogs have been reported with sparganosis; spargana were detected free in the abdominal cavity, in association with chronic fibrinous peritonitis or inflammation of the serosal surface of the GI tract or liver. Signs in three dogs included a palpable abdominal mass (n = 1) and abdominal distension (n = 2); in the remaining two dogs, sparganosis was an incidental finding at surgery (n = 2).[205] Another dog from southeastern Australia was evaluated for pneumothorax secondary to pulmonary involvement; exploratory thoracotomy revealed numerous white nodules throughout the pleura and pulmonary parenchyma (Fig. 115.20).[209]

DIAGNOSIS

Laboratory Abnormalities and Diagnostic Imaging

In animals with proliferative sparganosis, laboratory abnormalities and diagnostic imaging findings depend on the location of affected tissues. For example, pneumothorax was evident in one dog on plain thoracic radiographs, together with irregular soft-tissue opacities in the region of the distal eighth and ninth ribs (Fig. 115.20A).

Microbiologic Tests

Diagnosis Using Fecal Examination

Short (usually < 5 cm) chains of mature segments may be recovered from feces or vomit. Occasionally, longer chains are recovered (Fig. 115.21A and B). These segments can be identified as diphyllobothridean tapeworms by the presence of a medial uterine pore and operculated eggs within segments.[3,194]

Eggs can be recovered by flotation. However, lower SpG flotation solutions may be inadequate to float the heavy eggs; the diagnostic sensitivity of flotation methods using $ZnSO_4$ (specific gravity 1.18) or $NaNO_3$ (specific gravity 1.18) is significantly less than sucrose (specific gravity 1.27) for recovery of *Spirometra* spp. eggs.[194,210] Fecal sedimentation can also be used to recover *Spirometra* spp. eggs.[20] *Spirometra* spp. eggs are yellow-brown and 60 to 75 µm × 35 to 37 µm, have an operculum at one end, and are narrowed at both ends (Fig. 115.21C). They may be mistaken for the similar, but more rounded, eggs of *Diphyllobothrium* spp.[3,20] Geographic location can suggest the species involved. In the Americas, while *D. latum* is most common in the Great Lakes region of North America, *S. mansonoides* is most common in the southeastern USA and parts of South America.[17,194] Eggs of *Spirometra* spp. can also be mistaken for trematode eggs. Both *Spirometra* spp. and *Paragonimus* spp. produce eggs that are unembryonated when shed, but *Spirometra* spp. eggs are smaller than those of *Paragonimus kellicotti* (lung fluke; North America; eggs 75–118 µm × 42–67 µm) and other *Paragonimus* species around the world (e.g., *Paragonimus westermani*, the Japanese lung fluke, and *Paragonimus heterotremus* in Asia). The liver fluke of cats (*Platynosomum concinnum*), found in the southeastern USA and the Caribbean, produces smaller operculated eggs that contain a miracidium (see Chapter 118).[11,20,194]

Recovery of plerocercoids from tissue is necessary for diagnosis of sparganosis. Additionally, molecular identification can be performed by isolating DNA from segments of the tapeworm. PCR assays have been utilized to identify *S. erinacei*[209,211] and *S. mansonoides*.[212] In dogs, inflammatory tissue cysts may be filled with both intact and degenerate white spargana surrounded by red, cloudy, thick fluid.[206] Microscopic findings include large numbers of spargana surrounded by large numbers of pyogranulomatous inflammatory cells in variably sized cystic spaces and reactive fibrocollagenous stroma. Larval parenchyma is strongly PAS positive.[208] The absence of scolices and suckers helps differentiate plerocercoid larvae from those of cyclophyllidean tapeworms (*Mesocestoides*, *Echinococcus* spp.).

TREATMENT AND PROGNOSIS

There is no approved treatment for infection with *Spirometra* spp. in dogs or cats. Treating animals infected with adult parasites requires higher dosages of praziquantel than is required for *Taenia* spp. or *D. caninum*; a protocol of 25 mg/kg of praziquantel (PO or SC) for 2 consecutive days is effective (Table 115.8).[194] Treatment of proliferative sparganosis in dogs utilizing combination therapy with praziquantel (50 mg/kg SC once a week for 3 weeks) and fenbendazole (100 mg/kg PO q12h for 28 days), along with abdominal lavage to remove as many plerocercoids as possible, may be attempted, but prognosis is guarded.[206] There is also a report of a dog surviving proliferative sparganosis utilizing a protocol of alternating 3-week courses of mebendazole (20 mg/kg PO q24h for 21 days) and praziquantel (5 mg/kg PO q24h for 21 days) for 3 months.[205] The effect of substituting other benzimidazoles for mebendazole is unknown.[3]

PREVENTION

While reinfection in endemic areas is likely, the only preventive measure is to limit access to intermediate host species.[194] Therefore limiting a dog's or cat's access to amphibians, birds, reptiles, and small mammals that are potential intermediate hosts should aid in preventing *Spirometra* spp. infections.

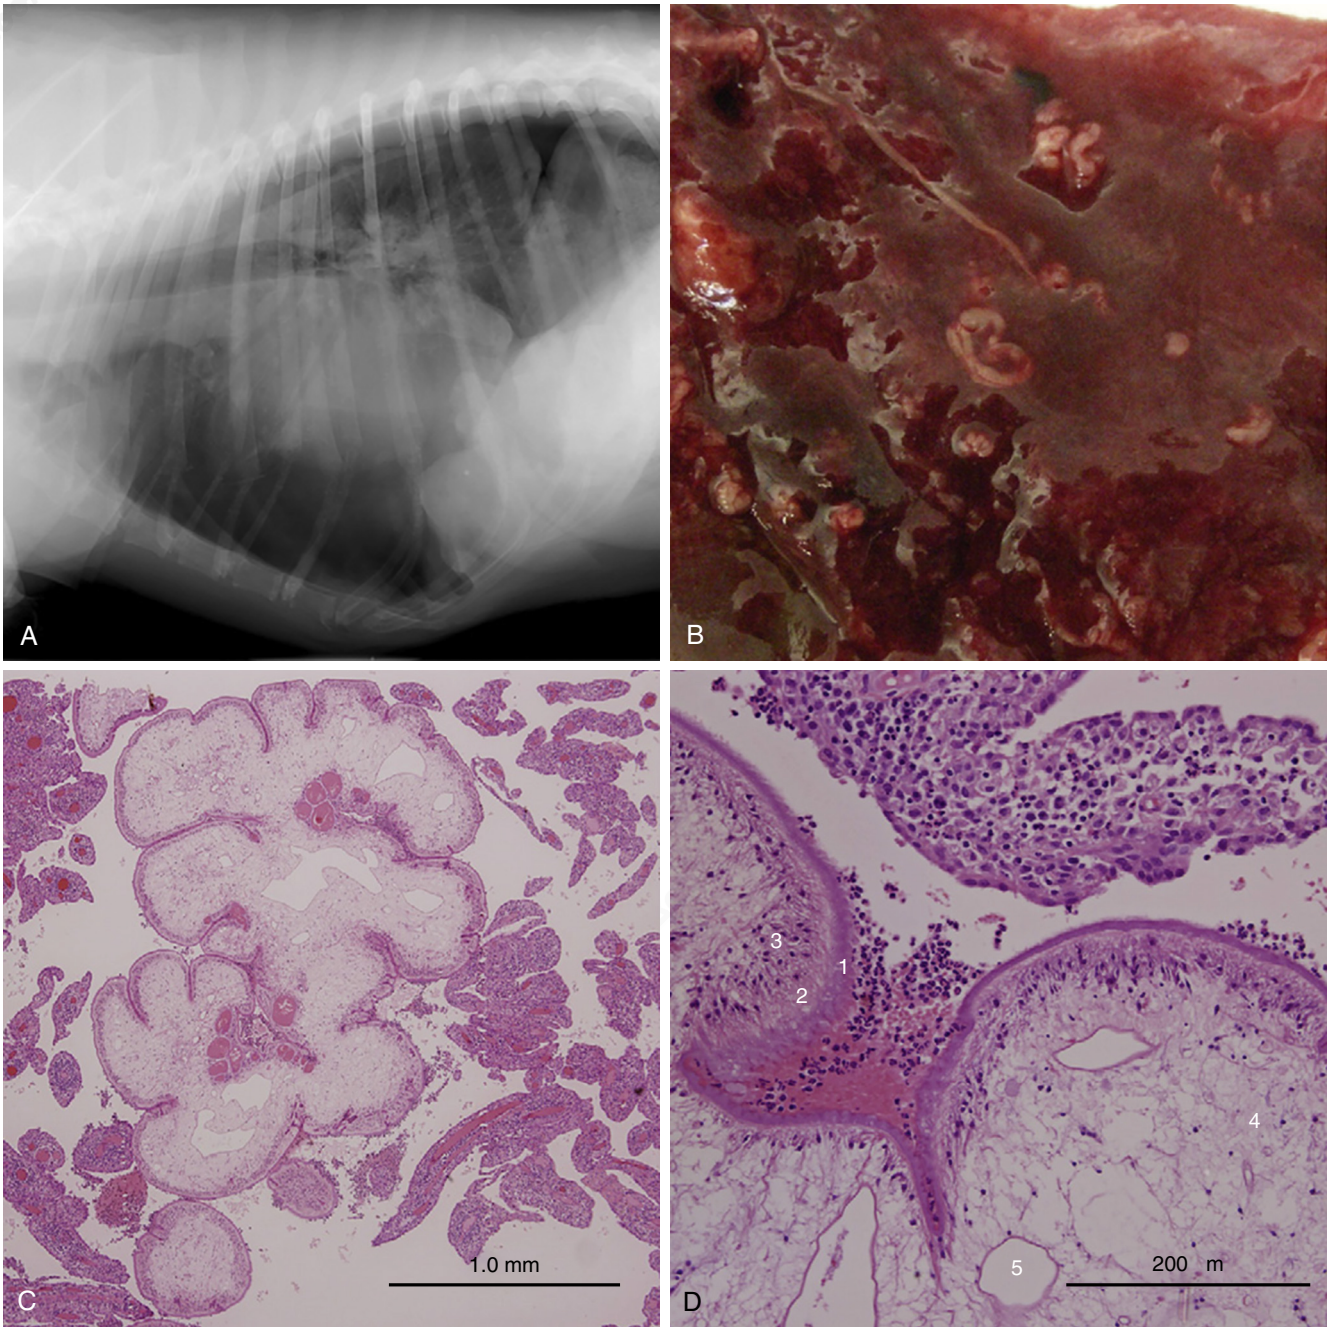

Fig. 115.20 Clinical images from a 12-year-old female spayed Labrador retriever from southeastern Australia with pulmonary sparganosis due to *Spirometra erinacei*. (A) Left lateral thoracic radiograph. There is evidence of pneumothorax, and soft-tissue opacities are present adjacent to the pleural surface of the diaphragm. (B) Pleural surface of the diaphragm with *Spirometra* plerocercoids. (C) Histological section of a plerocercoid and surrounding thickened omentum. (D) Histological section of omentum and plerocercoids showing the parasite's tegument *(1)*, subtegumental muscles *(2)*, perikaryon *(3)*, parenchyma *(4)*, and osmoregulatory canals *(5)*. There is neutrophilic inflammation around the parasite. (Reprinted from Simpson C, Jabbar A, Mansfield CS, et al. Molecular diagnosis of sparganosis associated with pneumothorax in a dog. *Mol Cell Probes*. 2012;26:60–62.)

PUBLIC HEALTH ASPECTS

Sparganosis of humans is caused by the plerocercoid stage of various tapeworms within the *Spirometra* genus. Humans can be infected by several routes including drinking water containing copepods infected with procercoids, ingesting the flesh of second intermediate hosts infected with plerocercoids (e.g., snakes, frogs), and via direct migration into a wound or across a mucous membrane from infected flesh (e.g., applying the incised body of a freshly caught frog to an open wound or injured eye as a traditional poultice).[11,203,213] Human sparganosis is a food-borne disease, therefore the risk of a human developing sparganosis directly from an infected dog or cat is minimal. Epidemiological data suggest

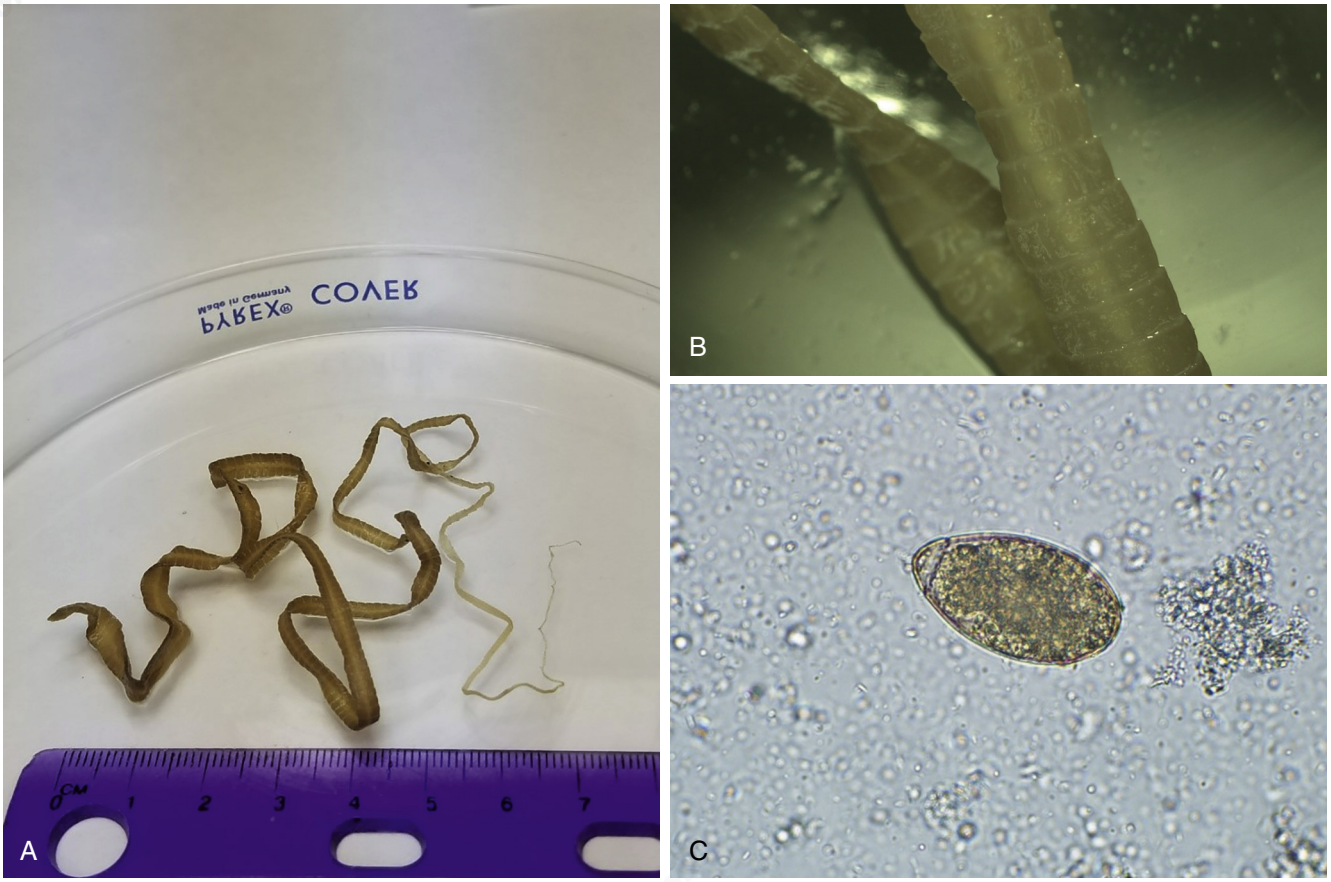

Fig. 115.21 Morphologic features of *Spirometra* sp. cestodes. (A) Formalin-fixed *Spirometra* sp. specimen of segments from a domestic cat. Note the small proximal segments relative to the larger distal (mature) segments with centrally located genital pores. (B) Strobila. Note the medial genital pores giving the appearance of a zipper. that the most common cause of human sparganosis is consumption of raw freshwater frogs or snakes.[203] Human sparganosis most often presents as subcutaneous nodules containing a plerocercoid; scrotal and breast nodules are also described, and surgical removal is indicated.[214,215] Occasionally, the plerocercoid develops in the lungs, peritoneal cavity, eyes, or CNS. Cerebral sparganosis is of particular concern as it may be associated with neurological signs and even death.[194] Such infections have primarily been described in eastern and southeastern Asia.

CASE EXAMPLE

Signalment
"Zoe," a 5-year-old female, spayed, shar-pei/beagle mix that lived in southern Ontario, Canada.

History
Zoe was evaluated at a Veterinary Emergency and Referral Hospital in southern Ontario with a history of urinary incontinence for the previous 18 months. She was able to urinate and postured normally during micturition. There was no history of polyuria, polydipsia, or stranguria. Bloodwork and urinalysis performed 12 months earlier by the referring veterinarian were unremarkable, but at this visit a CBC revealed non-regenerative anemia (HCT 34% [RR, 38–57%], MCHC 32.1 [RR: 32.6-39.2 g/L]). On urinalysis, SpG was 1.026; some calcium oxalate crystals were noted. The urine protein:creatinine ratio was unremarkable and aerobic bacterial urine culture was negative. An abdominal ultrasound examination revealed no abnormalities of the urinary tract. However, a poorly defined, 5 × 3 cm mass was detected within the left liver lobe adjacent to the diaphragm. Due to the location of the lesion, fine-needle aspirates were not possible. Thoracic radiographs were unremarkable. An abdominal CT scan revealed a 4.5-cm diameter, rounded mass lesion in the left cranioventral and lateral aspect of the hepatic parenchyma in close proximity to the diaphragm. The mass was suspected to involve the left medial and left lateral lobes (see Fig. 115.9). After contrast administration, small septations were evident in the lesion creating a subtle honeycomb appearance. The periportal, gastric, splenic, and pancreaticoduodenal lymph nodes were mildly enlarged. No other abnormalities were detected.

Zoe was started on phenylpropanolamine for suspected sphincter mechanism incontinence. However, the incontinence appeared to worsen. The phenylpropanolamine dose was increased, but without improvement. Zoe had a history of aggression and was known to bite dogs and people. As a result, limited physical examinations had been performed; sedation was required for any procedure. Two months after being seen at the referral hospital, Zoe was evaluated at Ontario Veterinary College. At that time the owner reported she had been eating and drinking normally; no vomiting or diarrhea had been noted. She was still incontinent despite daily treatment with phenylpropanolamine.

Physical Examination Findings
The dog was bright, alert, and responsive. Body weight was 19.8 kg. After sedation (15 μg/kg dexmedetomidine IM and 0.4 mg/kg butorphanol IM), pulse was 48/minute, respiration rate was 28/minute, temperature was 99.3°F (37.4°C). No heart murmurs, arrhythmias, or abnormal breath sounds were auscultated. No masses or organomegaly were detected on abdominal palpation. No abnormalities of the genitourinary tract were detected. All other parameters were unremarkable.

Laboratory Findings
A PCV and total protein by refractometry were unremarkable.

Imaging Findings
Abdominal ultrasound examination revealed an 8 × 8 × 6 cm mass in the left liver, close to the diaphragm, with echogenic material in the center.

The initial differential diagnosis for the hepatic mass was hepatic neoplasia (hepatocellular carcinoma, adenoma, hemangiosarcoma, lymphoma, other) or a benign liver mass (nodular regeneration, granuloma, hematoma). In order to obtain a biopsy specimen, exploratory laparotomy was performed. A 7 × 6 × 4 cm mass was identified within the left medial liver lobe that was white/brown and slightly nodular (see Fig. 115.11A). The affected lobe was removed using a thoracoabdominal stapler; two circumferential ligatures were placed on remaining hilar vessels. The remainder of the liver and other abdominal organs were grossly unremarkable.

Pathologic Findings
On cut section, the resected mass was soft, white, and irregular, and contained multiple small (1 to 5 mm) cavities. On histopathology, effacing and replacing 80% to 90% of the hepatic parenchyma was a well-demarcated, partially encapsulated, expansile nodule composed of coalescing cystic spaces. These spaces were surrounded by abundant, variably mature, fibrovascular tissue and mixed inflammatory cells. Cystic spaces were lined by a variably folded eosinophilic, homogeneous, laminated (hyaline) membrane and an inner, variably intact, germinal epithelial layer. Cysts contained eosinophilic necrotic debris and mixed inflammatory cells. Rare small calcareous corpuscles were observed. However, no protoscolices were seen in the sections (see Fig. 115.11B). The same tissue sections stained positive with PAS stain.

Microbiologic Testing
Fresh frozen liver tissue was submitted for PCR testing. A PCR product was generated using primers specific for *E. multilocularis*.[109] The sequence generated was 100% identical (344/344 bp) to reference sequence of *E. multilocularis*.

Diagnosis
Hepatic alveolar echinococcosis (AE).

Treatment
Zoe was treated with praziquantel (5 mg/kg PO), to eliminate a potential intestinal infection. When the results of nucleic acid testing became available, treatment with albendazole (10 mg/kg PO q24h) for life was commenced.

Comments
Because this mass was located at the liver hilus, it was possible that a small amount of affected liver tissue remained after surgery. Treatment with albendazole was therefore particularly important. Since albendazole can occasionally cause bone marrow suppression in dogs, a CBC was recommended every week for the first month, monthly for the first 3 months, then every 3 months thereafter. A repeat abdominal ultrasound/CT scan was recommended every 6 to 12 months to monitor for recurrent disease. The diagnosis of AE in this case was an incidental finding and not likely associated with the urinary incontinence, which remained unresolved.

Miscellaneous Nematode Infections

Jennifer K. Ketzis, Susan E. Little, Judit M. Wulcan

KEY POINTS

Physaloptera spp. Infection

- First Described: *Physaloptera praeputialis* was first isolated from a domestic cat and described in 1889 (von Linstow). *Physaloptera rara* was first isolated from a domestic dog in North America and described in 1918 (Hall and Wigdor).
- Cause: *Physaloptera praeputialis* and *Physaloptera rara.*
- Affected Hosts: Domestic and wild dogs and cats.
- Geographic Distribution: Worldwide (*P. praeputialis*), North America (*P. rara*).
- Route of Transmission: Ingestion of intermediate insect or paratenic hosts.
- Major Clinical Signs: May cause chronic intermittent vomiting. Infections often are subclinical.
- Differential Diagnosis: Any GI or systemic cause of chronic vomiting (e.g., idiopathic gastritis, gastric foreign body, gastric neoplasia, food intolerance/allergy, chronic pancreatitis). Eggs must be differentiated from those of *Spirocerca lupi.* Vomited nematodes must be differentiated from *Toxocara canis*, *Toxocara cati*, and *Toxascaris leonina.*
- Human Health Significance: *Physaloptera* spp. of dogs and cats are not considered a zoonosis.

Spirocerca lupi Infection

- First Described: Karl Asmund Rudolphi (Swedish parasitologist and "father" of helminthology), 1809.
- Cause: *Spirocerca lupi* (esophageal worm), superfamily Spiruroidea, order Spirurida.
- Affected Hosts: Domestic dogs, wild canids, and other carnivores; rarely cats.
- Geographic Distribution: Worldwide but primarily in tropical and subtropical regions with the highest prevalence in the southern United States, Brazil, the Caribbean, South Africa, and the Middle East.
- Route of Transmission: Dogs become infected after ingestion of the intermediate host (coprophagous beetles in the family Scarabaeidae, order Coleoptera) or paratenic hosts (e.g., birds, frogs, lizards and other reptiles, rodents) containing a third-stage larva.
- Major Clinical Signs: Vomiting or regurgitation, odynophagia, ptyalism, respiratory difficulty, cough, weight loss, and fever.
- Differential Diagnoses: Differentials for regurgitation include esophageal foreign bodies, esophageal strictures, esophageal neoplasia or granulomas of other origin, and megaesophagus. Differentials for vomiting include any GI or systemic cause of chronic vomiting (e.g., idiopathic gastritis, gastric foreign body, gastric neoplasia, food intolerance/allergy, chronic pancreatitis). Eggs must be differentiated from *Physaloptera* spp.
- Human Health Significance: *Spirocerca lupi* infection is not considered a zoonosis.

Strongyloides spp. Infection

- First Described: Larval stages of *Strongyloides stercoralis* were first isolated from human feces in 1876; the first identification of natural infection in a dog was in 1914. In cats, *Strongyloides planiceps* was isolated by Leiper from a rusty tiger cat (*Felis planiceps*) in 1927. *Strongyloides felis* was first isolated from cats in India in 1925. While *Strongyloides tumefaciens* was first noted in cats in the USA in 1929, it was not described or named until 1941.
- Cause: *Strongyloides* are commonly referred to as threadworms and belong to the family Strongyloididae in the order Rhabditida.
- Affected Hosts: *Strongyloides stercoralis* occurs in dogs, cats, non-human primates, and people. *Strongyloides felis* and *S. tumefaciens* have been described in domestic and wild cats; *S. planiceps* in domestic and wild cats, dogs, and wild carnivores.
- Geographic Distribution: Worldwide.
- Route of Transmission: Oral, percutaneous, and, less frequently, transmammary infections occur in dogs. Oral and percutaneous transmission occur in cats.
- Major Clinical Signs: Subclinical infections are common. Cough and other signs of bronchial involvement can occur in the early stage of infection in dogs. Severe enteritis with profuse diarrhea can occur in the later stage of infection. Skin papules are sometimes seen when larvae enter the dog percutaneously. In cats, clinical signs are rare, but diarrhea has been reported in some infections.
- Differential Diagnoses: The clinical signs are nonspecific and must be differentiated from other causes of diarrhea, for example, dietary, infectious, inflammatory, toxic, or extraintestinal causes of diarrhea. In puppies, *S. stercoralis* must be differentiated from other parasites that have larval lung migration stages (e.g., *Toxocara canis*, *Ancylostoma caninum*), cause diarrhea, and are able to enter the animal percutaneously (e.g., *Ancylostoma caninum*, *Uncinaria stenocephala*). In cats and dogs, recovered larvae must be distinguished from lungworm; hookworm larvae.
- Human Health Significance: *Strongyloides stercoralis* can be transmitted from dogs to people and from people to dogs. Zoonotic transmission of cat *Strongyloides* has not been studied; there have been no reports of *Strongyloides* being transmitted from cats to people.

Mammomonogamus spp. Infection

- First Described: *Mammomonogamus ierei* (synonym *Syngamus ierei*) was first described by Buckley in 1934, who isolated it from a domestic cat in Trinidad. *Mammomonogamus auris* (synonym *Syngamus auris*) was first described by Faust and Tank in 1934, who isolated it from the middle ear of several cats in China.
- Cause: *Mammomonogamus ierei* and *Mammomonogamus auris*, which occur in cats, are commonly referred to as gapeworms. These nematodes belong to the family Syngamidae.

- Affected Hosts: *Mammomonogamus ierei* and *M. auris* infect domestic cats.
- Geographic Distribution: The distribution of *Mammomonogamus* is disparate, with *M. ierei* reported in the Caribbean and *M. auris* found in Asia.
- Route of Transmission: Unknown. Given the life cycle of other parasites in this family, it is likely that paratenic hosts are involved.
- Major Clinical Signs: Subclinical infections are common. However, infections can be associated with inflammation of the nasopharynx resulting in a mucoid nasal discharge, coughing, sneezing episodes, and weight loss with *M. ierei.* Head shaking has been seen in a cat with *M. auris* infection.
- Differential Diagnoses: Other infections that cause nasal discharge and sneezing (e.g., viral infections, *Eucoleus aerophilus*, *Cuterebra* spp.). In the case of *M. auris*, *Otodectes cynotis* also can result in head shaking. The dark cerumen associated with *O. cynotis* infection does not occur with *M. auris* infection. Eggs of *M. ierei* and *M. auris* can be seen in a fecal flotation.
- Human Health Significance: There are no reports of *M. ierei* and *M. auris* infecting humans and neither are believed to be zoonotic.

Dioctophyme renale Infection

- First Described: *Dioctophyme renale* was first described by the German zoologist Johann Goeze in 1782; earlier reports of giant kidney worms date back to the late 1500s.
- Cause: *Dioctophyme renale*, the giant kidney worm, is the largest parasitic nematode of domestic animals (family Dioctophymidae in the order Ascaridida).
- Affected Hosts: Most cases of *D. renale* in domestic animals are reported in dogs, with infections occasionally seen in cats and other host species, including humans. Fish-eating vertebrates, especially mink and other mustelids, are the natural definitive host.
- Geographic Distribution: *Dioctophyme renale* has a sporadic, worldwide distribution although reports of infection are rare in Africa and Asia. The parasite is widespread in the Americas and has been reported from dogs and other hosts from Canada to Brazil.
- Route of Transmission: Eggs are shed in the urine of infected definitive hosts. First-stage larvae develop inside the eggs and hatch following ingestion by aquatic oligochaete annelid intermediate hosts found in the detritus of ponds and streams. Third-stage larvae develop within the tissues of the annelids and may be passed to paratenic hosts, such as fish and frogs, when they ingest the intermediate hosts. Dogs and other final hosts are infected upon ingestion of annelids, or, more commonly, by ingesting third-stage larvae in fish paratenic hosts.
- Major Clinical Signs: Most infections are subclinical. Some dogs have hematuria, renal pain, renal enlargement, abdominal pain, and abdominal effusion. Development of worms in subcutaneous fat has also been reported.
- Differential Diagnoses: Other causes of cystitis; renal neoplasia; or a retroperitoneal, abdominal, or subcutaneous mass. Abdominal *D. renale* infection in cats can resemble FIP. Eggs of *D. renale* are not always present in urine sediment and thus diagnosis may sometimes be made by ultrasound or exploratory laparotomy.
- Human Health Significance: Although rare, zoonotic infections with *D. renale* have been reported and are associated with ingestion of larvae in undercooked fish or frogs.

Dracunculus insignis Infection

- First Described: *Dracunculus* spp. have been described since antiquity. *Dracunculus medinensis* was described by Linnaeus in 1758, and *Dracunculus insignis* by Leidy in 1858.
- Cause: *Dracunculus insignis*, a subcutaneous worm of raccoons and other carnivores that also infects dogs, is a spirurid nematode closely related to the human Guinea worm, *Dracunculus medinensis.*
- Affected Hosts: Most cases of *D. insignis* infection in domestic animals are reported in dogs, although ferrets are also susceptible; a limited number of cases have been described in cats. Wild carnivores, especially raccoons, are most commonly infected and considered the natural definitive host of this parasite in North America. Although primarily a human parasite, *D. medinensis* also readily infects dogs in endemic areas.
- Geographic Distribution: *Dracunculus insignis* has only been reported from Canada and the United States. Due to concerted eradication efforts, *D. medinensis* is currently limited to three countries in Africa. Other *Dracunculus* spp. have been reported from mammals, snakes, and turtles in the Western Hemisphere and from snakes in Europe, Africa, Asia, and Australia.
- Route of Transmission: Gravid female *Dracunculus* spp. migrate to the extremities of the definitive host and form subcutaneous cysts. The presence of the nematode induces the formation of blisters; when immersed in water, the uterus of the nematode ruptures, releasing hundreds of thousands of larvae into the water. The motile larvae are ingested by copepod intermediate hosts. After third-stage larvae develop, copepods are ingested by definitive hosts drinking water; the nematodes then migrate to subcutaneous locations, mature, mate, and eventually form new cysts to continue the life cycle. Alternatively, infected copepods may be ingested by aquatic vertebrates which can then serve as paratenic hosts.
- Major Clinical Signs: Dogs with *D. insignis* present with fluctuant subcutaneous swellings, usually on a distal extremity or, less commonly, the thorax. Lesions are often pruritic and painful. The skin may appear ulcerated or bear a patent opening; when the affected limb is immersed in water, an adult nematode may emerge.
- Differential Diagnoses: Other, more common causes of subcutaneous masses include lipoma, reactive lymph nodes, neoplasia, or other dermal parasites (e.g., *Cuterebra*, *Dirofilaria repens*). However, the distinct location on a distal extremity and, when present, the appearance of a patent ulcer through which a nematode emerges, considerably narrows potential diagnoses. Specimen collection using fine-needle aspiration often leads to recovery of *D. insignis* larvae. Long female nematodes may be encountered during surgical exploration of the cystic lesion.
- Human Health Significance: Human infection is most commonly by *D. medinensis.* Recent reports of *D. medinensis* in domestic dogs have created challenges in the final stages of eradication efforts for the human Guinea worm.

Ocular Nematodes

- First Described: *Onchocerca lupi* was first described in a feral wolf in Russia. *Thelazia callipaeda* was first described by Ralliet and Henry in 1910 and *Thelazia californiensis* by Price in 1930.
- Cause: *Onchocerca lupi* and *Thelazia* spp. Aberrant migration has also resulted in other species of nematodes reported from the eye, including *Dirofilaria* spp., *Dracunculus* spp., and *Toxocara* spp.
- Affected Hosts: *Onchocerca lupi* is primarily a parasite of domestic dogs although feline onchocerciasis has been reported. *Thelazia callipaeda* and *T. californiensis* are described from dogs and cats with occasional reports from wildlife definitive hosts. Other *Thelazia* spp. infect the eyes of large animals.
- Geographic Distribution: Ocular nematodes occur sporadically around the world, with *O. lupi* reported from northern Asia, southern and central Europe, and the southwestern United States; *T. callipaeda* from Asia and, more recently, Europe; and *T. californiensis* from western North America.

- Route of Transmission: The life cycle of *O. lupi* is not fully understood, but other *Onchocerca* spp. are transmitted between definitive hosts by arthropod intermediate hosts, including black flies (*Simulium* spp.) and biting midges (*Culicoides* spp.). *Thelazia* spp. are transmitted by muscid flies feeding around the eyes.
- Major Clinical Signs: Ocular lesions due to *O. lupi* and *Thelazia* spp. may be mild to severe although many animals appear largely subclinical. In the acute phase of *O. lupi* infection, general ocular discomfort is seen with excessive lacrimation and photophobia. In chronic infections, nodules develop on the sclera, conjunctiva, and eyelids. Infection with *Thelazia* spp. may be associated with chronic conjunctivitis but nodules are not present.
- Differential Diagnoses: Many infectious, inflammatory, and traumatic conditions can cause ocular irritation and conjunctivitis. However, once nematodes are visualized coiled in inflammatory tissue on the conjunctiva (*O. lupi*) or free under the eyelids or nictitating membrane (*Thelazia* spp.), the diagnostic list of differentials is short. Other nematodes that occasionally migrate aberrantly to the eyes include *Angiostrongylus vasorum, Dirofilaria* spp., *Dracunculs insignis*, *Toxocara* spp., and *Trichinella spiralis* (eyelid).
- Human Health Significance: Human infection with both *O. lupi* and *Thelazia* spp. occasionally occurs resulting in ocular irritation, excessive lacrimation, and the presence of intraocular nematodes.

INTRODUCTION

This chapter reviews clinically relevant aspects of several nematode parasites of dogs and cats that are occasionally encountered in veterinary practice. Some affect the GI system, including *Physaloptera*, a stomach worm associated with chronic vomiting, and *Strongyloides stercoralis*. *Strongyloides stercoralis* is a nematode that alternates between a free-living and parasitic lifestyle and that, when parasitizing the small intestine, can induce severe diarrhea, particularly in puppies. Other nematodes in this chapter may cause esophageal (*Spirocerca lupi*), otic or nasopharyngeal (*Mammomonogamus* spp.), dermal (*Dracunculus insignis*), renal (*Dioctophyme renale*), or ocular (*Onchocerca lupi, Thelazia* spp.) pathology.

PHYSALOPTERA SPP. INFECTION

ETIOLOGY AND EPIDEMIOLOGY

Physaloptera is a genus of spirurid nematodes belonging to the family Physalopteridae in the order Spirurida. Numerous species have been reported in a variety of vertebrate hosts worldwide, but only two species, *Physaloptera praeputialis* and *Physaloptera rara*, are regularly reported in dogs and cats. *Physaloptera praeputialis*, first described in 1889 (von Linstow), occurs worldwide and is considered primarily a parasite of cats, although it infects a variety of other mammals including domestic dogs, foxes, and wild felids.[1–5] *Physaloptera rara,* first described in 1918 (Hall and Wigdor), occurs in North America and is considered primarily a parasite of coyotes but also is found in domestic dogs and cats, raccoons, and other wild animals.[1,2,6–8]

Adult nematodes are between 2 and 6 cm long, white or pink, and have a cephalic collar and triangular, toothed pseudolabia. The males are slightly shorter than the females and have pedunculated caudal papillae and alae, joined anterior to the anus (Fig. 116.1).[3,6,9] *Physaloptera praeputialis* can be differentiated from *P. rara* by a cuticular sheath that covers the posterior end.[2] The eggs of the two species are indistinguishable and are small (49 to 59 µm x 30 to 34 µm), oval, thick-shelled, and contain fully formed larvae in fresh feces (Fig. 116.2).[2,10,11]

The life cycle of *Physaloptera* spp. includes intermediate insect hosts from the orders Coleoptera, Orthoptera, and Blattodea (beetles, crickets, and roaches) and paratenic hosts (snakes, lizards, frogs, hedgehogs). The complete diversity of insect and paratenic hosts is unknown. Cats and dogs become infected via the consumption of intermediate or paratenic hosts or feces from these hosts containing third-stage larvae (L_3). Adult *Physaloptera* spp. and larvae reside mainly in the stomach with some also found in the cranial duodenum, usually with their anterior end attached to the mucosa.[9,12] Larvae are not known to migrate. The prepatent period ranges from as few as 35 days to 156 days, with most infections requiring at least 60 days to reach patency. This wide variation in the prepatent period is potentially due to the source of infection (intermediate or paratenic

Fig. 116.1 *Physaloptera sp.* adults; adults range from 2 to 6 cm long. (Courtesy J. Ketzis.)

host).[2,3,6,12] In cats and dogs, most infections consist of only a few adult worms (1 to 8), although much higher numbers have been found in feral cats (25 to 30).[13,14]

Physaloptera spp. occur worldwide with most reports of infections in cats and dogs from North and South America, Australia, and Asia. There have only been a few reports of *Physaloptera* spp. in Europe and Africa in domestic dogs and cats.[2,15] In domestic dogs and cats, prevalence is typically below 5% with most studies in dogs showing a prevalence of <2% and cats with the higher prevalence.[10,15–24] This contrasts with some older studies from the 1940s to the mid-1980s where prevalence in cats was found to be from 20% to 40% and differs from wildlife species where it can be over 50%.[6,25,5,26,27]

Given the issues with diagnosis using many common fecal flotation solutions with lower specific gravity (e.g., <1.3), the prevalence of *Physaloptera* spp. in domestic dogs and cats could be underestimated. At the same time, prevalence could be decreasing with more widespread use of regular monthly heartworm preventives. Conversely, the high prevalence in wildlife species could potentially pose a concern where these animals frequent urban areas, which could increase exposure of domestic dogs and cats.

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Physaloptera spp. attach to the gastric or duodenal mucosa and feed on blood and tissue. Adult and immature *Physaloptera* can induce a catarrhal gastritis which may manifest as chronic, intermittent vomiting. Diarrhea, anorexia, and weight loss also can occur, although many infections are subclinical.[13,18,28] Differentials for *Physaloptera* spp. are broad and can include any GI or systemic cause of chronic vomiting (e.g., idiopathic gastritis, gastric foreign body, gastric neoplasia, food intolerance/allergy, chronic pancreatitis).[29]

DIAGNOSIS

Physaloptera eggs are particularly heavy compared to other common nematode eggs and occur intermittently in feces; overall egg numbers can be low when infections are of low intensity.[30] In addition, clinical signs can be induced by larval stages before eggs are present in the feces. Therefore fecal diagnosis is insensitive. When eggs are present, flotation methods with solutions of specific gravity >1.3 can be used; however, many standard flotation solutions are <1.3 SpG.[31,32] Direct smear can overcome the heavy egg issue but also lacks sensitivity due to the limited quantity of feces examined.[18,31–33] When eggs are seen, they must be differentiated from those of *Spirocerca lupi*.

Frequently, a diagnosis is made when dogs or cats vomit nematodes or following gastroscopy.[13,28] When nematodes are vomited, they must be differentiated from *Toxocara canis*, *Toxocara cati*, and *Toxascaris leonina*. Although adult worms are readily visible using gastroscopy, immature stages, which also induce clinical signs, might be more challenging to see. Peripheral eosinophilia has been reported in a minority of cases.[13,28]

On gross necropsy examination the gastric wall may be normal or thickened, with mucosal petechiae or ecchymoses. Histologically, a diffuse lymphoplasmacytic gastritis is most commonly reported, sometimes with concurrent mucosal congestion, catarrhal gastritis, and histiocytic or eosinophilic infiltrates.[13,14]

TREATMENT AND PROGNOSIS

No anthelmintics are registered for the treatment of *Physaloptera* spp. infections in cats and dogs. Pyrantel pamoate (20 mg/kg PO repeated at 2 week intervals for a total of 2 to 3 administrations) is recommended, and with this treatment, prognosis is good.[33] Treatment with lower and single doses of pyrantel pamoate has shown limited efficacy; pyrantel pamoate (5 to 20 mg/kg PO) did not clear infections in cats.[34,35] In a single case report of infection in a dog, 5 mg/kg administered twice at a 2-week interval was effective; however, in a study of 10 dogs in which adult worms were removed via endoscopy prior to treatment, 15 mg/kg administered twice at 2- to 3-week intervals did not result in resolution of clinical signs in two dogs.[13,18] Other anthelmintics that have been used include ivermectin (200 µg/kg SC) in two dogs and two cats, fenbendazole (50 mg/kg, PO q24h for three days) in a single dog after manual removal of worms by endoscopy, and levamisole (8 mg/kg SC) in two cats.[13,28] The dose of ivermectin used was significantly higher than that in heartworm preventives and should not be used in sensitive breeds.

Endoscopic removal of adult nematodes can be effective. However, not all adult nematodes may be seen and larval stages can remain, requiring a follow-up anthelmintic treatment.[13,33]

IMMUNITY, VACCINATION, AND PREVENTION

There are no published data suggesting that dogs and cats develop immunity to reinfection and there are no vaccines to prevent infection. The primary means of prevention is to limit access to intermediate and paratenic hosts. No studies on the efficacy of monthly heartworm preventives (e.g., macrocyclic lactones) in preventing the establishment of *Physaloptera* spp. have been performed; however, data with ivermectin suggest that monthly heartworm preventives could limit infections.[28,33]

PUBLIC HEALTH ASPECTS

Physaloptera spp. of dogs and cats are not considered zoonotic.

SPIROCERCA LUPI INFECTION (SPIROCERCOSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Spirocerca lupi, first described by Rudolphi in 1809, belongs to the superfamily Spiruroidea in the order Spirurida.[36] *Spirocerca lupi* infects domestic and wild canids with some other mammals such as raccoons occasionally serving as a final host.[37–40] Adult *S. lupi* reside in nodules in the esophagus, are pink to red in color, and range in size from 3 to 7 cm, with the males being smaller than the females.[41–43] The eggs released by the female worms enter the lumen of the esophagus and are passed in the

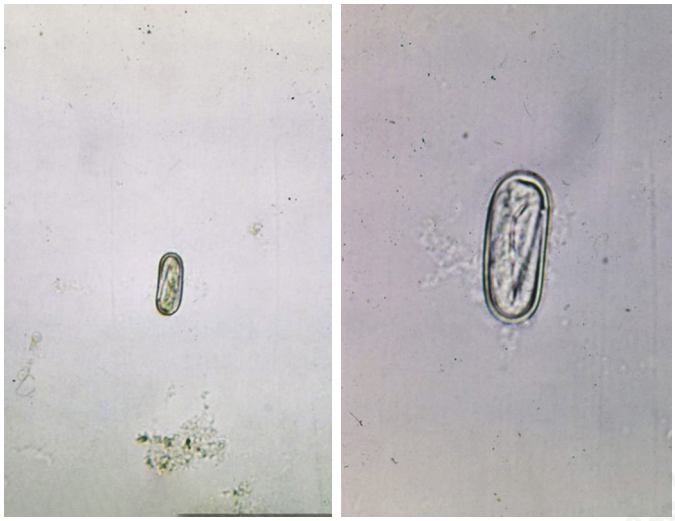

Fig. 116.3 *Spirocerca lupi* egg; eggs are larvated in fresh feces and are approximately 20 to 37 µm x 11 to 18 µm. (Courtesy of National Center for Veterinary Parasitology, Oklahoma State University.)

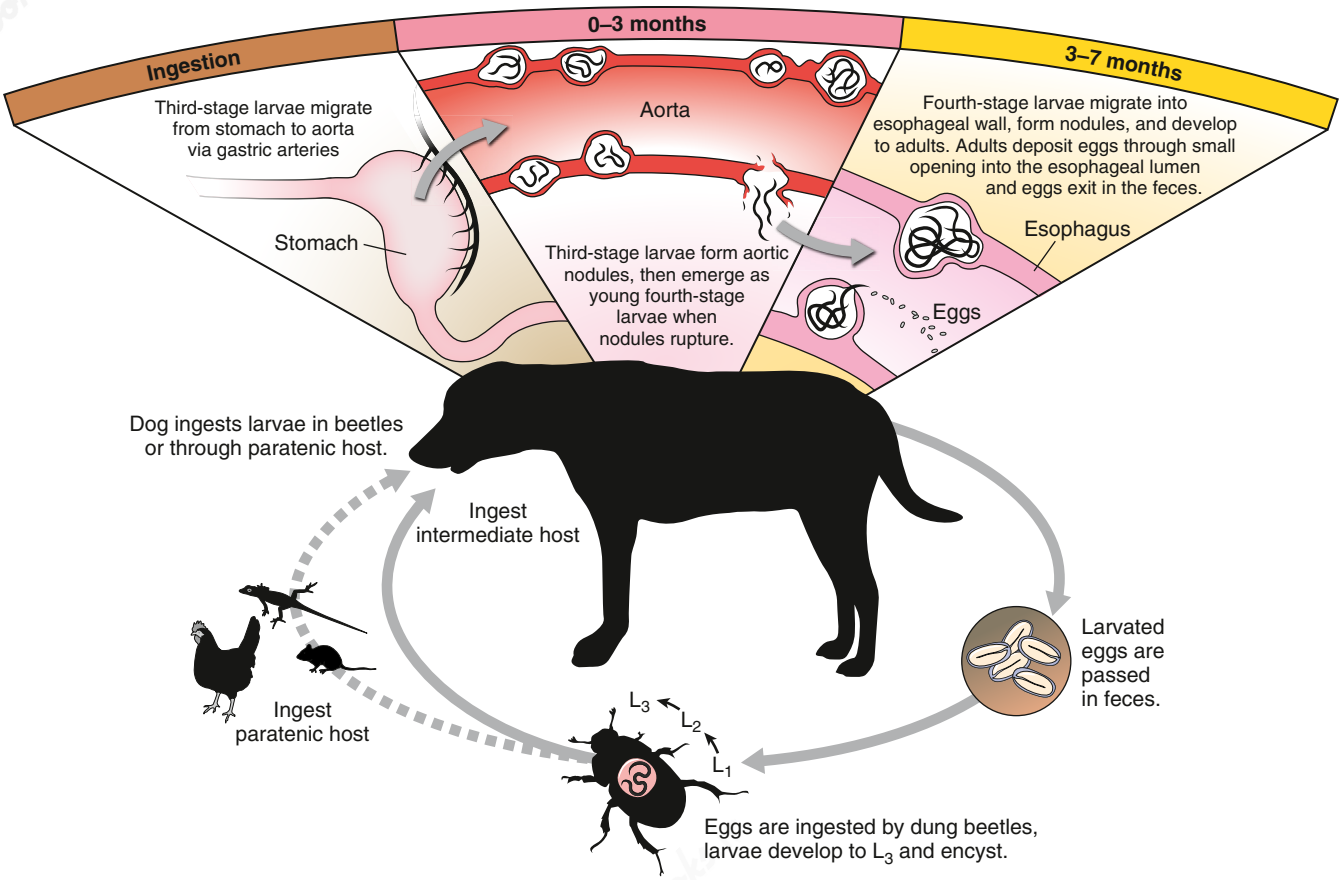

Fig. 116.4 Life cycle of *Spirocerca lupi*.

feces. Eggs recovered from fresh feces contain a first-stage larva (L_1) and are thick-shelled, elongated with parallel sides, and range in size from 20 to 37 µm x 11 to 18 µm (Fig. 116.3).[41,43,44] Coprophagous beetles from the family Scarabaeidae, order Coleoptera consume the eggs whereby the larva is released, develops to the third stage, and encysts. Dogs become infected when they ingest beetles with third-stage larvae (L_3) or by consuming paratenic hosts such as birds, frogs, lizards and other reptiles, and rodents (Fig. 116.4).[41,45–47] Once consumed, the L_3 are released in the stomach of the dog and proceed to penetrate the stomach mucosa and migrate toward the thoracic aorta via the gastric and celiac arteries. This migration typically requires 3 weeks. Once in the wall of the thoracic artery, the nematode develops to an immature adult stage in approximately 3 months, after which it migrates to the esophagus where further development to the adult stage occurs. During development from a larva to a mature adult, a tissue reaction develops in the esophageal wall, resulting in the esophageal nodule in which the adult nematode lives (Fig. 116.5). These nodules initially consist of granulation-like tissue, which later gradually is replaced by proliferating fibroblasts. They are often incorrectly referred to as granulomas.[41,43,45] The prepatent period is 3 to 6 months.[41,43]

Most reports of *S. lupi* infection in dogs are from the southern United States (Alabama, Mississippi, Oklahoma, Texas), South and Central America (Brazil, Mexico), the Caribbean, the Middle East, and South Africa with infrequent reports in Europe.[41,42,45,48–51] In general, occurrence in domestic dogs is <1% although in some areas, particularly in stray dogs, it can be as high as 40%.[22,25,52–54] The density of intermediate and paratenic hosts influences differences in occurrence in rural and urban areas and prevalence can be underestimated if less-sensitive diagnostic methods are used and overestimated if based solely on stray dogs.[45,49] Older dogs, working and sporting dogs, and large-breed dogs are at risk of infection.[49,55]

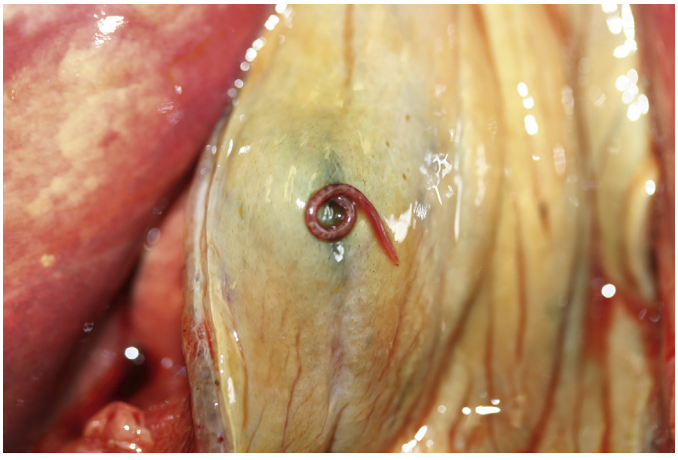

Fig. 116.5 *Spirocerca lupi* adult and esophageal nodule; adults range from 3 to 7 cm long. (Courtesy of Ross University School of Veterinary Medicine.)

Incidence has decreased in some locations and in Italy it is referred to as an "old-fashioned" parasite due to its lack of occurrence.[40] Reasons cited for decreasing prevalence are use of insecticides killing the intermediate host, changes in dog diets, and use of monthly heartworm preventives.[41,45] In endemic areas where macrocyclic lactones are used as a preventive, there is some concern that anthelmintic resistance development could occur. While no resistance has been documented, it does require investigation.[49]

In locations where *S. lupi* currently is rare in domestic dogs, there are concerns that migration of wild animal hosts, urbanization of foxes and raccoons, and the movement of domestic dogs

could pose a risk of reintroduction or increased occurrence.[40,56,57] In the USA, *S. lupi* has been identified in foxes and coyotes in Florida, Texas, and New Mexico, all areas where *S. lupi* is reported in domestic dogs.[27,39]

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Larval migration, esophageal nodules, and secondary infections can cause clinical signs in *S. lupi* infections. While the clinical signs can be severe, many infections are subclinical, with extensive pathology occurring prior to diagnosis.

The esophageal nodules may be single or few, <1 to several cm in diameter, and are typically located just a few centimeters cranial to the caudal esophageal sphincter.[45,49,58–61] The nodules may undergo malignant transformation and approximately 20% of affected dogs are diagnosed with either esophageal fibrosarcoma, osteosarcoma, or undifferentiated sarcoma.[45,49,59] These tumors may metastasize to lungs and other organs.[62,63] Small benign esophageal nodules can be subclinical, whereas larger nodules can disrupt normal swallowing, causing clinical signs such as regurgitation/vomiting, odynophagia, and weight loss.[45,49,59–61] Respiratory signs such as cough or dyspnea are not uncommon and may be secondary to physical compression by esophageal nodules or complications associated with migration or malignant transformation.[49,59,60,64] Fever may be present on physical examination.

A frequent but typically subclinical concurrent finding is a caudal thoracic spondylitis, which is seen in approximately 30% of cases. The pathogenesis of this periosteal bone reaction is not known, but is so rarely seen without *S. lupi* lesions that the combination of a caudal esophageal mass and caudal thoracic spondylitis by some is considered pathognomonic.[59–61] Concurrent hypertrophic osteopathy, which may present as lameness and/or swollen, hard extremities, is sometimes seen, including salivary gland enlargement and hypersalivation.[59] Both conditions have been reported to resolve with resolution of the esophageal lesion. The pathogenesis of both of these conditions is unknown.[65–67]

Clinical disease caused by aberrant or standard migration can occur with or without concurrent esophageal lesions. Migrating larvae can cause permanent intimal scars and aneurysms in the thoracic aorta. In some cases, the weakened aorta may rupture, causing sudden death.[41,52,68,69] In other cases, migration from the aorta to the esophagus causes mediastinitis, pleuritis, or pyothorax.[59,64] There also have been reports of thromboembolic disease, likely caused by turbulent blood flow through aortic aneurysms, presenting as peracute paresis/paralysis of pelvic limbs; and painful, cold, dysfunctional lower extremities with absent or weak femoral pulses.[70,71] Aberrant migration of larvae is not uncommon and nodules containing worms have been found in many thoracic and abdominal organs.[60] There are several reports of aberrant migration through the spinal cord presenting as acute-onset paresis or paralysis of one or both pelvic limbs. Apart from neurological deficits associated with spinal lesions, physical examination findings in these cases included pain along the spine.[72–75]

DIAGNOSIS

A diagnosis of canine spirocercosis heavily relies on diagnostic imaging and esophageal endoscopy. Clinical pathological findings are variable and unspecific. Findings compatible with inflammation such as inflammatory leukograms (typically characterized by neutrophilia and/or monocytosis), evidence of an acute phase reaction (e.g., increased serum CRP concentration), and non-regenerative anemia are sometimes, but not always, seen.[45,76]

Fecal analyses are of limited sensitivity for several reasons: pathology from larval migration and nodule formation can occur before egg excretion; high egg production occurs for only a short time at the beginning of patency; and few or no eggs are shed in single-sex infections, nodules that lack opercula, and late in infection if neoplastic conversion has occurred.[41,43–45,77] Regardless of the fecal analysis method used, none consistently achieves >70% sensitivity.[44,48,60,77] Examination of repeated fecal specimens improves detection, but by only 8 to 28%.[60] Unlike with *Physaloptera* spp., use of higher specific gravity flotation solutions does not improve sensitivity and can damage the eggs.[44] Nucleic acid–based detection methods have limited application in fecal diagnosis but could enable diagnosis using tissue specimens and have the potential to increase detection during early infection.[77]

Where infections are endemic, a tentative diagnosis can be made on identification of a soft-tissue mass in the caudal esophagus. The esophageal masses in clinically affected patients can be large enough to be seen on thoracic radiographs.[45] Radiographs also can be used to detect concurrent thoracic spondylitis, hypertrophic osteopathy, and other disease complications. Sensitivity of radiographs for nodule detection may be improved with administration of liquid barium sulfate in subclinically infected dogs where screening is considered desirable in order to prevent malignant transformation in hyperendemic regions.[48]

Esophageal endoscopy is useful for confirmation or detection of smaller lesions but requires general anesthesia and can only detect nodules and adult nematodes that are protruding into the lumen of the esophagus.[48,78] Computed tomography, in addition to detecting small esophageal nodules, can be used to detect extraesophageal nodules, aortic lesions, and potential metastasis in cases of neoplastic transformation.[45]

Endoscopic-guided biopsy has high specificity but low sensitivity for diagnosis of malignant transformation; instead, diagnosis is often made after surgical excision or on necropsy. In sections of nodules collected at necropsy, nematodes, eggs, or migratory tracts can be seen in most nonneoplastic nodules, but in only a minority of neoplastic nodules.[59]

The diagnosis of intraspinal *S. lupi* infection is extraordinarily challenging as esophageal nodules and patent infections are not always present. Nonspecific changes can be seen on CT or MRI. CSF analysis regularly shows marked pleocytosis with variable proportions of neutrophils and eosinophils; however, definitive diagnosis usually is made by direct visualization of nematodes during surgery or at necropsy.[72] There is one case report, however, where nematode eggs were visualized directly in CSF.[79]

TREATMENT AND PROGNOSIS

There are no registered anthelmintics for the treatment of *S. lupi*. In dogs without neoplastic nodules, treatment with doramectin, milbemycin oxime, and moxidectin halts egg excretion, resolves clinical signs (if present) within weeks, and results in disappearance of esophageal nodules in 95 to > 500 days (Table 116.1). These macrocyclic lactones must be used with caution in certain dog breeds. There have been mixed reports of ivermectin efficacy (0.4 mg/kg, SC, six doses at 2-week intervals; 0.6 mg/kg, SC, two doses at 2-week intervals).[49,80] Levamisole does not appear to be effective.[40] Prognosis, with treatment, is typically good for cases without malignant transformation.[45,59,81] This requires early detection, even in subclinically infected dogs, which can be challenging due to the limitations of routine fecal diagnostic methods.

Surgical treatment is required for dogs with neoplastic transformation. Partial esophagectomies may be successful, but median survival time after surgery is usually short (3 to 9 months), with metastatic disease reported as the most common cause of death.[63,82,83] More

TABLE 116.1 Extra-label Treatments with Reported Activity Against Adult *Spirocerca lupi*

Doramectin SC	Moxidectin Topical	Milbemycin Oxime Oral
0.2 mg/kg, 3 doses at 2-week intervals 0.4 mg/kg, 6 doses at 2-week intervals 0.5 mg/kg, 2 doses 2 weeks apart 0.8 mg/kg, 2 doses 1 week apart Additional treatments can be required; SC can be followed by 0.5 mg/kg PO q24h for 42–126 days	2.5 to 6.25 mg/kg weekly for 19 weeks	0.5 to 1 mg/kg, 2 doses 1 week apart, third dose 2 weeks later Initial treatment followed by monthly administration for 6 months or more

See references 49, 82, 205–210.

recently, transendoscopic esophageal mass ablation has been described as a method for removing nodules.[82,84,85] Removal of nodules is often combined with chemotherapy (doxorubicin or carboplatin as monotherapies or combined), but neither the use nor the type of drug has been demonstrated to increase survival time.[82] Esophageal resections have been attempted but are typically not successful, as patients often die within the immediate postoperative period.[63]

IMMUNITY, VACCINATION, AND PREVENTION

There is no indication that dogs develop immunity to reinfection and there is no vaccine available. Prevention should focus on limiting a dog's access to the intermediate and paratenic hosts. Removal of vomit and feces from the environment can decrease dung beetle access to the eggs.

Moxidectin 2.5%/imidacloprid 10% (Advocate for dogs in Europe and Advantage Multi in the USA; previously Bayer, now Elanco) applied monthly is approved in Europe as a preventive for *S. lupi* infection. Natural exposure studies have shown a preventive fraction of 94.7%.[86] Other macrocyclic lactones are active against immature stages, reducing establishment of *S. lupi* adults and the size of nodules. Milbemycin oxime (minimum 0.5 mg/kg, monthly for up to six treatments) decreased aortic lesions, establishment in the thoracic aorta, and establishment of adults; efficacy for prevention of adult infections ranged from 92.3% to 100% in experimental and natural infections.[87-89] Doramectin and ivermectin (0.2 mg/kg every 3 months) have been used as preventives in endemic areas, although the efficacy of these regimens have not been evaluated.[49]

PUBLIC HEALTH ASPECTS

Spirocerca lupi has not been identified as a zoonosis.

STRONGYLOIDES SPP. (STRONGYLOIDIASIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Strongyloides stercoralis (family Strongyloididae, order Rhabditida) has a unique life cycle; adult females reside in the host and reproduce via parthenogenesis (asexual reproduction), and free-living adult females and males reproduce sexually. In dogs, females reside in the small intestine and can be identified by their filariform esophagus, which is approximately one third of the length of their body. Larvated eggs and, more commonly, first-stage rhabditiform larvae (L_1) with straight tails can be recovered in host feces. These larvae can develop to L_3 (homogonic cycle), or, depending on environmental conditions, free-living adult rhabditiform female and male nematodes (heterogonic cycle) that produce offspring that develop into infective L_3. The environmental cycle can take as few as 2 days (homogonic cycle) and as long as 7 days (heterogonic cycle).[90-95] Infective L_3 primarily enter the host percutaneously. Oral infection can occur, although this more typically results in penetration of the oral mucosa by L_3.[96,97] The migration route varies with strain and species; pulmonary migration is common but not required.[98] Some larvae can arrest but the majority reach the small intestine within 4 to 6 days. The female then develops in the mucosal epithelium and lays eggs in small intestinal crypts. The prepatent period ranges from 5 to 21 days. *Strongyloides stercoralis* females range from slightly < 2 mm to 3.5 mm; mean egg dimensions are 42 to 58 µm x 30 to 34 µm; and L_1 recovered in feces are approximately 180 to 380 µm long with most 250 to 300 µm long.[90,91,93,97]

Although less common, transmammary infection is possible if the infection in the mother occurs in late gestation or early lactation.[99,100] Autoinfection is rare but can occur with the L_1 hatching from the egg and molting into an L_3 while in the host.[101,102] Hyperinfection, used to refer to high levels of autoinfection and migrating larvae, also can occur. In humans, "disseminated infection" refers to the migration of larvae beyond the GI tract, peritoneum, and lungs. This term is not directly applicable to dogs since the normal migratory route can be extrapulmonary.

The life cycle of *Strongyloides* in cats has not been as extensively studied but likely is similar to that in dogs with a few important exceptions. Female *Strongyloides* spp. worms in cats also can inhabit the colon and neither transmammary, autoinfection nor hyperinfection have been confirmed.[93-95] Also, with *Strongyloides planiceps,* embryonated eggs almost as large as *Ancylostoma* eggs are found in the feces instead of L_1.[93]

While *S. stercoralis* is the species found in dogs, the species infecting cats is much less clear. *Strongyloides planiceps*, first isolated in 1927 and described in 1943, has only been reported in cats and some wildlife species in Malaya and Japan.[93,103] *Strongyloides felis*, described in 1925, has been reported in India and Australia.[91,95] *Strongyloides tumefaciens*, the last to be described (1941) and the only species in which the parasitic female resides in the large intestine, has been reported in North and South America.[94,104-106] Reports of *S. stercoralis* in cats have been infrequent although it has been proposed that *S. felis* and *S. tumefaciens* are strains or subspecies of *S. stercoralis*; this has been supported by work with dog and human strains.[91,107-111] Nematodes in tissue that were thought to be *S. tumefaciens* based on lesion location and pathology were recently subjected to PCR-sequencing and determined to be *S. stercoralis*, supporting the theory of strains or subspecies.[112] However, given the difference in morphology that exists, *S. planiceps* is likely a distinct species. Hence, in the rest of this chapter, infections in cats are referred to as *Strongyloides* spp. unless the information is specific to *S. planiceps*.

In both cats and dogs, *Strongyloides* spp. occur worldwide, although prevalence is typically low; most studies report a prevalence of <5% in dogs (range, 0 to 50%).[113-124] The higher prevalence is reported more in tropical and subtropical regions. In cats, prevalence is typically 0 to 4% but up to 46% has been seen in some populations.[24,95,125-128] *Strongyloides* infections in dogs and cats are likely underreported, given that release of eggs and L_1 can be intermittent and routine fecal diagnostic methods lack sensitivity for *Strongyloides* spp. detection.

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Most *Strongyloides* spp. infections in dogs and cats are subclinical. Dogs with heavy infections can have chronic intermittent diarrhea and weight loss or stunted growth. Feces is typically of watery, mucoid consistency and can contain blood. Severe infections may be fatal.[114,115,121,123] In some cases, GI signs are preceded by respiratory signs and hemorrhagic pododermatitis. These signs may be caused by pulmonary migration and percutaneous infection, respectively.[129,130] As in humans, *Strongyloides* infection of dogs with immunosuppressive conditions (e.g., glucocorticoid therapy) can result in accelerated autoinfection or hyperinfection that is associated with exacerbated GI and pulmonary signs.[101,102,130,131] Less is known about clinical signs of infection in cats. However, infections have been associated with chronic diarrhea, weight loss, and death.[94,104,105]

DIAGNOSIS

Strongyloides infection is challenging to diagnose using conventional fecal analysis techniques due to a low parasite load and irregular larval output. Use of serial specimen collection and the Baermann test can increase sensitivity.[132] When L_1 are recovered (Fig. 116.6), *Strongyloides* spp. larvae can be differentiated from *Ancylostoma* spp. larvae by their shorter buccal capsule and a prominent genital primordium. If filariform L_3 are seen, these can be distinguished by their truncated notched tail and long esophagus. If eggs are seen, they are larvated in fresh feces and are smaller than *Ancylostoma* spp. eggs.

There are no commercially available serological or PCR assays for detection of *Strongyloides* spp. in dogs or cats. PCR methods have had variable sensitivity when used to detect *Strongyloides* spp. in humans. IFA tests and ELISA have good sensitivity but are of limited availability.[119]

CBC and serum chemistry results in clinically affected animals are nonspecific and may include stress leukograms, mild anemia, hypoproteinemia, and increased serum CRP.[121] While eosinophilia is typically associated with many parasitic infections, it is not consistently seen with *Strongyloides* spp. infections.[121,133]

On necropsy, parasitic females are typically located in the duodenal mucosa. The nematodes are small and may easily be overlooked on gross examination, but can be found on microscopic examination of duodenal scrapings or on histopathological sections. Pathological findings in clinically affected dogs range from none to mild to marked lymphoplasmacytic enteritis and may, in addition to the duodenum, affect the proximal jejunum, or occasionally the whole intestinal tract.[114,121,129] *Strongyloides* spp. also can be found in the anterior portion of the small intestine in cats.[95] However, in cats, parasitic female adult nematodes also can be found within nodules in the colonic submucosa (Figs. 116.7 and 116.8).[94,105,112]

Fig. 116.6 *Strongyloides* larva from a Baermann examination; first-stage rhabditiform larvae range from 180 to 380 μm in length. (Courtesy of Ross University School of Veterinary Medicine.)

TREATMENT AND PROGNOSIS

No anthelmintics are registered for the treatment of *Strongyloides* in dogs and cats, and effective doses are higher than those required for most other GI nematode infections. In dogs, ivermectin (0.2 mg/kg PO), fenbendazole (50 mg/kg PO for 3 to 5 days), and albendazole (100 mg/kg PO twice daily for 3 days) have been used.[134-136] In the treatment of hyperinfections, ivermectin (0.2 mg/kg PO) administered every 4 days with a total of three or four administrations and fenbendazole (50 mg/kg PO) for 7 to 14 days have been used.[136] Due to toxicity concerns, extra-label use of high-dose ivermectin or albendazole is not recommended in dogs or cats. Less is known about effective treatments in cats although ivermectin (0.2 mg/kg PO) and thiabendazole (25 mg/kg PO q12h for 2 days) have been suggested. Fenbendazole (20 mg/kg PO for 3 days), pyrantel emboate (12.5 mg/kg PO), and pyrantel pamoate (25 mg/kg PO) were not effective in cats.[137]

With treatment, dogs fully recover from non-hyperinfections. The prognosis for dogs with hyperinfections is poor. In cats, very little work on treatment has been performed and prognosis is difficult to assess. Most cats are subclinically infected.

IMMUNITY AND PREVENTION

Dogs develop limited immunity to reinfection with *S. stercoralis*. Infections can be chronic with female worms living for months or longer. Immunosuppression can result in recrudescence of larval shedding, higher autoinfection, and extensive dissemination of the larvae, which can be fatal.[101,130,133,138] Development of immunity has not been studied in cats. Prevention is primarily through hygiene, especially in kennel situations.

PUBLIC HEALTH ASPECTS

Strongyloides stercoralis is zoonotic. DNA and RNA sequencing have shown that people and dogs share some strains of *S. stercoralis*, while others are host specific, therefore people potentially serve as a source of infection for dogs and vice versa.[107-111]

Even if zoonotic infections are strain-specific, *S. stercoralis* must be considered a serious zoonosis. Between 30 and 100 million people are estimated to be infected with *S. stercoralis* worldwide. In the USA, community-based studies suggest a prevalence of 2.7%[139]; IgG seroprevalences of 12 to 77% have been reported in certain immigrant groups in North America from southeast Asia, Somalia, and Sudan. Hyperinfection, while rare, can be fatal and people with asymptomatic infections can develop hyperinfection when glucocorticoids are administered.

There have been no reports of cat *Strongyloides* spp. infecting people, and the role of cat infections in providing a reservoir for human or dog infections is unknown.

MAMMOMONOGAMUS SPP. INFECTIONS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Mammomonogamus spp. (family Syngamidae) typically reside in the upper respiratory tract. While five species have been described in either domestic or wild cats, three of the species, *Mammomonogamus dispar*, *Mammomonogamus felis,* and *Mammomonogamus mcgaughei*, have only been seen once or twice and are likely conspecific with other *Mammomonogamus* spp.[140] The remaining two species, *Mammomonogamus ierei* and *Mammomonogamus auris*, infect domestic cats and have been associated with upper respiratory signs and head shaking, respectively.[141,142] Both *M. ierei* and *M. auris* were first described in 1934; *M. ierei* was isolated from a domestic cat in Trinidad[143] and *M. auris* from the middle ear of several cats in China.[144] There have been reports of *Mammomonogamus* spp. infections in wild felids, but the species involved are unclear. *Mammomonogamus laryngeus*, a species found in ruminants, is morphologically similar to *M. ierei* and the two species have overlapping distribution. While it has been suggested that they might be synonyms, genetic sequence information does not support this theory.[140]

Fig. 116.9 *Mammomonogamus ierei* adult female and male; females range from 13.8 to 23.8 mm long and the males range from 3 to 6.9 mm long. (Courtesy of J. Ketzis.)

Mammomonogamus spp. are thick-bodied nematodes with large buccal capsules. They are characterized by the "Y" shape formed by male and female adult worms attached in permanent copulation (Fig. 116.9). The males are less than half the length of the females. Adult *M. ierei* reside in the nares and nasopharynx and are red to reddish-brown, and *M. auris* adults reside in the middle ear and are orange to red.[140,143,144] Both are considered haematophagous. Location in the host is the main differentiating feature for the two species. Sizes of the male and female worms are similar: *M. ierei* females are 13.8 to 23.8 mm long and the males are 3 to 6.9 mm long; *M. auris* females are 13.7 to 30 mm long and males are 3.3 to 8.1 mm long.[140,143-145]

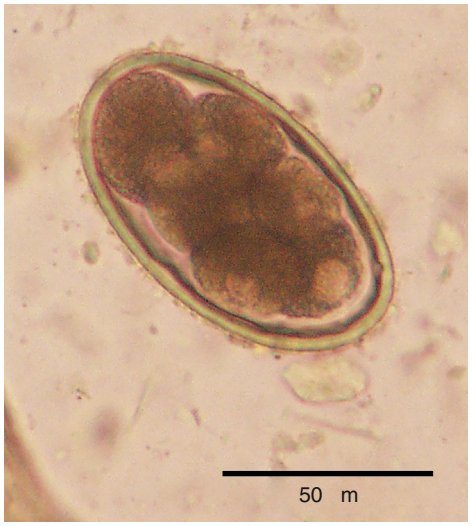

Fig. 116.10 *Mammomonogamus ierei* egg in a Sheather's sugar flotation; eggs are 78 to 100 µm long x 46 to 58 µm wide. (Courtesy of J. Ketzis.)

The eggs of both species can be found in feces or sputum with the eggs of *M. ierei* also found in nasal discharge. The eggs are oval with a clear, slightly thick shell and are 78 to 100 µm long x 46 to 58 µm wide (Fig. 116.10).[143-145] In fresh fecal material, the eggs are in the four- to eight-celled morula stage.[143,144]

The complete life cycle of the various *Mammomonogamus* species has yet to be determined. Neither oral infection nor percutaneous infection has been successful in limited studies, as is the case for other *Mammomonogamus* species.[143,146] It has been hypothesized that paratenic hosts are involved. The migratory path of the larvae to their respective predilection sites is not known. For *M. ierei*, eggs are likely coughed up and swallowed while those of *M. auris* are believed to pass down the Eustachian tubes into the pharynx where they are swallowed.[143,144] Larvae develop to the third stage in the egg before hatching and there are no data on differentiating the eggs or L_3 of the two species. The prepatent period is unknown but is potentially as short as a few days and as long as 2 weeks or more.[147-150]

All confirmed reports of *M. ierei* infection have come from the Caribbean islands. *Mammomonogamus auris* occurs in Asia with reports from China, Japan, Sri Lanka, and islands in the northwest Pacific Ocean.[140,142,144,145,151] There have been sporadic reports from other locations with the species not identified.[140,152] There are few recent studies on prevalence of infection in cats in endemic areas. A 2015 study from St. Kitts of 41 owned cats (indoor/outdoor and indoor only) found 2% to be infected and a 2010 study from the same location with 100 feral cats found 45% to be infected.[153,154] In less recent studies in the Caribbean, prevalence ranged from 32.5% to 47%.[142,141] In the case of *M. auris*, a 1934 study in China found 11 (23%) of 48 cats to be infected, and 5.6% (7 of 124 cats) were found to be infected in a 1982 study from Japan.[144,145] Little is known about infection intensity; one to four pairs of worms are most often seen although 27 pairs of *M. ierei* were described in one cat and six pairs of *M. auris* in another cat.[141,143,144]

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Most cats are subclinically infected. Clinical signs have included mucoid nasal discharge, cough, sneezing episodes, upper respiratory tract congestion, open mouth breathing, and weight loss with *M. ierei*.[141,153,155] Head shaking has been seen in a cat with *M. auris* infection.[142] Inflammation and hemorrhage of the nasopharyngeal mucosa have been observed in infections with both species.[141,143,144] In cats with *M. auris* infection, the tympanic membrane appears unaffected.[144]

DIAGNOSIS

Mammomonogamus spp. infections can be confirmed via fecal or sputum flotation. While simple flotation, direct smear, and sedimentation have been used, flotation with centrifugation and Sheather's sugar flotation solution (1.27 to 1.3 SpG) appears to be the most sensitive method.[140,154] On otoscopic examination, *M. auris* adults can be visible and on occasion *M. ierei* can be expelled during a sneeze. Both species can be recovered at necropsy, with *M. ierei* firmly attached to the mucosa.[141,143]

TREATMENT AND PROGNOSIS

In a single case report, fenbendazole (50 mg/kg PO q24h for 5 days) was effective for the treatment of an *M. ierei* infection.[155] Selamectin and a combination of thiabendazole, dexamethasone, and neomycin were used to treat an *M. auris* infection.[142] Thiabendazole, mebendazole, and ivermectin have been used with apparent success to treat *Mammomonogamus* spp. in other hosts, which suggests that both benzimidazoles and macrocyclic lactones could be effective.[147] Physical removal of nematodes from the ear also is possible and on occasion, cats eliminate the nematodes with forceful sneezing. With treatment or physical removal of the worms, cats fully recover.[141,142,152,155]

IMMUNITY, VACCINATION, AND PREVENTION

Cats are not known to develop immunity to *Mammomonogamus* spp. infection and there is no vaccine. Given that the route of infection is unknown, control/prevention measures are unclear. However, since infection is likely through paratenic hosts, preventing cats from hunting should decrease infection in endemic areas.

PUBLIC HEALTH ASPECTS

Neither *M. ierei* nor *M. auris* has been identified as zoonotic. Reports of *Mammomonogamus* spp. infecting people are extremely rare (approximately 100 cases in the literature), almost always associated with residence in or travel to the Caribbean or Brazil, and largely attributed to *M. laryngeus*. In humans, infections involve the trachea and are followed by violent coughing until the worms are expelled.[148] Molecular studies of *Mammomonogamus* spp. found in people are required to confirm that the species involved is the same as that infecting ruminants.

DIOCTOPHYME RENALE INFECTION (DIOCTOPHYMATOSIS, DIOCTOPHYMIASIS)

ETIOLOGY AND EPIDEMIOLOGY

Dioctophyme renale (also referred to as *Dioctophyma renale*, especially in the human literature), the giant kidney worm, is the largest nematode of domestic animals. The parasite has a sporadic, worldwide distribution although reports of infection are rare in Africa and Asia. It is widespread in the Americas and has been reported from dogs and other hosts from Canada to Brazil. Adults are usually dark red and thick, often measuring 1 cm or more in diameter; immature worms may be creamy white and smaller. Females are larger than males, and may measure as long as 50 to 100 cm. *Dioctophyme renale* is found in a

variety of fish-eating mammals; mink and other mustelids are considered definitive hosts. Adult nematodes do not become as large when in mink. In domestic animals, infection with *D. renale* is most commonly reported in dogs and, occasionally, cats, but has also been described in pigs, cattle, and horses.[156,157] Whether the name of the genus was *Dioctophyme* or *Dipctophyma* was contentious for over 2 centuries, but was resolved as "*Dioctophyme*" in 1989 (International Commission on Zoological Nomenclature).

Eggs are passed in the urine of an infected host and are long-lived in the environment. First-stage larvae develop within eggs, a process dependent on temperature; larvae may develop in as early as 30 days at 25 to 30°C or as late as 7 months at lower temperatures.[158] Aquatic oligochaete annelids commonly referred to as mud worms (e.g., *Lumbriculus variegatus*) serve as intermediate hosts. The annelids ingest the eggs; the larvae then hatch, penetrate the tissues, and develop through successive molts to third-stage larvae. These larvae are immediately infective to mink and dog definitive hosts if annelids are ingested. However, more commonly, a fish or frog bridges the ecologic gap by ingesting the annelid and serving as a paratenic host.[158]

Mink, dogs, and, rarely, cats become infected when they ingest infective larvae in the tissues of paratenic hosts, most commonly freshwater fish. Larvae emerge from paratenic host tissues, penetrate the wall of the duodenum, and migrate directly to the kidney. Based on anatomical proximity to the duodenum, the right kidney is most frequently infected. Adult worms develop over several months, with infections becoming patent in 4 to 6 months or as long as 2 years.[158] Adult worms also can remain in the abdominal cavity.

Infection of dogs with *D. renale* is largely sporadic and few epidemiologic studies have been undertaken. Dogs with *D. renale* infection in Manitoba were co-infected with *Metorchis conjunctus* and clinically normal when examined, but at necropsy had extensive destruction of the right kidney and, occasionally, hypertrophied left kidneys.[159] In Brazil, dogs with *D. renale* infection were more likely to be female, fed fish or fish offal by their owners, known to eat frogs, and reported to drink water from a river known to harbor infected annelids.[159] Some authors do not consider dogs to be definitive hosts because few worms are usually present in infected dogs and infections are often not patent. However, eggs recovered from dogs have been shown to be fertile and develop larvae, and thus dogs are thought to contribute to transmission of the parasite in some environments.[160]

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

A majority of renal infections are unilateral, involving only the right kidney, and subclinical; when both kidneys are involved, disease is more severe. When clinical signs are present, hematuria, polyuria, and pyuria are most commonly reported. Renal pain or generalized abdominal pain may be present. Some dogs are reluctant to move and anorexia, ascites, weight loss, and polydipsia may be present. When renal damage is severe, dogs can develop uremia, with associated lethargy, anorexia, and seizures. Adhesions and peritonitis may develop when *D. renale* is present in the abdominal cavity.[156,161]

Adult worms in the renal pelvis cause compression atrophy resulting in hemorrhagic, suppurative pyelitis. Over time, the renal tubules atrophy and fibrose, the pelvis dilates, and the entire parenchyma is lost resulting in a renal capsule that contains only large, coiled *D. renale* and hemorrhagic exudate. Adult worms in the abdominal cavity can result in adhesions and a serosanguinous exudate. Entrapment of a liver lobe with subsequent rupture and hemoperitoneum has been reported. A minority of dogs have both renal and abdominal *D. renale* nematodes.[157]

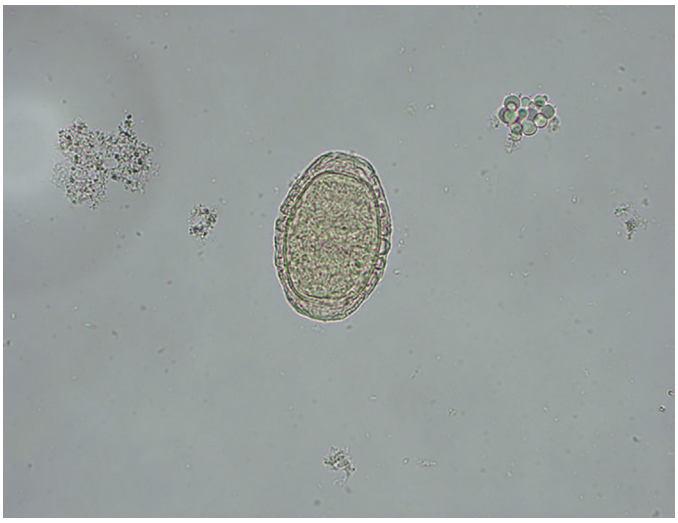

Fig. 116.11 Egg of *Dioctophyme renale* in urine sediment; eggs are 60 to 80 µm x 40 to 47 µm, oval, and have a dramatically corrugated surface. (Courtesy of National Center for Veterinary Parasitology, Oklahoma State University.)

DIAGNOSIS

Classical diagnosis of *D. renale* infection relies on detection of the characteristic eggs in urine sediment. Eggs are not detected in all infected patients; many dogs with a single nematode in the renal pelvis, and all dogs with nematodes only in the abdominal cavity, will not be excreting eggs in urine. When present, the eggs of *D. renale* have a distinct appearance; they are oval, 60 to 80 µm x 40 to 47 µm, often yellowish to brown in color, and have bipolar plugs and a dramatically pitted, rough outer coat (Fig. 116.11). A serum ELISA has been developed for research use but is not available commercially.[160]

Infection with *D. renale* may also be suspected radiographically when a distended right kidney is evident, but ultrasonography is preferred for confirmation. The large adults of *D. renale* will appear as ring-like structures with hyperechoic walls and a hypoechoic core that, when viewed laterally, are arrayed as bands in the renal pelvis of the right kidney.[162] Because confusion with normal structures can occur, ultrasound should be interpreted with care when attempting to identify *D. renale* in the abdominal cavity. When nematodes are present in the renal pelvis, compressive atrophy of the parenchyma is often evident; in advanced cases, nothing remains of the affected kidney except a capsule containing the adult worms and hemorrhagic exudate.

Entire adult nematodes are also occasionally found free or encysted in the abdominal cavity during routine surgical procedures such as ovariohysterectomy. They can also be found encapsulated during exploration of cystic lesions in tissues such as mammary glands, subcutaneous fat in the inguinal region, or mesenteric lymph nodes.[156,163] Adult worms have also been found in the urinary bladder, uterus, ovary, and urethra. The nematodes are usually dark red and very large; females are 30 to 100 cm x 1 cm and males are 15 to 45 cm x 0.5 cm. Histologic examination of affected tissues with encapsulated nematodes may reveal cross-sections of the distinct eggs, which appear as birefringent double-walled circular structures with regular radial striations.[164]

TREATMENT AND PROGNOSIS

Nephrectomy is recommended for animals with only one affected kidney as complete atrophy of the renal parenchyma is usually present; most dogs recover well.[165] Less commonly, in patients with both kidneys affected, nephrotomy may be attempted to remove the parasites and allow recovery of renal function but the prognosis is more guarded; careful evaluation of remaining renal structure and function should guide surgical decisions. Exploratory laparotomy to remove any nematodes free in the abdominal cavity is also recommended. Ectopic worms in subcutaneous fat or mammary tissue can also be removed surgically; when lesions are not complicated, the prognosis for recovery is excellent.

IMMUNITY AND PREVENTION

Prevention strategies focus on not feeding raw fish or fish offal to dogs or cats and keeping pets confined to prevent ingestion of frogs or other potential paratenic hosts. Infection may also occur by direct ingestion of the aquatic oligochaete annelid intermediate hosts in water, but this route is considered less common. Immunity to infection has not been described.

PUBLIC HEALTH ASPECTS

Human infection with *D. renale* is extremely rare (approximately 40 cases in the literature) but has been reported following ingestion of undercooked fish or frogs, as well as contaminated unfiltered and unboiled water.[164,166,167] Most cases have been from China.[168] Occasionally, nematodes develop in the kidneys or retroperitoneal space but in most cases developing larvae become encapsulated in subcutaneous nodules.

DRACUNCULUS INSIGNIS INFECTION (DRACUNCULOSIS)

ETIOLOGY AND EPIDEMIOLOGY

Dracunculus insignis is a spirurid nematode closely related to the human Guinea worm, *Dracunculus medinensis.*[169] *Dracunculus insignis* causes subcutaneous infections in raccoons and other carnivores, including domestic dogs. *Dracunculus* spp. have been described since antiquity. *Dracunculus medinensis* was described by the Swedish botanist Linnaeus in 1758, and *D. insignis* by Leidy (Pennsylvania, USA) in 1858.[158] Traditional treatments in people involved slowly winding the female nematodes around a stick over a period of several days.

Adult female *Dracunculus* spp. are long and thin and usually found coiled in subcutaneous cysts. Most reports of *D. insignis* include female nematodes 20 to 30 cm in length although longer specimens have been described; males die in subcutaneous tissues before the mature cysts form and are rarely encountered in clinical cases. *Dracunculus insignis* infections only occur in North America (especially in the southeast); wild carnivores, especially raccoons, are most commonly infected and considered the natural definitive host. Most cases of *D. insignis* infection in domestic animals are reported in dogs, although ferrets are also susceptible; a limited number of cases have been described in cats.[170-174] Because males are necessary to confirm species identification, although assumed *D. insignis*, most of these are now considered to be reports of *Dracunculus* sp. infection. Although primarily a human parasite, *D. medinensis* also infects dogs in Africa.[174,175]

Larvae are deposited directly into water from ulcerative cutaneous lesions on the limbs of the definitive hosts and ingested by cyclopoid copepod intermediate hosts, which are small crustaceans found widely in freshwater and saltwater habitats. First-stage larvae molt to third-stage in 3 to 4 weeks at temperatures of 24°C; at lower temperatures, development in the copepod is delayed or does not occur.[176,177] Infected copepods may be ingested directly by definitive hosts when they drink water, or by paratenic hosts, notably frogs, with definitive hosts ultimately infected through predation. Male and female *Dracunculus* spp. become sexually mature in approximately 2 to 3 months and mate in the subcutaneous tissues of the thorax or inguinal region; in experimental studies, fertilized females are identified as early as 4 months PI. Males die in the subcutaneous tissue after mating, while females migrate to the extremities, form cysts, become gravid, and release larvae into water. After larvae are expelled the females senesce and calcify.[158]

The identification of *D. insignis* infections in wildlife species follows a seasonal pattern. Historically, the highest prevalence of mature females in subcutaneous cysts was reported in the spring and early summer; these infections result from ingestion of copepods or paratenic hosts the previous year as mature females take as long as 10 to 12 months to develop in the definitive host.[178] A 2018 review of infections in North American dogs and cats showed that dogs could be diagnosed with dracunculosis in every month of the year, but 72% of infected dogs were seen in December to May, with the highest number of cases in March.[174] Although less common, *D. insignis* infections in cats were also seen between November and April. Cases were widespread throughout eastern North America. The average age at initial examination was 5.3 years, although patients ranged from 7 months to 15 years of age; no sex predilection was observed.[174]

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Most dogs infected with *D. insignis* are evaluated for non-painful skin nodules or subcutaneous swellings that are usually located on the extremities. Other common locations include the thoracic and abdominal wall, although nodules have been reported from a variety of locations including the head.[174] The skin overlying the nodule may be ulcerated or bear a patent opening; when the affected limb is immersed in water, an adult nematode may emerge.[179] Localized hair loss is often seen. Occasionally lesions are pruritic.

Nodule formation and ulceration are thought to be due to the inflammatory response to the adult female nematode. Ulcer formation is necessary to allow release of the larvae from the uterus into water to continue the life cycle. Most infected dogs have a single nodule containing only one adult female nematode, but multiple nodules and multiple nematodes have been reported. In one particularly severe case, more than 100 nematodes were removed from a dog over the course of a year.[180]

DIAGNOSIS

When characteristic nematodes are encountered in subcutaneous cysts on a leg, diagnosis is straightforward. Fine-needle aspirate of the subcutaneous cyst usually yields serosanguineous fluid containing numerous *Dracunculus* spp. larvae with a distinctly long, thin tail and measuring 600 to 800 µm (Fig. 116.12). Females can be removed by careful dissection (see Treatment); intact nematodes should be submitted to a diagnostic veterinary parasitologist for confirmation of their identity. This is particularly important when adults suspected to be *Dracunculus* spp. are recovered from unusual locations such as the eye or scrotum. Specimens can be submitted immediately in saline; alternatively, placing nematodes in 70% ethanol preserves key

Fig. 116.12 Larvae of *Dracunculus insignis*. Often present on fine-needle aspirate from a cyst containing adult female worms; the larvae are approximately 600 to 800 μm long and have a long, thin tapering tail. (Courtesy of National Center for Veterinary Parasitology, Oklahoma State University.)

morphologic features while also allowing subsequent evaluation of key nucleic acid sequences. Formalin is not recommended. Definitive morphologic confirmation of the species requires recovery of males which are usually not available.[175]

TREATMENT AND PROGNOSIS

Treatment of *D. insignis* in dogs with uncomplicated skin lesions usually involves careful surgical exploration of subcutaneous cysts and removal of any nematodes present followed by routine wound management. Care should be taken not to cut or break the nematodes during removal. Anthelmintic protocols to prevent or treat infection have not been reported. Some dogs that develop lesions are reported by their owners to be current on heartworm preventives, and experimental treatment trials in ferrets using ivermectin, albendazole, or diethylcarbamazine were not rewarding.[174,181] Despite the lack of data, follow-up treatment with macrocyclic lactones, including ivermectin at 0.2 mg/kg administered parenterally and repeated in 2 weeks, or transdermal 2.5% moxidectin/10% imidacloprid at the label-approved dose, is often recommended to attempt to eliminate developing, immature larvae that have not yet formed subcutaneous cysts. Prognosis is good in uncomplicated cases that involve a single nematode in the skin. When nematodes have migrated aberrantly, such as to the eye, scrotum, or other locations, or when numerous cysts are present, surgical removal is still recommended but prognosis may be more guarded.

IMMUNITY AND PREVENTION

Limiting *D. insignis* infection in dogs requires complete avoidance of ingestion of copepod intermediate hosts in natural bodies of water or predation on potential paratenic hosts. Dogs should be prevented from roaming, particularly in areas where raccoons or other definitive hosts known to be infected with *D. insignis* are also present.

PUBLIC HEALTH ASPECTS

Human infections with *D. insignis* have not been reported despite the fact that non-human primates are susceptible to experimental infection.[182] *Dracunculus medinensis*, also known as the Guinea worm or Medina worm, is currently limited in distribution to three countries in Africa; historically this parasite was much more widespread in Africa, southwestern Asia, and to a lesser extent, northeastern South America and the West Indies. Infection follows ingestion of water contaminated with infected copepods, with transmission occurring when people stand in water when filling water containers. Extensive eradication efforts have dramatically reduced both the number and geographic distribution of *D. medinensis* cases in people in Africa.[183] Canine infections with *D. medinensis*, while low in number and restricted geographically, continue to be monitored.

OCULAR NEMATODE INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Ocular nematodes reported from small animals include *Onchocerca lupi* in dogs, and *Thelazia* spp. in dogs and, less commonly, cats. Aberrant migration has also resulted in other species of nematodes reported from the eye, including *Dirofilaria* spp., *Dracunculus* spp., and *Toxocara* spp. *Onchocerca lupi* was first described in a feral wolf in Russia,[184] and causes onchocerciasis in dogs in northern Asia, southern and central Europe, and the southwestern United States. *Thelazia callipaeda* was first described by Ralliet and Henry (France) in 1910; infections occur in Asia, and more recently in Europe. *Thelazia californiensis* was first described by Price in 1930 and causes infections in dogs in western North America.

Onchocerca lupi infections are most commonly reported in domestic dogs although occasionally the parasite has been described in captive wild canids, domestic cats, and people.[185,186] Prevalence of infection is highest in adult dogs over 3 years of age, likely due to the very long development time of the nematodes, and particularly common in dogs kept outside.[187] German shepherds are overrepresented in case series.[188,189] In a survey in Greece and Portugal, 8.4% of adult dogs were infected.[190] Many infected dogs are subclinically infected. Knowledge of the epidemiology of *O. lupi* infections is hindered by lack of a full understanding of the vectors and intermediate hosts. In California, *Simulium tribulatum* was identified as a putative vector when PCR surveys revealed 2.8% harbored DNA of *O. lupi*.[191] Adults of *O. lupi* are found in conjunctival nodules and produce microfilaria which are distributed in the skin. Blood-feeding fly vectors ingest these microfilaria which then develop to third-stage larvae and are transmitted to the next host by subsequent feeding.[158]

Thelazia callipaeda and *T. californiensis* are described from dogs and cats with occasional reports from wildlife definitive hosts. Other *Thelazia* spp. infect the eyes of large animals.[158]Adults of *Thelazia* spp. are found in the conjunctiva, under the nictitating membrane, or in the lacrimal glands of definitive hosts. Larvae are shed in lachrymal secretions and are ingested by muscid flies feeding around the eyes. In Europe, *T. callipaeda* vectors are *Phortica* and *Amiota* spp., and drosophilid fruit flies. Prevalence in dogs can reach up to 40 to 60% in highly endemic areas.[192,193] In North America, *T. californiensis* is thought to be transmitted by latrine flies (*Fannia* spp.) although fruit flies may also be involved. Third-stage larvae develop in the flies in approximately 2 weeks, migrate to the mouthparts, and are deposited directly into the eyes of the next host when the fly again feeds.[158]

CLINICAL FEATURES

Clinical Signs, Pathogenesis, and Physical Examination Findings

Onchocerca lupi infections result in the development of episcleral and subconjunctival nodules. In acute infections, dogs have conjunctivitis with episcleral and conjunctival hyperemia and periorbital swelling

(Fig. 116.13A). As infections become chronic, mature nematodes are found within granulomatous nodules in the sclera, conjunctiva, orbital fascia, or eyelid. Exophthalmos and protrusion of the nictitating membrane may be present, along with edema, ocular discharge, lacrimation, and photophobia. Nematodes or nematode fragments are present in excised nodules. Occasionally, mild dermatitis develops in response to microfilaria in the skin.[187,194]

The presence of larval and adult *Thelazia* sp. results in lacrimation, ocular discharge, epiphora, conjunctivitis, keratitis, and, when trauma is severe or prolonged, corneal ulcers. Conjunctivitis appears more severe when gravid females are present. *Thelazia* sp. adults have a serrated cuticle that causes damage to the corneal epithelium; the resultant ocular discharge is both characteristic of the disease seen and important to continuing the life cycle by attracting secretophagous fly intermediate hosts. Nematodes are readily observed and collected during ocular examination (Fig. 116.14).[192,195]

DIAGNOSIS

Ocular onchocerciasis can be confirmed when nematodes are found within excised orbital nodules (Fig. 116.13B). Examination of saline digest of skin snips reveals microfilaria; preferred locations where *O. lupi* microfilaria concentrate include the head, ears, and intrascapular region.[190] Microfilaria are not present in blood and heartworm antigen tests do not appear to cross-react with antigen of *O. lupi*.

Thelazia spp. infections are diagnosed directly by observation of nematodes in the conjunctival sac (Fig. 116.14). Often several nematodes are present, necessitating thorough examination to allow complete removal. Once removed, nematodes can be submitted to a specialist for confirmation of identity by morphology, including the presence of distinct transverse striations on the cuticle.[192] Specimens should be submitted in 70% ethanol or 0.9% saline to preserve nucleic acid for amplification.

TREATMENT AND PROGNOSIS

Treatment of ocular *O. lupi* in dogs involves surgical removal of the nodules and the nematodes followed by anthelmintics to eliminate any remaining nematodes, reducing the recurrence of nodules after surgery (Fig. 116.13C).[187] Melarsomine (two injections 24 hours apart) and macrocyclic lactones are recommended.[188] However, some dogs infected with *O. lupi* were reportedly current on heartworm prevention and thus it is not clear if all macrocyclic lactone–based heartworm preventives protect dogs from infection. With appropriate surgery and postsurgical care, most dogs recover from ocular onchocerciasis.[187,188] One dog that appeared refractory to treatment appeared to benefit from addition of doxycycline for nematode-associated *Wolbachia* spp. infection (5–10 mg/kg PO q12h) as well as topical demecarium bromide (1 drop q12h in affected eye), which induces miosis and may have some activity against *Onchocerca* spp. (Fig. 116.13).

Macrocyclic lactones (extra-label) are effective for treatment of *Thelazia* spp., including application of label-approved doses of transdermal moxidectin/imidacloprid or oral milbemycin oxime.[196,197] Worms can also be manually extracted using forceps after application of topical proparacaine (Fig. 116.14). Prognosis for recovery is excellent, and treatment with sustained-release injectable moxidectin also provides protection.[198]

IMMUNITY AND PREVENTION

Preventing infection with *O. lupi* and *Thelazia* spp. requires protecting dogs and cats from the fly intermediate hosts. Keeping animals inside

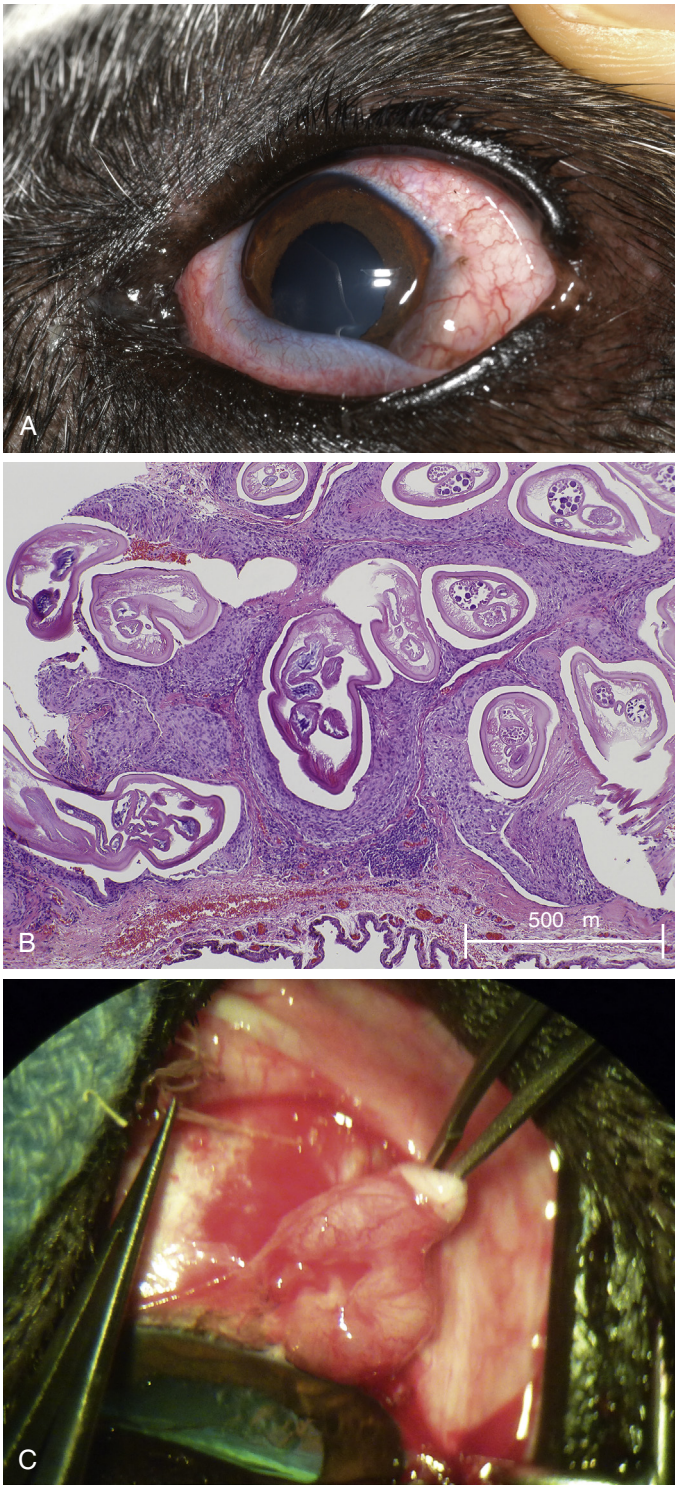

Fig. 116.13 Onchocerciasis in a 7-year-old female spayed Australian cattle dog mix. The signs began about 1 year after the dog moved from New Mexico and Arizona to northern California. (A) The initial problem was marked scleral swelling. (B) Histopathology of nodule biopsy showing *Onchocerca lupi* within granulomas (hematoxylin and eosin stain). (C) Treatment with surgical extraction and medical therapy with ivermectin and melarsomine was not immediately successful; ongoing treatment with monthly ivermectin, topical demecarium bromide and prednisone acetate, and oral doxycycline ultimately resolved the infection. (A, courtesy of University of California-Davis Veterinary Ophthalmology Service; B,C courtesy of Dr. Patricia Smith)

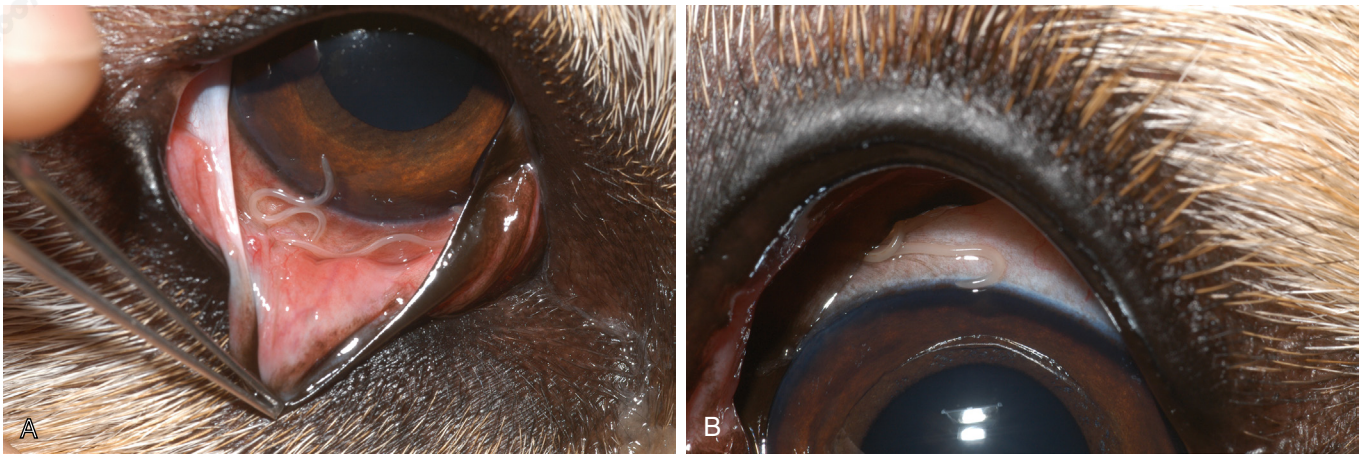

Fig. 116.14 *Thelazia californiensis* in a 1-year-old male intact malamute mix from Colfax in northern California. The dog was evaluated for a positive heartworm antigen test and the nematode was an incidental finding. A total of 15 worms were manually extracted from the conjunctival sac using forceps following application of topical proparacaine. (Courtesy of University of California-Davis Veterinary Ophthalmology Service.)

behind screens should reduce the risk of infection. Pyrethroid repellents in the form of topical, liquid permethrin spot-on products or deltamethrin collars are available for dogs and would also be expected to provide some protection from infection. A study in France showed that transdermal 2.5% moxidectin/10% imidacloprid protected dogs from *Thelazia callipaeda* infection;[199] a similar strategy may also be effective for treating *O. lupi* infections early, before development of clinical signs.

PUBLIC HEALTH ASPECTS

Human infection with both *O. lupi* and *Thelazia* spp. occasionally occurs, resulting in ocular irritation, excessive lacrimation, and the presence of intraocular nematodes.[200-202] Patients with *O. lupi* infections in most areas of the world develop conjunctival hyperemia and subconjunctival nodules containing nematodes; diagnosis is usually made upon histopathologic examination of excised tissues. In the United States, human patients are more commonly reported to have subdermal, spinal, and orbital nodules. In addition to removal of affected tissues and nematodes, treatment involves a combination of anthelmintics and antibiotics together with glucocorticoids to reduce inflammation.[203,204] Patients with *Thelazia* spp. infections generally report ocular discomfort and a foreign body sensation; nematodes are identified directly upon ophthalmologic examination and removed with forceps.[191] Prevention of zoonotic infection with *O. lupi* and *Thelazia* spp. requires avoiding contact with the respective fly vectors.

CASE EXAMPLE

Signalment
"Pirro," an adult male neutered mixed breed dog from St. Kitts, West Indies.

History
Pirro was seen for lethargy, anorexia, and regurgitation (approximately once daily), which were of a few days' duration. Pirro was adopted from an animal neglect situation 10 months before initial examination. At that time he was treated with Drontal Plus (praziquantel/pyrantel pamoate/febantel), and shortly thereafter he was vaccinated and started on monthly heartworm preventives (ivermectin/pyrantel pamoate). Shortly after adoption, a firm, indolent, 2 × 2 cm prominence was noted over the left third metatarsal.

Physical Examination
The dog was in adequate body condition (BCS 3/5). Apart from mild pyrexia, and an approximately 4 × 4 cm firm, indolent swelling over the left dorsal metatarsals, physical examination findings were within normal limits.

Laboratory Findings
There was moderate hypoalbuminemia (1.3 g/dL, reference interval 2.5–4.4 g/dL) and mild hyperglobulinemia (6.3 g/dL, reference interval 2.3–5.2 g/dL). All other CBC and serum biochemical parameters were within normal limits.
Fecal flotation and sedimentation: No parasite oocysts, ova, or larvae were seen.

Imaging Findings
Thoracic radiographs: A soft-tissue opacity, compatible with an esophageal mass was seen in the caudal thorax.
Left distal pelvic limb radiographs: Palisades of periosteal new bones were seen on the dorsal surface of the left metatarsal bones, consistent with hypertrophic osteopathy.
Esophagoscopy: A large (9 × 6 × 6 cm) intraluminal mass with superficial hemorrhage was partly obliterating the caudal esophageal lumen.

Pathologic Findings
Endoscopic biopsies: Histopathology revealed necrotic debris admixed with pieces of plant material.
Surgical biopsy (via gastrotomy): Osteosarcoma.

Diagnosis
Distal esophageal osteosarcoma.

Treatment
The dog was initially treated with ivermectin for presumed *S. lupi* infection. A lack of clinical response and the biopsy diagnosis of osteosarcoma led to a decision of humane euthanasia.

Necropsy Findings
The antemortem diagnoses of caudal esophageal osteosarcoma and hypertrophic osteopathy was confirmed at necropsy. No adult or larval stages of *S. lupi* were found.

Comments
In this case, an underlying previous spirocercosis was presumed based on the finding of an esophageal osteosarcoma in an endemic region.
Case example provided courtesy of Ross University School of Veterinary Medicine.

Nematode Infections of the Respiratory Tract

Gary A. Conboy, Jane E. Sykes

KEY POINTS

Aelurostrongylus abstrusus Infection (Aelurostrongylosis)

- First Described: First recovered from a cat in 1890, the cat lungworm was described and named as *Strongylus abstrusus* by Railliet in France in 1898 and renamed *Aelurostrongylus abstrusus* by Cameron in 1927.
- Causes: *Aelurostrongylus abstrusus* (cat lungworm). Nematode in the superfamily Metastrongyloidea, family Angiostrongylidae.
- Affected Hosts: Adult worms occur in the terminal bronchioles and alveolar ducts in the lungs of cats and some wild felids.
- Intermediate Hosts: Terrestrial gastropods (slugs and land snails) serve as intermediate hosts. Various amphibians, birds, reptiles, and rodents can serve as paratenic hosts.
- Geographic Distribution: Endemic throughout the world and reported from all continents except Antarctica.
- Route of Transmission: Cats may acquire infection by the ingestion of infective third-stage larvae in the tissues of the terrestrial gastropod intermediate hosts (slugs, land snails); however, transmission probably more commonly occurs by the ingestion of infected paratenic hosts (amphibians, birds, reptiles, rodents). Infection may also occur through ingestion of infective third-stage larvae released into the environment by infected gastropods.
- Major Clinical Signs: Cough, nasal discharge, tachypnea, and dyspnea. Weight loss and emaciation may occur in some cases. Infections can be fatal.
- Differential Diagnoses: Allergic respiratory disease, bacterial or viral pneumonia or infection with lungfluke (*Paragonimus kellicotti*), other metastrongyloids (*Oslerus rostratus, Troglostrongylus* spp.), or the capillarid nematode *Eucoleus aerophilus.*
- Human Health Significance: There are no reports of zoonotic infection; *A. abstrusus* is not considered a human health concern.

Crenosoma vulpis Infection (Crenosomosis)

- First Described: Recovered by Dujardin from a specimen bottle in a natural history museum in Paris in 1844, the fox lungworm was described and named as *Liorhynchus vulpis* and renamed *Crenosoma vulpis* by Railliet in 1915.
- Cause: *Crenosoma vulpis* (fox lungworm); nematode in the superfamily Metastrongyloidea, family Crenosomatidae.
- Affected Hosts: Adult worms occur in the bronchi, bronchioles, and trachea of dogs, wild canids, bears, badgers, and martens.
- Intermediate Hosts: Terrestrial gastropods (slugs and land snails).
- Geographic Distribution: Endemic in the northeastern quarter of North America as well parts of Europe and Asia.
- Route of Transmission: Dogs acquire infection by ingestion of infective third-stage larvae in the tissues of the terrestrial gastropod intermediate hosts (slugs, land snails). Infection may also occur through ingestion of infective third-stage larvae released into the environment by infected gastropods.
- Major Clinical Signs: Chronic productive cough, gagging.
- Differential Diagnoses: Airway collapse, chronic bronchitis, airway neoplasia, eosinophilic bronchopneumopathy, or other infectious respiratory diseases that can cause cough. Parasitic infections on the differential diagnosis list when examining fecal specimens include lung fluke (*Paragonimus kellicotti*), other metastrongyloids (*Angiostrongylus vasorum, Filaroides hirthi, Filaroides milksi, Oslerus osleri*), the capillarid nematode *Eucoleus aerophilus*, or intestinal threadworm (*Strongyloides stercoralis*).
- Human Health Significance: There are no reports of zoonotic infection; presently *C. vulpis* is not considered a human health concern.

Filaroides spp. Infection (Filaroidiosis)

- First Described: *Filaroides milksi* was first recovered and described from a dog in New York by Whitlock in 1956. *Filaroides hirthi* was first detected by Hirth and Hottendorf in research beagles in New York in 1973 and described and named by Georgi and Anderson in 1975.
- Causes: *Filaroides hirthi* and *Filaroides milksi* are nematodes in the superfamily Metastrongyloidea, family Filaroididae. These species are similar in morphology so there is some debate as to whether they may be the same species.
- Affected Hosts: *Filaroides hirthi* infection has only been reported in dogs. Subclinical infections have been reported in laboratory colony research beagles. Prevalence within research colonies may be high. Infrequent cases with severe clinical disease have been reported in client-owned dogs. These are usually associated with concurrent immunosuppression or some underlying disease process. *Filaroides milksi* has been reported from dogs and skunks.
- Intermediate Hosts: None—both species have a direct life cycle; L_1 are the infective stage.
- Geographic Distribution: *Filaroides hirthi* has been reported from the USA, Canada, Europe, Australia, Israel, and Japan. *Filaroides milksi* has been reported from the USA.
- Route of Transmission: Dogs acquire *F. hirthi* infection by ingestion of L_1 larvae in sputum, feces, or vomitus. The life cycle of *F. milksi* is unknown.
- Major Clinical Signs: Adult worms of both species occur in bronchioles and embedded in the lung parenchyma. Most *F. hirthi* infections are likely subclinical. With immunosuppression or the presence of another underlying disease or stress condition, a potentially fatal hyperinfection with signs of dyspnea, cough, cyanosis, and obtundation may occur.
- Differential Diagnoses: Other severe pulmonary conditions including CDV infection, bacterial bronchopneumonia (e.g., bordetellosis, *Streptococcus equi* subsp. *zooepidemicus*), toxoplasmosis, fungal pneumonia, heartworm disease, left-sided congestive heart failure, pulmonary thromboembolism, idiopathic eosinophilic pulmonary diseases, and infection with other metastrongyloid, capillarid, or trematode lungworms.

- Human Health Significance: There are no reports of zoonotic infection; neither *Filaroides* species is considered a human health concern.

Oslerus osleri Infection (Oslerosis)

- First Described: First recovered from dogs in Montreal, Canada by Sir William Osler in 1877, *Oslerus osleri* was described and named by Cobbold in 1879.
- Cause: *Oslerus osleri* is a nematode in the superfamily Metastrongyloidea, family Filaroididae.
- Affected Hosts: Wild and domestic canids.
- Intermediate Hosts: None—the life cycle is direct; L_1 are the infective stage.
- Geographic Distribution: Reported from all continents except Antarctica.
- Route of Transmission: Dogs acquire infection by the ingestion of infective L_1 in sputum or vomitus.
- Major Clinical Signs: Adult worms occur in nodules clustered at the bifurcation of the trachea. Signs include a non-productive hacking cough which may be paroxysmal, wheezing and in severe cases dyspnea, cyanosis, bronchospasm, and emaciation may occur. Infection can be fatal.
- Differential Diagnoses and Human Health Significance: See *Filaroides* spp. infection.

Angiostrongylus vasorum Infection (Angiostrongylosis)

- First Described: *Angiostrongylus vasorum* was first described in 1853 in a dog from southern France.
- Causes: *Angiostrongylus vasorum* (French heartworm), is a nematode in the superfamily Metastrongyloidea, family Angiostrongylidae.
- Affected Hosts: Domestic and wild canids, especially domestic dogs and red foxes.
- Intermediate Hosts: Terrestrial gastropods (slugs and land snails) are the primary intermediate hosts. Frogs can also serve as intermediate hosts. Both frogs and chickens can be paratenic hosts.
- Geographic Distribution: Infection is endemic throughout most of Europe, parts of Africa, and South America, and in North America it is restricted to the Canadian provinces of Newfoundland-Labrador and most recently in Nova Scotia.
- Route of Transmission: Dogs acquire infection by the ingestion of infective L_3 in the tissues of terrestrial gastropod intermediate hosts (slugs, land snails), or infected paratenic hosts (such as frogs or chickens). Infection may also occur through ingestion of infective L_3 released into the environment by infected gastropods. The importance of paratenic hosts or environmental contamination in transmission is unclear.
- Major Clinical Signs: Cough, gagging, dyspnea, tachypnea, exercise intolerance, evidence of bleeding disorders, neurological signs, uveitis, anorexia. Infections can be fatal.
- Differential Diagnoses: These include heartworm disease, other infectious causes of tracheitis and bronchopneumonia including other lungworms (metastrongyloids, *Eucoleus aerophilus*, *Paragonimus kellicotti*), systemic neoplasia, anticoagulant rodenticide toxicity, pulmonary thromboembolism, pulmonic stenosis, cardiomyopathy, and a variety of infectious and inflammatory disorders of the CNS and eye (rabies, CDV infection, toxoplasmosis, neosporosis, cryptococcosis, other CNS-migrating parasitic diseases such as *Baylisascaris procyonis* migration and cerebrospinal myiasis).
- Human Health Significance: *Angiostrongylus vasorum* does not infect humans.

Eucoleus aerophilus and Eucoleus boehmi Infection (Eucoleosis/Capillariosis)

- First Described: First recovered from a wolf in 1839 by Creplin (*Eucoleus aerophilus*) and from the frontal sinuses of a wolf (*Eucoleus boehmi*) in 1953 by Supperer.
- Cause: *Eucoleus aerophilus* (previously *Capillaria aerophila*) and *Eucoleus boehmi* (previously *Capillaria boehmi*) are nematodes in the superfamily Trichinelloidea, family Trichuridae, subfamily Capillariinae that parasitize the trachea, bronchi, and bronchioles (*E. aerophilus*) and nasal cavity and frontal sinuses (*E. boehmi*).
- Affected Hosts: *Eucoleus aerophilus*: Dogs, cats, wild carnivores (e.g., mustelids, foxes), occasionally people. *Eucoleus boehmi*: Dogs and various wild canids.
- Intermediate Hosts: The life cycle is unclear. Direct (i.e., without an intermediate host) or indirect involving earthworms have been proposed for both *Eucoleus* species.
- Geographic Distribution: Endemic throughout the world.
- Route of Transmission: Whether definitive hosts acquire infection by the ingestion of larvated eggs (fecal-oral) or earthworm intermediate hosts is unknown.
- Major Clinical Signs: Most infections are subclinical. Non-productive cough, nasal discharge, sneezing, tachypnea, and dyspnea may occur with heavy infections. Secondary bacterial bronchopneumonia may occur and may exacerbate clinical signs.
- Differential Diagnoses: These include allergic respiratory disease, bacterial, fungal, or viral pneumonia or infection with lungfluke (*Paragonimus kellicotti*), or other metastrongyloids (*Angiostrongylus vasorum, Crenosoma vulpis, Filaroides hirthi, Oslerus osleri* in dogs; *Aelurostrongylus abstrusus*, *Oslerus rostratus, Troglostrongylus* spp. in cats). In dogs, the bipolar-plugged eggs may also be mistaken for those of *Trichuris vulpis.*
- Human Health Significance: Very rare (< 20) cases of human infection by *E. aerophilus* exist in the literature.

OVERVIEW OF METASTRONGYLOID INFECTIONS OF THE RESPIRATORY TRACT

Metastrongyloids ("lungworms") are a varied group of nematode parasites of mammals. As the common name suggests, most species occur in the lungs; however, a few species occur in the pulmonary artery, veins, or frontal sinuses of the host. The life cycles for the majority of metastrongyloids are indirect, most often involving terrestrial gastropods as intermediate hosts; however, direct life cycles occur in a few species.[1] Although the significance remains unclear, recent studies have indicated that spontaneous shedding of infective third-stage larvae (L_3) into the environment by infected gastropods is widespread within the metastrongyloids and that these L_3 survive outside the host for several weeks to up to 4 months.[2] Therefore animals have the potential to acquire infections through ingestion or licking of grass and other plant sources. In North America, *Aelurostongylus abstrusus* occurs in the lungs of cats and *Angiostrongylus vasorum* in the pulmonary arteries and *Crenosoma vulpis, Filaroides hirthi, Filaroides milksi*, and *Oslerus*

osleri in the lungs of dogs.[3] First-stage larvae (L_1) are passed in the feces of infected dogs or cats for each of these species. Typical of the metastrongyloids, fecal larval excretion patterns may be sporadic.[4] Due to sporadic larval excretion and difficulty in recovery and identification of nematode larvae, diagnosis of metastrongyloid infection in dogs and cats tends to be challenging. An additional and perhaps the most significant impediment to diagnosis is a failure to consider metastrongyloid infection as a differential diagnosis in dogs and cats with signs of respiratory disease.

AELUROSTRONGYLUS ABSTRUSUS INFECTION (AELUROSTRONGYLOSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Aelurostrongylus abstrusus adult worms are 4 to 10 mm in length.[5] The bursa in males is greatly reduced, and the vulva in females is near the anus just anterior to the tail.[6] Mature females produce undifferentiated eggs which develop in the lung tissue and hatch L_1.

Aelurostrongylus abstrusus infects cats and wild felids (Amur cat, cheetah, Eurasian lynx, leopard, lion, ocelot, tiger) and has a worldwide distribution.[7–9] In North America, infection has been reported in the eastern USA (Alabama, Connecticut, Florida, Georgia, Maryland, Massachusetts, New Jersey, New York, North Carolina, Pennsylvania, South Carolina, Tennessee, Virginia) and in the western coastal states (California, Oregon, Washington) as well as in Hawaii and Puerto Rico.[10–14] In Canada, infection has been reported in Ontario and diagnosis based on fecal examination has occurred in British Columbia, Newfoundland-Labrador, New Brunswick, and Nova Scotia (author's unpublished observations).[15] In other global regions, infection has been reported in Africa (Kenya, South Africa), Asia, Australia, Europe (Albania, Bulgaria, Denmark, England, France, Germany, Greece, Hungary, Italy, Netherlands, Poland, Portugal, Romania, Scotland, Serbia, Spain, Switzerland, Turkey), the Middle East (Iran, Israel), and South America (Argentina, Brazil).[16–30] Infection in cats has been reported with increasing frequency in Europe in the last decade.[31] There have also been reports of *A. abstrusus* infection in dogs based solely on detection of L_1 on fecal examination.[10] These may be spurious diagnoses due to coprophagy. Attempts to experimentally infect dogs with *A. abstrusus* have been unsuccessful indicating dogs are probably not a susceptible host.[5]

The prevalence of infection varies within endemic regions. Fecal flotation surveys, which likely underestimate prevalence, indicated *A. abstrusus* infection rates in North America in cats as low as 0.1 to 1.1% in Pennsylvania, Connecticut, and New Jersey to 6.2% in upstate New York.[10–12,32] Although it may reflect a regional difference, a much higher prevalence (18.5%) was found in a fecal survey of cats in Alabama which utilized the more sensitive Baermann technique.[33] Various surveys have found prevalence values that range from 0.5 to 50% in Europe and 14 to 39.2% in Australia.[31] Infection appears to be more common in younger cats (3 months to 3 years), cats with access to outdoors, and in those living in rural environments.[17,27,34–38]

CLINICAL FEATURES

Pathogenesis

The life cycle of *A. abstrusus* is indirect involving terrestrial gastropods as intermediate hosts (Fig. 117.1). L_1 are passed in the feces of infected felids; slugs and land snails become infected while feeding on cat excrement. L_3 develop in tissues of the gastropod in about 3 to 4 weeks.[1] Cats acquire infection by ingestion of L_3 contained in the gastropod or in a wide range of paratenic hosts (amphibians, reptiles, birds, small rodents).[1] Recent studies have indicated that infected gastropods spontaneously excrete L_3 into the environment; this may be an additional exposure route for cats or paratenic host species by direct ingestion of L_3 through ingestion of plant material.[2] The PPP is about 5 to 6 weeks; infected cats may excrete L_1 in feces for about 2 to 7 months (peak excretion 10 to 17 weeks PI).[14,39,40] A prolonged period of larval excretion (1 to 2 years) occurs in some cats.[39,40] L_1 may survive for 5 months in moist soil.[14] In cats that have been re-exposed, there is a delayed onset of patency, a reduced excretion level, and a more erratic larval excretion pattern than that typical of a first exposure.[39,40] Cats may excrete large numbers of L_1 in the feces with counts as high as 144,800 larvae per gram of feces.[36]

Heavy infections can result in severe, potentially fatal, interstitial bronchopneumonia. Severe clinical disease occurred 6 weeks PI in experimentally infected kittens fed 800 L_3.[41] Chronic catarrhal

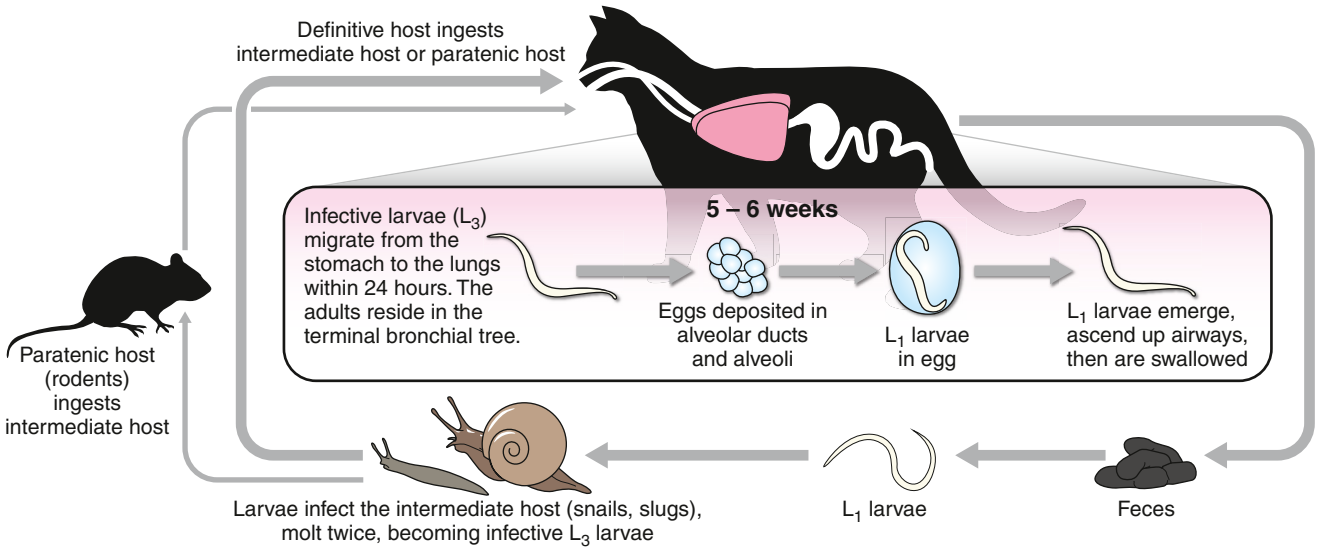

Fig. 117.1 Life cycle of *Aelurostrongylus abstrusus*.

eosinophilic bronchiolitis occurs in response to the presence of adult worms, eggs, and larvae. A necropsy survey of anesthetic-associated deaths in cats in New York found 9% were infected with *A. abstrusus*.[42] The infections were subclinical at the time of anesthesia and it was speculated that death may have occurred due to hypoxia and systemic hypotension secondary to lungworm infection resulting in cardiovascular collapse and arrest. Pneumothorax and pyothorax secondary to *A. abstrusus* infection has been reported in a kitten. Migrating L_3 may have become contaminated with *Salmonella typhimurium* in the lumen of the intestine and carried it to the lungs.[43] Although rare, there have been several reports of invasion of the large intestine by L_1 of *A. abstrusus*; in one of these cases, hyperinfection was considered the cause of death.[44,45]

Clinical Signs and Physical Examination Abnormalities

Most infections are subclinical and self-limiting.[14,21,39] Heavily infected cats show signs of cough, wheezing, dyspnea, and may suffer from anorexia and emaciation. Most cats are afebrile. Usually, cough can be elicited on tracheal palpation. Increased vesicular lung sounds may be noted on auscultation. Enlarged mandibular lymph nodes, nasal discharge, and increased respiratory rate (> 50/min) may be noted.[46]

Fig. 117.2 Lateral thoracic radiograph showing a severe, diffuse, bronchointerstitial pattern with peribronchial cuffing in a 6-month-old intact female Himalayan cat with *Aelurostrongylus abstrusus* infection. (Courtesy of University of California-Davis Diagnostic Imaging Service.)

DIAGNOSIS

Definitive diagnosis of *A. abstrusus* infection is achieved by the detection of L_1 in the feces or mucus of infected cats. The L_1 can be specifically identified based on size and morphology. Larvae can be detected in feces by both direct smear and flotation; however, the method of choice is the Baermann technique (see Chapter 5). In general, larval excretion in the feces of animals infected with metastrongyloids tends to be sporadic.[4] In *A. abstrusus* infections, the fecal larval excretion pattern becomes sporadic typically after 10 to 17 weeks of infection.[14] As a consequence, false-negative fecal examination results can occur. Examination of multiple fecal specimens increases detection sensitivity; most recommendations suggest the evaluation of three fecal specimens before discounting the possibility of metastrongyloid infection.[4]

Laboratory Abnormalities

In many cases, no abnormalities are detected. The CBC may show a peripheral eosinophilia.[47]

Diagnostic Imaging

Radiographic changes usually involve a mixed pattern (bronchointerstitital and alveolar), or may show bronchointerstitial, bronchial, or diffuse unstructured interstitial patterns (Fig. 117.2).[31,38,48,49] CT findings have also been described and include mixed pulmonary patterns with a "ground glass" appearance, interstitial-alveolar patterns, pulmonary nodules, tracheobronchial or mediastinal lymphadenomegaly, and subpleural thickening.[49–51] No evidence of pulmonary hypertension was identified using imaging and echocardiography in one study of 14 infected cats from Italy.[49] Bronchoscopic findings in affected cats include airway hyperemia and stenosis, increased bronchial mucus, airway collapse, and bronchiectasis (Fig. 117.3). In a small study that compared findings in 24 cats with aelurostrongylosis to 12 cats with feline idiopathic bronchial disease, bronchiectasis was only found in cats with aelurostrongylosis; airway hyperemia, epithelial irregularities, and bronchial stenosis were more often found in cats with bronchial disease.[52]

Microbiologic Tests

Diagnosis Using Fecal Examination

Although insensitive, examination of a direct fecal smear for L_1 is the simplest, least expensive, and quickest diagnostic test. A small speck of feces is mixed in a single drop of saline or water on a slide, coverslipped, and examined microscopically for L_1. In one study, direct smears identified larvae in 3 of 12 *A. abstrusus*-infected cats.[21] This test will only detect cats that excrete high numbers of larvae in the feces.

Centrifugal fecal flotation using zinc sulfate ($ZnSO_4$), sodium chloride, or sugar has been used to detect L_1. Flotation is less sensitive than the Baermann method and larval morphology may be damaged by the high specific gravity flotation media; this can complicate identification. Detection sensitivity of centrifugal flotation using $ZnSO_4$ was reported to be superior to that of sugar but both were inferior to the Baermann technique.[53]

The Baermann technique is the most sensitive method for detection of most species of nematode larvae.[4] Larval detection by this method requires that the L_1 are vigorous and motile. Only fresh fecal specimens should be evaluated. In cats this usually means restricting the use of a clean litterbox to one cat and collecting the next available specimen. Feces that cannot be submitted within several hours of collection should be refrigerated. False-positive results can occur if specimens are incubated at room temperature for about a day before collection due to the presence of newly hatched *Ancylostoma tubaeforme* eggs. Additionally, specimens collected from grass or soil can be invaded by free-living nematodes if left for prolonged periods on the ground before collection.[4] *Aelurostrongylus abstrusus* L_1 are 360–400 μm in length. There is a cephalic button (symmetrical indentations along the rostral edge of the head) present at the anterior end and the tail ends in a distinctive S-shaped kink with a dorsal spine (Fig. 117.4). Immobilization of the L_1 by the addition of a drop of dilute iodine (1:10) facilitates a detailed examination of the morphology.[4]

Cytologic Diagnosis

Analysis of respiratory lavage specimens in cats may reveal increased cell counts with mixed neutrophilic and eosinophilic inflammation, as found in cats with idiopathic bronchial disease. However, bronchoalveolar lavage specimens were normal in 21% of 24 cats in one study, and only 33% of specimens had evidence of eosinophilic inflammation.[52] Larvae may also be recovered from transtracheal wash or bronchoalveolar lavage specimens. In one study, larvae were found in bronchoalveolar lavage specimens from 5 (21%) of 24 cats with aelurostrongylosis (Fig. 117.5).

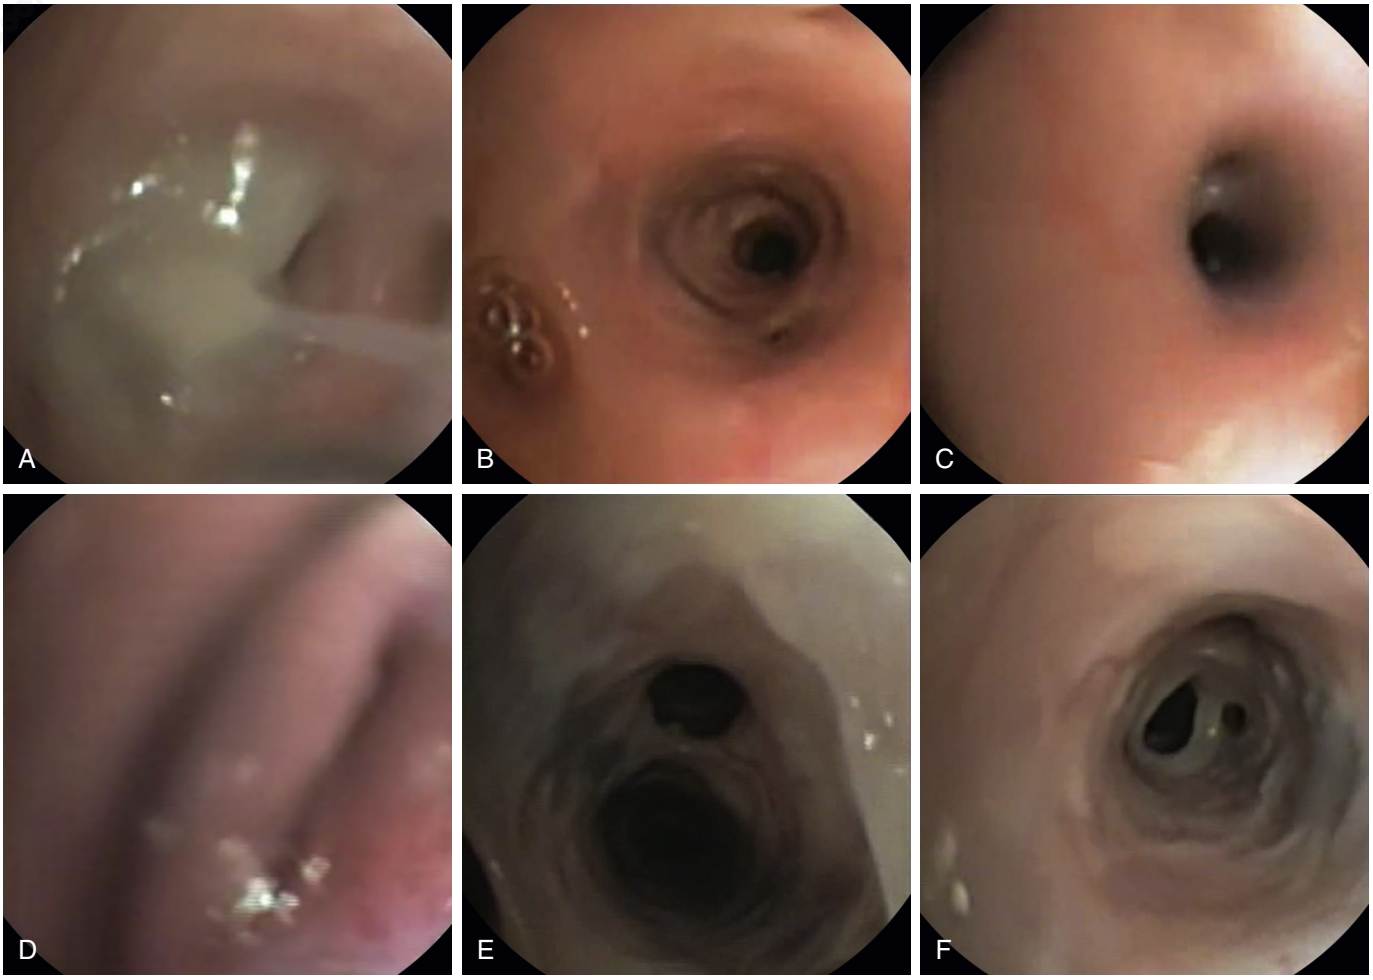

Fig. 117.3 Bronchoscopic findings in cats with aelurostrongylosis. (A) Mucus plug and bronchial obstruction; (B, C) hyperemia and stenosis; (D) bronchial collapse; (E, F) bronchiectasis and mucus accumulation. (From Crisi PE, Johnson LR, Di Cesare A, et al. Evaluation of bronchoscopy and bronchoalveolar lavage findings in cats with *Aelurostrongylus abstrusus* in comparison to cats with feline bronchial disease. *Front Vet Sci.* 2019;6:337.)

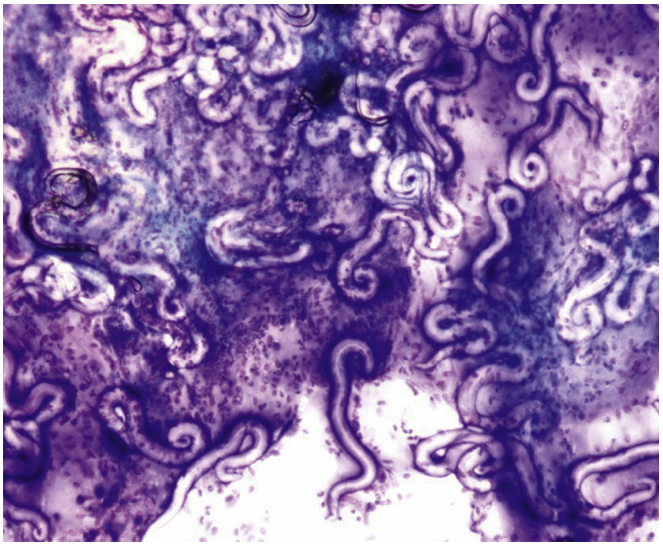

Fig. 117.5 Larvae of *Aelurostrongylus abstrusus* in a bronchoalveolar lavage specimen. Diff-Quik stain (40× magnification). (From Crisi PE, Johnson LR, Di Cesare A, et al. Evaluation of bronchoscopy and bronchoalveolar lavage findings in cats with *Aelurostrongylus abstrusus* in comparison to cats with feline bronchial disease. *Front Vet Sci.* 2019;6:337.)

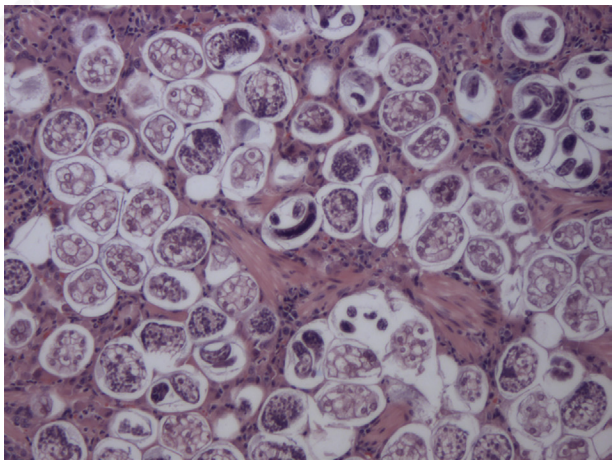

Fig. 117.6 Histopathology image of *Aelurostrongylus abstrusus* in the lung of a 15-year-old female spayed domestic shorthair with diabetes mellitus and fragile skin syndrome. Pyogranulomatous nephritis with intralesional coronavirus antigen (consistent with FIP), intestinal ascariasis, multiple biliary cystadenomas, and *A. abstrusus* infection were incidental findings at necropsy. This is also another example of a smiley-face pathogen image (see Fig. 58.2). (Courtesy of Dr. Jane Sykes, University of California-Davis Veterinary Medical Teaching Hospital.)

Molecular Diagnosis Using Nucleic Acid–Based Testing

A PCR assay for *A. abstrusus* infection used on Baermann sediment, feces, and pharyngeal swabs has been developed and shows promise; it had a reported specificity of 100% and sensitivity of 96.6%.[53–55]

Pathologic Findings

Yellow, firm protruding nodules (1–10 mm in diameter) may be apparent throughout the lungs on necropsy examination of cats with aelurostrongylosis. Histologically, a granulomatous (eosinophils, neutrophils, monocytes, and multinucleated giant cells) response occurs around adult worms, eggs, and larvae (Fig. 117.6). The uterus of adult female worms contain only undifferentiated eggs and undifferentiated eggs may be visible in the lung parenchyma. In most metastrongyloid species infecting companion animals, adult females produce fully formed L_1; only in the Angiostrongylidae (including *A. abstrusus* and *Angiostrongylus chabaudi* in wild felids) are undifferentiated eggs produced.[1] Although domestic cats are susceptible to infection with *Angiostrongylus* spp., infections are very rare and the few infections reported have been non-patent.[56] Therefore the detection of undifferentiated metastrongyloid eggs in the lung parenchyma of cats in histologic sections is nearly pathognomonic for *A. abstrusus* infection. There is hypertrophy and hyperplasia of smooth muscle in the walls of bronchioles and alveolar ducts.[21,31] Identification of *A. abstrusus* nematodes may be an incidental finding on necropsy of cats with other disorders.

TREATMENT AND PROGNOSIS

Emodepside, eprinomectin, fenbendazole, moxidectin, and selamectin have been used to treat cats with aelurostrongylosis. Based on fecal larval counts, emodepside (3 mg/kg, in combination with praziquantel) had an efficacy of 99% when used in a single topical application and 100% with two bi-weekly applications.[57,58] In an efficacy study based on total worm counts at necropsy, a single application of 3 mg/kg emodepside had an efficacy of 73%; with two doses 14 days apart, the efficacy rose to 99%.[59]

Based on fecal larval counts, an efficacy of 90% was reported for a single topical application of eprinomectin (with fipronil and praziquantel) at 0.5 mg/kg in naturally infected cats.[60] Efficacies of 91.6 to 98.9% with a single application and 99.9% after two treatments of eprinomectin (0.5 mg/kg) was reported in cats infected with *A. abstrusus*.[61]

Fenbendazole (50 mg/kg PO q24h for 3 days) greatly reduced but did not eliminate larval excretion in *A. abstrusus*-infected cats.[57,62] Extension of treatment duration appears to increase effectiveness. Dosages of 20 mg/kg for 5 days, 25 mg/kg for 5 days, and 50 mg/kg for 15 days have all been reported as effective treatments.[63–65] The efficacy of a single topical application of moxidectin (in combination with imidacloprid) at 1 mg/kg was 100% based on fecal larval counts.[66] Efficacy of topical moxidectin based on necropsy worm counts was reduced to 88% for a single application; administering two to three monthly applications resulted in an efficacy of 99 to 100% when used as either a treatment or preventive.[67] A single topical application of selamectin (6 mg/kg) resulted in cessation of fecal larval excretion in one of three naturally infected cats.[63] Administration of two selamectin treatments 23 days apart resulted in clinical improvement and negative post-treatment fecal examinations in 9 of 10 naturally infected cats.[68]

With timely diagnosis and treatment, prognosis is good. Case reports of fatal infections often involve prolonged periods of time from the onset of clinical disease to diagnosis. To what degree a delay in diagnosis contributes to a fatal outcome is unknown. Some airway changes, such as bronchiectasis, may be irreversible and predispose cats to chronic bronchial disease.

IMMUNITY AND VACCINATION

Infection in most cats is mild and self-limiting. Re-exposed cats have a delayed onset of patency and tend to shed lower numbers of larvae than that occurring with naïve exposures.[39,40] Cats likely develop some degree of immunity through previous exposure. No vaccines are currently available.

PREVENTION

Curtailing access of cats to the outdoors limits exposure to terrestrial gastropods and paratenic hosts. Topical eprinomectin and moxidectin have potential for use as monthly preventive treatments.[61,67] Most of the anthelmintics with activity against *A. abstrusus* are approved for monthly use to prevent infection with a range of different parasites. To what degree cats receiving monthly treatments with these anthelmintics are protected from developing clinical aelurostrongylosis is unknown.

PUBLIC HEALTH ASPECTS

There are no reports of zoonotic infection with *A. abstrusus*, and currently *A. abstrusus* is not considered to have any public health significance.

METASTRONGYLOIDS OF WILD FELIDS

Reports from Europe have indicated a growing recognition that domestic cats acquire infection with metastrongyloids (*Angiostrongylus chabaudi*, *Oslerus rostratus, Troglostrongylus brevior, Troglostrongylus subcrenatus*) that naturally occur in wild felids.[56,69] Previously, domestic cats infected with these wild felid lungworms were likely misdiagnosed as having *A. abstrusus* infections. In North America, *O. rostratus* and *Troglostrongylus wilsoni* have been reported from lynx

and bobcats in the USA (Alabama, Arkansas, Georgia, North Carolina, Texas, Virginia, West Virginia) and Canada (Alberta, Nova Scotia, Ontario).[70–75] To date, there have been no reports of domestic cat infection with either of these wild felid metastrongyloids in North America.

CRENOSOMA VULPIS INFECTION (CRENOSOMOSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Adult *Crenosoma vulpis* nematodes are 4 to 15 mm in length and are characterized by a distinctive anterior-end morphology; there are 18 to 26 ringlike folds in the cuticle.[3] Males possess a copulatory bursa, and female worms produce thin-shelled larvated eggs which hatch shortly after being laid.

The definitive hosts of *C. vulpis* are primarily wild and domestic canids. The natural definitive host is the red fox (*Vulpes vulpes*). Infection has also been reported in such wildlife as the arctic fox (*Alopex lagopus*), gray fox (*Urocyon cinereoargenteus*), coyote (*Canis latrans*), raccoon-dog (*Nyctereutes procyonoides*), and wolf (*Canis lupus*) and non-canid hosts such as the badger (*Meles meles*), black bear (*Ursus americanus*), and martens (*Martes* spp.).[1] Wildlife, particularly red fox, serve as reservoir hosts of infection for dogs.

In North America, *C. vulpis* is mainly restricted to the northeast. Endemic infection in dogs or wild canids has been reported in Canada (New Brunswick, Newfoundland-Labrador, Nova Scotia, Ontario, Prince Edward Island, Quebec) and the USA (Illinois, Massachusetts, New York).[76–82] The sole report of infection outside this region was in an arctic fox on St. Lawrence Island, Alaska.[83] Endemic infections have been reported throughout most of Europe.[30] Infection in a dog based on fecal examination was reported in South Korea.[84] Prevalence of infection in the red fox in North America ranges from 21 to 87% and is particularly high in the Atlantic Canadian provinces.[78,79,82]

Dogs acquire *C. vulpis* infection by ingestion of infective L_3 in the tissues of the terrestrial gastropod intermediate hosts.[1] Multiple slug and land snail species appear to be suitable intermediate hosts; however, gastropod species involved in natural infections are unknown.[3] Infected gastropods release L_3 in mucus trails and feces; shed L_3 may survive for periods of weeks to months free in the environment. Therefore the potential exists that dogs may also acquire infection when they ingest L_3 during consumption of grass and other vegetation.[2] The prevalence of infection in dogs is unknown for most regions. A necropsy survey of humane society dogs on Prince Edward Island, Canada, found 3.2% were infected with *C. vulpis*.[76] Crenosomosis is a frequent cause of chronic canine respiratory disease in Atlantic Canada with *C. vulpis* infection detected in 21% of the dogs with chronic cough.[85] There are no age, breed, or sex predispositions. Ages of infected dogs have ranged from 3 months to 16 years. In North America, the majority of the diagnoses occur from November to May.[85]

CLINICAL FEATURES

Upon ingestion, L_3 penetrate the duodenal wall, enter the liver, and travel to the heart and lungs via the hepatic portal circulation. The L_3 break through the pulmonary capillaries into the alveolar airspace and migrate to the bronchioles and bronchi to mature to the adult stage. In cases of heavy infection, adult worms may also be found in the trachea. The PPP is 18 to 21 days and the adult worm lifespan is about 10 months.[1] The magnitude of the exposure dose necessary to cause clinical disease and the prodromal period are unknown. The consequences of repeated exposure are also unknown. Infection results in eosinophilic bronchitis; signs consist solely of chronic, usually productive cough which may be accompanied by gagging.[86,87] The gagging may be so pronounced that the owner may perceive that the dog has esophageal obstruction. Affected dogs are otherwise usually bright, alert, and responsive with normal temperature and appetite. Mild hyperpnea may be detected. In most cases, a cough response is easily elicited through tracheal palpation.[86,87]

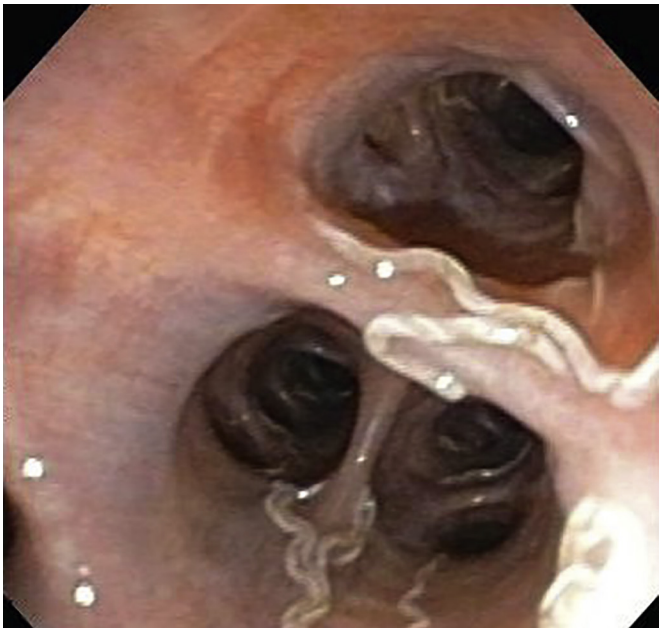

Fig. 117.7 Bronchoscopy image showing *Crenosoma vulpis* in the airways of a 6-year-old female spayed golden retriever-poodle mix with a 1-month history of cough, lethargy, and inappetence. (Courtesy of Dr. Michelle Miller and Dr. Lynelle Johnson, University of California-Davis Small Animal Internal Medicine Service.)

DIAGNOSIS

Laboratory Abnormalities

Bloodwork results in dogs with crenosomosis are generally unremarkable. Eosinophilia, basophilia, and mild monocytosis may be detected on CBC.[87]

Diagnostic Imaging

Thoracic radiographs in affected dogs may reveal an interstitial to bronchointerstitial pattern; focal alveolar patterns have also been described.[86,87] Findings on thoracic CT include diffuse bronchial wall thickening, parenchymal consolidation, multifocal peribronchial "ground glass" attenuation, parenchymal bands, and cylindrical bronchiectasis.[88] Airway mucus and hyperemia, irregular bronchial wall thickening, nodules, and adult worms may be visualized on bronchoscopy (Fig. 117.7).[89–91] Occasionally, adult worms may be identified using bronchoscopy when Baermann fecal examination is negative.[89]

Microbiologic Tests

Definitive diagnosis of crenosomosis is best achieved by detection and identification of L_1 in feces or sputum of infected dogs. Fecal flotation lacks detection sensitivity for *C. vulpis* L_1. In specimens where L_1 are

present, the morphology may be too severely affected by osmotic damage to allow larval identification. Centrifugal fecal flotation using zinc sulfate as the flotation media has been reported to detect *C. vulpis* larvae in about 10% of infected dogs.[85] The fecal examination method of choice is the Baermann technique (see Chapter 5).[3] As for aelurostrongylosis, the intermittent shedding pattern typical of metastrongyloids limits sensitivity. In order to minimize the chance of a false-negative result, submission of feces from 3 consecutive days is recommended.[3,4]

Recovered larvae should be killed by addition of a drop of dilute (1:10) iodine prior to examination on microscopy. Larvae are identified based on size (264 to 340 µm in length) and morphology (cephalic button, long esophagus, tail ends in a simple point lacking kinks and spines but showing a slight deflection) (Fig. 117.8).[4] A false-positive diagnosis of crenosomosis can occur as a result of larvae excreted passively as a result of coprophagia or predation. Additionally, fecal specimens collected from grass or soil hours to days after deposit may be invaded by free-living nematodes, which may be confused with *C. vulpis*. Finally, if fresh feces are not examined, hookworm eggs in fecal specimens may hatch and release larvae, which can also be confused with metastrongyloids.[4]

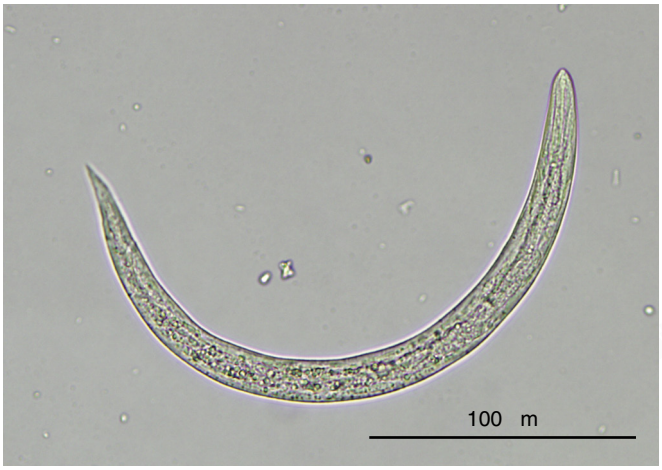

Fig. 117.8 First-stage larva of *Crenosoma vulpis* recovered on Baermann examination of a canine fecal specimen.

Cytologic Diagnosis

Analysis of respiratory lavage specimens in dogs with crenosomosis may reveal increased cell counts with mixed neutrophilic and eosinophilic inflammation. In one study of 10 affected dogs, bronchial lavage specimens revealed a predominance of eosinophils in seven dogs, eosinophils and neutrophils in two dogs, and neutrophils in one dog; larvae were identified in specimens from five dogs.[87]

Pathologic Findings

Since there have been no reports of fatal infection, details on gross and histologic lesions in dogs are limited. Slightly depressed red to purple discolored areas of consolidation in the mid to ventral portions of the lung lobes have been reported. On histopathology, multifocal histiocytic, eosinophilic bronchopneumonia may be present with complete blockage by inflammatory cells, nematodes, and debris occurring in bronchioles and in some cases, bronchi (Fig. 117.9).[92]

TREATMENT AND PROGNOSIS

Fenbendazole, milbemycin oxime, and moxidectin have been used to treat dogs infected with *C. vulpis*. Fenbendazole (50 mg/kg, PO, q24h for 3 to 10 days) has been used widely with resolution of clinical signs and cessation of larval excretion.[86,93] Milbemycin oxime (0.5 mg/kg, PO, single dose) had an efficacy of 99% in the treatment of experimentally infected dogs.[85,92] A single topical application of moxidectin (2.5 mg/kg) was similarly effective.[94]

The prognosis is excellent. In most dogs, full recovery occurs within 7 to 10 days of anthelmintic treatment. In some dogs, cough worsens in the first 48 hours after treatment. This is invariably followed by marked improvement and a full recovery.

IMMUNITY AND VACCINATION

As for cats with *A. abstrusus* infections, the onset of fecal larval shedding is delayed and the number of larvae shed is greatly reduced in dogs that have been re-infected with *C. vulpis* (author's unpublished observations). This likely reflects the induction of some degree of immunity from exposure. No vaccines are available.

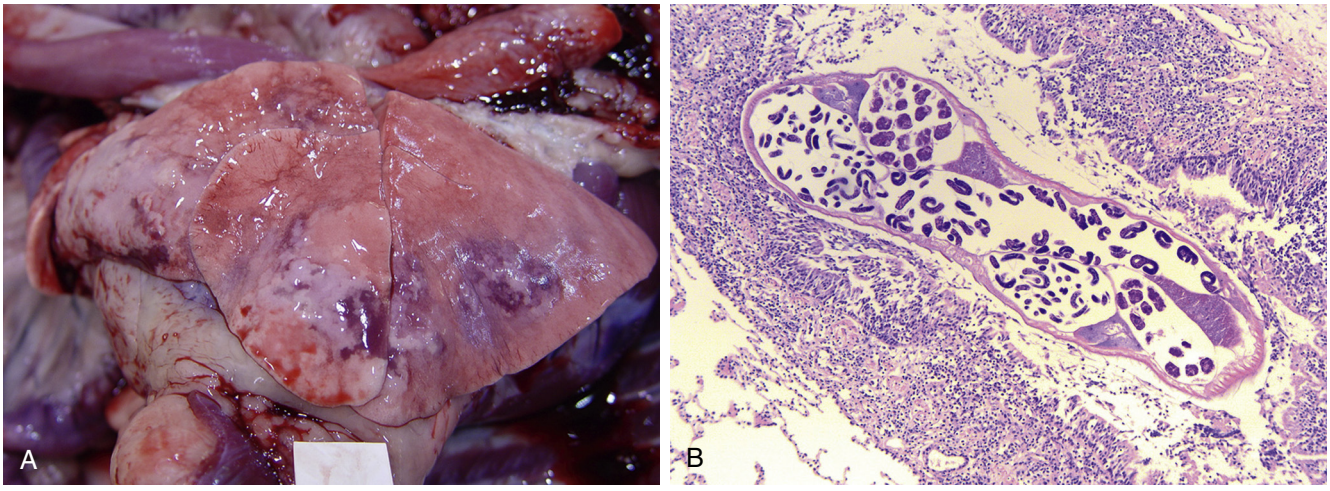

Fig. 117.9 Gross (A) and histopathologic (B) lesions in dogs 49 days after experimental infection with *Crenosoma vulpis*. Slightly depressed areas of consolidation are present, especially in the mid to ventral regions of the lung lobes. On histopathology, there is multifocal histiocytic, eosinophilic bronchopneumonia with obstruction of bronchi and bronchioles by inflammatory cells and nematodes (here shown in cross-section). (Reprinted from Conboy G, Bourque A, Miller L, et al. Efficacy of Milbemax (milbemycin oxime + praziquantel) in the treatment of dogs experimentally infected with *Crenosoma vulpis*. *Vet Parasitol*. 2013;198:319–324.)

PREVENTION

Dogs placed on monthly milbemycin oxime or topical moxidectin for heartworm prevention or other reasons are unlikely to develop clinical disease due to *C. vulpis* infection.

PUBLIC HEALTH ASPECTS

Crenosoma vulpis is not considered to have any public health significance.

FILAROIDES SPP. INFECTION (FILAROIDOSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Filaroides milksi was first found in 1956 as an incidental finding at necropsy in the bronchioles and coiled in nests in the lung parenchyma of a 10-year-old Boston terrier.[95] Adult worms were 3.4 to 10.9 mm in length. *Filaroides hirthi* was first reported, also as an incidental finding at necropsy, in the bronchioles and lung parenchyma of beagles from a purpose-bred research colony in 1975.[96,97] Adult worms were 2.3 to 13 mm in length. The morphology of both species is similar, with the vulva in the female located near the anus just anterior to the termination of the tail and the male tail lacking a well-developed bursa.[6] The two species are differentiated based on subtle differences in worm size and male spicule morphology and length.[98] Whether the two are different species or the same has been the subject of some debate.[98–100] There are few reports of *F. milksi* infection in dogs. Diagnosis based solely on histopathology has been reported in dogs in Australia, Canada, and the USA.[101–103] However, differentiation between *F. hirthi* and *F. milksi* is not possible based on histopathology and therefore these may have been *F. hirthi*.[100] Since the original description of *F. milksi* infection in 1956, there is only one other report of its diagnosis in a dog based on recovery and identification of adult male worms from a dog in Michigan.[104] There have been several reports of *F. milksi* infection in skunks.[99,105]

Filaroides hirthi infection has been reported in laboratory research dogs from Australia, Germany, Great Britain, Israel, Japan, and the USA, with a prevalence of infection in colonies as high as 78%.[96,106–111] However, most likely as a result of heightened awareness and control efforts, there have been no reports of infection in laboratory research beagle colonies since 1996. Diagnosis has been relatively rare in non-research colony dogs. Infected client-owned dogs have been reported from the USA (Alabama, Georgia, New York, Pennsylvania, Texas, Washington), Europe (France, England, Ireland, Spain), and Australia.[112–122] Most case reports involve young (< 3 years of age) toy breed dogs (Chihuahua, toy poodle, West Highland white terrier, Yorkshire terrier).

The life cycle of *F. milksi* is unknown. Transmission of *F. hirthi* occurs by ingestion of infective L_1 usually through coprophagy of fresh fecal material or in sputum, saliva, or vomitus. In research beagle colonies, this is thought to occur from mother to pup by 4 to 5 weeks of age through exposure to feces from infected dams.[123] The PPP is 35 days.[124] Infections appear to be long lived and may persist due to re-exposure to infective L_1 through autoinfection.[125]

CLINICAL FEATURES

Adult worms of both species occur in bronchioles and embedded in the lung parenchyma. Most infections of *F. hirthi* in dogs are probably subclinical. Clinical signs are usually associated with immunosuppression or comorbid diseases. Glucocorticoid therapy, concurrent demodectic mange, CDV infection, severe trauma, and neoplasia have all been associated with clinical disease.[108,109,112-114,116,117] Presumably, through autoinfection such dogs develop massive hyperinfections with life-threatening granulomatous pneumonia; larvae have also been found in mesenteric lymph nodes, the intestinal wall, and the liver. Most often, affected dogs develop a non-productive cough that progresses to dyspnea, tachypnea, cyanosis, and sometimes death. Dogs may become emaciated.

DIAGNOSIS

Laboratory Abnormalities

Eosinophilia may be detected on bloodwork. Other bloodwork abnormalities may be detected depending on the presence of co-existing diseases.

Diagnostic Imaging

Radiographic changes are non-specific. Radiographs may show an interstitial pattern with linear and nodular infiltrates involving all lung lobes.[113,117,119,126] Bronchoscopy can be done to rule out the possibility of *Oslerus osleri* infection. The absence of nodules at the bifurcation of the trachea in a dog in which L_1 are detected suggests *Filaroides* spp. infection.

Diagnosis Using Fecal Examination

Complicating the diagnosis of *Filaroides* spp. infection is the lack of a reliable fecal examination method. For reasons poorly understood, the L_1 of *Filaroides* spp. excreted in feces of infected dogs lack vigor to the point of being moribund and are therefore not reliably recovered by the Baermann method.[124] Zinc sulfate centrifugal flotation has greater detection sensitivity than the Baermann method but is still insensitive. Osmotic damage due to the high specific gravity flotation media may obscure the larval morphology preventing accurate identification. Larvae can be detected using fecal sedimentation, but this is time-consuming and laborious to perform.

Larval detection is best achieved through examination of sputum, saliva, or respiratory lavage specimens. This is the method of choice; larvated eggs and L_1 may be detected. The eggs are thin walled and measure about 38 × 80 µm; L_1 are 240 to 290 µm in length and have a bluntly rounded head (i.e., lack a cephalic button) and the tail has a kink (Fig. 117.10).[124] The L_1 of *Filaroides* spp.

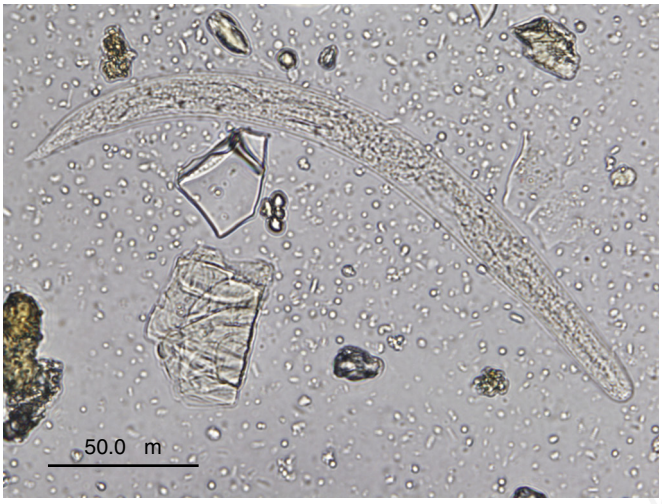

Fig. 117.10 First-stage larva of *Filaroides hirthi* recovered on a fecal sedimentation examination of a canine sample. Note the head lacks a cephalic button and the tail ends in a kink.

and *Oslerus osleri* are difficult to differentiate due to similarities in size and morphology.

Pathologic Findings

Grossly, the lungs of dogs infected with *Filaroides* spp. are firm and red. A large number of thin (35 to 102 μm wide) adult worms may be observed extruding from the cut surface of the lung tissue. Histopathology reveals granulomatous verminous pneumonia with adult worms in bronchioles and nested in the lung parenchyma. In some cases, only eggs and larvae are observed. Hepatic granulomas surrounding worms have also been also observed.[108,109,112,113,115-117,124] In massive infections, larvae may be found in mesenteric lymph nodes, liver, the intestinal wall, and the lungs.[108]

TREATMENT AND PROGNOSIS

There is no anthelmintic approved for use in the treatment of *Filaroides* spp. infection in dogs. Albendazole, fenbendazole, and ivermectin have been used to treat dogs infected with *F. hirthi*.[3] Albendazole and high-dose ivermectin are not approved for use in dogs and, due to safety concerns, are not recommended. Fenbendazole (50 mg/kg PO q24h) for 14 to 21 days has been used to successfully treat several dogs with clinical disease signs due to *F. hirthi* infection.[114,117,121] One dog was successfully treated with fenbendazole at 100 mg/kg PO q24h for 7 days.[122] Depending on the nature of the predisposing disease condition, prognosis may be guarded to poor. Infections in immunocompromised dogs may be overwhelming and fatal despite treatment.

IMMUNITY, VACCINATION, AND PREVENTION

Routine use of anthelmintics should prevent *Filaroides* spp. infections in research dogs.

PUBLIC HEALTH ASPECTS

Neither *Filaroides* spp. is considered to have any public health significance.

OSLERUS OSLERI INFECTION (OSLEROSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Oslerus osleri infects the trachea and bronchi of dogs and various wild canids (coyotes, dingos, wolves).[1] Adult worms are 6.5 to 13.5 mm long; males lack a well-developed bursa and the vulva and anus in females occurs at the termination of the tail.[6,127] Adult worms reside within wart-like nodules that are attached to the surface of the lumen in the trachea and bronchi clustered at the bifurcation.[127,128] Nodules range in size from 1 to 14 mm and can become confluent if present in large numbers.[129–135] Nodules from naturally infected coyotes contained 1 to > 100 worms per nodule.[136]

Oslerus osleri has a worldwide distribution. In North America, infection has been reported in wild and domestic canids in the USA (Alabama, Arizona, California, Colorado, Connecticut, Georgia, Illinois, Iowa, Hawaii, Kansas, Massachusetts, Michigan, Minnesota, Montana, Nebraska, New Mexico, New York, North Carolina, Ohio, Oklahoma, Pennsylvania, Rhode Island, South Dakota, Texas, Utah, Washington, Wyoming), Canada (Alberta, British Columbia, Manitoba, Ontario, Quebec, Saskatchewan, Nova Scotia), and Mexico.[13,137–148] Other endemic regions of the world include Australia, parts of Europe, Japan, New Zealand, and South Afr ica.[127–129,131,133–135,149–153] Infection can be common in wild canids, particularly in coyotes and Australian dingos, with a prevalence as high as 52%.[148] However, wild canids do not appear to serve as an infection reservoir for dogs; dogs exposed to infective larvae recovered from coyotes failed to become infected.[146] Infection in dogs appears to be relatively infrequent.[13] However, *O. osleri* infection was found to be the cause of 18% of the cases of chronic respiratory disease in dogs in a retrospective survey from the 1980s in England.[149]

The *O. oslerus* life cycle is direct with the L_1 as the infective stage. Female worms partially protrude through pores in the nodule to deposit thin-shelled larvated eggs (90 × 60 μm) into the lumen of the trachea and bronchi. The eggs hatch releasing the L_1 while in the process of being coughed up to either pass to the outside in the saliva or be swallowed and pass in the feces.[1] As for *F. hirthi*, larvae recovered from the feces tend to be sluggish and are often found to be dead and degenerating. Transmission in wild canids is thought to occur at the time of weaning from dam to puppy by regurgitative feeding.[150] Transmission in domestic dogs is likely also from dam to puppy but occurs more through exposure to L_1 in saliva when the dam cleans puppies by licking.[148] Infection may also follow ingestion of larvae in contaminating fecal matter but this is likely of lesser importance.[128,150] The PPP is about 70 to 126 days.[150,154] Consistent with exposure at an early age, infections are more common in younger dogs (6 months to 2 years of age).[148,149,155]

CLINICAL FEATURES

After ingestion, L_1 penetrate through the wall of the duodenum and travel to the heart via the lymphatics or hepatic portal circulation; they then travel to the lungs via the pulmonary artery. Immature worms arrive in the trachea about 34 days after exposure and by 70 days PI, nodules that contain adult worms become apparent.[150] In heavily infected dogs, nodules may be so large and numerous that they may obstruct 50% to almost the entire lumen of the trachea and bronchi.[130–132,149,152] Infection results in a chronic, non-productive cough which may become worse with exercise and is readily elicited on tracheal palpation. In some cases, wheezing, dyspnea, and cyanosis occur.[148] Severely affected dogs will show weight loss, emaciation, collapse, and even death.[156] Pneumothorax secondary to bronchial rupture was reported in one dog.[130] Subclinical infections occur in some dogs.

DIAGNOSIS

Laboratory Abnormalities

Bloodwork findings are mild and non-specific; a peripheral eosinophilia may be detected.

Diagnostic Imaging

Tracheal nodules or narrowing of the tracheal lumen secondary to a mural soft-tissue mass are occasionally visible using thoracic radiography.[131,132,134,135,149,155,157,158] Definitive diagnosis of *O. osleri* infection occurs by detection of the nodules by bronchoscopy (Fig. 117.11) along with the identification of nematode larvae with consistent morphology from respiratory specimens or feces. The absence of nodules at the bifurcation of the trachea in a dog excreting such larvae indicates *Filaroides* spp. infection.

Microbiologic Tests

The same fecal examination challenges that exist for *Filaroides* spp. exist for *O. osleri.* The diagnostic test of choice is examination of respiratory lavage specimens for larvated eggs and L_1. The eggs are thin walled and measure about 60 × 90 μm; L_1 have a bluntly rounded head

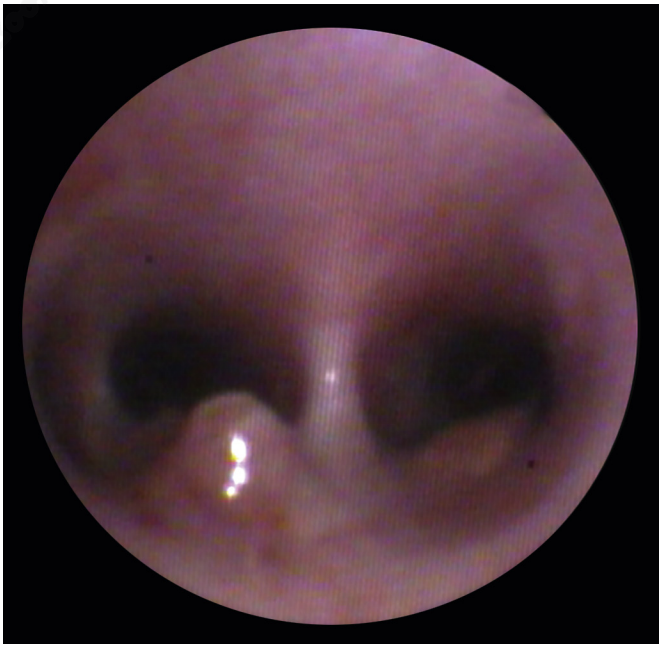

Fig. 117.11 Bronchoscopy image showing tracheal nodules associated with *Oslerus osleri* infection in a 1-year-old intact female toy poodle with a 6-month history of cough and gagging. (Courtesy of University of California-Davis Small Animal Internal Medicine Service.)

(i.e., lack a cephalic button) and a kinked tail.[150] Larvae recovered from mucus are 232 to 266 µm in length; those recovered from feces measure 326 to 378 µm (Fig. 117.12A).[128,151] The L_1 of *F. hirthi*, *F. milksi*, and *O. osleri* are similar in size and morphology.[4]

Pathologic Findings

Grossly, nodules are readily seen attached to the epithelial surface of the lumen in the trachea and bronchi clustered at the bifurcation. Individual nodules may be as large as 12 mm in diameter and contain adult worms coiled inside. Portions of female worms may be seen extruding out from the surface of the nodule. The presence of coiled adult worms in the nodule with the females containing a uterus with developing larvated eggs can be confirmed on histopathology, either following endoscopic biopsy of tracheal nodules or at necropsy (Fig. 117.12B).[128]

TREATMENT AND PROGNOSIS

There are no anthelmintics approved for use in the treatment of dogs infected with *O. osleri*. Variable results using a number of older anthelmintics (diethylcarbamazine, thiacetarsemide, thiabendazole, levamisole, oxfendazole) have been cited in the literature.[133,155,157,159–162] Currently, fenbendazole and high-dose ivermectin are treatment options. Fenbendazole (50 mg/kg PO q24h) for 7 to 14 days was reported to be effective in 19 of 20 dogs with clinical *O. osleri* infections.[149] The one remaining dog required a second 14-day course of treatment and although it showed marked clinical improvement, it still had evidence of a few tracheal nodules and a small number of larvae present on post-treatment examination. Fenbendazole at the same dose for approximately 1 month was reportedly effective in another dog with severe tracheal involvement.[158] Ivermectin (0.4 mg/kg, SC, repeated every 3 weeks for 4 treatments) was reported to be effective in the treatment of four dogs resulting in a clinical cure and resolution of tracheobronchial nodules.[163] This dose of ivermectin is not safe to administer to collies, collie-type breeds, and other dogs with a mutation in the multidrug resistance gene (*mdr1*). Marked clinical improvement was reported in a dog given a single oral dose of ivermectin (0.4 mg/kg); however, nodules persisted after treatment.[133] In general, prognosis for recovery following appropriate treatment is good to excellent.

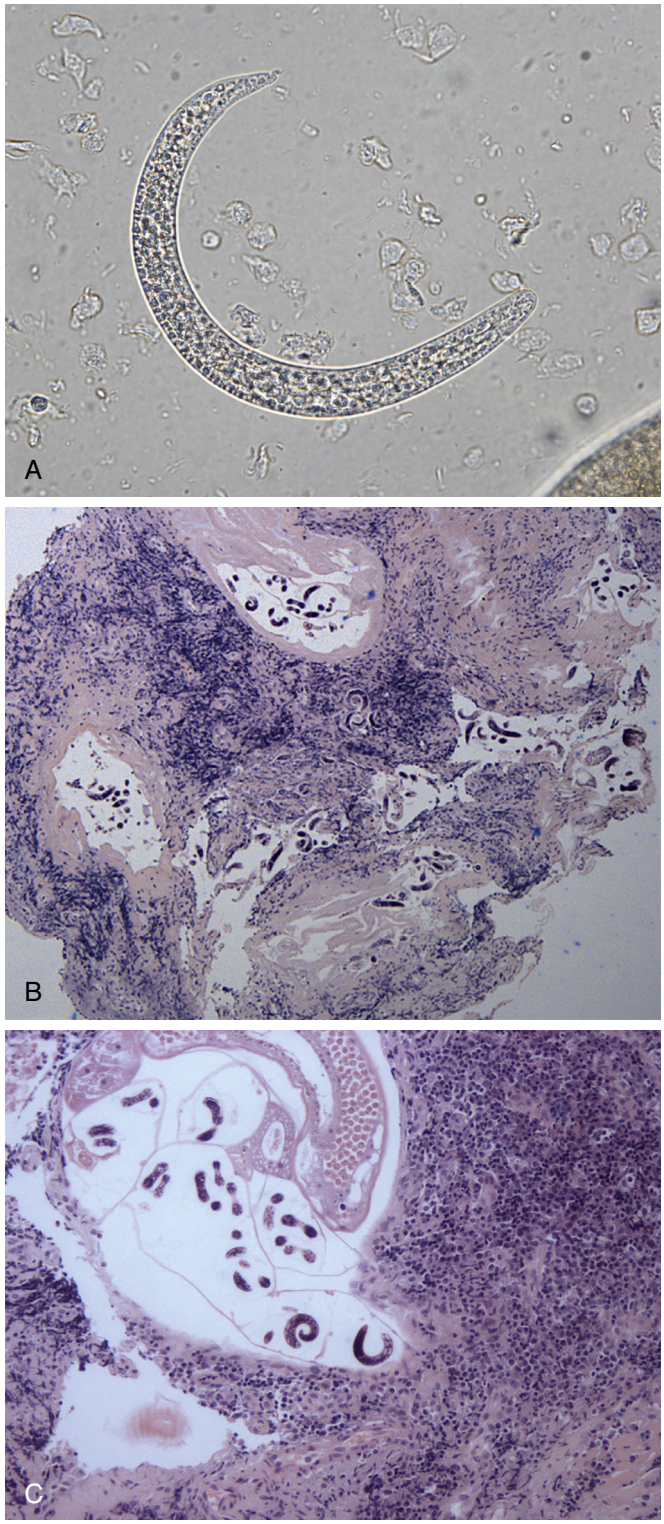

Fig. 117.12 (A) First-stage larvae of *Oslerus osleri* recovered from an impression smear of a nodule removed from the surface of the tracheal lumen of a coyote from Prince Edward Island, Canada. Note the lack of a cephalic button and the tail ends in a kink. (B, C) Histopathology of biopsies collected from nodules observed using bronchoscopy (the same dog as described in Fig. 117.11). Hematoxylin and eosin stain.

IMMUNITY, VACCINATION, AND PREVENTION

Routine use of anthelmintics should prevent *Oslerus* spp. infections.

PUBLIC HEALTH ASPECTS

There are no reports of zoonotic infection with *O. osleri* and it is not considered to have any public health significance.

ANGIOSTRONGLYUS VASORUM INFECTIONS (ANGIOSTRONGYLOSIS)

ETIOLOGY AND EPIDEMIOLOGY

Angiostrongylus vasorum (French heartworm) is a nematode in the superfamily Metastrongyloidea, family Angiostrongylidae. *Angiostrongylus vasorum* was first described in 1853 in a dog from southern France.[164] The life cycle is indirect with a wide variety of gastropods (slugs and land snails) as well as the frog as intermediate hosts, and both frogs and chickens reported as paratenic hosts (Figure 117.13). Although the precise role it may play in natural infection is unknown, the possibility of exposure through direct ingestion of L_3 has been suggested. Recent studies have shown a portion of the infective L_3 contained in the tissues of infected gastropods are shed into the environment where they can survive outside of a host for several weeks to several months.[2] This suggests that dogs might become infected through licking or eating grass and other plant materials.[2] Somewhat limited in geographic distribution, *A. vasorum* has shown a remarkable capability for expansion over the past 40 years with endemic foci currently occurring in southwestern France, the United Kingdom (espeically southwestern England and Wales), Ireland, Denmark; sporadic cases from other parts of Scandinavia (Finland, Sweden), the Netherlands, Austria, Switzerland, Italy, Hungary, Spain, Greece, Turkey, Argentina, Brazil, Colombia, Uganda, and Canada. *Angiostrongylus vasorum* is a significant pathogen of dogs, causing life-threatening cardiopulmonary and neurological disease. Various species of foxes, particularly the red fox, are considered to be the natural definitive host, but infections can also occur in other wild canids including the wolf (*Canis lupus*), coyote (*Canis latrans*), and jackal (*Canis aureus*). Disease is occasionally recognized in non-endemic regions following importation of infected dogs, including a dog imported into the United States (Michigan) from Ireland,[165] a dog imported into Canada (Alberta) from Cornwall, England, and another imported into Australia (Perth, Western Australia) from southern England.[166,167] Autochthonous cases in domestic dogs have not been reported from the United States, but infection based on histopathology was recognized in 2014 in a red fox from West Virginia;[168] and a focus of infection has been identified in domestic dogs, red foxes, and subsequently coyotes in Newfoundland, Canada.[169] Recently, infection in coyotes has been reported from the Canadian province of Nova Scotia, indicating the parasite has spread

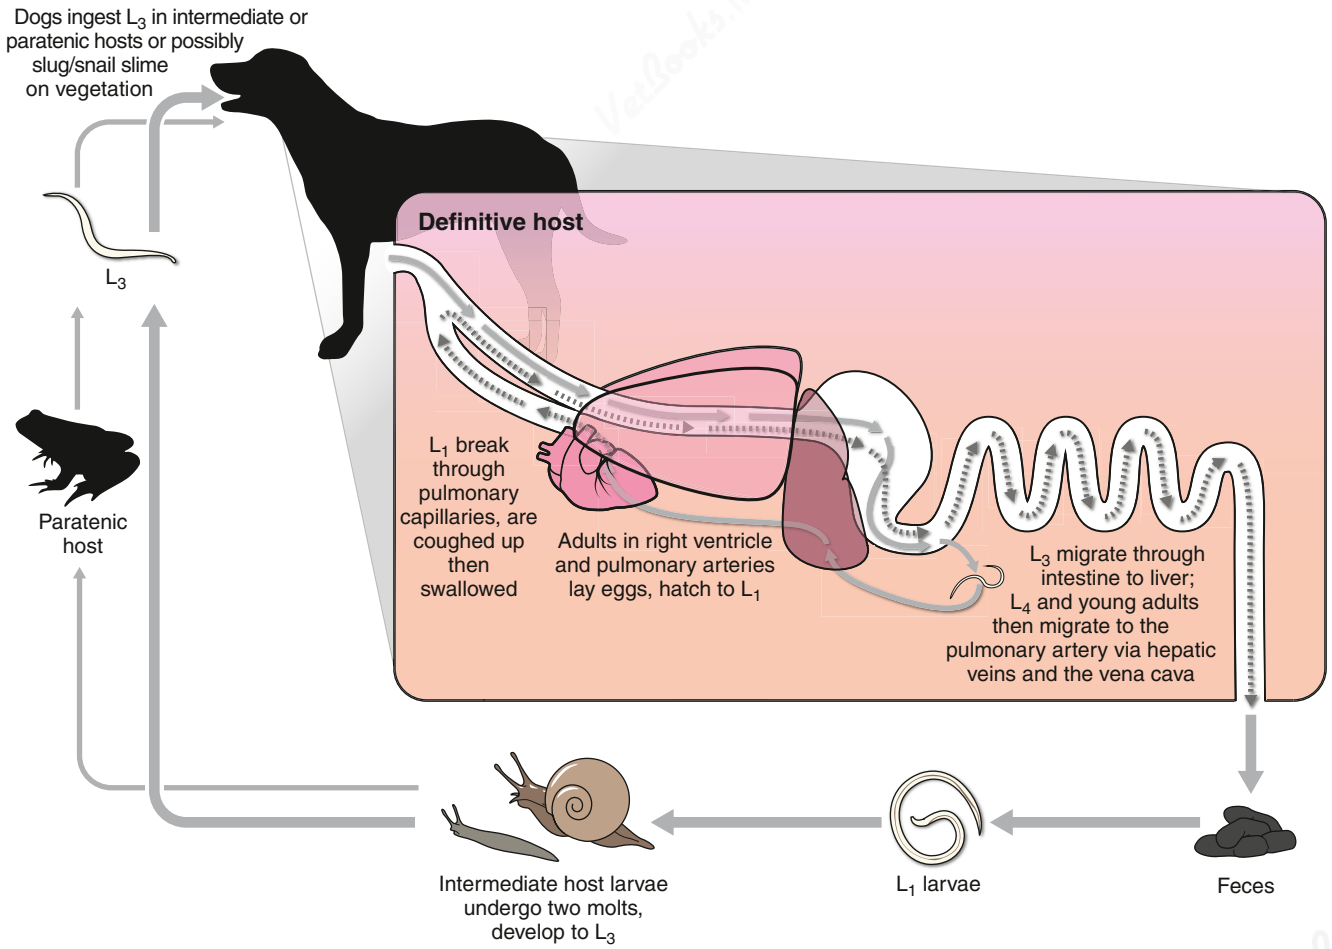

Fig. 117.13 Life cycle of *Angiostrongylus vasorum*.

from the island of Newfoundland to the mainland. The ongoing expansion of the geographic range of this parasite has raised concern about its impact following introduction into nonendemic regions as a result of climate change and the movement of foxes and gastropods (international movement of gastropods as a result of horticulture industry activities is significant).[170] Computer modelling has predicted that there is a high likelihood that the parasite will become established in much of North America, becoming endemic throughout the eastern half of the continent and in the states and provinces on the west coast.[171]

In endemic regions, the overall prevalence of infection in domestic dogs has ranged from 0.3 to 9.8%, and depends on factors such as the coprological method used to detect L_1 and the dog population studied (e.g., stray vs. owned dogs). In contrast, the prevalence of infection in foxes has ranged from 5 to 56%.[172] Increased awareness of the parasite and improved diagnostic testing has likely contributed to disease emergence as well.[173] Although infections with *A. vasorum* have been reported from South America (primarily Brazil, but also Argentina and Colombia),[174] molecular studies suggest that isolates from Europe and South America may be genetically distinct.[175]

There is no clear breed predisposition for angiostrongylosis. In the United Kingdom, purebred dogs, especially Cavalier King Charles spaniels, Staffordshire bull terriers, and beagles have been overrepresented.[172,176] Studies from other countries have shown no breed predisposition; in Newfoundland, Canada, hunting dogs were at greatest risk.[171,172] The median age of dogs in one case series was 10 months,[176] and in another survey of 160 dogs, over 50% of affected dogs were ≤ 1 year of age.[177] However, dogs from 3 months to 14 years of age have been affected. No breed predilection has been identified. In Canada, the majority of the cases are diagnosed from October to March with a similar winter-spring pattern (December to May) reported in Denmark.[176]

CLINICAL FEATURES

Adult nematodes live within the pulmonary arteries and right ventricle where they deposit undifferentiated eggs. The eggs lodge in capillaries in the lungs where they become larvated and hatch. The L_1 break through the pulmonary capillaries into the airways, are coughed up, swallowed, and passed in the feces. L_1 are ingested by the snail, slug, or frog intermediate host and mature into L_3 over about 10 to 16 days when conditions are optimal.[172] Domestic dogs acquire infection by ingesting intermediate or paratenic hosts; although the epidemiological significance remains unknown, infection may also be acquired by consumption of vegetation contaminated with L_3 released from gastropods in feces and mucus.[2,178] Frogs and chickens can act as paratenic hosts after ingestion of slugs or snails.[179] The L_3 are then released into the intestinal tract and migrate to the mesenteric lymph nodes, where they develop into L_4. L_4 migrate via the portal vasculature and liver to the lung by 9 to 10 days PI. The PPP is 38 to 57 days, but can range from 28 to 108 days (see Figure 117.13).[172]

Clinical signs of infection in domestic dogs can range from subclinical to life-threatening, with varying organ involvement; the disease has been referred to as "the great pretender"[180] because of the varying manifestations of illness. Respiratory signs are the most common manifestations of infection. The granulomatous response to the developing eggs and movement of L_1 through the capillary wall into the alveolar airspace results in fibrosis which eventually can affect large areas of the lungs.[181] This in turn is responsible for signs of productive or non-productive cough, dyspnea, tachypnea, syncope, exercise intolerance, and sometimes ascites. Increased lung sounds and a right-sided heart murmur secondary to tricuspid regurgitation may be detected on thoracic auscultation. Dogs may develop a coagulopathy that results in hemorrhage. Hemorrhage may lead to anemia with evidence of mucosal pallor on physical examination. Signs of hemorrhage include scleral ecchymoses, hyphema, retinal hemorrhage, epistaxis, hemoptysis, melena, gingival bleeding, excessive post-surgical bleeding, subcutaneous hematomas, or thoracic or abdominal cavity hemorrhage. The pathogenesis of the coagulopathy is poorly understood, but chronic DIC has been suggested to play a role.[182–184] Neurologic signs in dogs with *A. vasorum* infection are usually secondary to CNS hemorrhage, and include seizures, ataxia, nystagmus, blindness, tremors, paralysis, and coma. Rarely CNS signs have been reported to occur as a result of aberrant migration of L_1.[167,185] The acute onset of neurological signs may be the only evidence of infection.[186] Other reported signs include vomiting, diarrhea, abdominal pain, lumbar pain, inappetence, and weight loss. Sudden death may occur secondary to abdominal, cerebral, or thoracic hemorrhage or the rupture of a major blood vessel due to worm migrations.[184,187] Aberrant migration of L_1 has also been identified to the skin, myocardium, kidney, spleen, adrenal gland, thyroid gland, diaphragm, and pancreas.[172,177]

Rarely, visualization of aberrant migrating larvae in the anterior chamber has been reported on ocular examination, sometimes with accompanying signs of blepharospasm, epiphora, uveitis, episcleral congestion, hyphema, and corneal edema.[188]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, and Urinalysis

Findings on bloodwork are non-specific and include non-regenerative or regenerative anemia, leukocytosis due to a neutrophilia, bandemia, lymphopenia, mild to moderate eosinophilia (up to 2800 cells/μL in one study) and/or mild basophilia, and mild to moderate thrombocytopenia. Findings on serum chemistry profile are variable and include hyperglobulinemia, hypercalcemia, azotemia, and increased activity of serum ALP. Hypercalcemia has been reported secondary to granulomatous inflammation.[185,189] Urinalysis is often unremarkable, but proteinuria has been reported.[190]

Clotting Function

In dogs with evidence of a coagulopathy secondary to *A. vasorum* infection, coagulation test results are variable. In one study of 30 affected dogs, 18 dogs had signs of bleeding on physical examination.[183] Of these 18 dogs, 17 had thromboelastography results consistent with hypocoagulation. A total of 22 of 25 dogs had increased D-dimer concentrations, and fibrinogen concentrations were significantly lower in dogs with evidence of hemorrhage compared with those that did not. Although coagulation times (PT and APTT) were abnormal in some dogs, these were not associated with clinically evident hemorrhage.

Cytologic Analysis of Body Fluids

Analysis of the CSF in dogs with neurological signs may show no abnormalities or a mixed pleocytosis, variable degrees of hemorrhage, and increased protein concentration. Eosinophilic pleocytosis and L_1 were reported in the CSF of a dog with CNS signs secondary to aberrant larval migration.[185]

Bronchoalveolar lavage specimens have increased cellularity with a predominance of neutrophils; eosinophils may also be present. In one study, L_1 were found in 7 of 10 specimens.[176]

Diagnostic Imaging

Plain Radiography

Findings on thoracic radiography include interstitial, bronchial, and/or alveolar lung patterns with a patchy, peripheral distribution; mild pleural effusion; pneumothorax; subcutaneous emphysema; and a widened cranial mediastinum. Right ventricular enlargement may be evident as well as truncated pulmonary arteries, but these findings are more common with dirofilariasis (see Chapter 111).[190]

Advanced Imaging

MRI of the brain and spinal cord of dogs with *A. vasorum* infection and neurological signs may reveal evidence of intramedullary and intraparenchymal hemorrhage, including ill-defined T1-isointense, T2-hyperintense lesions and areas of signal void that are consistent with infarction on T2-weighted image gradient echo sequences.[186,191] In cases where CNS signs have been secondary to aberrant larval migration, evidence of focal meningitis has been described, with meningeal thickening and hyperintensity in T2-weighted images.[185]

Sonographic Findings

Echocardiography can reveal evidence of pulmonary hypertension with concentric and eccentric right ventricular hypertrophy, right atrial dilation, tricuspid valve regurgitation, pulmonic valve insufficiency, and a bulging interatrial septum. In one dog, a ruptured chordae tendineae was evident as a systolic flail of the anterior leaflet of the tricuspid valve, which represented the first report of tricuspid valve chordae tendineae rupture in any dog.[192] Abdominal ultrasonography may reveal ascites and distended hepatic veins in dogs with right-sided congestive heart failure.

Parasitological Tests

Adult worms may be identified at necropsy. They are approximately one-tenth the size of adult *D. immitis*; males are 14 to 18 mm long, with visible bursa, bursal rays, and spicules and females are 18 to 25 mm long and have the "barber's pole" appearance that has been described for *Haemonchus* spp. (Fig. 117.14).[172] L_1, the form shed in the feces, can be detected using the Baermann technique on feces and respiratory lavage specimens and are occasionally detected in the CSF or eye. They are 340 to 399 µm long, have an anterior cephalic button, and their tail ends with a marked kink with a dorsal spine (Fig. 117.15). In contrast, *Crenosoma vulpis* larvae have a straight tail and *Oslerus* spp. and *Filaroides* spp. larvae have a kinked tail but lack the dorsal spine. Because the larvae are highly motile, accurate identification requires the immobilization of the L_1 in order to examine them in detail. This can be achieved by the application of a drop of diluted Lugol's iodine (1:10) to the edge of the coverslip. Zinc sulfate fecal flotation may also reveal larvae, but is only 60% sensitive compared with the Baermann technique. Because the Baermann technique is time-consuming, a direct smear, which may detect L_1 in about half of the infections, can be used in order to rapidly assess for larvae initially. If the direct smear is negative, a Baermann examination should be done. Regardless of the method used, false-negative results can occur as a result of intermittent excretion of larvae in the feces. Examination of multiple (at least three) fecal specimens collected over a 7- to 10-day period or daily for 3 consecutive days can increase sensitivity. With the availability of tests for circulating antigen and PCR assays, which can be used in combination with fecal examination, the requirement for serial fecal examinations may be reduced.

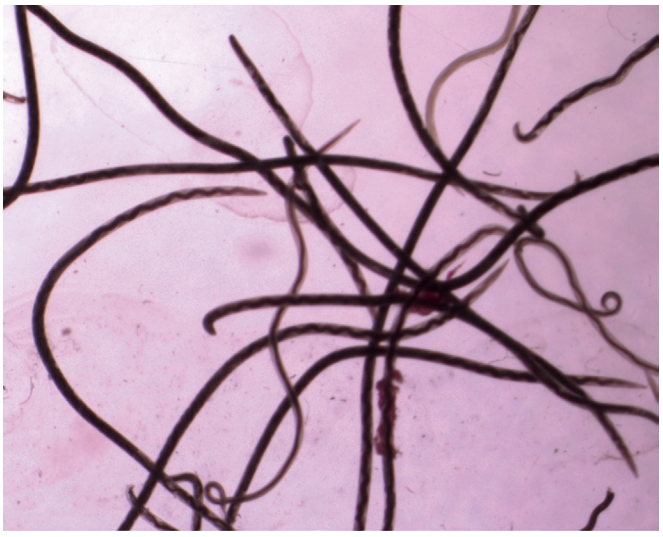

Fig. 117.14 Adult *Angiostrongylus vasorum* recovered from the pulmonary artery of a red fox from Newfoundland, Canada. Note the intestine filled with ingested blood entwined with the lighter-colored reproductive tract giving the worms a "barber's pole" appearance.

Fig. 117.15 First-stage larva (L_1) of *Angiostrongylus vasorum* recovered from the feces of a dog using the Baermann technique. Note the cephalic button and the kinked tail with a dorsal spine (see insert of tail).

Serologic Diagnosis

Sensitive and specific ELISA assays have been developed for detection of circulating antigens and antibodies to *A. vasorum* and can detect infection before 7 weeks PI, the period of patency. These assays have been made available by some university diagnostic laboratories. A rapid (15-minute) POC antigen-detection assay is also available in Europe (Angio Detect, IDEXX Laboratories). When applied to 214 dogs with suspected or confirmed disease, the sensitivity of this assay compared with the Baermann assay was 97.1% and specificity was 98.9%; there was no evidence of cross-reactivity with other common nematode parasites, including *Dirofilaria immitis*.[193] However, in one study of experimentally inoculated dogs, the Baermann assay became positive at 8 weeks, laboratory ELISA antigen assay at 11 weeks, and the POC assay at 14 weeks after inoculation, so the sensitivity of the POC assay may be low early in the course of infection.[194] Antibody testing has the potential to be positive with subclinical infection or in recovered dogs, so may lack predictive value.

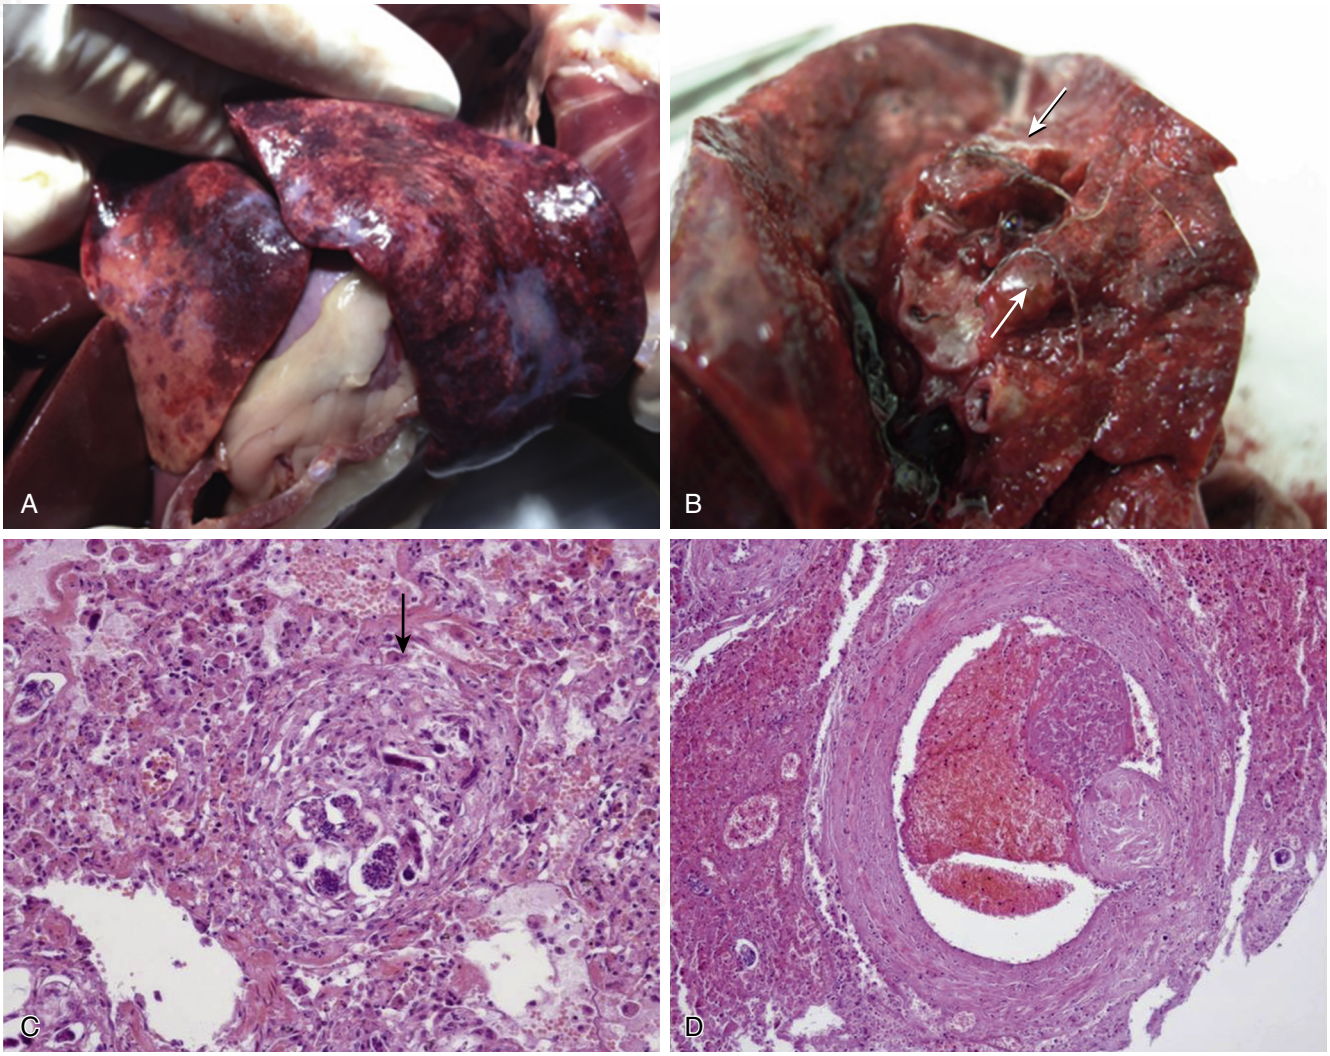

Fig. 117.16 Gross necropsy (A, B) and histopathologic (C, D) findings in a dog with *Angiostrongylus vasorum* infection. Findings at necropsy include mottled and congested lungs, multifocal pleural fibrosis, evidence of systemic petechial or ecchymotic hemorrhages, and adult worms in the pulmonary arteries. Histopathology of the lungs in dogs infected with *A. vasorum* reveals multifocal granuloma (C) that is accompanied by hemorrhage and arterial thrombosis (D). (A and B, from Di Cesare et al. Elusive *Angiostrongylus vasorum* infections. *Parasites Vectors*. 2015;8:438. C and D, from Rinaldi L, Cortese L, Meomartino L, et al. *Angiostrongylus vasorum:* epidemiological, clinical and histopathological insights. *BMC Vet Res*. 2014;10:236.)

The POC assay has been used to look for evidence of other angiostrongylid infections in domestic cats in Europe that were either positive or negative (50 cats each) for metastrongyloid nematodes on Baermann examination, none of which were positive. Cross-reactivity occurs with antigens of *Gurltia paralysans*, a related metastrongyloid nematode found in domestic and wild felids in South America.[195] *Gurltia paralysans* has a tropism for veins of the subarachnoid space, and causes chronic eosinophilic meningomyelitis and progressive paraparesis in cats (gurltiosis).

The POC assay has also been used to monitor resolution of infection with treatment,[196] but can also remain positive up to 7 weeks after treatment, possibly due to slow elimination of antigens from dying worms.[194]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Nucleic acid–based assays have been developed to detect *A. vasorum* DNA. These have been used to identify the parasite in gastropod intermediate hosts, as well as to detect infection in respiratory lavage specimens. In one study, use of a real-time PCR assay for *A. vasorum* on bronchoalveolar lavage specimens was more sensitive than Baermann analysis or detection of circulating antigen using the IDEXX POC assay.[197]

Pathologic Findings

Gross findings at necropsy include mottled and congested lungs, multifocal pleural fibrosis, evidence of systemic petechial or ecchymotic hemorrhages, and adult worms in the pulmonary arteries (Fig. 117.16A and B). Histopathology of the lungs in dogs infected with *A. vasorum* reveals multifocal granulomas in the periphery of the lungs that is accompanied by hemorrhage, arterial thrombosis, periarteritis, and with chronicity, fibrosis (Fig. 117.16C and D). Detection of undifferentiated metastrongyloid eggs together with L_1 in histologic sections of the lungs is considered pathognomonic for *A. vasorum* infection in the dog.

TABLE 117.1 Differential Features of Eggs of *Trichuris vulpis*, *Eucoleus aerophilus*, and *Eucoleus boehmi*

Nematode Species	Length (μm)	Width (μm)	Morphological Features	Plugs	Shell
Trichuris vulpis	72–94	31–42	Lemon-shaped, brownish	Symmetrical presence of rings	Thick, smooth wall
Eucoleus aerophilus	60–65	25–40	Barrel-shaped, zygote fills egg	Asymmetrical, no rings	Striated outer shell with a network of anastomosing ridges and bridges
Eucoleus boehmi	50–60	30–35	Barrel-shaped, clear to gold, space between the embryo and wall	Asymmetrical, no rings	Tiny pits on wall surface

Modified from Di Cesare A, Castagna G, Meloni S, et al. Mixed trichuroid infestation in a dog from Italy. *Parasit Vectors*. 2012;5:128.

TREATMENT AND PROGNOSIS

Treatment of *A. vasorum* infections has most often involved the use of fenbendazole (20–50 mg/kg PO for 5 to 21 days or 20–25 mg/kg PO for 20 days), topical moxidectin/imidocloprid (minimum 2.5 mg/kg moxidectin and up to 6.25 mg/kg; minimum 10 mg/kg imidacloprid and up to 25 mg/kg; one or two monthly treatments), or milbemycin oxime (0.5 mg/kg PO once weekly for 4 weeks).[190] Use of the latter two protocols represents licensed use in Europe. In addition, supportive care measures are often needed depending on clinical signs present, such as intravenous fluids, blood products, supplemental oxygen, anticonvulsants, treatment for congestive heart failure (diuretics, angiotensin-converting enzyme inhibitors), and sildenafil.

IMMUNITY AND PREVENTION

On recovery from infection, dogs are not immune and can experience repeated infections. Repeated infection also has been documented experimentally.[190] No vaccine is available. Prevention relies on minimizing access to slugs and snails as well as regular treatment with prophylactic anthelmintics. Licensed prophylactic treatments in Europe are topical moxidectin/ivermectin or oral milbemycin oxime in combination products. A single dose of a moxidectin (24 μg/kg) in combination with sarolaner (1.2 mg/kg) and pyrantel (5 mg/kg) (Simparica Trio, Zoetis) had a 95% efficacy in prevention of development of immature adults in dogs experimentally infected with *A. vasorum*; doses of 3 mg/kg and 12 mg/kg had efficacies of 7.2% and 54.5%, respectively.[198] Milbemycin oxime (0.75 to 1.0 mg/kg, PO) in combination with spinosad had an efficacy of 98.8% when administered 30 days after exposure to *A. vasorum*.[199]

PUBLIC HEALTH ASPECTS

Angiostrongylus vasorum does not infect humans.

NON-METASTRONGYLOID NEMATODE INFECTIONS OF THE RESPIRATORY TRACT

EUCOLEUS AEROPHILUS AND *EUCOLEUS BOEHMI* INFECTION (EUCOLEOSIS/CAPILLARIASIS)

Eucoleus aerophilus and *Eucoleus boehmi* (previously *Capillaria* spp.; the species name *Capillaria aerophila* was revised to *Eucoleus aerophilus*) are trichuroid nematodes with a worldwide distribution that infect the lower and upper respiratory tract, respectively. Infection with *E. aerophilus* occurs in dogs, cats, and various wild animals; *E. boehmi* infection only occurs in dogs and wild canids. Adult worms are embedded in the mucosal epithelium—*E. aerophilus* in the trachea, bronchi, and bronchioles; and *E. boehmi* in the turbinates of the nasal cavity. The life cycle of both nematode species is incompletely described although earthworms have been proposed as a possible intermediate host for *E. boehmi*.[200] Adults mate and produce bipolar-plugged eggs that are coughed up, swallowed, and passed unembryonated in the feces. Most infections appear to be subclinical, but animals infected with *E. aerophilus* may show episodes of non-productive cough, gagging, retching, tachypnea, and dyspnea. Secondary bacterial infections may lead to bronchopneumonia and a productive cough, and death can result from heavy infections.[201] Dogs infected with *E. boehmi* may show signs of sneezing, reverse sneezing, and/or nasal discharge. In addition, aberrant migration of *E. boehmi* to the CNS was reported in a dog from Texas that was evaluated for seizures and a possible meningioma based on findings on MRI.[202]

Thoracic radiographs in dogs and cats infected with *E. aerophilus* may show tracheal narrowing and mixed pulmonary patterns if secondary bacterial infection occurs. The nematodes can be visualized and retrieved for identification of adults and eggs using tracheobronchoscopy (*E. aerophilus*) or rhinoscopy (*E. boehmi*). Identification of eggs on centrifugal fecal flotation can also be used for diagnosis.[3,203] The eggs have bipolar plugs, similar to those of whipworms. Because the eggs of these nematodes may be misidentified as *Trichuris* spp., the true prevalence of *Eucoleus* spp. infections in dogs may be underestimated. Capillarid eggs can be differentiated from those of *Trichuris* spp. based on their morphologic appearance (Table 117.1). The eggs of *T. vulpis* are larger (72–90 × 32–40 μm) with a smooth shell wall surface, the plugs are symmetrical on the longitudinal midline (in most eggs), and the plugs have a series of "threaded" lines making them appear as if they were "screwed" into the shell wall (Fig. 117.17A). In contrast, capillarid (*Eucoleus* spp.) eggs are smaller, the plugs are asymmetrical on the longitudinal midline (in most eggs), the plugs lack "threaded" lines, and there is a surface shell wall pattern unique to each species (Fig. 117.17B). Eggs of *E. aerophilus* are 58–79 × 29–40 μm in size and the shell wall surface has a net-like pattern of interconnected ridges (Fig. 117.18A and B). Eggs of *E. boehmi* are 54–60 × 30–35 μm in size and the shell wall surface is covered with small pits (Fig. 117.18C and D).[3,4] In addition, a PCR assay that detects the mitochondrial *cox1* gene of

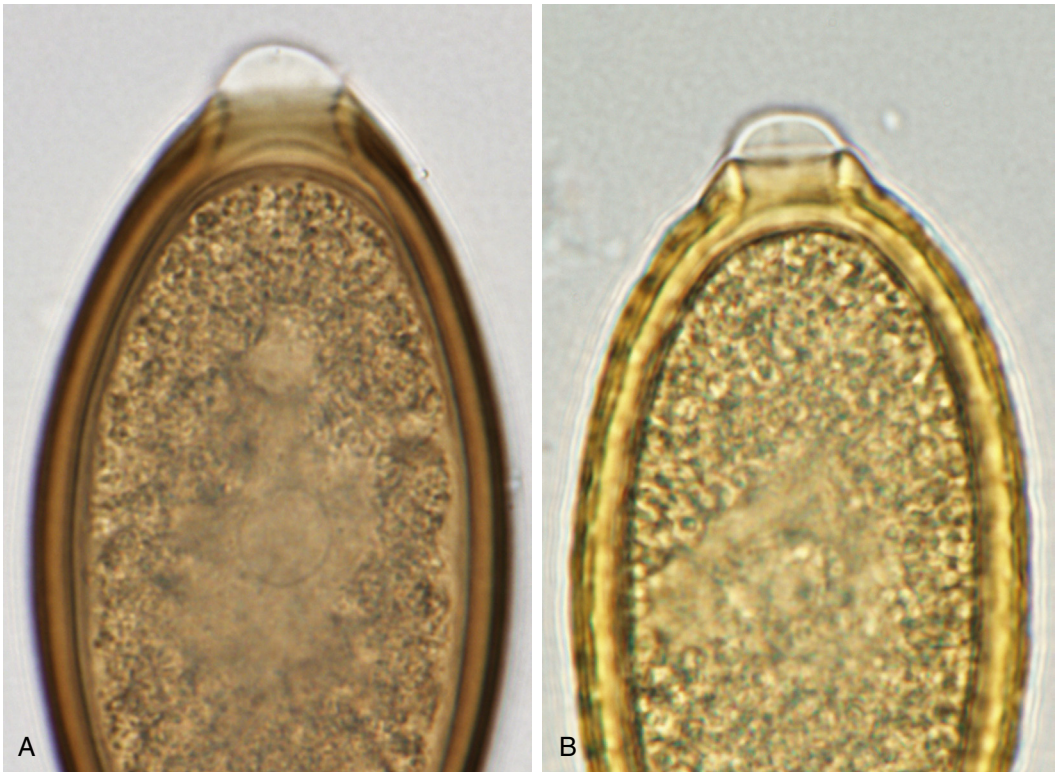

Fig. 117.17 Comparison of the morphology of trichuroid (*Trichuris* spp.) and capillarid (*Eucoleus* spp.) bipolar plugs. (A) Plug of a *Trichuris vulpis* egg from the feces of a dog. Note the "threaded lines" giving the appearance as if the plug has been "screwed" into the shell wall. (B) Plug of a *Eucoleus aerophilus* egg from the feces of a dog. Capillarid egg plugs of *Eucoleus* spp. lack the threaded lines.

nematodes in the subfamily Capillariinae has been used to identify *Eucoleus* spp. in stool specimens and differentiate them from *T. vulpis*.[203]

There are currently no anthelmintics approved for use in the treatment of dogs and cats infected with *E. aerophilus* or dogs infected with *E. boehmi*. Eprinomectin, fenbendazole, and moxidectin have been used to successfully treat cats infected with *E. aerophilus*. A single topical application of eprinomectin (0.5 mg/kg) in combination with fipronil, (S)-methoprene, and praziquantel had an efficacy of 82.4% in cats naturally infected with *E. aerophilus*. In a case report involving a single animal, fenbendazole (50 mg/kg, PO, q24h for 14 days) was reported as an effective treatment in a cat; clinical signs resolved after treatment; however, a second 14-day course was required due to a return of egg excretion.[204] Efficacies (based on fecal egg counts) of 99.8 to 100% were reported with topical moxidectin (1.0 mg/kg) combined with imidicloprid in cats infected with *E. aerophilus*.[205,206] Fenbendazole and milbemycin oxime have been used to successfully treat dogs infected with *E. aerophilus*. Treatment with fenbendazole (50 mg/kg, PO, q24h for 14 days) resulted in a clinical cure and the cessation of fecal egg shedding in a dog with Addison's disease also infected with *E. aerophilus*.[207] Negative fecal examination results occurred after the first treatment of eight dogs infected with *E. aerophilus* in a 6-month field study on monthly use of milbemycin oxime (0.5–1.0 mg/kg) combined with afoxolaner.[208]

Fenbendazole, ivermectin, and moxidectin have been used successfully to treat dogs infected with *E. boehmi*. Fenbendazole at several dosages (50 mg/kg, PO, q24h for 14 days or 110 mg/kg q12h for 14 days), ivermectin (0.2 mg/kg, PO, once), and milbemycin oxime (2 mg/kg, PO, once) have been reported to be effective in the treatment of dogs infected with *E. boehmi*.[202,209–211] In several field studies using topical moxidectin (2.5–6.25 mg/kg) in combination with imidacloprid to treat dogs naturally infected with *E. boehmi*, reported efficacies based on fecal egg counts were 99 to 99.7% with a single application and 100% after two applications.[203] A short course of glucocorticoids may be indicated for animals with severe respiratory difficulty to reduce tracheitis or bronchitis (e.g., prednisolone sodium succinate, dexamethasone sodium phosphate). There have been several reports of treatment failures with multiple anthelmintics (fenbendazole, milbemycin oxime, and moxidectin) in dogs infected with *E. aerophilus* and *E. boehmi*.[212,213] Whether failure to respond adequately to treatment reflects reinfection from the environment or is due to some other factor remains unknown. In some cases, further treatments are required, as well as efforts to clean the environment and limit coprophagy by dogs. Post-treatment fecal surveillance to monitor anthelmintic effectiveness is extremely important in the management of cases of capillarid infections in both dogs and cats. Rare (< 20) cases of human infection by *E. aerophilus* have been reported in the literature.[214]

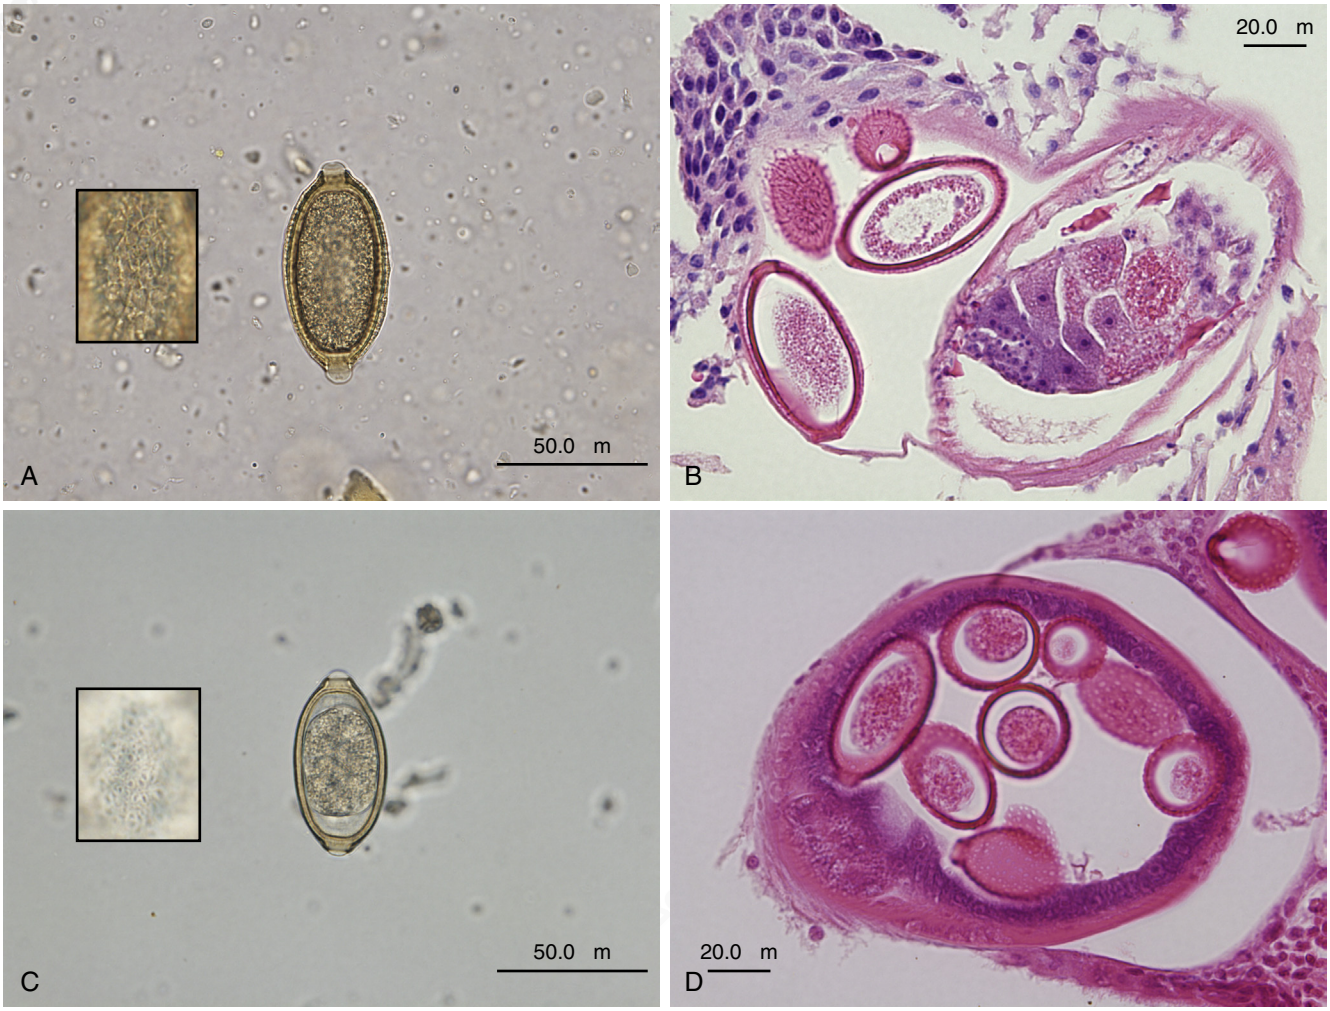

Fig. 117.18 Comparative features of *Eucoleus aerophilus* and *Eucoleus boehmi* eggs. (A) *Eucoleus aerophilus* egg recovered from the feces of a cat. Inserted is a high-magnification view of the shell wall surface showing the net-like pattern of interconnecting ridges. (B) Histologic section of an adult female *E. aerophilus* in the bronchi of a red fox. Plugs and the net-like ridges on the surface are visible in several of the eggs. Hematoxylin and eosin stain. (C) *Eucoleus boehmi* egg recovered from the feces of a dog. Inserted is a high-magnification view of the shell wall showing the small pits on the surface. (D) Histologic section of an adult female *E. boehmi* in the nasal turbinates of a red fox. Plugs and the pitted shell wall surface are visible in several of the eggs. Hematoxylin and eosin stain.

CASE EXAMPLE

Signalment

"Sass," a 1-year-old intact female toy poodle from West Sacramento in northern California.

History

Sass was evaluated at the University of California-Davis VMTH for a 6-month history of chronic intermittent cough and gagging that began 1 month after she was acquired. Episodes of clinical signs were sometimes associated with inappetence and lethargy and persisted for several weeks at a time; at least 8 episodes were reported. The cough was not associated with eating, drinking, or exercise. Diagnostics performed at several other veterinary clinics over the course of illness included thoracic and abdominal radiographs, CBC, chemistry profile, pancreatic lipase immunoreactivity, and a direct fecal smear and flotation, all of which had been negative. Sass had also been treated with clavulanic acid-amoxicillin and doxycycline with mild clinical improvement.

Current Medications

None

Other Medical History

There was no other known medical history. Sass was an indoor/outdoor dog and was current on routine vaccinations. The owner reported feeding a homemade chicken- and rice-based diet with some potato and dry dog food added.

Physical Examination

Body weight: 2.5 kg

Sass was quiet, alert, and responsive; had pale pink mucous membranes, HR 140 beats/min, RR 30 breaths/min, T = 102°F, and BCS 5/9. A cough was easily elicited on tracheal palpation. No other clinically significant abnormalities were identified on physical examination.

Centrifugal zinc sulfate fecal flotation and Baermann examination: Negative for parasites.

CASE EXAMPLE—cont'd

Imaging Findings

Tracheal fluoroscopy: There was no evidence of tracheal collapse when a cough was elicited. However, dynamic narrowing of the mainstem bronchi was noted that was suggestive of bronchiectasis.

Bronchoscopy: Four soft-tissue nodules were identified at the level of the carina (see Fig. 117.11). The remainder of the respiratory tract was within normal limits.

Cytology Findings

Bronchoalveolar lavage: Total nucleated cell count 1940 cells/μL with 9% neutrophils, 4% lymphocytes, 16% macrophages, 65% eosinophils, and 6% mast cells. The cytofuge specimen was highly cellular with moderate accumulations of mucinous material in a clear background. Large numbers of eosinophils were admixed with macrophages, some of which contained foamy cytoplasmic vacuoles.

Impression smear of nodule biopsy: There were numerous parasite larvae either free or within eggs in a moderately cellular background.

Histopathology of Nodule Biopsy (see Fig. 117.12B)

Sections are composed of nodules of extensively inflamed fibrous connective tissue that contains numerous tangential and cross sections of nematode parasites. The nodules are variably covered by a pseudostratified columnar ciliated-to-low cuboidal epithelium. The nematodes have a pseudocoelomic body cavity and an intestine. Consistent with metastrongyloids, the cuticle is smooth, the intestine is composed of a few multinucleate cells with short microvilli, and the uterus of female worms contain developing L_1. There are a few free larvae within the inflammatory nodules. Many of the nematodes are surrounded by a dense fibrous capsule. Inflammatory cells include numerous lymphocytes, plasma cells, and histiocytes that extensively expand the submucosal fibrovascular connective tissue separating collagen bundles.

Diagnosis

Oslerus osleri infection.

Treatment

Fenbendazole, 50 mg/kg PO q12h for 14 days and butorphanol (0.05 mg/kg PO up to q8h) for cough. Larvae were not detected on zinc sulfate centrifugal flotation and simple sedimentation fecal examinations performed 2 weeks later and the dog had improved clinically. The owner was informed that a second bronchoscopy to re-evaluate the nodules was advisable and additional treatment may be required. However, 2 days later she was brought to the emergency room when her owners found her vomiting and obtunded in their back yard. She was found to be in hypovolemic shock and was diagnosed with hemoabdomen. The owners elected euthanasia based on the guarded prognosis and financial concerns.

Comments

This dog was diagnosed with *O. osleri* infection based on the presence of nodules that contained parasitic larvae that had morphology supportive of that diagnosis. Larvae were not detected in the feces both before and after treatment by any of the methods employed (Baermann, flotation, sedimentation). Baermann examination has poor detection sensitivity due to the moribund state of *O. osleri* L_1 excreted in the feces; the primary use of the Baermann test in this case was to screen for possible infection with *A. vasorum* or *C. vulpis*. Although zinc sulfate centrifugal flotation has greater detection sensitivity than the Baermann examination, it also has a low sensitivity. The most reliable fecal examination method for detecting *O. osleri* L_1 is fecal sedimentation. Due to the considerable time and effort necessary to perform the fecal sedimentation test, it is useful to attempt to detect the larvae first by zinc sulfate centrifugal flotation. Larvae were also not detected by fecal sedimentation and this was likely due to the erratic shedding pattern typical of metastrongyloids. Had the *O. osleri* infection diagnosis not been made by the detection of nodules and larvae on bronchoscopy, further fecal specimens would have been requested before ruling out lungworm infection. The cause of the hemoabdomen was unknown, but the dog was reported to roam freely outdoors and had access to rodenticide, so anticoagulant rodenticide toxicity was considered most likely in light of the signalment and history.

Trematodes

Karen F. Snowden, Jennifer K. Ketzis

KEY POINTS

Heterobilharzia americana Infection (Heterobilharziasis/Canine Schistosomiasis)

- First Described: *Heterobilharzia americana* was first described as an adult worm recovered from a bobcat (*Lynx rufus*) in 1929, and more fully described in specimens from a raccoon (*Procyon lotor*) in 1943. The parasite was first reported in dogs in Louisiana in 1961.
- Cause: *Heterobilharzia americana* (Platyhelminthes, Trematoda, Digenea, Strigeidida, Schistosomatidoidea, Schistosomatidae).
- Affected Hosts: A variety of wildlife hosts, most commonly the raccoon (*P. lotor*). Dogs are the most frequently identified domestic animal hosts, but the parasite has also been shown to cause disease in horses and llama.
- Intermediate hosts: Freshwater snails in the lymnaeid family, with Galba (previously Fossaria or Lymnaea), *Galba humilis,* and *Pseudosuccinia columella* confirmed as intermediate hosts by experimental infection.
- Geographic Distribution: Primarily the southeastern United States, but the range appears to be expanding.
- Route of Transmission: Penetration of intact skin by the larval cercarial stage that is released from snails in fresh water.
- Major Clinical Signs: Many infections are subclinical, but the most frequent signs are chronic or recurrent diarrhea, weight loss, and sometimes hematochezia in response to adult parasites in the mesenteric veins and migrating eggs in the intestinal mucosa. Hepatic fibrosis and pancreatitis can occur due to inflammatory changes associated with hematogenously disseminated eggs in various tissues.
- Differential Diagnoses: Depending on signs, these are a wide variety of neoplastic, toxic, or infectious/inflammatory causes. In a case series review, possible differentials included cholecalciferol toxicity, ethylene glycol toxicity, lymphoma, and pancreatitis. A variety of infectious pathogens can cause enteritis and hemorrhagic diarrhea. The differential diagnosis for hypercalcemia (sometimes present) includes malignancy-associated disease, endocrinopathies, renal failure, or a variety of infectious or inflammatory diseases.
- Human Health Significance: No human infections with *H. americana* have been reported. However, it is possible that the free-swimming cercarial stage may be able to penetrate human skin causing "cercarial dermatitis" as reported from the closely related avian schistosomes found in waterfowl.

Paragonimus kellicotti Infection (Paragonomiasis)

- First Described: *Paragonimus kellicotti* was described as a new species by Ward in 1908 after a careful review of eggs and other parasitologic specimens from humans from different geographic localities.
- Cause: Over a dozen respiratory trematode species have been described in dogs and cats on a global basis. In the United States, *Paragonimus kellicotti* (Platyhelminthes, Trematoda, Paragonomidae) is the helminth parasite that localizes in cystic spaces in the lung parenchyma of dogs and cats.
- Affected Hosts: *Paragonimus* spp. infect domestic dogs and cats, and less frequently are reported in a variety of wildlife hosts and humans.
- Intermediate hosts: The first intermediate hosts for *Paragonimus* spp. are aquatic snails, and the second intermediate hosts are typically crabs or crayfish, depending on the parasite species. For *P. kellicotti*, reported snail intermediate hosts include *Pomatiopsis lapidaria, Pomatiopsis cincinnatiensis* or *Oncomelania nosophora*, and the crayfish hosts, *Cambarus* spp. or *Orconectes* spp.
- Geographic Distribution: Various species of *Paragonimus* are globally distributed in temperate climates, with *P. kellicotti* being the important species in North America.
- Route of Transmission: Mammalian hosts become infected by ingesting the metacercaria larval stage found in the tissues of the second intermediate host (crab or crayfish). Ingestion of infected paratenic hosts may also occur.
- Major Clinical Signs: *Paragonimus* infections may be subclinical or may be associated with signs of respiratory disease, most often intermittent or chronic cough.
- Differential Diagnoses: *Paragonimus kellicotti* is found in cystic spaces in the pulmonary parenchyma, so major differential diagnostic considerations include pulmonary abscesses, metastatic neoplasia, cavitated neoplasms, and mycotic pneumonia.
- Human Health Significance: *Paragonimus kellicotti* is a zoonotic parasite that causes respiratory disease in humans. Humans become infected through the ingestion of raw or undercooked crab or crayfish intermediate hosts, so contact with dogs or cats does not pose a direct risk to humans.

Platynosomum illiciens Infection (Platynosomiasis)

- First Described: *Platynosomum illiciens* (synonyms *Platynosomum concinnum* and *Platynosomum fastosum*) was isolated from civet cat by Braun in 1901 (named *Dicrocelium concinnum*) and *Felis minuta* by Kossack in 1910. Other potential synonyms are *Dicrocelium lanceolatum* var *symmetricum* and *Concinnum concinnum.*
- Cause: *Platynosomum illiciens* (previously *Platynosomum fastosum*), a liver fluke of cats, which belongs to the class Trematoda and family Dicrocoeliidae.
- Affected Hosts: Domestic cats and a variety of wild cats. *Platynosomum* spp. also have been found in other hosts (e.g., opossums, ferrets, mice, non-human primates, and birds); it is unclear if these are true or incidental hosts, or if it is *P. illiciens* or another species in these hosts.
- Intermediate and paratenic hosts: The first intermediate host of *P. illiciens* is a land snail (e.g., *Subulina octona*). Isopods (*Oniscidea* spp. and *Nagurus* spp.) are considered the primary second intermediate host. Paratenic hosts include reptiles and amphibians (e.g., *Anolis* spp., *Hemidactylus* spp., *Tropidurus* spp., *Bufo* spp.) with mice potentially serving as paratenic hosts and final hosts.

- Geographic Distribution: Tropical and subtropical regions of the world, including those in Central and South America, the Caribbean, Asia, and Africa. In North America, *P. illiciens* occurs in Florida; there are no reports of infection in cats from Europe.
- Route of Transmission: Ingestion of excysted metacercariae in paratenic hosts or encysted metacercariae in a second intermediate host.
- Major Clinical Signs: Most infections are subclinical. Clinical signs are consistent with liver disease and include anorexia, weight loss, jaundice, vomiting and diarrhea.
- Differential Diagnoses: Differentials include polycystic liver disease, biliary carcinoma, and other nonparasitic causes of liver disease. When geographic distribution overlaps or cats have traveled between endemic areas, differentials include other fluke species that infect the liver and bile ducts (e.g., *Opisthorchis felineus*).
- Human Health Significance: *Platynosomum illiciens* is not considered to be zoonotic.

Alaria spp. Infections

- First Described: The mesocercaria larval stage of *Alaria marcianae* was first described by La Rue (1917) in a garter snake and named *Cercaria marcianae.*[1] Walton (1949) proposed the scientific name *A. marcianae* based on studies in frogs.[2] The first description of *Alaria alata* was attributed to Goeze (1782). Adult *Alaria* parasites were first described in naturally infected cats (*A. marcianae*) and dogs (*Alaria canis*) in 1965.[3] Additional species have been described in dogs, cats, and a number of wildlife hosts, and several parasite species have been synonymized. Due to challenges in parasite identification, several clinical reports use only the genus name (*Alaria* sp.)
- Cause: Members of the genus *Alaria* are Diplostomatid trematode parasites that localize in the small intestine of the definitive mammalian host. Multiple species have been described in the cat and dog, especially *Alaria marcianae* (cats) and *Alaria alata* (dogs).
- Affected Hosts: Domestic dogs, domestic cats, a variety of wild canids and felids, and other small mammals serve as definitive hosts.
- First intermediate host: In the United States, planorbid snails including *Heliosoma trivola* and *Heliosoma campanulatum*; other snail species are first intermediate hosts on other continents.
- Second intermediate host: In the United States, frogs in the Ranidae family, including *Rana catesbeiana, Rana clamitans, Rana utricularia, Myla cinerea,* and *Gastrophryne carolinensis.* Other amphibian intermediate hosts have been identified for various *Alaria* spp.
- Paratenic host: A number of nonessential hosts such as rodents, frogs, garter snakes, feral swine, and domestic chickens have been described and may be important in maintaining the parasite until the life cycle is completed in the carnivore definitive host.
- Geographic Distribution: Temperate climates across North America from Canada to Louisiana, Mexico, and South America; Europe; Middle East; and Africa.
- Route of Transmission: Ingestion of an intermediate or paratenic host that contain mesocercaria.
- Major Clinical Signs: Adult *Alaria* spp. attach to the small intestinal mucosa but do not cause signs in dogs and cats. In other hosts, adult flukes may cause enteritis, and migrating larval stages may cause damage, inflammation, and hemorrhage in the lungs or other viscera.
- Differential Diagnoses: Infections are subclinical, so this is not applicable.
- Human Health Significance: *Alaria* spp. are generally considered zoonotic parasites. The migrating larval mesocercariae may cause serious clinical disease, and human fatalities have been reported. Humans become infected by ingesting raw or poorly cooked frogs or paratenic hosts, but human association with infected dogs or cats does not pose a direct transmission risk.

HETEROBILHARZIA AMERICANA INFECTION (HETEROBILHARZIASIS/CANINE SCHISTOSOMIASIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Heterobilharzia americana (Platyhelminthes, Trematoda, Digenea, Strigeidida, Schistosomatidoidea, Schistosomatidae) is a trematode parasite of wildlife and domestic mammals in North America, and it is the only species in this genus.[4–9] It was originally described by Price (1929) who reported an adult worm in a bobcat (*Lynx rufus*) in Florida, and was later redescribed from specimens recovered from a raccoon (*Procyon lotor*) in Texas.[4,5] The parasite was first described in dogs in Louisiana in 1961.[6] *Heterobilharzia americana* belongs to the Schistomatidae family that includes several species such as *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum* that are of global importance as "neglected tropical disease" pathogens in humans.[10] Adult worms of the majority of these species infect the blood vessels of the host intestine, with a few species infecting the vasculature of other organs. This group of parasites are informally called "schistosomes" and the clinical infection is often referred to as "schistosomiasis."

The life cycle of the parasite is maintained in wildlife and has been reported most frequently in raccoons,[11,12] as well a variety of other mammals including nutria (*Myocastor coypus*), swamp rabbit (*Sylvilagus aquaticus*),[6] opossum (*Didelphis virginianis*),[13] beaver (*Castor canadensis*),[14] and white-tailed deer (*Odocoileus virginianus*).[15] *Heterobilharzia americana* has also been identified in various wild carnivores such as coyote (*Canis latrans*),[16] mink (*Mustela vison*),[11] and black bear (*Ursus americanus*).[12] On occasion, *H. americana* also infects horses (*Equus ferus caballus*) and zebras (*Equus burchelli boehmi*).[17,18]

Cases in dogs have been reported across the southern United States, including Louisiana, Florida, North Carolina, Kansas, Arkansas, Georgia, and Texas.[7,19–21] The identification of cases in the last decade from California, Oklahoma, Kansas, Utah, and Illinois indicates a wider geographic distribution of the parasite than is generally recognized (Sykes, unpublished observations).[21,23,24]

The life cycle of *H. americana* requires fresh water for transmission among hosts (Fig. 118.1). Long slender adult male and female worms (6 to 12 mm in length) are typically paired *in copula*, and reside in the mesenteric veins. Eggs that contain already developed miracidia are excreted from adult females in mesenteric veins. The eggs then migrate through the small intestinal tissue to the gut lumen and are passed in feces. When eggs are deposited in water, the larval miracidium hatches and infects the first intermediate host, small conical aquatic lymnaeid snails (*Galba* (previously *Fossaria* or *Lymnaea*) *cubensis, Pseudosuccinia columella*, *Galba humulis*).[25–28] Following asexual multiplication through two sporocyst larval stages, motile cercarial larvae are released from the snails into the water and actively penetrate the intact skin of

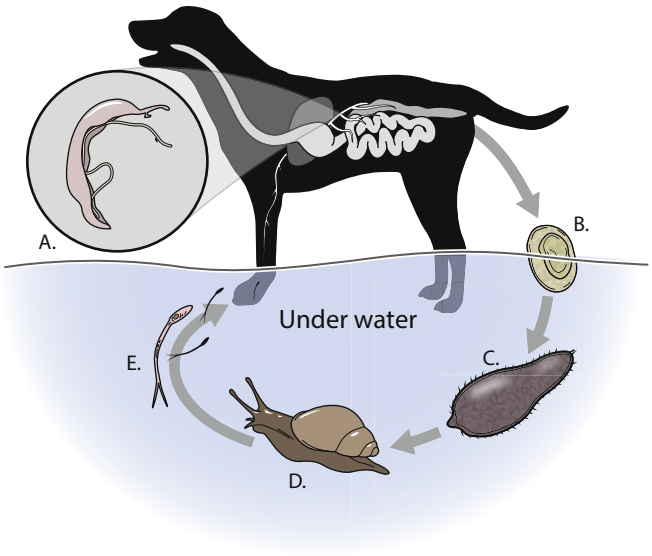

Fig. 118.1 Life cycle of *Heterobilharzia americana*. Adult trematodes in the mesenteric veins (A) produce eggs which pass through the intestinal wall and are excreted in the feces (B). When the egg contacts fresh water, a fully developed miracidium is released (C) and infects a snail first intermediate host (D). After asexual development in the snail, motile cercaria emerge and penetrate the skin of the definitive host (E) where they migrate to the mesenteric veins and, in 2–4 months, develop into adults.

mammalian hosts. The prepatent period (PPP) is estimated at 2 to 4 months based on egg excretion at 61 to 70 days and 65 to 121 days in a small number of experimentally infected dogs in two studies.[27,29] The longevity of adult *Heterobilharzia* in the mammalian definitive host has not been well studied, but closely related schistosome adult parasites live an average of 3 to 10 years and have been documented for as long as 40 years in humans.[10]

Only limited information is available on risk factors for canine schistosomiasis. In one report of 214 cases from Texas, the age range was 3 months to 17 years (median 5.5 years) with an even gender distribution.[7] All American Kennel Club breed groups were represented, with herding and sporting breeds and mixed breed dogs in the highest numbers. Affected dogs typically have an outdoor lifestyle with exposure to fresh water sources, which is consistent with the route of parasite transmission. No significant seasonality has been noted, but for 12 cases more than one dog in a household was infected, suggesting that multiple dogs were exposed to a common infected water source.

CLINICAL FEATURES

The clinical signs associated with heterobilharziasis range widely from no clinical signs to signs with a fatal outcome, and various stages of the parasite life cycle result in a spectrum of clinical problems. The presence of paired adult parasites in the mesenteric veins and migration of eggs through the intestinal wall from the serosa to the intestinal lumen typically results in signs associated with inflammatory intestinal lesions including intermittent diarrhea with or without blood and mucus, anorexia/hyporexia, weight loss of variable duration, and hematochezia.[7,8,21,30–32] Additionally, eggs may be carried by portal circulation to the liver causing chronic granulomatous inflammation and hepatic fibrosis.[7] Less frequently, eggs disseminate hematogenously to other organs including pancreas, spleen, lungs, lymph nodes, and kidneys and cause granulomatous inflammation resulting in organ-specific problems such as pancreatitis and glomerulonephritis.[7,32–34] The intensity and duration of infection impact the spectrum and severity of clinical problems.

DIAGNOSIS

Diagnosis of *H. americana* infections can be challenging because the parasite infection is under-recognized and the clinical signs are nonspecific and varied. Often infection is diagnosed at necropsy, and sometimes it is considered an incidental finding rather than the primary cause of clinical disease or fatality. In one retrospective case series of 22 dogs, the diagnosis was obtained by necropsy, histopathology, or fecal examination; in approximately one third of cases, *H. americana* infection was an incidental finding.[32] In another review of 238 cases, the diagnosis was confirmed by histopathology, egg identification on fecal examinations, or fecal PCR assays; a number of cases were positive using multiple methods.[7] In that study, infection was considered an incidental finding in 42% of dogs. In another retrospective evaluation of 60 cases from 2010 to 2019, diagnosis was made most commonly by fecal PCR alone (82%) followed by identification of eggs in feces or lesions on histopathology, and infection considered incidental in 12%.[22]

Laboratory Abnormalities

Complete Blood Count

Consistent hematologic changes in white or red blood cell counts are not seen in association with infection with this parasite although a mild anemia has been noted in a few case reports, probably secondary to chronic inflammation.[20,31,32] Anemia was reported in 18% and eosinophil count > 500/μL in 42% of dogs confirmed to be infected.[22]

Serum Chemistry Profile and Urinalysis

The most frequently reported clinical chemistry abnormalities are hyperglobulinemia and a variable, but inconsistent, hypercalcemia.[7,21,30–32,34] In one case series, more than 40% of dogs infected with *H. americana* were hypergammglobulinemic, while hypercalcemia caused by *H. americana* was identified in a minority (7%) of infected dogs and 17% were hypocalcemic.[22] Parathyroid hormone or

parathyroid hormone-related protein concentrations have been within normal limits or increased.[21,30,31,34] In some patients with *H. americana* infection, renal function is compromised based on increased BUN and/or creatinine concentrations, or significant proteinuria that suggests the presence of glomerulitis.[7,21,33] Other clinical chemistry changes occasionally reported include increased serum liver enzyme activities (ALT and/or ALP) or hypoalbuminemia.[7,12,20,22,32–35]

Diagnostic Imaging

Plain Radiography

Imaging techniques may be suggestive of granulomatous inflammatory tissue changes associated with chronic *H. americana* infection. Abdominal radiography can be helpful in documenting focal mineralized lesions associated with the chronic granulomas that may be distributed in the small intestine or other tissues.[21,35,36] Hepatomegaly may also be noted.[31]

Sonographic Findings

In a few canine case reports, abdominal ultrasonography showed thickened walls of small intestinal loops or enlarged mesenteric lymph nodes and splenomegaly.[20,21,34] In one case series, 8 of 13 infected dogs had hepatic abnormalities on abdominal ultrasonography.[32] One of the often-noted lesions in chronic infections are hyperechoic foci in small intestine and sometimes kidney or liver indicating egg-associated mineralized granulomas.[21,31,36,37]

Parasitologic Tests

Diagnosis Using Fecal Examination

Detection of eggs using fecal sedimentation test is a simple but insensitive diagnostic method that can be conducted in a primary care setting.[38] Since adult female *H. americana* intermittently produce thin-shelled eggs (clear to golden, round to oval, 74–113 × 60–80 µm) that are passed in feces, the likelihood of egg detection is increased if the test is conducted on three or more fecal specimens collected on different days (Fig. 118.2A). Unlike most trematode eggs, there is no obvious operculum as a distinctive morphologic feature, but a freshly voided egg contains a developed miracidium which serves as a distinguishing characteristic. Since these larval miracidia readily hatch from eggs in fresh water, it is important to use saline (0.9% to 1.2% NaCl) rather than water in the fecal sedimentation test. In multiple case reports, trematode eggs were recovered by sedimentation, confirming active infections, and often negative tests were considered as an indicator of successful treatment.[21,31]

Although eggs can be identified on a direct fecal smear or saline wet mount, those methods have very low sensitivity and are not recommended for diagnosis.[33] In several case reports, no eggs were recovered by fecal flotation, the most widely used routine parasitologic fecal screening test.[20,21,30] These negative results are not surprising since most trematode eggs are relatively dense and are not typically recovered by flotation methods.

Cytologic Diagnosis

Heterobilharzia americana infection can be diagnosed by light microscopic examination of biopsied tissues retrieved by upper GI endoscopy, exploratory laparotomy, or FNA.[19–21,23,31–33] Diagnosis is usually inferred based on the presence of eggs or egg fragments, or characteristic multifocal granulomatous lesions in the intestine, liver, or sometimes other tissues. In 24 dogs where diagnosis of *H. americana* infection was achieved by biopsy,[7] associated disease was present in 16 dogs, whereas the parasite was considered an incidental finding in 8 dogs. Interestingly, heterobilharziasis was not considered as a differential diagnosis in 14 of those cases, and biopsies were conducted based on suspected neoplasia or other hepatic disease. The sensitivity of biopsies for diagnosis depends on the intensity and distribution of granulomas and eggs in various tissues and the size of the specimen collected.

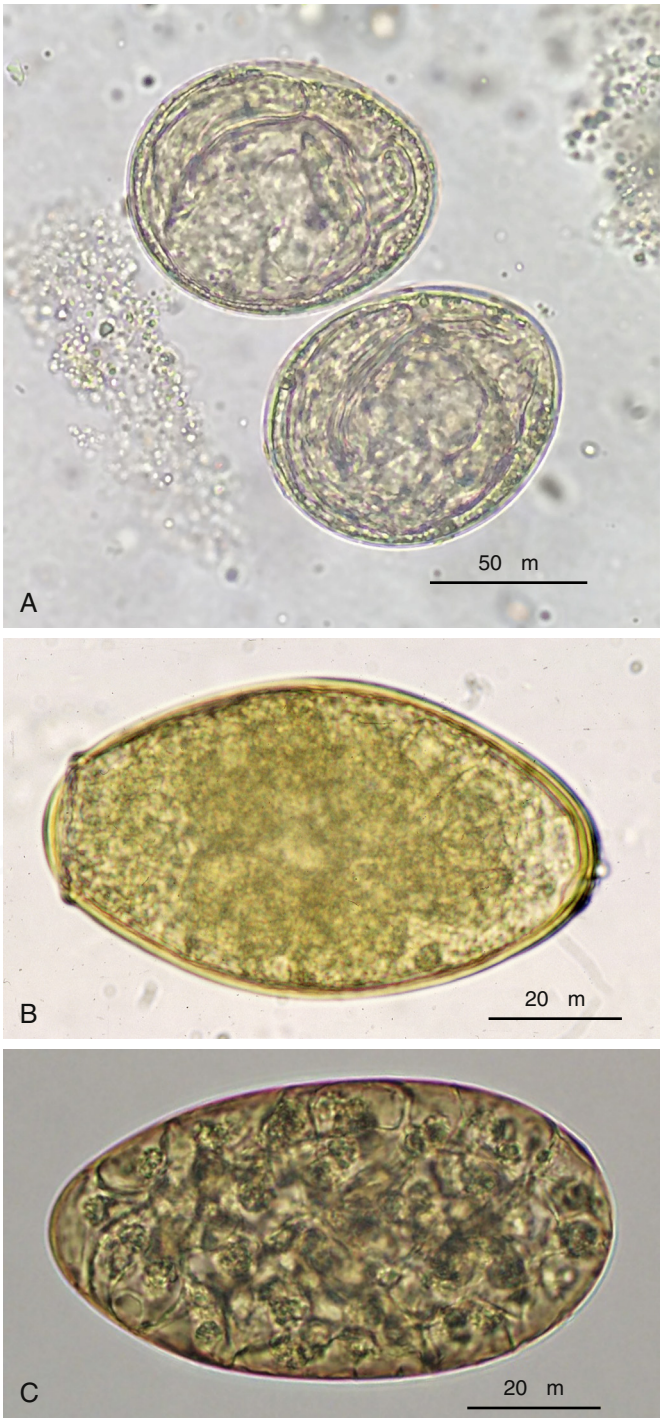

Fig. 118.2 Diagnostically important trematode eggs. (A) *Heterobilharzia americana* eggs containing developed miracidia at the time of detection on a fecal sedimentation test; bar = 50 µm. (B) *Paragonimus* sp. egg showing characteristic operculum with a lip and a small button structure on the opposite pole; bar = 25 µm. (C) *Alaria* sp. egg with an indistinct operculum and an undifferentiated embryo surrounded by yolk cells; bar = 20 µm. (A, Courtesy of Dr. Jessica Rodriguez, Zoetis Animal Health; C, Courtesy of Dr. Yoko Nagamori, Oklahoma State University, College of Veterinary Medicine.)

Serologic Diagnosis

Numerous immunologic methods for diagnosis of human schistosomiasis are described in the scientific literature. Both antigen and parasite-specific antibody detection tests are commercially available for use in individual cases or in serologic surveys in humans.[10] Since several

antigens have been shown to be highly conserved among various schistosome species, it is likely that some of these tests could be adapted for veterinary use. However, a lack of demand for these tests on a large scale makes it unlikely that tests validated for use in dogs will be available in the near future. In an interesting case report, an antigen capture ELISA detecting schistosome circulating anodic antigen and designed for human use was positive in a confirmed canine case.[20] Repeated ELISA testing showed a decrease in serum antigen level following anthelmintic treatment.

Molecular Diagnosis Using Nucleic Acid–Based Testing

While molecular diagnostic methods are increasingly used for detection of schistosome parasites in human infections, there is limited information on the molecular detection of *H. americana* in animals. At the time of writing, there is one commercially available fecal *H. americana* qPCR test for dogs (Texas A&M University, Gastrointestinal Laboratory, College Station, TX). Although commonly used for diagnosis at some academic centers, a full description of the methodology, gene target, sensitivity and specificity are not available.[21]

In another case report, the identity of histologically apparent parasites was confirmed at necropsy as *H. americana.* End-point (conventional) PCR amplification and sequencing of a 487 base pair sequence of the parasite *small subunit rRNA* gene was successfully completed using formalin-fixed, paraffin-embedded tissue from liver and small intestine.[35]

Pathologic Findings

Gross Pathologic Findings

Commonly reported gross lesions in dogs infected with *H. americana* include segmental areas of thickened small intestinal walls and enlarged mesenteric lymph nodes.[34,35] Other findings sometimes include pale, firm (fibrotic) liver, or pale kidneys with or without pale, firm foci of mineralized granulomas.[34] In some case reports, macroscopic lesions included firm white areas of dystrophic mineralization in the heart, thoracic aorta, kidney, or intercostal muscle.[30,35]

Histopathologic Findings

The most notable histopathologic finding in dogs with heterobilharziasis is granulomatous inflammation associated with eggs that are disseminated in a variety of tissues. In 39 dogs that were necropsied, the most commonly affected tissues were small intestine, liver, and pancreas, with occasional egg-associated lesions in the large intestine and rectum, kidney, and lung.[7] Thin-walled, clear to golden-colored eggs or egg shell fragments are sometimes visualized microscopically in association with granulomas in various tissues (Fig. 118.3). In the small intestine, eggs are sometimes arranged in linear rows as they migrate through the intestinal wall to enter the lumen.[5,35] Sections of adult parasites may be identified in veins of the small intestine, colon, rectum, liver, lung, or pancreas. In addition to granulomas, local to focally extensive lymphoplasmacytic and sometimes eosinophilic inflammation can be present. Other reported histopathologic changes include fibrosis, hemosiderin pigment in macrophages, focal mineralization associated with granulomas, and bile duct hyperplasia. In hypercalcemic dogs, dystrophic mineralization has been noted in the gastric mucosa, cardiac tissues, and skeletal muscle.[30,34,35]

TREATMENT AND PROGNOSIS

No anthelmintics are label-approved for the treatment of *H. americana* infection and current extra-label recommendations are mostly anecdotal. No data from clinical trials comparing different treatment protocols have been published. Praziquantel and fenbendazole have been used individually, sequentially, or in combination in various clinical reports (Table 118.1). In several cases, praziquantel at varying doses was generally effective. The canine dose of praziquantel labeled for the control of cestodes (5 mg/kg, PO) is inadequate for treating many trematode infections. Praziquantel is the treatment of choice for human schistosome infections (40 to 60 mg/kg, PO, depending on the parasite species).[10] The most significant adverse effect of high-dose praziquantel is GI irritation and vomiting, which can be mitigated by dividing the daily dose into several treatments and administering the drug with food.

In a clinical report and in one experimentally infected dog, fenbendazole treatment was considered effective.[21,39] In other case reports, a

combination of praziquantel and fenbendazole had varied therapeutic success using several different dosing regimens or repeated treatments.[7,21,32,33,40] In some cases, successful treatment was defined as remission of clinical signs, whereas in other cases, negative fecal sedimentation tests were used to determine therapeutic success (see Table 118.1). Both praziquantel and fenbendazole are readily available and labeled for use in dogs as treatment for infections by other helminths; concurrent extra-label use of these drugs at higher than labeled doses is currently considered the best treatment option.

IMMUNITY AND VACCINATION

No vaccines are available for canine schistosomiasis, and studies regarding protective immunity have not been reported. Reinfection has been noted in multiple clinical cases, so it is unlikely that dogs develop protective immunity.

PREVENTION

Based on the mode of transmission, the most obvious way to prevent infection is to limit dog access to surface water locations (wading or swimming in water). The lymnaeid snail intermediate hosts are typically found in shallow, stagnant fresh water such as persistent puddles and pond edges (not fast-running streams). They are small, conical snails which may not be obvious based on casual observation of the aquatic environment.[25,26] Since raccoons are common hosts, the presence of wildlife around a water source would increase the likelihood of contamination of the area with egg-containing feces, leading to establishment of the life cycle. Historically, the use of molluscicides for snail control was recommended in developing countries as part of human schistosome control programs, but no such efforts have been reported in the United States for this parasite.[41]

PUBLIC HEALTH ASPECTS

There are no reports of human infection with adult *H. americana*, and the parasite is not considered a zoonotic risk. However, it is theoretically possible that if larval cercariae have access to humans who are wading/swimming in fresh water, the parasite should be able to penetrate intact skin. The transient pruritic rash called "cercarial dermatitis" is typically attributed to skin penetration by the cercariae of avian schistosome parasites that are associated with ducks and other waterfowl that use the aquatic environment.[42] It is unknown whether *H. americana* cercariae may play a minor role in causing transient cercarial dermatitis in humans or other mammalian hosts.

PARAGONIMUS KELLICOTTI INFECTION (PARAGONOMIASIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

On a global basis, a number of trematodes in the genus *Paragonimus* and the closely related genera *Euparagonimus* and *Pagumogonimus* infect the respiratory tract of dogs or cats (Table 118.2).[43–45] Various species have been reported in dogs and cats across the Americas, Africa, and Asia. All have indirect life cycles involving an aquatic snail first intermediate host and a second intermediate host, usually a crab or crayfish, ingested by the mammalian definitive host (Table 118.3).[46,47] Ingestion of infected paratenic hosts may also lead to infection.[48] This chapter will focus on *Paragonimus kellicotti*, which is geographically located in much of the eastern half of North America from Canada to Louisiana, and the Mississippi River basin.[49,50]

The monoecious (hermaphrodite) adult trematode occurs in the lung parenchyma of a number of mammalian hosts including dogs, cats, a variety of wildlife species (skunk, red fox, coyote, raccoon, bobcat, mink), and rarely humans.[49–51] Adults are approximately 10 × 5 mm in size, ovoid, with typical oral and ventral suckers, and are found in pairs within encapsulated cysts in the lung parenchyma with connections to bronchiole airways. Operculated eggs are shed from adult flukes, coughed up in bronchial secretions, swallowed, and passed in feces. The life cycle requires fresh water for several stages. When eggs are deposited in water, the larval miracidium stage develops and hatches from the egg and infects the first intermediate host, aquatic snails (*Pomatiopsis lapidaria, Pomatiopsis cincinnatiensis, Oncomelania*

nosophora).[45,46] Following asexual replication as sporocyst and redia stages, cercarial larvae are released into water, penetrate the second intermediate crayfish host (*Cambarus* spp., *Orconectes* spp.), and develop to metacercaria.[49] The mammalian definitive host becomes infected through ingestion of an infected crayfish or paratenic host such as an infected rodent, so infection is possible in a dog or cat without direct access to crayfish and fresh water.[48] Metacercariae excyst in the duodenum, penetrate the intestinal wall into the peritoneal cavity, then migrate through the abdominal wall and diaphragm to the lungs, where they become encapsulated and mature into adults. Infections have been reported to last as long as 4 years in a dog, following a PPP of 5 to 7 weeks.[49] Human infections with the parasite have been reported to persist for several decades.[50]

Most descriptions of *P. kellicotti* infections in dogs and cats are included in the literature as case reports, and little information on risk factors is available. In a Louisiana survey of domestic cats with respiratory tract disease, 3 of 65 cats with clinical signs were infected with *P. kellicotti*, whereas 0 of 65 control cats were infected.[52] In a 5-year survey of parasitic infections in dogs and cats from New Jersey that was published in 1965, eggs of *P. kellicotti* were identified in three cats and one dog.[45] In a survey of 123 stray adult dogs from Michigan from 1964, *P. kellicotti* was identified in a single animal.[44]

CLINICAL FEATURES

In dogs or cats, *P. kellicotti* infections are often subclinical. Long-lived adult flukes localize in cystic spaces in lung parenchyma and intermittently shed eggs into the bronchial tree. Clinical disease in naturally infected dogs is characterized by a chronic or intermittent cough, which may be productive with frothy white sputum.[53,54] A mild, intermittent cough was the most frequently reported clinical sign in experimentally infected dogs.[55] Similarly, infected cats may have a mild cough.[56] In a study of 10 infected client-owned cats, the predominant reason for evaluation was cough.[57] In another feline case series, four of five infected cats were seen with a history of cough lasting from 3 days to 1 year.[58] Over time, exercise or exertion may exacerbate the cough in some animals. Infrequently, parasitic cysts may rupture causing acute pneumothorax, sometimes with sudden death.[55,59–61]

Most animals are afebrile with an adequate appetite and normal hydration.[53,62] The most notable finding on physical examination in infected animals is abnormal lung sounds on thoracic auscultation in both dogs and cats.[53,62,63] In some cases, cough can be elicited by tracheal palpation.[54,63]

DIAGNOSIS

The diagnosis of pulmonary paragonimiasis is usually based on recognition of suggestive lesions on thoracic radiographs. Confirmation of the infection is usually based on detection of *Paragonimus* eggs in fecal specimens or respiratory secretions.

Laboratory Abnormalities

CBC and serum chemistry test results are often within normal limits in naturally and experimentally infected cats and dogs.[62–64] In a case series of 10 infected cats, leukocyte counts ranged from normal to slightly high, sometimes with a neutrophilia or an eosinophilia.[57] Serum chemistry results for total protein concentration, BUN, and serum ALT activity in those cats were within normal limits. In a single canine case report, total serum protein was elevated with a hyperglobulinemia and hypoalbuminemia.[53] Secondary pneumonia in association with *Paragonimus* infection may be associated with elevated WBC counts and neutrophilia.[59]

Diagnostic Imaging

Plain Radiography

Cystic structures containing adult parasites are radiographically detectable on thoracic radiographs in both dogs and cats.[53,59,62,65] Lesions are described as interstitial nodular opacities or as thin-walled cavitated pulmonary cystic structures, usually ranging from 2 to 5 cm in diameter. Air-filled cysts containing adult parasites may be multilocular.

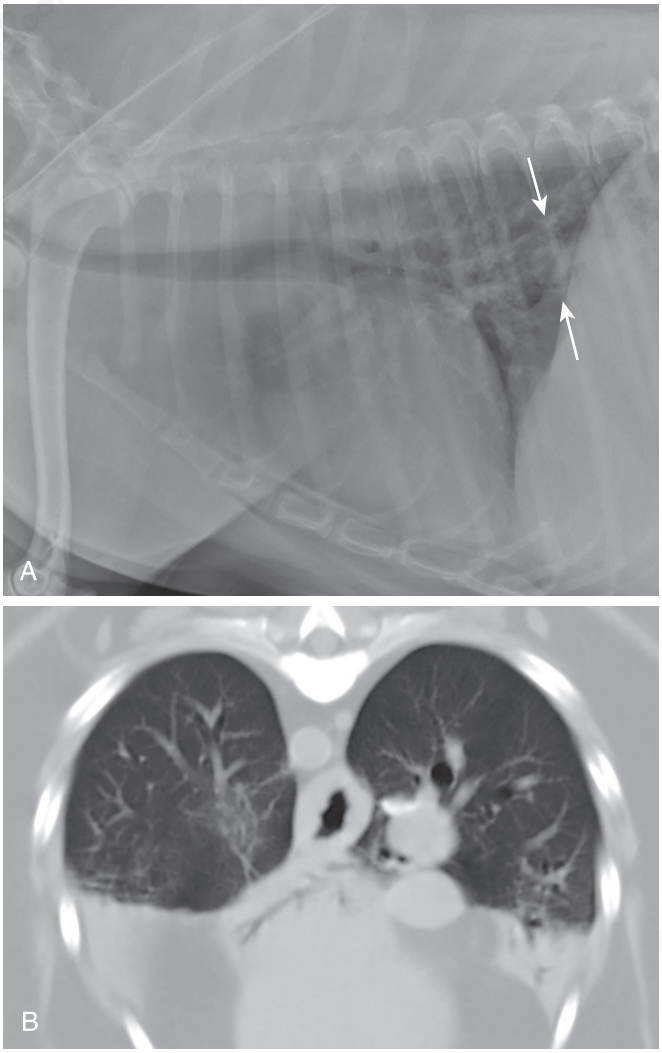

Fig. 118.4 Right lateral thoracic radiograph (A) and computed tomography (CT) scan (B) from a 10-year-old male neutered kelpie dog mix with paragonimiasis. There is a single soft tissue nodular opacity superimposed over the eighth rib in the caudodorsal thorax (arrows). On the CT scan there is a soft tissue spherical mass with a medial mineralized portion that abuts the pleural margin in the right dorsal aspect of the accessory lobe; the mass is also associated with the lobar bronchus. (Courtesy of the University of California, Davis Diagnostic Imaging Service.)

The caudal lung lobes are most frequently affected.[59] Other abnormalities include secondary pneumonia, peribronchial infiltrates, or rarely pneumothorax due to rupture of a cyst. Differential diagnoses include pulmonary abscesses, metastatic neoplasia, cavitated neoplasms, and mycotic pneumonia.[58] Findings on thoracic CT have been described in human patients and include peripheral lung nodules that are 1 to 3.5 cm in size with peripheral ground glass opacity. Sometimes linear tracks may be seen connecting nodules to the pleural surface.[66] One dog seen at the editor's institution had a solitary soft tissue spherical mass in the right dorsal aspect of the accessory lung lobe. The mass was adjacent to the pleura, associated with the bronchus and had a medial mineralized portion (Fig. 118.4A and B).

Serial thoracic images in the months following treatment reveal slowly resolving lesions; nodules may no longer be visualized, may decrease in size, or may change in appearance from cavitated to solid soft tissue opacities.[62] In experimentally infected dogs and cats, radiographic lesions were evident at 3 weeks PI.[64] Radiographic lesions resolved in dogs by 2 weeks post-treatment with praziquantel, but lesions were variably resolved by 4 weeks post-treatment in cats.

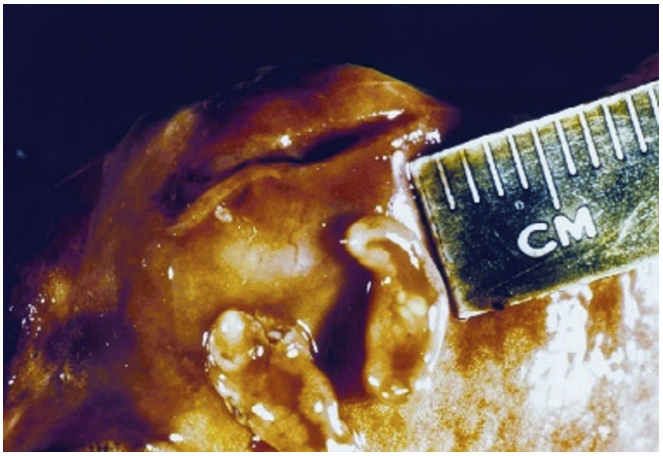

Fig. 118.5 Gross image of cat lung with an incised *Paragonimus* cyst and two adult flukes that were removed from the cyst.

Parasitologic Tests

Diagnosis Using Fecal Examination

Definitive diagnosis of *P. kellicotti* infection is made by detection of the oval, yellow-brown operculated egg (74–118 × 42–67 μm) in feces or respiratory secretions (Fig. 118.2B).[35] Eggs have a distinctive lip or ridge along the edge of the operculum, sometimes described as "flask-shaped," that is a key diagnostic feature. When evaluating fecal specimens, the eggs are dense and are difficult to detect in fecal flotation tests, so a fecal sedimentation test is the parasitologic method of choice. Eggs are excreted intermittently; a single fecal sedimentation test has a low sensitivity and multiple tests on multiple fecal specimens may increase the likelihood of egg detection.

Cytologic Diagnosis

Although adult flukes in lung parenchymal cysts are not visualized on bronchoscopy, characteristic "flask-shaped" eggs may be detected by cytologic evaluation of bronchial lavage secretions.[53]

Serologic Diagnosis and Nucleic Acid–Based Testing

No immunodiagnostic tests have been reported as diagnostic tools for detection of *P. kellicotti* infection in dogs or cats. The use of several experimental immunodiagnostic assays for *Paragonimus westermani*, *Paragonimus siamensis,* or *Paragonimus heterotremus* has been described in scientific literature to detect antibody production in experimentally infected cats.[67,68] Similarly, PCR-based assays have been used experimentally to detect *P. heterotremus* DNA in feces of experimentally infected cats, but the use of molecular tests that detect *P. kellicotti* DNA has not been reported for diagnostic purposes in dogs or cats.[69,70]

Pathologic Findings

At necropsy, subpleural cystic lesions up to several centimeters in size may be visualized as raised dark reddish-brown nodules on the lung surface, or may be located deeper in the lung parenchyma. On cut section, the nodules have a thin, dense fibrotic capsule and usually contain one or two adult flukes along with a small amount of brownish fluid (Fig. 118.5).[59] Bronchial lymph nodes may or may not be enlarged. Pulmonary areas adjacent to the parasitic nodules are usually grossly and histologically normal. Histologically, parasitic cystic structures are composed of fibrous capsular tissue with a variable collection of mixed inflammatory infiltrate cells including macrophages, plasma cells, and

eosinophils surrounding the cyst wall (Fig. 118.6).[65,71] Sometimes eggs may also be visualized in the lung parenchyma or small bronchioles surrounded with a localized granulomatous inflammatory infiltrate.

TREATMENT AND PROGNOSIS

No anthelminthics are label-approved for the treatment of *Paragonimus* spp. infection in dogs or cats. However, praziquantel, fenbendazole, and albendazole have been reported to be effective in a variety of studies (Table 118.4). Multiday treatment of dogs or cats with praziquantel administered at higher than the labeled dose has been generally reported as successful.[54,64,72,73] The most significant adverse effect of high-dose praziquantel is GI irritation and vomiting, which may be mitigated by dividing the the daily dose into several treatments and administering the drug with food. The recommended treatment for human paragonimiasis is also praziquantel (25 mg/kg, q8h, for 3 days).[50]

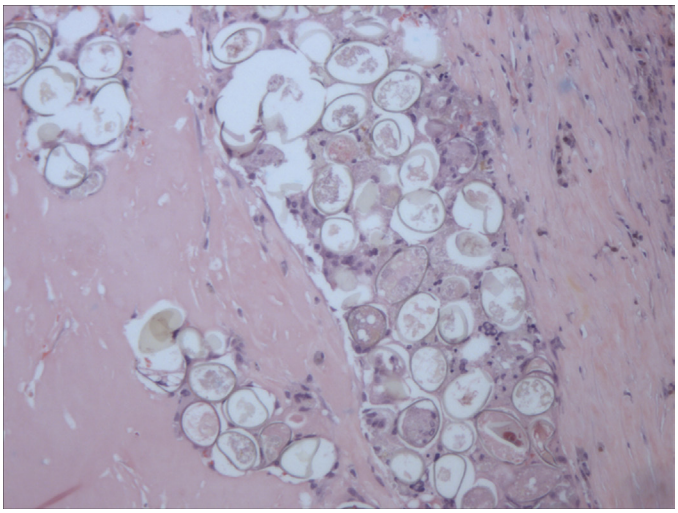

Fig. 118.6 Section of lung from a 10-year-old female spayed kelpie mix with paragonomiasis. There are multiple large coalescing cystic spaces at the edge of the lung that contain trematode eggs and are surrounded by inflammation.

Successful, multiday, high-dose fenbendazole treatment has also been reported in naturally infected cats and experimentally infected dogs.[63,74] Similarly, albendazole administered in varying doses for a prolonged period has been reported as effective in a small number of experimentally infected cats and in one naturally infected dog (see Table 118.4).[75,76] Albendazole is not label-approved for use in dogs or cats and can induce aplastic anemia, so alternative therapies are suggested.

IMMUNITY AND VACCINATION

No vaccines are available for paragonomiasis, and studies regarding protective immunity have not been reported.

PREVENTION

Prevention of paragonomiasis is focused on limiting dog and cat access to crayfish and their aquatic habitat, as well as paratenic hosts such as rodents. Since a variety of wild mammals can serve as reservoir hosts, proximity to wildlife associated with ponds or

streams increases the likelihood that the parasite life cycle will become established in a local environment.

PUBLIC HEALTH ASPECTS

Pulmonary paragonimiasis is considered a foodborne infection that affects as many as 23 million people, primarily in Asia and Africa.[51] Most of these infections are attributed to *P. westermani* or other closely related species.[51,77] A limited number of autochthonous cases of North American paragonimiasis have been described in humans caused by *P. kellicotti* infection and associated with ingestion of raw or undercooked crayfish.[51,78] Clinical disease in humans ranges from asymptomatic to serious respiratory disease, with similar clinical expression as the disease in dogs and cats. Eosinophilic meningitis has also been reported.[79]

Frequency of transmission in humans depends on dietary habits since mammalian definitive hosts, including humans, become infected by ingesting metacercaria in crab or crayfish intermediate hosts. Therefore, although *P. kellicotti* is considered a parasite with zoonotic potential, direct or indirect contact with infected pets or mammalian wildlife poses no direct risk to humans.

PLATYNOSOMUM ILLICIENS (PREVIOUSLY *FASTOSUM*) INFECTION (PLATYNOSOMIASIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Platynosomum illiciens (previously *fastosum*) belongs to the family Dicrocoeliidae and is synonymous with *Platynosomum concinnum* and *Platynosomum fastosum*. While most literature has used "*fastosum*" for infections in mammals and "*illiciens*" for infections in birds, molecular studies indicate these are the same with the trematode having a low host specificity. The name *P. illiciens* has been recommended rather than *P. fastosum* and so will be used from this point onwards.[80–85] Adult *P. illiciens* is found in the intrahepatic biliary ducts of the final host, domestic cats and a variety of wild cats,[86–88] and other hosts including non-human primates, opossums, birds of prey and parrots,[84] with no predilection for a specific hepatic lobe or lobule, and the gallbladder.[89] In heavy infections, adult trematodes also can be found within the pancreatic ducts, small intestine, and lungs.[87,88,90] Mature *P. illiciens* are 2.1 to 8 mm long and 0.5 to 2.5 mm wide (Fig. 118.7).[81,91,92] The location of the testes, ventral sucker, ovaries, and vitelline glands can be used to distinguish *P. illiciens* from other flukes in the biliary

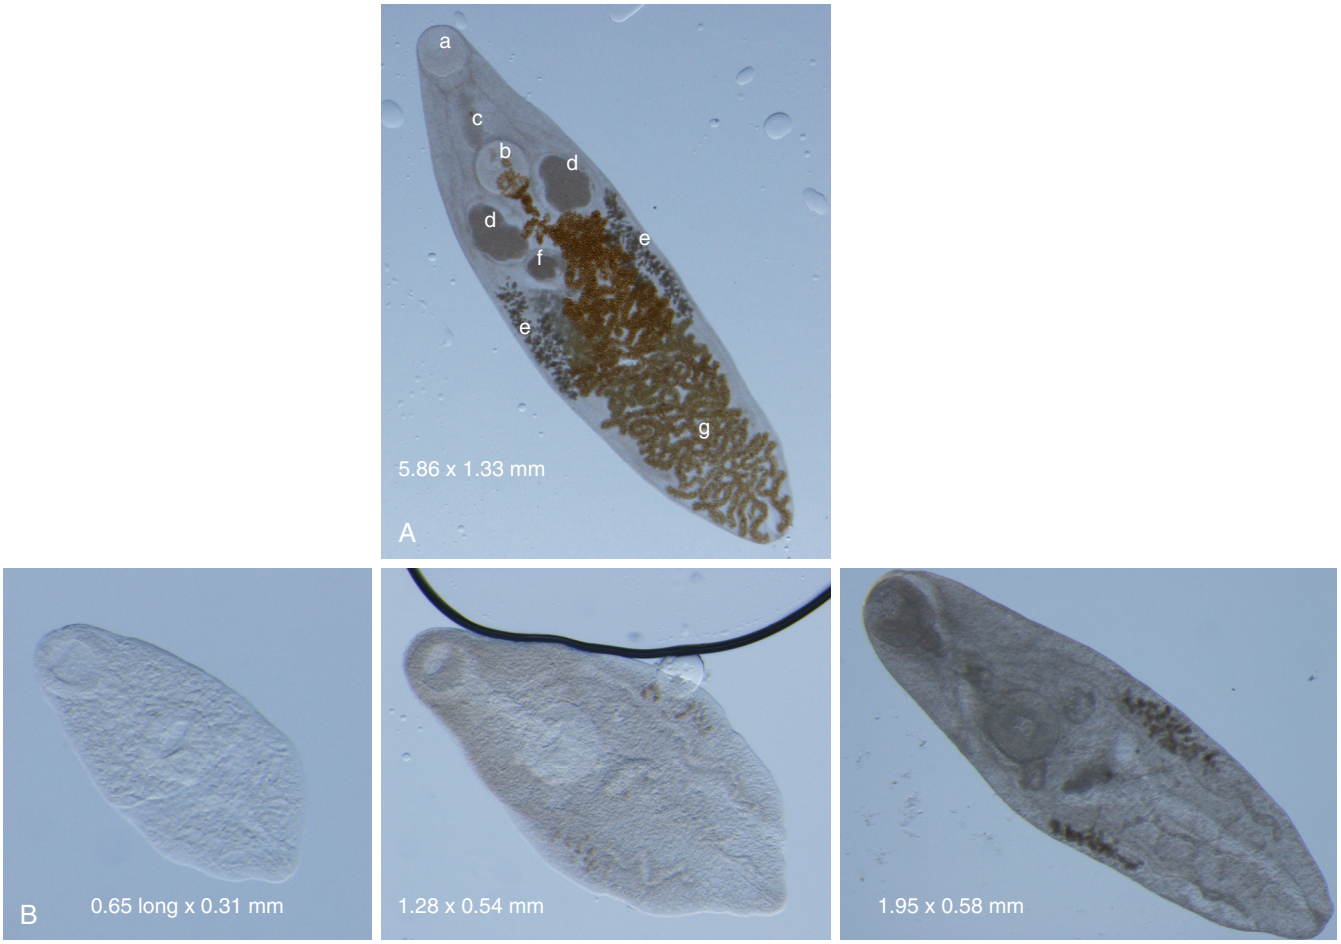

Fig. 118.7 (A) Adult *Platynosomum illiciens* and morphologic characteristics; *a,* oral sucker; *b,* ventral sucker; *c,* genital pore; *d,* two bilateral testes; *e,* two bilateral vitelline glands; *f,* ovary; *g,* oviducts. Testes are located just ventrolateral to the ventral sucker, the ovaries ventral to the testis, and the vitelline glands lateral to the testis. The genital pore is dorsal to the ventral sucker with the distance between these organs changing with maturity of the fluke. (B) With maturity, the digestive and reproductive tracts of *P. illiciens* develop and the trematode increases in size. The digestive tract forms in the first days after infection, the testis 2 to 3 weeks post infection followed by the vitelline glands, with the female genital tract and eggs forming approximately 4 to 5 weeks post infection.

See references 82, 177–183.

system in areas where more than one species is endemic (Fig. 118.7 and Table 118.5).[81]

The eggs, which are smaller than those produced by many other fluke species, are light brown, more oval than round, approximately 30 × 50 µm, and have an operculum that can be obscure (Fig. 118.8).[81,88] Damaged and immature eggs also occur in feces. Damaged eggs are shrunken and clear to pink; and immature eggs are clear, more ovoid, and smaller (16–20 × 27–30 µm).[88,92]

The life cycle of *P. illiciens* is indirect and utilizes two intermediate hosts and several paratenic hosts (Fig. 118.9).[81,93–95] Cats become infected when they ingest excysted metacercariae in a paratenic host or encysted metacercariae in the second intermediate host. Metacercariae are released in the intestine and the immature flukes travel to the common bile duct and within 3 days develop a digestive tract. In the following weeks, the fluke increases in size and the reproductive tract develops. Full maturity is reached in 8 to 12 weeks. Mature adult *P. illiciens* release 10 to 100 eggs per day which are stored within the gallbladder, released with bile into the GI tract, and excreted in feces.[81] The life span of *P. illiciens* can be > 1.5 years.[89]

Eggs are ingested by land snails (primarily *Subulina octona* but also *Eulota similaris*), the first intermediate host, resulting in the release of miracidia which move to the snails' connective tissues surrounding the respiratory tract. In the respiratory cavity, sporocysts develop resulting in cercariae. The cercariae release a glandulous fluid that helps the sporocysts exit the snail and re-enter the environment via the respiratory tract or the tunica propria, killing the snail in the process. Moisture and decreased light signal the exit of the sporocysts. A snail on average releases 7.6 sporocysts (approximately 134 cercariae) with the process from miracidium to sporocyst release requiring approximately 60 days.[81,89,91,96]

Isopods are considered the most likely second intermediate hosts.[81,89,91,96] These are tiny terrestrial crustaceans (woodlice), specifically *Oniscidea* sp. ("roly-polys") and *Nagurus* sp. (e.g., the "greenhouse woodlouse"). These consume cercariae in the environment, which then mature to metacercariae and encyst. Cats can become infected if they consume isopods, although most infections are believed to originate from the consumption of a paratenic host. In paratenic hosts the metacercariae excyst and reside in the hepatic and biliary systems. For many years, lizards, particularly *Anolis* spp. lizards (anoles), were considered an obligate paratenic host, resulting in the common name of "lizard poisoning" for platynosomiasis. Subsequent work has shown that several other lizard species (e.g. *Tropidurus* spp., *Hemidactylus* spp., *Lygosoma metallicum*), toads (*Bufo* spp.), frogs (*Eleutherodactylus* spp.), and, potentially, mice also can serve as paratenic hosts.[81,89,91,96–98] There are few studies on the prevalence and impact of metacercariae in paratenic hosts. A study from Puerto Rico found > 30% of *Anolis* spp. lizards examined to be infected (mean number of 16 metacercariae) with heavy infections (e.g., >300 metacercariae) associated with hyperplasia of the bile duct and atrophy of the gallbladder.[81]

Platynosomum illiciens can be found in cats in the Caribbean and other tropical and subtropical regions of the world, including Central and South America, southern areas of North America, Asia, and Africa.[88,90,93–95,99–102] In Australia, *P. illiciens* was found in cats in quarantine and treatment was pursued to prevent importation of the parasite.[103] In North America, *P. illiciens* occurs in Florida and Texas in the United States. It also has been found in cats outside of these regions such as in Ohio, Illinois, and Oklahoma within the United States; and Siberia, Russia. In some of these cases, the cats have originated from

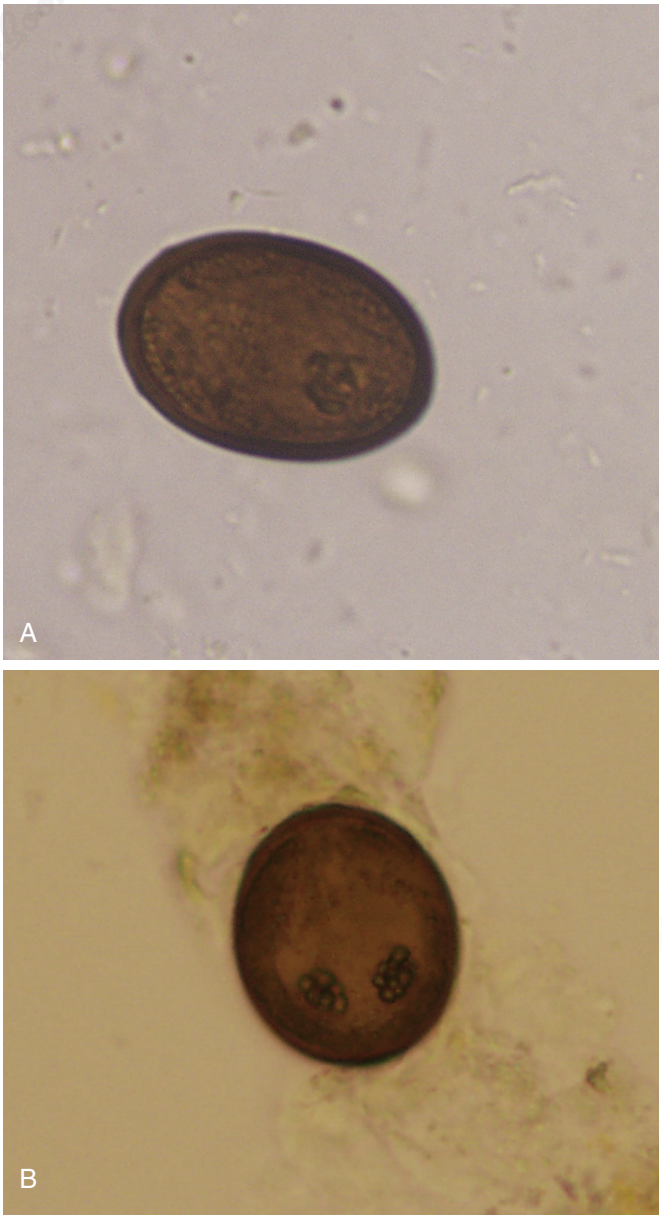

Fig. 118.8 *Platynosomum illiciens* eggs (30 × 50 μm) (A) in a fresh fecal specimen, examined using double centrifugation with Sheather's sugar flotation solution, and (B) in bile collected using percutaneous ultrasound-guided cholecystocentesis.

endemic areas.[104,105] However, travel was not demonstrated in all cases indicating that *P. illiciens* might have the potential to be present in or spread to nonendemic areas. This is supported by the presence of the trematode in non-feline hosts in areas where *P. illiciens* is not considered endemic in felids.

Within endemic areas, there are few recent studies on prevalence of infection in cats. Studies from St. Kitts in the Caribbean suggest that 22% of owned cats (indoor/outdoor and indoor only) and 81% of free-roaming cats are infected, with other Caribbean islands reporting a prevalence of <15% to >80%.[88,100,102] The prevalence in Brazil has been reported as <3% to >42%; in Yucatan, Mexico as 45%; and in different Asian countries, <1% to 73%.[1,88,106,107] Because paratenic hosts can gain access to homes, both indoor and outdoor cats are at risk for infection.[102,108]

Infection burden ranges from 1 to >4,000 flukes with average burden of 202 in St. Kitts and 110 in Yucatan; approximately one fourth of cats have high-burden infections (>125 flukes).[92,95] Older cats are more likely to be infected than younger cats, and some studies have suggested that female cats are more likely to be infected than male cats, a difference attributed to hunting behavior to feed offspring.[95,109]

While domestic and wild cats have been considered to be the definitive final host, other animals can be infected. Mice (*Mus musculus*) and birds (Australian parakeets, *Melopsittacus undulatus*) have been successfully experimentally infected with *P. illiciens* metacercariae, although the infection establishment level was lower than in cats.[89,91,96] *Platynosomum* adults also have been found in opossums (*Didelphis virginiana*), ferrets (*Grisson vittatus*), skunks (*Spilogale putorius*), North American hawks (*Buteo platypterus*), and nonhuman primates (marmosets, [*Callithrix jachhus*], orangutans [*Pongo pygmaeus*], monkeys [*Macaca* spp.]).[93,97,110–115] Molecular studies now suggest that all of these hosts contain the same species of *Platynosoumum,* indicating that the distribution is much larger then previously defined.

CLINICAL FEATURES

Most cats are subclinically infected and signs, when they do occur, are nonspecific. The presence of the flukes in the biliary system is associated with hepatic cirrhosis, cholangitis, and cholangiohepatitis. The occurrence of clinical signs are related to the parasitic load within the biliary system, level of continuous exposure to infection, chronicity of infection, and the cats' individual reaction to the parasite.[109] Increasing liver and biliary tract pathology result in general malaise, poor body condition, anorexia, weight loss, alopecia, vomiting, diarrhea, emaciation, dehydration, anemia, enlarged abdomen, hepatic encephalopathy, and progressive icterus.[89,109,116–119] On physical examination, hepatomegaly can be palpable.

While few studies have been conducted on the pathogenesis of *P. illiciens* infection, much can be extrapolated from the more studied liver flukes such as *Clonorchis* spp., *Opisthorchis* spp., *Dicrocoelium* spp., and *Fasciola hepatica*. Immature and adult flukes cause mechanical destruction of liver tissue via migration, attachment, and feeding. Localized toxic reactions and localized inflammatory reactions occur with fluke excretion/secretion products leading to eosinophilia. Fluke maturation and growth leads to bile duct dilation and adenomatous hyperplasia with duct dilation contributing to parenchymal cell damage and altered duct walls resulting in blood leakage. Younger flukes are believed to reside in the intrahepatic biliary ducts with more mature and larger flukes migrating to the extrahepatic biliary ducts.[91] As the flukes mature and their growth rate decreases, fibrotic connective tissues around the bile duct decrease bile and fluke excretion/secretion product flow into the parenchymal tissue limiting parenchymal tissue pathology.

Partial mechanical obstruction of the common bile duct or irritation of the common bile duct resulting in dyskinesia causes bile retention. Bile stagnation is believed to result in an environment conducive to secondary bacterial infections; however, little is known about secondary bacterial infection with *P. illiciens* infection.[88,97,109,110,120] With *Clonorchis* spp. infections, development of biliary calculi also has been attributed to bile stagnation and these are considered a factor in the occurrence of cholangiocarcinoma. While choleliths have not been identified in *P. illiciens* infections, cholangiocarcinomas have been noted, albeit rarely.

In experimental infections that involve a single exposure, clinical signs have not been seen during the early stages of infection. Approximately 2 months PI, lethargy, inappetence, slight weight loss, and abdominal distension have been documented with exposure to

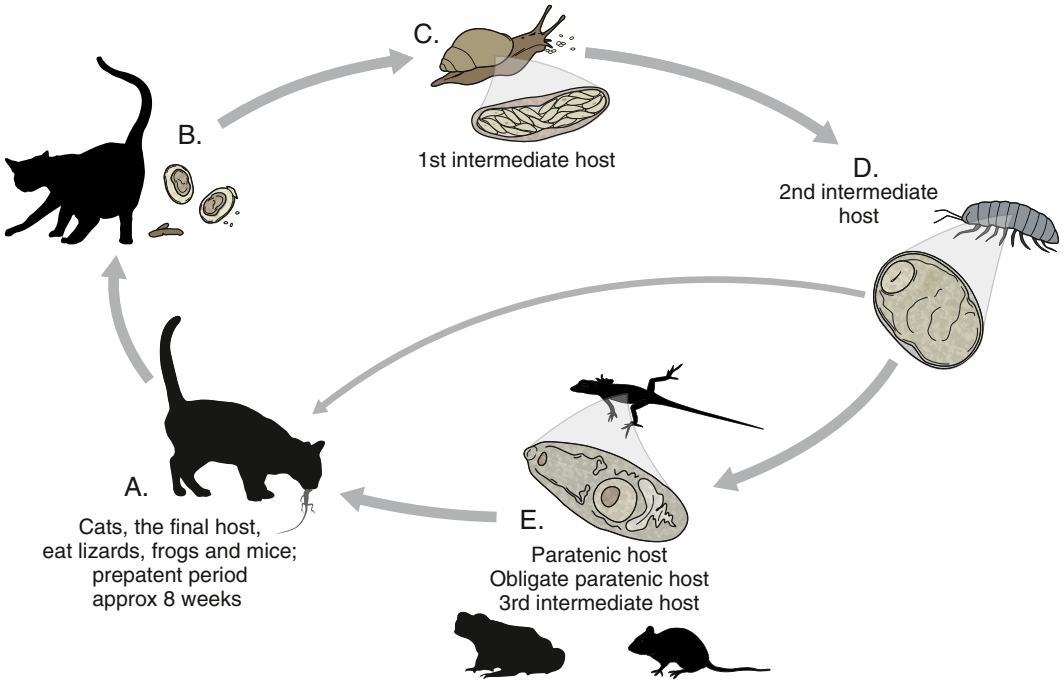

Fig. 118.9 The life cycle of *Platynosomum illiciens* includes the cat, two intermediate hosts, and frog, lizard, or rodent paratenic hosts. The adult trematode resides in the bile ducts of cats (A) with eggs released into bile and excreted in feces (B). Eggs are ingested by a snail and within approximately 2 months develop from miracidia to sporocysts containing several cercariae (C) which are released into the environment. These infect isopods (D) where they encyst as metacercariae. Paratenic hosts (usually lizards but also frogs and mice) (E) consume the isopods and are in turn consumed by the cat.

large numbers of trematodes, although most clinical signs resolved by 4 months PI with the cats remaining subclinical for up to an additional year. Less is known about progression of clinical signs during natural, continuous exposure. Natural infections of cats with > 125 flukes have been classified as high-intensity infections, with infection associated with pathology and clinical signs. Conversely, cats with > 1,000 flukes have been subclinical. It is possible that differences in pathology and clinical signs might differ between cats infected by consumption of a few paratenic hosts with a high number of metacercariae compared with those that develop more chronic infections as they consume many paratenic hosts that each harbor only a few metacercariae.

DIAGNOSIS

Fecal analysis is the recommended method for diagnosis of platynosomiasis.[88,121] However, the number of eggs recovered might not reflect the intensity of infection and negative fecal specimens can occur in heavy infections where there is partial or complete occlusion of bile ducts.[87,102,121] Bile collected using percutaneous ultrasound-guided cholecystocentesis can be used as an alternative to fecal specimen for retrieval of eggs and might be a more sensitive method.[122] Laboratory findings, abdominal ultrasound examination, and liver biopsy also can be useful for assessing the extent of liver damage but do not reveal findings specific for *P. illiciens* infection.[114,118] At necropsy, adult *P. illiciens* can be recovered from the liver and/or gallbladder and eggs can be found in bile.

Laboratory Abnormalities

Routine bloodwork can assist in determining the cause of liver disease and assessment of the extent of liver damage. The leukogram may be normal; however, an inflammatory leukogram with eosinophilia is a common finding, and occasionally a neutrophilia.[88,119] Anemia can be present in some infected cats.[119] Increased activities of serum AST and ALT can occur 4 to 5 months after infection and are indicative of cholestasis and hepatocyte damage.[88,108,110,118,119] Serum ALP activity may be normal, which is not unusual for cats even with severe or obstructive cholestastic disease.[123] Serum total bilirubin and bile acid concentrations may be increased in proportion to the severity of the infection. Serum pancreatic enzyme activities can also increase with *P. illiciens* invasion.

Diagnostic Imaging

The results of abdominal ultrasound examination are nonspecific in cats infected with *P. illiciens*, with some studies finding no significant abnormalities of the gallbladder, bile ducts, and liver of infected cats.[87,123,124] However, in endemic areas and when *P. illiciens* infection is suspected, changes in these structures would support examining multiple fecal specimens or bile for eggs. Changes that have been noted include distention of the gallbladder with a hyperechoic wall, distended and tortuous bile ducts and common bile duct, and hepatomegaly.[114,123–126] In one case study, cystic structures consistent with intrahepatic biliary duct dilatation were observed.[108] While *P. illiciens* can invade the pancreas, ultrasonographic changes to the pancreas have not been described.[126] Some relationship between intensity of infection and pathologic changes detected with ultrasound has been noted, but changes are likely also to be related to the chronicity of the infection.[109,123–125]

Parasitologic Tests

Diagnosis Using Fecal or Bile Examination

Two fecal diagnostic methods for egg recovery have been proposed as the "gold-standard" for diagnosis of platynosomiasis: traditional

Fig. 118.10 (A) Firm liver with a focal domed mass in the right medial lobe with a prominent accentuated lobular pattern. The cat, euthanized for nonrelated reasons, had a chronic *Platynosomum illiciens* infection. (B) Mottled, discolored appearance and a diffuse reticular pattern in a *P. illiciens*–infected liver of a cat.

formalin-ether sedimentation and the more sensitive double centrifugation (500 g for 5 minutes) with Sheather's sugar flotation solution (SpG ≥ 1.27).[94,100,121,127,128] Safety issues with the use of formalin-ether solutions make this method less desirable, and centrifugation and flotation also permit identification of a greater variety of other parasites.[129] False-negative results can occur due to intermittent egg excretion in feces, biliary obstruction, and low numbers of eggs in general.[89,118,130] Multiple fecal analyses, as well as complementary diagnostics should be performed before eliminating *P. illiciens* infection as a cause of liver disease in cats.

Light microscopic examination of bile can be a more sensitive diagnostic method than fecal analysis. Use of 10 to 20 μL in a direct smear preparation is considered sufficient to identify eggs (Fig. 118.8B).[102,122,130] In severe platynosomiasis, few to no eggs may be found in feces due to biliary obstruction, but are present in bile.[118] Bile collection, via percutaneous ultrasound-guided cholecystocentesis, can be safely performed in *P. illiciens*–positive cats even in cases when severe pathology of the gallbladder is present.[122]

Pathologic Findings

At necropsy, *P. illiciens* adults can be collected from the liver and gallbladder. To recover the parasites, the liver can be cut into pieces (approximately 1 to 2 cm) and massaged and washed over a sieve. The gallbladder also can be opened and washed over a sieve to retrieve adult flukes. Bile can be collected and a direct smear viewed using a 10× objective (100× magnification) for identification of eggs, which can be more sensitive than adult trematode collection.[123]

Gross pathologic findings include icterus, hepatomegaly, an accentuated hepatic parenchymal lobular or reticular pattern, intraparenchymal parasitic cysts, biliary obstruction, a distended gallbladder, ascites (usually a transudate), and abdominal lymphadenomegaly (Fig. 118.10).[88–90,95,104,105,108,116,119,130–132] Cholangiocarcinomas and polycystic livers have been described in a few cats.[108,131,133]

Histologic findings include: atrophy and fatty infiltration of hepatocytes, hepatic and biliary duct fibrosis, hyperplasia of epithelium lining biliary tubules, and infiltration by eosinophils, lymphocytes, plasma calls, and neutrophils.[89,109,116–119,130–134] Ultimately, this is associated with increasingly severe cholangitis and nonsuppurative cholangiohepatitis. If cholangiocarcinomas develop, metastasis to other organs may follow.[130,133]

TREATMENT AND PROGNOSIS

The treatment of choice for platynosomiasis is praziquantel (20–40 mg/kg, PO, q24h for 3–10 days). This use and dose is extra-label but within tested safety limits for healthy cats. Adverse events may include GI irritation causing vomiting, diarrhea, and salivation. Praziquantel disrupts the tegument of flukes causing permeability alterations in the membrane, disintegration of the tegument, and spastic paralysis.[135–137] The antigen presentation of the trematode to the host changes, permitting it to be recognized by the host immune system; hence the host's immune system can work synergistically with the treatment to eliminate the infection.[136,137] Disintegration of the tegument and spastic paralysis results in increased release of eggs with corresponding higher fecal egg counts after treatment. In most *P. illiciens* infections, if there are no signs of liver failure, prognosis is good with praziquantel treatment. Prognosis is poor in cats with diffuse liver pathology and with clinical signs of liver failure, with euthanasia being the outcome in many case studies.[99,108,118,119] Immature flukes may be more resistant to treatment, so treatment may need to be repeated 2 to 12 weeks later.[88,137–139] Drugs found insufficient to treat *P. illiciens* infections include fenbendazole, mebendazole, levamisole, thiabendazole, diamphenethide, rafoxanide, and pyrantel pamoate.[89,103,134]

The efficacy of the praziquantel dose and dosing regimen is based on case series rather than on controlled studies. In one study, five cats infected with adult mature flukes were treated with a single dose of praziquantel at 20 mg/kg, after which they appeared to be cured.[103] The use of 10 mg/kg for 3 consecutive days resulted in reversal of clinical signs in mildly to moderately ill cats.[90] In a field study with seven cats, 20 mg/kg, q24h, for 3 days and repeated 3 months later resulted

in cure, although the assessment of cure was based on single fecal egg counts following formalin-ether sedimentation.[140]

Oral administration of 20 mg/kg praziquantel can be challenging for the pet owner. Also, in high-burden infections, mass trematode death has the potential to cause acute bile duct blockage, which may worsen outcome. Alternative regimens of 20 mg/kg, IM, q24h, for 3 days or lower doses of praziquantel have been investigated with limited success.[92] In a study of six naturally infected cats with immature and adult flukes, praziquantel at 20 mg/kg, IM, for 3 days cured three cats based on fluke counts performed at necropsy 10 days after treatment. Two of the remaining cats had low-burden infections (1–2 flukes) and one cat had 40 flukes.[92] Adverse events from injection administration may include pain and/or swelling at the site of injection, vomiting, diarrhea, muscle tremors, weakness or lassitude, and anorexia. In addition, in a small study where one cat received 27 mg/kg, gross muscle pathology was noted at the injection site (paralumbar muscle) at necropsy. Histopathology revealed focal rhabdomyositis with evidence of myofiber regeneration.[92]

A dose of 5 mg/kg (the labeled dose of praziquantel, although the use is extra-label) administered twice at a 2- to 4-week interval has been proposed. In a case study, fecal egg excretion ceased after the initial dose but recommenced weeks later. After a second 5-mg dose, fecal egg count remained negative over an 8-month monitoring period.[141] In a study of six cats with natural infections (unknown fluke maturity), none of the cats were cured, based on fluke counts at necropsy, after being administered 5 mg/kg, twice, 2 weeks apart. However, egg counts and fluke burden decreased.[100] An advantage of this dose is that fewer tablets are administered and products in which praziquantel is combined with nematicides could be used, increasing the options available in a clinical setting. While this lower dose can be more convenient to administer, without further proof of efficacy it should be used with caution.

Regardless of the dose and regimen used, efficacy of treatment should be assessed, since chronic infections contribute to ongoing hepatobiliary damage. Fecal egg counts to assess efficacy should not be performed until 14 days after treatment. As a result of slow release from the bile or a few surviving adult flukes, eggs can continue to be excreted at low levels intermittently for up to 9 weeks post treatment.[103]

Other treatments administered to *P. illiciens*–infected cats with complicated infections include fluid therapy, nutritional support, antimicrobial drugs for secondary bacterial cholangiohepatitis, cholecystotomy, cholecystectomy, complete or partial liver lobectomy, or choledochoenterostomy. Prognosis is poor in these situations.[142]

IMMUNITY

Cats do not develop immunity to *P. illiciens* infection. Chronic infections and reinfection are common.

PREVENTION

Given the variety of intermediate and paratenic hosts, prevention of infection in endemic areas is challenging. Even indoor cats are at risk with paratenic hosts such as anoles able to enter homes. In endemic areas, regular examination of feces of indoor and outdoor cats is needed to identify infections and treat them before extensive biliary tract pathology develops. Administration of monthly praziquantel might be beneficial for cats at a high risk of infection, although the efficacy of the low dose of praziquantel is uncertain and the potential exists for selection for anthelmintic-resistant parasites. The selection for resistant flukes has been suspected in the case of other fluke species in other hosts, although most cases of reduced treatment efficacy have been attributed to overwhelming infections or incorrect dose.[135,137]

Reports of *P. illiciens* infection in cats outside endemic areas are a concern. While most of these cats have a history of travel from an endemic area, it is unknown if *P. illiciens* can adapt to other intermediate hosts and establish in new locations. Therefore, measures should be implemented to prevent transport of *P. illiciens* to currently nonendemic locations. Treatment should be administered before departure from endemic areas with follow-up fecal examinations and treatment as needed after arrival in nonendemic areas. Given the long PPP, need for repeated treatments to eliminate infection, the lack of sensitivity of the diagnostic methods, and the long lifespan of adult flukes, prevention of transporting infections to nonendemic areas represents a challenge.

PUBLIC HEALTH ASPECTS

Platynosomum illiciens is not considered a public health issue. There have been no reports of human infections.

ALARIA SPP. INFECTIONS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Members of the genus *Alaria* are Diplostomatid trematode parasites that localize in the small intestine of a variety of domestic and wild carnivores. Species described in domestic dogs and cats include *A. alata* (Goeze, 1782), *A. marcianae* (La Rue, 1917 and Walton, 1949); *A. canis* (La Rue & Fallis, 1936); *Alaria arisaemoides* (Augustine & Uribe, 1927); *Alaria americana* (Hall & Wigdor, 1918); *Alaria nasuae* (La Rue & Townsend, 1932); and *Alaria minnesotae* (Chandler, 1954) (Table 118.6).[1,143–147] Several *Alaria* species such as *A. canis*, *A. minnesotae,* and *A. americana* have been considered synonymous with *A. marcianae* by some authors,[148–152] while separate species identities are supported by other reports.[153] In relatively recent scientific literature, *A. marcianae* is most frequently identified in the intestinal tract of domestic cats, whereas *A. alata* is reported primarily in dogs. Due to challenges in morphologic identification of the various species in some clinical reports, the parasite is identified only to the genus level as *Alaria* sp.[154–158]

The life cycle of *Alaria* spp. is complex with multiple life stages in at least three hosts. In addition to dogs and cats, adult parasites are found in the small intestine of a variety of wild carnivores including wolves (*Canis lupus*), red fox (*Vulpes vulpes*), grey fox (*Urocyon cinereoargenteus*), mountain lion (*Felis (Puma) concolor*), striped skunk (*Mephistis mephistis*), and coyote (*C. latrans*).[147,148,152,159,160] The relative importance of these wildlife reservoirs with regard to dog or cat infections is unclear.

Alaria adults usually range in length from 1.5 to 4 mm and have an unusual two-compartment body structure. The flattened forebody contains oral and ventral suckers and a bulbous trybocytic organ, and attaches to the intestinal mucosa. The cylindrical hind body contains the reproductive organs and extends into the lumen of the small intestine.[143,148,161] Large, oval eggs with indistinct opercula (98–134 × 62–68 μm) are shed in the feces of the definitive host (Fig. 118.2C).[35] When the egg contacts fresh water, the larval miracidium develops and hatches in about 2 weeks. The motile miracidia infect planorbid snails of the genus *Helisoma* and undergo asexual replication as sporocysts. Motile cercaria are released into the water and penetrate the skin of larval amphibians (tadpoles) and transform into mesocercaria. Several frog species serve as second intermediate hosts by maintaining the larval stage in tissues as an adult.[148,159,162] Alternatively, the infected tadpole may be ingested by frogs, snakes, rodents, chickens, or other paratenic hosts.[148] The dog or cat definitive host becomes infected by ingesting an infected frog or paratenic host.

TABLE 118.6 Taxonomic Identification, Definitive and Intermediate Hosts, and Geographic Source of Various *Alaria* Species in Dogs or Cats[a]

Scientific Name	DH	IH, Naturally Infected	Geographic Source
Alaria alata	C	NR	Spain, Uruguay
A. alata	D, jackal	NR	Iran
A. alata	D	NR	Argentina, Denmark, Serbia, Sweden, Turkey
Alaria canis	D	NR	New Jersey, USA
Alaria marcianae	C	NR	New Jersey, USA
A. marcianae	C, bobcat, raccoon	S: *Helisoma trivolvis* F: *Rana catesbeiana, Rana clamitans, Rana utricularia, Myla cinerea, Gastrophryne carolinensis*	Louisiana, USA
A. marcianae (syn. *Alaria minnesotae)*	C	S: *Helisoma trivola, Helisoma campanulatum* F: *Rana pipiens*	Minnesota, USA
A. marcianae	D (exp)	F: *Rana pipiens*	Wisconsin, USA
Alaria arisaemoides	D	NR	North Dakota[b], USA
Alaria nasuae	D	NR	Mexico
Alaria spp.	D	NR	Canada; Italy; Nigeria; Turkey; Iowa, USA
Alaria spp.	D, C	NR	Oklahoma, USA

Biology of *Alaria* spp. and human exposition risk to *Alaria* mesocercariae: a review. *Parasitol Res.* 2009;105:1–15.
[b]Geographic source of infection not clearly identified in case report.
C, cat; *D,* dog; *DH,* definitive host; *F,* frog (second intermediate host); *IH,* intermediate host; *NR,* not reported; *S,* snail (first intermediate host).

Once ingested by a dog or cat, mesocercariae migrate through the diaphragm, transform into metacercariae in the respiratory tract, pass up the bronchial tree, and are swallowed to develop to adults in the small intestine.[148,161,162] In a single cat that was experimentally infected with *A. marcianae*, egg excretion was first noted 19 days after feeding mesocercariae.[148] The longevity of adult parasites in the cat or dog intestine is unclear.

In an unusual alternative transmission pathway for a typical trematode, based on experimental infections, *A. marcianae* can be transmitted through a transmammary route.[163] Mesocercariae were recovered from mammary tissues of lactating queens. In one report, inoculation of a single queen resulted in infection of 21 of her kittens over the course of 5 litters, and after 3 years, viable larvae were still present in the mammary tissue.[163] They were also found in kittens born from uninfected queens transferred to infected queens for nursing.

Alaria spp. have been reported in dogs or cats in temperate regions of several continents including the Americas, Europe, the Middle East, and a single report in Africa (see Table 118.6). In some epidemiologic surveys, the species of *Alaria* was not reported. It is unclear how these parasites were identified to the species level since the egg morphology for various *Alaria* spp. is not microscopically distinguishable. A report from Oklahoma, United States, that evaluated several thousand canine and feline fecal specimens identified *Alaria* spp. eggs in 9.0% of free-roaming cats and 1.8% of rescue and shelter dogs[164]; infections were less commonly detected in client-owned cats (1.4%) and dogs (0.2%).

CLINICAL FEATURES

Adult parasites attach to the small intestinal mucosa. However, no signs of enteritis or other tissue damage have specifically been reported in dogs and cats.[165] In a single case report, adults of *A. arisaemoides* were surgically removed from the small intestine of a 4-month-old Labrador retriever puppy with a history of vomiting, anorexia, and chronic signs of malnutrition.[166] It has been suggested that the migration of mesocercariae could cause tissue damage or hemorrhage, particularly in the lungs, but clinical signs consistent with these migrations have been reported in infected cats.[161] However, two different disease patterns have been suggested in other hosts: adult flukes causing intestinal inflammation and larval migrations causing "metacercarial alariosis" in lungs and other viscera.[159]

DIAGNOSIS

The diagnosis of *Alaria* infection in dogs or cats is primarily based on finding large, oval unembryonated eggs (62–68 × 98–134 μm) in feces of the infected host (see Fig. 118.2C).[146] Adult trematodes attached to small intestinal mucosa may be identified on necropsy and are sometimes considered incidental findings.

Parasitologic Tests

Since trematode eggs are usually dense and are not routinely recovered by fecal flotation techniques, fecal sedimentation is the diagnostic method of choice. Egg excretion can be intermittent; sensitivity is improved by testing multiple fecal specimens from different days. No immunodiagnostic or molecular assays have been reported as diagnostic tools for detection of *Alaria* spp. infections in dogs or cats. In one survey of adult parasites recovered from foxes in Ireland, parasite identity was confirmed as *A. alata* by sequencing of a DNA fragment amplified using a broad-spectrum 18S rRNA PCR assay.[160]

Pathologic Findings

In several parasitologic surveys, necropsy examination was performed to determine parasite infection status.[154,167,168] However, no gross or histopathologic evaluations of host tissues were pursued. Similarly, for several *Alaria* species, the life cycles have been completed experimentally to characterize the various larval and adult parasite stages.[143,148,169] No evaluations of host tissues were conducted in those studies.

TREATMENT AND PROGNOSIS

No anthelminthics are label-approved for the treatment of *Alaria* spp. in dogs or cats, and no treatment trials have been reported. Praziquantel is anecdotally recommended at the label-approved dose since the drug has efficacy against some trematodes as well as cestodes.[161,165]

IMMUNITY, VACCINATION, AND PREVENTION

No vaccines are available for *Alaria* spp. infection, and studies regarding protective immunity have not been reported.

Dogs or cats become infected with *Alaria* spp. by ingesting frogs or paratenic hosts infected with mesocercariae, and confinement of pets indoors or in well-managed outdoor areas should decrease the risk of scavenging infected intermediate hosts. Since a variety of wild carnivores may also serve as definitive hosts, the presence of wildlife may allow the parasite life cycle to become established in the local environment, increasing the possibility of infection in pets. Access to aquatic habitats with frogs may increase exposure risk.

PUBLIC HEALTH ASPECTS

A few human infections with *Alaria* sp. have been documented and at least two human fatalities caused by infection with *A. americana* have been reported.[159,170,171] Humans become infected by ingesting poorly cooked frogs; contact with infected dogs or cats or their feces poses no direct risk to humans.

CASE EXAMPLE

Signalment

"Trooper," a 5-year-old male neutered Labrador retriever from Austin, Texas.

History

According to his owner, Trooper had a 4-month history of progressive weight loss, inappetence, and lethargy. He was drinking normally. The owner reported multiple intermittent episodes of diarrhea and soft stools, sometimes with blood. The other dog in the household, "Sergeant," a 4-year-old neutered male pointer mix, was reported to be clinically normal. The dogs lived in an urban neighborhood but were periodically taken to a nearby farm property to run, play, and swim in the farm pond.

Current Medications: Monthly heartworm preventive and flea/tick control medications were administered regularly.

Other Medical History: Trooper was neutered at a young age and was generally healthy with annual wellness visits to the local veterinary clinic. Previous pelvic radiographs indicated mild hip dysplasia. Both dogs were up to date on vaccinations including distemper, hepatitis, parvovirus, *Bordetella,* and rabies.

Physical Examination

General: Active, alert, and responsive. Temperature = 101.1°F (38.4°C), HR = 72 beats/minute, panting, mucous membranes pink, CRT = 1 second. There were no clinically significant findings on examination of the integument, eyes, ears, nose, cardiovascular system, respiratory system, and peripheral lymph nodes.

Musculoskeletal: BCS of 4/9 was noted with symmetrical muscle overdevelopment in shoulders, and some minor symmetrical muscle loss in hips, attributed to hip dysplasia.

GI: Abdominal palpation revealed a somewhat tense abdomen with possible enlargement of mesenteric lymph nodes. No abnormalities were detected on rectal examination, and no feces were present in the rectum.

Laboratory Findings

CBC: HCT 36% (35%–52%), WBC 14,800 cells/μL (4,000–15,500 cells/μL), platelets adequate.

Cytology Findings

Impression smear of intestinal biopsies: *Heterobilharzia americana* eggs and egg fragments were present in small numbers in the intestinal tissue (see Fig. 118.3C). Mononuclear and neutrophilic inflammation and granulomatous inflammatory tissue reaction was noted in association with the presence of parasite eggs.

Fecal Examination

Centrifugal fecal flotation ($NaNO_3$ solution, SpG 1.25): negative for parasite eggs, cysts, oocysts.

Fecal sedimentation: *Heterobilharzia americana* eggs < 1 per 10× field (see Fig. 118.2A).

Diagnosis

Canine heterobilharziasis (canine schistosomiasis).

Additional Case Information

Because of the diagnosis of heterobilharziasis in Trooper, a fecal sedimentation test was also conducted for the clinically normal cohort dog, "Sergeant." Eggs were also detected in the feces of that dog; therefore, both dogs received praziquantel and fenbendazole combination treatment.

Treatment

Praziquantel, 25 mg/kg twice daily with food for 2 days; fenbendazole, 50 mg/kg/day for 10 days with food.

Comments

Trooper was diagnosed with canine heterobilharziasis (canine schistosomiasis) based on identification of characteristic eggs in an impression smear of an endoscopic biopsy. Subsequently, the parasite infection was confirmed through the identification of parasite eggs on a fecal sedimentation test. Another clinically normal dog that shared the same environment, "Sergeant," was also positive for eggs on a fecal sedimentation test. Both dogs received praziquantel/fenbendazole treatment, and fecal sedimentation tests were negative at 2 and 3 months post-treatment. The dogs likely became infected with *H. americana* by penetration of cercariae in water while swimming in a farm pond where infected wildlife (raccoon, coyote, etc.) could be found in the local environment.

SECTION 6

Infectious Diseases of Body Systems and Clinical Problems

Jane E. Sykes

The final section of this book discusses infectious diseases of specific body systems such as the skin, musculoskeletal system, respiratory and gastrointestinal systems, central nervous system, eye, and genitourinary tract. It also includes chapters on systemic problems such as bloodstream infections, infections of the immunocompromised, and fever. These chapters are designed to help readers develop a knowledge of the possible infectious agents that could cause or contribute to disorders of different anatomic body systems, the optimum approach to diagnosis, and what treatments should be implemented should an infectious disease be strongly suspected or confirmed as the cause. Most discussion is limited to bacterial infections. For many bacterial infections, the recommended duration of treatment has typically been shortened, and recommended first-line antibiotic choices for most conditions have been tailored based on our knowledge of susceptibility patterns to improve antimicrobial stewardship. Following on from this, in sites where commensal bacteria are present, it has been increasingly recognized that sometimes disease follows disruption of the microbiome, or *dysbiosis*. As a result of the availability of high-throughput sequencing technology (also known as next-generation sequencing), the last 5 years have seen a rapid expansion of our understanding of the dog and cat microbiome in different body systems and how different disorders and treatments modify viral, bacterial, and fungal populations. These techniques are described in more detail in Chapter 125 (Gastrointestinal and Intra-abdominal Infections), but referred to in multiple chapters in this section. Analysis of effects of different variables on thousands of bacterial and fungal species requires reference to phyla and classes instead of individual species, classifications which veterinary practitioners are often less familiar with. It is likely that familiarity with populations of microorganisms will increase with further elucidation of the clinical relevance of microbiome analyses.

The final chapter of this book discusses the approach to diagnosis of fever of unknown origin. In this case, an infectious disease might be suspected but no localizing signs are available to narrow the list of differential diagnoses. Without localizing signs, it can be helpful to refer to tables that provide a categorized list of infectious diseases to consider for diagnostic efforts; these are included at the end of the chapter. In complex cases involving fever of unknown origin, the astute clinician should be sure to consider snuffleupagitis (see Chapter 77, Miscellaneous Bacterial Infections). Perhaps SARS-CoV-2 should also be considered. Alas, further research is needed (FRIN).[1]

Pyoderma, Otitis Externa and Otitis Media

Stephen D. White , Lynette K. Cole

KEY POINTS

Pyoderma

- Cause: *Staphylococcus pseudintermedius*, *Staphylococcus aureus*, and *Staphylococcus schleiferi.* Occasionally coagulase-negative *Staphylococcus* species.
- Affected Hosts: Dogs, less commonly cats.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Epidermal collarettes, pruritus, erythema, papules, pustules, alopecia. Deep pyoderma is characterized by deep nodules and fistulous tracts. Local lymphadenopathy may be present. Hyperpigmentation and lichenification occur with chronicity.
- Differential Diagnoses: Superficial pyoderma: pemphigus foliaceus, dermatophytosis, demodicosis, allergic dermatitis, drug eruptions, erythema multiforme, *Malassezia* dermatitis. Deep pyoderma: sterile pyogranulomatous dermatitis, sterile nodular panniculitis, juvenile cellulitis, neoplasia, foreign body reactions, deep cutaneous mycoses, pythiosis.
- Human Health Significance: *Staphylococcus pseudintermedius* prefers not to colonize humans, but zoonotic transmission has been reported. *Staphylococcus aureus* infection in dogs likely represents reverse zoonotic transmission from humans to dogs. *Staphylococcus schleiferi* has also been reported to infect humans.

Otitis Externa and Otitis Media

- Cause: The most common bacterial organisms identified in cases of infectious otitis externa and otitis media are *Staphylococcus pseudintermedius* and *Pseudomonas aeruginosa.* Less common bacterial cocci include *Staphylococcus schleiferi, Staphylococcus aureus*, enterococci, and β-hemolytic streptococci, while less common bacterial rods include *Proteus mirabilis, Escherichia coli, Corynebacterium* spp., and *Klebsiella* spp. The most common fungal cause of infectious otitis externa and otitis media is *Malassezia pachydermatis*; other uncommon to rare fungal pathogens include *Candida* spp. and *Aspergillus* spp.
- Affected Hosts: Dogs, less commonly cats.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: The most common clinical signs of otitis externa include otic pruritus (head shaking, scratching, rubbing ears on the floor), otic erythema, otic exudate, otic pain, and odor. With chronicity, proliferative changes and ulceration occur. Vestibular signs, deafness, Horner's syndrome, nystagmus, and facial paralysis may be present with middle and inner ear involvement.
- Differential Diagnoses: Otitis externa is not an isolated disease of the ear canal, but rather a syndrome that reflects underlying dermatologic disease. The etiologies of otitis externa are classified into predisposing factors, primary causes, and perpetuating factors. Differentials for otitis media/otitis interna depend on the clinical signs. For animals with peripheral vestibular signs and nystagmus, diseases to consider include feline idiopathic vestibular disease, geriatric canine vestibular disease, and hypothyroidism, while differentials for Horner's syndrome include FeLV infection, retrobulbar injury, and idiopathic causes.
- Human Health Significance: Zoonotic transmission of *S. pseudintermedius* from the skin and ears of dogs to humans is very uncommon but has been reported. Owners should be advised to wash their hands frequently or wear gloves while handing their pet with known or suspected drug-resistant infectious otitis externa or otitis media.

BACTERIAL PYODERMA

ETIOLOGY AND EPIDEMIOLOGY

Pyoderma is defined as a pyogenic infection of the skin, although pus may not always be grossly evident. The bacteria most commonly associated with pyoderma in dogs are *Staphylococcus pseudintermedius* (previously identified as *Staphylococcus intermedius*),[1,2] *Staphylococcus aureus*, and *Staphylococcus schleiferi* (both *S. schleiferi* subsp. *coagulans*, which is coagulase positive, and *S. schleiferi* subsp. *schleiferi*, which is coagulase negative) roughly in that order of frequency.[3,4] The role of other coagulase-negative staphylococcal (CoNS) species is probably more important than previously thought.[5] Gram-negative bacteria such as *Pseudomonas aeruginosa*, *Proteus* spp., and *Escherichia coli* may be involved in dogs with deep pyoderma.[6] These organisms are thought to invade secondary to alteration of local environmental conditions by *S. pseudintermedius*.

Staphylococcus pseudintermedius is a normal resident of mucosal sites such as the anus and nares and is thought to colonize the skin transiently following grooming and excessive licking in dogs with pruritus,[3,7] although more recent microbiome studies have shown that it can colonize the skin of healthy dogs.[2,8] Resident flora of healthy canine skin in these studies have primarily been staphylococci (especially *S. pseudintermedius*), *Streptococcus* spp., anaerobes, and *Malassezia* spp. The exact number of species that make up the canine cutaneous biome is continually expanding as various higher throughput methods are brought to bear on this research.[8,9] Similar research is ongoing in cats.[10,11] In one study that used next-generation sequencing, *Staphylococcus epidermidis* was the most abundant *Staphylococcus* spp. isolate found on the skin of healthy cats; *Staphylococcus felis* and *Staphylococcus capitis* were the most abundant isolates from the skin of allergic cats.[11]

In cats, pyoderma is less common, and is more likely to be caused by either *S. aureus* or *S. pseudintermedius*.[12] Feline acne is often a form of deep pyoderma, complicated by keratinization abnormalities.

Pyoderma is usually secondary to some disruption in the animal's cutaneous barrier and/or immune system. The usual primary diseases are allergic (flea allergy, atopic dermatitis, cutaneous adverse food reaction [CAFR]), endocrine (hypothyroidism, hyperadrenocorticism, diabetes mellitus [less commonly]), or demodicosis, but other diseases that cause severe pruritus or suppress the immune system have occasionally been implicated.

Over the past decade, clonal spread of methicillin-resistant *S. pseudintermedius* (MRSP) has occurred across Europe and North America.[13] Methicillin resistance has also been described among *S. aureus* (MRSA) and *S. schleiferi* (MRSS) isolates from dogs and cats with pyoderma.[4,14] These methicillin-resistant staphylococci (MRS) encode an altered penicillin binding protein (PBP) that confers resistance to all β-lactam antimicrobials, and many also demonstrate resistance to other antimicrobials becoming MDR isolates (see Chapter 51).[14]

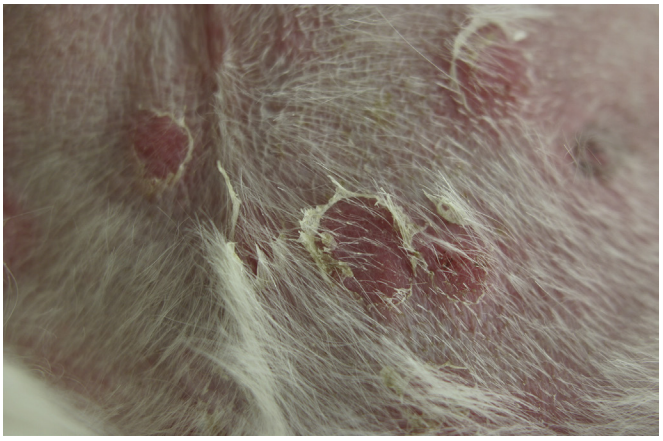

Fig. 119.1 Superficial pyoderma on the abdomen of a mixed breed dog showing erythema and several epidermal collarettes.

Fig. 119.2 Deep pyoderma on the dorsum of a German shepherd dog. Ulceration and fistulous tracts are present.

CLINICAL FEATURES

Classification of Pyoderma

Three broad classifications of pyoderma exist, based on the depth of skin and presumed follicle involvement: surface pyoderma, superficial pyoderma, and deep pyoderma.

Surface Pyoderma

Surface pyoderma occurs when bacteria proliferate on the surface of the skin and incite an inflammatory response, without invading the skin. Surface pyodermas include intertrigo ("fold" pyodermas), pyotraumatic dermatitis ("hot spots"), and mucocutaneous pyoderma, which most commonly affects German shepherd dogs.[15] Intertrigo may be found on the lip, face, vulva, and tail. Pyotraumatic dermatitis occurs secondary to self-trauma, such as that secondary to flea allergy dermatitis, and is commonly found in the lumbosacral area. Clinical signs include erythema, variable pruritus, alopecia, moist exudation, and a foul odor. Chronic lesions may be characterized by lichenification and hyperpigmentation. Mucocutaneous pyoderma is characterized by erosions and ulcerations with or without crusting, which involve the lips, nasal planum, nares, perioral skin, and sometimes the anus, vulva, prepuce, and eyelids. This may have an immunologic as well as a bacterial etiology, and is histologically identical to discoid lupus erythematosus; thus differentiation between these diseases should be made clinically and based upon response to antibiotics.[12,16]

Microbial overgrowth syndrome has also been categorized as a surface pyoderma when it involves bacteria.[17] Microbial overgrowth syndrome usually involves the ventral aspect of the body and is characterized by erythema, pruritus, a foul odor, erythema, alopecia, hyperpigmentation, lichenification, and excoriations, but no evidence of papules, pustules, epidermal collarettes, or crusts.[17]

Superficial Pyoderma

In superficial pyoderma, bacteria infect the superficial epidermal layers that lie immediately under the stratum corneum and/or the portion of the hair follicle above the sebaceous duct (the infundibulum). This is the most common type of pyoderma. It includes superficial bacterial folliculitis, superficial spreading pyoderma, and impetigo or juvenile pustular dermatitis ("puppy pyoderma"). Early lesions of superficial pyoderma are erythematous follicular papules (papules from which a hair shaft protrudes). As pus accumulates within the epidermis and hair follicles, these lesions become pustules. Papules and pustules are primary skin lesions. Epidermal collarettes are circles of epidermal scale with a free edge facing toward the center of the circle (Fig. 119.1), and may be remnants of ruptured pustules. In thick-coated dogs, the scale may become trapped throughout the haircoat as the epidermal collarettes exfoliate. Microscopically, epidermal collarettes consist of interfollicular, epidermal spongiotic pustules.[18] This may mean that epidermal collarettes do not always denote a folliculitis, although they almost always denote a pyoderma.[19] Hair fragments are shed from damaged follicles, which results in alopecia. Crusted papules, epidermal collarettes, and alopecia are secondary lesions.

Impetigo generally occurs in dogs less than a year of age. In impetigo, pustules are confined to the epidermis, without follicular involvement, and are most commonly found in the poorly haired (glabrous) areas on the ventral abdomen and inguinal region and around the chin. The pustules often evolve into honey-colored crusts.

Deep Pyoderma

Deep pyoderma is defined by infection deep within the hair follicle, with or without follicular rupture (furunculosis) (Fig. 119.2). Nodules with or without fistulous tracts may be present. German shepherd dogs seem prone to a more severe and extensive form of deep pyoderma[20]—the frequency of this form seems to have diminished concurrently with the advent of more effective medications for flea control. Other examples of deep pyoderma include pedal folliculitis and furunculosis, pressure-point pyoderma, pyotraumatic folliculitis and furunculosis, and muzzle folliculitis and furunculosis ("canine acne"). A similar process is seen in cats ("feline acne").[21,22]

Physical Examination Findings

Because the lesions of bacterial pyoderma are directly visible, in many cases, diagnosis can be made based on a thorough physical examination. Use of a hand lens may be helpful. In some cases, clipping of small areas of the haircoat may be required. This can help to identify epidermal collarettes in dogs with dry scale. Careful attention should be paid to the presence of follicular papules, pustules, crusted papules, epidermal collarettes, alopecia, nodules, fistulous tracts, and the presence or absence of pruritus. The distribution of lesions should be noted because it can be a clue to underlying disease, such as demodicosis or flea allergy. In dogs with deep pyoderma, the skin may feel warm to the touch and peripheral lymphadenomegaly may be detected.

DIAGNOSIS

The diagnostic approach to pyoderma should involve confirmation of the presence of pyoderma and a thorough search for possible underlying causes. The differential diagnosis includes many diseases that predispose to and/or mimic pyoderma, such as demodicosis, dermatophytosis, and pemphigus foliaceus (see Key Points). When crusts are present, cornification disorders should be considered, although crusting may also result from self-trauma. The presence or absence of *Malassezia* spp. must also be determined (Chapter 79).

In addition to a thorough physical examination, diagnostic procedures that may be necessary include skin scrapings, cytologic examination, aerobic bacterial culture and susceptibility testing, and skin biopsy. Dermatophyte culture is indicated when dermatophytosis is suspected or needs to be ruled out (see Chapter 78). Identification and subsequent treatment of underlying allergic skin disease may require additional testing such as intradermal skin testing, serologic tests for environmental allergy, and/or a limited allergen diet trial.

Skin Scrapings

Skin scrapings should be performed in any dog suspected to have pyoderma to assess for underlying demodicosis. Pustules or papules that are associated with hair follicles should be targeted, because *Demodex* mites have a predilection for this site.

Microbiologic Tests

Cytologic Examination

Cytology can be performed on tape preparations of the skin or smears made after swabbing pustules or draining tracts. Cytologic examination is essential in order to identify concurrent infection with *Malassezia* spp. Slides should be air-dried and stained with a modified Wright stain such as Diff-Quik. The presence of cocci suggests a staphylococcal infection (Fig. 119.3). Infection is supported by the presence of degenerate neutrophils and intracellular cocci. Inflammatory cells may be absent in dogs with underlying immunosuppressive disorders or those receiving glucocorticoid treatment. It is the opinion of the authors that the failure to see cocci on cytologic examination does NOT rule out a staphylococcal pyoderma, especially if clinical signs such as epidermal collarettes are present.

Culture and Susceptibility Testing

Due to the rapidly increasing prevalence of MRS worldwide, aerobic bacterial culture and susceptibility testing is playing a more important role in diagnosis of canine pyoderma. While probably not necessary for dogs with a first-time diagnosis of pyoderma, culture and susceptibility testing is never contraindicated and should always be offered in dogs with recurrent or refractory pyoderma, a history of recent treatment with systemic antimicrobial drugs, or who have had surgery or a hospital stay within the previous 6 to 12 months.[14] Refractory pyoderma is defined as pyoderma that fails to respond to treatment within a 3- to 4-week treatment period. Culture also can definitively identify the staphylococcal species involved, which may have public health implications (see Public Health Aspects, later). The results of culture and susceptibility testing must always be interpreted in light of the clinical signs present and any history of antimicrobial drug treatment.

The best lesions for culture in dogs with superficial pyoderma are pustules. A thorough search for pustules is recommended. Pustules can be ruptured using a sterile needle, and a swab used to obtain purulent material. If pustules cannot be detected, culture can be performed on swab specimens collected from the skin that lies beneath crusts or from under the edge of epidermal collarettes.[19] No surface antisepsis should be performed. Any hair should be clipped from the lesion using sterile scissors, and crusts should be lifted with sterile forceps. Alternatively, a sterile culturette can be rolled two to three times over the collarette. Papules can be biopsied using local anesthesia and submitted for culture. In this case, surface antisepsis with a single 70% alcohol wipe may be performed before collection of the biopsy. Culture of biopsy specimens from nodules and furuncles is best for dogs with deep pyoderma. After collection of the biopsy, the epidermis can be removed using a sterile blade and the deeper tissues submitted for macerated tissue culture.

Minimum reporting by microbiology laboratories should include complete speciation of staphylococci—regardless of tube coagulase status—and complete antibiotic susceptibility results. The pathogenic

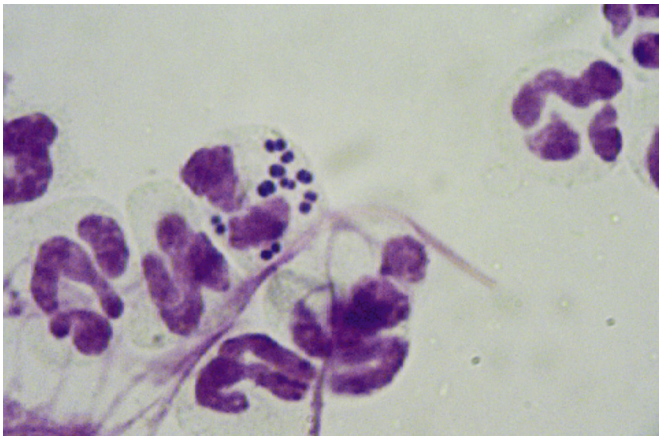

Fig. 119.3 Cytology findings from a pustule, showing neutrophils and intracellular cocci.

BOX 119.1 Interpretation of Susceptibility Panels for Staphylococci to Aid Selection of Antimicrobials for Pyoderma[23]

- Beta-lactam antibiotics should not be used for methicillin-resistant staphylococcal (MRS) infections, irrespective of susceptibility results. This includes third generation cephalosporins (cefovecin and cefpodoxime) as they do not have efficacy against MRS.[21,22]
- When possible, fluoroquinolones should be avoided for empirical therapy when an MRS is suspected.[23]
- If the staphylococcal species is reported as susceptible to clindamycin but resistant to erythromycin, another antibiotic should be chosen, as this may be an organism with inducible clindamycin resistance.
- Choice of a tetracycline is complicated by the fact that resistance to these antibiotics is mediated by four different genes. Genes most commonly expressed by *S. pseudintermedius* are *tet*(M) and *tet*(K). Strains which possess only *tet*(K) maintain susceptibility to minocycline but not to other tetracyclines. Canine breakpoints for doxycycline are a reasonable surrogate for minocycline susceptibility.[20]

potential of any CoNS isolate obtained from a skin lesion should be interpreted in light of the clinical findings and with respect to any other pathogenic species of bacteria that may be co-isolated with it.[23] Other suggestions about interpretation of susceptibility panels are outlined in Box 119.1.

Pathologic Findings

Findings on histopathology in dogs with uncomplicated pyoderma include a neutrophilic infiltrate and abundant bacterial organisms. Folliculitis, furunculosis, or the features noted in epidermal collarettes[18] (described above) are all potential findings. Histopathologic evaluation of skin biopsy specimens allows classification of the extent and type of pyoderma and identification of other conditions such as allergic dermatitis, demodicosis, dermatophytosis, pemphigus foliaceus, neoplasia, deep mycoses, and vasculitides. Biopsy should be considered in recurrent or refractory cases, in dogs with deep pyoderma, or when the underlying cause is not apparent. Biopsies can be performed under local anesthesia using a 6-mm punch biopsy. When possible, the biopsy specimen can be halved with half submitted for culture and half for histopathology. The biopsy site should be sutured after the specimen has been collected.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Molecular strain typing methods are research tools used to investigate the epidemiology and ecology of MRS. However, at this time, strain typing often has no impact on patient- or clinic-level management, even in the context of most outbreaks.[23]

TREATMENT AND PROGNOSIS

Factors to consider when treating dogs for pyoderma include the underlying disease, the severity and extent of lesions, and the local geographic prevalence of staphylococcal resistance. Veterinarians' reliance on systemic antimicrobial drug treatment has been challenged by the increasing prevalence of MDR staphylococci. Topical treatments that help to restore skin structure and function, as well as topical antimicrobial therapy, should be considered as alternatives. In dogs with mild disease, treatment aimed at the underlying disorder may be sufficient to resolve infection (see Prevention). Guidelines for the treatment of superficial bacterial pyoderma have been developed by ISCAID.[24]

Topical Treatments

Topical therapy should be used as the sole on-animal antibacterial treatment for surface and superficial infections whenever the pet and owner can be expected to be compliant.

Antibacterial shampoos may be effective alone in some dogs with surface or mild superficial pyoderma and should be used as adjunctive therapy in dogs with deep pyoderma. They aid in debridement, reduce surface bacterial numbers, and decrease pain and pruritus. Options include shampoos that contain ethyl lactate, chlorhexidine, miconazole (in combination with chlorhexidine), benzoyl peroxide, or sodium hypochlorite. Initially, they should be used at least twice weekly with a 10-minute contact time. A combination of chlorhexidine and miconazole may be particularly effective.[25] Benzoyl peroxide shampoos can be drying and so are best reserved for dogs with greasy dermatitides. Daily shampooing may be required for dogs with deep pyoderma. If available, treatment with daily whirlpool baths containing chlorhexidine may also be helpful for these dogs. Important points about shampooing are noted in Box 119.2.

Topical antimicrobial drugs and antiseptics in ointment or cream form result in high concentrations of drug at the skin surface that can overwhelm bacterial drug resistance mechanisms, and can be useful when pyoderma is limited to small areas of skin. Aside from having the potential to be messy, these drugs have minimal adverse effects and result in minimal exposure of bystander organisms (such as intestinal flora) to antimicrobial drugs. Examples of topical drugs with excellent activity against staphylococci include neomycin, gentamicin, polymyxin B, bacitracin, hydroxyl acids (such as acetic acid), novobiocin, and silver sulfadiazine. Mupirocin and fusidic acid are additional topical antimicrobial drug preparations that may also be useful for treatment of pyoderma that is restricted to small areas. While resistance to mupirocin and fusidic acid has been documented in MRSA isolates from humans,[26,27] *in vitro* evidence of resistance of *S. pseudintermedius* to these two medications is rare.[27,28] However, there is a report of subclinical nasal carriage of a mupirocin-resistant MRSA isolate in a pet dog, so some caution is warranted.[29]

BOX 119.2 Points to Optimize the Use of Shampoos for Prevention of Pyoderma

- Water temperature should be lukewarm, not hot. If the dog is bathed outside using a hose, the owner should be told to run the water first to make sure it is not hot—water in hoses in the summer can easily reach temperatures capable of causing burns.
- A hand-palm size amount of shampoo should be used, often placed in 0.5 to 1 gallon of water before it is applied to the haircoat. This reduces frustration associated with the decreased lathering tendency of medical shampoos.
- The shampoo should always be applied in the direction of the hair, not against it. Aggressive scrubbing should be avoided, as this may lead to follicular damage and even post-bathing folliculitis-furunculosis.[25]
- Sprays, mousses, wipes, and conditioners with the same or similar medications used following or in between shampoo sessions may also be useful.[26,27]
- *Diluted* sodium hypochlorite (bleach) has been used as a leave on, then rinse off after, application. Starting as a commercial 6.15% solution, a dilution of 1:32 with water was effective *in vitro* against *Staphylococcus pseudintermedius*, including methicillin-resistant strains.[28,29]

Systemic Antimicrobial Drug Therapy

When pyoderma is widespread, deep, or topical treatment is ineffective or impractical, treatment with systemic antimicrobial drugs may be required. If an antibiotic is selected for empiric treatment, it should be based on the local prevalence of resistance, and narrow-spectrum drugs that target staphylococci are preferable. Clindamycin, first-generation cephalosporins (such as cephalexin), lincomycin, and amoxicillin-clavulanic acid are reasonable first choices (Table 119.1). Other acceptable alternatives when the local regional susceptibility of *S. pseudintermedius* is known include doxycycline, trimethoprim- or ormetoprim-potentiated sulfonamides.

The use of third-generation cephalosporins for empiric therapy is controversial because their use in particular has been associated with selection for MRS in humans and they have the potential to select for resistant populations of gram-negative bacteria in the GI tract.[30] Whether this holds true for dogs and cats is unknown at present. What is known is that the percentage of MRS and MDR isolates among all species of *Staphylococcus* is increasing.[14,23,31] However, there is little evidence for a difference in outcome between MRS and methicillin-susceptible *Staphylococcus* infections in animals, and the prognosis for MRS skin infections in pets is good, depending on the underlying cause and co-morbidities.[23]

It is currently recommended that treatment be for a minimum of 4 weeks for superficial pyoderma and 8 weeks for deep pyoderma. Dogs should be re-evaluated at the end of the suggested periods while still

TABLE 119.1 Oral Antibacterial Drugs Useful for Treating Canine Pyoderma and Otitis Externa/Otitis Media[a]

Drug (Dose)	Advantages	Disadvantages	Assessment/Indication
Clindamycin (10 mg/kg q12h, or 11 mg/kg q24h or q12h)	Infrequent dosing	Only ~75% effective, development of resistance during therapy	Second-choice therapy for a once-daily drug. Can be used for staphylococcal otitis
Ormetoprim-sulfadimethoxine (27.5 mg/kg q24h)[b]	Less frequent dosing, broad spectrum, useful for MRS	Relatively expensive	Good first empiric choice, especially if need once-daily drug, useful for MRS. Rarely used for staphylococcal otitis
Cephalexin or cefadroxil (22–30 mg/kg q12h)	Less frequent dosing, broad spectrum, resistance uncommon, good tissue penetration	Cefadroxil expensive, some generics moderately expensive	Excellent first empiric choice, choice for refractory-recurrent deep pyoderma, twice-daily drug. Can be used for staphylococcal otitis
Enrofloxacin (5–20 mg/kg q24h)	Less frequent dosing, broad spectrum, rapidly absorbed, excellent tissue penetration	Expensive, cannot use in growing dogs	Excellent choice for refractory-recurrent deep pyoderma, once-daily drug. Can be used for otitis
Marbofloxacin (2.5–5 mg/kg q24h)	As for enrofloxacin	As for enrofloxacin	As for enrofloxacin
Orbifloxacin (7.5 mg/kg q24h)	As for enrofloxacin	As for enrofloxacin	As for enrofloxacin. Rarely used for otitis
Amoxicillin-clavulanate (12.5–20 mg/kg q12h)	Broad spectrum, adverse effects rare	Expensive, moisture sensitive, *in vivo* effect may not be as good as would be predicted, slow response	Reasonable first empiric choice, somewhat expensive. Can be used for staphylococcal otitis
Trimethoprim-sulfonamide (22 mg/kg q12h)	Inexpensive, less frequent dosing, broad spectrum, useful for MRS	Adverse effects: keratoconjunctivitis sicca, severe cutaneous drug reactions, hepatic necrosis	Good empiric choice, concern for adverse drug reactions, useful for MRS. Can be used for staphylococcal otitis
Cefpodoxime proxetil (5–10 mg/kg q24h)	Less frequent dosing, relatively broad spectrum, good penetration of tissues, low toxicity, can give with food	Expensive, not recommended for longer than 28-day intervals	Second choice because of expense, first choice where multiple daily dosing of medication is problematic. Can be used for staphylococcal otitis
Doxycycline (5 mg/kg q12h)	Helpful in treating MRS	Moderately expensive	Second choice due to expense. Can be used for staphylococcal otitis
Ciprofloxacin (30 mg/kg q24h)	Inexpensive, less frequent dosing	Variable absorption in dogs	Helpful in large-breed dogs due to less expense. Can be used for otitis due to *Pseudomonas* spp. and *Staphylococcus* spp.
Azithromycin (5–10 mg/kg q24h)	Often effective against MRS	Expensive, GI adverse effects; contraindicated in animals with liver disease	Long-term dosage regimen not well worked out in small animals. Not been reported for use for staphylococcal otitis

[a]For additional information on listed drugs, see Chapter 10. Treatment generally lasts for a *minimum* of 21 days for pyoderma. *Staphylococcus pseudintermedius* and *Pseudomonas aeruginosa* are the most common pathogenic bacterial organisms cultured from the external and middle ears of dogs; however, other organisms cultured from the external and middle ears may also be pathogens. Therefore, systemic antibacterial therapy should be selected based on the results of a bacterial culture and susceptibility test. Treatment for infectious otitis externa/otitis media should be continued until the otic infection has resolved.
[b]Give dose q12h on the first day.
GI, gastrointestinal; *MRS*, methicillin-resistant staphylococci.

receiving antibiotic therapy. Continued clinical signs such as pruritus in the face of resolution of the pyoderma (reduction or absence of epidermal collarettes or follicular papules) should prompt investigation of underlying diseases. For superficial pyodermas, treatment should be continued for at least 7 days beyond clinical resolution of lesions, because inflammation subsides before infection is completely resolved. For deep or recurrent superficial pyoderma, treatment should be continued for 14 days beyond clinical resolution. It is possible that in the future, shorter durations of treatment may be recommended to reduce antimicrobial selection pressure, especially when combinations of topical and systemic treatment are used together with control of the underlying cause.

Although intermittent administration of antimicrobials on a regular basis ("pulse therapy") has been used to treat some dogs with recurrent pyodermas, there is concern for induction of resistance using these protocols. This mode of therapy was initiated in the early 1980s, when the current high incidence of resistance was not present, and it may not be relevant or advisable at this time. If necessary, referral to a veterinary dermatologist is recommended.

PREVENTION

Prevention of recurring pyoderma relies on addressing the underlying cause or causes whenever possible. This may involve investigating the possibility of food allergy, flea allergy, atopic dermatitis, *Demodex* spp. infestation, hypothyroidism, or hyperadrenocorticism. This could include skin scraping, initiating or increasing flea control, frequent bathing to restore skin condition, dietary management for dogs with food allergies, management of atopic dogs, and/or breeding practices that aim to select against atopic dogs and dogs with abundant skin

folds. Specific prevention of MRS infections relies on hand washing, disinfection practices, as well as judicious use of antimicrobial drugs, as outlined earlier. Previous treatment with antibiotics, previous hospitalization, and cohabitant dogs have been identified as risk factors for the development of infection with MRS.[14,32,33] There is currently not enough evidence to recommend routine decolonization of MRS carrier animals.[23]

When treatment of the underlying cause or use of topical therapy is unsuccessful in preventing recurrence of pyoderma, subcutaneous administration of autogenous bacterins or commercial bacterial antigens (such as Staphage Lysate, Delmont Laboratories, USA) may be beneficial in some dogs.[34,35] These are generally given once or twice weekly.

PUBLIC HEALTH ASPECTS

In vitro studies have shown that the majority of *S. pseudintermedius* adhere better to canine than human corneocytes.[36] However, human infection has been reported occasionally, including among veterinarians.[37,38] In these cases, pet dog contact was reported and suggested to be the source of infection. In one case, an isolate from the dog matched that isolated from the human as determined using pulsed-field gel electrophoresis.

In contrast, contact with human hospitals and children may be risk factors for acquisition of MRSA infections by dogs, as *S. aureus* infections in dogs appear to be a reverse zoonosis. MRSA isolated from animals has been shown to be human clonal in nature.[39] Colonization is generally transient in dogs and cats, so specific treatment to decolonize dogs and cats is neither necessary nor effective.[40] See the suggested reading list for a complete discussion of screening for MRSA in both dogs and humans.[23]

Although it may be carried elsewhere on the body, *S. schleiferi* subsp. *coagulans* has been isolated primarily from dogs with otitis externa and has been reported as a cause of endocarditis in an immunocompromised person, while *S. schleiferi* subsp. *schleiferi* was reported as causing a prostatic abscess and bacteremia in a man.[41,42]

Frequent and proper hand washing using soap and water and disinfectant foams or gels is the number one practice that limits spread of these infections in human hospitals. Hands should be washed before and after handling each patient. Clean clothing should be worn and doctors' coats changed regularly. Attention should be paid to regular disinfection of other fomites such as stethoscopes, cell phones, rectal thermometers, computer keyboards and mice, calculators, and bandage scissors. Disinfectant wipes that contain alcohol or accelerated hydrogen peroxide can be used to clean these surfaces.

OTITIS EXTERNA AND OTITIS MEDIA

ETIOLOGY AND EPIDEMIOLOGY

Otitis Externa

Otitis externa is defined as inflammation of the external ear canal; in some cases, the inflammation may extend onto the surface of the pinna. Etiologies of otitis externa have been divided into predisposing factors, primary causes, and perpetuating factors (Box 119.3). Successful treatment of otitis externa depends on identification, along with controlling or eliminating these factors and causes. Simply treating the complicating infection without addressing the primary cause, or eliminating the primary cause without control of the secondary infection, likely will result in treatment failure.

BOX 119.3 Etiologies of Otitis Externa

Predisposing Factors

Conformation: stenotic canals, hair in canals, pendulous pinnae
Excessive moisture: "swimmer's ear," high-humidity climate
Treatment effects: improper antibacterial use, cotton swab trauma, irritant antiseptic solutions

Primary Causes

Allergic disease: atopic dermatitis, cutaneous adverse food reaction, contact allergy
Parasites: *Otodectes cynotis, Demodex canis, Demodex cati, Otobius megnini*
Foreign bodies
Juvenile cellulitis
Keratinization disorders: primary idiopathic seborrhea
Endocrine disorders: hypothyroidism
Autoimmune diseases: pemphigus foliaceus
Masses: neoplasia, nasopharyngeal polyps

Perpetuating Factors

Progressive pathologic changes, bacterial infections, yeast infections, otitis media

Modified from August JR. *Solvay Veterinary Inc: The Complete Manual of Ear Care*. Trenton, NJ: Veterinary Learning Systems; 1986.

In a retrospective study evaluating 100 dogs with acute (37%) and chronic-recurrent (63%) otitis externa, the most common primary causes were allergic dermatitis ($n = 43$ dogs; e.g., CAFR, canine atopic dermatitis), parasites (13 dogs), and grass awns (12 dogs).[43] Most bacterial and yeast infections are perpetuating factors and therefore are secondary to the primary, underlying disease. In cats, the most common primary causes of recurrent otitis externa are *Otodectes cynotis* and nasopharyngeal polyps. Unlike dogs, underlying allergic diseases such as CAFRs and feline atopic skin syndrome are much less commonly associated with secondary infectious otitis externa. A rare painful idiopathic proliferative and necrotizing feline otitis externa (PNOE) has been reported, which may or may not involve the concave pinnae.[44,45]

In health, the external ear canal is colonized by numerous bacterial as well as yeast species. Species that can be cultured from the external ears of dogs without ear disease include CoNS, *Bacillus* spp., coagulase-positive staphylococci (e.g., *S. pseudintermedius*), *E. coli, Corynebacterium* spp., streptococci, *Micrococcus* spp., and *Malassezia* spp. However, it is uncommon to culture bacteria from healthy ears (with the exception of *Bacillus* spp., CoNS, and low numbers of coagulase-positive staphylococci). *Pseudomonas* spp. and *Proteus* spp. are rarely cultured from clinically healthy ears. Instead, these microorganisms proliferate when there is inflammation in the ear canal as a result of primary conditions. Although less common, *S. schleiferi* subsp. *schleiferi* also has been isolated from the external ear canal of dogs. More recent studies that have used next-generation sequencing to analyze the microbiota of healthy ears have shown a diverse microbial community with the most abundant species being *Cutibacterium acnes* (previously *Propionibacterium acnes*), *S. pseudintermedius*, and *Streptococcus* spp.[8]

Bacterial organisms cultured from the external ear canal in dogs with chronic otitis externa include *S. pseudintermedius, P. aeruginosa, Proteus* spp., β-streptococci, *Corynebacterium* spp., *Enterococcus* spp., and *E. coli*, with the most commonly identified cocci and rods being *S. pseudintermedius* and *P. aeruginosa*, respectively. Using next-generation sequencing, the most abundant species were *Malassezia* spp., *S. pseudintermedius*, *S. schleiferi*, and a variety of anaerobes.[8]

Knowledge of the most likely organism based on cytologic examination allows one to commence early and targeted antimicrobial therapy.

Staphylococcus schleiferi subsp. *schleiferi* has been isolated from the ears of dogs with recurrent otitis, and *S. schleiferi* subsp. *coagulans* can be found in dogs with both first-time and recurrent otitis externa. Infectious otitis externa is much less common in cats than in dogs. Organisms identified in the ear canals of cats associated with otitis externa include CoNS, *S. aureus, S. pseudintermedius,* and *Pasteurella* spp.

Otomycoses have been reported in dogs and cats, with the most common organism being *Malassezia pachydermatis*; *Candida* spp. is an uncommon fungal pathogen. *Aspergillus* spp. is a rare cause of otitis externa and otitis media in both dogs and cats.[46]

The ear mite *O. cynotis* may be responsible for most feline cases of otitis externa; dogs have a much lower prevalence of this infestation. Most animals develop a hypersensitivity reaction to the mite that results in an inflammatory reaction; however, some animals are subclinical carriers. In others, the inflammation may lead to a secondary bacterial or yeast-associated otitis externa that can eventually result in the death of the mites.

In a study of 3,707 small animal consultations from 20 general practices, the reported prevalence of otitis externa was 4.5% for dogs (of 2,322 dogs) and 1.2% for cats (of 1,043 cats).[47] Breeds that are overrepresented among dogs with otitis externa include the cocker spaniel, Jura des Alpes, and Brittany spaniel.[43] However, any breed as well as mixed-breed dogs may develop otitis externa. Among cats, the incidence of otitis externa has been reported to be highest in Himalayan and Persian cats.[48]

Otitis Media

Otitis media is defined as inflammation of the middle ear. Causes of otitis media may be divided into those that are infectious and those that are noninfectious. Infectious otitis media (bacterial, fungal) is an important perpetuating cause of recurrent otitis externa. Animals may traumatize their external ears because of discomfort caused by irritation in the middle ear. Infectious otitis media occurs as a direct extension from an existing otitis externa through a ruptured tympanic membrane. Less common routes of infection include extension through the auditory tube or the hematogenous route. The reported prevalence of infectious otitis media in dogs with acute otitis externa is 16%, whereas in dogs with chronic, recurrent otitis externa the reported prevalence is 50% to 82.5%.[49,50] Although a ruptured tympanic membrane is indicative of otitis media, the presence of an intact tympanic membrane does not rule out otitis media because the defect in the membrane may have healed.

The middle ear of dogs, like the external ear canal, has a resident microflora consisting of low numbers of yeasts and bacteria including *E. coli, Staphylococcus* spp., *Branhamella* spp., *Streptococcus* spp., *Enterococcus* spp., *Bacillus* spp., *Bordetella bronchiseptica,* and *Clostridium perfringens*. The most common organisms isolated from dogs with infectious otitis media include yeasts, *S. pseudintermedius, P. aeruginosa, Proteus* spp., β-hemolytic streptococci, *Corynebacterium* spp., and *Enterococcus* spp. The resident microflora of the feline middle ear has not been described. In cats with infectious otitis media secondary to nasopharyngeal polyps, the most common bacterial organism identified was *S. pseudintermedius*. Other bacterial organisms in the middle ears of cats with infectious otitis media include *P. aeruginosa*, *B. bronchiseptica*, *Bacteroides* spp., *Fusobacterium* spp., and *Mycoplasma* spp.

There are also noninfectious causes of otitis media (congenital palatine defects, trigeminal nerve disorders, primary secretory otitis media [PSOM], otic masses, cholesteatomas, cholesterol granulomas, sinonasal disease, parasitic nematodes, trauma, grass awns). Congenital palatine defects (i.e., secondary cleft palate, soft palate hypoplasia) have been associated with radiographic signs of middle ear disease in both dogs and cats.[51–53] Neurologic signs indicative of otitis media were identified in cats but not in dogs. Trigeminal nerve disorders due to neoplasia, neuritis, or neuropathy in dogs have been associated with a middle ear effusion. Interruption of trigeminal nerve innervation of the tensor veli palatine muscle (which opens the pharyngeal opening of the auditory tube) alters the function of the auditory tube, which could result in the middle ear effusion. PSOM has been described in the Cavalier King Charles spaniel. These dogs do not have a history of concurrent otitis externa. Clinical signs include moderate to severe pain in the head or cervical region; neck/ear scratching; neurologic signs, such as facial paralysis, nystagmus, or head tilt; and hearing loss.[54,55] An increased soft palate thickness and decreased nasopharyngeal dimension are associated with bilateral middle ear effusion in this breed. These changes may then result in auditory tube dysfunction with resultant bullae effusion.[56–58] The majority of middle ear and external ear cultures from these dogs are negative, so the role of bacteria in this disorder remains unclear.[59]

Masses can occur in the external ear canal as well as in the middle ear and can be neoplastic (benign or malignant) or nonneoplastic. Ceruminal gland neoplasia is the most common neoplastic mass of the external ear canal. In cats, these tumors are usually malignant, whereas in dogs, they are usually benign. Tumors that occur in both the ear canal and tympanic bulla are usually malignant, but biopsy is needed for confirmation. Nasopharyngeal (inflammatory) polyps are nonneoplastic masses. Although inflammatory polyps can contribute to chronic recurrent otitis externa, they originate in the auditory tube and can expand into the tympanic bulla or pharynx or both. Whereas inflammatory polyps are common in cats, especially kittens, they are relatively uncommon in dogs.[60] Feline ceruminal cystomatosis is an uncommon, nonneoplastic otic condition consisting of striking multiple blue-gray to purple papules and nodules often mistaken for melanotic or vascular tumors.[61] It is important to biopsy all masses for histopathologic identification.

Cholesteatomas are abnormal growths of the epithelium within the middle ear consisting of keratinizing stratified squamous epithelium, inflammatory cells, and ceruminous debris. These may occur congenitally or secondary to chronic otitis media. Cholesterol granulomas are granulomatous lesions containing cholesterol crystals that may also occur in the middle ear. These two entities can present similarly, but cholesteatomas typically cause more bony destruction of the tympanic bulla and more severe clinical signs and have only been reported in dogs, while cholesterol granulomas have been reported in both dogs and cats. Furthermore, in dogs, cholesteatomas and cholesterol granulomas may co-exist.[61–63]

Cats with sinonasal disease (e.g., rhinitis, neoplasia) are at increased risk of having concurrent bulla effusion and may not exhibit any clinical signs of middle ear disease.[64] *Mammomonogamus auris*, a strongylid nematode that resides in the middle ear, has been identified as the cause of head shaking in domestic cats in Asia and the Caribbean (see Chapter 116).[65,66]

Otoliths (stone-like mineral concretions of necrotic material within the bulla) of the middle ear have been reported in three dogs. The clinical significance of otoliths is unknown, as only one of the dogs reported with these had clinical signs of vestibular disease.[67] In a retrospective study, stalked bony globular structures that have been named *hyperostotic tympanic bone spicules* were identified in the middle ear; these should be considered on a differential diagnosis list for otolith-like structures identified on a CT scan but can only be differentiated from otoliths histologically.[68]

BOX 119.4 Questions for Owners Regarding Recurring Otitis Externa

When did the problem begin?
Did it begin unilaterally or bilaterally?
Is it seasonal or nonseasonal?
What are the current and previous treatment(s) used?
What has been the posttreatment outcome?
Have there been any adverse effects to medications?
Was there previous treatment with glucocorticoids?
Are there other dermatologic concerns: pruritus, alopecia, "rash"?
What are current and previous diets and treats?
What are current medications for other concurrent diseases?
What current preventive treatments are being administered (flea or tick control, heartworm prevention)?
Are there any others (human or animal) in the home with skin problems?

Fig. 119.4 Erythema of the inner pinna as well as erythema and mild yellow ceruminous exudate at the opening of the vertical ear canal in a dog with acute otitis externa.

Fig. 119.5 Right ear of a dog with chronic, recurrent otitis externa, with purulent exudate and ulceration on the entire inner pinna, as well as hyperplasia and stenosis of the opening of the vertical ear canal.

CLINICAL FEATURES

The most common clinical signs of otitis externa include otic pruritus (head shaking, scratching, rubbing ears on the floor), otic erythema, otic exudate, otic pain, and odor. Additional clinical signs (e.g., pedal pruritus, indicating primary underlying allergic disease) may be present and identification of these signs can help with determination of the primary cause of the otitis externa.

Usually, the only clinical signs of otitis media are those also seen with otitis externa listed above. Specific clinical signs indicative of otitis media are facial nerve paralysis and Horner's syndrome. Injury to the facial nerve, as it courses near the middle ear, produces clinical signs such as drooping of or inability to move the ear or lip, drooling of saliva, or decreased or absent palpebral reflex. In one study, 21.5% of 79 dogs and 18.8% of 16 cats had facial neuropathy (facial paresis, paralysis, hemifacial spasm, or contracture) secondary to otitis media/interna. Cocker spaniels with facial neuropathy were more likely to have otitis media/interna as the underlying cause compared to other breeds with facial neuropathy.[69] Horner's syndrome is due to injury to the sympathetic nerve fibers, which course near the middle ear, and is characterized by ptosis, miosis, enophthalmos, and protrusion of the nictitating membrane. In one study of Horner's syndrome, the underlying cause was otitis media/interna in 27% of cats and 2.7% of dogs.[70] Keratoconjunctivitis sicca may occur if the parasympathetic nerves that innervate the tear gland are injured. The parasympathetic nerve fibers course with the facial nerve, so keratitis may be aggravated by concurrent facial paralysis.

Otitis media may lead to otitis interna, which is associated with damage to the vestibular and cochlear branches of cranial nerve eight (CN VIII). Clinical signs of otitis interna include horizontal nystagmus, asymmetrical ataxia, head tilt, circling, falling, or rolling toward the affected side.

Physical Examination Findings

Obtaining a complete and thorough history from the owner is critical before a physical examination is performed. Providing the client with a dermatologic history form to complete before the appointment can facilitate this (Box 119.4).

A complete dermatologic examination as well as an otic examination should be performed. In some cases, a neurologic examination may be needed if concurrent otitis media or otitis interna is suspected. However, the most common clinical sign of otitis media is recurrent otitis externa. A head tilt, circling, and nystagmus may indicate otitis interna. Central extension of otitis media/interna into the adjacent subarachnoid space and brainstem can be a life-threatening complication.[71,72]

The pinnae should be examined for alopecia and excoriations. The vertical and horizontal ear canals should be palpated. In acute otitis externa, clinical findings may be minimal and only include erythema and ceruminous discharge (Fig. 119.4). The tissue surrounding the external auditory meatus may be swollen, occluding the canal. In chronic or recurrent otitis externa, an increase in the otic discharge is evident, along with varying degrees of hyperplasia and canal stenosis (Fig. 119.5). Palpation of the ear canals may reveal thickened or calcified canals or elicit discomfort (Fig. 119.6).

The otic examination is performed with either a handheld or video otoscope. The purpose of the otic examination is to evaluate the vertical and horizontal ear canal for evidence of hyperplasia, stenosis, and ulceration. It is also used to evaluate the amount, consistency, and

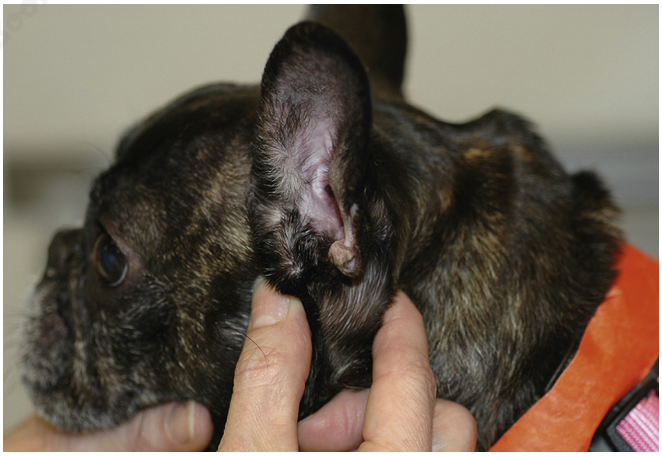

Fig. 119.6 Palpation of the vertical and horizontal ear canals is necessary to evaluate for progressive pathologic changes such as calcification.

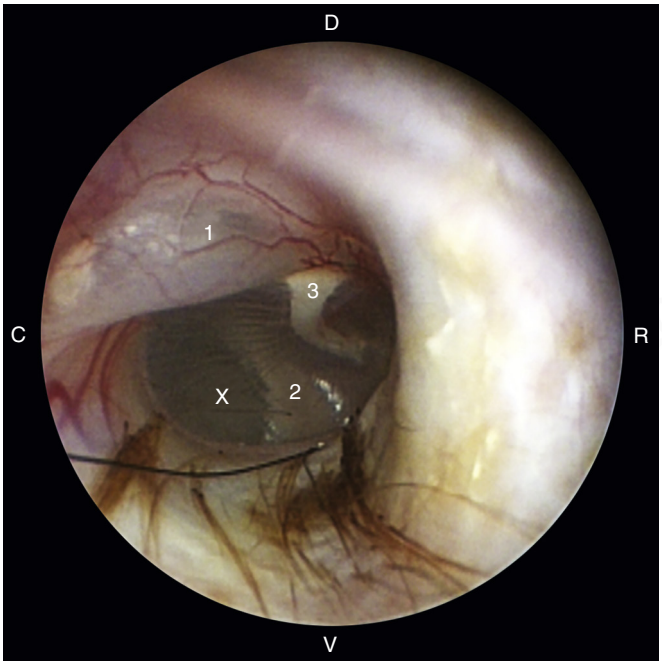

Fig. 119.7 The right tympanic membrane of the dog. The *X* depicts the proper area on the tympanic membrane for performing a myringotomy incision (caudoventral quadrant). *1,* Pars flaccida; *2,* pars tensa; *3,* stria mallearis; *C,* caudal; *D,* dorsal; *R,* rostral; *V,* ventral. (Courtesy of The Ohio State University, Columbus, OH.)

color of the otic exudate. If possible, the tympanic membrane is examined. In some instances, there is so much disease in the ear canal that otic examination is not possible. In those cases, the otic examination is delayed until after initial treatments have been implemented.

The tympanic membrane is divided into two sections, the small upper pars flaccida and the larger lower pars tensa (Fig. 119.7). When visualizing the tympanic membrane, the healthy pars tensa should be translucent and concave. Otitis media should be suspected if the pars tensa is ruptured, bulging, opaque, or cloudy. However, an intact tympanic membrane does not rule out otitis media in the dog. If the tympanic membrane is intact, it should be examined to determine if it is normal (translucent) or if the pars tensa is abnormal. A healthy pars flaccida is the pink, small, loosely attached region forming the upper

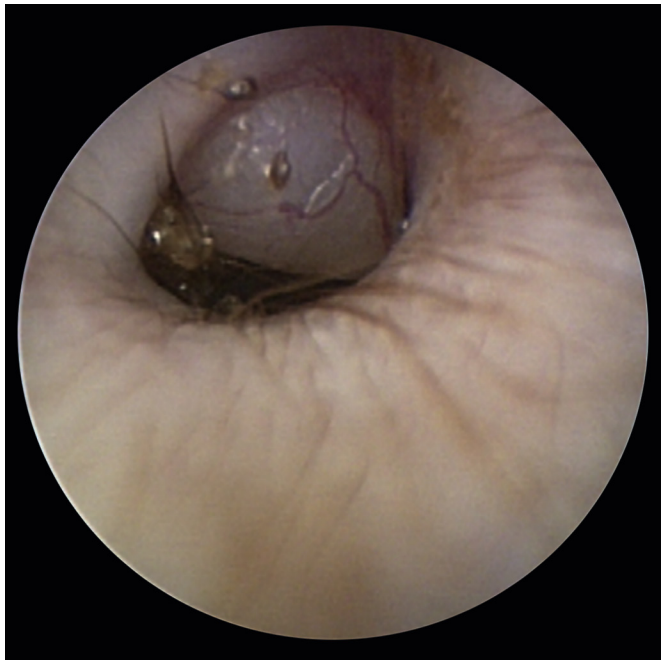

Fig. 119.8 Right ear of a Cavalier King Charles spaniel with primary secretory otitis media (PSOM). Note the large, bulging pars flaccida.

quadrant of the tympanic membrane that contains small blood vessels. On otic examination, the pars flaccida in most dogs is flat. Bulging pars flaccidas, although uncommon, may be found in the ears of clinically healthy dogs, as well as in ears of dogs with otitis. No histologic differences have been identified between flat and bulging pars flaccidas in clinically healthy dogs, so it appears unlikely that a structural difference explains a bulging pars flaccida.[73] In the Cavalier King Charles spaniel, a bulging pars flaccida is indicative of PSOM (Fig. 119.8). Unfortunately, a flat pars flaccida does not rule out PSOM.[55]

DIAGNOSIS

The diagnostic approach to otitis includes identification and management of the primary cause as well as identification and treatment of the infectious (e.g., bacteria, *Malassezia*) agent(s). In addition, predisposing factors need to be controlled or eliminated. Perpetuating factors such as otitis media and progressive pathologic changes must be diagnosed and treated. If all aspects of otitis are not identified, treated, and managed, the otitis will become recurrent and chronic. Additional diagnostics to identify predisposing factors may include, but are not limited to, a food trial, serum allergy testing, biopsy, skin scraping, or clinical laboratory evaluation (CBC, biochemical profile, thyroid testing).

Microbiologic Tests

Cytologic Examination

After the otoscopic examination, otic exudate should be collected for cytologic evaluation using a cotton swab. Specimens should be collected from each external ear canal because the organisms may differ between ears and a separate, clean otoscopic cone should be used for each ear to prevent cross-contamination. It is also important to soak otoscopic cones for 20 minutes before their use, in either 2% chlorhexidine gluconate or a dual quaternary ammonium compound (Cetylcide-II).[74] If otoscopic cones are to be stored in a solution, the optimum solution is glutaraldehyde (Cetylcide-G) (glutaraldehyde).[75]

The material obtained is rolled onto a microscope slide, which is heat fixed, then stained with a Romanowsky-type stain (Wright stain, Giemsa stain, Diff-Quik) or Gram stain. After staining, the slides should be rinsed and allowed to dry. If there is a possibility of the patient having aural mites, a second specimen should be obtained from each ear. The cotton tip should be rolled into a drop of mineral oil on a slide, a cover-slip placed on top of the slide, and examined for *Otodectes* or *Demodex* mites.

Once the slide for cytologic evaluation is dry, it should be viewed microscopically. The slide is first scanned with the low power lens (10× objective; 100× magnification) to find keratinized squamous epithelial cells or inflammatory cells, which are typically associated with infectious agents. Once these are located, they should be examined under oil immersion (100× objective; 1000× magnification). Smears should be evaluated for the number and morphology of bacteria, the number of yeast, the number and type of leukocytes, the presence of excessive cerumen, the presence of excessive keratinized squamous epithelial cells, and the presence of neoplastic cells. Ten fields under oil immersion should be evaluated, allowing estimation of the number of organisms and leukocytes in those 10 fields. For consistency, a grading system of the numbers of organisms and leukocytes counted should be developed. In one report, 2 or fewer yeast organisms per high-dry field (HDF, 40× objective, 400× magnification) in dogs and cats were within reference limits, whereas 5 or more yeast per HDF in dogs and 12 or more yeast in cats were abnormal.[76] Any rod bacteria detected cytologically should be considered abnormal. For coccoid bacteria, 5 or fewer per HDF in dogs and 4 or fewer per HDF in cats were within reference limits, whereas 25 or more per HDF in dogs and 15 or more per HDF in cats were considered of pathogenic significance. The intermediate values were considered suspect, and the decision to treat should be based on clinical signs as well as the results of cytology. Cytologic examination should be performed at the initial visit as well as at each recheck to monitor the response to therapy. Evaluation for mites should be conducted with the low power lens (10× objective; 100× magnification) with the condenser in the lowest position. Leukocytes should not be present on cytologic examination of otic specimens from healthy patients and only on occasion are identified from animals with ceruminous otitis; however, leukocytes may be abundant in purulent otic debris.

Culture and Susceptibility Testing

Bacterial culture and susceptibility testing are not needed at every visit. The purpose of performing bacterial culture and susceptibility testing is to identify the organism(s) present in the ear and to be used to guide the use of systemic (oral) antimicrobial therapy. Topical otic antimicrobial treatments may attain 100 to 1,000 times higher drug concentrations in the ear than can be attained in the plasma. This exposes the bacteria to very high concentrations of the antimicrobial agent, far exceeding the levels that may be attained with an orally administered antimicrobial agent. Therefore, susceptibility testing is not clinically useful for determining the appropriate topical otic antimicrobial agent. Some examples of indications to perform a bacterial culture are when rod-shaped bacteria are detected cytologically (to verify the organism is *P. aeruginosa*), when the patient is not responding to appropriate oral empiric therapy, or when otitis media is suspected (to identify an oral antibiotic for treatment).

Diagnostic Imaging

General anesthesia is required to perform diagnostic imaging procedures and is recommended to properly flush and clean the ears for examination of the deep canal if discomfort of the patient or occlusion of the canal have prevented adequate visualization. Anesthesia, rather than sedation, is also imperative for myringotomy because endotracheal intubation prevents any of the otic flush solutions that enter the auditory tube from reaching the nasopharynx and larynx. A general recommended order of procedure follows.

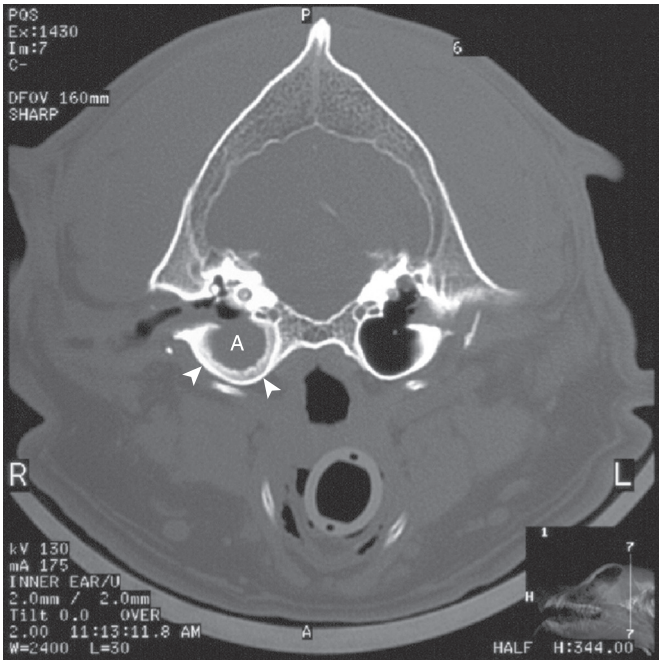

Fig. 119.9 A computed tomography scan of the tympanic bulla in a dog, which has a soft tissue density in the right bulla *(A)* with a significantly thickened wall *(arrowhead)*, a thickened right ear canal that is partially occluded, and a thickened left ear canal that is occluded. Tomographic diagnosis: Bilateral otitis externa, right-sided otitis media and bulla osteitis. *L,* left; *R,* right. (Courtesy of The Ohio State University, Columbus, OH.)

Once the patient is under anesthesia, radiographic imaging should be done first, because cleaning or flushing fluid in the ears can obscure structures that require visualization. Radiographic imaging (bulla radiographs, CT, MRI) is indicated when there is chronic otitis externa, or if neurologic signs (facial paralysis, Horner's syndrome, vestibular disturbances, deafness) are present, to determine the extent of involvement of the middle and inner ear. Radiographic changes indicative of middle ear disease include increased soft tissue opacity in the tympanic bulla, sclerosis and thickening of the tympanic bulla wall, sclerosis and bony proliferation of the petrous temporal bone, bone lysis of the bulla and petrous temporal bone, and increased soft tissue opacity within the tympanic bulla. However, normal radiographic imaging results do not rule out otitis media. With significant radiographic changes, such as sclerosis or lysis, surgical intervention (total ear canal ablation with bulla osteotomy or ventral bulla osteotomy) may be required for resolution. The most commonly used radiographic projections for examining the bullae include the dorsoventral, right and left lateral obliques, and rostroventral-caudodorsal open-mouth views. The rostroventral-caudodorsal open-mouth view is the most useful projection but the most difficult to obtain. It is valuable for comparing the thickness and opacity of the osseous bullae for asymmetry, which reflects chronic osteomyelitis. In cats, the rostro 10 degrees ventrocaudodorsal oblique view is easier to perform and as accurate as the rostroventral-caudodorsal open-mouth view.[77]

CT examination allows cross-sectional imaging of the external, middle, and internal parts of the ear and is used to better define bony structures. The overall accuracy and specificity of CT and conventional

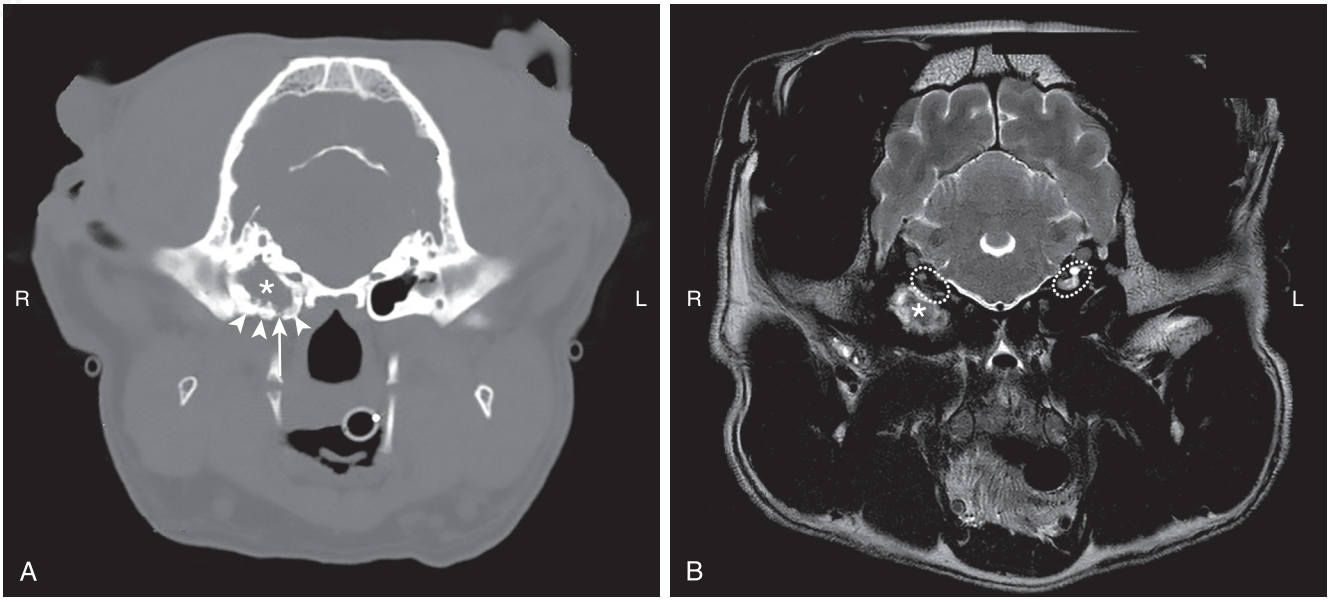

Fig. 119.10 (A) A computed tomography (CT) scan and (B) magnetic resonance imaging (MRI) scan of the tympanic bullae, inner ear, and brain in a 6-year-old male castrated French bulldog with a 2-week history of right-sided head tilt and facial paralysis. On the CT scan, there is soft tissue material completely occupying the right tympanic bulla *(asterisk)*. The right tympanic bulla is thickened, irregular *(arrowheads)*, with ill-defined areas of lysis *(arrow)*. On the MRI, the right tympanic bulla is filled with T2-weighted hyperintense material *(asterisk)*; the left bulla is unremarkable. There is lack of signal from the inner ear fluid of the right cochlea compared with the left *(dots outlining inner ear)*. Tomographic diagnosis CT scan: Right otitis media with tympanic bulla osteitis. Tomographic diagnosis MRI: Right otitis media and interna. Without the CT scan, the bulla osteitis diagnosis would have been missed while without the MRI, the diagnosis of the otitis interna would have been missed. *L,* left, *R,* right. (Courtesy of The Ohio State University, Columbus, OH.)

radiography for the diagnosis of otitis media are similar; however, CT is a more sensitive indicator of otitis media.[78,79] Both CT and conventional radiography are more accurate for predicting severity of otitis media, rather than its presence,[78] and the absence of radiographic evidence of otitis media does not rule it out. Evidence of otitis media on CT images include change in the bulla contour, presence of bony proliferation, or osteolysis of the bulla, with or without increased fluid or tissue within the bulla (Fig. 119.9). MRI and CT are complimentary modalities: MRI is superior to CT for detecting soft tissue changes, in the inner ear and brain, while CT is superior to MRI for detecting bony changes, such as in the bullae (Fig. 119.10A and B).

Ultrasound imaging of the canine tympanic bulla has been performed on healthy greyhounds[80]; cadaver dogs with gel or saline infused into their middle ears[81,82]; beagles with no evidence of middle ear disease in which saline was infused into their ear canals as well as the bulla via a myringotomy[83]; cadaver cats with lubricant infused into their ventral tympanic cavity via a needle through the bony septum[84]; Cavalier King Charles spaniels suspected of having PSOM[55]; and dogs with chronic otitis externa.[84] In dogs with chronic otitis externa, using CT results as the gold standard, a combination of conventional radiographic and ultrasonographic examinations provides a more accurate assessment of the bulla than either technique alone, but the accuracy of ultrasonographic results is operator dependent.[85] In the Cavalier King Charles spaniel, sensitivity and specificity of bulla ultrasonography is too low for accurate diagnosis of PSOM.[55] In cats, CT remains the gold standard for differentiating fluid from gas in the bulla; ultrasonography was slightly better than plain radiography.[84]

Positive-contrast ear canalography can be used to help evaluate the patency of the tympanic membrane. A 1:1 concentration of either iohexol or urografin and sterile saline is infused into the ear canals of an anesthetized dog, and pre- and postcontrast bullae radiographs are performed. The presence of the contrast medium in the bulla confirms a ruptured tympanic membrane; however, lack of contrast medium in the tympanic bulla does not rule it out. This procedure should always be the last imaging procedure, because it will obscure details of all the other methods.

Specimen Collection During Deep Ear Flushing and Cleaning

Knowledge of the anatomy of the middle ear is important to understand the relationship of the inner ear structures to the middle ear, in order to avoid damaging them during flushing or myringotomy. Possible complications of these procedures are Horner's syndrome, facial nerve paralysis, vestibular disturbances, and deafness. Owners should understand these complications and sign a consent form before the procedure.

The middle ear consists of an air-filled tympanic cavity, three auditory ossicles and their associated muscles and ligaments, and the tympanic membrane (Fig. 119.11). The round (cochlear) window is covered by a thin membrane that oscillates to dissipate the vibratory energy of the perilymph in the scala tympani (tympanic duct). The oval (vestibular) window lies above the round window adjacent to the pars flaccida. It is covered by a thin diaphragm to which the footplate of the stapes is attached. Movement of the stapes against the vestibular window is transmitted to the perilymph. When flushing the middle ear, one must be very careful to avoid damaging these windows, which in turn can damage the inner ear. The auditory tube equalizes pressure on both sides of the tympanic membrane. The tympanic cavity consists of a small epitympanic recess, a large ventral cavity, and the tympanic cavity proper. In dogs, there is an elliptical opening in the dorsal wall of the ventral cavity (the bulla septum), which

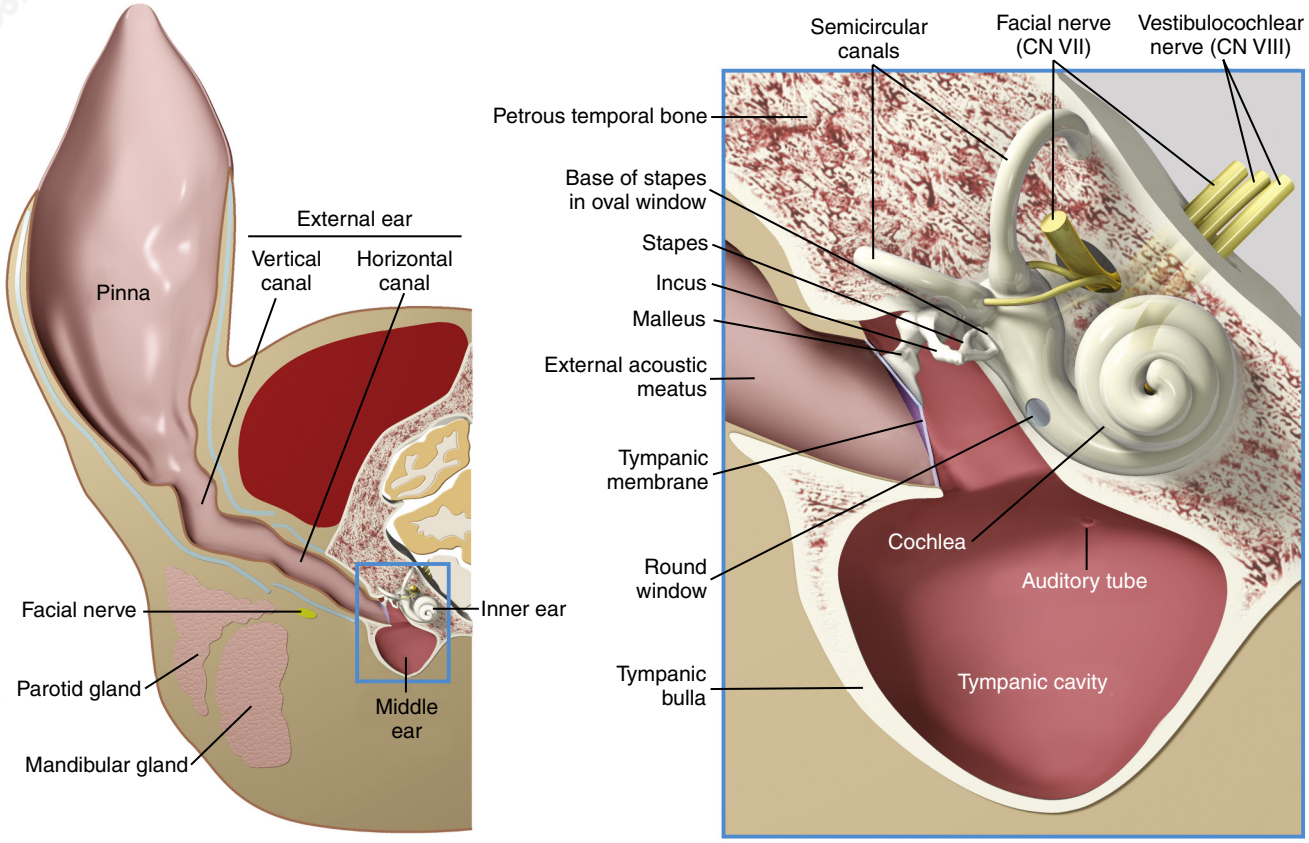

Fig. 119.11 Structures of the external, middle, and inner ear of the dog. (Courtesy of The Ohio State University, Columbus, OH.)

communicates with the tympanic cavity proper. Therefore, in dogs, both compartments of the bulla can be flushed. The middle ear cavity of cats is divided by a septum into two separate cavities. In the small dorsolateral compartment lie the auditory ossicles, the ostium of the auditory tube, and the tympanic membrane. The larger ventromedial compartment is the air-filled tympanic bulla. In order to remove exudate or a mass from the ventromedial compartment, the bony septum needs to be perforated and thus can only be accessed surgically. Rough handling of the septum may result in damage to the postganglionic sympathetic nerves, resulting in Horner's syndrome.

Deep ear flushing is best done under general anesthesia to completely clean and evaluate the ear and tympanic membrane. Indications for deep flushing are chronic, recurrent otitis externa; persistence of exudate in the external canals despite at-home cleaning; lack of response to medical management; and the presence of concurrent neurologic deficits that suggest middle or inner ear disease. First, the external ear canal is soaked for 10 minutes with a non-ototoxic ceruminolytic ear cleaner. Cerumene (Vetoquinol, Buena, NJ) is recommended, because unlike most ceruminolytic agents, it is non-ototoxic. The ear is then flushed with warm sterile isotonic saline and a bulb syringe used to remove large debris and exudate. This is followed by flushing with saline using a 12-mL syringe attached to an 8F polypropylene catheter passed through an otoscopic cone. Additional ear cleaning is performed using a video otoscope with an external flushing unit, if available.

The tympanic membrane can then be visualized. If the tympanic membrane is not intact, then the patient most likely has otitis media, and additional specimens should be obtained from the middle ear cavity. If a handheld otoscope is being used, this can be done by inserting a small sterile otoscopic cone into the horizontal ear canal and passing a sterile swab into the middle ear cavity. The first swab is used for bacterial culture and susceptibility testing. A second swab is used to collect a specimen for cytologic analysis. If a video otoscope is used, an open-end 3.5F diameter "Tomcat" catheter or 5F catheter attached to a 12-mL syringe is placed through the otoscope port. Sterile saline (1 mL) is flushed into the middle ear cavity and aspirated back for cytologic evaluation, and this process is repeated to obtain a specimen for culture. After this, the middle ear can be cleaned by flushing repeatedly with a 12-mL syringe containing 1 mL of warm sterile isotonic saline through the catheter placed in the middle ear. This procedure is repeated until the aspirated saline is clear.

Once the ear canal has been cleaned, any masses noted in the vertical ear canal, horizontal ear canal, or middle ear should be biopsied using biopsy forceps and submitted for histopathology. The biopsy should be the last procedure performed, because blood from the biopsy site may obscure visualization of more proximal structures in the ear. Foreign bodies can also be visualized and removed using forceps.

Myringotomy for Specimen Collection. If the tympanic membrane is intact but the pars tensa appears abnormal, or if otitis media was diagnosed on imaging, a myringotomy is needed to obtain diagnostic specimens and to flush the middle ear cavity. An intact tympanic membrane does not rule out otitis media. Using a handheld otoscope, the cone is inserted into the horizontal ear canal and the tympanic membrane visualized. Using a small sterile swab passed through the otoscope, a perforation is made into the caudoventral quadrant of the tympanic membrane (the pars tensa). The swab is then removed and retained for culture. A second swab is inserted into the original incision for cytologic analysis. If a video otoscope is used, one of the catheters described above for flushing is placed through the otoscope port, and used to perforate the caudoventral quadrant of the pars tensa (Fig. 119.12). Sterile saline (1 mL) is flushed into the middle ear cavity and aspirated back using a 12-mL syringe. The first specimen is used for culture and the second for cytologic evaluation. Thereafter, the middle ear is flushed as described above. Provided the ear is kept free of infection after myringotomy, the tympanic membrane should heal in 21 to 35 days.

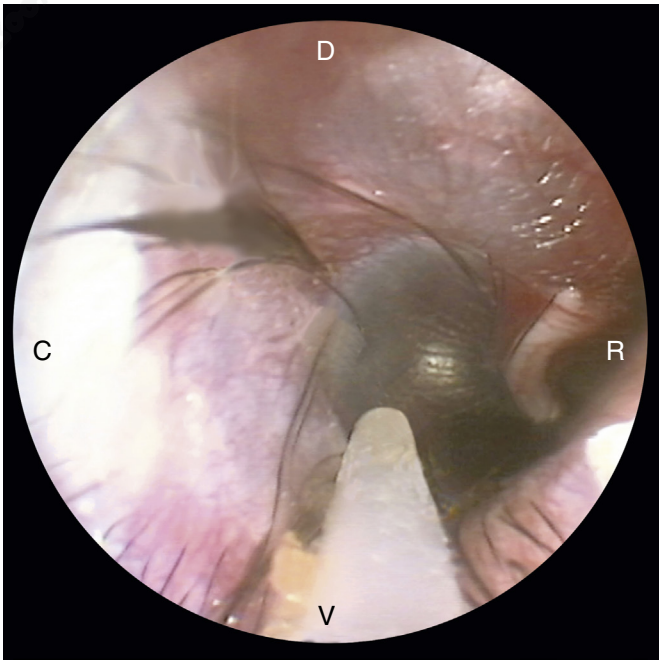

Fig. 119.12 Proper site for performing a myringotomy, right tympanic membrane. The caudoventral quadrant of the pars tensa is approached with a tomcat catheter. *C,* caudal; *D,* dorsal; *R,* rostral; *V,* ventral. (From Cole LK. Otoscopic evaluation of the ear canal. *Vet Clin North Am Small Anim Pract.* 2004;34:397–410.)

Flushing the middle ear with saline does not eliminate all bacteria from the tympanic cavity in dogs with otitis media.[86] However, when middle ear flushing was combined with at-home treatment, the otitis media resolved in 36 of 44 dogs, with a mean time to resolution of 117 days (range 30 to 360 days). At-home treatment included otic cleaners and antimicrobial agents (40 dogs treated with both topical and systemic antimicrobial agents and 4 treated with topical agents only).[87]

TREATMENT

The most common treatment for infectious otitis externa are cleaning and drying agents and combination antimicrobial/anti-inflammatory topical therapies. In severe cases, the epithelium in addition to the lumen of the vertical ear canal is infected,[50] and oral antimicrobial agents are indicated as well. The probability of successful management of the ear disease without topical therapy is low. Furthermore, when inflammation and associated ear pain is severe, a short course of systemic glucocorticoids is indicated in addition to topical therapies. For parasitic otitis externa, such as ear mites, topical or systemic therapies are used.

The goals of medical management of otitis media are to reduce inflammation and resolve infection. As for otitis externa, topical therapy is recommended and may include ear cleaning and drying agents, glucocorticoids, antibacterials, and antifungals. Systemic antibacterials and antifungals are indicated in patients with otitis media. The selection of systemic antibacterial agents should be made based on culture and susceptibility results from the middle ear. However, therapy may be initiated based on cytologic results while awaiting the culture results.

Cleansing Agents (Table 119.2)

Topical cleaning agents are divided into *ceruminolytic agents* and *cleansing and drying agents*. Ceruminolytic agents remove ceruminous and purulent exudate from the external ear canal during ear flushing. They may also be sent home with the owner if the tympanic membrane is intact. These agents work by surfactant, detergent, or effervescent activity. They are contraindicated with a ruptured tympanic membrane, because many are ototoxic, with the exception of the squalene-containing ceruminolytic Cerumene (Vetoquinol, Buena, NJ). Water-miscible preparations containing dioctyl sodium sulfosuccinate or propylene glycol are well tolerated. Oils, such as squalene or mineral oil, are effective but messy. Products containing urea peroxide are very potent and recommended for in-hospital use only.

Once the ear has been flushed with the ceruminolytic, at-home cleaning is done with a topical cleaning and drying agent in order to minimize exudate accumulation. Most products contain acids, some in combination with isopropyl alcohol, to dry the ear canal and discourage overgrowth of bacterial and yeast organisms. These products may also be used after swimming or bathing to prevent "swimmer's ear." Cleansing and drying agents are also used before topical antimicrobial agents for treatment of infectious otitis externa.

In vitro antimicrobial efficacy has been demonstrated for EpiOtic Advanced (Virbac Corporation, Fort Worth, TX), MalAcetic Otic (Dechra Veterinary Products, Overland Park, KS), and TrizCHLOR Flush (Tromethamine [Tris], EDTA, chlorhexidine 0.15%, Dechra Veterinary Products). Antimicrobial activity has been demonstrated for EpiOtic Advanced in dogs with bacterial- and yeast-related otitis externa, whereas MalAcetic Otic has benefit for dogs with yeast-related otitis externa. In some cases, use of these products for cleaning and drying alone may be sufficient to treat infection.

Application of Ear Cleaners

In some cases of otitis, the exudate in the ear canal can be kept to a minimum with routine at-home cleaning. The frequency of ear cleaner application depends on the chronicity of the otitis externa, the severity of the infection, and the amount of exudate in the ear canal. The goal is to begin treatment with the most frequent application (e.g., daily) and over time, decrease to a maintenance frequency (e.g., weekly). It is important to explain proper cleaning technique to the owner, and in some cases demonstrate the technique. The owner should fill the ear with the cleaner, gently massage the ear, let the animal shake its head, then gently wipe the opening of the vertical ear canal with a cotton ball or gauze sponge. The use of cotton-tipped applicators to clean the ear should be discouraged, because it can cause trauma to an already inflamed ear, induce ulcerations in the ear canal, or push exudate further down the ear canal. In some cases when at-home cleaning is ineffective or there is too much exudate in the ear canal, in-hospital deep ear flushing is the best option for cleaning the ear (see Deep Ear Flushing and Cleaning earlier).

Topical Glucocorticoid Therapy

Glucocorticoids are antipruritic, anti-inflammatory, and antiproliferative. During acute otitis, the ear canal becomes edematous and erythematous. As the inflammation progresses, the dermis becomes infiltrated with inflammatory cells. Apocrine glands dilate and become hyperplastic, which leads to excessive cerumen production. Glucocorticoids decrease both inflammation and sebaceous and apocrine secretions. Therefore, they decrease the pain, pruritus, stenosis, and edema associated with otitis. They are usually used in combination with other agents, but may be beneficial when used alone in treatment of allergic animals with otitis and in some animals with ceruminous otitis. To prevent iatrogenic hyperadrenocorticism, the lowest potency glucocorticoid at the lowest frequency needed to control otitis, should be used. Cort/Astrin Solution (Vedco, St. Joseph, MO) contains a low-potency topical glucocorticoid (1% hydrocortisone) in addition to a drying solution (Burrow's solution) in a water-miscible propylene glycol base. A more potent product is Synotic Otic Solution (Zoetis, Inc., Parsippany, NJ, USA), which contains 0.01% fluocinolone acetonide and 60% dimethyl sulfoxide (DMSO). DMSO is anti-inflammatory and facilitates the absorption of fluocinolone into the epidermis and dermis. This product is very effective in the management of proliferative otitis.

TABLE 119.2 Topical Otic Ceruminolytic and Cleaning and Drying Agents

Ceruminolytic Agents

Name (Company)	Ingredients
Cerumene (Vetoquinol)	25% squalene in isopropyl myristate liquid petrolatum base
Douxo Micellar Solution (Ceva)	Phytosphingosine, nonionic surface-acting agent, polidocanol, polysaccharides, light fragrance
KlearOtic (Dechra)	22% squalene
pHnotix Ear Cleaner and Wax Remover (Vetoquinol)	Calendula, capryloyl glycine, glycerin, isopropyl alcohol, labrasol, lemon synthetic perfume, polysorbate 80, transcutol V, tromethamine, undecylenoyl glycine
Milytic Otic Ear Cleanser (VetBiotek)	Micellar solution (PEG-6 caprylic/capric glycerides, polysorbate 80, disodium EDTA, cetrimonium bromide), methylchloroisothiazolinone, methylisothiazolinone, fragrance, N-octadecanoylphytosphingosine
Dermoscent PYOclean Oto (Animal Dermocare)	Lipoaminoacids, honey and propolis, essential oil of red myrtle, N-acetylcysteine

Cleaning/Drying Agents

Name (Company)	Ingredients
DermaPet Malacetic Otic (Dechra)	Acetic acid, boric acid, surfactants
Epi-Otic Advanced (Virbac)	Salicylic acid 0.2%, disodium EDTA, docusate sodium, PCMX, a monosaccharide complex (l-rhamnose, d-galactose, d-mannose)
Ear Cleansing Solution (Vetoquinol)	Denatured alcohol 10%, lactic acid 1.76%
Nolvasan Otic (Zoetis)	Special solvent, surfactant
Oti-Clens (Zoetis)	Purified water USP, propylene glycol, malic acid, menthol/citronella fragrance, benzoic acid, salicylic acid, simethicone
OtoCetic Solution (Vedco)	2% boric acid, 2% acetic acid, surfactants

TABLE 119.3 Otic Topical Medications

Medication	Use/Infectious Agents	Active Ingredients	Vehicle
Baytril Otic Emulsion (Elanco)	Chronic otitis/bacterial (rods/cocci)	Enrofloxacin 0.5%, silver sulfadiazine 1%	Emulsion
Claro Otic Solution (Elanco)	Acute otitis/bacterial (cocci)/yeast	Florfenicol, terbinafine, mometasone furoate	Solution
EasOtic (Virbac) Otic Suspension	Acute otitis/bacterial (cocci/rods), yeast	Gentamicin sulfate, miconazole nitrate, hydrocortisone aceponate	Suspension
GenOne Otic Solution (VetOne)	Acute otitis/bacterial (cocci/rods)	Gentamicin sulfate, betamethasone valerate	Solution
Miconazole 1% lotion (generics)	Acute otitis or chronic otitis/yeast	Miconazole	Lotion
Mometamax Otic Suspension (Merck Animal Health)	Acute otitis/bacterial (cocci/rods), yeast	Gentamicin sulfate, clotrimazole, mometasone furoate monohydrate	Suspension
Osurnia Otic Gel (Dechra)	Acute otitis/bacterial (cocci)/yeast	Florfenicol, terbinafine, betamethasone acetate	Gel
Otomax Ointment (Merck Animal Health)	Acute otitis/bacterial (cocci/rods), yeast	Gentamicin sulfate, clotrimazole, betamethasone valerate	Ointment
Posatex Otic Suspension (Merck Animal Health)	Chronic otitis/bacterial (cocci/rods), yeast	Orbifloxacin, posaconazole, mometasone furoate monohydrate	Suspension
Surolan Otic Suspension (Vetoquinol)	Chronic otitis/bacterial (cocci/rods), yeast	Polymyxin B sulfate, miconazole, prednisolone acetate	Suspension
Tresaderm Dermatologic Solution (Boehringer Ingelheim)	Acute otitis/bacterial (cocci/rods), yeast	Neomycin sulfate, thiabendazole, dexamethasone	Solution
Tritop Ointment (Zoetis)	Acute otitis/bacterial (cocci/rods) I don't think any component of Tritop is anti-yeast	Neomycin sulfate, isoflupredone acetate, tetracaine hydrochloride	Ointment

Topical Antimicrobial Therapy

Topical antimicrobial therapy is indicated in all cases of otitis externa (Table 119.3). Commercially available topical preparations usually contain various combinations of glucocorticoids, antibacterials, and/or antifungals in a vehicle base. Selection of the active ingredient of the topical product should be based on cytology results. The patient's progress while on these medications should be monitored cytologically at each re-evaluation and the topical therapy adjusted accordingly. Most topical otic treatments are administered twice daily, and the volume administered should reflect the size of the animal's ear canal, ranging from a few drops in very small dogs and cats to up to 1 mL in large-breed dogs. Topical antiseptics such as acetic acid and chlorhexidine have also been used to treat otitis externa. However, these products are usually used in addition to topical antimicrobials.

Most cases of acute bacterial otitis externa, whether due to gram-positive or gram-negative organisms (even *P. aeruginosa*), respond to aminoglycosides (e.g., neomycin, gentamicin). Antifungal agents are used in cases of acute or chronic otitis externa caused by *Malassezia* spp. or *Candida* spp. Ingredients that are active against yeast include nystatin, miconazole, ketoconazole, posaconazole, terbinafine, and clotrimazole. Furthermore,

animals with acute otitis externa usually have clinical improvement after a short course of topical antimicrobial agents, such as a "triple" combination product (antibacterial, antifungal, glucocorticoid), either in an ointment vehicle (e.g., Otomax, Merck Animal Health, Madison, NJ) or solution vehicle (e.g., Tresaderm, Boehringer Ingelheim, Duluth, GA). Newer FDA-approved topical antimicrobials (e.g., Claro Otic Solution, Elanco Animal Health and Osurnia Otic gel, Dechra) which are administered in the clinic may be preferred, as the client does not have to treat the ears at home and these products are efficacious for 30 to 45 days, respectively. Unlike lanolin otic packs, these products coat the ear canal, and do not "pack" the ear and cause temporary conductive hearing loss.

Chronic or recurrent otitis externa does not respond as well to products that contain an ointment or suspension vehicle, possibly because it is difficult for an ointment or suspension to penetrate the stenotic and hyperplastic ear canals. Products containing a solution, emulsion, gel, or lotion vehicle are preferred.

Chronic infections due to *P. aeruginosa* are one of the most challenging otic diseases to treat because of *P. aeruginosa*'s high level of resistance to antimicrobial agents. Antibacterial treatments for acute otitis externa are usually not effective, and the next line of topical antimicrobial agents is needed, which includes enrofloxacin, orbifloxacin, silver sulfadiazine, and polymyxin B. Presoaking the ear canals for 15 minutes with a tromethamine EDTA (Tris-EDTA) product before application of the topical otic agent is recommended. Cell surfaces of gram-negative bacteria are damaged by exposure to EDTA, whereas tromethamine (Tris) enhances the antibacterial effect of EDTA.

None of the commercially available otic topical treatments or any extra-label otic preparations are labeled for use with a perforated tympanic membrane. However, some of these products have been used to treat otic infections in dogs with otitis media.

Ototoxicity and Topical Otic Treatments

It is the author's (LKC) opinion that the use of ointment- or suspension-based otic topical agents or otic packs in ears with a perforated tympanic membrane should be avoided. Owners should always be warned of the possibility of neurologic signs following administration of topical medications when the tympanic membrane is damaged.

Numerous compounds and classes of compounds of drugs can be ototoxic, including antibiotics (e.g., aminoglycosides), loop diuretics, antiseptics (e.g., chlorhexidine), antineoplastic agents, and miscellaneous agents (e.g., ceruminolytic agents). Toxicity may result from parenteral or topical applications. In veterinary medicine, topical otic use of aminoglycosides, chlorhexidine, and ceruminolytic agents is common. Few studies have been published evaluating ototoxicity of topically administered agents. Topical aminoglycosides and topical chlorhexidine are ototoxic in humans as well as in cats. However, treatment of healthy greyhounds with experimentally ruptured tympanic membranes with topical gentamicin sulfate[88] or topical 0.2% chlorhexidine[89] for 21 days failed to induce clinical vestibular or brainstem auditory evoked potential changes. Another study evaluated the ototoxicity of four ceruminolytic agents instilled into the middle ears of 24 dogs: these each contained dioctyl sodium sulfosuccinate; carbamide peroxide; triethanolamine; and squalene, respectively. Only the product that contained 25% squalene (Cerumene) did not cause morphologic and/or histologic changes in the majority of bulla at necropsy on day 29.[90] Results of a study determined that a Tris-EDTA and polyhexamethylene biguanide solution was not ototoxic when applied daily to dogs' ears for 21 and 14 days, with an intact and experimentally ruptured tympanic membrane, respectively.[91]

Systemic Glucocorticoid Therapy

When severe chronic changes to the ear canal exist, treatment with systemic glucocorticoids for an initial period of 2 to 3 weeks, with re-evaluation at the end of the treatment period, is recommended. Dose and frequency should be adjusted depending on the severity of the otitis. For mild otitis externa in dogs, prednisone or prednisolone (0.5 mg/kg, PO, q24h for 7 days) can be used. Dose frequency is then decreased to every other day. For more chronic changes, 1 mg/kg, q24h is used; for severe disease, 2 mg/kg, q24h, for 3 days is used, and then the dose is decreased to 1 mg/kg, q24h. Although rarely needed, prednisolone or dexamethasone can be used in cats.

Systemic Antimicrobial Therapy (see Table 119.1)

In most cases of otitis externa, topical antimicrobial treatment is sufficient. However, in severe cases, deep infection of ear tissue is present, and both topical and systemic therapy is necessary. Although every attempt should be made to treat topically, some owners are not able to administer topical medications properly, in which case systemic antimicrobial therapy may be required. Oral antibacterial selection is the same for otitis media as for otitis externa and should be based on culture and susceptibility results (see Table 119.1).

While awaiting culture results, empiric treatment for otitis may be initiated based on the cytologic results. Good empiric oral antimicrobial choices if cocci are seen include amoxicillin-clavulanic acid or cephalexin. Poor choices would be penicillin, ampicillin, and amoxicillin.

If rods are detected cytologically, *P. aeruginosa* should be suspected. Fluoroquinolones are appropriate choices, with reported susceptibilities of *P. aeruginosa* isolates from ears of 75%, 66.7%, and 46.9% for ciprofloxacin, marbofloxacin, and enrofloxacin, respectively.[92,93] However, variable absorption has been reported for ciprofloxacin in dogs, so the use of this oral antibiotic in some patients could result in treatment failure.[94]

If the bacterial culture and susceptibility data indicate intermediate susceptibility or resistance to the chosen antimicrobial agent, the oral drug should be discontinued. Another drug to which the bacteria are susceptible should be started, if one exists. As noted above, MICs are irrelevant for topical drugs because of the high concentrations reached. In the case of MDR *P. aeruginosa* or other bacteria, the only option is topical therapy alone to treat the infection.

In most cases of *M. pachydermatis* otitis externa, systemic therapy is not indicated. However, for severe yeast otitis externa, an oral antifungal agent (usually an azole or terbinafine) may be administered in addition to a topical antifungal medication (see Chapters 11 and 79).

Surgical Therapy

Animals that fail to respond to medical management of otitis media are candidates for surgical intervention. In dogs with end-stage otitis externa, the surgery of choice is total ear canal ablation with *lateral* bulla osteotomy (TECABO) and bulla curettage. This procedure removes the infected ear canal tissues as well as a portion of the ventrolateral wall of the osseous bulla to aid in complete removal of debris and epithelium within the tympanic cavity. Bacterial cultures should be obtained from the tissue (mucosa) and exudate from the tympanic bulla during this procedure. This procedure has a potential for numerous postoperative complications; however, they are usually short-lived and resolve with medical treatment. Recurrent infectious otitis media occurs in approximately 10% of dogs after TECABO. Because these recurrences rarely respond to systemic antibacterial treatment alone, a second surgical procedure (*ventral* bulla osteotomy and curettage) may be required to resolve the otitis media.[95]

Inflammatory polyps in the cat are usually treated surgically via a ventral bulla osteotomy. However, if the inflammatory polyp is in the nasopharyngeal region only, traction, plus postoperative prednisolone at anti-inflammatory dosages, is an effective alternative to surgery.[92] Inflammatory polyps in the dog are uncommon and have been successfully treated by either a ventral bulla osteotomy or TECABO.[60]

PROGNOSIS

The prognosis for infectious otitis externa is good for cases that are acute, those without progressive pathologic changes to the ear canal

(stenosis, hyperplasia), those without concurrent otitis media, and those for which the underlying primary disease has been diagnosed and controlled. Chronic otitis media may occur if infection does not completely resolve. Rarely, an aural cholesteatoma (epithelial-lined cavity) will develop in the middle ear secondary to chronic otitis media. Should these complications develop, and if the ear becomes calcified, the prognosis for medical management is poor, and surgical intervention is required for resolution. Intracranial sepsis is a rare complication of bacterial otitis media/interna, but may have grave consequences if it is not diagnosed and treated promptly.[96]

CASE EXAMPLE

Signalment
"Colonel", a 3-year-old golden retriever living in the Central Valley of California.

History
The dog was evaluated for a history of pruritus for approximately 2 months. Pruritus was first noted on the ventral abdomen, but had since spread to the axilla and on the ventral neck. The dog was on flea control (afoxolaner monthly), as was the cat in the household (selamectin monthly). A plant awn had been removed from between the 3rd and 4th digits of the left pelvic limb paw 1 month previously, for which the dog received ampicillin PO for 10 days.

Physical Examination
Multiple epidermal collarettes and erythema were found on the entire ventrum and ventral neck. There was interdigital erythema, especially on the thoracic limbs.

Cytology Findings
Deep skin scraping: No evidence of *Demodex* spp.
Multiple superficial scrapings: No evidence of *Sarcoptes scabei* (in addition, treatment with afoxolaner made mite infestation unlikely).
Acetate tape preparations (inguinal, axillary and ventral neck areas): many neutrophils with numerous intracellular and extracellular cocci.

Microbiologic Findings
Aerobic bacterial culture (epidermal collarette; done because of the recent exposure to antimicrobial drugs): *Staphylococcus pseudintermedius*, resistant to ampicillin but otherwise broadly susceptible, including to cephalexin.

Diagnosis
Superficial pyoderma.

Treatment
Cephalexin (30 mg/kg, PO, q12h) for 30 days.

Outcome
At a follow-up examination 2 weeks after starting cephalexin, pruritus had reduced by approximately 30%, along with reduction in erythema and the number of epidermal collarettes. Cytologic examination of tape preparations showed fewer neutrophils and cocci than at the initial visit. Follow-up at 30 days after starting treatment continued to show lessened erythema, epidermal collarettes, neutrophils, and cocci, but the pruritus persisted. Because of concern for an underlying allergy, a hypoallergenic diet trial using a prescription diet composed of proteins to which the dog had not been previously exposed was used. The owners were instructed to stop all other foods, and switched to a topical anti-flea product (afoxalaner is flavored with soy protein). Because there was still both cytologic and clinical evidence of the pyoderma, cephalexin was continued for another 30 days. After the second month of the cephalexin, the erythema, epidermal collarettes, and pyoderma had resolved, and cytologic examination of tape preparations revealed no abnormal findings. Cephalexin was discontinued. After another month of feeding the new diet, the dog remained apparently healthy. The original diet was reinstated, and after 5 days the pruritus returned.

Comments
This dog had a dietary allergy, which led to pruritus. Mechanical trauma from pruritus led to disruption of the cutaneous barrier, with secondary *S. pseudintermedius* pyoderma. This resolved with the cephalexin, and was apparently making a 30% contribution to the pruritus. After the owners re-commenced the prescription diet, they then tried adding various proteins for a week at a time. With this approach, a beef allergy was identified. The owner was instructed to avoid beef protein-based diets in the future. The afoxolaner was recommenced.

Abscesses and Cellulitis

Jane E. Sykes

KEY POINTS

- Abscesses and cellulitis occur in any tissue and are one of the most frequent conditions of cats.
- Anaerobes and *Pasteurella multocida* are most often isolated from abscesses when culture is performed.
- Many abscesses will heal following incision and drainage. Lavage with copious volumes of saline and surgical placement of a Penrose drain may also be indicated. For large abscesses or where there is evidence of cellulitis and systemic signs, treatment with antimicrobials for 5 to 10 days is recommended. A drug with activity against anaerobes and *Pasteurella* spp. is recommended, such as amoxicillin.
- In endemic regions, plague and tularemia should be considered as differential diagnoses for abscesses in dogs and cats with systemic illness, lymphadenomegaly, fever, and subcutaneous lesions because of their zoonotic significance. When lesions are in the inguinal region of cats, mycobacterial infections should be considered because routine surgical approaches to treatment have the potential to exacerbate disease.
- Testing for FeLV and FIV should be considered for cats with bite and fight wounds, with a follow-up test no earlier than 60 days later.

ETIOLOGY AND PATHOGENESIS

Abscesses, which are characterized by an accumulation of pus, can occur in any tissue. Subcutaneous abscesses are the most common bacterial infections of feline skin and probably the most common site of abscess formation in dogs and cats (Fig. 120.1). The following discussion focuses on feline cutaneous abscesses, although the principles of diagnosis and treatment are similar in any location. In general, abscesses are more commonly diagnosed in cats than in dogs, likely because of frequent fighting behavior and needle-like teeth and claws that facilitate inoculation of bacteria under the skin through a small wound. Feline skin is also elastic and readily seals over small contaminated puncture wounds, with accumulation of subcutaneous exudate. The size and extent of abscessation also depends on the overlying skin tension, amount of dead space, and gravitation of exudate below the point of penetration. Pus-filled cavities that form above a puncture site drain easily. Cavities that gravitate below the puncture site may repeatedly drain through the puncture site without complete resolution.

Because subcutaneous abscesses in cats usually result from bites and scratches, the most common organisms found within them are resident oral microflora (Table 120.1). Anaerobes are isolated from more than two-thirds of abscesses, and the most common facultative aerobe isolated is *Pasteurella multocida*. Chapter 75 includes a more detailed discussion of bacteria isolated from cat-bite wounds. Cats that sustain bite injuries are more likely to become infected with FIV and to a lesser extent FeLV.[1]

CLINICAL FEATURES

Clinical Signs and Physical Examination Findings

Cat-bite/fight abscesses are usually located around the limbs, head, dorsum, and base of the tail. Some cats have discernable cutaneous masses with few other signs of illness, whereas more extensive infection is associated with fever (103.6° F to 105.2° [39.7° C to 40.6°C]), anorexia, lethargy, and regional lymphadenomegaly. Pain is usually present at the site of infection, and obvious swelling or warmth may or may not be present. Mature abscesses that are at the point of rupture are usually tender with a soft, fluctuant central area. Erythema or discoloration is occasionally apparent. Drainage of purulent material occurs spontaneously or after surgical lancing. Foul-smelling, red-brown discharges occur, especially with tissue necrosis and anaerobic bacterial infection (Fig. 120.2). Systemic signs often resolve once the abscess ruptures, and the only evidence of infection may be matted hair at the site of drainage. Careful examination in the area of swelling usually reveals a small puncture wound covered by a crust. Recurrent abscesses at the same site suggest underlying osteomyelitis or neoplasia, poor surgical drainage, immunodeficiency (e.g., FeLV or FIV infection), antimicrobial resistance, or the presence of a foreign body. Abscesses associated with foreign bodies, underlying osteomyelitis, or certain fastidious organisms such as *Nocardia* or *Mycobacterium*, or fungi such as *Sporothrix schenckii* also tend to recur, persist, or spread in tissues. Abscesses in dogs and cats are often associated with noticeable regional lymphadenomegaly. Sometimes the overlying skin may become necrotic.

Additional clinical manifestations reflect possible involvement of other organs or tissues. Lameness or paralysis may be apparent with myositis, osteomyelitis, septic arthritis, or discospondylitis. Stiffness, lethargy, nuchal rigidity, or seizures can be seen with meningitis. Osteomyelitis may be manifested by chronic or recurrent draining fistulas that only temporarily respond to antibacterial drugs. Respiratory distress, dyspnea, and stridor are noted with pyothorax or abscesses that occur in the cervical region. Vestibular signs can be noted if otitis media or interna develops. Signs of bacteremia and systemic infection include malaise and fever or reflect those of another organ system of hematogenous localization.

Retrobulbar abscesses or cellulitis are associated with proptosis, decreased globe mobility, oculonasal discharge, chemosis, conjunctival congestion, protrusion of the third eyelid, pain while opening the mouth,

TABLE 120.1 Examples of Bacteria Isolated from Feline Abscesses[a]

Genus	Species Examples
Anaerobes	
Porphyromonas spp.	*gingivalis, tectum, heparinolyticus, salivosa, melaninogenicus, corrodens, fragilis, circumdentaria,* others
Fusobacterium spp.	*nucleatum, necrophorum, russii,* others
Prevotella spp.	
Peptostreptococcus spp.	*anaerobius*
Clostridium spp.	*perfringens, novyi, sordellii, septicum, chauvoei, tetani, villosum*
Cutibacterium (formerly *Propionibacterium*) spp.	*acnes*
Bifidobacterium spp.	
Eubacterium spp.	*lentum*
Facultative Aerobes	
Pasteurella spp.	*multocida*
Actinomyces spp.	*viscosus, odontolyticus*
Nocardia spp.	
Staphylococcus spp.	
Rhodococcus	*equi*
Enterobacterales	
Streptococcus spp.	
Enterococcus spp.	
Lactobacillus spp.	

[a]See references 5, 8, 10, 11, 15–21.

periocular swelling or discomfort, lethargy, weight loss, and fever. Corneal ulcers may develop from exposure keratitis or self-trauma associated with retrobulbar pain. In some cases, swelling and discoloration may be seen caudal to the maxillary molar teeth on opening the mouth.

DIAGNOSIS

Diagnosis of abscesses and cellulitis is usually based on the history and physical examination findings. The possibility of an abscess should also be considered in cats that develop acute or subacute fever of unknown origin before extensive and invasive diagnostic tests are performed. It should be considered in cats that are acutely anorexic and/or lame, even in the absence of a subcutaneous swelling, given that formation of visible abscesses may be delayed or hidden. In endemic regions, plague and tularemia should be on the differential diagnosis list in febrile cats with subcutaneous swellings, lymphadenopathy, and fever. Although much rarer than cat-bite abscesses, they have the potential to cause life-threatening infections in exposed humans. Atypical bacteria such as *Nocardia* spp., *Mycobacterium* spp., and fungal pathogens, especially *Sporothrix* spp. and *Cryptococcus* spp., should be considered should there be a lack of response to standard treatment. Mycobacterial infections should be high on the differential diagnosis list for subcutaneous lesions that occur in the inguinal region of cats. It is critical that these be considered early because attempts to drain these abscesses surgically as if they were routine bacterial infections have the potential to spread infection further in tissues and worsen disease.

Culture of typical abscess wounds is not generally indicated because surgical debridement with or without empiric antimicrobial therapy is often effective, anaerobes are difficult to culture, and aerobic and anaerobic culture adds significant expense for owners. In addition, unless there is evidence of systemic illness, laboratory findings on bloodwork usually do not reveal abnormalities that would change treatment. Testing for retroviruses is recommended for cats with an unknown retrovirus status. Because it can take several weeks for cats

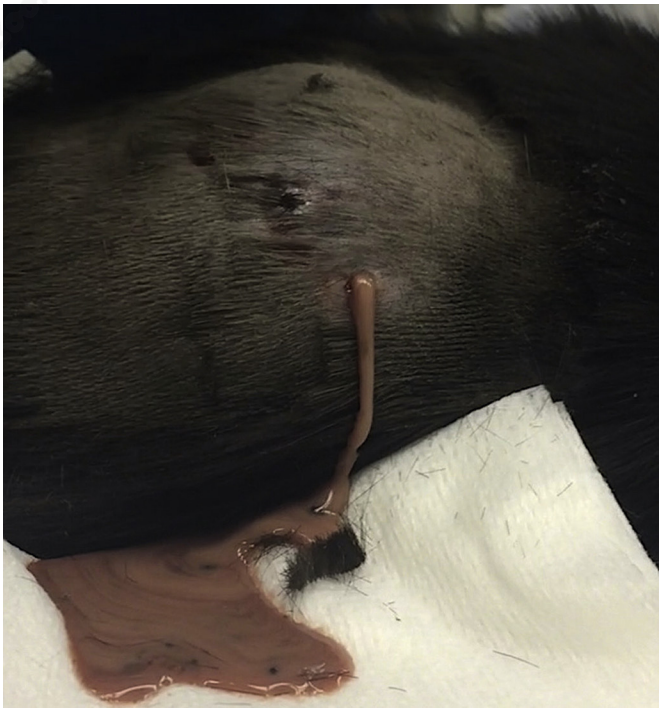

Fig. 120.2 Subcutaneous abscess in a domestic shorthair. Incision under sedation released a large amount of red-brown purulent fluid. Lavage of the abscess cavity, placement of a Penrose drain, and treatment with 5 to 7 days of oral amoxicillin with re-evaluation and removal of the drain at this time would be recommended for treatment. (Courtesy Dr. Steven Epstein, University of California, Davis Veterinary Emergency and Critical Care Service.)

to become FeLV antigen–positive or FIV antibody–positive after exposure, retesting is recommended 2 months after a cat is seen for a cat fight wound.[1]

Ultrasonography can be used to view the extent of a swelling, locate accumulations of fluid or pus in soft-tissue planes, and evaluate for foreign bodies, which are more common in dogs than in cats. Grass awns characteristically appear as double or triple spindle-shaped echogenic objects within soft tissues.[2,3] Minimally invasive ultrasound-guided retrieval of foreign material has also been helpful in avoiding standard surgical methods.[2,4] Instillation of radiographic contrast medium may be helpful in determining the extent or depth of a draining fistulous tract if a foreign body is likely, although improvements in ultrasound image quality have reduced the requirement for such procedures. Use of ultrasound guidance to inject methylene blue dye around a plant awn can facilitate identification and removal of awns during surgery.

Chronic or recurrent draining abscesses should be evaluated by radiography for underlying osteomyelitis, by cytology and culture for possible fungal or atypical bacterial infection, or by surgical exploration for the presence of a foreign body or fly larva.

TREATMENT

Abscesses vary in severity and in the extent of therapeutic intervention required. Small, localized abscesses that drain spontaneously by the time animals are examined require that the hair around the wound be clipped, and the margins of the wound be cleaned. Should abscesses not be open, incision and drainage (IAD) may be needed under sedation or general anesthesia. The abscess cavity should then be lavaged with copious amounts of normal saline (500 mL–1 L) or a dilute antiseptic such as 0.05% chlorhexidine or 0.1% povidone iodine. Consideration should be given to the use of normal saline. There is no evidence that antiseptics improve outcome; they have the potential to damage tissue, and severe nosocomial infections have been reported in association with use of antiseptic solutions that become contaminated with antiseptic-resistant bacteria such as *Pseudomonas* spp.. In one report, five cats developed *Burkholderia cepacia* complex (formerly *Pseudomonas cepacia*) skin infections and the organism was isolated from a 2% chlorhexidine scrub solution in the clinic; two cats developed sepsis and died.[5] More extensive infections that cause signs of systemic illness may require parenteral antibacterial administration, surgical drainage, or supportive care with hospitalization and intravenous fluid administration. Considerable variability in the approach to treatment of cutaneous abscesses has been observed in human medicine.[6]

Antibacterial Therapy

Antibacterial therapy has a decided but not absolute role in the management of abscesses in cats. Although mortality and complications resulting from abscesses have been reduced with the use of antibacterials, these agents should not be given indiscriminately or in the absence of other adjunctive measures. Antibacterials alone are ineffective in penetrating walled-off abscesses that require drainage. Indiscriminate antimicrobial use may also select for drug-resistant bacteria or cause drug reactions.[7]

Although antimicrobials are often routinely used in veterinary practice for cat-bite abscesses, drainage and lavage may be sufficient to resolve the abscesses in many cases. In human medicine, antimicrobials are only considered necessary when there are systemic signs of infection, comorbidities such as immunosuppressive illnesses and diabetes mellitus, or if there is extensive (> 5 cm in humans) surrounding cellulitis.[8] No difference in outcome was identified when humans with uncomplicated subcutaneous abscesses were treated with drainage with or without antimicrobials.[9] If antimicrobials are used, they should be given for a short duration (e.g., 5 to 7 days). Penicillin derivatives such as amoxicillin are antibacterials of choice for treating abscesses because they are active against *Pasteurella* spp. and anaerobes; addition of clavulanic acid is generally not necessary, adds expense, and is more likely to cause GI adverse effects (Table 120.2). Other antimicrobials likely to be effective are clindamycin and metronidazole, but these are less well tolerated by cats. Although effective against pathogens found in cat-bite abscesses,[10-12] widespread use of third-generation cephalosporins (e.g., cefovecin, cefpodoxime) and pradofloxacin has raised concerns about selection for resistant bacterial populations.[13] Cefovecin is widely used because it requires only a single injection, and one study from Australia showed that the most common reason for administration of cefovecin in cats was cat fight injuries and abscesses.[13] In another study of 4.4 million veterinary visit records from Australia, cefovecin and clavulanic acid-amoxicillin were the most common antimicrobials prescribed for dogs and cats.[14] Although convenient, because of concerns about resistance, cefovecin and pradofloxacin should only be used for treatment of cat-bite abscesses when there is a need for antibiotics and oral amoxicillin is not tolerated. In general, systemic antibacterial therapy may be beneficial in minimizing abscess formation when given immediately after bite wound contamination in order to prevent abscess formation or with diffuse cellulitis (see also Chapter 75). Antimicrobial treatment of abscesses in cats should also be considered when there are systemic signs of illness and lesions are large. Without surgical drainage, medical therapy could be continued for 7 to 10 days.

Surgery

Diffuse cellulitis or early abscesses may need to be monitored for accumulation of pus before surgical drainage is performed. Applying warm compresses daily may hasten this process. Surgical therapy usually

TABLE 120.2 Antimicrobial Drugs for Treatment of Skin and Soft Tissue Infections in Cats

Drug	Dose	Route	Interval (Hours)	Duration (Days)
Ampicillin, amoxicillin	20 mg/kg	PO, IV	12	5–7
Cefadroxil	22 mg/kg	PO	12	5–7
Cefovecin	8 mg/kg	SC	once	NA
Clindamycin	10 mg/kg	PO, IM	12	5–7
Metronidazole	10 mg/kg	PO, IV	8–12	5–7
Pradofloxacin	7.5 mg/kg	PO	24	7

involves creating drainage openings at the most ventral portion of an abscess cavity. Controversy exists as to the degree and type of surgical closure indicated. The abscess cavity can be debrided and a small portion of overlying skin removed to prevent premature closure. Placement of a Penrose drain that exits at the lowest point of incision with partial closure can also be used to maintain a drainage opening. The drain should only have a ventral exit through a new stab incision; the proximal aspect of the drain should be placed in the dorsal aspect of the wound and can be secured to the skin in this location with a mattress suture. The drain should be removed within 3 to 5 days when drainage becomes serosanguineous or decreases in volume.

Surgical drainage must be established whenever abscess formation occurs within closed cavities. Retrobulbar abscesses can be drained by passing a probe from immediately behind the last upper molar upward into the retrobulbar space. Infraorbital abscesses are usually associated with infection of the upper carnassial tooth, which must be extracted. Abscesses of the middle ear also require surgical drainage with debridement of bone because of the loculation of pus within cavities surrounded by bone. Abscesses associated with underlying osteomyelitis must be treated by surgical debridement of infected bone. Foreign bodies or material must be removed from abscess cavities before they heal.

Castration and indoor housing are recommended as a preventive measure to abscess formation because they reduce the fighting and roaming behavior of male cats.

Osteomyelitis, Discospondylitis, and Infectious Arthritis

Jane E. Sykes, Amy S. Kapatkin

KEY POINTS

- Causes: The most common causes of osteomyelitis and infectious monoarthritis in dogs are *Staphylococcus* spp., but streptococci, other gram-negative bacteria, anaerobes, and fungi may be involved. *Bartonella, Nocardia,* and *Mycobacterium* can also cause osteomyelitis. *Brucella* can cause osteomyelitis and discospondylitis. Polyarthritis may be caused by a wide range of gram-positive and gram-negative bacteria; vector-borne bacterial pathogens (*Rickettsia rickettsii, Ehrlichia canis, Anaplasma phagocytophilum, Ehrlichia ewingii, Borrelia burgdorferi*); protozoa (*Leishmania*); and fungi.
- Geographic Distribution: Worldwide, although the prevalence of brucellosis and vector-borne and fungal causes varies geographically.
- Major Clinical Signs: Pain, lameness, fever, inappetence, lethargy, draining skin lesions, and soft tissue swelling may occur with osteomyelitis. Spinal pain, fever, lethargy, inappetence, and pelvic limb paresis or paralysis can occur with discospondylitis. A stiff gait, reluctance to move, lameness, fever, inappetence, lethargy, and swollen joints may occur with polyarthritis.
- Differential Diagnoses: Differential diagnoses for suspected osteomyelitis, monoarthritis, and discospondylitis include bone neoplasia, sterile foreign body reactions, and degenerative osteoarthritis. Primary immune-mediated polyarthritis is the major differential diagnosis for suspected infectious polyarthritis.
- Human Health Significance: When draining wounds are present, resistant bacteria such as methicillin-resistant *Staphylococcus* spp. associated with osteomyelitis and arthritis in dogs and cats may have the potential to colonize human patients. Discospondylitis and polyarthritis caused by *Brucella* spp. can be transmitted to humans through contact with infected urine. Because vector-borne pathogens and fungi of importance to human health can cause polyarthritis, hospital staff should take special care to avoid sharps injuries when working with animals with polyarthritis.

Infectious osteomyelitis is defined as infection of the cortical bone, periosteum, and myeloid cavity, and the associated inflammatory response. The axial and/or appendicular skeleton may be involved. *Discospondylitis* refers to inflammation of the intervertebral discs and adjacent cartilaginous endplates, and almost always results from infection by bacteria or fungi. *Infectious arthritis* refers to inflammation of the synovium, synovial fluid, and associated cartilage secondary to infectious causes.

Osteomyelitis, discospondylitis, and arthritis can result from: (1) hematogenous spread of bacteria or fungi to these sites, or (2) from direct introduction of bacteria as a result of penetrating wounds or surgery. When fungi are involved, molds such as *Aspergillus* spp. or *Paecilomyces* spp. are more likely than yeasts to cause osteomyelitis and discospondylitis (especially in genetically predisposed breeds such as German shepherds, see Chapter 86); *Candida* has rarely been associated with discospondylitis in dogs.[1] In contrast, osteomyelitis can be caused by opportunistic molds or dimorphic fungi, especially *Coccidioides* spp. or *Blastomyces* spp. Fungal arthritis is uncommon but has been associated with infection by *Coccidioides* spp., *Blastomyces* spp., and *Cryptococcus* spp.

OSTEOMYELITIS

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Bacterial osteomyelitis most often results from direct introduction of bacteria into wounds adjacent to bone. Bacteria can be introduced into the bone as a result of penetrating foreign bodies, surgical wounds (especially orthopedic surgeries with implant placement), traumatic wounds, bite wounds, or extension of soft tissue infections. In one study from Brazil, 78% of cases followed a motor vehicle accident, 17% dog bite wounds, and 5% were secondary to pododermatitis.[2] Human research shows a low incidence of osteomyelitis for elective procedures, but high (33%) reinfection rates after a *Staphylococcus* infection occurs. There are three ways that staphylococci from an implant biofilm invade bone tissue and evade inactivation: (1) formation of abscesses in the soft tissues and bone marrow; (2) glycocalyx formation on the implant; and (3) colonization of the osteocyte lacuna-canalicular network of cortical bone.[3] Veterinary orthopedic infection rates are poorly reported. Infection rates reported depend on the orthopedic procedure.[4] Tibial plateau leveling osteotomy (TPLO) surgery for cranial cruciate rupture, one of the most common orthopedic surgical procedures performed, has a postoperative implant removal rate of 2.7% to 8.5% because of confirmed implant-associated infection.[5–11] For unknown reasons, the surgical site infection (SSI) rate after TPLO appears to be higher than that after routine "clean" orthopedic surgeries that involve osteotomy (as opposed to fracture repair). In a report that was published before the TPLO procedure was described, the overall infection rate after any orthopedic surgery procedure was 3 (<1%) of 502 surgeries.[12] In contrast, radiographically detectable osteomyelitis was reported in 14 (7.3%) of 193 dogs that underwent TPLO surgery and was the single most common complication of the procedure.[6] A 1% rate of osteomyelitis was reported in

a prospective study of 100 dogs undergoing stifle surgery, whereas the incision infection rate was 8%.[13] One recent review reported TPLO infection rates that ranged from 0.8% to 14.3%.[14] Total joint replacement infection rate was reported to be up to 11%.[4,15,16] Infection rate after fracture repair varies. It was 9 (8%) of 110 surgeries in one study.[17] In this study, 20% of the fractures were open. Open fractures were 4 times more likely to be contaminated with bacteria at the time of surgery than the closed fractures, and contaminated wounds were 5 times more likely to develop complications (seroma, drainage, and dehiscence) than those without contamination. Distal radius/ulna and tibial fractures were 10.5 times and 7.5 times more likely to be contaminated than femoral fractures, respectively. Animals with a normal postoperative temperature and a clean surgical wound did not develop postoperative complications.

Although gram-positive aerobes such as staphylococci and, to a lesser extent, streptococci predominate as a cause of osteomyelitis in dogs and cats, the organisms present and the bone(s) affected generally reflect the underlying type of injury that led to infection. For example, osteomyelitis that follows SSI is often caused by *Staphylococcus pseudintermedius*, a common commensal of canine skin (Table 121.1). *Staphylococcus aureus* and gram-negative bacterial infections can also cause orthopedic SSIs.[8] In contrast, anaerobes (e.g., *Bacteroides, Cutibacterium acnes, Peptostreptococcus, Clostridium, Fusobacterium, Actinomyces*) and aerobic gram-positive bacteria (staphylococci, enterococci, streptococci) or gram-negative bacteria (*Pseudomonas, Escherichia coli, Klebsiella pneumoniae, Proteus, Pasteurella*) predominate in osteomyelitis that results from bite wound infections, tooth root abscesses, or penetrating foreign bodies.[18,19] Such mixed bacterial infections are also common in dogs with digital osteomyelitis. Anaerobes were isolated from 64% of osteomyelitis cases in dogs in one study.[19]

Osteomyelitis secondary to bacteremia, also known as *hematogenous osteomyelitis,* is very rare and usually affects young to middle-aged animals.[4,20] The metaphyseal regions are often involved, sometimes with extension to the epiphyses and joints (Fig. 121.1). The pathogenesis remains obscure. It has been suggested that discontinuous endothelium in the primary spongiosa may predispose to extravasation of erythrocytes and bacteria in this region.[21] In humans, acute hematogenous osteomyelitis results from bacterial seeding secondary to transient bacteremia, which may result from conditions such as otitis media. Trauma to the bone and upregulation of bacterial virulence factors may also be important for allowing establishment of infection.[22] Sternal, pelvic, and vertebral osteomyelitis can also result from hematogenous spread of bacteria.[20] Osteomyelitis occasionally also results from hematogenous spread of fastidious bacteria such as *Brucella, Bartonella, Mycobacterium, Nocardia,* and *Nocardiopsis* spp.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The development of bacterial osteomyelitis requires the presence not only of bacteria but also of compromised bone. Bone necrosis can result from trauma (i.e., fracture), surgery, or underlying bone neoplasia. Bacteria adhere to fibronectin, a connective tissue glycoprotein, through the use of a variety of adhesins. The presence of foreign material promotes persistence of infection in the form of biofilm (Fig. 121.2). *Staphylococcus pseudintermedius*, *S. aureus, Pseudomonas aeruginosa,* and *E. coli* are particularly apt to form biofilms. Adherent bacteria produce a matrix of condensed exopolysaccharides known as a glycocalyx.[23] The biofilm is composed of a cluster of microorganisms and glycocalyx on an inanimate surface. Embedded in the biofilm mixture of glycocalyx, host-derived serum proteins, and cellular debris, bacteria often form into microcolonies. Within biofilm, bacteria evade opsonization and phagocytosis and are protected from the effects of antimicrobial drugs. Staphylococci can reside within osteoblasts, and when cell death occurs, they are released and can re-establish a productive infection.[23] Bacteria within biofilms intercommunicate via cytokines (quorum sensing), and this appears to assist them in their ability to evade host defense mechanisms. Bone sequestra can also become colonized by bacteria, which evade host defenses in the absence of adequate blood supply. Loose implants and fracture instability contribute to bone resorption, compromised blood supply, and persistent infection.[21] Some implant types are more apt to be colonized by bacteria.

TABLE 121.1 Bacteria Isolated from 31 Dogs with Surgical Site Infections After Tibial Plateau Leveling Operations[a]

Bacterial Classification	Species	Number of Isolates (%)	Proportion of Staphylococci Methicillin Resistant	Proportion of Staphylococci Multidrug Resistant[b]
Gram-positive aerobes (*n* = 30)	*Staphylococcus pseudintermedius*	20 (49)	4/20 (20%)	7/20 (35%)
	Staphylococcus aureus	3 (7)	2/3	1/3
	Coagulase-negative staphylococci	3 (7)	1/3	0
	Staphylococcus schleiferi subsp. *coagulans*	1 (2)	0	0
	Enterococcus spp.	3 (7)	NA	2/3
Gram-negative aerobes (*n* = 9)	Enterobacterales (*Escherichia coli, Proteus, Klebsiella pneumoniae*)	4 (10)	NA	1/2[c]
	Pseudomonas aeruginosa	3 (7)	NA	2/3
	Eugonic fermenter-4–like	1 (2)	NA	0
	Pasteurella canis	1 (2)	NA	0
Anaerobes (*n* = 2)	*Actinomyces*	1 (2)	NA	ND
	Cutibacterium acnes	1 (2)	NA	ND

Mixed infections with two or three bacterial species or strains were present in 7 (23%) of the dogs (total 41 isolates).
[a]Cases seen at the University of California-Davis Veterinary Medical Teaching Hospital.
[b]Resistant to three or more classes of antimicrobial drugs.
[c]One of two *E. coli* and the *Proteus* isolate did not undergo susceptibility testing because isolation was performed at necropsy.
NA, not applicable; *ND,* not done.

Stainless-steel plates have been associated with a higher risk of SSIs than titanium plates.[24] In one study, Slocum TPLO plates were more likely to be removed than other types of TPLO plates because of local bacterial infection and clinical signs of inflammation.[11] In another retrospective study of 104 TPLO procedures, the rate of SSI was higher among dogs treated with Synthes implants than among those with Slocum implants, but there was no significant difference in the rate of infection among the New Generation, Synthes, and Slocum implants.[25]

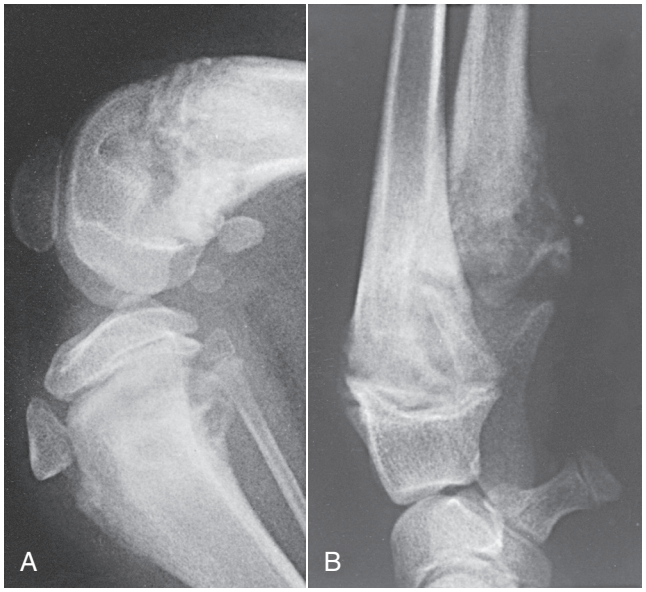

Fig. 121.1 Polyostotic metaphyseal osteomyelitis in a Border collie puppy that had persistent neutropenia. (A) Disruption of metaphyseal architecture of distal femur and proximal tibia, with irregular areas of radiolucency and sclerosis and some adjacent periosteal new bone. (B) Similar changes are evident in the distal radius and ulna. (From Ettinger SJ, Feldman EC, eds. *Textbook of Veterinary Internal Medicine*. 7th ed. St. Louis, MO: Saunders; 2010.)

Inflammatory cells recruited to the site of infection release enzymes that cause additional bone necrosis, with destruction of cancellous and cortical bone and abscessation of associated soft tissue. The end result is focal swelling, pain, draining skin lesions, and lameness. Small draining skin lesions often represent the "tip of the iceberg", with extensive bone involvement hidden beneath the skin (see Fig. 121.2). The presence of anaerobes can be associated with a foul odor or gas production. Fever, inappetence, lethargy, and leukocytosis are occasionally present in animals with acute osteomyelitis but are often absent in chronic osteomyelitis. In a 2018 study of dogs that required removal of tibial tuberosity advancement (TTA) cages to resolve SSIs, the mean time to appearance of signs related to SSI was 403 days after surgery (median: 287 days, range: 10 to 1,547 days).[26] Occasionally, infection reactivates in dogs years after surgery and implant placement. In human patients, latent periods between infection and development of osteomyelitis can last many decades.[27]

Physical Examination Findings

Physical examination findings in dogs and cats with osteomyelitis include lameness, localized pain, soft tissue swelling, muscle atrophy, and the presence of draining tracts. Fever and lethargy can also be identified in some animals.

DIAGNOSIS

In most cases, osteomyelitis is diagnosed on the basis of history, physical examination, and diagnostic imaging findings. Aerobic and anaerobic bacterial culture of affected bone or any implants present is required for definitive diagnosis.

Laboratory Abnormalities

The CBC of animals with osteomyelitis may be unremarkable or reveal mild anemia, neutrophilia with bandemia, and monocytosis. The serum biochemistry panel and urinalysis are usually unremarkable, unless bacteremia or other systemic disease is also present.

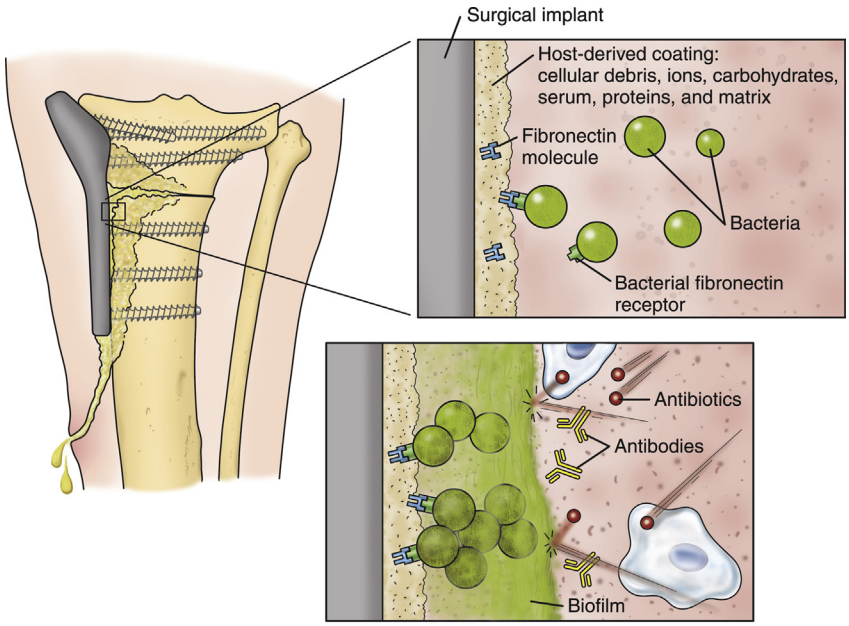

Fig. 121.2 Pathogenesis of osteomyelitis. Necrotic bone is colonized by bacteria, which adhere to fibronectin and in the presence of foreign material (in this case, an implant) can form biofilm. Biofilm consists of bacterial aggregates embedded in a matrix of exopolysaccharide (bacterial slime). The biofilm protects the bacteria from antibodies, phagocytosis, and antimicrobial drugs.

Diagnostic Imaging

Radiographic changes in dogs and cats with osteomyelitis vary considerably in extent and character. In some dogs and cats, only soft tissue swelling may be evident. Plain radiography is insensitive and can be poorly specific for diagnosis of osteomyelitis, and interpretation can vary from one board-certified radiologist to another. In one study, plain radiographic findings were interpreted as osteomyelitis by two radiologists in only five of eight dogs with experimentally induced osteomyelitis.[28] One radiologist diagnosed osteomyelitis in only three of the eight dogs, but that radiologist was less likely than the other radiologists to diagnose osteomyelitis when infection was absent.

When radiographic bony changes are evident, they consist of periosteal proliferation, which may be smooth or speculated; focal osteopenia with cortical resorption or thinning; loss of trabecular markings; lucency around implants such as cages, plates, or screws; and sequestration (Fig. 121.3). Pathologic fractures may be evident in dogs with fungal osteomyelitis. Scintigraphy with technetium-99m methylene diphosphonate, gallium-67 citrate, and indium-111-labeled leukocytes has been used in human medicine but is considered expensive and can lack specificity.[29] Bone scintigraphy has also been used for diagnosis of hematogenous arthritis in dogs with multiple site involvement.[20] Ultrasound imaging, contrast CT, MRI, and 18F-flurodeoxyglucose PET are sensitive diagnostic tools and may be useful for identification of sequestra, foreign material, and abscess formation. IV administration of ultraparamagnetic iron oxide nanoparticles during MRI, which are taken up by macrophages, has shown promise for detection of vertebral osteomyelitis and differentiation of osteomyelitis from aseptic inflammation.[4,30,31] Serum immunoassays that detect antibody responses to staphylococcal proteins, such as iron acquisition proteins and secreted toxins, have also shown utility for diagnosis and prognostication in human patients with osteomyelitis, although they can lack specificity due to previous exposure or asymptomatic colonization.[3]

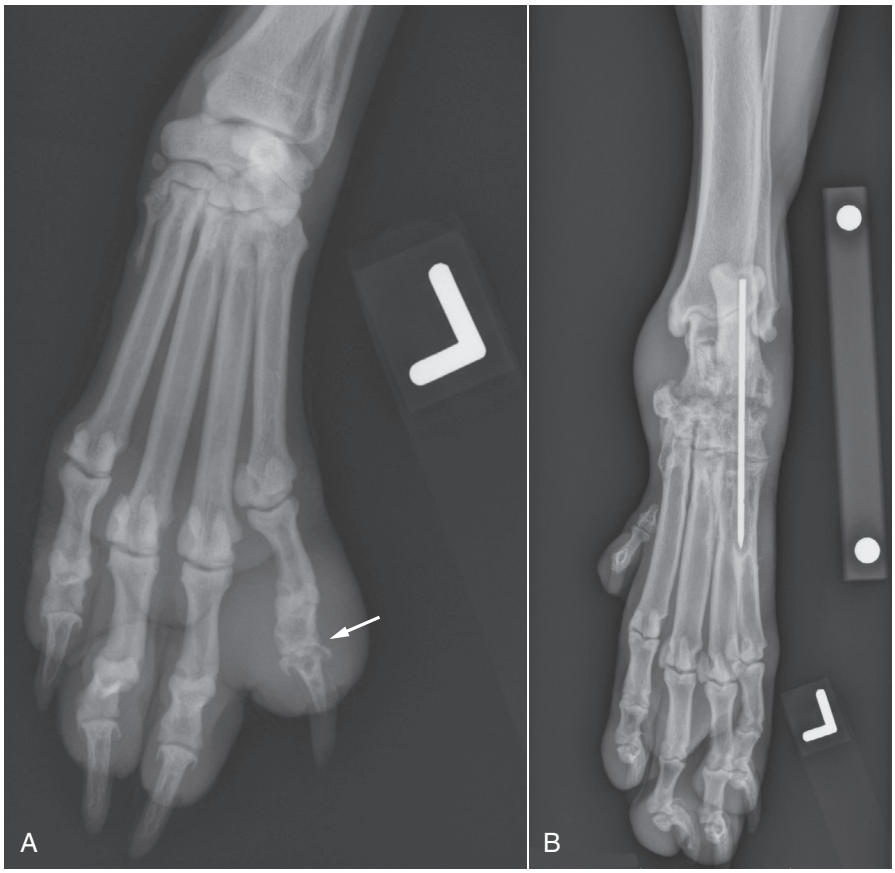

Fig. 121.3 Radiographic changes in bacterial osteomyelitis. (A) Osteomyelitis of the third phalanx of the fifth digit in a 7-year-old female spayed fox terrier with systemic lupus erythematosus that had been treated with prednisone and cyclosporine. There is severe soft tissue swelling, moderate lysis of the distal aspect of the third phalanx, and an irregular cortical margin with loss of the normal P2-P3 joint space *(arrow)*. A *Nocardia* sp. was isolated from the draining lymph node. (B) Radiographs of the left tarsus of a 5-year-old male neutered pit bull terrier with implant-associated osteomyelitis. A partial left tarsal arthrodesis had been performed a year previously after the dog suffered a traumatic injury. Draining tracts then developed in association with the screw heads, and treatment with cephalexin was unsuccessful. There is severe irregular bone lysis on both sides of the proximal intertarsal joint. A surgical pin extends from the proximal calcaneus through the tarsal joint to the level of the mid-diaphysis of the fifth metatarsal bone. There is a region of lucency that surrounds the tip of the surgical pin within the fifth metatarsal bone. The cortex of the fourth metatarsal bone adjacent to the pin is thickened with a slightly irregular periosteal reaction. The first phalanx of the first digit is incomplete (likely congenital). There is marked soft tissue swelling associated with the tarsus. A methicillin-susceptible *Staphylococcus aureus* was cultured from the implant at surgery to remove the pin. Tobramycin-impregnated calcium sulfate beads were used to fill the pin tract.

Microbiologic Tests

Isolation and Identification

Aerobic and anaerobic bacterial culture and susceptibility should be performed on aspirates of pus, bone biopsies, or removed implants from dogs and cats with osteomyelitis. Aspirates should be collected in a sterile manner from the focus of infection to avoid contamination with surface bacteria (e.g., via aspiration of lesions through healthy skin after skin antisepsis, or through collection of biopsies or implants during surgical exploration). Negative culture results may reflect an insufficient specimen size, or the presence of fastidious bacteria such as anaerobes, *Bartonella, Brucella, Nocardia,* or *Mycobacterium* spp. Sonication of implants removed from humans that had implant-associated osteomyelitis increased the sensitivity of culture from 67% to 90%.[32] Blood cultures should be performed if hematogenous osteomyelitis is suspected based on the history and clinical findings (young animal, multiple sites affected, sternal or vertebral involvement, other systemic illness, or immunosuppression).

Pathologic Findings

Pathologic findings in osteomyelitis depend on the causative agent and chronicity of infection. Inflammatory cell infiltrates may range from suppurative (acute osteomyelitis) to pyogranulomatous or lymphoplasmacytic. The neutrophilic infiltrate in dogs with acute osteomyelitis may be accompanied by the presence of fibrin, free red blood cells, and necrotic debris. There may be evidence of bone resorption with multinucleated osteoclasts and new bone and fibrous tissue formation. In some cases, intralesional bacteria or fragments of foreign material (such as plant material) are observed (Fig. 121.4).

TREATMENT AND PROGNOSIS

Treatment recommendations for focal osteomyelitis secondary to trauma, surgery, or foreign body penetration depends on the severity and chronicity of disease, the location of osteomyelitis, the presence or absence of foreign material or implant, and the extent of blood supply to the bone. In animals with fractures, early detection and treatment of osteomyelitis is critical to prevent extensive bone necrosis and nonunion. Antimicrobial drug treatment alone is usually not sufficient to resolve chronic bacterial osteomyelitis, because sequestra and biofilm are avascular and are not effectively penetrated by antimicrobial drugs. In general, treatment requires debridement, removal of sequestra and foreign material, dead space removal, copious lavage with sterile saline, rigid fracture stabilization, systemic and/or local administration of appropriate antimicrobial drugs, and grafting of bone deficits. Because implants may ultimately need to be removed to resolve infection, fractures may need stabilization through alternative means, such as external skeletal fixation or one- or two-stage implant replacement revision surgeries. Removal of the infected implant and replacing it at the time of debridement helps to prevent colonization of the lacunar canaliculi by staphylococci.[33] Maintenance of bone stabilization is considered paramount in human medicine, because unstable fractures or surgical sites are considerably more prone to infection than those that are stable.[29] It is considered better to leave an implant in place and maintain stabilization than to remove an implant early. In a study of 121 people with infection after fracture fixation, approximately 70% of the time, stable implants could be salvaged following extensive irrigation, debridement, and appropriate systemic antibiotics.[34] Systemic antimicrobial drug therapy (and often regional antibiotic therapy in the form of antimicrobial drug–impregnated beads or gel) is required while the bone heals. In some cases, foci of osteomyelitis may be removed en bloc without the need for further graft placement or stabilization (e.g., digital osteomyelitis). Resected bone should be submitted for histopathology (to confirm the presence of osteomyelitis and identify other processes such as fungal infection or neoplasia) as well as aerobic and anaerobic culture and susceptibility testing. Wounds are left open after debridement if continued debridement is needed via wet-to-dry bandaging. In severely infected cases, vacuum-assisted wound closure techniques are recommended. If all nonviable tissue has been removed, closed irrigation systems or vascularized tissue flaps may be used to manage dead space. A sterile dressing should be used to cover the wounds, with daily bandage changes until exudation resolves. If needed, autogenous cancellous bone graft placement is delayed until infection has been controlled and granulation tissue has begun to fill the wound (usually 1 to 2 weeks after initiation of antimicrobial drug treatment).[35] When graft placement or fracture stabilization is not possible because of financial concerns or uncontrollable infection, amputation may be necessary.

The choice of antimicrobial drugs should be based on the results of aerobic and anaerobic bacterial culture and susceptibility. If the animal is stable, treatment should be withheld until results are available, and medications to manage pain should be administered. If earlier antimicrobial

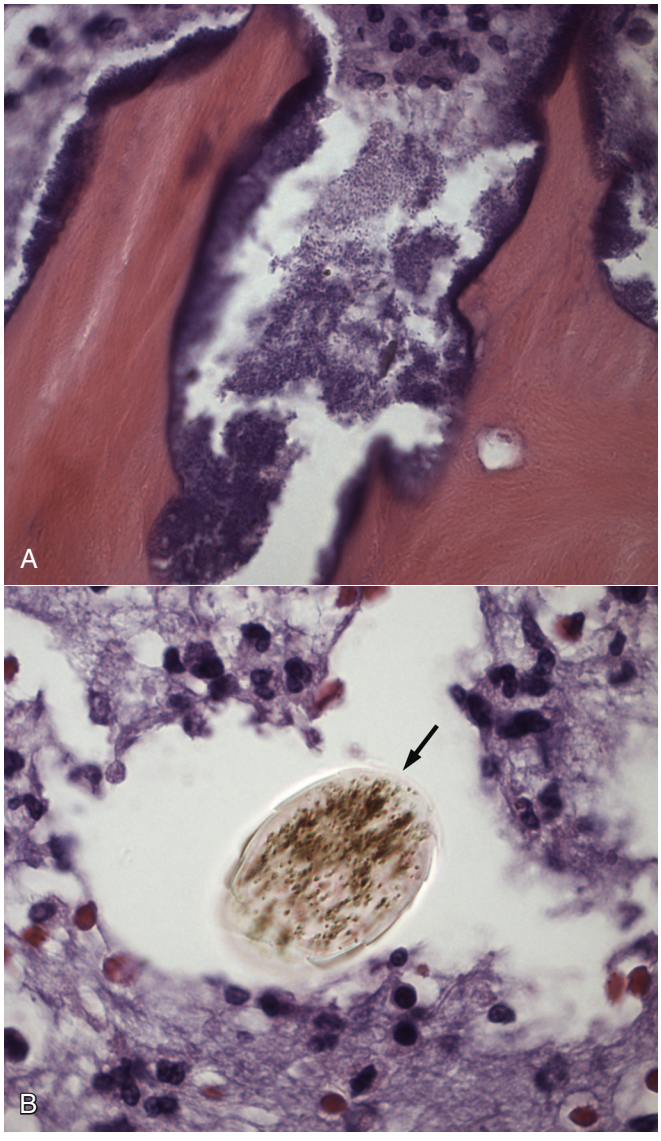

Fig. 121.4 Histopathology from the right pelvic fourth digit of a 3-year-old intact male Labrador retriever with an open articular fracture and chronic suppurative bacterial osteomyelitis. (A) Large numbers of bacteria are adhered to bone fragments (eosinophilic material) with an associated neutrophilic inflammatory response. (B) In other fields, intralesional plant material was visible *(arrow).*

treatment is deemed necessary pending the results of culture and susceptibility, the drug chosen should be based on the history (e.g., postsurgical infection versus bite wound infection) and local prevalence data for the practice (Table 121.2). The presence of anaerobes should be assumed if anaerobic culture is not performed, or anaerobes are not isolated, especially if the underlying insult was a bite wound or a traumatic injury. Clindamycin is a reasonable initial choice for infections that could include susceptible staphylococci and/or anaerobic bacteria and was effective in experimental models of *S. aureus* osteomyelitis in dogs,[36] but a significant proportion of MRS exhibit clindamycin resistance or inducible clindamycin resistance (see Chapter 51). In a study of dogs with osteomyelitis from Brazil, nearly 60% of isolates exhibited clindamycin resistance.[2] In that study, a greater proportion of isolates (79%) were susceptible to amoxicillin-clavulanic acid. If gram-negative bacteria or MRS are suspected, the addition of an aminoglycoside may be necessary if treatment must be instituted before the results of culture and susceptibility become available. However, aminoglycosides penetrate poorly into purulent material, so adequate debridement is essential. Combinations of antibiotics are sometimes required in animals with polymicrobial infections. Systemic antibiotic treatment should be continued for at least 4 to 6 weeks. Longer periods of treatment may be required in some dogs and cats, especially if an implant is present. The duration of therapy should be considered on a case-by-case basis, depending on the underlying problem (fracture, corrective osteotomy, bite wound), the likely organisms present, and depth of infection. Antimicrobial drugs should be given parenterally in the hospital for at least the first 3 to 5 days, and for longer if possible. There is evidence that use of fluoroquinolones may delay bone healing, and so in human medicine it is recommended that the use of fluoroquinolones be avoided if possible.[29] The use of linezolid has been reported for treatment of MDR orthopedic MRSP SSIs in 4 dogs.[37] Adverse effects of vomiting, lethargy, and anorexia (2 dogs) and regenerative anemia (1 dog) were reported. Infections recurred in 2 dogs after discontinuation of treatment.

In addition to systemic treatment, antibiotic-impregnated beads or gel can be used to treat chronic osteomyelitis and septic arthritis in dogs.[38,39] Beads are prepared in the operating room by mixing an antimicrobial drug with commercially available calcium sulfate bead sets and setting through the use of a rubber mold. The beads are placed at the site of infection, where they deliver high concentrations of drug to the site (e.g., initially 500-fold that of normal serum concentrations with systemic treatment), sometimes for several weeks, without systemic adverse effects.[40] The antimicrobial drugs used are generally heat stable, hydrophilic, and have activity against MRS, such as aminoglycosides (gentamicin or tobramycin) or vancomycin. Gentamicin-impregnated beads were shown to reduce biofilm formation by methicillin-resistant *S. pseudintermedius*.[41] Other products include antibiotic-impregnated collagen, bone graft substitutes such as calcium phosphate (Fig. 121.5), and a variety of synthetic polymers such as polylactic acid, polylactide-co-glycolides, and cross-linked polydimethylsiloxane.[40] Tobramycin-impregnated calcium phosphate beads have been used successfully to treat osteomyelitis in dogs.[39] Polymers have been engineered to control the duration and concentration of antibiotic treatment at the site. Hydrogel is another medium to deliver antibiotics. The gel is aliquoted and then sterilized before use. It has to be refrigerated and mixed with the antimicrobial of choice in a hood to avoid contamination. The gel can be injected through a rubber catheter or placed in the site before wound closure. It has the advantage of being less expensive than beads but has a shorter duration of antimicrobial elution. The gel may be preferred when the infection is near a joint or a surgical approach is not being used.[38] Recently, IV administration of activated mesenchymal stem cells in conjunction with antibiotic therapy has also shown efficacy for treatment of chronic osteomyelitis.[42] Optimization of local antibiotic delivery systems in order to promote continuous delivery of appropriate concentrations of antibiotics, while avoiding colonization of the materials used, is currently the subject of extensive research.

TABLE 121.2 Suggested Initial Antimicrobial Drug Doses for Stable Animals with Bacterial Orthopedic Infections Pending Culture and Susceptibility Results

Disease	Drug	Dose (mg/kg)	Route	Interval (Hours)
Osteomyelitis or monoarthritis	Clindamycin hydrochloride, clindamycin phosphate	11–33 (dogs) 11 (cats) 10	PO PO IV,[a] IM	12 (dogs) 24 (cats) 12
	Enrofloxacin[b]	5–20 (dogs)	IV, IM, PO	24
	Gentamicin sulfate[c]	14 (dogs) 8 (cats)	IV, IM, SC	24
	Amikacin[c]	15–30 (dogs) 10–14 (cats)	IV, IM, SC	24
Discospondylitis	Ampicillin sodium	20	IV	6
	Ampicillin-sulbactam[d]	20	IV	8
	Amoxicillin–clavulanic acid	20–25	PO	12
	Cefazolin sodium	20–35	IV, IM	8
	Cephalexin	20–30	PO	6–8

[a]For IV administration, dilute 1:10 in 0.9% saline and administer over 30–60 minutes.
[b]Addition of fluoroquinolones to clindamycin or a β-lactam is indicated if gram-negative bacteria may be present and methicillin resistance among staphylococci is not prevalent in the region. In cats, other fluoroquinolones such as pradofloxacin or marbofloxacin are preferred because of the risk of retinopathy (see Chapter 10 for doses and contraindications). Use of pradofloxacin has been associated with bone marrow suppression in dogs, especially at high doses.
[c]Addition of aminoglycosides to clindamycin or a β-lactam is indicated if gram-negative bacteria and/or methicillin-resistant staphylococci may be present. See Chapter 10 for contraindications.
[d]Dose based on ampicillin component.
IM, intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

PREVENTION

Although not a substitute for sterile surgical technique and strict hospital infection control measures (see Chapter 15), perioperative antimicrobial drug treatment is an accepted aid for prevention of soft tissue surgical infections and osteomyelitis, especially when orthopedic implants are anticipated. Recommendations published for human medicine state that adequate prophylaxis requires: (1) antimicrobial agents with activity against organisms likely to be encountered in the surgical field; (2) timely preoperative antimicrobial drug administration (within 60 minutes of incision); (3) bactericidal concentrations of drug in the serum and tissues during the time that the wound is open; and (4) a duration of 24 hours after surgery.[43] Additional intraoperative doses should be given if the procedure lasts longer than two half-lives of the drug being administered (usually at least 2 hours). However, one study showed that administration of antibiotics longer than 60 minutes before incision was associated with a higher SSI rate than when antibiotics were administered within 60 minutes of incision, but the risk of SSI did not increase if antibiotic administration occurred after incision.[44] In practices where the prevalence of postoperative infections with MRS is low, preoperative treatment with cefazolin may be effective. Where the regional prevalence of skin colonization with MRS is high (e.g., >10%), preoperative treatment with cefazolin and an aminoglycoside such as amikacin could be used. Nevertheless, use of perioperative vancomycin in humans undergoing orthopedic procedures to prevent SSI was associated with an increased risk of SSI (OR 1.75), whereas administration of cefazolin decreased the risk of SSI (OR 0.49).[44] Whether administration of antimicrobials for multiple days postoperatively decreases the risk of infections after orthopedic procedures in dogs has been controversial, with some studies showing no significant benefit, and others showing reduction in the prevalence of SSIs. In a prospective study of 400 dogs that underwent implant surgery, dogs were randomized to receive either 5 days of postoperative antibiotics, or only perioperative antibiotics. The rate of SSI was similar between the two groups.[45] In another prospective study of 100 dogs undergoing clean orthopedic procedures that required stainless-steel plates, postoperative administration of antimicrobials (cephalexin or amoxicillin-clavulanic acid) for 7 days was associated with a lower risk of SSI (4.3%) than for dogs that did not receive postoperative antimicrobials.[46] Prophylactic treatment should never be continued for longer than 24 hours after surgery because it can select for drug-resistant bacterial infections. In human patients, antibiotic-impregnated implants have been used to prevent attachment of bacteria to their surface.[3,40,47] Silver-impregnated coatings show promise for prevention of colonization by *S. pseudintermedius*.[48] Minimization of surgery time, careful surgical technique, and use of plate types that are associated with a lower risk of postoperative infection (i.e., non–Slocum-type TPLO plates) may also prevent postsurgical osteomyelitis.[11] Metals used in implants should be of the same type (e.g., plate and screws) to minimize the chance of galvanic corrosion. Galvanic corrosion occurs when metals of different electrochemical properties are placed in close proximity in an electrolytic environment. This can predispose to implant loosening, local infection, or sarcoma formation.[49] Currently, it is considered acceptable to leave implants in place after healing unless the animal has persistent pain associated with the implant, or radiographic evidence of osteomyelitis or osteopenia is present. This is because the process of implant removal itself can be costly and may be followed by osteomyelitis or fracture. However, owners of pets with implants should be advised that although rare, possible long-term complications of implant placement include reactivation of infection in the future or development of malignancy at the implant site.

PUBLIC HEALTH ASPECTS

Dogs and cats with bacterial osteomyelitis can shed antibiotic-resistant gram-positive and gram-negative bacteria that have the potential to colonize humans and later be a source of human infection. Infections acquired after orthopedic surgeries, especially TPLOs, and joint replacements are problematic. Most dogs are infected with *S. pseudintermedius*, but a smaller percentage of dogs are infected with *S. aureus*,

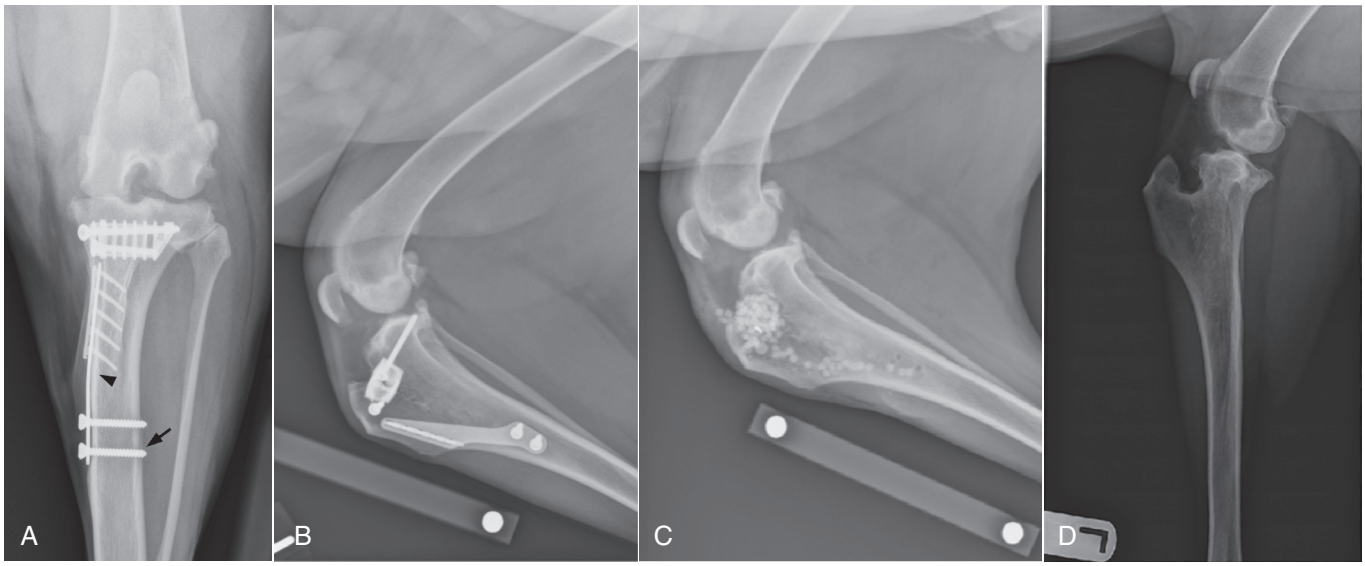

Fig. 121.5 Lateral radiographs of the left stifle from a 10-year-old female spayed greyhound–pit bull terrier mix that developed osteomyelitis at the site of a left tibial tuberosity advancement surgery (see Case Example). (A) Anteropalmar and (B) lateral radiographs of the left stifle 13 months after the surgery. The osteotomy site has filled with bone to some extent, but the site is still visible as a result of incomplete union. There was also lucency in the region of the most distal screw *(arrow)* and thinning of the cortical bone adjacent to the plate *(arrowhead)*. (C) The cage was removed by drilling around it, and calcium sulfate (Osteoset) beads were used to fill the defect. (D) Radiograph taken 13 months postoperatively showing resolution of osteomyelitis and degradation of the calcium sulfate beads. The region of cage removal never refilled with bone.

which is more likely to colonize humans (see Table 121.1). However, in some cases, the human in the household may have been the source of *S. aureus* infection. Some hospitals experience a high prevalence (>10%) of postoperative wound infections with MRS. In a case-control study that included dogs with methicillin-resistant *S. aureus* infection (cases) and dogs with methicillin-susceptible *S. aureus* infection (controls), surgical implant placement was associated with a 33-fold increased risk of methicillin-resistant *S. aureus* infection ($P = .001$).[50] Infected osteomyelitis wounds should be covered with a suitable dressing at all times, and owners should be advised to wear gloves when handling their pets (especially if the wound is infected) and to wash their hands properly afterwards. In the hospital, animals with draining orthopedic surgical wound infections due to methicillin-resistant or MDR bacteria should be handled by a limited number of individuals who wear gloves, a gown, and dedicated equipment, and signage should be posted. Hand washing should be performed after protective wear is removed, and all equipment used should be disinfected properly (see Chapter 15).

DISCOSPONDYLITIS

ETIOLOGIC AGENTS, PATHOGENESIS, AND EPIDEMIOLOGY

Discospondylitis most often follows hematogenous spread of bacteria or fungi to the cartilaginous vertebral endplates, with extension to the intervertebral discs. Bacteria or fungi are thought to lodge in the endplates because blood flow slows in this region. In most cases, the source of infection cannot be identified, but infection can originate from the urogenital tract, abscesses, skin wounds, respiratory tract infections, or the oral cavity. Occasionally, discospondylitis follows extension of infection from an adjacent site, such as following vertebral column SSIs, complications of epidural anesthesia, bite wounds, or migrating grass awns.

Risk factors for discospondylitis in dogs include male sex, older age, and breed.[1] Predisposed breeds are often large-breed dogs, such as great Danes, boxers, rottweilers, English bulldogs, German shepherd dogs, and Doberman pinschers. German shepherds and Rhodesian ridgebacks are predisposed to systemic mold infections that can target the intervertebral discs.[51] Although discospondylitis is frequently diagnosed in Labrador and golden retrievers, these dogs are popular breeds and were not found to be at risk.[1] Discospondylitis is extremely rare in cats and usually follows trauma such as cat bites, with associated meningomyelitis.[52–56] Concurrent disorders identified in dogs include genitourinary tract infections (prostatitis, orchitis, metritis, and/or UTI), pyoderma and otitis, immunosuppressive drug treatment, heartworm disease, recent vertebral column surgery, respiratory tract infection, bite wounds and other traumatic injuries, migrating foreign bodies, recent nonvertebral surgery, septic arthritis, severe intestinal parasitism, and infective endocarditis.

The incidence of discospondylitis in dogs and prevalence of different causative infectious agents vary geographically. In one study in the United States, the incidence of discospondylitis was higher in the southern states than in the northern states.[1] In 123 dogs with discospondylitis from the southern United States, the most common pathogen isolated was *Staphylococcus* (41% of 63 isolates), followed by *Streptococcus* (12%), and *E. coli* (11%).[1] Other bacteria included *Klebsiella*, *Brucella canis*, *Pseudomonas*, *Proteus*, and *Actinomyces* spp. (<10% each). When the results of *Brucella* serology and culture were combined, 13 of the dogs were diagnosed with brucellosis. Only two dogs were infected with fungal organisms, one with *Candida tropicalis* and the other with an unidentified fungal agent. Mixed infections were detected in 11 (9%) dogs. In 23 dogs with discospondylitis from the Pacific northwest of the United States, 10 of 18 isolates were staphylococci, 3 were streptococci, and 3 were *E. coli*; *Brucella* infection was not reported and a filamentous fungal species (*Phialemonium* or *Paecilomyces*) was isolated from two dogs.[57] In contrast, filamentous fungal species were isolated from nearly one third of dogs diagnosed with discospondylitis at the University of California, Davis (Table 121.3). The most common bacterial isolate was methicillin-susceptible *S. pseudintermedius*; MRS were not detected. In more than half of dogs with discospondylitis, the causative agent is not identified. Lumbar discospondylitis caused by *Actinomyces* spp. and anaerobic bacteria may occur as a result of migration of inhaled grass awns, which lodge in the retroperitoneal space. Sexually intact male dogs and dogs from the southeastern states are at increased risk for *B. canis* discospondylitis,[58] but it can occur in any region and in dogs of any sex. In a German study, 4 dogs with *B. canis* discospondylitis were described; the dogs were young (7–30 months of age) and had been imported into Germany from eastern Europe (Moldavia, Macedonia, Romania).[59] Other reported agents include *Enterobacter*, *Nocardia, Salmonella*, and *Erysipelothrix*.[60–64]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Clinical signs of discospondylitis include fever, lethargy, inappetence, weight loss, spinal pain, a hunched stance, lameness, reluctance to move, and/or reluctance to jump or climb stairs. The duration of signs is extremely variable, but are usually present for less than 1 month.[58] Spinal cord compression as a result of vertebral subluxation, abscess formation, disc protrusion or extrusion, and soft tissue proliferation can lead to neurologic deficits such as delayed or absent placing reactions, paresis with ataxia or paralysis, and loss of deep pain sensation. Neurologic deficits were detected in 59 (48%) of 123 dogs in one study.[1] In another study, paresis or paralysis was detected in 20 (87%) of 23 dogs and 8 of these dogs were nonambulatory.[58] The neurologic signs reflect the severity and location of discospondylitis lesions; in the latter study, the severity of neurologic signs was correlated with the number of compressive lesions and the percentage of spinal cord or cauda equina compression.[58] The majority (50% to 60%) of dogs have lesions in the thoracolumbar spine (especially the lumbosacral junction); cervical lesions are present in fewer than 20% of dogs.[1,58,65,66] Around 30% to 40% of dogs have multiple lesions. Thus, tetraparesis (which reflects the

TABLE 121.3 Infectious Agents Isolated from 31 Dogs with Culture-Positive Discospondylitis[a]

Organism Type	Infectious Agent	Number of Isolates (%)
Gram-positive aerobes (*n* = 15, 42%)	*Staphylococcus pseudintermedius* (methicillin-susceptible)	12 (33)
	Coagulase-negative staphylococci	2 (6)
	Streptococcus equisimilis	1 (3)
Gram-negative aerobes (*n* = 5, 14%)	*Klebsiella pneumoniae*	2 (6)
	Escherichia coli	2 (6)
	Brucella canis	1 (3)
Anaerobes (*n* = 4, 11%)	*Actinomyces* spp., *Prevotella, Fusobacterium, Porphyromonas*	4 (11)
Fungi (*n* = 11, 31%)	*Aspergillus* spp.	6 (17)
	Paecilomyces spp.	3 (8)
	Other molds	2 (3)

[a]Cases seen at the University of California-Davis Veterinary Medical Teaching Hospital. Based on culture of blood and/or disc material (26 dogs) or urine only (5 dogs; 3 with mold infections, 1 with *E. coli*, and 1 with *K. pneumoniae* infections).

presence of compressive cervical lesions) is less common (<5% of dogs) than pelvic limb paresis or paralysis (33% of dogs). The location of discospondylitis lesions (e.g., L7 to S1 versus C5 to C6) does not seem to affect the likelihood of cord compression.[66]

Physical Examination Findings

Dogs with discospondylitis may have fever (although it is often absent), lethargy, weakness, and pain on palpation or manipulation of the spine. Spinal pain is not consistently present. In some dogs, pain is difficult to localize or manifests as apparent abdominal pain when the abdomen is palpated, especially if upward pressure is placed on the spine. Dogs with neurologic deficits can be tetraparetic or have pelvic limb paresis or paralysis. Loss of deep pain sensation can occur in dogs with severe compression lesions. Neurologic examination may reveal delayed or absent placing reactions and exaggerated or reduced segmental reflexes. Evaluation for abnormalities that reflect the presence of concurrent disorders (such as cardiac murmurs in dogs with endocarditis or swollen joints in dogs with polyarthritis) should be carefully performed. Occasionally, discospondylitis is an incidental finding on plain radiography (performed to evaluate concurrent disease such as fever of unknown origin), and clinical signs that suggest discospondylitis are absent.

DIAGNOSIS

Diagnosis of discospondylitis is based on physical examination findings; imaging (plain radiography, CT/MRI); culture of blood, CSF, or aspirates of disc material; and serologic testing for *Brucella* spp. (antibody tests) or fungi (antigen tests). The reader is referred to Chapter 71 (Brucellosis) and Chapter 86 (Aspergillosis and Penicilliosis) for information on serologic testing for these diseases. Serologic testing for *Aspergillus* galactomannan antigen is inexpensive, and positive results (galactomannan indices > 1.5) correlate strongly with an underlying mold infection.[67] Rarely, mixed infections with bacteria and fungi occur, and bacterial contaminants can complicate interpretation of blood and disc aspirates. Thus, all dogs with discospondylitis should ideally be tested for *Aspergillus* antigen before antibiotic treatment is initiated. It is especially important to test predisposed breeds such as German shepherds and Rhodesian ridgebacks. Affected dogs should be evaluated for evidence of disease at other anatomic sites. If possible, this should consist of thoracic radiographs and abdominal ultrasound, echocardiography (for infective endocarditis), and aerobic bacterial culture of the urine.

Laboratory Abnormalities

Often the CBC and biochemistry panel are surprisingly unremarkable in dogs with discospondylitis. There may be mild to moderate neutrophilia with bandemia and/or lymphopenia on the CBC. Mild hypoalbuminemia and mild to moderate hyperglobulinemia are the most common abnormalities on the biochemistry panel. Dogs with fungal discospondylitis may be azotemic because of concurrent fungal pyelonephritis.[51] Urinalysis may show pyuria, bacteriuria, funguria, proteinuria, and/or cylindruria in dogs with concurrent UTIs. Analysis of the CSF often reveals mild to markedly increased CSF protein concentration and rarely increased total nucleated cell count.[57]

Diagnostic Imaging

Plain Radiography

Radiographic changes in dogs (and cats) with discospondylitis include narrowing or widening of the intervertebral space, irregularity or lysis of the vertebral body endplates, endplate lucency, sclerosis at the margins of bone loss, proliferative or osteolytic lesions within adjacent vertebral bones and bridging spondylosis, and, in some cases, vertebral subluxation or fracture (Fig. 121.6).[63] It has been suggested that there may be differences in the radiographic appearance of lesions in young dogs when compared with adult dogs, but more studies would help to verify this. Because multiple disc spaces are frequently affected, radiographs of the entire spine should be performed to properly assess the extent and severity of disease. Radiographic changes may lag behind clinical signs for as long as 6 weeks in dogs with discospondylitis, so radiographs should be repeated every 1 to 2 weeks if discospondylitis is suspected and plain radiographs are initially normal. Alternatively, advanced imaging with CT or MRI may reveal lesions not seen on plain radiographs. Plain radiography does not allow visualization of the degree of spinal cord compression, so advanced imaging is required to further evaluate dogs with neurologic signs. Ultrasonography may be useful for detection of retroperitoneal grass awns in dogs with localized lumbar discospondylitis on plain radiography, and can also show changes associated with discospondylitis, such as loss of reverberation artefact. Bone phase nuclear scintigraphy may also be helpful for diagnosis.

Contrast Radiography

Myelography can identify the site(s), type (vertebral subluxation or soft tissue proliferation), and extent of spinal cord compression in dogs with discospondylitis and allow planning for decompressive surgery (Fig. 121.7).[66] However, MRI is less invasive, more sensitive, and is now the preferred method for diagnosis of cord compression due to discospondylitis.

Advanced Imaging

CT and MRI may have increased sensitivity for diagnosis of discospondylitis when compared with plain radiography. MRI is the gold standard

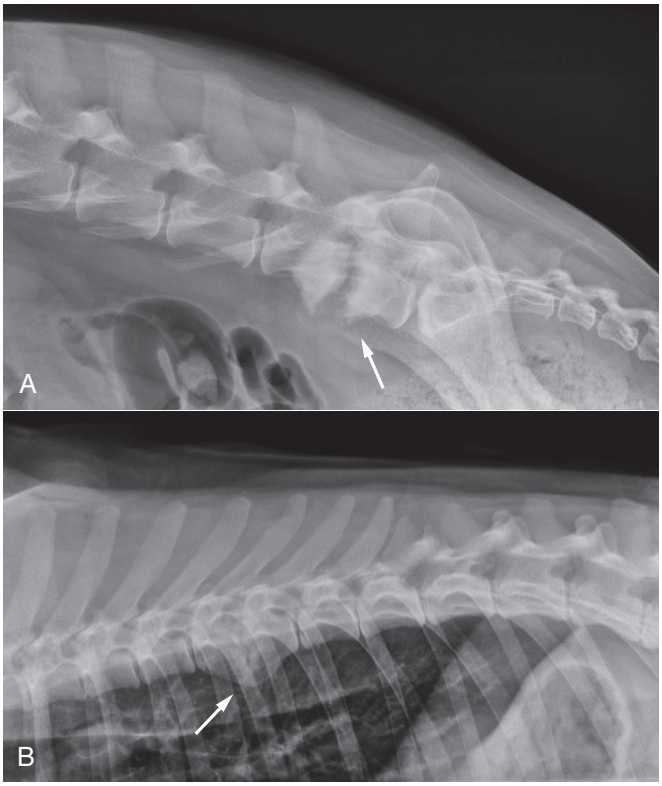

Fig. 121.6 Radiographic changes in discospondylitis. (A) Lateral radiograph of the lumbosacral region of a 3-year-old female spayed German shepherd with *Aspergillus* spp. discospondylitis. There is severe destruction of the endplates at L6-L7 *(arrow)* with sclerosis and ventral periosteal proliferation. (B) Lateral radiograph of the thoracic spine of a 1-year-old female malamute. Resolving discospondylitis is present at T8-T9 *(arrow)*. There is lysis and irregularity to the endplates of these vertebrae. There is bridging spondylosis ventrally.

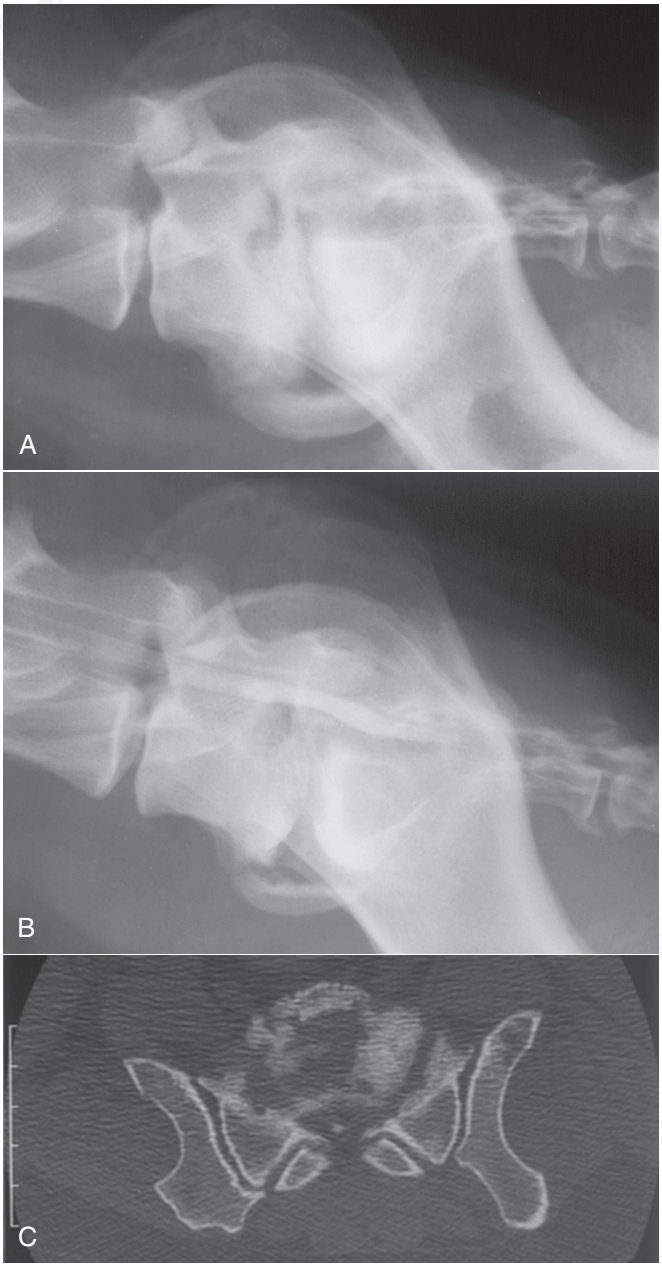

Fig. 121.7 Images from a 9-year-old intact male rottweiler with a 3-day history of difficulty standing and decreased appetite. Findings on neurologic examination included lumbosacral spinal pain, left pelvic limb paresis, and right pelvic limb paralysis. Blood and synovial fluid cultures yielded a methicillin-susceptible *Staphylococcus pseudintermedius*. Radiographic findings were consistent with chronic discospondylitis at the lumbosacral disc space and secondary compression of the spinal cord. (A) Plain lateral radiograph of the pelvis. The lumbosacral joint space is narrowed and there is significant bridging spondylitis, with endplate osteolysis. (B) Myelogram. Dorsal elevation of the conus is present at the lumbosacral junction. (C) Contrast tomography of the lumbosacral junction. There is substantial endplate osteolysis. (All images courtesy the University of California, Davis, Veterinary Neurology/Neurosurgery Service.)

for diagnosis of discospondylitis in human patients and is the method of choice for diagnosis and characterization of discospondylitis in dogs.[57,63,65,68] Affected vertebral bodies are classically hypointense on T1-weighted images (which illustrate bone lesions) and may be hypointense (most commonly), isointense, or hyperintense on T2-weighted images when compared with normal surrounding structures.[57,65] T2-weighted images highlight tissues with high water content, including the nucleus pulposus, CSF, epidural fat, and inflammatory lesions. Hyperintensity of the vertebral bodies in dogs is even more commonly observed in short tau inversion recovery (STIR) images, which suppress the signal from fat. Two adjacent vertebrae are consistently involved. Intervertebral discs are hyperintense on T2-weighted and STIR images when discospondylitis is present. Marked uniform or heterogenous contrast enhancement is usually apparent in vertebral endplates, within the disc, and in surrounding soft tissue (Fig. 121.8). Paravertebral soft tissues may also be hyperintense on T2-weighted and especially STIR images.[57] Hyperintensity of adjacent spinal cord on T2-weighted images has also been described.[63] With more chronic infection, there is loss of definition and cortical continuity and destruction of cortical margins in T1-weighted images. Distortion and narrowing of the disc space is also apparent, and subluxation and disc protrusion with associated spinal cord compression can be easily identified. The severity of spinal cord compression on MRI correlates with severity of neurologic signs, whereas this does not appear to be true for myelography.

Microbiologic Tests

Isolation and Identification

The optimal specimens for identification of the causative agent of discospondylitis are blood or fluoroscopically guided disc aspirates (or biopsies performed during decompressive surgery), because organisms isolated from these specimens are most likely to reflect those involved in disc destruction. Blood cultures are indicated in all dogs with discospondylitis (see Chapter 3 for blood culture technique and interpretation). Because anaerobes are uncommonly isolated from dogs with discospondylitis and they have predictable susceptibilities, the decision to perform anaerobic blood culture should be considered in light of any underlying disease processes and client financial constraints. Negative blood cultures occur in more than half of dogs with discospondylitis and may reflect low-level bacteremia or fungemia, the presence of fastidious or unculturable organisms such as *Brucella* or anaerobes, or recent antimicrobial drug treatment. Urine cultures may reveal the causative organism when blood cultures are negative, but not uncommonly bacterial species present in the urine differ from the organism present in affected discs. However, isolation of a mold species from the urine suggests a disseminated mycosis. Serologic testing for *Aspergillus* antigen and *Brucella* antibody should be performed in dogs with culture-negative discospondylitis. *Aspergillus* serology should also be considered for dogs that have blood culture-positive discospondylitis, especially in predisposed breeds (such as German shepherds, Rhodesian ridgebacks, vizslas) because mixed infections with fungi and bacteria can rarely occur. Dogs with *Paecilomyces* discospondylitis can have positive *Aspergillus* serum and urine antigen tests due to serologic cross-reactions between these fungi.[67]

When blood cultures are negative, disc aspirates can be obtained under anesthesia with fluoroscopic (or other advanced imaging such as CT) guidance after preparation of the skin in a sterile manner.[69] Aspiration is performed with a 22-G, 1.5- to 2.5-inch spinal needle into a syringe that contains a small amount of sterile saline. In one study, 0.3 to 0.5 mL of sterile saline was injected and immediately reaspirated,[69] but dry aspiration can also be performed into the needle. The saline in the syringe can then be used to flush the contents of the needle into a plain sterile tube, which is submitted for bacterial and fungal culture. Only 3 of 11 aspirates or biopsies were positive in one study.[1] However, in another study, positive bacterial cultures were obtained in 9 of 12 disc aspirates.[69] Other specimens that may yield growth include CSF, aspirates of cellulitis or abscesses adjacent to sites of discospondylitis, or synovial fluid. When disease is present at other sites, every effort should be made to perform culture for aerobic and anaerobic bacteria and fungi from these sites in order to identify an infectious etiology.

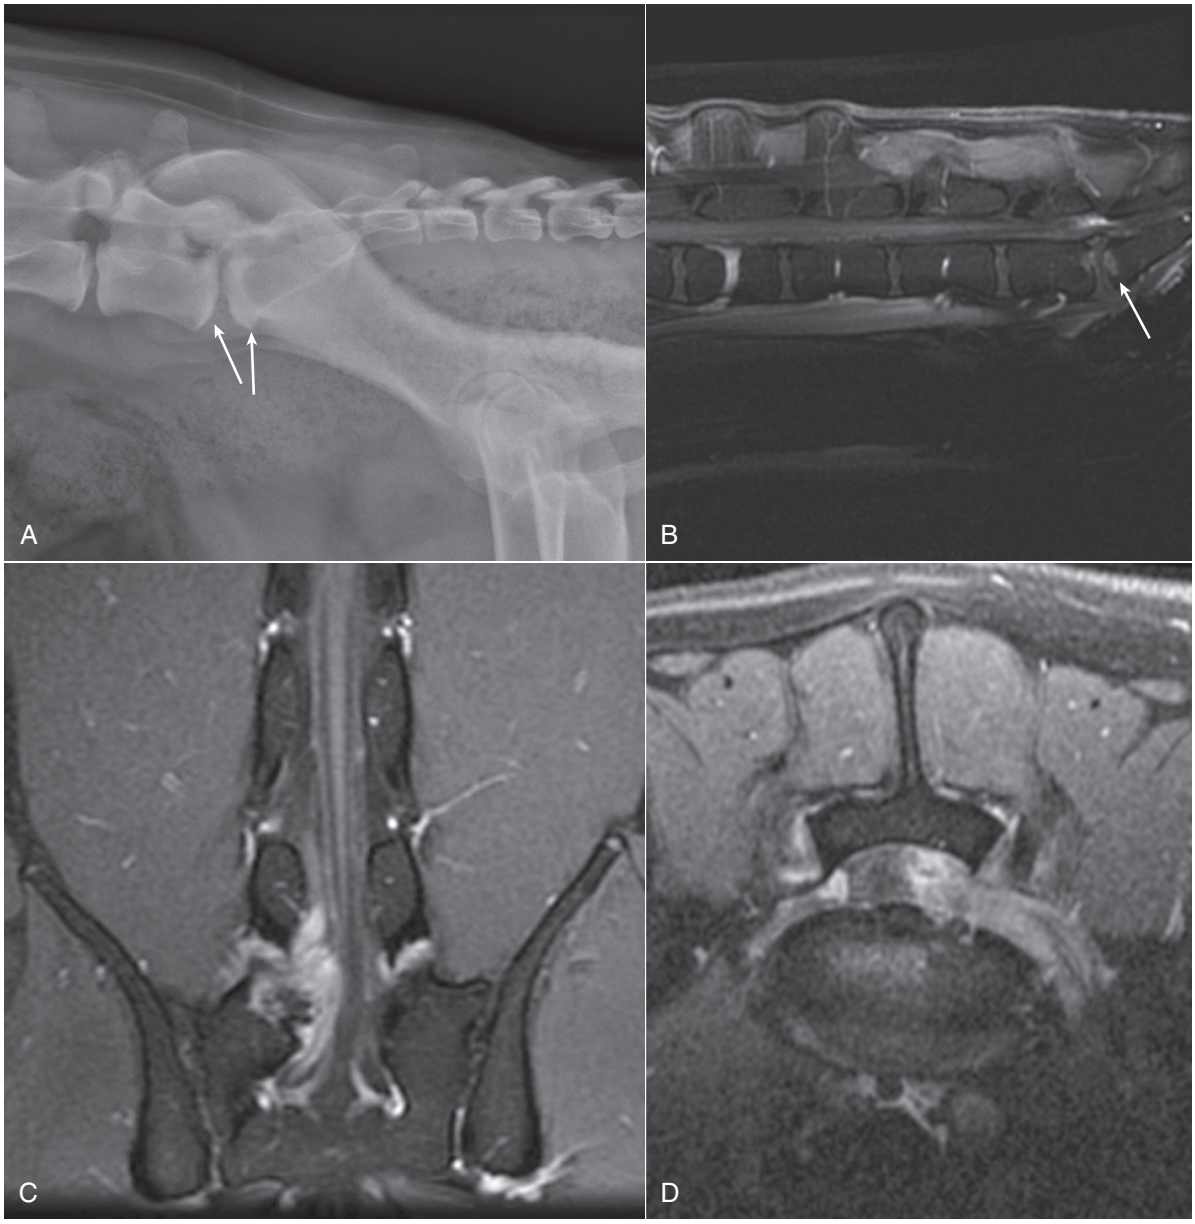

Fig. 121.8 Images from a 5-year-old intact male German shepherd dog with a history of progressive reluctance to jump over the previous 18 months. Neurologic examination revealed decreased pelvic limb placing reactions and lumbosacral pain. Blood cultures were negative. Clinical signs and radiographic lesions improved dramatically with cephalexin treatment. (A) Plain right lateral radiograph of the pelvis. The lumbosacral disc space is narrowed and there is vertebral endplate sclerosis *(arrows)*. There is also bony proliferation of the endplates at the level of the vertebral canal. (B) Sagittal T1-postcontrast magnetic resonance imaging with fat saturation, caudal lumbar and lumbosacral vertebral column. There is strong contrast enhancement in the endplates of L7 and S1 *(arrow)* on either side of the disc space. (C) Dorsal view. There is diffuse contrast enhancement of the tissues around the seventh lumbar nerve root with displacement of neural structures. (D) Transverse view. There is marked enlargement and strong uniform enhancement of the right seventh lumbar spinal nerve. The primary differential based on radiologic findings was chronic lumbosacral discospondylitis with regional soft tissue inflammation on the right, and severe neuritis of the right seventh lumbar nerve. The impingement of the right seventh lumbar nerve by contrast-enhancing material was thought to result from granulation tissue formation. (All images courtesy the University of California, Davis, Veterinary Neurology/Neurosurgery Service.)

Pathologic Findings

Gross pathologic findings in dogs with discospondylitis include the presence of pus and necrotic debris in the intervertebral disc spaces, irregularity and collapse of the disc spaces, and discoloration and friability of the vertebral endplates (Fig. 121.9). Protrusion of disc material and compression of the spinal cord may be apparent. There may also be evidence of bony callus material (ankylosing spondylosis). The nature of the inflammatory infiltrates on histopathology varies with the chronicity of the lesions and the underlying cause. For example, fungal discospondylitis may be associated with granulomatous or pyogranulomatous inflammation and intralesional fungal hyphae, whereas chronic bacterial discospondylitis lesions typically display neutrophilic

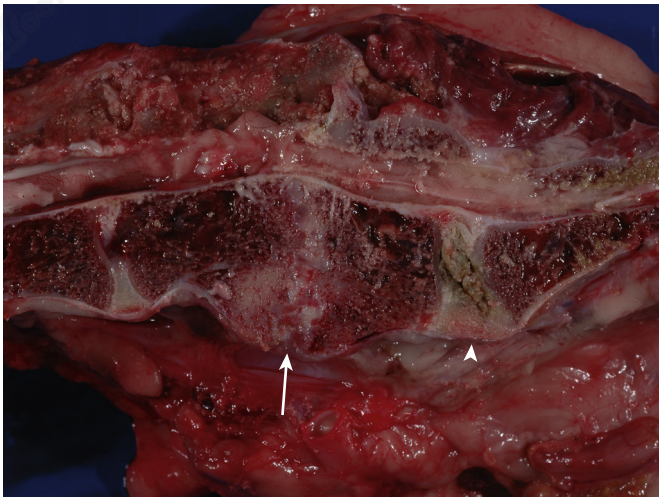

Fig. 121.9 Vertebral column of a 4-year-old female spayed German shepherd at necropsy that had multifocal discospondylitis caused by *Aspergillus* spp. The L6-L7 disc space *(arrow)* is collapsed with degenerate disc material, sclerotic endplates, and marked ventral proliferation of bone. The lumbosacral disc space *(arrowhead)* has an irregular annulus with friable, pale tan nuclear material that protrudes ventrally. (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

and lymphoplasmacytic infiltrates, with perilesional fibrosis and granulation tissue. Osteonecrosis may be present, as well as necrosis of the compressed spinal tissue.

TREATMENT AND PROGNOSIS

Treatment of discospondylitis involves prolonged antimicrobial drug treatment and strict restriction of movement for several weeks to prevent herniation of disc material or subluxation, with a gradual increase in movement once lesions have healed. It is important to stress to owners of dogs with discospondylitis that it is a serious, life-threatening condition. Analgesics such as fentanyl patches can also be administered provided they do not encourage excessive movement. NSAIDs may also be beneficial. Gabapentin may alleviate neurogenic pain and can be used with opioids and nonsteroidal drugs.[70]

The antibiotic chosen to treat discospondylitis should ideally be based on the results of culture and susceptibility. Treatment recommendations for dogs with *Brucella* discospondylitis are described in Chapter 71. Dogs with fungal discospondylitis should be treated with antifungal drugs that have activity against molds, such as voriconazole (if finances allow) or itraconazole (*not* fluconazole, which is not active against molds) with or without amphotericin B; prognosis is guarded, and lifelong treatment may be required (see Chapter 86). Dogs with culture-negative discospondylitis that have negative serum or urine *Aspergillus* galactomannan antigen tests should be treated with high doses of a drug with activity against susceptible staphylococci and *E. coli*, such as amoxicillin-clavulanic acid or cephalexin (see Table 121.2). Amoxicillin-clavulanic acid also has activity against penicillinase-producing anaerobes. However, occasionally gram-negative organisms such as *K. pneumoniae* or *P. aeruginosa*, and MRSP cause discospondylitis, and these may not respond to treatment with β-lactam drugs. Addition of a fluoroquinolone or an aminoglycoside should be considered if there is no improvement after 1 week of treatment with a β-lactam drug. Linezolid was used successfully in one case report to treat a dog with MDR MRSP discospondylitis.[71] Use of critical antimicrobials such as linezolid should be based on culture and susceptibility testing. For dogs that are systemically unwell or that have neurologic abnormalities, antimicrobials should be administered parenterally in the hospital for as long as possible (ideally at least 10 days) before changing to oral administration. Antimicrobial drugs should be administered for at least 6 to 8 weeks; in some cases, treatment may need to be extended for many months. In one study, the mean ± standard deviation for duration of antimicrobial treatment in dogs that were cured of discospondylitis was 54 ± 45 weeks; for dogs with staphylococcal infections, it was 74 ± 62 weeks.[1] Dogs with fungal discospondylitis may require lifelong treatment with antifungal drugs (see Chapter 86). Dogs should be reevaluated clinically and radiographically every 3 to 4 weeks. Improvement is characterized by resolution of bone lysis, sclerosis of bone, and vertebral fusion, although radiographic improvement can lag behind clinical improvement by 1 to 2 months, and there may be progression of osteolysis in addition to sclerosis and increased osseous proliferation within the first month.[63] It has been recommended that antimicrobial drug treatment be continued until lysis resolves completely, but whether this is truly needed is controversial. MRI may be the most sensitive imaging technique to confirm resolution of active infection, but requires general anesthesia. Imaging should also be performed 1 to 2 months after antimicrobial drugs are discontinued. If clinical deterioration occurs during treatment, additional imaging (ideally with MRI) should be offered to evaluate for development of new lesions, abscessation, subluxation, fracture, or disc protrusion.

Dogs with severe neurologic deficits (such as paralysis) may require decompressive surgery, debridement of abscesses or vertebral osteomyelitis, and stabilization of the vertebral column. Discospondylitis of L7-S1 may be a particular therapeutic challenge. Although antimicrobial therapy will produce an apparent initial cure, relapse will occur in about 25% of cases, possibly due to residual instability of the intervertebral articulation that predisposes the disc to reinfection or prevents total resolution of the original infection by interfering with neovascularization. Surgical distraction and arthrodesis of the articular facets between L7 and S1 is recommended by some clinicians in conjunction with antibacterial therapy.

Return of neurologic function can sometimes occur with antimicrobial drug treatment alone, provided deep pain is present. Decompressive surgery should be performed within 24 hours if deep pain is absent. Referral to a specialist surgeon is recommended in this situation. In one study, 9 of 27 dogs with discospondylitis received some form of decompressive surgery.[66] Physical therapy may also be beneficial in these animals.

PUBLIC HEALTH ASPECTS

The most important public health consideration in dogs with discospondylitis is the possibility of *Brucella* infection. Human disease has occurred as a result of contact with dogs with *B. canis* discospondylitis and is typically an influenza-like illness. The possibility of *B. canis* infection should be considered in all dogs with discospondylitis, and precautions such as routine hand washing, minimization of exposure to urine, and the wearing of gloves should be taken until appropriate diagnostic testing has ruled out *Brucella* as a cause.

ARTHRITIS

ETIOLOGIC AGENTS, PATHOGENESIS, AND EPIDEMIOLOGY

Infectious arthritis may be classified as *monoarthritis* or *polyarthritis*. Bacterial monoarthritis can follow orthopedic surgeries that involve the joint (such as TPLOs, arthroscopies, or joint arthrodesis), spread from soft tissue or bone infection at adjacent sites, or result from trauma or bite wound infections. Less commonly, monoarthritis follows systemic spread of bacteria to a single joint. Bacterial causes of

monoarthritis are similar to those involved in osteomyelitis; the most common causes are *Staphylococcus* spp., especially *S. pseudintermedius* but also *S. aureus* and CoNS. Other reported causes are *Streptococcus canis* and *Streptococcus equi* subsp. *zooepidemicus*, *E. coli*, and *P. aeruginosa*.[72,73]

Systemic spread of bacteria to the joints more often results in polyarthritis. Infection with a variety of bacteria, protozoa, fungi, and, rarely, viruses (West Nile virus in dogs, calicivirus in cats) have been associated with polyarthritis in dogs and cats. In areas where tick-borne infections are endemic, the most common bacterial causes are *Anaplasma phagocytophilum, Ehrlichia ewingii, Ehrlichia canis, Borrelia burgdorferi,* and *Rickettsia rickettsii,* but non–vector-borne bacteria such as *S. canis, S. aureus, Erysipelothrix, Salmonella, Brucella,* and mycoplasmas can also be involved. Although its importance as a cause of polyarthritis remains unclear, *Bartonella* should also be considered. Endocarditis is frequently (if not almost always) present in dogs with polyarthritis caused by facultative aerobic gram-positive and gram-negative bacteria, and among dogs with endocarditis, *S. canis* infections are most likely to be associated with polyarthritis. Worldwide, the most important cause of protozoal polyarthritis in dogs is *Leishmania*. Fungal polyarthritis is uncommon but can result from infection by dimorphic fungi and, very rarely, molds such as *Aspergillus.* Infectious polyarthritis is an important differential diagnosis for primary (idiopathic) immune-mediated polyarthritis (IMPA) in dogs. Although infectious polyarthritis is less common than primary IMPA, failure to identify an underlying infection can have disastrous consequences when treatment with immunosuppressive drugs is initiated. In some cases, polyarthritis is a secondary immune-mediated reaction to systemic infections that are not localized in the joint (in human medicine, a condition known as "reactive arthritis").

After bacterial localization in the joint, an acute inflammatory response occurs within the joint. There is a marked synovial effusion, causing increased intra-articular pressure, ischemia, and release or activation of cartilage matrix-damaging enzymes. Cartilage damage occurs quickly and, if severe, is irreversible. Glycosaminoglycan depletion occurs within the first 5 days followed by cartilage softening and fissuring. This leads to mechanical weakening of the subchondral bone, as well as the cascade of changes within the synovial fluid and articular cartilage. After recovery from infection, persistent inactivated antigens or bacterial fragments may perpetuate the inflammatory process.

CLINICAL FEATURES

Clinical signs of monoarthritis may be acute or chronic in onset and include variable fever, lethargy, inappetence, lameness that involves a single limb, and a swollen joint that may be erythematous, warm to the touch, and occasionally drain purulent or blood-tinged fluid (Fig. 121.10). The draining lymph node may be enlarged and firm. Occasionally, edema of the distal limb may be apparent. The most common joints affected in one study were the stifle and elbow joints, followed by the tarsi and coxofemoral joints, and signs developed within 2 to over 8 weeks after articular or periarticular surgery.[72] In polyarthritis, multiple peripheral joints are affected, and dogs (and less commonly cats) show signs of recumbency, reluctance to move, generalized peripheral lymphadenopathy, a stiff gait, and/or shifting leg lameness; drainage of fluid is not usually apparent. Dogs with bacterial polyarthritis can also show signs of severe sepsis.

DIAGNOSIS

Diagnosis of infectious arthritis is based on the history, clinical signs, and cytology and culture of joint fluid; serologic assays for *B. canis* and fungal pathogens; and/or molecular diagnostic and/or serologic testing for vector-borne pathogens in endemic regions. Blood cultures may also allow identification of the underlying etiology in dogs with bacterial polyarthritis. As for discospondylitis, dogs with bacterial polyarthritis should ideally be evaluated for evidence of disease at other sites with thoracic radiographs, spinal radiographs (for concurrent discospondylitis) and abdominal ultrasound, echocardiography (for endocarditis), and aerobic bacterial culture of the urine. However, it should be kept in mind that bacterial isolates made from urine may represent unrelated subclinical bacteriuria.

Fig. 121.10 Surgical site of a 5-year-old male neutered mastiff dog with non–weight-bearing lameness and a draining skin lesion that developed along the incision site approximately 1 month after a tibial plateau leveling operation. The right stifle was swollen and warm. Synovial fluid aspirated from the joint was red and turbid and contained 161,550 nucleated cells/μL (98% nondegenerate neutrophils) and 90,000 red blood cells/μL. Aerobic and anaerobic cultures of the fluid yielded a methicillin-resistant, multidrug-resistant *Staphylococcus pseudintermedius* that was resistant to all β-lactams, macrolides, and clindamycin, fluoroquinolones, and trimethoprim-sulfamethoxazole. The infection was treated successfully with joint exploration, lavage, and oral chloramphenicol for 8 weeks.

Laboratory Abnormalities

Routine laboratory testing in animals with bacterial arthritis typically shows leukocytosis due to a neutrophilia, which can be accompanied by bandemia. The CBC may also be normal. Thrombocytopenia may be present in dogs with bacteremia or vector-borne bacterial infections and should prompt diagnostic evaluation for vector-borne infections with PCR assays and serology, or at least assessment of response to treatment with doxycycline in the absence of client funds to pursue a diagnosis. Urinalysis may be normal or show pyuria, bacteriuria, proteinuria, and/or cylindruria in dogs with concurrent aerobic bacterial UTIs.

Synovial fluid from affected joints is often yellow or blood-tinged, cloudy, increased in volume, and thin or watery in consistency (normal synovial fluid is clear and tenacious). Cytologic examination of synovial fluid reveals increased numbers of leukocytes (>5000 cells/μL), with a predominance of nondegenerate and/or degenerate neutrophils. Importantly, in the majority of dogs with septic arthritis, degenerate neutrophils are not visualized,[72,73] so the presence of only nondegenerate neutrophils does not rule out an underlying bacterial infection. Rarely, bacteria or fungal organisms are visualized extracellularly or within leukocytes. Morulae are occasionally seen within neutrophils in synovial fluid of dogs infected with *A. phagocytophilum* or *E. ewingii* (see Fig. 45.1C).

Diagnostic Imaging

When changes are apparent, radiographs of the joints in dogs and cats with infectious arthritis most often reveal soft tissue swelling and joint effusion. In severe and chronic bacterial monoarthritis, associated osteomyelitis may be present, with subchondral bone lysis, articular erosion, and periarticular new bone formation.

Microbiologic Tests

Isolation and Identification

Confirmation of bacterial arthritis requires culture of synovial fluid or of the synovium itself. Synovial fluid from dogs with neutrophilic polyarthritis should be submitted for aerobic bacterial culture and susceptibility, and anaerobic, fungal, or *Mycoplasma* culture should at least be considered if the history is suggestive. Inoculation of blood culture bottles with synovial fluids followed by subculture may increase sensitivity. Situations in which anaerobic culture may be indicated include a history of foreign body (such as plant awn) exposure or bite wounds. Although rare, the possibility of *Mycoplasma* arthritis should be considered in cats and dogs with a history of immune compromise, surgery, or bite wounds, and when treatment with β-lactam drugs fails (see Chapter 57). Dogs with fungal polyarthritis may have lesions elsewhere (e.g., chorioretinitis, pulmonary disease) that support a diagnosis of disseminated fungal disease. However, anaerobic and *Mycoplasma* culture may be insensitive (especially when there are delays in specimen transport to the laboratory); *Mycoplasma* and fungal cultures require prolonged incubation; and anaerobes, fungi, and mycoplasmas tend to have predictable susceptibilities. Broad-spectrum 16S rRNA PCR has also been used to detect and speciate bacteria in synovial fluid from dogs, but in one study, it was not more sensitive than culture and yielded more false-positive results.[74] Aerobic blood cultures may assist in identification of bacteria involved in polyarthritis.

If arthroscopy or arthrotomy is performed as part of evaluation and treatment of bacterial monoarthritis, a biopsy of the synovium could also be submitted for culture and susceptibility and may yield growth when synovial fluid culture is negative.[73] In most cases, synovial fluid culture alone is sufficient for diagnosis of bacterial arthritis.

TREATMENT AND PROGNOSIS

Treatment of infectious arthritis depends on whether one joint is involved or whether polyarthritis is present, as well as on the identity of the causative agent. Infectious monoarthritis may require surgical exploration, lavage and drainage, and treatment with appropriate antimicrobial drugs based on the results of culture and susceptibility. Monoarthritis is considered a surgical emergency, and lavage should be performed immediately after diagnosis, either via an ingress-egress approach, an arthroscope, or with open surgery. For ingress-egress lavage, large-bore (14- to 16-G) needles are inserted percutaneously into two to three fluid pockets around the joint while the animal is heavily sedated or anesthetized. Several liters of sterile saline is then administered through one portal under pressure and allowed to drain from the other portal(s). The sites of ingress and egress are switched until the fluid becomes clear. Arthroscopy can also be used. Arthrotomy may be necessary if there are large accumulations of fibrin or inspissated purulent debris that cannot be effectively flushed from the joint. If implants are present, they should be removed when healing has occurred or if stabilization has failed. If the implant is stable but the bone has not healed, lavage is performed and the implant is often left in place because bone can heal if rigidly stable despite infection. Implant exchange is the "gold standard" in human medicine to decrease the bacterial load from the biofilm.[3] Cost may be prohibitive in animals and subjectively, many of the cases in animals will heal with rigid stability and can be removed later. Usually, the implant must ultimately be removed and should be done as soon as possible after healing. Antimicrobial drugs should initially be given parenterally if possible. Treatment should continue until implants can be removed if left in place. Once implants are removed, treatment may need to be continued for another 2 to 4 weeks, depending on the severity of infection. If local antibiotic therapy is used in associated osteomyelitis lesions (i.e., impregnated beads), systemic antimicrobial drug treatment should also be used. Activated mesenchymal stem cells IV can be considered as an adjunct therapy with antibiotics.[42] The prognosis depends on the degree of cartilage and bone destruction, the degree to which progressive osteoarthritis occurs, and the joint affected. Unfortunately, evidence-based clinical studies that document long-term prognosis or prognostic indicators for infectious monoarthritis are not available. In one retrospective study, dogs that fully recovered tended to have a shorter duration of lameness before treatment (median, 11 days compared with 26 days) and lower synovial fluid cell counts (median, 54×10^9 cells/mL compared with 100×10^9 cells/mL) than dogs that never fully recovered, and had significantly lower body weights (median, 29 kg compared with 44 kg).[72]

Polyarthritis caused by vector-borne bacteria usually responds to treatment with doxycycline within 24 to 48 hours. Antimicrobials for treatment of polyarthritis caused by other bacteria should be selected based on the results of cytologic examination of synovial fluid (cocci versus rods) and culture and susceptibility of blood or synovial fluid. Because streptococci, staphylococci, and *Erysipelothrix* are usually involved, a β-lactam drug such as amoxicillin-clavulanic acid (or amoxicillin if streptococci are more likely) could be used. Because bacterial polyarthritis is frequently associated with endocarditis or discospondylitis, the duration of treatment should be based on resolution of these lesions. The reader is referred to Chapters 122 and 123 for additional information on treatment of bacteremia and sepsis.

PUBLIC HEALTH ASPECTS

Polyarthritis can be caused by organisms of public health significance, such as *Salmonella, Brucella, S. aureus*, pathogenic fungi, *Leishmania,* and vector-borne bacterial pathogens of importance to human health. This should be kept in mind when handling dogs with polyarthritis. Care should be taken to avoid needle-stick injuries during venipuncture, arthrocentesis, and aspiration of other tissues such as lymph nodes. Deep sedation or anesthesia is recommended for arthrocentesis.

CASE EXAMPLE

Signalment

"Tilly," a 10-year-old female spayed greyhound/pit bull terrier mix from Davis, CA (Fig. 121.11).

History

Tilly was brought to the University of California, Davis, VMTH Orthopedic Surgery service, for evaluation of a draining tract on her left medial proximal tibia that developed after a TTA surgery for left cranial cruciate ligament tear. The ligament tear had been diagnosed at the VMTH 15 months previously after an acute onset of lameness, and the surgery was performed 2 months after diagnosis at another veterinary hospital after there had been no improvement with conservative management (activity restriction and anti-inflammatory drugs). Immediately after the surgery, the dog was placed on a 10-day course of doxycycline. The tract was first observed 2 weeks after the doxycycline course had finished, and the owner (a veterinary student) noted that the tract subsequently healed over, then drained again. When the wound initially appeared, treatment with doxycycline was reinstituted for a month, with no improvement. A radiograph of the limb was performed at the end of the course of treatment at the VMTH. Soft tissue swelling was identified at the medial aspect of the stifle, but there was no radiographic evidence of implant infection or motion. Regional osteopenia of the left tibial tuberosity and proximal tibia was present, and there was progressive left stifle osteoarthrosis. Culture of the wound yielded very small numbers of *S. canis* and a CoNS. The wound subsequently closed over again and antibiotic treatment was not initiated, but 11 months later the tract reappeared. Since the surgery, the incision had appeared healthy. Tilly had been bearing progressively more weight on the limb, although some lameness persisted. Other treatments had included activity restriction and carprofen (2 mg/kg, PO, q12h) for pain relief. Tilly had no other significant medical history apart from multiple lipomas that had been evaluated with FNA cytology, which had not changed in size.

Physical Examination

Body weight: 37.2 kg.

General: Bright, alert, responsive. T = 101.0°F (38.3°C), HR = 80 beats/minute, panting.

Eyes, ears, nose, and throat: No abnormalities were identified apart from moderate periodontal disease.

Musculoskeletal: Left pelvic limb lameness was present, but there was intermittent right pelvic limb lameness and muscle atrophy of both pelvic limbs. There was pain on extension of both coxofemoral joints. Examination of the left pelvic limb revealed a 1-cm, open round wound on the medial aspect of the proximal left tibia, which oozed serosanguineous fluid. A positive cranial drawer sign and tibial thrust were present.

All other systems: No clinically significant abnormalities were detected.

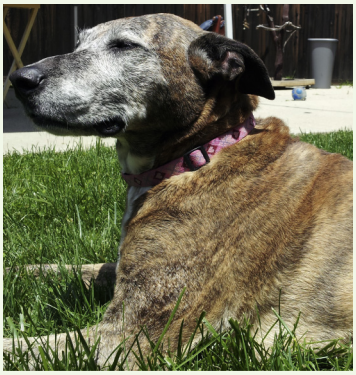

Fig. 121.11 Tilly, 10-year old female spayed greyhound–pit bull terrier mix that developed osteomyelitis at the site of a left tibial tuberosity advancement surgery.

Imaging Findings

Plain radiographs (pelvis): Bilaterally there was poor coverage of the femoral heads by the acetabulae. The femoral heads and necks were thickened and irregularly margined. There was periarticular osteophytosis of the acetabulae. Atrophy of the pelvic musculature was appreciated bilaterally although somewhat worse on the left than the right. Findings were consistent with bilateral hip dysplasia with severe degenerative change.

Plain radiographs (left stifle): The implants associated with the TTA procedure were in place and intact (see Fig. 121.5A and B). The osteotomy site had filled in with bone to some extent, although the site was still visible nearly its entire length, and bridging bone was absent at the proximal aspect of the osteotomy and around the basket implant. There was thinning of the cortical bone adjacent to the TTA plate that was associated with the tibial tuberosity and proximal tibial diaphysis, and mild lucency surrounded the medial aspect of the distal-most screw, which suggested implant-associated osteomyelitis. A gap was present between the bone plate and the tibia. Distal to the bone plates, there was smooth periosteal proliferation. The patella was displaced distally. There was moderate intracapsular soft tissue swelling of the stifle. There was also persistent, moderate periarticular osteophytosis of the distal femur and proximal tibia.

Diagnosis

TTA implant-associated osteomyelitis with incomplete union of osteotomy; severe canine hip dysplasia.

Treatment

Surgical exploration of the left stifle joint was performed. The draining tract was followed to the plate and screws. The TTA plate and screws were removed. The cage was removed by drilling around it, which left a 2-cm round defect in the tibia. During the procedure, it was discovered that a titanium plate had been used together with 316L steel screws, which led to concerns that osteomyelitis may have developed secondary to a galvanic reaction. The area was extensively flushed, and the defect was filled with calcium sulfate beads. Beads were also placed in the area previously occupied by the plate (see Fig. 121.5C). The fascia, subcutaneous tissue, and skin were closed, and a modified Robert-Jones bandage was placed. Aerobic and anaerobic bacterial cultures of the implant yielded small numbers of methicillin-susceptible *S. pseudintermedius*. The organism was resistant to ampicillin, penicillin, ticarcillin, and doxycycline. Tilly was therefore treated with amoxicillin-clavulanic acid (10 mg/kg, PO, q12h). At the time of suture removal 2 weeks later, Tilly was weight bearing on the left pelvic limb, and the draining tract had resolved. A small draining tract reappeared 2 weeks later, and a swab from the tract again grew *S. pseudintermedius* with the same antibiogram, but only from the enrichment broth. Treatment was continued for an additional month, all lesions resolved, and lameness was reduced. Several years later, the dog was doing well and there had been no recurrence of draining tracts (see Fig. 121.5D).

Comments

Diagnosis and treatment of osteomyelitis in this case was delayed because of the lag in radiographic changes and the appearance and disappearance of the draining tract. This illustrates the difficulties associated with diagnosis of osteomyelitis. Although unconfirmed, use of two different metals may have contributed to development of osteomyelitis in this dog, which required costly and difficult surgical intervention with implant removal. The defects were closed with biodegradable beads and infection resolved after 2 months of systemic antimicrobial drug treatment, based on the results of culture and susceptibility.

Cardiovascular Infections (Bacteremia, Endocarditis, Myocarditis, Infectious Pericarditis)

Steven E. Epstein, Joshua A. Stern, Jane E. Sykes

KEY POINTS

- Causes: Most common bacterial causes are staphylococci, streptococci, and *Escherichia coli.* Gram-negative bacterial etiologies predominate in cats. Culture-negative infections of the bloodstream may be caused by *Bartonella* spp. or other fastidious bacteria. Anaerobes, fungi, and mycobacteria are less commonly involved. *Rickettsia rickettsii* can cause vasculitis and myocarditis.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Highly variable. Fever, inappetence, lethargy, and tachycardia are common with sepsis. GI signs such as vomiting and diarrhea may also be present. Additional findings in infective endocarditis patients include cardiac murmurs, lameness, and neurologic signs due to thromboembolic disease. Spinal pain, paresis or paralysis may occur when discospondylitis complicates bacteremia or fungemia.
- Differential Diagnoses: Noninfectious conditions that can mimic sepsis include pancreatitis, trauma, hypoadrenocorticism, heat stroke, anaphylaxis, pulmonary thromboembolism, hemorrhage, cardiac tamponade, and some toxicities. Dogs with primary immune-mediated disorders may also show clinical signs that resemble those of chronic bacteremia and infective endocarditis. The major differential for infectious pericarditis is idiopathic or benign pericardial effusion and neoplastic disorders such as mesothelioma.
- Human Health Significance: Dogs and cats with cardiovascular infections may be infected with pathogens that have the potential to cause disease in humans, such as *Salmonella* spp., *Bartonella* spp., *Brucella* spp., and *R. rickettsii.*

ETIOLOGIC AGENTS, EPIDEMIOLOGY AND CLINICAL FEATURES

A variety of pathogens can cause infections of the cardiovascular system, including viruses, bacteria, fungi, protozoa, and parasites. This chapter focuses on bacterial infections of the cardiovascular system; information on other types of pathogens can be found in their respective chapters in this book. Bacterial infections of the cardiovascular system include bacteremia, infective endocarditis (IE), myocarditis, and infectious pericarditis. These infections are frequently associated with *sepsis*, or the host systemic inflammatory response to infection. Various terminologies are used to define the clinical manifestations associated with sepsis (see Chapter 123).

Bacteremia

Bacteremia has been defined as *uncomplicated* and *complicated bacteremia* (Table 122.1). Transient, low-level (≤10 CFU/mL) subclinical bacteremia follows a variety of procedures such as dental prophylaxis, endoscopy, GI surgery, and catheter placement. This is typically cleared rapidly (within 15 to 30 minutes) by a functional mononuclear phagocyte system. However, persistent release of large numbers of bacteria into the bloodstream can overwhelm the host immune response and culminates in clinically significant bacteremia. Overwhelming bacteremia can occur with disorders such as pyelonephritis, pyothorax, severe pyoderma, bacterial peritonitis, pyometra, pneumonia, pancreatitis, a variety of GI disorders, bite wounds, orthopedic infections, or catheter-related infections. Underlying immune system dysfunction (such as occurs with diabetes mellitus, malignancy, and neutropenia) also predisposes to clinically significant bacteremia because unhindered multiplication of bacteria occurs in the bloodstream.

The most common organisms isolated from the bloodstream of sick, bacteremic dogs are *Staphylococcus* spp., *Streptococcus* spp. (especially *Streptococcus canis*), and *Escherichia coli* (Table 122.2).[1] Less than 10% of bacteremic dogs in the authors' hospital are infected with anaerobes, but in a study of critically ill dogs and cats from Colorado, anaerobes were isolated from 31% of 39 dogs and 40% of 10 cats.[2] With the exception of bartonellosis, bacteremia is less commonly recognized in cats than in dogs, and usually results from infection with gram-negative bacterial pathogens.[1] Polymicrobial infections of the blood are common and typically occur in 10% to 20% of dogs and cats with positive blood culture results. Mixed infections with two or more different strains of a single bacterial species can also occur. Polymicrobial infections often occur when anaerobes are involved or secondary to compromise of the GI tract.

In addition to sepsis and septic shock (see Chapter 123), bacteremia may be followed by the development of IE, discospondylitis, and metastatic abscess formation in a variety of tissues. Chronic bacteremia may be associated with secondary immune-mediated disorders, especially immune-mediated polyarthritis and glomerulonephritis, and rarely IMHA. This can result in erroneous diagnosis of a primary immune-mediated disorder and inappropriate treatment with immunosuppressive drugs, sometimes with fatal outcome.

Infective Endocarditis

The reported incidence of canine IE has ranged from < 0.1% of cases evaluated by veterinary teaching hospitals to approximately 1% of cases evaluated by veterinary cardiologists.[3–6] IE is uncommonly diagnosed in cats; in one study, cats with IE represented < 0.01% of cats evaluated by a university teaching hospital.[7] Most cats were diagnosed with congestive heart failure (CHF) at the time of IE diagnosis and prognosis

TABLE 122.1 Definitions that Apply to Cardiovascular Infections in Dogs and Cats[a]

Term	Definition
Bacteremia	The presence of viable or cultivable bacteria in the bloodstream
Uncomplicated bacteremia	Positive blood culture results and the following: exclusion of endocarditis; no implants; negative follow-up cultures 2–4 days after the initial set; defervescence within 72 hours of initiation of effective treatment; and no evidence of metastatic sites of infection
Complicated bacteremia	Animals with positive blood culture results that do not meet the criteria for uncomplicated bacteremia
Fungemia	The presence of viable fungi in the bloodstream
Infective endocarditis	Infection of one or more endocardial surfaces of the heart; almost always involves a cardiac valve

[a]See Table 123.1 for definitions that apply to SIRS and sepsis.

was poor. Dogs with IE are typically middle aged to older, large-breed dogs such as German shepherd dogs, golden and Labrador retrievers, Weimaraners, mastiffs, and rottweilers. For unclear reasons, male dogs are affected approximately twice as often as females. Factors that predispose to IE are similar to those that predispose to continuous bacteremia. However, virulence factors possessed by bacteria subsequently impact whether IE develops, which explains why some bacterial species (especially gram-positive bacteria) are more likely to produce IE than others (gram-negative bacteria). Although congenital heart defects, especially subaortic stenosis (SAS), may predispose young dogs to development of IE, the vast majority of dogs with SAS never develop IE, and over 80% of dogs with IE have no identifiable underlying cardiac abnormality.[5,8] It remains unclear if the associated risk of IE in patients with SAS is related to the pathophysiology of this condition or simply an association secondary to the increased incidence of IE in large-breed dogs and a similarly increased incidence of this common, inherited heart disease in this population of large, sporting-breed dogs. Furthermore, IE is rarely diagnosed in small-breed dogs, which are predisposed to myxomatous mitral valve degeneration. The observed link between periodontal disease and IE in human subjects is less clear in dogs and cats. One study found no association between periodontal disease and IE in dogs.,[8] A 2016 investigation identified the same enterococcal pathogen from the mouth and IE lesions in 7 out of 32 dogs with IE and periodontal disease.[9] However, in 2021 this publication was retracted because of concerns about the validity of the results.[10]

The most commonly reported etiologic agents in canine IE are streptococci, staphylococci, and to a lesser extent, gram-negative rods, enterococci, and *Bartonella* spp. (Table 122.3).[4,8,11–13] Organisms that are less commonly incriminated include fungi, gram-positive rods, mycobacteria, and anaerobes. In dogs, the mitral and/or the aortic valves are most commonly affected (Fig. 122.1). The larger, septal leaflet of the mitral valve may be more commonly affected than the mural leaflet.[5] The tricuspid valve and ventricular wall are rarely involved. This distribution correlates with the degree of pressure that rests on the closed valve. Classically, vegetative lesions develop along the line of valve closure. In a case series of cats with IE, the aortic valve was affected 62% of the time while the mitral valve was affected in 38% of cats.[7]

The development of IE begins with colonization of a heart valve by bacteria, and deposition of fibrin, platelets, leukocytes, and erythrocytes. Colonization may be facilitated by changes in the valve surface as a result of turbulent blood flow, which in turn leads to the deposition of platelets, fibrin, and fibronectin; the end result is a sterile vegetation, or *nonbacterial thrombotic endocarditis*. Bacteria then adhere to this matrix, induce inflammatory cytokine and tissue factor release, and become covered with additional layers of platelets and fibrin, which promote bacterial growth to extremely high densities in an environment that is protected from the immune system. Properties of bacteria known to promote valve colonization include adhesins such as *fimA* in streptococci, and clumping factor and fibronectin-binding proteins in staphylococci,[14,15] as well as factors that cause platelet aggregation. Portions of the vegetation that results can then dislodge and embolize in a variety of different tissues, especially the kidneys, spleen, brain, joints, and muscles, with a huge spectrum of associated clinical manifestations. Thromboembolic complications are more likely to occur in dogs with mitral valve involvement than those with aortic valve IE.[5] Regardless of the valve affected, valvular dysfunction can lead to impaired cardiac output and CHF. CHF secondary to moderate to severe valvular insufficiency is a common sequela to IE in cats.[7]

As in humans, IE in dogs may be best classified on the basis of the etiologic agent involved, because the etiologic agent often determines the clinical course of disease, disease manifestations, prognosis, and the most appropriate antimicrobial drugs for treatment. For example, *Bartonella* IE is more likely to involve the aortic valve than the mitral valve; often occurs in the absence of fever; has a high prevalence of CHF when compared with IE caused by other bacterial pathogens; and is negatively correlated with survival (see Fig. 70.7). In contrast, *S. canis* IE usually involves the mitral valve and is often associated with neutrophilic polyarthritis. Dogs with gram-negative IE appear less likely to develop CHF than those with IE caused by other pathogens.[11]

The clinical signs and physical examination abnormalities that occur with IE are extremely variable and depend not only on the causative organism but also on the valve affected, the presence or absence of thromboembolic complications, and the sites and extent of thromboembolism. Common historic findings include lethargy; inappetence; locomotory problems such as lameness, shifting lameness, joint pain, reluctance to move, and inability to walk; as well as vomiting, respiratory difficulty, weight loss, and/or cough. Locomotory abnormalities can result from peripheral arterial thromboembolism, embolic or immune-mediated polyarthritis, neurologic abnormalities, and rarely, hypertrophic osteopathy. The most common initial physical examination findings in dogs with IE are fever, tachycardia, and a cardiac murmur (Table 122.4).[5] In one study of dogs with IE, fever was documented in the history or serial physical examinations of only 41 (60%) of 68 dogs with IE, and a cardiac murmur in 53 (76%) of 70 dogs with IE, so an absence of fever or a cardiac murmur does not make IE an unlikely diagnosis.[5] Although diastolic murmurs may be suggestive of IE, more than 90% of dogs with murmurs due to IE have systolic murmurs.

Infectious Myocarditis

Infectious myocarditis in dogs and cats usually results from hematogenous spread of microorganisms to the myocardium or extension of IE lesions to the myocardium. Viruses, bacteria, protozoa, or fungi may be involved. Certain organisms appear to have a particular tropism for the myocardium (Table 122.5). Infectious myocarditis is rare in cats.

Myocarditis may be subclinical or result in a variety of arrhythmias, CHF, or sudden death. Simultaneous infection of a variety of other organs is frequent for the majority of pathogens that cause myocarditis, so clinical signs of systemic infection (fever, lethargy) and other organ dysfunction are often present. In one case series of dogs with myocarditis, fever was present in 21% of dogs and a heart murmur in 19%.[16] Definitive diagnosis is often only made at necropsy.

TABLE 122.2 Organisms Cultivable Using Routine Blood Culture from Dogs and Cats with Bacteremia[1,2,11]

	Dogs	Cats
Common (>10% of isolates)	*Staphylococcus* spp., including *S. pseudintermedius, S. aureus,* and coagulase-negative staphylococci *Streptococcus* spp., especially *S. canis,* but also *S. bovis* complex organisms and rarely other streptococci *E. coli*	*Escherichia coli* Other Enterobacterales (*Klebsiella pneumoniae, Citrobacter freundii, Enterobacter cloacae*) Anaerobes
Uncommon (1% to 10% of isolates)	*Enterococcus* spp. *K. pneumoniae, Serratia* spp., *E. cloacae* *Pasteurella canis* and *Pasteurella dagmatis* *Pseudomonas aeruginosa* Anaerobes (*Clostridium perfringens, Prevotella* spp., *Bacteroides* spp., *Fusobacterium* spp., *Actinomyces* spp., *Peptostreptococcus* spp.)	*Salmonella* spp. Non-Enterobacterales gram-negative bacteria (*Pasteurella multocida, Pseudomonas aeruginosa, Acinetobacter baumanii*) Staphylococci Streptococci
Rare (≤1% of isolates)	*Erysipelothrix* spp. *Brucella* spp. *C. freundii* *Acinetobacter* spp. *Salmonella* spp. *Mycobacterium* spp. *Campylobacter* spp. Other nosocomial pathogens, e.g., *Ralstonia pickettii, Burkholderia cepacia, Achromobacter xylosoxidans*	*Enterococcus* spp.

TABLE 122.3 Causes of Infective Endocarditis in Dogs

Microorganism	Prevalence[11]
Streptococci (primarily *S. canis* but also *S. bovis* complex)	29%
Bartonella spp.	20%
Staphylococci (*S. pseudintermedius, S. aureus,* and coagulase-negative staphylococci)	15%
Gram-negative rods (most commonly *Escherichia coli,* but also *Pseudomonas aeruginosa, Salmonella* spp., *Citrobacter freundii, Klebsiella pneumoniae, Proteus* spp., *Pasteurella* spp., *Brucella* spp.)	15% (7% *E. coli*; < 5% other species)
Other gram-positive bacteria (*Erysipelothrix* spp., *Granulicatella adiacens, Actinomyces* spp., *Corynebacterium* spp., *Mycobacterium* spp.)	7% (<5% each species)
Enterococcus spp.	5%
Fungi (e.g., *Aspergillus* spp.)	<5%

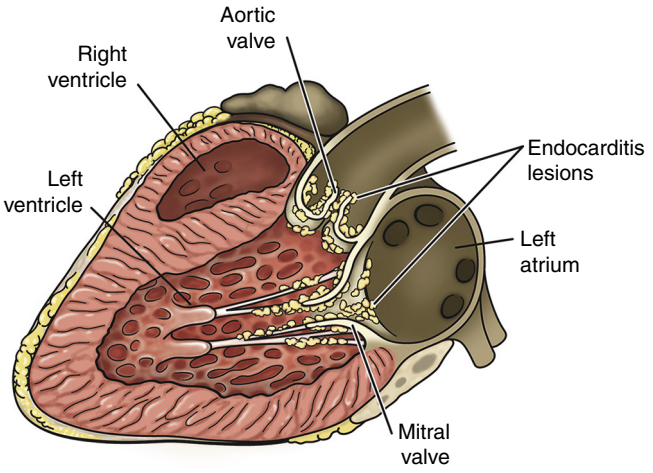

Fig. 122.1 Infective endocarditis. Vegetations are attached to the mitral and aortic valves and may be mobile or sessile.

Infectious Pericarditis

Infectious pericarditis may result from direct inoculation of organisms into the pericardium (such as occurs with penetrating wounds),[17,18] extension of infection from adjacent organs such as the pleural space or lungs, or hematogenous dissemination of viral, bacterial, protozoal, or fungal pathogens to the pericardium. Bite wounds or grass awn migration often result in mixed aerobic-anaerobic infections that involve organisms such as *Actinomyces* spp. (see Chapter 59). Infectious pericarditis as a result of hematogenous spread of pathogens is rare. Idiopathic pericardial effusion and heart base neoplasia are the most common causes of inflammatory or hemorrhagic pericardial effusion in dogs; neoplasia and hypertrophic cardiomyopathy were the most common causes of pericardial effusion in cats in one study.[19] Pathogens with particular tropism for the pericardial sac include FIP virus and *Coccidioides* spp. Pericardial effusion was also reported in association with *Leishmania* infection.[20] Pericarditis results in diastolic cardiac dysfunction with subsequent development of right-sided heart failure, which is manifested as weak pulses, tachycardia, jugular venous pulsation or distension, ascites, and pleural effusion. Muffled heart sounds may be detected on cardiac auscultation as a result of pericardial and/or pleural effusion.

DIAGNOSIS

Antemortem diagnosis of bacteremia is based on culture of bacteria from the bloodstream. Reasons to consider blood culture are shown

TABLE 122.4 Physical Examination Findings in 70 Dogs with Infective Endocarditis Seen at the University of California, Davis William R. Pritchard VMTH[a]

Physical Examination Finding	Number Affected (%)
Cardiac murmur	41 (59)
Tachycardia	34 (50)
Fever	26 (38)
Tachypnea	24 (35)
Abnormal lung sounds	24 (34)
Recumbency	21 (30)
Mental dullness	19 (27)
Neurologic signs (ataxia, decreased conscious proprioception, strabismus, nystagmus, head tilt, obtundation)	16 (23)
Swollen joints	15 (21)
Stiffness or lameness	13 (19)
Arrhythmias	14 (19)
Dehydration	11 (16)
Bounding pulses	10 (14)
Muscle atrophy	10 (14)
Thin body condition	9 (13)
Weak pulses	8 (11)
Reluctance to stand	8 (11)
Peripheral edema	7 (10)
Spinal pain	7 (10)
Abdominal pain, mucosal pallor, red mucous membranes, muscle pain, weakness, cyanosis, cool or cold limbs, oral ulceration, abdominal enlargement, hepatomegaly, icterus, uveitis, petechial or ecchymotic hemorrhages, cutaneous ulceration	6 or fewer (< 10)

[a]Cases seen at the University of California-Davis Veterinary Medical Teaching Hospital.

	Neospora caninum	D
	Hepatozoon americanum	D
	Toxoplasma gondii	D, C

C, cats; *D,* dogs.

BOX 122.1 Reasons to Consider Blood Culture in Dogs and Cats

- Fever (especially when viral infection is not likely or underlying immunosuppression or barrier disruption is present)
- Unexplained peripheral edema in dogs
- Evidence of thromboembolism in dogs (e.g., organ infarction, cold limbs)
- Neutrophilic polyarthritis in dogs
- Discospondylitis in dogs
- Echocardiographic evidence of infective endocarditis or new heart murmur (dogs or cats)
- Neutrophilic lymphadenitis (dogs or cats)
- Severe pneumonia or pyothorax (dogs or cats)
- Peritonitis (dogs or cats)
- Development of leukopenia, bandemia or leukocytosis in association with immunosuppression, catheters or other devices (dogs or cats)
- Thrombophlebitis in association with an indwelling catheter (dogs or cats)
- Sepsis in a patient from which a culture cannot be obtained from the suspected source (e.g., pneumonia in severely hypoxemic patient, GI bacterial translocation)

in Box 122.1. The diagnosis of IE is based on a set of criteria modified from the Duke criteria used for diagnosis of IE in human patients, which consider the results of blood culture and echocardiography as major criteria, and other clinical manifestations of IE as minor criteria (Table 122.6). Diagnosis of infective pericarditis relies on echocardiography and the results of cytologic examination and culture of pericardial fluid, or alternatively, histopathologic examination and culture of pericardial biopsies obtained during thoracotomy or thoracoscopy. In dogs and cats, infectious myocarditis is usually a necropsy diagnosis because myocardial biopsy is rarely performed. However, bacterial myocarditis may be suspected based on echocardiographic abnormalities, the presence of arrhythmias, increased serum cardiac troponin I, concentration and positive blood cultures or serologic testing.

Laboratory Abnormalities

Complete Blood Count

Common CBC findings in dogs and cats with bloodstream infections are mild nonregenerative anemia, neutrophilia with a left shift and neutrophil toxicity, bandemia, lymphopenia, and/or monocytosis. Degenerative left shifts may be present, and dogs and cats with DIC may be thrombocytopenic or have evidence of schistocytosis. Rarely, bacteria may be seen within circulating leukocytes on blood smear examination.

Serum Biochemical Tests

The serum chemistry profile may show evidence of sepsis, or bacterial embolization and infarction. Abnormalities include azotemia, increased activities of liver enzymes, mild to moderate hyperbilirubinemia

TABLE 122.6 Modified Duke Criteria Used for Diagnosis of Infective Endocarditis in Dogs and Cats[5,28]

Major Criteria	Minor Criteria
Identification of a typical organism using blood culture • *Streptococcus* spp. • *Staphylococcus* spp. • *Escherichia coli*	Predisposing heart condition (congenital valvular malformation) New or worsening heart murmur Fever (≥103°F [39.4°C]) Presence of vascular/embolic phenomena
Growth in all 3, or most of 4, separate blood cultures, with first and last specimens drawn at least 1 hour apart	Immunologic phenomena: nondegenerate neutrophilic polyarthritis, glomerulonephritis, immune-mediated hemolytic anemia
Two positive blood cultures for any microorganism, when blood cultures are drawn more than 12 hours apart	Microbiologic phenomena: positive blood culture not meeting major criteria, *or* serologic evidence of infection with a typical organism, *or* detection of a typical organism using a nucleic acid amplification test
Findings on echocardiogram positive for infective endocarditis	

Definite endocarditis: 2 major criteria, or histopathologic confirmation of endocarditis.
Possible endocarditis: Positive echocardiographic findings and 1 minor criteria, or 1 major and 3 minor criteria, or 5 minor criteria. In recent human guidelines, 1 major and 3 minor criteria, or 5 minor criteria, are considered sufficient evidence for diagnosis of definitive endocarditis.[24]

(usually < 5 mg/dL), and electrolyte and acid-base abnormalities (such as a high anion gap metabolic acidosis due to azotemia or lactic acidosis). Hyperglycemia may be present early in sepsis in cats while hypoglycemia may develop in either cats or dogs. Hypoglycemia may also be present as a result of decreased hepatic gluconeogenesis or upregulation of non–insulin-dependent glucose transporters. Hypoalbuminemia occurs in most dogs with IE, ranges from mild to severe, and may result from decreased hepatic production, increased vascular permeability, or as part of the inflammatory response (albumin is a negative acute-phase reactant protein). Dogs with thromboembolism to muscle tissue may have markedly increased activity of serum CK.

Urinalysis

Urinalysis findings in dogs and cats with bacteremia or IE may include proteinuria, pyuria, cylindruria, microscopic hematuria, and bacteriuria. Severe proteinuria (urine protein-to-creatinine ratio > 5) may occur as a result of glomerular damage in dogs with IE which may contribute to a hypercoagulable state.

Coagulation Profile

Dogs and cats with DIC may have prolonged aPTT and PT, increased concentrations of fibrin degradation products or D-dimers, and/or decreased concentrations of plasma fibrinogen and antithrombin. If viscoelastic testing is used, either hyper- or hypocoagulability may be documented in dogs.[21] In dogs with IE, PT is often shortened, and fibrinogen concentration is often increased.[5]

Cardiac Biomarkers

A large body of evidence has accumulated to support that cardiac biomarkers, such as the N-terminal fragment of the prohormone B-type natriuretic peptide (NT-proBNP) and cardiac troponin I, represent biochemical tests with acceptable sensitivity and specificity for the diagnosis of myocardial injury, stress, or stretch.[22,23] Serum cardiac troponin I is a useful, quantitative assessment of myocardial injury. Although not specific for endocarditis or myocarditis, one study showed that serum cardiac troponin I concentrations were significantly higher in dogs with IE (n = 29) than dogs with stage-B myxomatous mitral valve disease (n = 27) and dogs with immune-mediated disease (n = 16).[25] A cut-off value of 0.625 ng/mL had 100% specificity and 52% sensitivity for diagnosis of IE in that study. Severe myocardial injury such as myocardial infarction and myocarditis is commonly associated with significantly increased concentrations of serum cardiac biomarker molecules. However, a small percentage of dogs with myocarditis may have normal serum cardiac troponin I concentrations.[16] Ultimately, increased concentrations of cardiac biomarkers supports a diagnosis of cardiovascular infection but is not required for diagnosis.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with IE often show no detectable abnormalities. When present, abnormal findings include pulmonary infiltrates as a result of pneumonia, ARDS or CHF; generalized cardiomegaly; left atrial enlargement; pulmonary venous distension; mild pleural effusion; and occasionally, even microcardia or vascular attenuation (see Fig. 70.10). Infectious pericarditis may be associated with radiographic evidence of pleural effusion or cardiomegaly. Changes to the intervertebral disc spaces that suggest discospondylitis may also be detected in dogs with bacteremia or endocarditis (see Chapter 121).

Echocardiography

Echocardiography is indicated when IE, myocarditis, or pericarditis is suspected based on the history and physical examination findings (such as fever, arrhythmia, a new murmur, or signs of left- or right-sided CHF). It is also indicated for all dogs and cats with bacteremia, even in the absence of a cardiac murmur or arrhythmia; for dogs with neutrophilic polyarthritis; and for dogs and cats with evidence of systemic thromboembolic disease. Echocardiographic findings in IE can include valvular hyperechogenicity, thickening and irregularity, and valvular vegetations, which may be nodular, discrete, or have a shaggy or moth-eaten appearance (Fig. 122.2 and see Fig. 70.13). Large vegetations may oscillate or vibrate, and follow-up echocardiography sometimes reveals disappearance of a vegetative lesion in association with thromboembolism. Mild or severe valvular regurgitation or insufficiency may be present in association with lesions. Other echocardiographic findings include left ventricular eccentric hypertrophy, chamber dilation, mural hyperechogenicity, ruptured chordae tendineae, acquired defects in the valves or myocardium, and mild pericardial effusion. Echocardiography is a sensitive tool for diagnosis of IE (87.5% in one study of dogs with IE when necropsy was used as the gold standard),[5] but negative results do not completely rule out the possibility of IE. Echocardiography is also useful for monitoring treatment of IE (see Treatment).

Echocardiographic findings in infectious pericarditis include pericardial effusion, adhesions of the pericardium to the epicardium, and sometimes focal or diffuse pericardial thickening and hyperechogenicity (Fig. 122.3). Restrictive disease is characterized by impairment of diastole, with decreased left ventricular internal dimensions during diastole, and variation of blood flow velocity across the mitral valve with the respiratory cycle (increased with expiration and decreased with inspiration). In addition, deviation of the interventricular septum

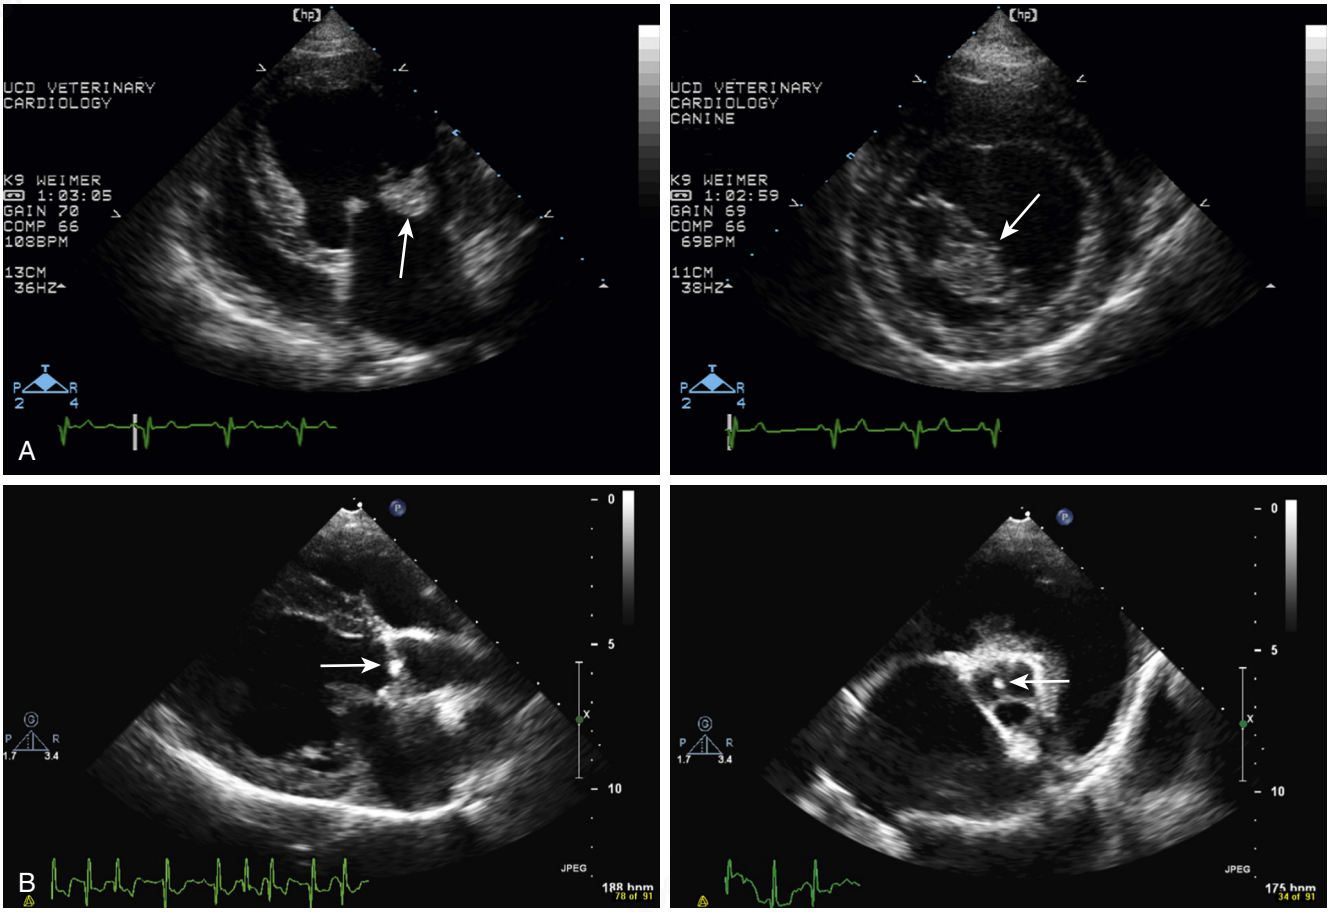

Fig. 122.2 Canine endocarditis lesions as viewed using transthoracic echocardiography. (A) Right parasternal (left) and short axis (right) views from a 7-year-old male neutered Weimaraner with *Enterococcus faecium* endocarditis that followed a perineal urethrostomy procedure. There is a large vegetative lesion attached to the anterior leaflet of the mitral valve *(arrow)*. A smaller lesion is attached to the septal leaflet. (B) Right parasternal (left) and short axis (right) views of the aortic valve from a 4-year-old intact male Doberman pinscher with aortic and mitral valve culture-negative endocarditis. A nodular, hyperechoic lesion is associated with the aortic valve *(arrow)*.

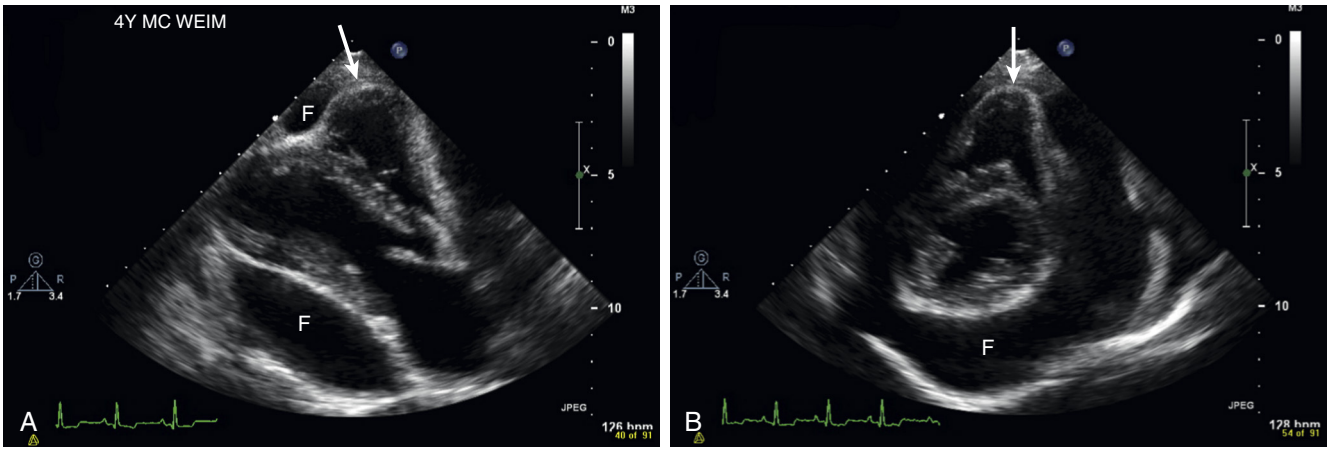

Fig. 122.3 Long axis (A) and short axis (B) echocardiography images that show pericarditis in a 4-year-old male neutered Weimaraner with disseminated coccidioidomycosis. The epicardium is adhered to the pericardium *(arrow)* and a moderate quantity of anechoic pericardial fluid *(F)* can be appreciated. The cardiac chambers are distorted.

into the left ventricle can occur during inspiration and right ventricle during expiration. Echocardiographic findings in myocarditis may include a heterogeneous appearance to the ventricular myocardium, systolic dysfunction, and volume overload.[16] Regional septal or free-wall motion abnormalities may be seen in areas of more severe ischemia or infarction.

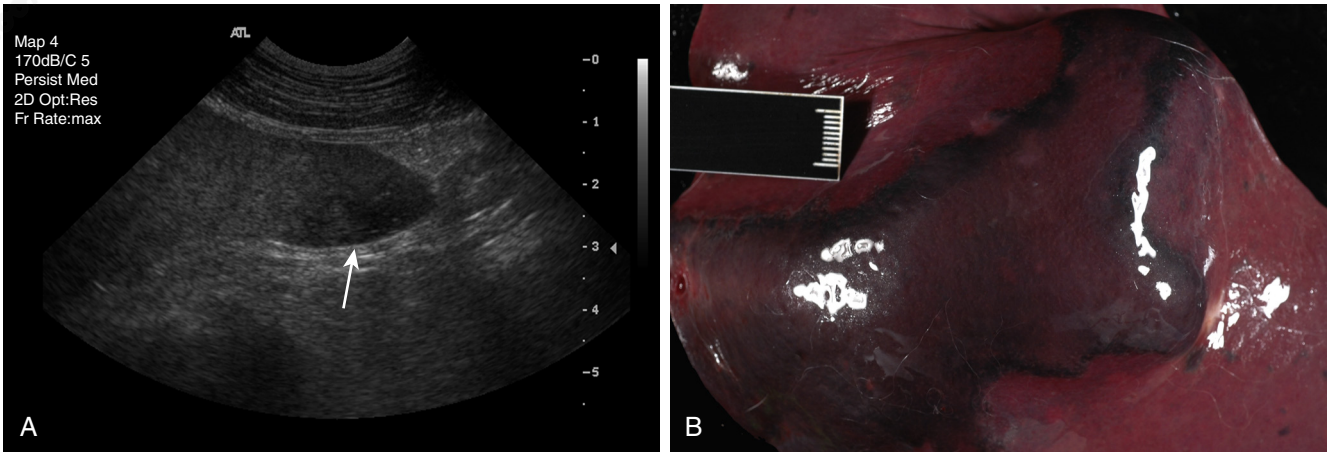

Fig. 122.4 (A) Abdominal ultrasound image that shows a splenic infarct *(arrow)* in a 6-year-old female spayed Bouvier des Flandres with *Staphylococcus aureus* infective endocarditis. (B) Splenic infarct at necropsy.

Abdominal Sonographic Findings

Sonographic abnormalities may be present in a variety of organs in dogs with IE, and may reflect underlying disease processes (such as neoplasia or bacterial peritonitis) or septic thromboembolism. Infarction and hemorrhage secondary to thromboembolic disease may result in focal cavitary or hypoechoic lesions in the spleen (Fig. 122.4) or focal hyperechoic or hypoechoic lesions in the kidney. Thrombi may be found in the iliac arteries or aorta.

Microbiologic Tests

Culture

Routine blood cultures assist in identification of infecting pathogens and permit susceptibility testing. Ideally, at least three blood cultures should be obtained from separate sites within a 24-hour period. A suggested protocol for blood cultures is outlined in Chapter 3 (Box 3.2). Although the use of separate venipuncture sites has been suggested, this is not considered essential for diagnosis of human IE; however, the use of indwelling catheters should be avoided.[24] If a catheter-related bloodstream infection is suspected, collection of paired specimens has been recommended in humans, with one specimen collected from the catheter prior to removal and the other collected from a peripheral site.[26] The skin should be prepared in the same manner used for surgery, and utmost care should be taken to avoid contamination with commensal bacteria. Because IE is generally associated with continuous bacteremia, positive results in a single bottle should be interpreted with caution. Positive results for *Bacillus* spp. or coagulase-negative staphylococci in a single bottle generally reflect contamination.

The decision to perform anaerobic blood culture should be considered in light of the animal's underlying disease process and client financial constraints. For example, anaerobic culture may not be cost effective in dogs with IE, given the rare involvement of anaerobes in this condition. Anaerobes are more likely to be present in dogs with histories that suggest involvement of plant awn foreign bodies, bite wounds, GI, or biliary tract compromise.

False-negative blood cultures may occur as a result of low-level bacteremia or fungemia, the presence of fastidious or unculturable organisms such as *Bartonella*, insufficient specimen size, or recent antimicrobial treatment. Nevertheless, blood culture is still indicated in animals with a history of antimicrobial treatment, especially if antimicrobials have only been administered for 2 to 3 days. If an animal with IE is in stable condition, discontinuation of existing antibiotic treatment for several days (ideally 7 to 10 days) could be considered before blood cultures are obtained. Specific culture and serology for *Bartonella* is also indicated in dogs and cats with IE or suspected myocarditis (see Chapter 70). This should be considered even if routine blood cultures are positive, because polymicrobial infections that include *Bartonella* spp. and other bacteria can occur.[11] Special media used to isolate *Bartonella* spp. (*Bartonella* alpha-Proteobacteria growth medium [BAPGM]) may also yield other fastidious bacteria such as *Sphingomonas* spp., the clinical significance of which requires further study.[27] Serologic testing for *Brucella* antibody and *Aspergillus* antigen could also be considered for dogs with culture-negative IE (see Chapters 71 and 86, respectively).

Attempts should also be made to isolate causative organism(s) from other sites that are suspected to be a source of infection based on the history and clinical findings. Appropriate specimens could include transtracheal or bronchoalveolar lavage specimens, urine, ascites fluid, wounds, or pleural effusion. UTIs may reflect ascending pyelonephritis or spread of bacteria from the blood into the urine. However, bacteria cultured from the urine may not always reflect those present in the bloodstream,[11] so blood cultures should always be performed even when urine cultures are positive. Isolation of the same organism from the blood as well as an additional site facilitates interpretation of the significance of a single positive blood culture and aids decisions regarding appropriate antimicrobial drug treatment.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays have been used to rapidly detect bacterial DNA within whole blood and especially valvular tissue (obtained at necropsy) of animals with IE, and are especially useful for detection of fastidious bacteria such as *Bartonella* spp. within the heart valves (see Chapter 70). These assays use broad-range primers that target bacterial 16S ribosomal subunit DNA, and the identity of the organism is determined by sequence analysis of resulting PCR products.

In one prospective study that examined the performance of a conventional broad-range bacterial PCR assay on whole blood for diagnosis of the etiology of IE in 18 dogs, there was no difference in the overall sensitivity of the PCR assay and culture, but the combined use of the PCR assay and blood culture was more sensitive than the use of either assay alone.[28] This was because the PCR assay detected several fastidious organisms, which included *Bartonella vinsonii*, *Brucella*, and *Granulicatella adiacens*, but appeared less sensitive than culture for detection of less fastidious organisms such as streptococci. Studies that include larger numbers of dogs and cats, and that examine the

performance of other PCR assays such as real-time PCR assays are required before broad-range bacterial PCR can be recommended for routine diagnosis of bacteremia and IE in dogs and cats, but they show promise when used in conjunction with blood cultures. Of major concern is the possibility of false positives with highly sensitive PCR assays due to detection of contaminating bacteria. Even in human medicine, evidence is considered insufficient to recommend the routine use of whole blood or serum real-time PCR assays for the diagnosis of culture-negative IE.[24]

Pathologic Findings

There are no specific pathologic findings in sepsis or bacteremia, but underlying causes such as pneumonia, pyometra, or peritonitis may be apparent. Microabscesses may be present in multiple tissues of animals with bacteremia. Isolation of the same bacterial species from multiple different tissues is supportive of a diagnosis of bacteremia. Pathologic findings in IE include valvular vegetations; avulsion or perforation of valvular structures; and gross and histopathologic evidence of infarction, widespread thrombosis, and CHF (Fig. 122.5). The inflammatory process may be chronic, with lymphoplasmacytic and histiocytic cell infiltrates and fibrosis; or acute, suppurative, and fibrinous, with or without microscopically visible intralesional bacteria (see Fig. 50.7). *Bartonella* IE is characterized by chronic inflammation and may be associated with valvular mineralization (see Fig. 70.14), whereas IE due to other microorganisms may be acute or chronic, and is rarely associated with valvular mineralization.[11] Use of tissue Gram stains and silver stains can reveal the presence of organisms within valvular vegetations. Necrotizing vasculitis may also be present in organs such as the lungs, myocardium, kidney, spleen, liver, and/or brain. Erythrophagocytosis has been described in reticuloendothelial tissues of dogs with IE due to gram-positive cocci. Membranoproliferative, membranous, or necrosuppurative glomerulonephritis may also be identified.[5]

Gross examination of the heart of animals with myocarditis may reveal focal or multifocal areas of myocardial pallor and/or friability. Histopathologic characterization of myocarditis in dogs showed that the most frequent type of inflammation present in the myocardium was lymphoplasmacytic, although granulocytic and eosinophilic inflammation may also be present.[29] The pericardium of dogs and cats with pericarditis may be thickened and discolored, and pericardial effusion may be present. Histopathology reveals acute or chronic inflammatory infiltrates, depending on the underlying cause, sometimes with intralesional bacteria or fungi.

TREATMENT AND PROGNOSIS

The mainstay of treatment of bacteremia, IE, sepsis, and bacterial myocarditis or pericarditis is early antimicrobial drug treatment. The initial choice of antimicrobial drugs should be based on knowledge of the prevalent bacterial species and their antimicrobial drug susceptibilities for each hospital and/or geographic region, as well as the likely source of infection (which provides information about the likely bacterial species involved) (Tables 122.7 and 122.8). The presence or absence of IE and/or sepsis also affects treatment recommendations. The treatment of sepsis and septic shock is covered in detail in Chapter 123.

In addition to antimicrobial drug therapy, the underlying cause of infection or chronic bacteremia should be identified and removed if possible. All catheters or devices should be removed and replaced at new sites if they are still needed. An attempt should be made to locate foreign bodies such as grass awns with imaging techniques and surgically remove them. Surgery may be required to resolve GI compromise,

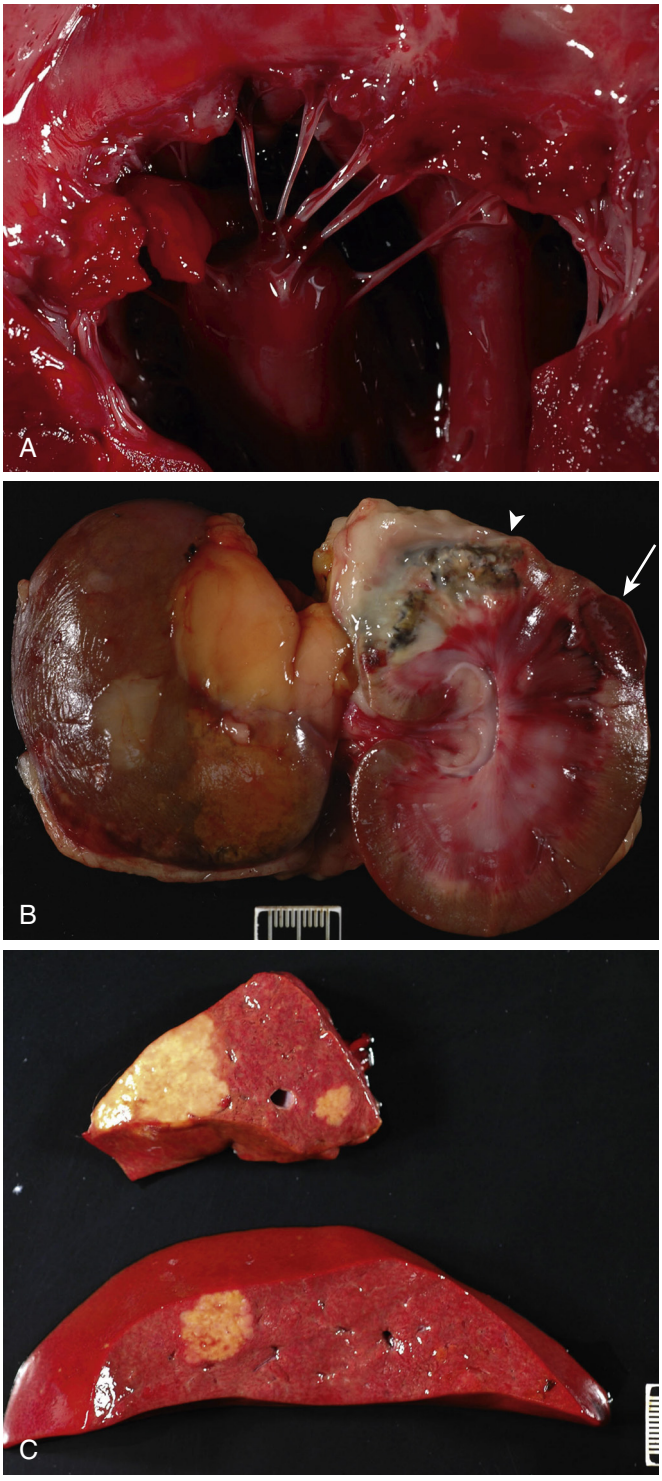

Fig. 122.5 Gross pathology findings in a 12-year-old male neutered Irish water spaniel with *Enterococcus durans* infective endocarditis and widespread thromboembolic disease. (A) Mitral valve. The leaflets are thickened and nodular. (B) Left kidney. Multiple, variably sized, well-demarcated red foci with dark red rims and numerous well-demarcated tan slightly depressed foci are present. On cut surface, these foci extend to and beyond the corticomedullary junction as wedge-shaped lesions *(arrow)*. On one pole there is a 2.0 cm × 1.5 cm × 1.4 cm tan to brown-green abscess *(arrowhead)*. (C) Spleen. Several well-demarcated lesions that measured 0.3 to 0.5 cm in diameter are present. (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

TABLE 122.7 Suggested Empiric Antimicrobial Drug Choices for Intravenous Use in Dogs and Cats with Severe Sepsis or Septic Shock[a]

Antimicrobial Drug	Spectrum	Suspected Source of Infection	Comments
Ampicillin or clindamycin AND an aminoglycoside[b]	Activity against gram-negative bacteria, MRS, streptococci, enterococci, and most anaerobes.	Urinary tract, abdomen	Good first choice for most infections, except when the respiratory tract is involved. Consider use of ampicillin-sulbactam instead of ampicillin or addition of metronidazole if infection with penicillinase-producing anaerobes is possible (e.g., gastrointestinal compromise or plant foreign body, IE absent).
Ampicillin or clindamycin AND a fluoroquinolone	Active against most anaerobes, streptococci, susceptible staphylococci, and aerobic gram-negative rods. Not active against some MRS, enterococci, and MDR gram-negative bacteria.	Lung, urinary tract, abdomen, pyothorax	Consider when MDR gram-negative bacteria, enterococci or MRS are *unlikely* based on local resistance patterns and aminoglycosides are contraindicated due to toxicity or concerns related to drug penetration. Consider use of ampicillin-sulbactam instead of ampicillin or addition of metronidazole if infection with penicillinase-producing anaerobes is likely.
Meropenem	Active against aerobic gram-negative rods including *Pseudomonas*, anaerobes, streptococci. Not active against MRS and enterococci.	Abdomen, aspiration pneumonia	Use when infection with MDR gram-negative bacteria and anaerobes is likely but aminoglycosides are contraindicated due to toxicity or concerns related to drug penetration (e.g., airway involvement). Consultation with a respiratory or infectious disease veterinary specialist or veterinary pharmacologist recommended prior to use.
Vancomycin AND meropenem	MRS, streptococci, MDR aerobic gram-negative bacilli, anaerobes	Skin/soft tissue, urinary tract, abdomen	Last line for treatment of mixed infection with MDR gram-negative bacteria, MDR enterococci, anaerobes, and MRS when aminoglycosides are contraindicated due to toxicity or concerns related to inadequate drug penetration. Consultation with a respiratory or infectious disease veterinary specialist or veterinary pharmacologist recommended prior to use.

[a]Pending the results of blood culture and susceptibility testing, which should be followed by reduction in spectrum as appropriate.
[b]In human patients, amikacin is less nephrotoxic than gentamicin and may be preferable for treatment of dogs and cats with severe sepsis or septic shock.
Dosages for IV administration (normal renal function). See Chapter 10 for precautions.
Amikacin 15 mg/kg q24h (dogs)
Ampicillin sodium, 20mg/kg q6h
Ampicillin sulbactam, 20-50 mg/kg q6-8h
Clindamycin phosphate, 10 mg/kg q12h (dilute 1:10 in sterile saline and give slowly over 30 minutes)
Enrofloxacin, 15 mg/kg IV q24h (dogs)
Gentamicin sulfate, 14 mg/kg q24h (dogs), 8 mg/kg q24h (cats)
Meropenem, 12 mg/kg q8–12h
Vancomycin, 15 mg/kg q8h (dilute in sterile saline and give slowly over 30 minutes)
IE, infective endocarditis; *MDR,* multidrug resistant; *MRS,* methicillin-resistant staphylococci.

TABLE 122.8 Suggested Empiric Antimicrobial Drug Treatment for Intravenous Use in Dogs and Cats with Infective Endocarditis[b]

Antimicrobial Drug	Spectrum	Comments
Ampicillin AND gentamicin	Streptococci, *Bartonella*, MRS, enterococci, aerobic gram-negative rods	Covers all major causes of IE including most MDR gram-negative rods. Consider substitution of gentamicin with a fluoroquinolone if impairment of renal function is present.
Vancomycin AND meropenem	MRS, enterococci, gram-negative aerobes	Use only when infection with MRS is likely and aminoglycosides are contraindicated due to toxicity (e.g., refractory pyoderma, history of orthopedic surgery or antimicrobial treatment or hospitalization in the last year, contact with other animals or humans known to have MRS infections). Consultation with a respiratory or infectious disease veterinary specialist or veterinary pharmacologist recommended prior to use.

[a]Pending the results of blood culture and susceptibility testing, which should be followed by reduction in spectrum as appropriate.
IE, infective endocarditis; *MDR,* multidrug resistant; *MRS,* methicillin-resistant staphylococci.

such as occurs with foreign bodies, intestinal neoplasia, or torsion. Underlying immunosuppressive disease such as neoplasia or diabetes mellitus should be identified and treated if possible.

Infective Endocarditis

Guidelines for the treatment of IE in humans have been published and updated.[24,30] However, many factors considered for treatment of

human patients do not apply to dogs and cats, and include the availability of valve replacement; penicillin allergy in some patients; the higher incidence of infections with MRS and VRE; evidence that supports use of specific antimicrobial drugs or drug combinations; and the possibility of long hospitalization times for parenteral antimicrobial drug therapy. In many human IE patients, valve replacement is also essential for resolution. Indications for cardiac surgery in humans include severe acute regurgitation or valve obstruction with refractory pulmonary edema; uncontrolled infection with enlarging vegetations; persistent fever and positive blood culture for at least 10 days after appropriate antimicrobial drug treatment is commenced, infection caused by fungi or MDR bacteria, and large vegetations (> 10 mm) in association with embolic episodes or other complications, and isolated large vegetations (> 15 mm).[24]

For dogs and cats, valve replacement is not a readily available option, so treatment must rely on antimicrobial drugs and resolution of any predisposing factors. Where the local prevalence of MDR gram-negative bacteria and MRS is low, a combination of ampicillin and an aminoglycoside is a good choice for empiric treatment of IE pending the results of culture and susceptibility. Where MDR gram-negative bacteria and MRS are locally prevalent, empiric recommendations made for human patients could be considered for dogs and cats pending the results of culture and susceptibility, provided there is a chance of treatment success in the absence of valve replacement. When severe sepsis is absent and IE follows an indolent course, it is recommended in human patients that antimicrobial treatment be withheld pending the results of culture and susceptibility, or a combination of penicillin with or without low-dose gentamicin (1 mg/kg, IV, q12h) be administered until results are available. Aminoglycosides are used at this low dose, twice daily for their synergistic activity with penicillin against enterococci and viridans streptococci, which are uncommon causes of IE in dogs. Empiric treatment protocols that have activity against drug-resistant bacteria are used in human patients pending results of culture and susceptibility when severe sepsis is present, such as vancomycin and low-dose gentamicin (no risk factors present for gram-negative bacterial infection), or vancomycin and meropenem (risk factors present for MDR Enterobacterales and *Pseudomonas* infection). However, the use of vancomycin and meropenem in dogs and cats has been controversial and may not be permitted or feasible in some geographic locations.

Recommendations for treatment of IE in dogs once the microbial etiology is known are shown in Table 122.9. Intravenous antimicrobial drugs should be continued in hospital for as long as possible (ideally at least 7 to 10 days). A switch to oral medications is not recommended for human IE patients because of poor activity when compared with IV medications.[24] However, oral antibiotic treatment has been used with success to treat some dogs with IE and may be the only viable option. At-home treatment with IV drugs through peripheral indwelling catheters may be possible for some dogs, but dog, owner, and drug factors should be considered very carefully and proper client education is critical. If oral antimicrobial drugs are used, bactericidal drugs with good oral bioavailability are preferable.

The role of antiplatelet therapy is controversial in human and veterinary patients with IE. The importance of thromboembolic disease in canine and feline IE is well documented; however, prospective studies identifying any risks or benefits of concomitant antiplatelet therapy are lacking. In the authors' hospital, the use of antiplatelet therapy such as clopidogrel is largely driven by clinician preference. Antiplatelet therapy is administered to animals considered at risk of or with clinical evidence of thromboembolic events such as those with spontaneous contrast on echocardiography, or ultrasonographic evidence of organ infarction. Given the high frequency of CHF and apparent thromboembolic events associated with IE in cats, antiplatelet therapy with clopidogrel may be warranted in this population.[7] The use of antiplatelet therapy should be carefully weighed against the risk of hemorrhage particularly in patients with concurrent thrombocytopenia or potential hypocoagulable states.

Medical treatment should be continued for at least 4 to 6 weeks, and until the underlying disease process has resolved, and valvular lesions have also resolved based on echocardiographic examinations. In the authors' experience, this treatment often extends well beyond 6 weeks before resolution of lesions is observed. Echocardiography should be

TABLE 122.9 Suggested Antimicrobial Drugs for Treatment of Major Causes of Infective Endocarditis in Dogs and Cats Once Cause Is Known

Cause	Preferred Treatment	Oral Equivalent
Methicillin-susceptible *Staphylococcus* spp.	Ampicillin IV Ampicillin-sulbactam IV (beta-lactamase producer)	Amoxicillin PO Flucloxacillin PO Clavulanic acid-amoxicillin PO
Methicillin-resistant but rifampin-susceptible *Staphylococcus* spp.	Gentamicin IV and rifampin PO OR vancomycin IV and rifampin (compromised renal function)	None
Streptococcus spp.	Benzylpenicillin IV Ampicillin IV	Amoxicillin PO
Penicillin-susceptible enterococci	Ampicillin IV	Amoxicillin PO
Penicillin-resistant enterococci	Vancomycin IV and gentamicin IV	None. Linezolid may be given orally but is bacteriostatic so may be ineffective.
Aerobic gram-negative rods	Ampicillin IV and gentamicin IV Ampicillin IV and fluoroquinolone IV Meropenem IV (or base on susceptibility)	Base on susceptibility
Bartonella spp.	Ampicillin IV and gentamicin IV Doxycycline IV and rifampin PO	Doxycycline PO and rifampin PO
Aspergillus spp.	Voriconazole or posaconazole	Voriconazole or posaconazole

repeated after 4 weeks, or earlier if there is evidence of complications (CHF, embolic disease) or inadequate treatment response. Successful resolution of IE is associated with reduction in size and consolidation of valvular vegetations. With unsuccessful treatment, lesions remain unchanged, and/or new lesions may appear on other valves.[5]

Infective Pericarditis

In addition to specific antimicrobial drug treatment, surgery may be required in dogs with infective pericarditis in order to debride the pericardium and minimize cardiac diastolic function. This carries a significant risk of mortality, and if feasible, referral to an experienced cardiac surgeon is recommended.

Prognosis

The prognosis for dogs and cats that develop IE, myocarditis, or pericarditis is guarded and depends on underlying disease processes, the severity of organ damage, and the etiologic agent or agents. In a study of dogs with IE, mortality rate due to IE was at least 40/71 (56%), and median survival time was only 54 days.[5] Factors strongly associated with negative outcome in dogs with IE were thrombocytopenia, increased serum creatinine concentration, renal complications, thromboembolic complications, and IE associated with *Bartonella* infection.

PREVENTION

Methods to prevent bloodstream infections and sepsis include limitation of the use of invasive devices and catheters unless absolutely necessary and attention to routine hygiene in the hospital to minimize nosocomial infections. Other measures include management of immunosuppressive disorders such as diabetes mellitus, minimizing use of immunosuppressive drugs such as glucocorticoids, and prompt attention to wounds or other underlying infections that have the potential to spread to the bloodstream.

The role of prophylactic antimicrobial drugs to prevent bacteremia and sepsis has been controversial. Beneficial outcomes have been reported when antimicrobials are used to prevent infection after chemotherapy. In one study, the use of a 14-day course of a trimethoprim-sulfonamide reduced morbidity and mortality in dogs with osteosarcoma or lymphoma during the first 14 days after treatment with doxorubicin.[31] In human patients a 7-day course of a fluoroquinolone during the expected neutropenic period after chemotherapy for solid tumors and lymphomas was shown to reduce the incidence of fever, probable infection, and hospitalization.[32] Prophylactic treatment with antimicrobial drugs could also be considered for animals with severe neutropenia (<500 cells/μL), although more studies are required that examine the prevalence of bacteremia in neutropenic animals and the benefits of prophylactic antimicrobial drug treatment. Finally, prophylactic antimicrobial drug treatment has been suggested for dogs and cats with congenital heart defects that undergo dental procedures, but evidence to support the need for this practice is lacking.

PUBLIC HEALTH ASPECTS

Dogs with bloodstream infections may harbor bacteria such as MRSA that have the potential to colonize humans, and so routine precautions should be taken when these dogs are handled, with special attention to hand hygiene and fomite disinfection. Dogs and cats with signs of cardiovascular infection may also be infected with important human pathogens such as *Salmonella* spp., *Bartonella* spp., *Brucella* spp., and *Rickettsia rickettsii*, so caution should be taken when handling blood from animals with cardiovascular infections and needle-stick injuries should be avoided.

CASE EXAMPLE

Signalment

"Rugby," a 12-year-old male neutered Labrador retriever from Napa, CA.

History

Rugby was seen at the University of California-Davis, VMTH emergency service for treatment of possible sepsis. One week before he was evaluated, he had been swimming in the lake in the owner's backyard and when exiting was shivering and reluctant to move. Since then, he has had a waxing and waning appetite. Over the last day, he had been unwilling to walk. He was taken to the local veterinary clinic that evening where his temperature was 104.6°F (40.3°C), he was laterally recumbent, moderately obtunded, had thoracolumbar pain, and had decreased patellar reflexes bilaterally. Blood work showed moderate leukocytosis, thrombocytopenia, hypoglycemia, hyperbilirubinemia, and a mildly elevated activity of serum ALP. Oscillometric blood pressure was normal, and hydromorphone was administered. Abdominal radiographs showed bridging spondylosis and multiple narrowed intervertebral disc spaces. Rugby was up to date on vaccinations, including for rabies.

Physical Examination

Body weight: 44 kg.

General: Obtunded, laterally recumbent, T = 104.4°F (40.2°C), HR = 120 beats/minute, RR = 20 breaths/minute, mucous membranes dark pink, CRT = 1 s.

Integument: Multiple generalized small freely moveable subcutaneous masses.

Musculoskeletal: Nonambulatory and unable to stand. BCS was 8/9.

Cardiovascular: A grade 3/6 systolic murmur with a musical quality was auscultated. Strong, symmetric femoral pulses were palpated bilaterally with frequent pulse deficits noted.

Respiratory: Increased bronchovesicular sounds were present in all fields.

Abdominal palpation: Moderate abdominal distention was noted. Palpation was difficult because of recumbency and the large size of the patient.

Neurologic evaluation: Mentation was severely obtunded with intact cranial nerves. Postural placing reactions were delayed to absent in all limbs, worse in the pelvic limbs. Segmental reflexes were intact bilaterally. Apparent pain on palpation of caudal thoracic vertebra. Neuroanatomic localization: Intracranial +/– T_3-L_3 myelopathy.

All other systems: No abnormalities detected.

Laboratory Findings

Venous blood gas: pH 7.386, pCO_2 25.6 mmHg, pO_2 35.4 mmHg, base deficit –9.0 mmol/L, bicarbonate 15.0 mmol/L, lactate 2.3 mmol/L, glucose 65 mg/dL.

CBC: HCT 43.7% (40%–55%), MCV 72.2 fL (65–75 fL), MCHC 33.4 g/dL (33–36 g/dL), WBC 40,500 cells/μL (6,000–13,000 cells/μL), neutrophils 34,020 cells/μL (3,000–10,500 cells/μL), band neutrophils 405 cells/μL, lymphocytes 1,215 cells/μL (1,000–4,000 cells/μL), monocytes 4,860 cells/μL (150–1,200 cells/μL), platelets clumped (150,000–400,000 platelets/μL).

Serum chemistry profile: Anion gap 29 mmol/L (12–20 mmol/L), sodium 152 mmol/L (143–151 mmol/L), potassium 4.2 mmol/L (3.6–4.8 mmol/L), chloride 112 mmol/L (108–116 mmol/L), bicarbonate 15 mmol/L (20–29 mmol/L), phosphorus 6.1 mg/dL (2.6–5.2 mg/dL), calcium 9.9 mg/dL (9.6–11.2 mg/dL), BUN 15 mg/dL (11–33 mg/dL), creatinine 116 mg/dL (0.8–1.5 mg/dL), glucose 60 mg/dL (86–118 mg/dL), total protein 6.4 g/dL (5.4–6.9 g/dL), albumin 3.3 g/dL (3.4–4.4 g/dL), globulin 3.1 g/dL (1.7–3.1 g/dL), ALT 63 U/L (21–72 U/L), AST 84 U/L (20–49 U/L), creatinine kinase 394 U/L (55–257 U/L), ALP 213 U/L

CASE EXAMPLE—cont'd

(14–91 U/L), cholesterol 384 mg/dL (139–353 mg/dL), total bilirubin 1.1 mg/dL (0–0.2 mg/dL), magnesium 2.1 mg/dL (1.9–2.5 mg/dL).

Urinalysis (free catch): SpG 1.022; pH 7.0, 150 mg/dL protein (SSA), 6 mg/dL bilirubin, 150 erythrocytes/μL hemoprotein, no glucose or ketones, 4–10 WBC/HPF, 3–5 RBC/HPF, no bacteria or casts seen.

Arterial blood gas (post–dextrose bolus) (FiO_2 21%): pH 7.401, pCO_2 20.8 mmHg, pO_2 78.1 mmHg, ionized calcium 1.30 mmol/L, bicarbonate 12.7 mmol/L, base deficit –11.2 mmol/L, lactate 1.9 mmol/L, glucose 157 mg/dL.

Electrocardiography

The ECG rhythm showed an underlying sinus rhythm with frequent uniform ventricular premature complexes and paroxysms of an accelerated idioventricular rhythm (120 beats/minute).

Imaging Findings

Thoracic radiographs: Diffuse bronchointerstitial pattern most pronounced caudodorsally. There was an additional wispy alveolar pattern associated with the right middle lung lobe compatible with aspiration pneumonia. The cardiovascular structures were within normal limits.

Abdominal ultrasound: The liver was diffusely hypoechoic and the spleen was mildly enlarged. The gallbladder wall was edematous. Bright mesentery surrounded the left limb of the pancreas. Throughout the small intestine, there was a segmental thickening of the submucosa layer with more subtle segmental thickening of the muscularis layer.

Echocardiography

The left and right ventricles and atria were normal in size. There was laminar flow through the pulmonary artery and aorta. There was no tricuspid, pulmonic, or aortic regurgitation. There was a pedunculated and independently oscillating vegetative lesion seen on the atrial surface of the anterior mitral valve leaflet with associated mild mitral valve regurgitation (Fig. 122.6).

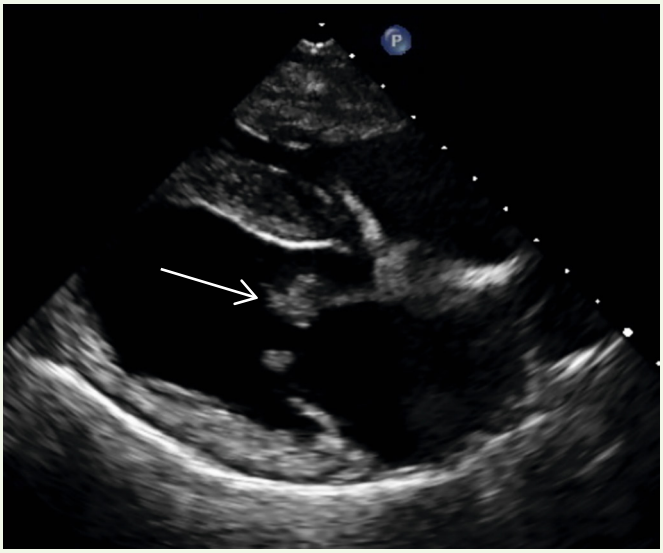

Fig. 122.6 Right parasternal view of the heart from a 12-year-old male neutered Labrador retriever with *Streptococcus dysgalactiae* endocarditis. There is a large vegetative lesion attached to the anterior leaflet of the mitral valve *(arrow)*.

Microbiologic Testing

Aerobic urine culture not performed due to concern for bleeding following cystocentesis in association with reported thrombocytopenia.

Aerobic and anaerobic blood culture (6 specimens): Large numbers of *Streptococcus dysgalactiae* from the 6 of 6 bottles. Susceptible to all antimicrobials tested.

Diagnosis

Streptococcus dysgalactiae IE with arterial thromboembolus formation.

Treatment and Outcome

Lactated Ringer's solution with 2.5% supplemental dextrose was started at a maintenance fluid rate to maintain normoglycemia and ampicillin/sulbactam constant rate infusion (CRI) was started (6 mg/kg/hour), enrofloxacin (15 mg/kg, IV, q24h), and hydromorphone (0.05 mg/kg, IV, q4h). Continuous ECG and arterial blood pressure monitoring, and urine output via urinary catheter were started. Mean arterial pressure was > 80 mmHg overnight and supplemental oxygen was provided via nasal cannulas to keep P_aO_2 > 80 mmHg. Over the next 3 days, the patient's mentation steadily improved and he was able to stand for short periods with support. However, he remained anorexic. On day 4, the arterial blood pressure tracing suddenly disappeared from continuous blood pressure monitoring; on abdominal ultrasound examination, a thrombus was detected in the caudal abdominal aorta that extended into the right external iliac artery. Multiple cortical renal infarcts were also present. A nasogastric tube was placed and a commercial liquid diet was fed starting at 25% RER to increase until full RER was reached 3 days later. Enoxaparin (0.8 mg/kg, SC, q6h) and clopidogrel (75 mg by nasogastric tube q24h) were started on day 4. On day 8, a recheck CBC showed a mild neutrophilia (23,800 cells/μL) and normalization of platelet count (304,000 platelets/μL). Biochemical analysis showed persistent hyperbilirubinemia (1.1 mg/dL) and hypoalbuminemia (1.6 g/dL). The ampicillin-sulbactam CRI was switched to intermittent dosing (50 mg/kg, IV, q8h). The dog was still not able to stand independently, but could with support. Over the following 6 days, his ambulatory status improved until he could walk with harness support. His appetite returned so he was consuming 1.25 RER voluntarily. On day 14, a focused recheck abdominal ultrasound showed diminishing clot size in the aorta and external iliac artery. He was discharged on day 15 with oral amoxicillin-clavulanate (17 mg/kg, PO, q12h) and enrofloxacin (11 mg/kg, PO, q12h) along with his anticoagulant medications until scheduled recheck in 2 weeks.

Comments

This dog had mitral valve IE with associated sepsis. Echocardiography was performed as the patient had a fever and a new-onset murmur. Broad-spectrum antibiotics were initiated based on the level of illness of the patient and multiple potential sources of infection (endocarditis and aspiration pneumonia). An antibiotic CRI of a beta-lactam was initiated in an attempt to provide 100% of time > MIC. It is likely that the arterial thrombus represented a thromboembolus based on the presence of a large oscillating valvular vegetation; portions of such lesions may break off and embolize in the periphery. The source of bacteremia and endocarditis was not apparent.

Sepsis

Deborah Silverstein, Cynthia M. Otto

KEY POINTS

- Sepsis is the systemic inflammatory response to an infectious agent. The presence of organ function is now included in the human definitions.
- The pathophysiology of sepsis is complex and includes both a proinflammatory and anti-inflammatory response that, when exuberant, can lead to organ dysfunction and death of the host.
- Potential septic foci should be determined as soon as possible, and cultures of infected fluid or tissue obtained to help guide long-term therapy.
- Pending culture results, treatment should be aimed at the most likely etiologic agent(s) and tissue infected.
- Intensive monitoring and aggressive supportive care are of utmost importance to increase the chance for survival. The presence of multiple organ dysfunction syndrome increases the mortality rate.
- The prognosis for patients with sepsis relies on the severity and pathogenicity of the underlying infection, as well as the ability to provide appropriate and early treatment.

DEFINITIONS AND EPIDEMIOLOGY

Bacteremia is defined as live microorganisms in circulation. *Endotoxemia* refers to circulation of the LPS component of the gram-negative bacterial cell wall and may or may not be associated with the presence of live bacteria. *Sepsis* represents the clinical signs associated with a systemic inflammatory response to an infectious agent.[1] More recently, sepsis was redefined as a life-threatening organ dysfunction caused by a dysregulated host response to infection.[2] Bacteremia in dogs and cats is expected to occur in a variety of infections (e.g., peritonitis, mastitis, prostatitis, pneumonia, pulmonary abscess, pyothorax, pyometra, pyelonephritis, intra-abdominal abscess, biliary tract infections), as well as during dentistry, but is not always associated with a systemic inflammatory response.[3]

Subclinical bacteremia probably also occurs during rectal palpation, intestinal endoscopy and surgery, and when indwelling venous or arterial catheters have been placed. Normally, circulating bacteria are cleared by the mononuclear-phagocyte system; therefore, blood cultures are not always reliable in documenting bacteremia. Bacterial molecules, along with molecules from other infectious agents (e.g., fungi, virus), are referred to as "pathogen-associated molecular patterns" or PAMPs.[4] Macrophages and other cells of the innate immune system recognize these PAMPs through toll-like receptors (TLRs) and initiate a complex local inflammatory response and upregulate systemic host defenses, thus preparing the animal to combat potential spread of infection.[5]

Typical clinical signs associated with bacteremia include altered body temperature, tachycardia, tachypnea, and neutrophilia or neutropenia; these signs represent the systemic inflammatory response syndrome (SIRS) which, when initiated by an infectious agent and accompanied by organ dysfunction, is referred to as sepsis. Not all patients with bacteremia demonstrate clinical signs of sepsis.[3] Dysregulated inflammation and SIRS is characterized by a complex cytokine-mediated response and can also be initiated by endogenous danger signals (danger-associated molecular pathogens or DAMPs) from damaged cells as a result of trauma, pancreatitis, hypoxia, and other insults.[4] The host benefits if the inflammatory response remains localized and balanced by anti-inflammatory pathways; however, systemic inflammation or failure to resolve the inflammatory response can lead to high mortality.

The terminologies *SIRS* and *sepsis* were clarified in the 1990s in human medicine[1]; relevant terms and the various categories of severity are defined in Table 123.1. SIRS criteria, however, are very insensitive and nonspecific features of sepsis that were designed to identify patients eligible for clinical trials of antisepsis therapies (Tables 123.2 and 123.3). Subsequently, a human consensus conference[6] identified a more elaborate classification system (PIRO) that focuses on host factors (predisposition), infectious agent factors (infection), the host-organism interaction (response), and the consequences of systemic inflammation (organ failure) (Table 123.4). In 2016, updated definitions were introduced in an attempt to more accurately identify patients at high risk for morbidity and mortality from sepsis. These new definitions, Sepsis-3, are based on the presence of an abnormal mentation using the Glasgow coma scale, RR > 20 breaths/minute, and/or a Doppler blood pressure < 100 mmHg.[2,5] The terms SIRS and severe sepsis were eliminated. Sepsis or severe inflammatory diseases often lead to an inappropriate, dysregulated generalized systemic response that leads to a progression of severe sepsis, septic shock, and ultimately multiple organ dysfunction syndrome (MODS) (see Table 123.1).[7] This chapter will continue to refer to the terms SIRS and severe sepsis because they have been core to so many studies in the recent past that have contributed to our understanding of sepsis, and the PIRO system cannot be applied to animals. Much of our knowledge of sepsis has been derived from experimental animal models and human (and a few veterinary) clinical studies. Animal models of sepsis can be divided by the type of insult, the route of administration of the infectious agent or substance, and the endpoints of the study.[8] One of the most commonly used agents to study the physiologic response to systemic bacteria has relied on the use of endotoxin. Endotoxin (lipopolysacharride [LPS]) consists of a lipid A moiety (the toxic component) and polysaccharides (O antigens) (see Fig. 53.2). LPS is released from the outer membrane of gram-negative bacteria when they lyse and is normally confined within the gut and portal circulation. The source of endotoxin is usually a member of the Enterbacterales family (*Escherichia* spp., *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp.), as well as *Pseudomonas* spp. Studies of endotoxemia are highly

reproducible, but administration of endotoxin to animal models does not account for all of the factors involved in clinical conditions in which endotoxin is a component of the disease. The innate immune system has evolved to recognize and respond to LPS in tissues and fluids early in gram-negative infections.[9] A major function of the innate immune system is to recognize threats to host survival. These threats can be exogenous or pathogen-associated (PAMPs), or endogenous danger signals released from damaged or dying cells (DAMPs).[4] The pathway for recognition of endotoxin has been well defined and is the prototypical example of activation of the innate immune response. The innate immune system is also capable of recognizing gram-positive bacterial products, flagellin, bacterial or viral DNA, and fungal products via the TLR (Table 123.5).[10,11]

The prevalence of naturally occurring sepsis in dogs and cats is unknown, even though the dog has been used for many years as a model of sepsis and endotoxemia for humans.[12] Risk factors for endotoxemia, with or without concurrent bacteremia, in dogs include canine parvovirus (CPV) enteritis, gastric dilation and volvulus, pyometra, mastitis, other gram-negative infections, and heat stroke. Endotoxemia can develop when hepatic clearance of LPS is reduced, as in hepatic insufficiency and portosystemic shunts. Obstructive biliary disease may be a risk factor because bile salts bind endotoxin in the gut. Endotoxin may also play an important role in the pathogenesis of severe acute pancreatitis in dogs.[13] In the dog, sepsis is most commonly associated with disruption of the normal mucosal barrier and movement of bacteria into the circulation or tissues. The most commonly reported causes of sepsis in dogs include peritonitis (from GI or urogenital origins) and pneumonia.[14–16] Dogs receiving chemotherapy are susceptible to developing sepsis.[17] Smaller dogs with lymphoma, after receiving doxorubicin, or vincristine are at highest risk.

Sepsis is recognized less commonly in cats. Even severely affected cats do not commonly display the classic hyperdynamic signs of sepsis (tachycardia, red mucous membranes, fever, bounding/hyperkinetic pulses), making diagnosis a challenge.[18,19] In an experimental study of low-dose endotoxin infusion, cats developed hypotension but not tachycardia.[20] Risk factors for severe sepsis in cats include pyothorax, septic peritonitis, bacteremia secondary to GI disease, pneumonia, endocarditis, pyelonephritis, osteomyelitis, pyometra, and bite wounds.[21] In cats with pyothorax, identified risk factors include indoor-outdoor environment and multicat households.[22] In cats with peritonitis, neoplasia[23] or trauma[24] are the most commonly recognized causes. Endotoxemia is likely a component of some of these

TABLE 123.1 Definitions of Systemic Inflammatory Response Syndrome and Sepsis[1,2,13]

Term	Definition
Bacteremia	Living bacterial organisms in circulating blood
Endotoxemia	Lipopolysaccharide of gram-negative bacterial cell wall circulating in blood
Systemic inflammatory response syndrome	Systemic signs of inflammation (two of the four criteria; this term has been removed from the Sepsis-3 definitions in human medicine)
Sepsis	Confirmed infection plus systemic signs of inflammation. In human medicine, this is now defined as life-threatening organ dysfunction[a] caused by a dysregulated host response to infection.
Severe sepsis	Sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion (this term has been removed in the Sepsis-3 definitions for humans)
Sepsis-induced hypotension	Systolic blood pressure (SBP) < 90 mmHg, mean arterial pressure < 70 mmHg, or a decrease in SBP of > 40 mmHg
Septic shock	Sepsis-induced hypotension despite adequate fluid resuscitation. In the Sepsis-3 definitions for humans, this is now defined as sepsis and vasopressor therapy needed to maintain mean arterial pressure ≥ 65 mmHg and lactate to ≥ 2 mmol/L despite adequate fluid resuscitation
Sepsis-induced hypoperfusion	Septic shock with an elevated lactate or oliguria

[a]As assessed by an acute change of ≥ 2 points in the sequential organ failure assessment score (components: PaO_2/FIO_2 ratio, Glasgow coma scale, mean arterial pressure, vasopressor use, serum creatinine or urine output, bilirubin, and platelet count).

TABLE 123.2 Systemic Inflammatory Response Syndrome Criteria for Dogs, Cats, and Humans

Criteria	Cats	Dogs	Humans
Temperature	< 37.8°C, > 40.0°C (< 100°F, > 103.5° F)	< 37.2°C, > 39.2°C (< 99°F, > 102.6°F)	< 36.0°C, > 38.0°C (< 96.8°F, > 100.4°F)
Heart rate, beats/minute	< 140, > 225	> 140	> 90
Respiratory rate, breaths/minute	> 40	> 30	> 20
Leukocyte count, × $10^3/\mu L$	< 5,000, > 19,500	< 6,000, > 19,000	< 4,000, > 12,000

TABLE 123.3 Various Proposed Canine Systemic Inflammatory Response Syndrome Criteria

Heart Rate (Beats/Min)	Respiratory Rate (Breaths/Min)	Temperature (°F)	Leukocyte Count (×10^3 Cells/μL)	Reference
160	20	100.0–103.5	4.0–12.0	209
120	20	100.4–104.0	5.0–18	210
120	20	100.6–102.6	6.0–16.0	211
160	40	100.0–103.5	4.0–12.0	106
140	30	100.0–102.5	6.0–19.0	212

infections. Sepsis is also recognized as a cause of neonatal death in puppies and kittens.

In a human study performed in a tertiary care hospital, 68% of individuals admitted to the wards or the ICU had signs of SIRS. Of those patients, 26% went on to develop sepsis, 18% developed sepsis with hypotension or hypoperfusion, and only 4% developed septic shock. Not all patients, even those who developed septic shock, had bacteremia. Pneumonia and UTIs were the most common sources of infection in patients with septic shock. Diseases associated with development of septic shock included cardiovascular disease, neoplasia, GI disease, diabetes mellitus, renal disease, respiratory disease, and pancreatitis.[25] Uncomplicated sepsis is not a negative prognostic finding if recognized early and managed appropriately; however, the prognosis worsens as an animal develops septic shock and MODS.

TABLE 123.4 PIRO System for Staging Sepsis[6]

	Present	Future
Predisposition	Concurrent illness Age, sex, species, breed	Genetic expression of inflammatory response
Insult/infection	Culture and susceptibility of infection site Disease that is controllable	Assay of microbial products (LPS, bacterial DNA)
Response	SIRS, other signs of sepsis, shock	Nonspecific markers of inflammatory response (PCT or IL-6), impaired host responsiveness (HLA-DR), or specific detection of target therapy (protein C, TNF, PAF)
Organ dysfunction	Number of organ systems with dysfunction or composite score (SOFA)	Dynamic measures of cellular response to insult—apoptosis, cytopathic hypoxia, cell stress

HLA-DR, human leukocyte antigen-DR; *IL*, interleukin; *LPS*, lipopolysaccharide; *PAF*, platelet activating factor; *PCT*, procalcitonin; *PIRO*, predisposition, infection, response, organ dysfunction; *SIRS*, systemic inflammatory response syndrome; *SOFA*, sequential organ failure assessment score; *TNF*, tumor necrosis factor.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Molecular Pathogenesis

The clinical signs of sepsis described earlier in this chapter occur as a result of expression of proinflammatory cytokines and activation of the coagulation cascade.[5] Endotoxin is released into the intestinal lumen or tissues when gram-negative bacteria lyse, as occurs with rapid bacterial replication or with bactericidal action of some antibacterials. Within the intestinal lumen, most endotoxin is bound by bile salts and contained by the mucosal barrier; the small amounts normally absorbed into the portal circulation are cleared by hepatic macrophages. Endotoxin absorbed through the lymphatic system is cleared in regional lymph nodes. Thus, endotoxin levels in the systemic circulation are usually extremely low to immeasurable. Clinical signs of endotoxemia occur only when binding and clearance mechanisms are overwhelmed. Bacteria can also translocate into the bloodstream as a result of disruption of the intestinal epithelial barrier. Bacteria and other pathogens can also gain access to the circulatory system from other mucosal surfaces, surgical or traumatic wounds, or invasive monitoring devices. The innate immune system is equipped with pattern recognition receptors that allow a response without prior exposure to the pathogen. These receptors are part of the TLR pathway.[5,10,11]

The first step in recognition of gram-negative bacteria is the binding of LPS to the acute-phase protein known as LPS-binding protein (the canine molecule has been described and cloned).[26]

TABLE 123.5 Microorganism Features That Are Recognized by Toll-like Receptors[2,14]

TLR	Host Ligand	Parasites	Fungi	Viruses	Bacteria	Small Molecules	Other
1, 2	HMGB1	GPI-linked proteins	Zymosan		Di- and triacyl lipopeptides Lipomannan, lipoteichoic acid	HSP 60, HSP 70, HSP 96	
3	mRNA			Double-stranded RNA			
4	HSP60, HSP 70, HSP 96, fibrinogen, fibronectin, hyaluronic acid, HMGB1, OxLDL*, beta amyloid* (*in association with TLR6)			F protein	LPS		
5					Flagellin		
2–6		GPI-linked proteins	Zymosan		Diacyl lipopeptides		
7 or 8	Single stranded RNA, microRNA, possibly mRNA			Single-stranded RNA		Imiquimod, resiquimod	
9	Self DNA			Herpesvirus DNA	CpG DNA sequences		Synthetic CpG oligoDNA
11					Uropathogenic bacteria		

CpG, regions of DNA where a cytosine (C) nucleotide occurs next to a (G) guanine nucleotide, where p represents the phosphodiester backbone, found abundantly in bacterial DNA; *GPI*, glycosylphosphatidylinositol; *HSP60*, heat shock protein 60; *LPS*, lipopolysaccharide; *mRNA*, messenger RNA; *TLR*, toll-like receptor.

This protein complexes with LPS and shuttles it to the macrophage, where the complex binds to the surface receptor, CD14, a glycosylphosphatidylinositol-anchored membrane protein that lacks a transmembrane domain. CD14 can be shed from cells, and soluble (free) CD14-endotoxin complexes can bind to endothelial cells and induce a cytokine response. Recognition of the TLR4 receptor provided the missing link between LPS binding to CD14 and the initiation of the signaling cascade.[27]

In response to the activation of the TLR4 receptor, transcription factor NF-κB (originally identified in B cells) is activated and leads to the expression of many cytokines.[28] This activation requires the recruitment and activation of a series of adapter proteins and signaling molecules. Myeloid differentiation primary response protein 88 (MyD88) is an adapter protein found on all of the TLR. TLR4 activation and MyD88 recruitment leads to the activation of the IL-1 receptor-associated kinase (IRAK) family members, and TNF receptor-associated factor-6 subsequent signaling pathways. Phosphorylated IRAK1 associates with TRAF6 and forms a complex with another signaling molecule, transforming growth factor β activated kinase (TAK1). NF-κB resides in the cytoplasm as a complex with inhibitory proteins of the inhibitors of NF-κB (I-κB) family. Eventually, TAK1 activation leads to phosphorylation of the I-κB kinase complex (IKK), releasing the transcription factor, NF-κB.[9] This also leads to activation of the NF-κB pathway.[9,10] Activation of NF-κB via phosphorylation of the inhibitory proteins (referred to as the canonical pathway of activation) can be triggered by cellular interactions with bacteria and bacterial products, viruses, parasites, and cytokines, involving activation of the TRL receptors 2, 3, 5, 6, and 9, or cytokine receptors.[28] The phosphorylation step involves three IKKs and results in proteosomal degradation of the inhibitory protein. Once released from the inhibitory I-κB, NF-κB is free to translocate to the nucleus and regulate expression of numerous genes involved in the inflammatory response. NF-κB can also be activated independent of the IKK complex by hypoxia, free radicals, and ultraviolet radiation.[28] Activation of NF-κB may be a biomarker of inflammation and serve as a therapeutic target for diseases of excessive inflammation. The wide range of genes regulated by NF-κB, however, may result in untoward systemic effects if the transcription factor is completely inhibited. Similar to endotoxin, products of gram-positive bacteria, fungi, and bacterial or viral DNA are capable of binding TLR receptors and activating the innate immune response. In SIRS, the innate immune system is activated by DAMPs such as the DNA-binding protein, high mobility group box 1 (HMGB1).[29] This highly conserved ubiquitous nuclear protein is released from cells dying from necrosis and, after acetylation or ADP ribosylation, can be actively secreted by macrophages, monocytes, and dendritic cells. HMGB1 activates TLRs 2, 4, and 9 and the receptor for advanced glycation end products. In addition, HMGB1 can enhance the response to other danger signals. Circulating HMGB1 levels persist longer than most other cytokines in acute inflammatory states, and HMGB1 may represent a therapeutic target to limit inflammation. HMGB1 induces the release of numerous cytokines from inflammatory cells, including TNF-α, IL-1 α and β, IL-1 receptor antagonist, IL-6, IL-8, and macrophage inflammatory protein-1 α and β.

The macrophage is the main cell of the innate immune system that initiates the response to PAMPs and DAMPs (Fig. 123.1). The early macrophage response to endotoxin is characterized by release of multifunctional proinflammatory cytokines, especially IL-1β and TNF-α. In dogs, TNF-α levels increase within 15 minutes of exposure to LPS, peak at 2 hours, and return to baseline levels in 4 hours. TNF-α mediates many immune and inflammatory functions, as well as further stimulating macrophages to secrete IL-1, IL-6, macrophage colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor. IL-1 is released in similar burst fashion; it is a major co-stimulator of Th2 cells, stimulates the acute-phase response, induces fever, and has a multitude of other proinflammatory effects. Other cytokines, such as IL-6, IL-8, and IFN-α, are additional early mediators in sepsis.[30] Proinflammatory cytokines are released early and transiently in response to endotoxin, before the animal shows clinical signs. Novel therapeutics directed toward these mediators have not demonstrated significant benefit in most human clinical trials.[31] However, late mediators, such as HMGB1, may be more appropriate therapeutic targets.[21] The cytokine cascades increase the levels or activity (or both) of inflammatory phospholipid-derived mediators (prostacyclin, thromboxane, and platelet-activating factor),[32] coagulation factors, complement, reactive oxygen species, and nitric oxide (NO; which is an important molecule associated with hypotension),[33–36] endothelin-1 (a vasoconstrictor),[37] β-endorphin, histamine, serotonin, vasopressin, angiotensin II, and catecholamines. The biologic effects of these mediators include neutrophil activation, aggregation, and chemotaxis; platelet activation and aggregation; a procoagulable state; increased activity of plasma proteases; and vasodilation and potentially systemic hypotension, generalized endothelial inflammation, increased vascular permeability, and GI ulceration.[38,39] Lysosomal enzymes such as elastase and chymotrypsin deplete fibronectin and activate blood clotting, triggering DIC.

There are multiple effects of sepsis on the coagulation cascade (Fig. 123.2).[40] Sepsis promotes coagulation, inhibits anticoagulation, and impairs fibrinolysis. Early in sepsis, patients exhibit a procoagulant state which is followed by DIC.[41,42] Inflammation

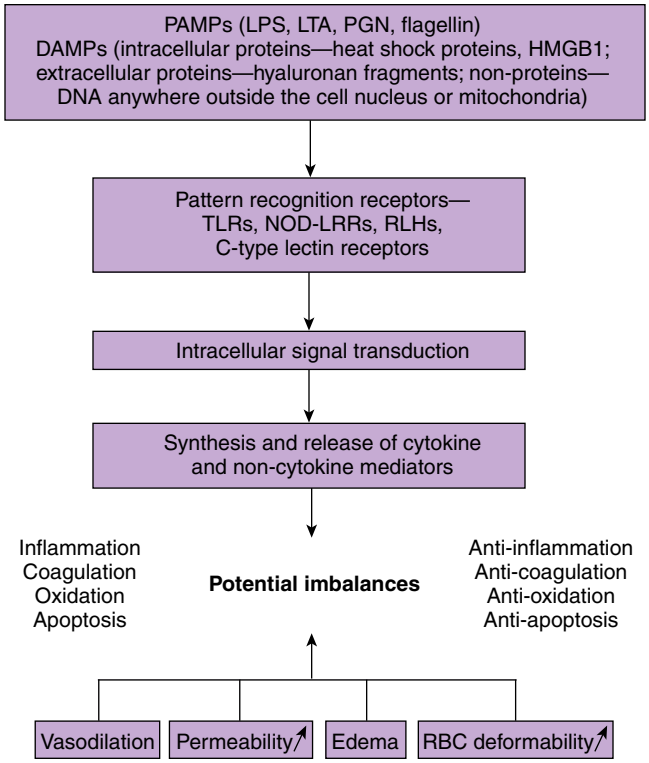

Fig. 123.1 Pathophysiology of severe septic shock. *DAMPs,* danger-associated molecular pathogens; *HMGB1*, high mobility group box 1; *LPS*, lipopolysaccharide; *LTA*, lipoteichoic acid; *NOD-LRRs*, nucleotide-binding oligomerization leucine-rich repeats; *PAMPS*, pathogen-associated molecular patterns; *PGN*, peptidoglycan; *RBC*, red blood cell; *RLHs*, retinoic acid inducible gene-like helicase; *TLRs*, toll-like receptors. Fig. 123.2 Overview of the interrelationships between the pathways of coagulation, anticoagulation, fibrinolysis, and inflammation. +, stimulatory; –, inhibitory; *IL*, interleukin; *PAI-1*, plasminogen activator inhibitor-1; *TAFI*, thrombin activatable fibrinolysis inhibitor; *TNF*, tumor necrosis factor; *u-PA*, urinary plasminogen activator; *u-PAR*, urokinase-type plasminogen activator receptor. (From Levi M, van der Poll T. The central role of the endothelium in the crosstalk between coagulation and inflammation in sepsis. *Adv Sepsis.* 2004;3:93–101, with permission.)

leads to the exposure and induction of tissue factor, a potent procoagulant that complexes with factor VII(a) to activate factor IX and factor X and eventually lead to fibrin formation. Platelets are also activated by endotoxin, proinflammatory cytokines, and thrombin. Endothelial cell damage associated with sepsis results in the release of von Willebrand's factor and further platelet aggregation. Activation of platelets leads to release of proinflammatory mediators and consumption of platelets. Clinically, septic patients frequently have low platelet counts. The three main anticoagulant protein systems, antithrombin (AT), tissue factor pathway inhibitor (TFPI), and protein C (PC), are all deranged during sepsis. Endothelial cells are actively involved in the production/activation of TFPI and PC. TFPI is secreted by and then bound to endothelial cells and inhibits the activation of factor X by tissue factor–factor VII(a) complexes. Sepsis impairs the binding of TFPI to endothelial cells and appears to decrease its effectiveness. The other anticoagulant protein that relies on normal endothelial function is PC. Healthy endothelial cells express the surface protein thrombomodulin, which binds circulating thrombin (see Figs. 123.2 and 123.3). When thrombin is bound to thrombomodulin, it is not available for cleavage by fibrinogen, and the complex acts to cleave PC into active PC (aPC). Endothelial cells exposed to cytokines have a reduction in thrombomodulin expression; thus, less PC can be activated. In addition, aPC is consumed in the inactivation of factor Va and factor VIIIa. Septic patients and dogs have reduced PC, which may be related to survival.[43] The only clinical trial in sepsis that has shown any outcome benefit was a trial of aPC in patients with severe sepsis.[44] Unfortunately, the benefits of aPC do not seem to be generalizable to wider populations,[45] and has subsequently been withdrawn from the sepsis market. In addition, the expense and species specificity of the recombinant aPC have precluded clinical trials in dogs. A major advance that resulted from investigations of aPC was recognition of the interaction between coagulation and inflammation. aPC inhibits neutrophil-endothelial interactions, limits proinflammatory cytokine production, blocks chemotaxis of neutrophils, and protects endothelial barrier function.[45]

AT is another anticoagulant protein reported to have anti-inflammatory functions (i.e., increase prostacyclin and decrease neutrophil-endothelial cell interactions). AT is reduced in sepsis through multiple mechanisms.[40] Although AT therapy looked promising in experimental models of sepsis, no benefit of AT supplementation has been demonstrated in human clinical trials.[46]

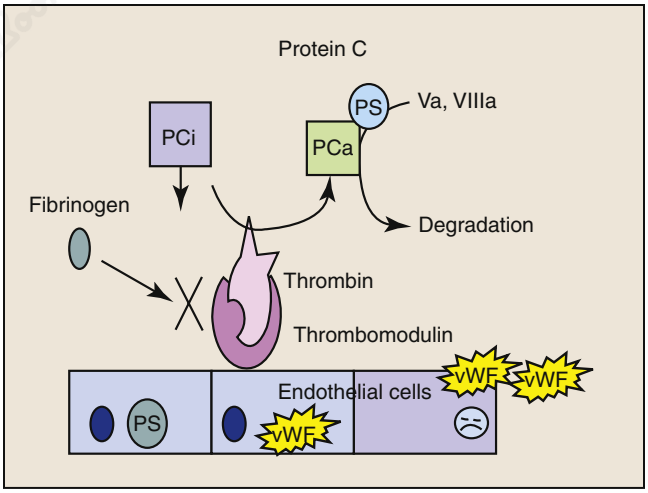

Fig. 123.3 Interaction of protein C with coagulation. The normal endothelium expresses thrombomodulin, which binds thrombin, removing it from the coagulation cascade and altering its substrate from fibrinogen to protein C *(PCi)*. Activation of protein C *(PCa)* allows it to associate with protein S *(PS)* and leads to the degradation of activated factors V and VIII. Endothelial cell injury leads to release of von Willebrand's factor *(vWF)* and decreased expression of thrombomodulin.

In addition to increased activation of procoagulants and decreased anticoagulants, fibrinolysis is also impaired during sepsis. Initially, plasmin (the main fibrinolytic protein) activation is accelerated by increased release of plasminogen activators (tissue plasminogen activator and urokinase-type plasminogen activator) from the endothelial cells. This effect is short-lived as cytokines induce the production and release of plasminogen activator inhibitor.[40] Thrombin-activatable fibrinolysis inhibitor antigen was increased in dogs with sepsis and not in other evaluated diseases.[47] Fibrin deposition results from impairment of all components of the coagulation cascade and can contribute to tissue hypoxia and development of multiple organ dysfunction.

The innate immune system includes the complement system.[48] Complement functions in neutrophil chemotaxis, drawing neutrophils to the sites of infection and inflammation, enhancing clearance of bacteria through opsonization, and causing lysis of cells (both bacterial and host). Complement is also involved in the integration between the innate and adaptive immune system and facilitates removal of apoptotic cells and immune complexes. Complement can be activated by one of three pathways, all of which converge with the activation of C3. Cleavage of C3 leads to production of the anaphylatoxin C3a and the eventual cleavage and activation of C5. C5 cleavage produces the chemotactic protein and anaphylatoxin C5a and C5b, a major component of the membrane attack complex responsible for lysing cells. The classic pathway is activated by immune complexes on cells, apoptotic cells, and some bacteria and viruses. The mannose-binding lectin pathway provides an antibody-independent mechanism to activate the complement cascade by binding bacterial mannose residues. Independent of antibody binding, endotoxin and other surface molecules on bacteria activate the alternate pathway.[48,49] In sepsis, high levels of C3a and C5a are associated with a worse prognosis. In addition to its role as a chemotactic protein, C5a activates endothelial cells, causes vasodilation, and increases vascular permeability. Like many inflammatory mediators, the effects of C5a appear to be complex. C5 can be proinflammatory or protective or even lead to immune paralysis. The response, at least in part, appears to depend on the amount of C5a, the receptor it binds, and the presence of proinflammatory or anti-inflammatory cytokines.[50] Strategies to limit C5 activation continue to be investigated.

If the systemic inflammatory state progresses, structural and metabolic changes develop in vascular endothelial cells. Endothelial adhesion molecules are upregulated, and neutrophils and platelets are sequestered in various organs. The endothelium also becomes more permeable, and plasma proteins move from the intravascular space to the interstitium, resulting in edema. In addition to the vasodilation mentioned earlier, the vascular endothelium may become unresponsive to commonly used vasopressor therapy, a condition termed *catecholamine-refractory vasodilatory shock*.

Despite normalization of macrohemodynamic indices (blood pressure, perfusion, and global tissue oxygenation), multiorgan dysfunction and failure may still develop in septic patients. Advances in the ability to study the microcirculation have found alterations in blood flow through the arterioles, capillaries, and venules. These changes have significant prognostic implications in people with severe sepsis.[51] Even though the percentage of perfused small vessels and vascular density are similar at the onset of shock in both survivors and nonsurvivors, small vessel perfusion improves with time only in survivors.[52,53] However, both survivors and nonsurvivors have similar measures of global perfusion and cardiovascular parameters after initial stabilization, demonstrating that microcirculation, not macrocirculation, is important for determining prognosis and survival. This may provide a valuable monitoring tool in veterinary patients to help guide diagnostic and therapeutic decisions and monitoring.[9]

Concurrent with inflammatory mediator upregulation, anti-inflammatory mediators are secreted to balance and limit the inflammatory response. An insufficient or inappropriate anti-inflammatory response can allow sepsis to progress.[38]

The prevailing theory has been that sepsis is a result of a *cytokine storm*, leading to uncontrolled systemic inflammation. Newer studies indicate that, for at least some patients, the hyperinflammatory state is followed by severe acute immunosuppression, caused by the apoptosis of B cells, CD4+ T cells, and follicular dendritic cells. The mechanism of immunosuppression is not known; however, release of endogenous glucocorticoids may be an important contributor.[54] Thyroid hormone production and secretion have been impaired in endotoxin-treated dogs.[55]

In summary, PAMPs act as a signal to the immune system that pathogens have invaded the host, whereas DAMPs are signals of damage to host cells (see Fig. 123.1). A localized response along with a primed or controlled systemic response is beneficial in containing and resolving the infection, whereas an uncontrolled host response leads to systemic inflammation, immunosuppression, severe sepsis, septic shock, and ultimately organ failure.

Organ Dysfunction in Sepsis

Abnormalities of the coagulation and fibrinolytic pathways play a major role in the development of organ dysfunction in septic patients. Mechanisms for derangements of the coagulation system include: (1) activation of the coagulation cascade; (2) defective physiologic anticoagulant pathways; and (3) impaired fibrinolysis. Clinically, activation of procoagulant pathways can lead to an early hypercoagulable or prothrombotic state that is difficult to diagnose but can contribute to organ dysfunction through inflammatory mediators and development of microthrombi. As sepsis progresses, coagulation disorders reflect a consumptive coagulopathy, impairment of anticoagulant mechanisms, and inhibition of fibrinolysis that is recognized clinically as DIC.[44,56–59]

Cardiovascular system. Disruption of normal cardiovascular function is common in patients with sepsis. Circulating cytokines have been implicated in leading to these derangements via three primary mechanisms: increased vascular endothelial permeability, which allows leakage of intravascular fluid into the extravascular space, leading to hypovolemia and tissue edema; impaired cardiac contractility and subsequent decrease in cardiac output; and heterogenous loss of vasomotor tone, causing maldistribution of blood flow. Although a single "myocardial depressant factor" was previously implicated as the cause of impaired cardiac performance in septic animals and humans, several circulating cytokines have been found to play a role (e.g., TNF-α, IL-1β, IL-2, and IL-6).[60,61] Additional factors might include alterations in intracellular calcium trafficking with a reduction in systolic intracellular calcium concentration and decreased myocyte contraction; downregulation of beta receptors in the heart; and myocardial "hibernation" to preserve cardiac myocytes via decrease in oxygen consumption, energy requirements, and ATP demands.[50,62]

Respiratory system. Acute respiratory distress syndrome (ARDS), a severe form of acute lung injury (ALI), is the manifestation of lung injury that may occur in human and veterinary patients with sepsis and SIRS.[63–66] ARDS and ALI are labels that describe the syndrome of SIRS- or sepsis-associated lung injury, rather than disease entities themselves. Impaired gas exchange in patients with ALI and ARDS is multifactorial and involves endothelial and epithelial injury; neutrophil-dependent lung injury; proinflammatory cytokines; abnormalities of the coagulation system; and abnormalities in the production, composition, and function of surfactant. Ultimately there is an accumulation of protein-rich fluid in the alveoli and infiltration of the alveolar interstitial space with inflammatory cells, fluid, and debris. This is typically recognized as alveolar infiltrates on thoracic radiographs. The lungs are the shock organ in cats and are especially vulnerable to injury during sepsis in this species; tachypnea was a common finding in cats with severe sepsis and, although only 11 of 29 cats in one study had an underlying respiratory cause of sepsis (pneumonia or pyothorax), 17 of 29 had clinical or radiographic signs of respiratory disease.[18] Septic cats are commonly fluid intolerant and quite susceptible to fluid overload. Veterinary definitions for the development of ARDS and ALI have been published (Box 123.1).[67]

Urinary system. Acute kidney injury (AKI) is a common sequela to sepsis in humans. A retrospective study proposed a scoring system for AKI in dogs (Box 123.2). Although there are no veterinary clinical studies that have investigated the incidence of AKI in patients with sepsis, retrospective sepsis studies and clinical impression suggest that sepsis-induced AKI is infrequent in dogs and cats, except in dogs with severe babesiosis.[18,23,68,69] Dogs with bacterial endocarditis may be another exception.[70] Sepsis-associated AKI has been historically attributed to acute tubular necrosis secondary to renal ischemia (e.g., due to afferent arteriolar vasoconstriction and/or poor cardiac output).[37,70–72] However, sepsis-associated AKI may be more complicated than a simple reduction in renal blood flow.[29,71–73] Tissue injury may be due to ischemia-reperfusion injury and/or activation of macrophages and neutrophils; alterations in NO metabolism; cytopathic hypoxia; and renal apoptosis. Reactive oxygen species may contribute to vasoconstriction directly or through depletion of endogenous vasodilators such as prostacyclin and NO. Apoptotic pathways may be activated in reaction to potentially lethal insults (e.g., TNF, ischemia, bacterial toxins).[71,72] Based on the human literature and retrospective veterinary studies, there has been debate as to the role of hydroxyethyl starch in contributing to AKI in veterinary patients.[74,75]

BOX 123.1 Veterinary Definitions for Acute Respiratory Distress Syndrome and Acute Lung Injury

ARDS: Acute respiratory distress syndrome. Acute fulminant respiratory failure leading to diffuse lung injury resulting from a variety of causes.

ALI: Acute lung injury, similar to ARDS but with less severe defects in gas exchange (classically defined as a PaO_2/FiO_2 ratio < 300 mmHg versus ARDS < 200 mmHg)

Diagnostic Criteria for Veterinary ARDS

1. Acute onset (<72 hours) of tachypnea and labored breathing at rest
2. Presence of known risk factors
3. Evidence of pulmonary capillary leak without increased pulmonary capillary pressure
4. Evidence of inefficient gas exchange
5. Evidence of diffuse pulmonary inflammation

BOX 123.2 Scoring System for Acute Kidney Injury in Dogs[216]

Stage 0	Creatinine increase < 150% from baseline
Stage 1	Creatinine increase of 150%–199% from baseline OR Creatinine increase of 26.5 μmol/L (0.3 mg/dL) from baseline
Stage 2	Creatinine increase of 200%–299% from baseline
Stage 3	Creatinine increase of ≥ 300% from baseline OR An absolute creatinine value > 354 μmol/L (4.0 mg/dL)

Neurologic dysfunction. Sepsis-associated neurologic dysfunction is poorly characterized or understood. CNS signs such as decreased alertness, stupor, coma, or seizures are common in people with septic shock. Anatomic, histopathologic, and reversible neurologic changes may be responsible for these derangements, including a direct effect from toxins of infectious organisms, a reduction in cerebral blood flow, capillary leakage, and dysfunction of the blood-brain barrier.[76,77] The incidence and pathogenesis of neurologic dysfunction in dogs and cats with sepsis remains to be determined.

Gastrointestinal and hepatic systems. GI dysfunction in septic patients often manifests as ileus, poor tolerance to enteral feedings, vomiting, diarrhea, GI ulceration, melena, and hematochezia. Subsequent disturbances often include malnutrition, fluid and electrolyte losses, and small intestinal bacterial overgrowth. An increase in GI mucosal permeability frequently occurs and may predispose the patient to bacterial translocation into the lymphatics and/or the bloodstream. Human patients in the ICU were found to have altered microbiota that were associated with inflammation, contained a loss of diversity, and were more pathogenic than healthy individuals.[78] Because of the prominent role of the liver in host defense, the derangements in liver function can contribute to both the initiation and progression of sepsis. The reticuloendothelial system of the liver acts as a first line of defense in clearing bacteria and their products; therefore, liver dysfunction leads to a spillover of these products into the systemic circulation. Possible mechanisms of increased GI epithelial permeability and hepatic dysfunction include dysregulation of blood flow, alterations in energy metabolism and mitochondrial function, oxidant stress, or direct effects of cytokines promoting apoptosis.[79–82] The liver is commonly referred to as the "shock organ" in dogs, and

hepatic dysfunction can result in hypoalbuminemia, coagulopathies, hypoglycemia, icterus, mental depression, and encephalopathy. Decreased albumin levels may also result from loss into the extravascular space, a shift toward production of acute-phase proteins, and, secondary to LPS-induced downregulation of NF-κB.

Microcirculatory system. In addition to alterations in smooth muscle tone and microcirculatory perfusion, vascular endothelial cells are also commonly involved in the septic process.[83–85] This negatively influences their normal roles in antithrombosis, profibrinolysis, and inhibition of platelet and leukocyte aggregation, often resulting in DIC and further negative effects on microcirculatory perfusion. In addition, sepsis-induced alterations in vascular endothelial function and perfused capillary density may result in capillary leak syndromes and heterogenous blood flow within organs. Tissue ischemia may result from decreases in both diffusive (i.e., tissue edema) and convective (i.e., decreased perfused capillary density) oxygen delivery, possibly due to changes in the endothelial glycocalyx.[86–90] In this sense, endothelial dysfunction can be implicated as the "motor of MODS." Technology such as sidestream dark field imaging has been studied in dogs and cats and enables visualization and assessment of microcirculatory derangements during sepsis and in response to therapy.[51–53,91,92] The use of endothelial biomarkers such as endocan, syndecan-1, angiopoietin-2, and soluble vascular endothelial cadherin (sVE-cadherin) to predict the severity of sepsis and outcome is currently under investigation in human medicine.[93,94] Proteomic panels have also been used to identify differential inflammatory biomarker expression that could help to predict outcome in patients with sepsis.[95]

DIAGNOSIS

The clinical features of sepsis result from the systemic inflammatory response to microbial products. The diagnosis of sepsis is often presumptive in clinical practice, based on the accumulation of clinicopathologic and biochemical data. Although a "sepsis test" does not exist, it is possible to use the patient's clinical picture combined with a high level of suspicion to quite accurately diagnose a septic patient. However, it has been reported that 82% and 60% of bacteremic dogs and cats, respectively, were found to suffer from clinical sepsis in one retrospective study.[3] It is important to maintain a high index of suspicion for sepsis since recent studies found that 6.2% of cats and 4.2% of dogs admitted to a hospital were septic and 1.5% of cats and 1.6% of dogs developed sepsis while hospitalized.[96,97]

The diagnosis of sepsis must always begin with suspicion based on the patient's clinical signs and history. Additional diagnostics that may be indicated include imaging of the thorax and abdomen, spinal radiographs, echocardiography, diagnostic peritoneal lavage, tracheal or bronchoalveolar lavage, arthrocentesis, and CSF collection. The use of serum biomarkers is an area of intense investigation and may prove quite useful in differentiating septic and nonseptic SIRS in dogs and cats.[98,99]

Laboratory Abnormalities

Complete Blood Count

The most common hematologic abnormalities in people with sepsis include anemia, leukocytosis, thrombocytopenia, and activation of the hemostatic system.[100] Similar changes have been reported in dogs and cats.[15,18,23,101,102] A leukocytosis with bandemia and cytologic evidence of toxic neutrophils indicate ongoing and premature release of leukocytes from the bone marrow and continued inflammation.[101] Increased vascular endothelial permeability due to vasculitis, platelet sequestration in the lymphoreticular system, and DIC can all contribute to thrombocytopenia. Blood loss (e.g., GI loss secondary to poor perfusion and ulcerations), hemolysis, and/or decreased erythrocyte production may all lead to anemia (more common in septic cats than dogs). Potential causes of anemia in septic animals include premature clearance by the reticuloendothelial system with a low-grade hemolysis and increased susceptibility to oxidative damage leading to a Heinz body anemia, especially in cats.[102–105]

Serum Chemistry Profile

Biochemical profile changes in animals with sepsis are typically reflective of the underlying disease process (e.g., azotemia with pyelonephritis), but may also be due to sepsis-induced changes (e.g., cholestasis). Patients with severe sepsis and septic shock often develop derangements indicative of organ dysfunction or failure (e.g., hepatic failure, DIC). Some of the more common, nonspecific abnormalities include hyperglycemia, hypoglycemia, hypoalbuminemia, and hyperbilirubinemia.[15,18,56,106,107]

Clotting Function

DIC is common in humans and animals with sepsis.[15,42,47,108,109] Hemostatic derangements are typically characterized by hypercoagulability initially, then hypocoagulability as the disease progresses. It is often challenging to diagnose hypercoagulability clinically; therefore, this stage is often overlooked. Some potential clues might include a progressively decreasing platelet count and fibrinogen levels, low AT activity, elevated D-dimers and fibrin/fibrinogen degradation products (FDPs), the presence of schistocytes on blood smear evaluation, evidence of hypercoagulability using viscoelastic indices, or clinical evidence of abnormal clotting (e.g., catheters, anticoagulated blood samples, vascular thromboses to major organs). The later hypocoagulable state is more frequently recognized clinically and typifies the progression of a septic patient into DIC.[15,42] A statistically significant lower PC and AT activity and higher PT, PTT, D-dimer, and FDPs compared with controls have been described.[15] Dogs with naturally occurring CPV enteritis had decreased AT activity and increased maximum amplitude on the thromboelastogram, consistent with hypercoagulability.[42] Hematologic and hemostatic changes in septic animals are summarized in Table 123.6.

Biomarkers

Early detection of sepsis is desirable because mortality increases with the development of organ dysfunction, hypotension, and hyperlactatemia. Early clinical signs such as tachypnea, tachycardia, fever, and leukocytosis are nonspecific, so research investigating the use of biomarkers is ongoing. Ideal biomarkers of sepsis would be able to not only detect the presence of infection but also temporally track severity of infection and progression from sepsis to septic shock. Their ability to allow monitoring response to treatment and provide prognostic information is also desirable. Potential categories of early diagnostic biomarkers might include markers of infection (e.g., LPS, bacterial DNA), markers of cellular responsiveness (intercellular cellular adhesion molecule 1, CD11/CD18),[110] and products of inflammatory cells and humoral activation (ILs, AT, aPC).[15] Procalcitonin and neutrophil CD64 appear to be potentially useful biomarkers for human sepsis, but their application to veterinary patients is yet to be defined.[111–114] Heparin-binding protein was more predictive of septic shock in people compared with several other well-studied biomarkers.[115] Additional biomarkers that have received attention in people include IL-6, aPC, IL-8, acute-phase proteins (CRP, amyloid A, haptoglobin, fibrinogen,

TABLE 123.6 Hematologic and Hemostatic Changes in Sepsis[215]

Hematologic Parameter	Tests Available	Possible Abnormalities
WBC count	WBC count, differential	Leukocytosis or leukopenia
	Blood smear, cytologic evaluation	Toxic changes; immature neutrophils
	Bone marrow evaluation	Myeloid hyperplasia
RBC count	Hematocrit	Hemoconcentration or anemia
	Reticulocyte count	Nonregenerative anemia
	Blood smear, cytologic evaluation	Heinz bodies (cats)
	Bone marrow evaluation	Erythroid hypoplasia
Platelets	Platelet count	Thrombocytopenia
	Blood smear, cytologic evaluation	Thrombocytopenia
Hemostatic parameters	PT	Normal (early) or prolonged (late)
	PTT	Normal (early) or prolonged (late)
	Activated coagulation time	Normal (early) or prolonged (late)
	FDP	Increased
	D-dimers	Increased (late)
	Antithrombin[a]	Decreased activity
	Thromboelastography[a]	Increased coagulation index
	Protein C[a]	Decreased

[a]Less commonly performed tests; may only be available through reference laboratories.
FDP, fibrinogen degradation products; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *WBC*, white blood cell; *RBC*, red blood cell.

α-1-acid glycoprotein, and ceruloplasmin), LPS, LPS-binding protein, nitrate/nitrite concentrations (byproducts of NO metabolism), soluble intercellular cellular adhesion molecule 1, AT, TFPI, CD14, CD11b/CD18, T-cell function assays, IL-12, neutrophil gelatinase-associated lipocalin, and IL-1 receptor antagonist.[116–119] Serum IL-6 has been studied in experimental models of endotoxemia or inflammation in dogs; this biomarker rises within hours, stays elevated for days when inflammation persists, and may have a prognostic role in this species.[120–123] Initial serum CRP concentration in dogs with sepsis did not correlate with survival.[124,125] However, decreasing concentrations were observed with recovery from sepsis. Monocyte chemoattractant protein-1 is increased in critically ill dogs and highest levels have been observed in those with sepsis.[126] This level of cytokine mediator in dogs appeared to increase in proportion to the severity of sepsis, similar to what has been observed in humans. aPC is decreased in septic human patients and canine models of sepsis and represents a therapeutic target that reduces mortality in limited populations with severe sepsis.[127–129] Treatment of sepsis with aPC failed to improve survival in a large randomized clinical trial,[130] the product, when it was available was quite costly and species specific; therefore, clinical use of this product was not investigated in veterinary medicine. Plasma von Willebrand factor antigen concentration, a marker of endothelial activation, was increased in dogs with sepsis compared with that in clinically healthy control dogs.[131] However, there was no significant difference between levels in surviving and nonsurviving dogs.

Microbiologic Tests

Bacterial Isolation and Identification

The identification of a septic focus and the procurement of infected tissue or fluid for culture and sensitivity testing are of paramount importance. Although this might be difficult in certain patients (e.g., those that are unstable, coagulopathic), cytology or histopathology can also be used to make a definitive diagnosis of infection.[16,18,23,132] Specimen collection is further described in Chapter 3. Faster turnaround times for canine and feline blood cultures (<24 hours) may soon be clinically available to help guide earlier therapy.[133]

Molecular Diagnosis Using Nucleic Acid–Based Testing and Metagenomic Approaches

Rapid NAAT tests are increasingly being used in human medicine for rapid identification of pathogens associated with sepsis. Such assays may detect more pathogens than culture, have a shorter turnaround time, and may still be positive in the face of empirical antimicrobial therapy.[134–136] Commercially-available diagnostic tests that use metagenomic approaches such as next-generation sequencing (NGS) are also increasingly available and in clinical use in human patients; an example is the Karius NGS test (Karius, CA, USA). At the time of writing, these assays can be expensive and their performance and value requires further study.[136]

Pathologic Findings

Because sepsis is not a specific disease, but rather a clinical entity describing the host response to systemic inflammation initiated by a pathogen, there are no specific gross or histopathologic findings that are diagnostic for sepsis. Histologic findings associated with SIRS include widespread vascular endothelial injury, neutrophil margination, edema, and microthrombosis. The focus of infection will often represent the key pathologic abnormality (e.g., CPV enteritis, pyometra, bacterial endocarditis).

Necropsy studies do not definitively reveal the cause of death in many human patients with sepsis, and there is frequently discordance between histologic findings and the degree of clinical and laboratory indices of organ dysfunction. One possible reason for this might be the occurrence of *cell stunning*, in which sepsis activates defense mechanisms that cause cellular processes to be reduced to basic housekeeping roles, but further investigation is required. Many animals develop secondary organ dysfunction that may prove life-threatening; derangements of the coagulation, cardiovascular, respiratory, renal, GI, hepatic, and microcirculatory systems are most common.

TREATMENT

The mainstay of therapy for septic patients remains source control to remove the inciting cause and provide supportive care.

Circulatory Support

Septic patients commonly suffer from circulatory collapse despite volume resuscitation; therefore, cardiovascular support is a primary objective of treatment. To maintain adequate tissue perfusion and prevent the development of MODS, aggressive fluid therapy is essential. Isotonic crystalloids, hypertonic crystalloid solutions, synthetic colloids, and blood component therapy are typically administered during fluid resuscitation and maintenance of the septic patient.[137,138] Many septic patients have increased vascular endothelial permeability and hypoalbuminemia; thus, judicious use of fluid products is recommended. Synthetic colloids may prove helpful in animals with severe decreases in colloid osmotic pressure, and

colloidal blood component therapy, including human/canine albumin or plasma, may be beneficial in animals that are severely hypoalbuminemic or coagulopathic, respectively. Although not proven in small animals, the use of hydroxyethyl starch in humans with sepsis has been found to increase the risk for AKI.[139] Because large volumes of fresh frozen plasma are required for albumin replacement (e.g., 22 mL/kg of plasma to raise the albumin concentration by 0.5 g/dL),[140] fresh frozen plasma is used primarily for animals that are coagulopathic or to prevent a further decline in those with severe hypoalbuminemia.

Human and canine serum albumin are in the early stages of clinical use in veterinary medicine, and further research is ongoing. The 25% human serum albumin solution is hyperoncotic (100 mmHg) and should be used judiciously in patients with limited fluid tolerance. Anemia and thrombocytopenia may prompt the use of erythrocyte- or platelet-containing products (e.g., packed RBCs, fresh whole blood, lyophilized platelets). In contrast to the debated value of placement of a central venous catheter in humans, in veterinary patients this tool provides a way to monitor trends in central venous pressures during aggressive fluid therapy.[137] In a landmark study, the use of early goal-directed therapy, including central venous oxygen saturation, was shown to improve outcome in humans with sepsis and septic shock[141]; however, subsequent large-scale clinical trials failed to confirm a survival benefit of this approach.[142,143] Noninvasive cardiac output monitoring may prove useful in management of septic patients by providing trends in systemic vascular resistance, cardiac output, and pulmonary capillary wedge pressure.[143] This information will assist with treatment decisions regarding the use of fluids, vasopressors, and/or inotropes. Frequent monitoring of body weight and urine output via placement of an indwelling urinary catheter is also helpful in assessing total fluid balance. Various fluid types and doses can be found in Table 123.7.

Cardiovascular Support

Persistent hypotension (mean arterial pressure less than 65 mmHg or Doppler less than 90 mmHg) despite restoration of a normal intravascular volume signals the need for vasopressor and/or inotropic therapy to support oxygen delivery to the tissues and prevent organ damage.[141,144] The choice of treatment drug depends on the clinical picture combined with objective information regarding the septic patient (Table 123.8). Vasopressors such as norepinephrine, dopamine, phenylephrine, and vasopressin are typically used in patients with peripheral vasodilation. The use of dopamine has been discouraged in septic humans due to an increased risk for arrhythmias, but this has not been proven in dogs or cats.[145] Phenylephrine is a pure α-agonist, whereas norepinephrine and dopamine have a combination of both α- and β-agonist activity.[146] Vasopressin, also known as antidiuretic hormone, is a nonadrenergic vasopressor agent that aids in the regulation of free water balance in healthy animals, but serves as an important endogenous vasoconstrictor during states of hypotension.[147] Decreased vasopressin concentrations have been found in animals and humans with catecholamine-refractory shock, and exogenous vasopressin treatment works synergistically with adrenergic pressor substances, primarily norepinephrine. Therapeutic restoration of blood vasopressin levels in patients suffering from shock works primarily via the vasopressin-1 receptor to cause vasoconstriction of most capillary vessels, although the cerebral, renal, pulmonary, and mesenteric vessels are spared with low-dose therapy.[148,149] A combination of vasopressin and glucocorticoids may further increase survival.[150] Use of vasopressin in dogs and cats is limited thus far, but preliminary findings in dogs are promising.[151–153]

Hypotensive animals that are most likely to benefit from vasopressor therapy include those with clinical evidence of peripheral vasodilation, such as bright red mucous membranes, bounding pulses, and fast CRTs. However, cats rarely exhibit these signs. Invasive or noninvasive measurements of systemic vascular resistance can also guide the use of vasopressor therapy but can be difficult to measure in the clinical setting. Vasoconstricting drugs are often effective at increasing arterial blood pressure but may also result in excessive vasoconstriction to some areas, particularly the splanchnic and/or renal circulation, which may lead to GI and/or renal ischemia and dysfunction. Especially in the septic canine patient, splanchnic vasoconstriction may exacerbate the endotoxemia by compromising normal intestinal integrity and enabling bacterial translocation into the bloodstream.

Positive inotropes such as dobutamine are generally used in septic patients with evidence of impaired myocardial contractility (e.g., decreased fractional shortening on M-mode echocardiography, decreased cardiac output on invasive or noninvasive measurements of cardiac output). The β-agonist drug most commonly used for the treatment of decreased systolic function is dobutamine, although isoproterenol, epinephrine, and dopamine also have beta-adrenergic activity.[148]

TABLE 123.7 Fluid Choices for Circulatory Support

Fluid Type	Dose	Comments
Isotonic crystalloids	Dog: up to 90 mL/kg (start with 20–30 mL/kg) Cat: up to 60 mL/kg (start with 10–20 mL/kg)	Used in animals for intravascular and interstitial volume deficits. May cause edema in animals with capillary leak or a low oncotic pressure.
Synthetic colloid solutions (hydroxyethyl starches)	Dog: 5–20 mL/kg Cat: 5–10 mL/kg	Used in animals for volume replacement and oncotic support. May cause coagulopathies and increase the risk for acute kidney injury in humans.
Human albumin	2 g/kg or calculate albumin deficit (g): 10 × (desired-patient albumin) × weight (kg) × 0.3	Used for albumin and oncotic support and volume replacement. Monitor closely for reactions. One-time dose recommended.
Canine albumin	1–2 g/kg	Limited safety studies thus far. Use with caution.
Fresh frozen plasma	10–15 mL/kg as needed	Used to treat clotting factor deficiencies and provide albumin-containing oncotic support.
Frozen or cryoprecipitate-poor plasma		Used to provide albumin-containing oncotic support or for treatment of rodenticide toxicity.
Packed red blood cells	10–15 mL/kg to raise HCT by 10%–15%	Used to treat anemia.
Fresh whole blood	20–25 mL/kg	Used to treat anemia, thrombocytopenia, and clotting factor deficiencies and provide albumin-containing oncotic support.

HCT, hematocrit.

TABLE 123.8 Dosages and Receptor Activity of Vasopressor and Inotropic Drugs

Drug	Alpha Activity	Beta Activity	Dosage	Comments
Dobutamine	+	B_1 +++, B_2 ++	2–20 μg/kg/min	May cause seizures in cats
Dopamine (low dose)	0 to +	0 to +	1–4 μg/kg/min	Vasodilatory dose
Dopamine (medium dose)	+ to ++	+ to +++	5–10 μg/kg/min	Inconsistent plasma levels
Dopamine (high dose)	+++	+ to +++	10–20 μg/kg/min	Inconsistent plasma levels
Epinephrine	+++	++ to +++	0.05–1.0 μg/kg/min	Significant adverse effects
Norepinephrine	+++	+ to ++	0.05–1.0 μg/kg/min	Primarily alpha adrenergic activity
Phenylephrine	+++	0 to +	0.1–1.0 μg/kg/min	Significant vasoconstriction and potential adverse effects
Vasopressin	0	0	0.5–5 mU/kg/min	Nonadrenergic vasopressor activity via vasopressin receptors

0, zero; +, slight; ++, moderate; +++, strong.

Antimicrobial Use in Sepsis

The Surviving Sepsis Campaign Guidelines were updated in 2012, 2016, and 2021 and recommend the administration of broad-spectrum antibacterial therapy within 1 hour of diagnosis of severe sepsis or septic shock.[154,155] Timely localization of the septic focus and procurement of infected tissue or fluid for bacterial identification and determination of antibacterial susceptibility are of paramount importance in the treatment of a septic patient. However, sample collection may be impossible because of cardiopulmonary instability or the presence of a coagulopathy in some patients. Pending culture and susceptibility results, empiric antibacterial therapy should be selected based on the following factors: antibacterial properties (bactericidal versus static); the expected bacterial flora in the affected tissue; the ability of the antibacterial to penetrate the infected tissue; recent history of antibacterial use and considerations for resistance; and source of infection (whether nosocomial or community-acquired). Readers are referred to Chapters 8 and 10 for further details.

Appropriate empiric therapy is vital for success. Broad-spectrum bactericidal antimicrobial agents are typically administered to septic patients via the IV route. Adjustments are made pending availability of antibacterial susceptibility testing results. Box 123.3 contains examples of four-quadrant, empiric therapy (i.e., effective against many gram-positive and gram-negative aerobes and anaerobes). One study highlighted the importance of appropriate antibacterial selection; in five dogs in which inappropriate antibacterial drugs were empirically administered, mortality was 80%.[16] Studies have failed to show an association between appropriate antimicrobial use and mortality[156,157]; the complexity of management of septic patients warrants a prospective study to define the impact of early appropriate antimicrobial administration. Polymyxin B, an antibacterial which binds to the lipid A subunit of endotoxin molecules, has been used in the treatment of cats with experimental endotoxemia.[158] When administered IV, at a rate of 1 mg/kg over 30 minutes, polymyxin B reduced the plasma TNF activity and increased leukocyte counts with no adverse effect. Further studies in naturally affected cats will be helpful to determine its clinical efficacy. Delaying administration of antimicrobials or withholding their use in a septic patient increases the ability of the organisms to reproduce, spread, and induce a greater inflammatory response.

Gastrointestinal Protectants

The initial strategy to prevent GI complications in critically ill dogs and cats is to ensure adequate GI perfusion and employ early enteral nutrition. High-risk patients should receive pharmacologic prophylaxis for stress-related GI hemorrhage. Based on the available evidence in human medicine, it appears that proton pump inhibitors (PPIs) are superior to histamine-2 receptor antagonists (H2RAs), which are superior to sucralfate in the prevention of stress-related mucosal disease in adult critical care patients.[159–161] Drugs available include omeprazole (0.7–1.0 mg/kg, PO, q24h); pantoprazole (0.7–1.0 mg/kg, IV, q12–24h); famotidine (0.5–1.0 mg/kg, IV, q12–24h); and sucralfate (0.25–1 g/25 kg, PO, q6–8h). Lower doses of sucralfate (0.1–0.2 mg/kg) have claimed equal efficacy.[162]

BOX 123.3 Examples of Empiric, Broad-Spectrum (Four-Quadrant) Antibacterial Therapy for the Treatment of Sepsis

Ampicillin and: enrofloxacin, amikacin, gentamicin, cefoxitin, cefotaxime, or ceftazidime
Clindamycin and: enrofloxacin, amikacin, gentamicin, or ceftazidime
Imipenem or meropenem

Additional Treatment Strategies for Sepsis

There have been a number of landmark studies in human medicine regarding treatment strategies for sepsis over the past several years, some of which have subsequently been called into question. Some strategies, however, may also prove applicable to small animal medicine, although further research is needed. These highly acclaimed strategies include early goal-directed therapy to direct resuscitation treatment of relative adrenal insufficiency, tight glycemic control, neutralization of endotoxin, and physiologic anticoagulant therapy. The benefits of treatment of human patients with IV vitamin C and thiamine in combination with hydrocortisone is also being studied.[163] This has occurred in response to evidence of low vitamin C and thiamine concentrations in septic patients, and some initial evidence of positive outcomes in initial human clinical trials.

Early goal-directed therapy was initially shown to decrease mortality and severity of illness in humans with sepsis, although more recent investigations have not confirmed these earlier findings.[141,144,164] Preliminary evidence suggests a beneficial response in dogs treated with goal-directed therapy.[165] This invasive approach uses multiple criteria, including central venous oxygen saturation > 70%, central venous pressure ≥ 8–12 mmHg, mean arterial pressure ≥ 65 mmHg, urine output ≥ 0.5 mL/kg/hour, oxygen saturation ≥ 93%, and hematocrit ≥ 30%, as a rapid goal within the first 6 hours of hospitalization in humans. In an observational study,[166] 38% of

canine shock patients had central venous oxygen saturation < 70% despite normalization of blood pressure, HR, and physical parameters. Although formal studies have not been performed in veterinary patients, it seems reasonable to expect that a rapid correction of hemodynamic and organ function indices would be beneficial to the animal. The use of central venous oxygen saturation monitoring in animals is limited, primarily because of the expense of the equipment required.

The hypothalamic-pituitary-adrenal axis is crucial for host response to infection. The early inflammatory response to sepsis stimulates endogenous release of cortisol, which subsequently modulates the synthesis and release of pro- and anti-inflammatory mediators to restrict inflammation of infected tissues. The cause of critical illness-related corticosteroid insufficiency (CIRCI)[167] in septic patients appears to be multifactorial, including factors such as vascular or ischemic damage, inflammation, and apoptosis within the hypothalamic-pituitary-adrenal axis; use of drugs that modify cortisol metabolism; and/or tissue resistance to glucocorticoids.[168,169] CIRCI may occur in up to 70% of people with sepsis and is correlated to hypotension and death in these patients. Preliminary research in dogs, cats, and foals suggests that a similar phenomenon also occurs with critical illness in these species.[170–174] Sepsis-induced CIRCI in humans is not easily diagnosed and a matter of considerable controversy.[45] Some recommendations suggested that a diagnosis could be made by identifying a basal cortisol less than 10 μg/dL or a change in cortisol (delta cortisol) of less than 9 μg/dL after administration of ACTH. Administration of ACTH to diagnose the syndrome is no longer recommended, rather administration of hydrocortisone is recommended in patients who have not responded to adequate fluid resuscitation and vasopressor therapy.[155] The use of physiologic doses of hydrocortisone has been found to improve 28-day mortality rates and decrease the duration of vasopressor therapy in septic humans with a poor response to ACTH testing.[175] However, one systematic review performed in 2013 found no clear benefit of glucocorticoids on mortality, although subgroup analysis of low-dose glucocorticoid use is suggestive of a beneficial drug effect on short-term mortality, particularly in more critically ill patients.[155] In contrast, a 2019 meta-analysis showed faster shock reversal, fewer vasopressor-dependent days and decreased length of ICU stay, in addition to a reduced 28-day mortality rate. In summary, although routine use of hydrocortisone in adults with sepsis is still controversial, its use is recommended in adult patients with septic shock who are poorly responsive to fluid and vasopressor therapy, as well as pediatric patients with suspected or proven adrenal insufficiency.[153,176,177] The diagnosis and treatment of CIRCI in veterinary medicine is also subject to controversy.[170] In one study, critically ill dogs with a delta cortisol ≤ 83 nmol/L were almost six times as likely to need vasopressor therapy.[174] Similar to the Surviving Sepsis Guidelines for humans,[155] the use of hydrocortisone should be limited to those veterinary patients in shock who have not responded to adequate fluid resuscitation and vasopressor treatment, until further evidence provides more specific recommendations.

Prevention of hyperglycemia in septic and critically ill patients has been the focus of much research, and glycemic control was recommended in the 2021 Surviving Sepsis Guidelines.[153,155,178–181] Although there are several etiologies for the elevated glucose in septic animals, hepatic insulin resistance appears to play a major role.[181] Hyperglycemia may serve to potentiate the proinflammatory response and cause endothelial and neutrophil dysfunction.[182,183] A decrease in morbidity and mortality, as well as the incidence of sepsis, was found when intensive insulin therapy was used to strictly regulate glucose levels (e.g., >180 mg/dL) in critically ill humans.[155,184–187] Tight glycemic control (glucose < 110 mg/dL) is associated with an increased prevalence of hypoglycemia. In a series of randomized controlled studies, tight glycemic control was either associated with no improvement or an increase in mortality and a high incidence of hypoglycemia.[155] Current recommendations from the Surviving Sepsis Guidelines are to maintain blood glucose ≤ 180 mg/dL.[155] There are few studies concerning glucose monitoring in small animals, but preliminary data show a similar trend.[188–191] Until there is more evidence of a broad benefit and institution of precise monitoring in small animals, the risk of hypoglycemia likely outweighs the benefit of tight glucose control. Critically ill small animal patients may benefit from strategies to maintain their glucose between 80 and 180 mg/dL.

Directed therapy of sepsis has attempted to follow the advances in our understanding of the cascade of inflammation.[192] The most common and potent trigger of SIRS in sepsis is bacterial endotoxin. Several strategies have been investigated to eliminate or neutralize endotoxin. The list of promising agents included glucocorticoids, anti-endotoxin antibodies, competitive inhibitors (e.g., lipid X), and natural inhibitors (e.g., bactericidal permeability increasing protein). Despite survival benefits in experimental animals, none of these agents has proven successful in human or veterinary (bactericidal permeability increasing protein) trials.[193,194] One of the proposed reasons for the failure of this strategy was that endotoxin is an early and transient mediator that initiates the cascade of events in the host immune response. Therefore, in the next wave of investigations, attention was directed toward the inflammatory cytokines and other later mediators. Similar to the experience with endotoxin inhibition, inhibition of cytokines and other individual inflammatory mediators has failed to show benefit and, in some cases, was detrimental. These circulating mediators have been demonstrated in septic veterinary patients, but there are no veterinary clinical trials investigating inhibition of these compounds. Immune paralysis has been recognized in some patients with sepsis. Immune stimulation using granulocyte colony-stimulating factor in puppies with CPV was not beneficial.[195] However, investigations in experimental animals and clinical trials are ongoing. Overall strategies targeting individual mediators of sepsis have failed.

The use of aPC therapy in humans with septic shock has received much attention over the past 10 years as it was the only directed therapy that had shown any benefit in human sepsis clinical trials. aPC inhibits factor Va and factor VIIIa and has effects on *in vitro* coagulation, fibrinolysis, and the immune system. Although initial studies showed a decrease in mortality in patients with sepsis and septic shock, subsequent trials failed to demonstrate a benefit and the drug was withdrawn from the market.[130,196] aCP was quite expensive and associated with an increased risk of serious bleeding in humans; the human formulation was known to have a short half-life and to be antigenic in dogs and, therefore, was not well studied in small animals.

Novel Drugs With Potential for Benefit in Sepsis

Nitric Oxide

NO is an important molecule in vasoregulation and the immune system.[197] In the endothelial cell, the enzyme responsible for NO production (endothelial NO synthase) is constitutively expressed. In the vascular system, NO is released at low levels and mediates vascular smooth muscle relaxation and opposes the interactions between endothelial cells and leukocytes. In the inflammatory response, macrophages are responsible for generation of large quantities (100-fold greater than the endothelial cells) of NO that are important in bactericidal activity. Excessive production of NO leads to tissue damage, particularly as a

result of interactions with superoxide and the formation of the highly reactive peroxynitrite. The effects of sepsis on NO synthesis are complex. Although NO is implicated as a mediator of septic hypotension and cardiac depression (among other things), global inhibition of NO has multiple adverse effects and has failed to demonstrate a benefit in human clinical trials.[198]

Statins

Statins have been used in the treatment and prevention of atherosclerosis and lower serum lipids through the inhibition of 3-hydroxy-3-methylglutaryl coenzyme A reductase. These drugs also affect intracellular signaling, including NF-κB activation, in the inflammatory response. The anti-inflammatory effects of statins have been documented on both innate and acquired immunity, the coagulation system (promoting an anticoagulant state and enhancing the synthesis of aCP), and the vascular endothelium (improving endothelial function and normalizing NO production). Despite evidence from experimental studies and a meta-analysis of the observational studies,[199–201] two published randomized controlled trials evaluating statins in patients with ARDS[202,203] failed to demonstrate a benefit of treatment.

Toll-Like Receptor Antagonists

The attempt to intervene in the response to endotoxin has not proven beneficial in the past through anti-endotoxin antibodies, soluble CD14 (which conversely increased the inflammatory response), or through LPS-binding agents (BPI). Another target of the endotoxin pathway has been the TLR4 receptor. In a phase II clinical trial, one TLR4 antagonist did not show any more adverse events than the placebo and overall did not change mortality. In a phase III multinational study of 1,961 patients with severe sepsis, treatment with a TLR4 antagonist failed to demonstrate an effect on mortality.[204] Targeting TLR pathways continues to be an area of investigation for treatment of sepsis.[205,206]

High Mortality Group Box 1

HMGB1 is a nuclear protein that has been shown to be a late biomarker in sepsis. Serum levels of HMGB1 are measurable in mouse models of sepsis/endotoxemia within 8 hours and remain elevated for up to 32 hours.[29,207] In addition to its value as a biomarker, it appears that HMGB1 mediates part of the inflammatory response, thus making it a potential target for therapy. Antibodies to HMGB1 were protective in a mouse model of sepsis, even when they were administered 24 hours after the onset of sepsis.[207] Several agents have been shown to modify HMGB1 activity or release and these include anticoagulant agents (i.e., AT, thrombomodulin), endogenous hormones (i.e., insulin, vasoactive intestinal peptide, ghrelin), vagus nerve stimulation, green tea, the Chinese herb danshen, and ethyl pyruvate. Despite promising experimental studies, there are no clinical trials documenting the benefit of HMGB1 inhibition in patients with sepsis.[29,208,209]

Nuclear Factor-κB Inhibitors

Although NF-κB is a major transcription factor involved in the inflammatory response, it is also vital in several other pathways including the anti-inflammatory response and antiapoptotic pathways. Several compounds known to influence NF-κB signaling have failed clinical trials, (e.g., glucocorticoids, NSAIDs, antioxidants). These drugs have numerous other effects, and potentially improved specificity and selective timing of administration will still have a role in the future of sepsis therapy.[209]

Individualized Approach

One concept that arises from the PIRO scheme (see Table 123.4) is that each patient may require tailored therapy based on predisposition, age, sex, genetic background, and, in the case of veterinary patients, species and breed. Furthermore, the type and location of infection influence how a patient is treated. This approach is employed in antibacterial selection, but as additional information accumulates, it may also guide specific treatment that enhances or downregulates specific signaling pathways. Defining the host response as monitored by biomarkers is becoming more commonplace and has great potential to identify patients that could benefit from either suppression or enhancement of the host immune response depending on whether the patient was in a state of hyperinflammation or immune paralysis. The final component of PIRO is organ failure. One of the few advances in treating septic patients has come from implementing "protective ventilation" strategies in which low (6 mL/kg) tidal volume mechanical ventilation is used in patients with ARDS. Individualizing treatments and multimodal approaches are likely to be important in sepsis, given the heterogeneity in the patients and the inciting cause and the dynamic nature of response to sepsis.[209]

PROGNOSIS

Most dogs suffering from sepsis have a guarded prognosis. The published survival rate in dogs and cats with sepsis is 33% to 68%, respectively, and survival in animals with septic shock is worse.[15,168,210,211] Mortality rate increases as the number of dysfunctional organ systems increases.[7] In septic peritonitis, this survival rate does not seem to have improved over the past 20 years despite improvements in critical care management.[14] To maximize success, appropriate diagnostics as well as timely and aggressive therapeutic support are necessary. Future studies in veterinary medicine will likely focus on novel diagnostic modalities as well as superior treatment options.

CASE EXAMPLE

Signalment

"Opal," a 9-year-old, female spayed Siamese cat from Philadelphia, PA.

History

Opal's owner reported a 1-week history of fever, lethargy, and anorexia. There had been no vomiting, diarrhea, coughing, or sneezing. Two months prior to evaluation, the owner noticed that the cat was drinking and urinating more than usual for 1 week, but this resolved without treatment. Opal was an indoor-only cat with no travel history and was up to date on all vaccinations. Opal was not on flea, tick, or heartworm preventative. Opal received no medications and had no prior medical history. She ate a commercial cat food and there was no recent diet change.

Physical Examination

Body weight: 3.4 kg.

General: Quiet, alert, and responsive. Ambulatory on all four limbs. Temperature = 104.1°F (40.1°C), HR = 140 beats/minute, RR = 52 breaths/minute, mucous membranes pale and dry, CRT = 1.5 second.

Integument: A full, mildly dry haircoat was present and there was no evidence of ectoparasites.

Eyes, ears, nose, and throat: No significant abnormalities were noted. There was intermittent ptyalism and a mild amount of brown waxy debris in both ear canals.

Musculoskeletal: A BCS of 4/9 with symmetrical muscling was noted.

Continued

CASE EXAMPLE—cont'd

Cardiovascular: Weak femoral pulses were noted. No murmurs or arrhythmias were detected on thoracic auscultation.

Respiratory: An increased RR was observed and there were clear breath sounds in all lung fields on auscultation.

GI and genitourinary: The cranial abdomen was tense with abdominal splinting upon abdominal palpation. No masses were palpated, although the liver and kidneys were subjectively enlarged. A rectal examination was not performed.

Lymph nodes: All peripheral lymph nodes were < 0.5 cm.

Doppler BP: 60 mmHg (120–160 mmHg)

Laboratory Findings

CBC: HCT 31.0% (31.7%–48.0%), MCV 51.2 fL (36.7–53.7 fL), MCHC 31.1 g/dL (30.1–35.6 g/dL), WBC 13.9 × 10^3 cells/μL (4.04–18.7 × 10^3 cells/μL), neutrophils 12.9 × 10^3 cells/μL (2.3–14 × 10^3 cells/μL), band neutrophils 0.42 × 10^3 cells/μL, lymphocytes 0.56 × 10^3 cells/μL (0.8–6.1 × 10^3 cells/μL), monocytes 0 cells/μL (0–0.7 × 10^3 cells/μL), platelets 148,000 platelets/μL (175,000–500,000 platelets/μL). A clinical pathologist reviewed the slide and noted moderate toxic changes in many WBCs. Bacterial rods were noted infrequently within neutrophils (Fig. 123.4) and rarely extracellularly.

Serum chemistry profile: Sodium 149 mmol/L (146–157 mmol/L), potassium 4.0 mmol/L (3.5–4.8 mmol/L), chloride 118 mmol/L (116–126 mmol/L), bicarbonate 20 mmol/L (16–25 mmol/L), phosphorus 3.5 mg/dL (3.0–6.6 mg/dL), calcium 7.1 mg/dL (9.1–11.2 mg/dL), BUN 42 mg/dL (15–32 mg/dL), creatinine 1.6 mg/dL (1.0–2.0 mg/dL), glucose 170 mg/dL (67–168 mg/dL), total protein 4.9 g/dL (6.0–8.6 g/dL), albumin 2.0 g/dL (2.4–3.8 g/dL), globulin 2.9 g/dL (3.1–5.0 g/dL), ALT 63 U/L (33–152 U/L), AST 84 U/L (137 U/L), ALP < 20 U/L (27–87 U/L), GGT < 10.0 U/L (5–19 U/L), cholesterol 116 mg/dL (96–248 mg/dL), total bilirubin 1.5 mg/dL (0.1–0.8 mg/dL), magnesium 3.3 mg/dL (1.9–2.6 mg/dL).

Urinalysis: SpG 1.024; pH 7.0, 3+ protein (SSA), 2+ glucose, no ketones, no bilirubin, 4+ hemoprotein, 31–40 WBC/HPF, 0–5 RBC/HPF, mild epithelial cells, moderate bacterial rods.

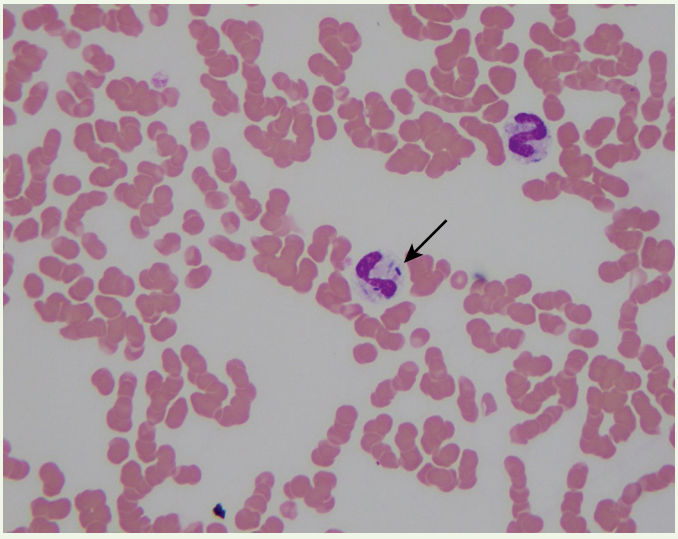

Fig. 123.4 A blood smear from the case example, Opal. Note the intracellular rod *(arrow)* that supports a diagnosis of bacteremia. Magnification 100×. (Courtesy of Dr. Dana Clarke.)

Urine culture: >100,000 CFU/mL *Escherichia coli*, susceptible to all antimicrobials tested.

Blood culture and susceptibility testing: *Escherichia coli* resistant to ampicillin with or without clavulanate or sulbactam.

SNAP FeLV/ FIV ELISA antigen/antibody (IDEXX Laboratories): Negative.

Imaging Findings

Thoracic radiographs: The cardiovascular and pulmonary structures appeared within normal limits.

Abdominal ultrasound: There was a small amount of sludge in the gallbladder. The right kidney was enlarged (47.4 mm long) with pyelectasia (3.9mm). Mild to moderate retroperitoneal effusion with perirenal steatitis and renal mineralization were present. The right ureter was dilated throughout its length (proximal: 3.5 mm in diameter; mid: 3.6 mm; distal: 4.2 mm) with a thickened wall. Within the ureter at the ureterovesicular junction there was a 2.0-mm calculus. The left kidney had decreased corticomedullary definition with hyperechoic speckling throughout the medullary cavity. Several calculi were within the renal pelvis (largest 3.9 mm in length). The left lobe of the pancreas was mildly heterogeneous with hyperechoic foci throughout, and there was a mild rim of hyperechoic surrounding fat. Very scant free peritoneal effusion was seen.

Treatment

Aggressive fluid therapy was instituted due to the hypotension. Despite 30 mL/kg of isotonic crystalloid fluids administered over 45 minutes, blood pressure only increased to 85 mmHg. Norepinephrine was administered at 0.1–0.5 μg/kg/minute as an IV infusion as needed to keep Doppler BP ≥ 100 mmHg. A vasopressin infusion was also necessary to maintain normotension (0.5–0.8 mU/kg/hour). An isotonic fluid infusion was administered at 4 mL/kg/hour. Clindamycin (10 mg/kg, IV, q12h) and ceftazidime (40 mg/kg, IV, q6h) were administered pending blood and urine culture results. Clindamycin was discontinued after 72 hours when susceptibility testing from the cultures was completed.

Opal developed clinically significant anemia and became coagulopathic based on a prolonged PT and APTT. Packed RBCs (15 mL/kg) and fresh frozen plasma were administered. Vitamin K1 was also administered (1 mg/kg, SC, q24h). Treatment with gastroprotectants, including pantoprazole (1 mg/kg, IV, q 24h) and maropitant (1 mg/kg, IV, q24h), were also started. Analgesia with methadone (0.1–0.2 mg/kg, IV, q4h) was initially used for pain control. This was later switched to a fentanyl infusion for management of continued discomfort (2–4 μg/kg/hour IV). A repeat ultrasound 1 and 2 days following initial evaluation revealed that the ureteral calculus had passed into the urinary bladder. Surgery was therefore not necessary.

Comments

This cat had several abnormalities that are common in cats with sepsis. Although this species does not get the classic hyperdynamic physical examination changes, as typically seen in dogs, the presence of an increased rectal temperature, bradycardia, and tachypnea represents a SIRS. The additional findings of pale mucous membranes, poor femoral pulse quality, hypotension, mildly increased bilirubin, toxicity and a left shift on the CBC, and the presence of bacteria in the intracellular and extracellular space upon blood smear evaluation all raise the suspicion for sepsis. Multiple organ dysfunction, as evidenced by vasoplegia and coagulopathy, is common and frequently involves additional organs such as the heart, lungs, GI tract, liver, and kidneys. The need for vasopressor therapy following fluid resuscitation indicates the cat was suffering from septic shock. Aggressive, rapid, and empiric therapy pending culture and susceptibility led to a successful outcome in this cat.

Bacterial Respiratory Infections (Tracheobronchitis, Pneumonia, and Pyothorax)

Carol Reinero, Tekla Lee-Fowler

KEY POINTS

Bacterial Tracheobronchitis and Pneumonia

- Causes: Primary bacterial pathogens include *Bordetella bronchiseptica* and *Mycoplasma* spp. A wide variety of secondary bacterial pathogens can also be implicated including anaerobes, *Escherichia coli*, *Pasteurella* spp., *Staphylococcus* spp., and *Streptococcus* spp.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Community acquired (contagious) or secondary to aspiration or impaired local or systemic immune defenses.
- Major Clinical Signs: Cough, nasal discharge, sneeze, tachypnea, respiratory distress, cyanosis, and systemic signs of illness (lethargy, anorexia, fever).
- Differential Diagnoses: Differentials for bacterial tracheobronchitis include other nonbacterial infectious airway disorders (primarily viral and parasitic), noninfectious inflammatory airway disease, and structural airway disorders; differentials for bacterial pneumonia include other infectious pneumonia (viral [especially CDV infection], fungal, parasitic, protozoal), noninfectious inflammatory pneumonia (sterile aspiration pneumonia and foreign body pneumonia), neoplasia, interstitial lung disease, cardiogenic or noncardiogenic pulmonary edema, pulmonary vascular disease, and hemorrhage.
- Human Health Significance: *Bordetella bronchiseptica* can cause disease in immunocompromised humans. While further study is needed, MDR bacteria colonizing the canine and feline respiratory tract may be able to colonize humans.

Bacterial Pyothorax

- Causes: Pyothorax is often polymicrobial. Anaerobic bacteria and mixtures of anaerobic and facultative aerobic bacteria are common in both dogs and cats. Although more often cultured from the pleural fluid of cats, *Pasteurella* is also implicated in both species.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Direct inoculation of the pleural cavity (e.g., migrating foreign material, bite wounds, trauma), extension of local infection (e.g., pneumonia, lung abscess, thoracic wall infection), hematogenous spread.
- Major Clinical Signs: Restrictive respiratory pattern (rapid, shallow respiration with increased inspiratory effort), obtundation, exercise intolerance, cough, lethargy, anorexia, weight loss, and fever. Cats may exhibit hypothermia, bradycardia, and hypersalivation.
- Differential Diagnoses: Other nonbacterial infections that can be associated with pleural effusion (e.g., *Aspergillus* spp.), chylothorax, hemothorax, neoplasia, FIP (cats).
- Human Health Significance: Because commensal organisms of the oral cavity and upper respiratory tract are most typically associated with pyothorax in dogs and cats, pyothorax does not have human health significance.

BACTERIAL TRACHEOBRONCHITIS AND PNEUMONIA

ETIOLOGY, EPIDEMIOLOGY, AND PATHOGENESIS

There is a continuum between the conducting airways and pulmonary parenchyma without a physical barrier separating the respiratory tract from the external environment. In healthy dogs, cultivable bacteria have been identified from the upper airways, lower airways, and thoracotomy-derived pulmonary parenchyma, with the assumption that bacteria identified in the lung were transient populations derived from the pharynx due to aspiration.[1] In cats, an analogous study with culture of lung tissue has not been performed, but healthy cats similarly have cultivable bacteria from their upper and lower airways.

Common bacterial isolates have been obtained from nasal swabs (Table 124.1) and airway lavage specimens (Table 124.2) of clinically healthy dogs and cats. In one study, bacterial isolates from the trachea in healthy dogs included *Streptococcus* spp., *Staphylococcus* spp., *Pasteurella multocida*, *Klebsiella pneumoniae*, and *Corynebacterium* spp.; when considering simultaneous positive cultures from the pharynx and trachea, in 80% of dogs, the same organism found in the trachea was identified in the pharynx.[2] These results underscore the fact that presence of bacteria cultured from the respiratory tract does not equate with infection; healthy dogs and cats have an abundance of respiratory commensal organisms. Respiratory disease may occur due to a shift in abundance of one or more commensal species to create inflammation and damage to tissue. Certain bacteria considered to be contagious may also exist as part of the respiratory microbiome, including *Bordetella bronchiseptica*, *Mycoplasma* spp., and some *Streptococcus* strains. Bacterial respiratory tract infections may also originate from primary pathogens in the environment and/or reservoir hosts such as *Nocardia* spp., *Mycobacterium* spp., or *Yersinia* spp.

Complimentary techniques to standard laboratory-based cultures have provided a wealth of information on resident complex microbial populations in the respiratory tract. Using next-generation sequencing of microbial DNA, healthy dogs have been shown to harbor a rich and diverse respiratory microbiota.[3–5] While bacterial communities from the upper and lower airways are topographically continuous, sharing

TABLE 124.1 Bacterial Species Frequently Isolated from Nasal Swabs of Healthy Dogs and Cats[a]

Dogs[122–124]	Cats[125]
Gram-positive aerobic or facultative	
Staphylococcus spp. (coagulase negative)	*Streptococcus* spp.
Streptococcus spp. (alpha and non-hemolytic)	*Staphylococcus* spp.
Corynebacterium spp.	*Corynebacterium* spp.
Bacillus spp.	*Micrococcus* spp.
Staphylococcus spp. (coagulase positive)	
Streptococcus spp. (beta-hemolytic)	
Gram-negative aerobic or facultative	
Neisseria spp.	*Pasteurella multocida*
Escherichia coli	*Escherichia coli*
Enterobacter spp.	*Pseudomonas aeruginosa*
Pasteurella multocida	*Proteus* spp.
Moraxella spp.	*Klebsiella* spp.
Proteus spp.	*Enterobacter* spp.
Pseudomonas aeruginosa	*Bordetella bronchiseptica*
Alcaligenes spp.	*Moraxella* spp.
Bordetella bronchiseptica	*Mycoplasma* spp.
Obligate anaerobes	*Clostridium* spp.

[a]Bacteria are listed in approximate order of frequency of isolation.

TABLE 124.2 Bacterial Species Frequently Isolated from Tracheal and Bronchoalveolar Lavage Specimens from Healthy Dogs and Cats

Dogs[1,2]	Cats[12,126]
Staphylococcus spp. (coagulase positive and negative)	*Staphylococcus* spp.
Streptococcus spp. (alpha and non-hemolytic)	*Streptococcus* spp.
Pasteurella multocida	*Micrococcus* spp.
Klebsiella pneumoniae	*Escherichia coli*
Enterobacter aerogenes	*Pasteurella multocida*
Acinetobacter spp.	*Pseudomonas aeruginosa*
Moraxella spp.	*Klebsiella* spp.
Corynebacterium spp.	*Enterobacter* spp.
	Proteus spp.
	Haemophilus felis

many bacterial species, there are distinct differences between sites suggesting each possesses unique resident communities, and lower airway populations are not solely a reflection of aspirated upper airway bacteria.[3] Healthy cats evaluated over time demonstrated a rich lower airway microbiome with dynamic respiratory bacterial populations.[6] The microbiome of the feline nasal cavity has also been examined, and was shown to display a high degree of individual variability; the most prevalent species in healthy cats and cats with URTD was *Moraxella* spp.[7] Use of DNA-based sequencing to characterize resident bacterial populations may provide insight to interpretation of microbial cultures as well as aid in an understanding of the impact of the respiratory microbiome on health and disease. Similar to GI dysbiosis in which disruption of the normally dominating species and imbalances of other minority species has been associated with a variety of local and systemic illnesses, respiratory dysbiosis has been identified in dogs and cats with inflammatory airway disease[8,9] and dogs treated with antimicrobial drugs.[5] Understanding deviations from a healthy respiratory microbiome is relevant to tracheobronchial and pulmonary bacterial infections and is a field that is still in its infancy.

Identification of bacteria solely using routine cultures is not synonymous with bacterial infection. A positive culture needs to be interpreted in light of clinical signs, evidence of concurrent suppurative inflammation ideally with intracellular bacteria, and bacterial growth conditions (e.g., heavy growth, single species). In general, the host effectively prevents bacterial respiratory infections by physical and chemical barriers and the innate and adaptive immune system. Traditionally, bacterial infection of the airways or pulmonary parenchyma has been thought to result secondary to inhalation of primary respiratory pathogens (aerosols or direct oronasal contact), macro- or microaspiration, compromised respiratory defenses, direct extension (e.g., migrating foreign body, penetrating wound, bronchoesophageal fistula), or hematogenous spread. Additional research is needed to determine the role of dysbiosis in bacterial tracheobronchitis and pneumonia when co-morbid respiratory disorders alter the local microenvironment.

Bacterial tracheobronchitis and pneumonia are two separate disease syndromes that can share routes of exposure (and thus types of infecting bacteria) as well as predisposing factors of susceptibility. Both conditions can be acute or chronic and primary or secondary.

Primary bacterial tracheobronchitis in immunocompetent dogs (i.e., community-acquired CIRD complex; the reader is referred to Chapter 28 for more details) is generally self-limiting with supportive care. Primary bacterial tracheobronchitis in cats is rare, with very common upper respiratory tract infections nearly always causing nasal and ocular but not tracheobronchial pathology. Unlike in dogs where *B. bronchiseptica* is often considered a highly contagious primary pathogen, *B. bronchiseptica* can be found in healthy cats and in cats without cough (with or without upper respiratory tract infections) housed in shelters with canine outbreaks.[10,11] *Mycoplasma* species are considered normal commensals of the upper respiratory tract and have the potential to be opportunistic invaders. Attempts to isolate *Mycoplasma* spp. from the lower airway of clinically healthy cats have not been successful,[12,13] but they are typically associated with concurrent airway disease suggesting that they are most likely opportunistic invaders. Their role as a primary pathogen causing bronchitis is still unclear (see Suggested Reading list for more information).[14] (Editor's note: In 2021, a novel bacterial species belonging to the genus *Filobacterium* was reported in association with chronic neutrophilic bronchitis in cats from Europe and Australia.[15] The name *Filobacterium felis* was proposed; a related organism, *Filobacterium rodentium* (previously cilia-associated respiratory bacillus [CARB]) is considered a primary pathogen of rodents. The existence of similar organisms has been described in cats with and without respiratory disease from the United States.[16,17]

Secondary bacterial tracheobronchitis is usually associated with inflammatory or structural airway disease of the dog and cat and can be responsible for clinical disease exacerbation. Bacterial tracheobronchitis has been reported secondary to airway collapse,[18,19] chronic bronchitis, eosinophilic bronchitis/eosinophilic bronchopneumopathy, bronchiectasis, or bronchomalacia in dogs. In cats, reports of positive bacterial cultures have been linked to airway disease including asthma, chronic bronchitis, and bronchiectasis. Bacterial tracheobronchitis that is associated with bacterial species that are not "community-acquired" should prompt a search for an underlying disorder. It is reiterated

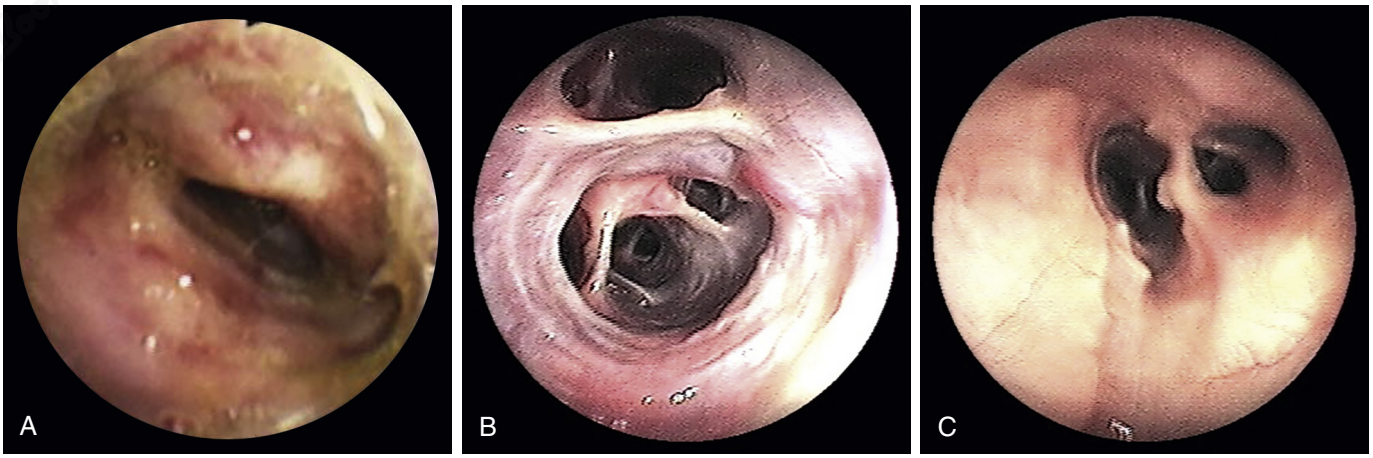

Fig. 124.1 A–C Endoscopic appearance of airway disorders that may predispose to secondary bacterial infection. (A) In tracheal collapse, the dorsal tracheal membrane sags into the lumen and the tracheal cartilages become flattened. In this case, there is accumulation of mucoid and purulent secretions associated with a positive bacterial culture. (B) Bronchiectatic airways are dilated and cavernous, failing to taper appropriately with distal progression of the endoscope. (C) The endoscopic appearance of bronchomalacia reflects a reduced and irregular airway lumen from softening of the cartilage. Note the loss of circular outlines of the airways (i.e., flattening, distortion, and narrowing) leading to airway collapse. (Courtesy of Dr. Carol Reinero, University of Missouri.)

that identifying cultivable bacteria does not necessarily imply active infection.

Dogs

Tracheal Collapse (Fig. 124.1A)

While bacteria can be frequently cultured from specimens collected from the trachea in dogs with tracheal collapse, the absence of concurrent evidence of inflammation or intracellular bacteria makes diagnosis of secondary bacterial infections unlikely in most cases.[19] The prevalence of positive bacterial cultures of dogs with tracheal collapse decreased in one study after tracheal stent placement.[20]

Chronic Bronchitis

Chronic bronchitis is classically associated with cough, mucus hypersecretion, and neutrophilic airway inflammation.[21] Chronic bronchitis is considered a sterile process that occurs secondary to airway epithelial damage and impaired mucociliary function. While dogs with chronic bronchitis have impaired mucosal defense and can theoretically be predisposed to infection, infection appears uncommon especially when quantitative, not qualitative cultures are performed.[22] Qualitative cultures using the threshold of $> 1.7 \times 10^3$ CFU/mL of BAL fluid are proposed to represent clinically relevant bacterial growth. Unlike qualitative cultures, quantitative cultures take into consideration the possibility of contamination from upper airways and/or microaspiration (subclinical aspiration of upper GI secretions) without true infection.

Eosinophilic Bronchopneumopathy

Eosinophilic bronchopneumopathy has been associated with positive BAL cultures (albeit qualitative) including growth of *Pseudomonas aeruginosa*, *K. pneumoniae*, and *Aeromonas* spp., among others.[23] As eosinophilic bronchopneumopathy can be associated with bronchiectasis, it is unclear if the aforementioned identified bacteria were a sequela to eosinophilic inflammation and/or bronchiectasis. Another study of 75 dogs with eosinophilic inflammation in BAL fluid (due to eosinophilic bronchopneumopathy, eosinophilic bronchitis, or eosinophilic pneumonia) reported bacterial growth in BAL cultures rarely; only three dogs had positive culture results (*Pasteurella* spp., *Pasteurella canis*, and mixed growth of *Escherichia coli* and *Streptococcus* spp.).[24]

Bronchiectasis (Fig. 124.1B)

Bronchiectasis may be a consequence of primary ciliary dyskinesia, chronic bronchitis, infectious pneumonia, eosinophilic bronchopneumopathy, and tracheal collapse.[24–28] Bronchiectasis can also predispose to recurrent bacterial infection because of poor clearance of mucus and exudate in the distal airways and impaired local immune responses. This in turn creates a vicious cycle of inflammation, secondary infection, and further airway damage. In one study of dogs with bronchiectasis, bacterial growth from airway lavage specimens was frequent (17/18 dogs) with a variety of bacterial species isolated as either alone (7 dogs) or as part of polymicrobial infections (10 dogs).[26] In another study, bacteria (predominantly *Streptococcus* spp., *Pasteurella* spp., enterics, and *Stenotrophomonas maltophila*) were isolated in 24/86 dogs (28%) with bronchiectasis.[27]

Bronchomalacia (Fig. 124.1C)

In bronchomalacia, weakened bronchial walls, with associated static or dynamic reduction of airway diameters results in clinical signs of cough, wheeze, and respiratory distress. In one study, intracellular bacteria were noted on cytologic examination of BAL specimens in 25/45 dogs with bronchomalacia; cultures were not performed.[29] Another study documented intra- and extracellular bacteria in 39% of specimens, with cultures yielding one isolate in 62% and two isolates in 39% of specimens.[30] The most common isolates were *B. bronchiseptica*, *Alcaligenes* spp., *Pasteurella* spp., and *Bacillus* spp. Dogs that had bronchoscopic evaluation for other causes of cough that had concurrent tracheal and bronchial collapse were less likely to have bacterial infection than dogs without evidence of airway collapse.[31]

Bacterial Pneumonia

Bacterial pneumonia generally arises due to local or systemic immune compromise and can be life-threatening. Primary bacterial pneumonia caused by *B. bronchiseptica*, virulent strains of *Streptococcus* spp., and possibly *Mycoplasma* (particularly *Mycoplasma cynos*) tends to occur most frequently in dogs under a year of age, and dogs with immune defects (overexuberant or insufficient immune responses), concurrent respiratory infections, or those in stressful or overcrowded environments.[32–34] Dogs with a variety of predisposing factors including

dysphagia, regurgitation, gastroesophageal reflux, vomiting, diminished consciousness (secondary to drugs including anesthesia, or neurologic disease), and impaired airway defenses (e.g., brachycephalic airway syndrome) can develop aspiration pneumonia.[35–41] Aerodigestive disorders often go unrecognized because aspiration pneumonia can develop in the absence of GI signs.[42]

Aspiration pneumonia is not synonymous with bacterial infection, as a sterile chemical pneumonitis may occur. Commonly identified bacteria from dogs with aspiration pneumonia include *E. coli, Mycoplasma* spp., *Pasteurella* spp., *Staphylococcus* spp., *Klebsiella* spp., and *Enterococcus* spp.[38] Impaired airway defenses can also cause pneumonia even in the absence of aspiration, and these disorders can be congenital or acquired.[43] Direct extension of bacterial infection to the parenchyma can occur from inhaled[35] or migrating foreign bodies.[39,44,45] The most common isolates from dogs with foreign bodies include anaerobes, *Pasteurella* spp., *Streptococcus* spp., and *Actinomyces* spp.[46] Often foreign bodies are inhaled into caudodorsal principle bronchi; in other words the accessory, right, and left caudal bronchi.

Ventilator-associated pneumonia represents a type of nosocomial infection that is hospital-acquired.[39] Patients requiring mechanical ventilation have a different spectrum of bacterial isolates from airway cultures when compared with other patients with respiratory disease; these isolates are more likely to be resistant to the common antimicrobials used to treat patients with pneumonia.[47]

Cats

Chronic Bronchitis

In cats, secondary bacterial bronchitis is far less common than noninfectious inflammatory airway disease. Importantly, quantitative tracheobronchial lavage cultures in healthy cats were positive in 8 of 24 cats in one study[12] and 10 of 13 (77%) in another.[10] In the latter study, cultures yielded 100–100,000 CFU/mL, and organisms such as *Staphylococcus* spp., *Streptococcus* spp., *B. bronchiseptica*, and *P. multocida* were identified. In that same study, 42% of cats with bronchopulmonary disease (i.e., asthma and chronic bronchitis) had positive cultures, mostly yielding low numbers of bacteria.[10] Positive cultures for *Mycoplasma* species were not identified in the first study or performed in the second, but are of interest as in human asthma, mycoplasmas are postulated to contribute to induction of and exacerbation of disease. In a more recent study, *Mycoplasma* spp. were detected in BAL fluid from 6 of 17 cats with asthma/chronic bronchitis and 4 of 9 sick cats without respiratory disease, which was not a significant difference.[48] Overall, bacterial bronchitis (without involvement of the pulmonary parenchyma) in cats is rare, with 1/245 cats with necropsy-confirmed lower respiratory tract infection attributed to bronchitis alone.[49]

Bronchiectasis

Bronchiectasis in cats has been associated with inflammatory airway disease, pneumonia, and neoplasia.[50–53] Radiographic evidence of bronchiectasis was noted in 43% of cats with aspiration pneumonia, inflammatory airway disease, and bronchopneumonia in one study.[53] It has also been reported in cats with bronchial dysgenesis, presumptive primary ciliary dyskinesia, and broncholithiasis.[54–56] Bronchiectasis is rarely described in cats when compared with dogs, with too few positive cultures to reliably report common bacterial species that act as secondary invaders.[50]

Bacterial Pneumonia

Bacterial pneumonia is rare in the cat. Even when present, it may be difficult to identify as some cats may lack clinical signs, inflammatory leukograms, or classic radiographic lesions.[57] Bacteria often gain access to the respiratory tract through a hematogenous route, including from the GI tract, uterus, umbilicus, gingiva, and bite wounds.[57] Other reported routes include inhalation (aspiration or from inhaling airborne bacteria) and local extension.[53,57] Although an uncommon condition in the cat compared with the dog, approximately one third of cats treated for laryngeal paralysis with bilateral arytenoid lateralization developed aspiration pneumonia.[58] The most common underlying conditions in cats with aspiration pneumonia in another study from a tertiary referral institution were megaesophagus, esophageal stricture, esophageal dysmotility, and acute or chronic vomiting; 27% had a recent history of general anesthesia.[53] Mycoplasmas, *Pasteurella* spp., *Streptococcus* spp., and anaerobes represented the most common bacterial isolates from airway lavage specimens from cats with bronchopneumonia.[53] In contrast, mycoplasmas were not isolated from cats with aspiration pneumonia; cultures from these cats yielded aerobic gram-positive or gram-negative bacteria and/or anaerobes.

CLINICAL FEATURES

Clinical Signs and Physical Examination Findings

Dogs with primary or secondary bacterial bronchitis may show no signs, or have respiratory signs, generally cough. Contagious causes of tracheobronchitis may be associated with involvement of other parts of the respiratory tract, thus additional clinical signs referable to those sites may be noted (e.g., sneezing or nasal discharge, see Chapter 28). Dogs with secondary bacterial bronchitis may have clinical signs associated with an underlying disorder, for example, stridor or wheeze with airway collapse. Secondary infection should be suspected in stable patients with chronic tracheobronchial disorders that suddenly develop signs of disease exacerbation.

If systemic signs such as fever, lethargy, or inappetence are present, this should prompt search for pneumonia or another co-morbid respiratory condition as systemic signs are rarely seen in dogs with bacterial bronchitis. There should be a high index of suspicion for CDV infection in young dogs that develop these signs. Canine bacterial pneumonia may be associated with local signs such as nasal discharge, cough, tachypnea, adventitial lung sounds, decreased lung sounds in regions of consolidation, exercise intolerance, respiratory distress (mixed inspiratory and expiratory distress), and cyanosis; additionally, systemic signs can be seen such as fever, anorexia, lethargy, dehydration, weakness, and weight loss.[38,39,59] Some animals with pneumonia show no signs or only a few of these signs. Hemoptysis is rare but reported in dogs.[60] Other clinical signs may reflect an underlying illness, for example, vomiting or regurgitation in the case of aspiration pneumonia.[38]

As mentioned above, there is controversy about the role of *B. bronchiseptica* and *Mycoplasma* spp. in feline tracheobronchitis as these organisms can be isolated from many clinically healthy cats that lack respiratory signs (see Chapters 55 and 57).[48] Cats with secondary bronchial infection may be subclinically infected or have clinical signs (usually cough; sometimes wheeze, tachypnea, and respiratory distress) relative to their underlying inflammatory airway disease or bronchiectasis.[10,48,50] Many owners do not recognize cough in cats, confusing it with "hacking" up hairballs or retching. Cats with aspiration pneumonia may show only systemic signs of illness such as fever, lethargy, and/or inappetence. In contrast to dogs, cats with pneumonia often lack clinical respiratory signs, especially cough. In one retrospective study, cough was significantly more common in cats with bacterial pneumonia (25/26 cats, 96%) or inflammatory airway disease (30/44 cats, 68%) than in cats with aspiration pneumonia (8/33 cats, 24%). In another study of cats with fatal infectious pneumonia (of which 54% were bacterial), 36% lacked clinical signs referable to the respiratory tract.[57] Of the cats displaying respiratory signs, tachypnea or respiratory distress and nasal discharge were most common; cough was present in only 8%

of cats. Systemic signs of illness (anorexia, lethargy, and fever) were absent in 41% of these cats despite histopathologic evidence of systemic infection in 74% of cats. A high index of suspicion for pneumonia is required in cats, especially if evidence of infection exists in other organs. In a review of 21 cases of lower respiratory tract infection in cats that were not all fatal, signs were chronic cough (11), acute cough (6), respiratory distress (2), anorexia (1), and neurologic signs (1).[61]

DIAGNOSIS

The diagnosis of bacterial tracheobronchitis or pneumonia is made based on a combination of historical information (e.g., exposure to contagious pathogens, underlying co-morbid respiratory conditions or disorders predisposing to aspiration, etc.), clinical signs, radiographic findings and ideally findings on cytologic examination of respiratory specimens (suppurative inflammation with extra- or intracellular bacteria), and a positive culture. With the exception of the transtracheal wash and FNA, collection of respiratory specimens is performed under general anesthesia. A step-wise approach should be taken: functional laryngeal examination using doxapram to stimulate deep respiration, thorough oropharyngeal examination (including sweeping the tonsillar crypts for foreign material), CT imaging (if indicated), endoscopic examination of the trachea and bronchi (if indicated), collection of respiratory specimens for cytology and culture, and choanal examination (retroflexed view using an endoscope). Before anesthesia, there are a wide variety of minimally invasive respiratory diagnostics that can help define underlying or concurrent conditions and gauge severity, extent, and cause of infection (discussed below).

Laboratory Findings

Complete Blood Count, Serum Biochemical Profile, and Urinalysis

Although not specific to the respiratory system, the minimum database, including a CBC, serum biochemical profile, and urinalysis, can provide useful information regarding systemic health. Especially in the case of bacterial pneumonia, a systemic response to infection or organ dysfunction may be detected. Dogs and cats with bacterial pneumonia can have normal or abnormal leukograms.[38,39,57,59] Abnormalities include a neutrophilia with a left shift or neutropenia. Peripheral eosinophilia may be present in dogs with eosinophilic bronchopneumopathy[23,24] or cats with asthma.[62] Because bacterial pneumonia can result from hematogenous spread of bacterial infection originating elsewhere in the body, sepsis and multiple organ dysfunction can contribute to morbidity and mortality, making a serum biochemical profile and urinalysis useful to determine the extent of disease. They may also reflect an underlying disorder associated with impaired immune function (e.g., endocrinopathy).[43]

Diagnostic Tests for Pathogens Other Than Bacteria

Other infectious agents affecting the respiratory tract should be considered in the differential diagnosis (viruses such as CDV, atypical bacteria, protozoa such as *Toxoplasma gondii*, fungi, and parasites), with diagnostic tests selected based on the history (geographic location, season, length of illness, other systemic signs), minimum database (e.g., presence of thrombocytopenia), and physical examination findings. Tests may include fecal analysis (fecal flotation or Baermann analysis for parasites) or blood or urine testing (e.g., serology for antibodies to *Leptospira*, *T. gondii*; parasite or fungal antigen testing).

Assessment of Oxygenation and Ventilatory Status

Arterial blood gas analysis is useful to determine the severity of respiratory compromise as it can provide information on gas exchange and acid-base balance which can be disrupted with bacterial respiratory disease (in particular pneumonia). Hypoxemia ($PaO_2 \leq 80$ mmHg at sea level) can be detected in roughly three quarters of dogs with aspiration pneumonia that have arterial blood gases measured.[38,59] Hypocapnia or hypercapnia has also been described.[59] The alveolar-arterial (A-a) oxygen gradient can be increased; values > 15 mmHg indicate lung dysfunction.[38] Serial use of arterial blood gas measurements can help to determine what treatment to use (e.g., supplemental oxygen, mechanical ventilation) as well as provide information on response to treatment. Pulse oximetry is a simple, rapid, widely available, and noninvasive indicator of oxygen status, but is relatively insensitive and does not provide information on ventilatory or acid-base status. In patients receiving mechanical ventilation, capnography can provide information about ventilatory status.

Diagnostic Imaging

Radiography, fluoroscopy, ultrasonography, and CT have been used to image the respiratory tract. Each have distinct advantages and disadvantages.

Plain Radiography

Thoracic and possibly cervical radiography should be performed first, with a minimum of two views (lateral and ventrodorsal or dorsoventral); however, both right and left lateral views are recommended because differential aeration that results from positional atelectasis can improve or impair visualization of lesions.[39] Static airway collapse may be appreciated with standard views (Fig. 124.2), however, inspiratory and expiratory cervical and thoracic radiographs aid in diagnosis of dynamic tracheal or mainstem bronchial collapse. Thoracic radiography may demonstrate bronchial or bronchointerstitial patterns with chronic bronchitis, eosinophilic bronchitis (Fig. 124.3), or feline asthma, with hyperinflation and/or lobar atelectasis in the latter condition.[62,63] Radiographic findings in eosinophilic bronchopneumopathy

Fig. 124.2 Left lateral thoracic radiograph showing tracheal collapse in the region of the thoracic inlet. (Courtesy of Dr. Carol Reinero, University of Missouri.)

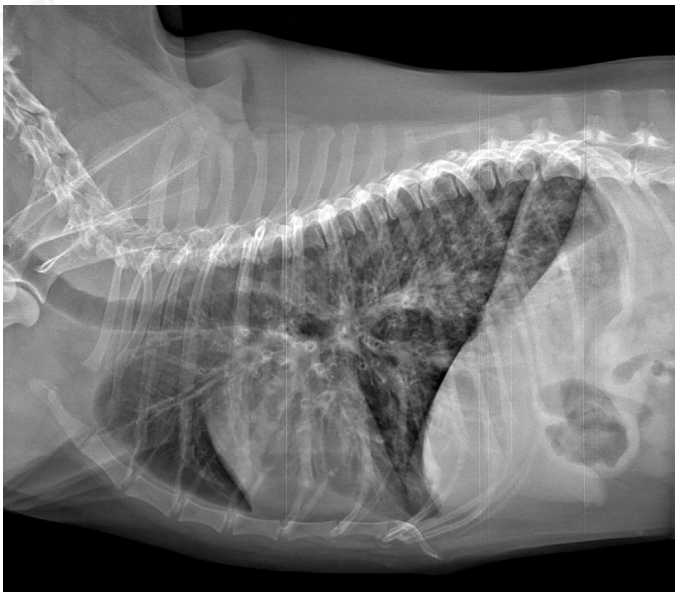

Fig. 124.3 Left lateral thoracic radiograph from a dog with eosinophilic bronchitis demonstrating a severe bronchointerstitial pattern with prominent peribronchial cuffing. (Courtesy of Dr. Carol Reinero, University of Missouri.)

in dogs include a bronchial or bronchointerstitial pattern or an alveolar pattern; bronchiectasis was seen in 26% of cases in one report[23] and 60% in another.[24]

Radiographic features of bronchiectasis include thickened airway walls with a lack of tapering as the airways track to the periphery with either a cylindrical or saccular (cystic) shape (Fig. 124.4).[26,50] Dogs with bronchomalacia generally lack radiographic evidence of bronchial collapse, but can have bronchial or bronchointerstitial patterns, poor visibility of their lobar bronchi, or have normal radiographs.[29,30] In dogs and cats with pneumonia, interstitial, alveolar, and mixed patterns are commonly seen with focal, multifocal, and diffuse distributions.[39,57] Aspiration pneumonia in dogs most commonly affects the right middle lung lobe, and plant awn pneumonia frequently involves the accessory and caudal lobes; however, any lung lobe can be affected.[38,39,45] Right middle lung lobe consolidation in cats can occur not only with aspiration pneumonia but also with bronchopneumonia and inflammatory airway disease.[53]

Videofluoroscopy

Videofluoroscopy allows visualization of the intra- and extra-thoracic trachea and mainstem bronchi during the breathing cycle and with spontaneous and induced cough. It can be helpful for diagnosis of airway collapse that is not appreciated on static plain radiographs. Videofluoroscopic swallow studies (VFSS) can also be used to determine if a swallowing disorder may be contributing to aspiration pneumonia.[42,64] Although under-recognized, there are many respiratory disorders that result from aspiration (aside from aspiration pneumonia) which affect the airways and parenchyma and can contribute to secondary bacterial infections.[35]

Ultrasonographic Examination

Thoracic ultrasonography can be used to evaluate the lungs and pleural space in cases of lung lobe consolidation, masses, pulmonary abscess, and foreign bodies.[44,45,65] A combination of transthoracic, transesophageal, and intraoperative ultrasonography helped to identify 91% of dogs with migrating grass awns in one study.[44] Lung ultrasonography was also useful for identification and monitoring of cardiogenic pulmonary edema; this is evidenced by an increase in the number of artifacts known as "B-lines" caused by increased pulmonary water.[67] Ultrasonography can also be used to guide collection of specimens by FNA. The Vet BLUE (veterinary bedside lung ultrasound exam) scan is emerging as a rapid POC examination used to screen dogs and cats with respiratory compromise, including those with lung consolidation.[67,68] A major limitation of ultrasound is the requirement for lesions to extend to the periphery as ultrasound cannot penetrate through aerated lung.

Computed Tomography

Cervical and thoracic CT can be performed to obtain further information regarding structural abnormalities and provide more accurate correlative information with histopathologic lesions. Advantages over plain radiography include increased sensitivity and ability to provide three-dimensional reconstructions to eliminate superimposition of body parts. In particular, CT is more sensitive for detection of bronchiectasis than plain radiography.[39] It can also be a useful tool for surgical planning. Paired inspiratory and expiratory scans achieved with breath holds at end inspiration and end expiration can highlight dynamic airway collapse inclusive of tracheal collapse and bronchomalacia (Fig. 124.5A and B). Peribronchial cuffing or increases in the peribronchovascular density may be seen with inflammatory airway disorders. CT changes associated with eosinophilic bronchopneumopathy include increased bronchial wall thickening, intraluminal bronchial plugging, opacity of the parenchyma (e.g., nodules and masses), and bronchiectasis.[69] Pneumonia can present with increased opacity of the lung including ground glass opacity and consolidation. In some cases, foreign bodies may be seen, such as in airways.[39,45] CT findings can also raise suspicion for some infectious diseases of the lung other than "routine" bacterial infections, such as mycobacterial, fungal, and parasitic diseases.

Tracheobronchoscopy

Endoscopic examination allows direct visualization of the trachea and bronchi which is valuable for diagnosing structural abnormalities such as tracheal collapse, bronchiectasis, and bronchomalacia (see Fig.

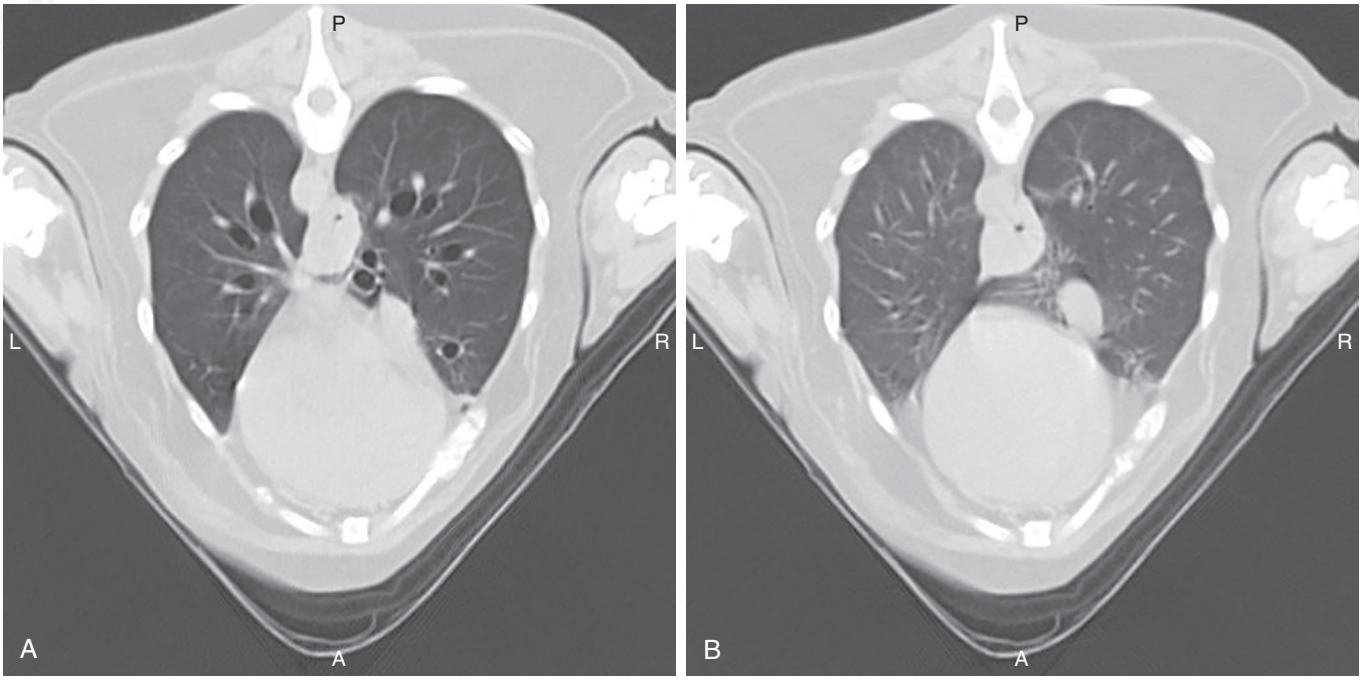

Fig. 124.5 Axial computed tomographic images at the same section from a dog with dynamic airway collapse. During inspiration (A) bronchi are round and open but collapse nearly completely during expiration (B). (Courtesy of Dr. Carol Reinero, University of Missouri.)

124.1A–C). Nonspecific changes associated with inflammatory airway disease such as thickened mucosa, hyperemia, and mucus hypersecretion may also be seen. Another use of endoscopy is to facilitate collection of specimens using brush catheters, transbronchial needles, BAL, and biopsy forceps for culture or microscopic examination from locally affected areas of the lung. Endoscopy can also be used to remove foreign bodies (e.g., grass awn) (Fig. 124.6).

Microbiologic Tests

Cytologic Diagnosis

Specimens for cytologic evaluation can be collected using FNA, transtracheal washing, endotracheal washing, BAL, bronchial brushing, or by making impression smears from tissue collected using biopsy forceps. Visible strands of exudate may then be teased onto a microscope slide, smeared, and stained. Small quantities of material can be centrifuged and smears made of the sediment. New methylene blue wet mounts and Wright-Giemsa or Gram stain of air-dried smears can be used for identification of cellular elements and bacteria. Bacterial infections are typically associated with degenerate neutrophils and intracellular bacteria; in addition, excess mucus, proteinaceous material, and activated alveolar macrophages can be present. Bacteria are demonstrable only in a fraction of washings from pneumonic animals, and their absence in cytologic specimens, especially if the patient has been placed on antibacterial therapy, does not rule out bacterial pneumonia.

Transtracheal lavage. This is well tolerated by the majority of large dogs and requires only minimal restraint of the unanesthetized patient, although some dogs require mild sedation. Endotracheal washing with anesthesia (see later discussion) is usually used for small dogs and cats. Although complications from transtracheal washing and aspiration are uncommon, the procedure is not without risk. Transtracheal washing should not be attempted in the fractious or uncooperative patient without adequate chemical and manual restraint. Contraindications include defects in hemostasis, severe pyoderma of the ventral skin of the neck, and respiratory distress. The most common complication associated with transtracheal washing is subcutaneous emphysema. Other complications include endotracheal hemorrhage, tracheal laceration, and infection at the puncture site.

Endotracheal lavage. Endotracheal lavage is recommended for small dogs and cats and requires short-acting general anesthesia. The volume of sterile nonbacteriostatic saline recommended has ranged in small animals from 3 to 10 mL per animal. Advantages of endotracheal lavage over transtracheal lavage is avoidance of tracheal injury, the need for minimal supplies, and its ease in cats and small dogs. Disadvantages are the potential for oropharyngeal contamination, a lack of airway visualization to guide specimen collection, especially when focal disease is present, and comparatively poor retrieval of fluid when compared with BAL.

Blind BAL technique. A blind BAL can be performed using short-acting general anesthesia without an endoscope.[70] This method is similar to endotracheal lavage except the red rubber catheter used is advanced through the endotracheal tube until gentle resistance is felt; this should correspond to wedging in a small airway. The catheter should be measured against the endotracheal tube before the procedure to ensure it advances well past the point of the end of the tube. The authors use 10 mL aliquots of saline in patients ≤ 3 kg, and 20 mL aliquots of saline in patients > 3 kg. If negative pressure is felt during aspiration, the catheter is slightly withdrawn, and suction reapplied until air appears in the syringe. The presence of foam in the lavage reflective of surfactant indicates a deep wash. With bacterial infection, the BAL fluid may be visibly purulent.

Bronchoscope-guided BAL. Bronchoscope-guided BAL allows collection of a specimen from an affected airway or lung lobe. In general, cytologic preparations collected using this method are superior to those obtained by transtracheal or endotracheal lavage because larger volumes of cells and proteinaceous materials are obtained from the deeper portions of the lungs. Collection of multiple specimens from different parts of the lung is recommended when disease is multifocal or diffuse, as findings may vary from one lobe to another.[39] Suppurative inflammation with or without intra- or extracellular bacteria supports a diagnosis of bacterial infection. Quantification of

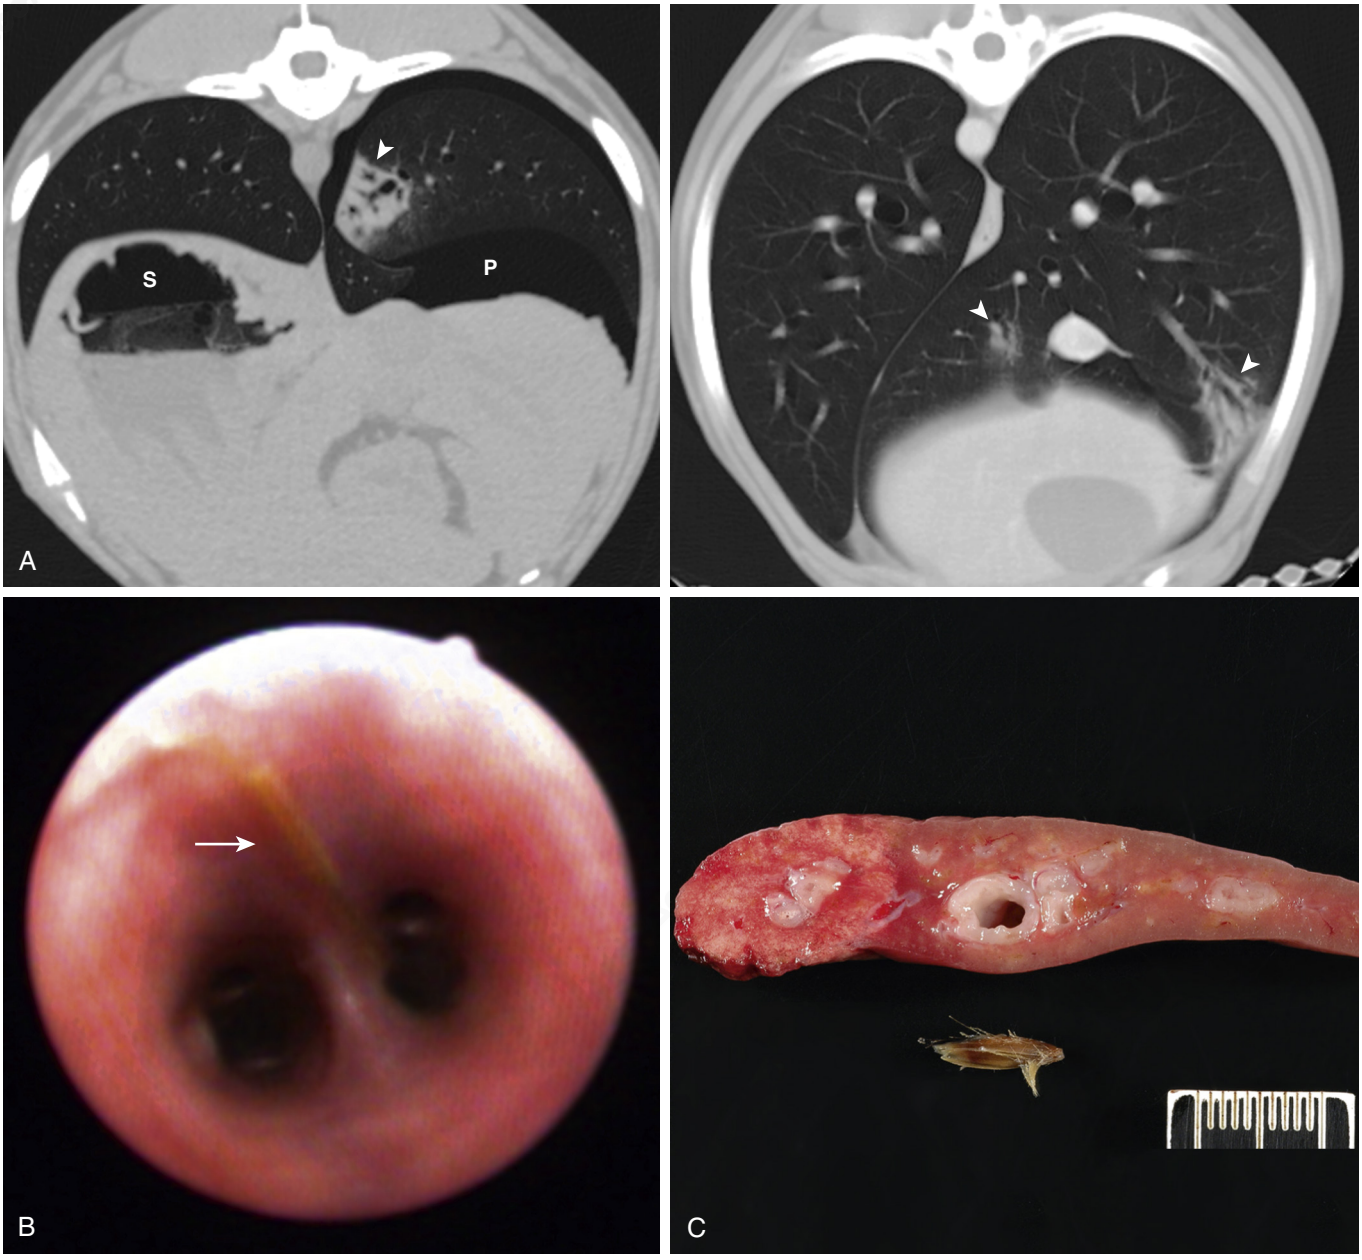

Fig. 124.6 Migrating plant awn foreign bodies. (A) Computed tomography scan images from a 1-year-old female spayed German short-haired pointer dog. A pneumothorax *(left, P)* and multifocal opacities *(arrowheads)* are present (*S*, stomach). (B) Bronchoscopic image showing a plant awn in a bronchus of a 2-year-old male neutered Belgian Malinois. (C) Portion of the right middle lung lobe of a 2-year-old female spayed Labrador retriever, which was removed during thoracotomy. A 1-cm plant awn was removed from a pocket of mucoid material within a bronchus. (C, courtesy of UC Davis Veterinary Anatomic Pathology Service.)

bacteria present is needed to distinguish lower airway contamination or transient colonization from actual infection. In addition to BAL, brush catheters can be passed through the biopsy channel of the endoscope to obtain specimens. Given the expense of a catheter system that can be used only once, the authors feel there is no advantage of using brush catheters compared with BAL for identification of bacterial infection.

Fine-needle aspiration. FNA can be performed without guidance in or with the aid of ultrasound, fluoroscopy, CT, or endoscopy to procure material for culture and cytologic examination.[71–73] Transthoracic FNA may have a higher diagnostic yield than lavage (especially tracheal washings and blind BAL) when focal lesions are present. Transbronchial needle aspiration can be performed using bronchoscopic guidance. Needles that are designed to pass through the endoscope can be used to aspirate enlarged hilar lymph nodes or discrete masses. Use of FNA (typically with a 25 or 27 gauge, 1.5" needle and a 6-mL syringe) is less risky than use of a Tru-Cut needle, which can cause severe pulmonary hemorrhage or pneumothorax. The recommended size of the needle is 25 or 27 gauge and 1.5 inches in length but may vary depending on patient size.

Culture and Susceptibility Testing

Specimens obtained by FNA or transtracheal or BAL should be cultured for aerobic and anaerobic bacteria. Mycoplasmas can either be cultured using special media (requires laboratory notification) or

Mycoplasma-specific PCR assays can be requested. The latter is more sensitive because many *Mycoplasma* species are very fastidious or uncultivable, although the clinical significance of positive *Mycoplasma* spp. PCR results is unclear. A Gram stain can help make an early diagnosis of bacterial infection, and an acid-fast stain may be of use in dogs with suspected *Mycobacterium* spp. or *Nocardia* spp. infections. Bacterial colonization versus infection must be differentiated by use of cytology and quantitative bacterial cultures.[22] The threshold for clinically relevant bacterial growth in BAL specimens from dogs is proposed to be over 1.7×10^3 CFU/mL of BAL fluid.[22] The identification of more than two intracellular bacteria after microscopic examination of 50 oil immersion fields of a Gram-stained slide also supports the presence of bacterial infection.[22]

Dogs or cats with severe bacterial pneumonia may have substantial respiratory compromise, and invasive airway specimen collection can be risky and/or relatively contraindicated. While yet to be definitively proven, in some cases, blood cultures could represent an option to identify relevant bacteria and provide information about antimicrobial susceptibility. Further studies need to be performed to determine the utility of blood cultures in dogs and cats with bacterial pneumonia.

Pathologic Findings

Histopathologic specimens of the respiratory tract can be obtained by endoscopic biopsy (generally either masses or superficial mucosal tissue), surgical biopsy (thoracoscopy or thoracotomy), and, rarely, for consolidated and peripheral mass-like lesions, ultrasound or CT-guided biopsy. Histopathologic evaluation of masses within the upper and lower respiratory tracts can help confirm a definitive diagnosis of an underlying/predisposing cause of infection and identify intralesional bacteria. Special stains can also be applied to increase the sensitivity of organism detection. This assessment must be coupled with culture to definitively identify causative agents and determine their antimicrobial susceptibility. Although invasive, biopsy can provide complementary and additional information in complicated cases of pulmonary parenchymal disease,[51,74,75] and lung lobectomy may provide cure in cases of isolated bronchiectasis, foreign body pneumonia, and isolated lobar pneumonia unresolved by antimicrobial therapy. It also allows collection of larger specimens for culture and molecular detection methods (with improved sensitivity than techniques such as FNA or airway lavage).

TREATMENT

When designing a therapeutic plan for a patient with bacterial bronchitis or pneumonia, an investigation for all co-morbid conditions is important as secondary infections may not fully resolve or will recur if the primary disease condition is not simultaneously treated. In addition, because the presence of bacteria does not necessarily equate with infection, positive cultures must be interpreted in light of clinical signs and clinicopathologic findings. Veterinarians play an important role in promoting antimicrobial stewardship, so indiscriminate use of antibiotics should be avoided. Antibiotics should not be a first-line drug for dogs with acute cough in the absence of systemic signs where CIRD complex is suspected, as many are of viral etiology and the vast majority resolve with supportive care.[76] They are also not recommended for dogs with uncomplicated tracheal collapse or cats with cough that is likely secondary to inflammatory lower airway disease. To minimize selection for antimicrobial resistance, whenever possible, culture and susceptibility testing should be used to guide antimicrobial therapy. Additionally, certain antibiotics do not pass the blood-bronchus barrier, and while they may be useful for pneumonia, are not effective for bacterial bronchitis. Antimicrobials such as tetracyclines and fluoroquinolones are examples of drugs that cross the blood-bronchus barrier.

More aggressive antimicrobial therapy is indicated for bacterial pneumonia when compared with upper airway infections. Supportive therapies (discussed in more detail below) including systemic and airway hydration, nebulization and coupage, and supplemental oxygen are also important components of therapy, especially in severe cases. Cough suppressants are absolutely contraindicated in cases of pneumonia, as they prevent the beneficial reflex intended to clear secretions from the respiratory tract. Furosemide should be given only if critical to manage congestive heart failure as it will dry respiratory secretions and impair activity of the mucociliary apparatus. If furosemide is administered, increasing the frequency or duration of nebulization may help counterbalance this. Antihistamines are also known to dry secretions and should be avoided. There have been no studies on the use of bronchodilators in bacterial pneumonia in dogs or cats, but they may worsen ventilation:perfusion mismatch by dilating airways leading to consolidated regions of lung where gas exchange is ineffective. It is the authors' opinion that bronchodilators are most appropriately used in cats with evidence of bronchospasm (e.g., asthma). Although not routinely recommended, a trial in cats might be warranted for emergency treatment of bronchospasm and acute respiratory distress with terbutaline (0.01–0.02 mg/kg SC). Care must be taken with administration of theophylline if chloramphenicol or fluoroquinolones are being used concurrently because these drugs increase the serum theophylline concentration. Other suggested treatments without scientific evidence of efficacy in canine or feline bacterial pneumonia include N-acetylcysteine, NSAIDs, and glucocorticoids.

Identification and Management of Underlying Causes

A comprehensive discussion of the treatment for underlying disorders contributing to secondary bacterial infection of the lower respiratory tract is beyond the scope of this chapter, but brief mention of management/treatment strategies is warranted. Tracheal collapse requires a combination of weight management, avoidance of triggers of clinical signs (robust exercise, excitement, etc.), use of a harness instead of a neck collar, cough suppressants, and anxiolytics/sedatives. Canine chronic bronchitis, whether eosinophilic or neutrophilic, and feline chronic bronchitis and asthma, should be managed with avoidance of inhaled triggers (antigens such as environmental smoke; particulates such as cleaning aerosols/powders or dusty cat litter; or allergens), weight management, and glucocorticoids (oral or inhaled, tapered to the lowest effective dose). The use of bronchodilators is best reserved for asthmatic cats with episodic expiratory respiratory distress. Recurrent infections are particularly problematic in patients with bronchiectasis. If bronchiectasis is confined to a single lobe, surgical lobectomy may be curative. If bronchiectasis is generalized, recurrent infections must be managed as they arise, and low doses of glucocorticoids (0.25–0.5 mg/kg of prednisone or prednisolone in dogs and cats, respectively) may help reduce concurrent inflammation. Reduction of environmental inhaled irritants and allergens and weight management are also helpful; airway humidification may help reduce tenacious secretions. Bronchomalacia, like bronchiectasis, also requires management of underlying or co-morbid respiratory conditions and may benefit from environmental modulation, weight management, and airway humidification. If sterile inflammation is documented during a period where there is no concurrent infection, addition of low-dose glucocorticoid therapy may also be helpful. Bronchodilators have not been proven to be useful for this condition as airway smooth muscle constriction is not part of the underlying pathology.

Implementing appropriate husbandry practices and when available (based on patient risk), vaccination for causes of contagious tracheobronchitis may help reduce incidence of these diseases. As previously mentioned, identifying underlying causes of bacterial pneumonia and

addressing them directly is also important in the overall management strategy and to help prevent recurrence.

Antimicrobial Drug Treatment

No single antibacterial drug is routinely effective against the wide variety of organisms causing bacterial pneumonia. Selection of an antibacterial drug based on identification of the pathogen and its antimicrobial susceptibility results in recovery of substantially more patients than when therapy is empiric.[77] Recent antimicrobial therapy that is empiric also negatively impacts susceptibility to subsequently required antimicrobials.[78] Over half (57.4%) of dogs with pneumonia previously treated empirically with antibiotics and subsequently referred for airway lavage were infected with bacteria that exhibited resistance to the empirically used antibiotic.[78] Thus, if absolutely necessary to select an antimicrobial without culture and susceptibility testing, recently administered antimicrobials should be avoided.

Morphologic characteristics of bacteria on a Gram-stained slide can aid in selection of an antibacterial drug while awaiting the results of bacterial culture and susceptibility.[22] Doxycycline has been recommended for treatment of suspected *B. bronchiseptica* or *Mycoplasma* spp. pneumonia.[76] When streptococcal pneumonia is suspected (e.g., shelter outbreak of pneumonia associated with Gram-positive cocci), a penicillin is the drug of choice.[76] Additional detail on treatment of dogs with pneumonia due to CIRD complex can be found in Chapter 28.

Because aspiration pneumonia is not always associated with bacterial infection, routine antimicrobial use is controversial. Antimicrobial treatment should ideally be delayed until secondary bacterial infection can be documented or until the animal fails to respond appropriately to other supportive therapy. When infection plays a role in aspiration pneumonia, a multiplicity of aerobic and anaerobic organisms can be involved,[38] and combination antimicrobial therapy may be required, ideally guided by results of culture and susceptibility. Cough or respiratory distress, fever, leukocytosis, and radiographic evidence of severe interstitial or alveolar patterns do not definitively prove the pneumonia is due to bacterial infection. In one study of canine aspiration pneumonia, roughly 25% of dogs had negative cultures; however, only 47 of 125 dogs in this study had airway lavage cultures and only 2 of 126 dogs had BAL instead of an upper airway wash, so focal infections may have been overlooked.[38] The consensus opinion of the Working Group of ISCAID is that in the absence of evidence of systemic sepsis, either no treatment or parenteral treatment with a beta-lactam antimicrobial may be sufficient for cases of aspiration pneumonia.[76]

Empiric antimicrobial therapy is particularly important to initiate early (within 1 to 2 hours) in dogs or cats with evidence of sepsis (see Chapter 123). A broad-spectrum parenteral antimicrobial strategy should be considered to address the possibility of gram-negative bacteria (e.g., a fluoroquinolone) and gram-positive and anaerobic bacteria (e.g., ampicillin or clindamycin) which is later adjusted based on culture and susceptibility results.[76] The reader is referred to ISCAID Working Group Guidelines (see Suggested Reading list) for detailed discussion of antimicrobial treatment options for canine and feline respiratory tract infections, including doses and other considerations.[76] Regardless of initial selection of antimicrobial, results of culture and susceptibility testing should be used to modify therapy, including de-escalation when possible.

In stable patients with documented evidence of bacterial infection of the airways or pulmonary parenchyma, oral antibiotic monotherapy that is prescribed on an outpatient basis should be sufficient. If patients are hospitalized, parenteral antimicrobial therapy is recommended regardless of disease severity; when discharged from the hospital, they can be transitioned to oral antimicrobials.[76]

Routine intratracheal or aerosol administration of antimicrobials is not recommended in pneumonia. With severe alveolar consolidation in pneumonia, airway penetration of antimicrobials is inferior to systemic administration. Inhaled aminoglycosides have been used to treat refractory *B. bronchiseptica* pneumonia in dogs, but concerns have been raised about the possibility of toxicity. Treatment of experimental dogs with inhaled gentamicin at 7, 14, and 41 mg/kg was associated with renal tubular necrosis at the highest dose, but with no evidence of respiratory tract irritation (in contrast to findings in rats in the same report).[79] Another study of dogs with naturally occurring *B. bronchiseptica* pneumonia concluded that use of an undiluted 5% solution of gentamicin in a nebulizer for 10 minutes twice daily was safe and effective.[80]

Duration of antimicrobial therapy for bacterial pneumonia has long been recommended for 3–6 or more weeks, and at least 1–2 weeks beyond clinical and radiographic resolution of signs of disease.[39] This recommendation has not been based on evidence and differs from recommendations for humans with bacterial pneumonia. In humans, meta-analyses show that in randomized controlled clinical trials of bacterial pneumonia, use of longer courses of antibiotics versus shorter courses do not lead to significant differences with respect to clinical success, bacterial eradication, adverse effects, or mortality.[81] Additionally, radiographic improvement in humans lags far behind the clinical response and offers no benefit in identifying treatment failure over physician or patient assessment of symptoms, underscoring the lack of utility of this diagnostic to guide therapy.[81–83] Until controlled peer-reviewed studies can be performed, the ISCAID Working Group consensus statement recommends reevaluation of patients with pneumonia in 10 to 14 days after initiating antimicrobial therapy.[76] One prospective study reported no difference in outcome in dogs treated for 10 days with pneumonia compared with those treated for 21 days.[84] While the best means to monitor efficacy of therapy is currently lacking, consensus opinion is that a recheck should consist of physical examination, CBC, and thoracic radiography, keeping in mind that radiographic changes may lag behind clinical improvement.

Ancillary Supportive Therapy

Maintenance of normal systemic and airway hydration is an important therapeutic objective in hospitalized patients with bacterial pneumonia. Dehydration hinders mucociliary clearance and mobilization of secretions because normal respiratory secretions are more than 90% water. Judicious use of IV fluids is recommended. Airway hydration can be directly addressed using aerosol therapy to mobilize secretions by adding water to the mucociliary blanket. A nebulizer that produces particles between 0.5 and 3.0 μm ensures that water is deposited in the lower airways. Water vaporizers or humidifiers are inadequate because the water particulate size is larger and droplets are generally deposited in the nasal cavity. For nebulization, the animal is placed in an enclosed chamber, and a bland aerosol (normal saline) is nebulized into the chamber. Physiotherapy should always be performed immediately after aerosolization to enhance secretion clearance. Methods include increased cough frequency by chest wall coupage or tracheal manipulation, mild exercise, and postural drainage. The animal should be nebulized two to six times daily for 10 to 20 minutes per treatment. Careful attention must be paid to appropriate cleaning/sterilization of the nebulizer.

Animals with severe tachypnea, respiratory distress, or moderate to marked hypoxemia (arterial oxygen tension below 80 mmHg or SpO_2 < 94% on room air) require supplemental oxygen therapy. Oxygen should be humidified to prevent drying of respiratory membranes. Oxygen can be administered in a cage, by intratracheal cannula or nasal catheter (unilateral or bilateral), or in intubated patients

with or without a mechanical ventilator. Mechanical ventilation may be required when there is severe hypoxemia unresponsive to oxygen supplementation or evidence of labored respiration with inappropriate oxygenation for the degree of ventilation and with increasing $PaCO_2$ (i.e., impending respiratory muscle fatigue). High-flow oxygen therapy using high-flow nasal prongs may be an alternative approach for dogs failing traditional oxygen therapy when mechanical ventilation is not a viable option.[85]

If aspiration pneumonia is a complicating factor or has the potential to be a complicating factor, maintaining sternal recumbency with the cranial part of the body elevated, and minimizing gastric volume by small frequent feedings or use of antiemetics or prokinetics (e.g., maropitant, ondansetron, cisapride) can be considered. A pilot study in four dogs with acquired idiopathic megaesophagus indicated a potential benefit of at-home intermittent esophageal suctioning (via esophagostomy tube or per os) for prevention of aspiration pneumonia, and deserves further study as a long-term management strategy.[86] A perioperative IV CRI of metoclopramide did not affect the incidence of aspiration pneumonia in dogs undergoing arytenoid lateralization surgery.[87] If a patient with bacterial pneumonia is receiving immunosuppressants or chemotherapeutics and it can be safely done, temporary withdrawal of these drugs or a decrease in their dose may aid in resolution of pneumonia.

Surgery

Surgical intervention may be required in patients in which appropriate antimicrobial therapy has failed to fully resolve all clinical and/or radiographic lesions. For example, surgery may be indicated if, after discontinuing antimicrobial therapy, pneumonia recurs in the same lobe, which may raise suspicion for a foreign body or focal bronchiectasis. In some pulmonary abscesses, a residual nidus of infection may persist even after long-term antimicrobial therapy. Lobectomy may be curative. Additionally, histopathologic examination of lung biopsies may reveal evidence of co-morbid respiratory conditions requiring targeted therapy.

PROGNOSIS

Bacterial tracheobronchitis and bacterial bronchitis are not generally considered life-threatening, but bacterial infection can be an important contributor to clinical signs and exacerbation of co-morbid respiratory conditions. Prognosis depends on the severity of disease, response to treatment, and reversibility of pathology, if any.

Studies have shown survival to discharge rates of dogs with "community-acquired" pneumonia to be 96% and with aspiration pneumonia to be 77%–83%.[37,38,78] There was no association between survival rates and more severe evidence of disease on radiographs or duration of hospitalization in one study,[37] but multiple lobe involvement had a worse outcome than single lobe involvement in another study.[38] Prognosis for survival was not correlated with the number or types of bacteria responsible for aspiration pneumonia, the underlying cause for aspiration, or the existence of multiple underlying reasons for aspiration.[37,38] When evaluating long-term follow-up in dogs having unilateral arytenoid lateralization with postoperative aspiration pneumonia, 1-, 2-, 3-, and 4-year survival rates were 83%, 64%, 52%, and 26%, respectively, underscoring the importance of the larynx in upper airway protection.[36] Collectively, these findings demonstrate the importance of identifying and aggressively managing any underlying cause for aspiration to prevent subsequent recurrence of pneumonia and other permanent damage to the airways and pulmonary parenchyma (e.g., bronchiectasis).

PREVENTION

Contagious causes of bacterial tracheobronchitis and pneumonia can be prevented using good husbandry practices and targeted vaccination (see Chapters 17, 22, 26, and 28). For secondary bacterial infections of the respiratory tract, appropriate early identification and management of underlying disorders is critical. The risk of aspiration pneumonia can be minimized by fasting prior to anesthesia, altering feeding practices in dysphagic dogs (optimizing food/liquid consistency, low-fat diets and prokinetics to facilitate gastric emptying, upright feedings, and in some cases [e.g., megaesophagus] placement of gastric tubes with multiple frequent feedings), and use of antiemetics for animals with severe or protracted vomiting. Prophylactic antimicrobials are not recommended for animals with recurrent aspiration. Overuse or inappropriate use of antimicrobials is likely to predispose patients to infections with MDR bacteria.

PUBLIC HEALTH ASPECTS

Humans and their pets share the same environment, and close contact can lead to exposure of susceptible humans with zoonotic pathogens. A few bacterial pathogens causative of respiratory tract infection in dogs and cats are considered to have the potential to be zoonotic including *B. bronchiseptica, Streptococcus equi* subsp. *zooepidemicus, Mycobacterium tuberculosis,* and *Yersinia* spp.[88] The likelihood of infection as well as the severity of disease is higher in immunocompromised humans. Routes of transmission of zoonotic bacteria are unclear but could include inhalation of aerosols and ingestion; thus, immunocompromised individuals should minimize contact with dogs that are sneezing or coughing, and routine precautions including use of appropriate personal protective equipment and thorough hand washing are prudent for all in-contact humans. An additional concern given widespread and often indiscriminate veterinary use of antimicrobials is the MDR bacteria that may be isolated from the respiratory tract as was demonstrated in one dog with bronchopneumonia.[89]

PYOTHORAX

ETIOLOGY, EPIDEMIOLOGY, AND PATHOGENESIS

Purulent pleuritis, pyothorax, and thoracic empyema describe septic processes of the pleural cavity that are associated with exudate accumulation. The pleural cavity normally contains a small amount of transudative fluid. With bacterial infections, the resultant host inflammatory immune response leads to alterations in vascular permeability and lymphatic function leading to an effusion rich in cells and protein.

Pyothorax can result from either local or systemic disease. Local disease follows extension of infection from the thoracic wall, tracheobronchial tree, pulmonary parenchyma, or esophagus. Examples include bacterial infection from penetrating bite wounds, parapneumonic spread, migrating foreign bodies or parasites, thoracic trauma (including iatrogenic inoculation), and esophageal perforation, among others. Pyothorax that is part of a systemic disease process implies hematogenous or lymphatic spread of bacteria.

Definitive identification of the source of bacterial pleuritis is frequently not achieved.[90] Pleural infections are commonly polymicrobial in nature.[45,91–98] There is a high prevalence of obligate anaerobic bacteria as sole pathogens or in combination of facultative aerobes and other anaerobes.[95–97] The most prevalent organisms isolated from pleural exudate of the dog and cat are summarized in Table 124.3.

TABLE 124.3 Common Bacterial Species Associated with Pyothorax in Dogs and Cats[a]

Dogs	Cats
Bacteroides spp. (34)	*Pasteurella* spp. (41)
Fusobacterium spp. (34)	*Bacteroides* spp. (29)
Escherichia coli (31)	*Fusobacterium* spp. (23)
Pasteurella spp. (29)	*Clostridium* spp. (20)
Peptostreptococcus spp. (29)	*Peptostreptococcus* spp. (17)
Actinomyces spp. (28)	*Actinomyces* spp. (12)
Prevotella spp. (24)	*Porphyromonas* spp. (10)
Staphylococcus pseudintermedius (12–20)[b]	*Prevotella* spp. (8)
Streptococcus spp. (10–18)[b]	
Nocardia spp. (12)	
Corynebacterium spp. (11)	
Clostridium spp. (7)	
Klebsiella spp. (6)	
Porphyromonas spp. (6)	
Acinetobacter spp. (5)	

[a]Numbers in parentheses represent total cumulative number of isolates reported. Organisms with fewer than five isolates reported were not included.
[b]Study by Rooney and Monnet[95] did not differentiate between these two organisms; therefore, range accounts for eight isolates that could be either.
Data taken from references 92,93,95–98,107,117.

TABLE 124.4 Characteristics of Pleural Fluid from Dogs and Cats with Pyothorax

Parameter	Reference Characteristics	Pyothorax
Physical characteristics	Color: clear, transparent	Color: variable yellow to reddish-brown, opaque, flocculent; sometimes granules can be odorous
Cells	<500/μL	>7,000/μL
Protein	<1.5 g/dL	>3 g/dL
Specific gravity	<1.017	≥1.025
Biochemistry of fluid	LDH activity and glucose concentration in reference blood range	LDH activity increased; glucose concentration decreased compared with blood[a]

[a]These changes have presently been documented in cats and humans.
LDH, lactate dehydrogenase.

Dogs

Pyothorax in dogs most commonly occurs in young adult medium to large breeds, especially of working and sporting varieties.[92,93,95] These breeds are thought to be at risk because they are prone to grass awn inhalation during vigorous exercise. When *Actinomyces* spp. are isolated, there should be a high index of suspicion for plant material (grass awns) as the underlying cause.[99,100] Barbed awns migrate down the bronchial tree, carrying commensal microflora from the oropharyngeal cavity into the lung parenchyma. The awns may exit the visceral pleura and enter the pleural cavity where they can cause pyothorax. The relative importance of grass awns as a cause of pyothorax in dogs may be regionally variable, with only 3 of 50 dogs in a UK retrospective study being associated with plant inhalation.[93] Pyothorax may also occur in dogs due to penetrating trauma to the thoracic wall, bite wounds, or esophageal trauma. For example, the esophageal parasite *Spirocerca lupi* has also been responsible for pyothorax in dogs from damage to the esophagus at the site of granulomas and leakage of esophageal material into the thoracic cavity (see Chapter 117).[101] Pyothorax can also be a complication of thoracic drainage techniques (e.g., thoracostomy tube placement and maintenance) or thoracic surgery.[102,103] When pyothorax is a complication of indwelling thoracostomy tubes, it is typically diagnosed within 4 days of tube placement.[102]

Cats

Risk factors for pyothorax in cats include young age and being part of a multiple-cat household, but not indoor or outdoor status (i.e., free roaming does not appear to increase risk).[96] Possible overrepresentation of male cats has been documented in some studies, but this has not been a statistically significant finding. Feline pyothorax generally results from contamination of the pleural cavity with oropharyngeal flora. The most common aerobic organism isolated in feline pyothorax is *Pasteurella,* although anaerobes are frequently cultured as well.[91,94,96,97] Parapneumonic spread and bite wounds are the most common routes of infection.[91,104] Previously, bite wounds were thought to be the major route of infection, especially in young, free-roaming intact male cats.[105] However, with more cats being neutered and kept indoors, pyothorax secondary to bite wounds is seen less frequently.

CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Clinical signs of pyothorax result from restrictive respiratory disease, including increased respiratory rate, shallow respirations, inspiratory respiratory distress, and orthopnea. Other signs include obtundation, exercise intolerance, cough, lethargy, anorexia, weight loss, and fever. Physical examination may reveal muffled heart sounds and decreased breath sounds in the dependent areas of the thorax. Chronic or severe infections may result in a dehydrated, debilitated, collapsed, or hypothermic patient. Approximately one half of cats with pyothorax develop sepsis.[96] In cats with pyothorax, hypersalivation and bradycardia can occur and are associated with a worse clinical outcome.[96,106]

DIAGNOSIS

The diagnosis of pyothorax in dogs and cats is usually established based on radiography and microbiologic and cytologic analyses of pleural effusion (summarized in Tables 124.3 and 124.4).

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Abnormalities on CBC are typically nonspecific including mild-to-moderate nonregenerative anemia, neutrophilic leukocytosis of varying severity with or without a left shift, and presence of toxic neutrophils.[91,93,95,96,107,108] In some patients, the CBC may be unremarkable. In cases of sepsis and concurrent DIC, thrombocytopenia may also be present. Serum biochemistry profile abnormalities may include hyponatremia, hypochloremia, hypoalbuminemia, hyperglobulinemia, azotemia, hyperglycemia or hypoglycemia, and hypocalcemia.[93–96] Hyperbilirubinemia may also be present in cats.[94,96]

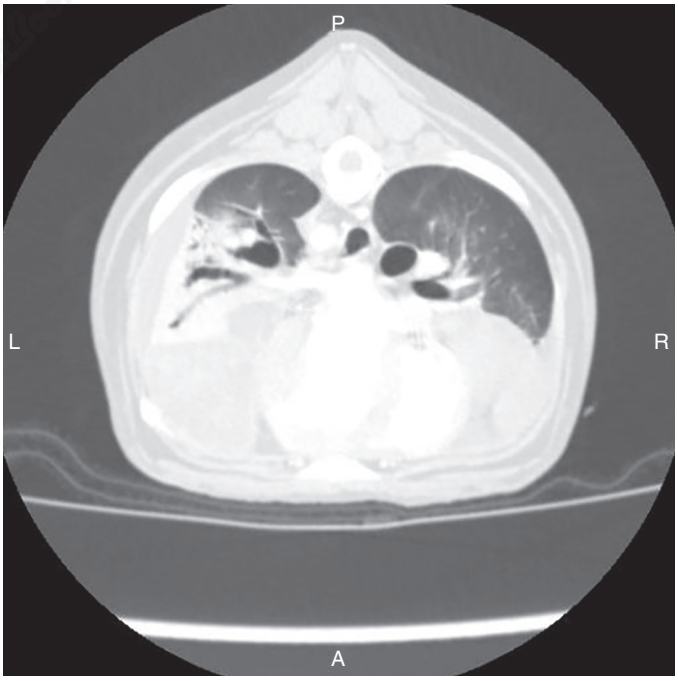

Fig. 124.7 Computed tomography image (0.625-mm thick slice during arterial phase of contrast administration) of a dog presented for increased respiratory effort and lethargy. A large volume of pleural effusion is present with a concurrent lesion in the pulmonary parenchyma of the left cranial lung lobe. (Courtesy of Dr. Tekla Lee-Fowler, Auburn University.)

Diagnostic Imaging

Thoracic Radiography

Pleural effusion is noted on thoracic radiography, particularly if this is performed prior to thoracocentesis. Bilateral effusion is most common, but unilateral effusion may be seen.[91–93,95,96,109] Thoracic radiography should be repeated after drainage of pleural effusion to evaluate for underlying etiology such as lesions in the pulmonary parenchyma, pleural space, and lymphadenomegaly.

Ultrasonographic Examination

Thoracic ultrasound (TFAST) can be used to visualize pleural effusion location and presence of fibrinous adhesions. Pleural effusion associated with pyothorax is typically echogenic. Ultrasonographic examination can also be used to further evaluate consolidated lung parenchyma, possible abscesses, intrathoracic masses, and thoracic lymph nodes. In some cases, foreign material (e.g., plant awns) may be identified.[45,110] Ultrasound can be useful to guide needles for specimen collection or thoracocentesis, particularly when loculated fluid is present.

Advanced Imaging

CT may provide more detail regarding pulmonary parenchymal lesions and correlates well with findings at surgery (Fig. 124.7).[111] CT reliably provides information on the presence and volume of pleural fluid.[111] Pleural gas may be noted, either due to procedures such as thoracocentesis or as a result of plant foreign body migration.[111] Pleural thickening, mediastinal lesions, and lymphadenomegaly can all be reliably detected.[111] Improved identification of pulmonary parenchymal lesions is also a benefit of CT over plain radiography, and lesions may be identified that are not evident at surgery.[111] For this reason, CT results can be useful to guide surgical intervention. Use of a combination of CT and bronchoscopy may be most effective for identification of migrating plant awns.[112]

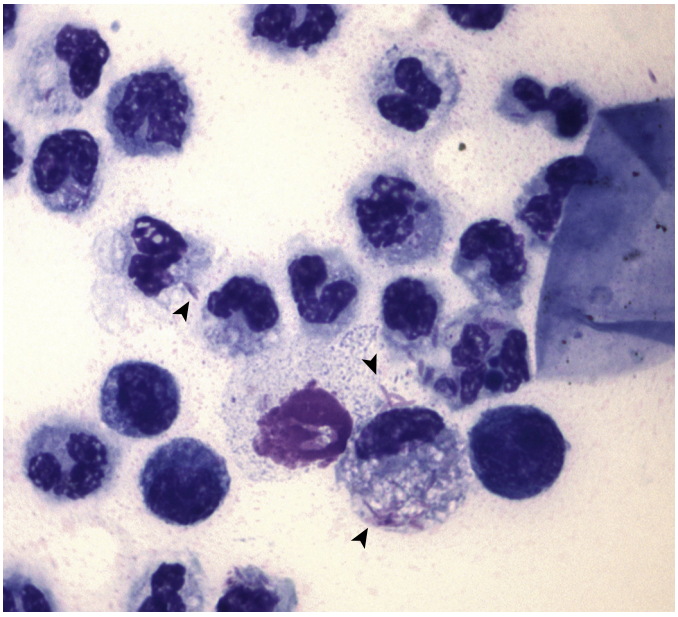

Fig. 124.8 Cytology of pleural effusion from a 3-year-old male neutered domestic shorthair cat with pyothorax. There are many neutrophils, which are variably karyolytic. Many of them contain bacterial rods, which can also be seen extracellularly *(arrowheads)*. Anaerobic bacterial culture yielded *Fusobacterium russii*, and aerobic culture was negative.

Microbiologic Tests

Cytologic Diagnosis

Grossly, pleural exudate obtained using thoracocentesis from dogs and cats with pyothorax is typically turbid and/or hemorrhagic and may contain flocculent debris. In anaerobic infections, it may also be malodorous. Sulfur granules within the effusion may be visualized with *Actinomyces* spp. or *Nocardia* spp. infections. Bacteria can often be identified microscopically, and mixed populations of bacteria may be noted; however, failure to identify bacteria does not rule out bacterial pyothorax. Infection with nonstaining bacteria such as *Mycoplasma* spp. or a history of antimicrobial therapy may mean bacteria are not visible. *Actinomyces* or *Nocardia* infection should be suspected if filamentous bacteria are seen microscopically (Fig. 124.8).

Culture and Susceptibility Testing

Specimens for aerobic and anaerobic culture should be collected before antimicrobial administration whenever possible. Pleural fluid should be placed into appropriate tubes, including anaerobic transport medium, with minimal exposure to air to optimize the chance of positive cultures. Specimens intended for anaerobic culture should not be refrigerated and should be processed with minimal delay.[90] Consideration should also be given to specific culture for *Mycoplasma* spp., and it is recommended that the laboratory be informed if there is a clinical suspicion of *Actinomyces* spp. or *Nocardia* spp. infection. Because anaerobic cultures and *Mycoplasma* spp. cultures are often low yield when transported to a commercial diagnostic laboratory from a practice environment (as opposed to immediate submission to an on-site laboratory as occurs in teaching hospital environments), aerobic bacterial culture and empiric therapy for anaerobes (which are almost always present) is a suitable alternative.

TREATMENT

Treatment of pyothorax should be prompt and aggressive. Initial goals are to relieve respiratory distress by removal of effusion from the

pleural space, to provide appropriate IV fluid therapy and supportive care, and to inactivate bacteria using systemic antimicrobial drugs.

Drainage and Lavage

Drainage of pleural exudates is essential for management of pyothorax. Delayed pleural drainage leads to incomplete resolution of signs and predisposes to formation of loculated abscesses and fibrosis, which could necessitate later thoracotomy. Placement of indwelling thoracostomy tubes has been recommended as the initial treatment of choice in most cats, with 95% of cats having resolution when this is combined with appropriate concurrent antibacterial drug therapy.[91] Dogs may also benefit from indwelling tube placement and aggressive medical management. Indwelling tubes have the advantages of closed chest drainage and facilitate pleural fluid sampling to monitor therapeutic response; the tubes also allow direct instillation of isotonic lavage fluid (with or without additives) into the pleural space (see later). Disadvantages of indwelling tubes include challenges associated with maintenance of drain placement and patency and the risks of pneumothorax and infection.[102] Large-bore thoracostomy tubes have been traditionally utilized to minimize the chance of obstruction with purulent fluid. However, small-bore wire-guided thoracostomy tubes have been shown to be suitable for the management of pyothorax without any occurrences of tube obstruction.[113] When these tubes were used, thoracic lavage was incorporated into the management protocol, which may explain why obstruction did not occur. Small-bore tubes offer advantages such as patient tolerance of placement and ease of placement.

After fluid removal, radiographs should be taken to more accurately evaluate the pulmonary parenchyma, pleural space, and mediastinum for lesions that may alter treatment plans. Additionally, post-drainage radiographs can be used to assess whether drainage is complete, especially on the contralateral side. If fluid removal is incomplete, bilateral tube placement may be required. Intermittent suction every 2 to 4 hours or continuous suction can be used.[114] Use of one-way continuous suction requires close monitoring as the risk of potentially fatal complications in cases of malfunction is increased. The median duration of indwelling thoracostomy tubes for drainage has been approximately 6 to 7 days (range, a few hours to 21 days).[91–93,96]

A single-needle thoracocentesis has not been routinely advocated for management of pyothorax although one study reported complete long-term resolution of pyothorax in 15 of 16 dogs after complete drainage and 6 weeks of treatment with ampicillin and metronidazole.[107] Single drainage protocols are usually not curative if pulmonary lobar masses (associated with abscesses or consolidation) are evident by radiography after initial fluid drainage. Repeated thoracocentesis is relatively simple and inexpensive but is generally not recommended due to associated morbidity.

Thoracic lavage may be performed through indwelling thoracostomy tubes. There is controversy about the efficacy of lavage of the pleural cavity. Lavage may facilitate removal of accumulated pus and bacteria and break down clots and fibrin bands; in addition, it may dilute bacteria and other inflammatory mediators. However, prospective studies are lacking. Some retrospective studies have suggested that lavage led to decreased duration of thoracostomy tube drainage[93] and increased the likelihood of survival.[92] However, one retrospective study in cats concluded that thoracic lavage should not be routinely recommended as the benefits of lavage did not outweigh the risks.[96] Lavage has been implemented as part of a medical management protocol in some studies with apparently good success[91–93,115]; however, it is unclear how much of the beneficial outcome was directly related to lavage and not to the other medical management strategies or differences in patient populations.

Fluid volumes for lavage are generally 10 to 20 mL/kg of warmed 0.9% saline infused slowly over 5 to 10 minutes two to four times per day.[116] Respiratory pattern and effort are monitored closely during infusion, and infusion is discontinued and fluid immediately aspirated if respiratory distress occurs. The fluid volume can then be reduced for subsequent lavage. The patient can be rotated from side to side, or mild coupage can be performed followed by immediate removal of any accessible fluid. Lavage can be continued until the removed fluid is clear of pus. Cytologic improvement is exhibited by decreasing cell count, with loss of degenerative changes in neutrophils, and absence of bacteria. Repeated culture is also recommended to confirm resolution of infection. Addition of antimicrobial agents to the lavage fluid is controversial and is currently not recommended based on limited data.[76]

Antimicrobial Therapy

Systemic antimicrobial therapy is indicated for pyothorax, but it is usually insufficient without lavage or drainage of the infected pleural cavity. Initial empiric antibacterial selection should be active against a mixture of facultative and obligate anaerobic bacteria.[76,97] Penicillin or penicillin derivatives are often given because they are active against obligate anaerobes, *Pasteurella* spp., or *Actinomyces* spp. As an initial empirical choice, a combination of a fluoroquinolone (e.g., enrofloxacin or marbofloxacin) with a penicillin or clindamycin is recommended.[76] Culture and susceptibility testing should be evaluated in light of clinical condition for further adjustments to antibacterial therapy. Regardless of the anaerobic or facultative anaerobic bacteria that are cultured, the regimen should always contain drugs effective against anaerobes. Systemic antibacterial therapy should ideally be continued for at least 4 to 6 weeks.[76]

Surgery

Surgical intervention is more costly, particularly when medical management has been attempted first and failed.[117] Therefore, it is important to try to identify candidates that require surgical intervention as early in the disease course as possible.[117] Evidence of foreign material, pulmonary or mediastinal masses, radiographic evidence of fluid encapsulation, repeated blockage of drainage tubes, recurrent pneumothorax, and lack of significant improvement in fluid consistency during lavage are indications for surgical exploration and/or lobectomy.[93,95,96] Because *Actinomyces* spp. have been associated with a high likelihood of plant material,[100,118,119] isolation of these bacteria is another potential indication for surgical exploration. Although surgical exploration is expensive, one report suggested that dogs having surgical exploration and debridement followed by medical management have a better outcome after treatment than those undergoing pleural evacuation and lavage alone.[95] Thoracoscopy (or *video-assisted thoracic surgery, VATS*) is a less invasive alternative to thoracotomy.[109,120,121] In one study, conversion to open thoracotomy was only required for 2 of 14 dogs with pyothorax that underwent thoracoscopy, and only 1 dog had recurrence of pyothorax that required a second surgery 17 months later (median follow-up time: 143 days, range: 14–2,402 days).[121]

Monitoring

Radiographic monitoring is essential during treatment and follow-up of pleural infections. Serial radiographic examinations should be performed first after initial thoracocentesis, when the chest tube is removed, 10 to 14 days after starting antibacterial therapy, and at completion of therapy.[76] Additionally, radiographs can be acquired 1 to 2 weeks after discontinuing antimicrobials to monitor for subclinical recurrence of disease. If there is persistence of effusion or recurrence, repeated thoracocentesis, fluid analysis, and culture and susceptibility should be performed.

PROGNOSIS

The highest period of mortality for dogs and cats with pyothorax is within the initial 48 hours of drainage and stabilization.[93] After that time, prognosis improves. Survival to discharge of 74% and long-term survival of 63% were reported in one study,[92] whereas other studies have reported higher percentages.[93,107,117] Recurrence rates have been reported to be < 20% with most recurrences occurring within a few months of discharge [92,93,95,96,107,109,115,117]

PREVENTION

When possible, reducing exposure of dogs to areas where grass awns are prominent may assist in pyothorax prevention. Grooming dogs that are exposed to areas of abundant grass awns thoroughly and frequently may reduce the risk of related complications.[100] Housing cats indoors and in stable colonies may reduce the risk of pyothorax.

CASE EXAMPLE

Signalment

"Sam," a 5-year-old, female, intact, English pointer from the southeastern United States.

History

Sam was evaluated for a 3-day history of behavioral change and 2-day history of anorexia. Labored breathing was noted the morning of evaluation which prompted presentation on an emergent basis. The patient was up-to-date on vaccinations and routine parasite prevention. The dog lived in an outdoor kennel setting and was an active field trial dog that traveled frequently to events. There was no history of prior illness.

Physical Examination Findings

Body weight: 17.5 kg, BCS 3/9.

General: Obtunded but responsive, 5% dehydration, T = 102.4°F (39.1°C), HR = 140 beats/minute, RR = 50 breaths/minute, mucous membranes pink, CRT = 2 seconds.

Ears, eyes, nose, and throat: Mild mucoid ocular discharge bilaterally.

Respiratory: Restrictive respiratory pattern (shallow with greater effort on inspiration), decreased bronchovesicular sounds ventrally over both the right and left thorax.

Lymph nodes: Mild bilateral lymphadenomegaly of the superficial cervical lymph nodes.

No clinically significant abnormalities were noted in other systems following full physical examination.

Laboratory Findings

CBC: HCT 44.1% (38.7%–59.2%), MCV 69.6 fL (60.5–73.8 fL), MCHC 34.6 mg/dL (32–37.2 mg/dL), platelets 468,000/µL (152,000–518,000 platelets/µL), WBC 28,820 cells/µL (5,090–17,410 cells/µL), neutrophils 26,806 cells/µL (2,600–10,400 cells/µL), band neutrophils 576 cells/µL (0–300 cells/µL), lymphocytes 865 cells/µL (390–6,730 cells/µL), monocytes 576 cells/µL (160–1,160 cells/µL), eosinophils 0 cells/µL (10–2,050 cells/µL), cell morphology – slight toxic granulocytes.

Serum chemistry profile: Total protein 6.4 g/dL (5.5–7.7 g/dL), albumin 1.6 g/dL (3–4.3 g/dL), globulin 4.8 g/dL (2–4.3 g/dL), ALP 177 U/L (14–152 U/L), ALT 22 U/L (13–151 U/L), AST 29 U/L (18–55 U/L), total bilirubin 0.1 mg/dL (0–0.2 mg/dL), creatine kinase 145 U/L (53–337 U/L), BUN 9.0 mg/dL (9–34 mg/dL), creatinine 0.3 mg/dL (0.5–1.6 mg/dL), calcium 9.1 mg/dL (9.6–12 mg/dL), phosphorus 5.5 mg/dL (2.6–7.9 mg/dL), glucose 84 mg/dL (76–116 mg/dL), cholesterol 328 mg/dL (132–335 mg/dL), bicarbonate 15.2 mmol/L (14–29 mmol/L), sodium 141 mmol/L (142–151 mmol/L), potassium 3.6 mmol/L (3.6–4.9 mmol/L), chloride 104 mmol/L (105–117 mmol/L).

Imaging Findings

At the time of initial examination, a brief thoracic ultrasound was performed and confirmed the presence of pleural effusion. Thoracic radiographs revealed a moderate amount of pleural effusion characterized by retraction of the lung lobes, partial silhouetting of the cardiac outline and numerous pleural fissure lines. An alveolar pattern was also noted within the caudal aspect of the left cranial lung lobe. Interpretation: Pleural effusion. Alveolar pattern within the caudal aspect of the left cranial lung lobe was most consistent with pneumonia. An underlying presence of a foreign body could not be ruled out.

Cytologic Findings

A pleural effusion specimen was obtained for analysis using thoracocentesis.

Fluid analysis: Color: red; transparency: cloudy; nucleated cells: 124,900/µL; RBC: 370,000/µL; protein: 4.0 g/dL; specific gravity: 1.027.

Cytologic description: Predominance of neutrophils with fewer macrophages and scattered reactive mesothelial cells. Neutrophils were degenerative, and low numbers had phagocytized thin, filamentous rod bacteria and fewer small cocci. Bacteria were also seen free in the background.

Interpretation: Septic inflammation.

Microbiologic Testing

Aerobic and anaerobic culture: *Actinomyces* spp. from broth only and heavy growth of *Bacteroides capillosus*.

Diagnosis

Bacterial pyothorax.

Treatment

The patient was stabilized upon initial presentation with thoracocentesis and IV fluid therapy. Once results of the pleural fluid analysis were available, an exploratory thoracotomy was performed via median sternotomy. Effusion was suctioned from the thoracic cavity and thorough lavage was performed. The right caudal lung lobe was abnormal in appearance with an apparent mass present, and a right caudal lung lobectomy was performed. Foreign material was not visualized within the thoracic cavity. A thoracostomy tube was placed on the right side.

The patient recovered from surgery without complication. IV fluids were continued postoperatively, postoperative analgesic therapy was instituted, and empiric antimicrobial therapy was begun with ampicillin-sulbactam (30 mg/kg, IV, q8h) and clindamycin (11 mg/kg, IV, q12h). Pleural effusion was manually suctioned q4h. The thoracostomy tube was removed on day 5 post-hospitalization when very little pleural fluid production was documented, and antibiotic therapy was transitioned to clavulanic acid-amoxicillin (20 mg/kg, PO, q12h) and clindamycin (8 mg/kg, PO, q12h). Histopathology of surgically resected lung tissue revealed focal suppurative pneumonia, chronic pyogranulomatous pleuritis, and mediastinitis. Sam was discharged on day 6 of hospitalization. He continued to recover well after discharge. No evidence of recurrence was documented as of follow-up 18 months after discharge.

Comments

The growth of *Actinomyces* spp. and the mass lesion in one lung lobe in this dog suggested the possibility of plant awn migration as a cause of the pyothorax.

Gastrointestinal and Intra-Abdominal Infections

Jane E. Sykes, Ingrid Balsa, William T.N. Culp, Boaz Arzi, Sina Marsilio, Stanley L. Marks

KEY POINTS

- Causes: A wide variety of gram-negative and gram-positive bacteria can infect the GI tract and peritoneal cavity, including *Escherichia coli, Enterococcus* spp., other gram-negative aerobes, *Streptococcus,* and *Staphylococcus* spp. and anaerobes. *Candida* spp. may also be involved, particularly in immunocompromised patients or patients receiving antibacterial drug therapy. Viruses, atypical bacteria (e.g., *Mycobacterium* spp.), protozoa (e.g., *Toxoplasma gondii, Giardia duodenalis*, *Tritrichomonas blagburni*), endemic fungi (e.g., *Histoplasma spp.*), algae (*Prototheca* spp.), and helminth parasites also cause GI disease.
- Mode of Transmission: Most GI infections result from opportunistic invasion by commensal bacteria and fungi of the GI and urogenital tracts. Other pathogens are transmitted by a variety of different routes.
- Major Clinical Signs: Signs are extremely variable depending on the site of infection, the underlying etiology, and the immunocompetence of the host, but include dysphagia, hypersalivation, inappetence, fever, vomiting, diarrhea, and abdominal pain.
- Human Health Significance: Enteric bacteria involved may be multidrug-resistant organisms that have the potential to colonize humans. In addition, certain assemblages of *Giardia duodenalis* have the potential to be zoonotic.

THE GASTROINTESTINAL MICROBIOME AND METABOLOME

Thousands of microbial species reside within the GI tract as commensal organisms. The resident gut microbiome is composed of viruses, bacteria, and eukaryotic organisms that perform a number of vital functions, including resisting colonization with pathogenic microbes by maintaining oxygen tension, competing with nutrients, and producing antibacterial substances (bacteriocins); assisting with nutrient breakdown and synthesizing essential vitamins and short-chain fatty acids; stimulating and maintaining mucosal immunity; metabolizing bile acids and drugs; and inactivating potentially carcinogenic and toxic ingested substances.[1,2] Antimicrobial administration can induce gut dysbiosis, with broad-spectrum antibiotics causing rapid and significant drops in taxonomic richness, diversity, and evenness. In addition, disruption of the gut microbiome as a result of disease, immunosuppression, or antimicrobial therapy can adversely affect the health of the GI tract and has the potential to allow organisms that are normally nonpathogenic to proliferate opportunistically and cause disease.

For decades, our understanding of the identity and quantity of the resident microflora was hampered because of a reliance on traditional culture methods. This is because the use of culture methods overestimates the species that are culturable and underestimates those that are fastidious or unculturable. The more recent advent of high-throughput molecular approaches has revolutionized our understanding of the intestinal microbiome in health and disease, especially when layered upon our existing knowledge based on culture-dependent methods. Application of next-generation sequencing (NGS) methods (also known as massive parallel sequencing) allows rapid sequencing of 1 million to 43 billion short reads (up to 1000 bp) with each run. Microbial DNA is amplified using PCR and then sequenced; several different types of sequencing methods can be used but common methods applied are 454 pyrosequencing, reversible dye terminator (Illumina) sequencing, and real-time sequencing.[3] The PCR assays used commonly target bacterial 16S rRNA genes. The internal transcribed spacer (ITS) gene has also been used as a target; across bacterial populations, the ITS gene is more variable than the 16S rRNA gene, and so ITS gene PCR methods offer improved discrimination between bacterial species (taxonomic resolution). In-depth whole metagenomic sequencing (WMS) methods capture total microbial DNA (rather than just 16S rRNA gene information) and are not subject to bias that results from preferential amplification of certain 16S rRNA gene sequences; however, they are more expensive than amplification-based methods and so amplification-based methods continue to be utilized.[2] The use of mixed methodology across studies and often small numbers of animals has led to considerable variation in microbiome composition results, but as more studies accumulate, our understanding of the canine and feline microbiome is improving. Targeted techniques such as FISH (see Chapter 6) are complementary to these studies and allow identification of bacteria or fungi within lesions in formalin-fixed tissues (Fig. 125.1).

Because microbiome analysis provides information on the identity of hundreds of bacterial species, including many previously unidentified organisms, data are usually presented by grouping bacteria into phyla, and within phyla, orders. Descriptions of microbial populations generally only refer to individual species when those species represent a significant proportion of organisms within an order. Table 125.1 provides examples of common phyla found within the GI tract, and some of the orders and species within those phyla. A phylum can contain both aerobes and anaerobes, but they tend to be primarily gram-negative or gram-positive species (e.g., organisms that belong to the Firmicutes are generally gram positive).

Terms used to describe microbiome communities include *diversity*, *richness*, *abundance*, and *evenness.* Richness is the total number of bacterial species present in a microbiome; a rich microbiome has many species present. Species diversity is a measure of the number

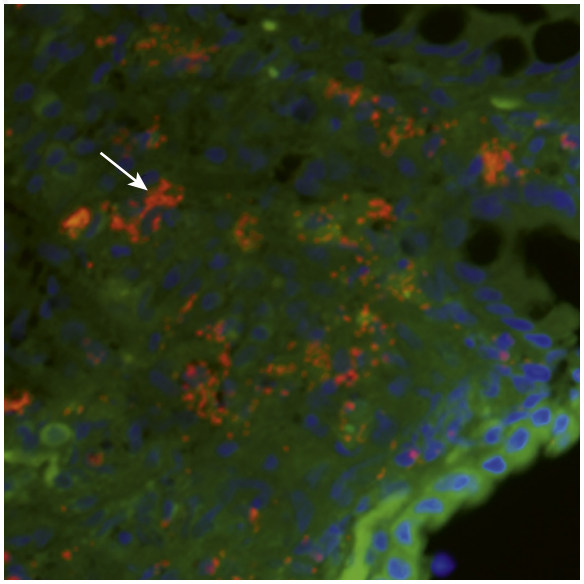

Fig. 125.1 Fluorescence in situ hybridization image using probes *E. coli*-cy3 and non-EUB 338-6FAM. *E. coli* stain red and are found abundantly in the mucosal tissue and within cells (*arrow*) in areas of inflammatory cell infiltrates. DAPI-stained nuclei (DNA) are blue. In healthy colonic tissue the bacteria are only found in superficial mucus and glandular lumens on the bowel surface (×400). (Courtesy Kenny Simpson, Cornell University, Ithaca, NY.)

of species *and* the abundance of each species. Alpha-diversity is the diversity within a particular region or sample, and beta-diversity is the diversity between two regions or samples (measured as the number of species that are unique to each region being compared). Evenness describes the distribution of abundance across a population; an even population is when all species in the population have the same abundance. Indices have been developed in order to quantify diversity (e.g., Shannon's index) and evenness (e.g., Pielou's evenness index) using mathematical equations. A *canine dysbiosis index (DI)* is a PCR-based algorithm that allows veterinarians to quantify gut dysbiosis and can be used to monitor disease progression and response to treatment.[4] A DI ≥ 2 indicates dysbiosis, a negative DI suggests normobiosis, and values in between have been considered equivocal.[5] Antimicrobial administration induces a rapid and significant drop in taxonomic richness, diversity, and evenness. In light of this phenomenon, there has been renewed vigor to study the effects of probiotics, prebiotics, and fecal microbiota transplantation (FMT) on reversing intestinal dysbiosis and optimizing the intestinal microbiome.

Several studies also have described the metabolic products generated by the canine and feline intestinal microbiota, including volatile fatty acids; amino acids such as tryptophan; lactate; ammonia; and other end products.[6,7] The chemical signature that results is reflective of the bacterial populations present, and is referred to as the GI metabolome.

INFECTIONS OF THE ORAL CAVITY

THE ORAL MICROBIOME

The resident microbial flora of the canine and feline oral cavity is composed of a wide variety of aerobic bacteria and facultative and obligate anaerobic bacteria, mycoplasmas, and yeasts, but differs significantly from that in humans. Examples of anaerobes found in canine saliva using culture include *Actinomyces, Streptococcus,* and *Granulicatella* (previously nutritionally variant streptococci), and in dental plaque, *Porphyromonas, Actinomyces,* and *Neisseria.*[8]

High-throughput sequencing methods have demonstrated the diversity of species in the bacterial and fungal biomes in the oral cavity of healthy dogs and cats and those with periodontal disease, with considerable variations from one anatomic region to another.[9] In one study, three different niches were identified in dogs—saliva, supragingival plaque, and the soft-tissue structures of the tongue and buccal mucosa.[9] The most abundant organisms were *Filofactor villosus* for supragingival plaque (5% of total DNA composition), an unclassified Pasteurellaceae for buccal mucosa (12%), *Conchiformibius* sp. for the dorsal tongue mucosa (17%), and an unclassified *Escherichia coli-Shigella* sp. for saliva (20%). Proteobacteria were the dominant group for all of the sites except supragingival plaque, where Firmicutes were dominant. Supragingival plaque also exhibited the greatest microbial diversity. *Capnocytophaga*, *Porphyromonas*, *Neisseria*, and *Fusobacterium* spp. were all observed among core microbiota. In healthy cats, the most prevalent species in swabs from the oral cavity in one study was an unidentified Pasteurellaceae (19%), followed by *Moraxella* spp. (11%). When the subgingival microbiota was examined, *Porphyromonas* spp. was most abundant, followed by *Moraxella* spp. and *Fusobacterium.*[10] In another study of cats with and without periodontal disease, the most abundant genera in healthy cats were *Enhydrobacter*, *Moraxella*, and *Capnocytophaga* spp.[11] Organisms that are found to a greater extent in cats with periodontal disease than healthy cats are *Filofactor* spp. and the spirochete *Treponema* spp.

Antimicrobial agents used in treating oral infections such as gingivitis and stomatitis should be chosen with the composition of the resident microflora in mind. However, clearly not all organisms that comprise the resident microflora are capable of causing disease or replicating when inoculated into tissue; bacterial virulence factors, the local tissue environment, and the host response to infection ultimately influence what bacteria are able to replicate and cause pathology. Some of the organisms are found in bite wound infections (see Chapter 75).

GINGIVITIS AND PERIODONTITIS

Inflammation and recession of the gingival margins are common findings in dogs and cats. Factors that predispose dogs and cats to periodontal disease include tooth crowding and rotation, persistent deciduous dentition, malocclusions, congenital abnormalities, trauma, soft food diets, and genetic factors.[12] Lesions are initially caused by excessive accumulation of dental plaque resulting from deposition of by-products from breakdown of food and saliva by normal resident microflora. Plaque is an organic matrix of salivary glycoproteins and polysaccharides that adheres to the tooth surface and provides sites for oral bacteria to proliferate. Resident bacteria produce a glycopolysaccharide referred to as a *glycocalyx*, which facilitates the attachment of other bacteria. This biofilm is further consolidated into a film, or plaque. Plaque accumulation results in inflammation of the gingiva. Plaque can become mineralized, resulting in calculus deposition (Fig. 125.2). The deposition of calculus facilitates additional plaque formation and periodontal inflammation.

In dogs, periodontitis is associated with proliferation of gram-positive and gram-negative anaerobic organisms that belong to the Firmicutes, Actinobacteria (such as *Actinomyces* spp.), Bacteroidetes (especially *Porphyromonas* spp. and *Fusobacterium* spp.), and Spirochaetes (e.g., *Treponema* spp.).[13,14] In humans, periodontitis has been associated with an increased population of *Porphyromonas gingivalis, Tannerella forsythia,* and *Treponema denticola* (collectively referred to as "the red complex").[15] Pups have very few *Porphyromonas* species in their dental plaque; however, bacterial numbers increase as

TABLE 125.1 Common Phyla Present in the Gastrointestinal Microbiome

Phylum	Class Examples	Order Examples	Species Examples
Firmicutes (mostly gram positive)	Clostridia	Clostridiales	*Clostridium filofactor* *Peptostreptococcus* *Eubacterium*
	Bacilli	Bacillales	*Bacillus* *Listeria* *Staphylococcus*
		Lactobacillales	*Lactobacillus* *Streptococcus* *Enterococcus*
	Erysipelotrichia	Erysipelotrichales	*Erysipelothrix*
Proteobacteria (mostly gram negative)	Gammaproteobacteria	Enterobacterales	*Escherichia* *Enterobacter* *Klebsiella* *Proteus* *Salmonella* *Yersinia*
		Pasteurellales	*Pasteurella* *Haemophilus*
	Epsilonproteobacteria	Campylobacterales	*Helicobacter* *Campylobacter*
	Betaproteobacteria	Neisseriales	*Neisseria*
Bacteroidetes (mostly gram negative)	Bacteroidia	Bacteroidales	*Bacteroides* *Prevotella* *Porphyromonas*
Fusobacteria	Fusobacteria	Fusobacteriales	*Fusobacterium*
Spirochaetes	Spirochaetia	Spirochaetales	*Treponema* *Leptospira* *Borrelia (Borreliella)*
Actinobacteria	Actinobacteria	Actinomycetales	*Actinomyces* *Nocardia* *Mycobacterium* *Corynebacterium*
		Bifidobacteriales	*Bifidobacterium*

puppies mature and inevitably periodontal disease develops. Although spirochetes such as *Treponema* spp. have been considered important pathogens in canine periodontal disease, one study found no difference in the prevalence of various *Treponema* species as detected using nucleic acid–based methods in gingival plaque from dogs with and without periodontal disease.[16]

Subgingival plaque incites an inflammatory response in the gingival tissue that can lead to chronic periodontal disease with eventual loss of teeth. Early bacterial damage occurs in the subgingival epithelial tissues with penetration of the interdental rete pegs. Many bacteria possess proteolytic enzymes that allow them to colonize and invade periodontal tissues. Periodontal pathogens destroy the integrity of the dentition and oral mucosae.

Endodontal disease and periodontitis can also develop whenever tooth damage occurs, exposing the dental pulp. Acute periapical periodontitis (i.e., periapical lesion) begins within 20 days of pulp exposure in dogs and progresses with time.[17] Fractures of teeth usually result in pulp infection before revascularization of the canal by vital tissue can occur. In advanced human root canal infections, anaerobes, corynebacteria, and streptococci predominate.[18] Although not widely practiced in veterinary medicine and human endodontics, debridement and treatment of the canal with a triple antibacterial paste (ciprofloxacin, minocycline, and metronidazole) in a resorbable matrix base early after injury may eliminate endodontal infection and promote revascularization of the pulp canal.[19]

Radiographic examination of the teeth and associated bony structures is required to determine the condition of the tooth roots and secondary bone or tooth resorption before treatment. Furthermore, endodontal involvement, neoplastic destruction of bone, and nasal and sinus passages can be evaluated to determine the extent of disease before treatment.

Treatment includes the extraction of severely affected teeth, debridement of necrotic or proliferative gingival margins, root planing with curettes, and scaling calculi from the remaining involved supragingival and subgingival dental surfaces by manual or ultrasonic means. Complete removal of all supragingival and subgingival calculus and plaque is essential in control of periodontal disease. More aggressive surgical debridement is needed for advanced periodontal disease.

Although bacterial pathogens are important in periodontitis, antimicrobial therapy alone does not eliminate progression of disease. Because proinflammatory cytokines, such as TNF-α, Il-1β, and matrix metalloproteinases have been important in the progression of periodontal disease, a variety of anti-inflammatory and immunomodulatory drugs and dietary supplements have been examined

Fig. 125.2 Moderate to severe periodontal disease with accumulation of dental calculus in a 9-year-old male neutered terrier mix. (Courtesy University of California-Davis Community Medicine Service.)

as treatments.[20,21] Genetic predisposition to periodontal disease in humans may reflect differences in cytokine responses to invasion of tissues by oral cavity bacteria.[21] Oral IFN-α administered to dogs and cats with naturally occurring gingivitis reduced both periodontal bacterial counts and associated gingival inflammation.[22,23] The use of anti-inflammatory diets or supplements with omega-3 fatty acids may reduce the local gingival inflammatory response and has shown some benefit in small human clinical trials.[24] However, a prospective study in dogs showed no benefit for reduction of gingivitis, plaque, or calculus when a diet supplemented with either corn oil or fish oil was fed.[25]

Although administration of systemic antimicrobial drugs such as tetracyclines, clindamycin, metronidazole, and tinidazole have been shown to reduce gingivitis, plaque accumulation, halitosis, and alveolar bone resorption in dogs and cats,[26-28] the use and efficacy of systemic antimicrobial therapy for this purpose has been questioned as an alternative for indicated dental procedures[29] and may select for antimicrobial-resistant bacterial populations. Currently it is recommended by AAHA that the use of systemic antimicrobials in conjunction with dental procedures be considered on a case-by-case basis.[30] In most cases, antimicrobials are not required. Postoperative treatment with clindamycin or amoxicillin-clavulanic acid is indicated for at least 7 to 14 days if there is radiographic evidence of osteomyelitis.[30] Treatment for several days before surgery has been suggested for animals with Stage IV disease to facilitate tissue handling, but this may not be necessary and has the potential to select for resistant bacteria.

Perioceutics are pharmaceutical formulations that are placed into periodontal pockets to allow for sustained antimicrobial activity against periodontal pathogens. They are used as an adjunct to scaling and cleaning the dental surfaces. The perioceutics containing antimicrobials are delivered into the periodontal pocket via a blunt cannula. Once there, the biodegradable polymer gels coagulate, allowing for sustained release of the drug for up to 13 weeks. Products that contain 2% clindamycin gel or 8.5% doxycycline hyclate are available for veterinary use.[12] Their use has been recommended by AAHA when a > 5-mm cleaned pocket exists in dogs with Stage II or Stage III periodontal disease. However, one study evaluated the use of these gels in conjunction with closed root planing in dogs with periodontal pockets that ranged from 3.5 to 5.5 mm deep.[12] Use of the gels did not lead to greater improvement in periodontal disease indices over closed root planing alone.

Long-term intermittent periodontal care for dogs is highly recommended because it slows the progression of gingival recession and depth of periodontal crevices that develop in dogs not receiving dental hygiene.[31] Gingival enlargement and abscess formation are sequelae of calculus formation.[32] The type of microflora present, diet, and the animal's chewing habits may influence the formation of calculus.[33,34] Daily tooth brushing is more effective than diet for optimization of oral health in dogs; in one study it was three times as effective at controlling plaque accumulation than a dental diet or daily dental chews.[35] Tooth brushing has also been shown to be effective in cats.[36,37] The use of special diets supplemented with dental chews can reduce calculus deposition further in dogs and cats.[37] Feeding of a commercial dental food to dogs significantly reduced plaque and gingivitis by 39% and 36%, respectively, compared with daily feeding of a control dry-food diet.[38] Cats fed large kibbles with mechanical cleaning qualities had less gingivitis and calculus than cats on small kibble diets with or without daily brushing.[39]

Flushing dental surfaces once daily with 0.1% to 0.2% chlorhexidine and/or alternate-day brushing may delay accumulation of dental calculus. A commercial product formulated especially for dental purposes (Nolvadent, Zoetis) does not stain teeth blue like other chlorhexidine formulations. Daily application of chlorhexidine gel was effective in reducing recurrence of dental plaque in dogs.[40] Numerous cleansers and brushes have been developed for daily brushing of dogs' teeth, and they warrant consideration when a dog has a tendency to form calculus. Oral probiotics have been examined for their ability to prevent the growth of pathogenic bacteria or modulate mucosal immunity in the oral cavity. Oral probiotic bacteria should adhere to and colonize on dental tissue and should be part of the biofilm. They should not ferment sugars, which subsequently lowers the pH and is detrimental to dental health.[41] A split-mouth, double-blind randomized pilot study, involving eight beagle dogs with moderate experimentally induced periodontitis, documented the impact of multiple subgingival applications of pellets containing *Streptococcus sanguinis, Streptococcus salivarius,* and *Streptococcus mitis.*[42] The bone density within periodontal pockets treated with the beneficial bacteria improved significantly after 12 weeks, whereas there was a nonsignificant change in the control group that received a single root planing at baseline. In addition, there was a significant increase in the alveolar bone level at the end of the study based on repeat radiographs compared to the control group. Unfortunately, a randomized controlled clinical trial in humans with Stage III periodontitis showed no benefit of a *Lactobacillus* probiotic or azithromycin as an adjunct to scaling and root planing.[43] Also, a study that examined the effect of an oral probiotic containing *Enterococcus faecium* (Fortiflora, Purina) showed no change in the oral microbiota of dogs, which remained stable over a 7-week time period regardless of diet or administration of the probiotic.[44] More needs to be known about what organisms are capable of restoring and maintaining health when delivered in a probiotic format. The Veterinary Oral Health Council website lists products that have been shown to be effective for retarding plaque and calculus deposition in dogs and cats (vohc.org/all_accepted_products.html).

A *P. denticanis-gulae-salivosa* bacterin that was commercially available as an aid in preventing periodontal disease is no longer licensed due to concerns surrounding lack of efficacy.

Systemic Effects of Oral or Periodontal Infections

Ophthalmic manifestations can occur from dental disease because of the close proximity of the caudal maxillary teeth and the orbit. Systemic complications of periodontal disease, including cerebral and myocardial infarction, systemic hypertension, adverse pregnancy outcomes and early mortality, have been described in people.[45,46] Human patients with poorly controlled diabetes mellitus are at an increased risk of developing periodontal disease[47] and resolution of periodontal inflammation can improve metabolic control of blood glucose in diabetics.[48]

Associations between periodontal inflammation and heart (endocarditis, cardiomyopathy), liver, and kidney (CKD) disease have been reported in dogs.[49-53] These have included studies that have correlated

lesions at necropsy with whole mouth periodontal scoring. In other retrospective studies, no statistical association was found between bacterial endocarditis in dogs and either dental or oral surgical procedures or oral infection.[54,55] However, detailed prospective screening and grading of oral cavity changes were not undertaken in these studies.

Bacteremia associated with dental manipulations may be subclinical or has the potential to cause sepsis or subsequently result in bacterial endocarditis or localized embolic tissue infections (see Chapter 122). In cats with periodontitis undergoing dental scaling and extraction, 36% had positive blood culture results at the time of the dental procedures.[56] Bacteria most commonly isolated were *Cutibacterium* (formerly *Propionibacterium) acnes, Pasteurella multocida,* and *Staphylococcus epidermidis*. None of the cats subsequently became ill. Similarly, blood culture results have shown subclinical bacteremia in 30% of dogs with periodontal disease undergoing periodontal treatment and tooth extraction, although a group of control dogs that were anesthetized but that did not undergo dental procedures had a similar prevalence of bacteremia.[57] It is generally recommended that dental procedures should not be performed at the same time as other surgical procedures, because the release of bacteria from the dental procedure may have the potential to establish themselves in tissue injured or devitalized by routine surgical procedures, sutures, or foreign implants. Current guidelines from AAHA recommend that intraoperative antibiotic administration be used for immunosuppressed animals or those with implants or subaortic stenosis to reduce the likelihood of bacteremia. A rational approach is to follow the recommendations for prophylactic antimicrobial use for "dirty" surgical procedures or when the implications of a surgical site infection may be devastating (see Chapter 76). In summary, the goal is to maintain therapeutic drug levels throughout the period of risk by administering the first dose IV 30 to 60 minutes before starting the procedure, with intraoperative dosing every 2 half-lives of the antimicrobial as long as the procedure is underway. Ampicillin is a rational choice for dental procedures, and it has a half-life of 20 minutes in the dog and 72 minutes in the cat, meaning intraoperative redosing is indicated every 40 and 145 minutes, respectively. Prerinsing the oral cavity with chlorhexidine solutions can also be performed just before the procedure. Drug administration should be terminated no longer than 24 hours after the dental procedure because no additional benefits are gained and additional antimicrobial exposure increases the risk of selection for resistant bacteria. Interestingly, IV administration of aqueous penicillin during ultrasonic scaling in dogs did not alter the prevalence of bacteremia before or after dental manipulation.[58] More studies are required to examine the effects of intraoperative antimicrobial administration on bacteremia in dogs undergoing dental procedures and whether prophylaxis impacts outcomes.

Because of the large numbers of bacteria in the oral cavity and especially the gingival crevices, public health considerations are important when dental procedures are performed. Face masks, ocular shields, and gloves should always be worn by humans who clean animals' teeth. In addition, biofilms that form on the inside surface of water lines of ultrasonic scalers may harbor *Legionella* species, which might produce acute pneumonia in susceptible individuals.[59]

GLOSSITIS AND STOMATITIS

Glossitis may be caused by viruses, bacteria, fungi, and protozoa. Fungi such as *Blastomyces* spp. and protozoa such as *Leishmania* spp. typically cause nodular tongue lesions.[60] Viral causes in dogs include CDV, canine calicivirus, and CPV. In cats, FCV and FHV-1 can cause lingual ulceration as well as ulceration of the buccal mucosa. *Rickettsia rickettsii* can cause lingual ulceration as a result of endothelial cell damage. Primary physical injury can occur via trauma, bite wounds, burns, caustic substances, and foreign bodies, with secondary infection with bacteria or *Candida* spp. Lesions in the mouth that disrupt the normal host barriers include those caused by eosinophilic granuloma complex and neoplasms such as squamous cell carcinoma and epitheliotropic T-cell lymphoma. Systemic disorders that may lead to lingual ulceration include uremia; autoimmune diseases such as pemphigus vulgaris, bullous pemphigoid, erythema multiforme, and systemic lupus erythematosus; and embolic disease (including septic thromboemboli). Organisms are not often found on histologic examination; however, suppuration and overlying ulceration are usually apparent. Foreign material such as hair, bone, or plant matter can be present in lingual wound infections.

The most prevalent disorders associated with gingivostomatitis in dogs and cats are canine chronic ulcerative stomatitis (CUS; also known as chronic ulcerative paradental stomatitis) and feline gingivostomatitis. Canine CUS is a chronic painful ulcerative condition of the mouth with an unclear pathogenesis.[61] Predisposed breeds include the Maltese terrier, Cavalier King Charles spaniel, greyhound, and Labrador retriever. Male neutered dogs are also overrepresented. Ulcers typically occur on the buccal mucosa opposite the dental plaque, but can also occur on the lateral margins of the tongue, the palatoglossal folds, and the mucocutaneous border of the lips (Fig. 125.3).

(B) Histopathology findings of a biopsy from the buccal mucosa showing severe, diffuse, lymphoplasmacytic, ulcerative gingivitis. H&E stain. (Courtesy the Dentistry and Oral Surgery Service and Veterinary Anatomic Pathology Service, University of California-Davis.)

Histopathology reveals a lymphoplasmacytic infiltrate at the interface between the mucosal epithelium and the subepithelial connective tissue that is comprised of CD79+ B cells, plasma cells, CD3+ T cells, and regulatory T cells.[61,62] There has also been evidence of IL-17 expression in the lesions, a cytokine that is often associated with regulation of autoimmune diseases. Infectious agents have not been identified in association with CUS. Extraction of teeth opposite the ulcers may result in clinical improvement.[61]

Feline chronic gingivostomatitis (FCGS) is a common and painful disease of the oral cavity characterized by inflammation of the buccal and caudal oral mucosa, lateral to the palatoglossal folds. Ulcerative/erosive and proliferative phenotypes have been described (Fig. 125.4).[63] Often young adult cats are affected, and in some cats there may be minimal evidence of accompanying periodontal disease. However, most cats with FCGS often have significant generalized periodontitis and are more likely to have external inflammatory root resorptive lesions.[64] Affected cats may show evidence of dysphagia with reduced appetite, weight loss, halitosis, ptyalism, pawing at the mouth, and reduced grooming. Some of the signs may also result from esophagitis, which has been detected using endoscopy in affected cats.[65]

Although a variety of infectious agents have been associated with this disorder, direct causation has not been proven because most of the pathogens postulated to play a role commonly infect cats without causing clinical signs; these have included FeLV, FIV, FCV, FHV-1, and *Bartonella* spp.[63,66-68] The strongest associations have been made with FCV infections, although not all evidence has supported a role for this virus (see Chapter 35).[63] Disease may occur in a number of cats within a household and tends to be recurrent after the initial treatment or is unresponsive to treatment. Cessation of FCV shedding was associated with resolution of chronic gingivostomatitis in one cat.[67] Coinfections with FIV or FeLV may result in more severe lesions. In one study, cats with chronic gingivostomatitis were more likely to shed FCV and FHV-1 together than either virus alone.[68] Biopsy of affected regions reveals lymphoplasmacytic inflammation. Large numbers of B cells and both CD4+ and CD8+ T cells can be found within the lesions, as well as regulatory T cells.[69] In another study, compared with nondiseased cats, affected cats showed a significant increase in expression of IL-2, IL-4, IL-6, IL-10, IL-12 (p35 and p40), and IFN-γ.[70] The predominant bacterial species present in the oral cavity of cats with FCGS in one study with *Pasteurella multocida* subsp. *multocida*.[71] Hyperproteinemia due to a polyclonal gammopathy is often present on the serum chemistry panel, and may be moderate to severe, likely reflective of chronic antigenic stimulation.

Treatment with antibiotics that have activity against anaerobes (such as clindamycin) can result in some improvement; however, the response is temporary. Other medical treatments that have been used are topical lactoferrin and oral IFN-ω (see Chapter 9). Treatment with prednisolone may also result in some clinical improvement, but long-term treatment tends to have gradual reduction in efficacy and is not recommended because of adverse effects.[63] Although the number of cats was small, treatment with cyclosporine also seemed to be effective when compared to a placebo-treated group, and 5 of 11 cats followed for 3 or more months remained in remission.[72] If cyclosporine is used, measurement of trough concentrations is recommended on a regular basis to avoid excessive immunosuppression, and the drug should be used at the lowest possible dose that controls clinical signs. To date, the most effective treatment has been proper management of periodontal disease, and, for refractory cases, partial- or full-mouth tooth extractions. Because the outcome following extraction of all premolar and molar teeth does not appear to differ significantly from that following full-mouth extractions, premolar-molar extraction has been recommended initially, moving to full-mouth extraction 1 to 4 months later if there is insufficient reduction in clinical signs.[63,73] In cases with generalized periodontitis and stomatitis, full-mouth tooth extraction is recommended. It is estimated that approximately 20% to 30% of cats will show minimal or no improvement.

INFECTIONS OF THE ESOPHAGUS AND STOMACH

Infections of the esophageal wall in dogs and cats usually follow esophageal perforation or full-thickness ulceration secondary to foreign bodies, esophageal neoplasia, or gastroesophageal reflux during anesthesia.[74] Uncommon infectious causes of esophagitis that have been documented in dogs include *Candida* spp. esophagitis and *Pythium insidiosum* esophagitis. *Candida* spp. were isolated from two immunocompromised chow-chow puppies that were coinfected with CAdV-2 and CDV,[75] and *Pythium*-associated esophagitis was confirmed on necropsy in two dogs from rural Tennessee, USA.[76] One of the authors (SLM) has also confirmed *Pythium*-associated esophagitis in three dysphagic large-breed hunting dogs from northern California via esophageal biopsy and immunohistochemistry, and positive serum

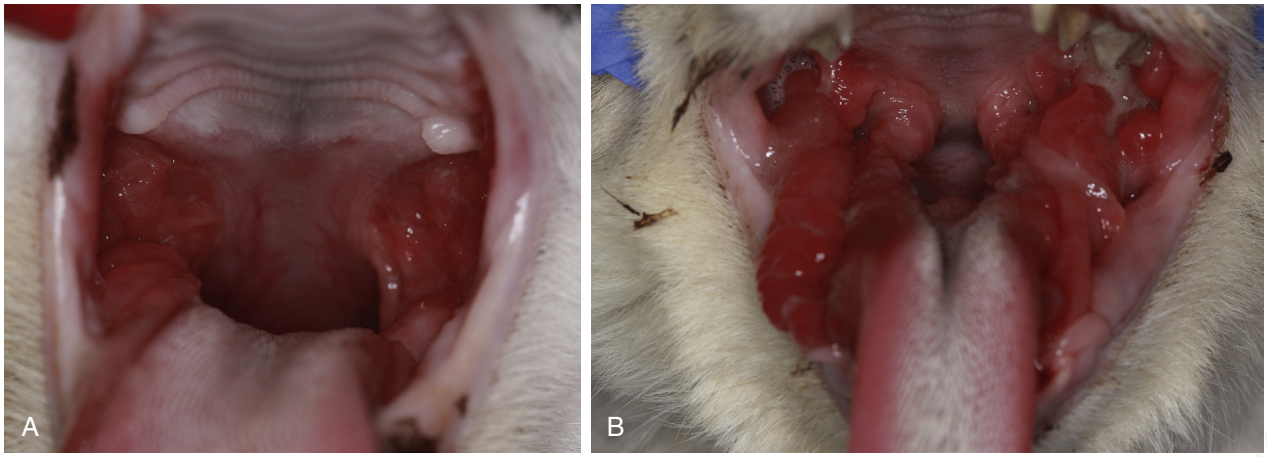

Fig. 125.4 Feline gingivostomatitis. (A) Severe proliferative form. (B) Ulceroproliferative lesions. (Courtesy University of California-Davis Dentistry and Oral Surgery Service.)

anti-*P. insidiosum* ELISA. Nevertheless, uncommon complications, esophageal abscesses, mediastinal empyema, or pyothorax may result. Migrating plant awns have been incriminated as an underlying cause in some cases.[77] Clinical signs include inappetence, ptyalism, fever, lethargy, weight loss, regurgitation, odynophagia, tachypnea, cough, and abdominal pain.[77,78] One dog developed respiratory distress secondary to tracheal collapse and bilateral laryngeal paralysis that were associated with a paratracheal abscess that had entrapped the recurrent laryngeal nerves.[79] Plain radiography may show evidence of pleural effusion or mass lesions associated with the esophagus. CT imaging and ultrasound may also be useful for visualizing esophageal abscess lesions.[77,78] Esophagoscopy findings were normal in several dogs and a cat with caudal mediastinal paraesophageal abscesses.[77,78] Treatment has generally involved open surgical drainage (lateral thoracotomy or median sternotomy) or omentalization through a diaphragmatic incision. Antimicrobials indicated for pyothorax are likely to be appropriate for paraesophageal abscesses.

Because of the acidic milieu of the stomach and the presence of pepsin, the stomach has relatively low concentrations of resident microflora relative to other portions of the GI tract, and bacterial gastritis and gastric abscesses rarely occur. *Physaloptera* spp. infection can cause gastritis, and should be considered in dogs and cats with chronic vomiting, especially those with a history of consuming insects or vertebrate prey (see Chapter 116). A higher dose and longer duration of fenbendazole in combination with pyrantel pamoate is recommended for treatment of suspected or confirmed infections. Reinfection is common in some dogs and should not be viewed as treatment failure. *Ollulanus tricuspis* nematodes are worms found in the gastric mucosa of the cat, and rarely in dogs.[80,81] The parasite has a direct life cycle and does not require an intermediate host. Clinical signs of chronic vomiting, weight loss, and anorexia are most commonly reported. Effective therapies include tetramisole at 5 mg/kg (single dose) and fenbendazole at 50 mg/kg (PO q24h for 5 days).

The reader is referred to Chapter 66 for information on gastric helicobacteriosis.

INFECTIONS OF THE INTESTINAL TRACT

THE INTESTINAL MICROBIOME

Concentrations of bacteria in the proximal small bowel are relatively low because of the influence of gastric acid and bile, but they gradually increase toward the ileocecal region. Numbers of microorganisms in the distal small bowel or the large bowel are not affected by feeding and remain relatively constant after meals. Increased numbers of resident organisms may be found in the stomach and upper small intestine, or pathogenic organisms may proliferate when normal bowel defenses are impaired. Excessive use of acid suppressants, intestinal obstruction, ileus, impaired bile acid signaling, exocrine pancreatic insufficiency, or decreased mucosal or IgA secretions can result in disruption of the normal microbiome and bacterial overgrowth in the small intestine.[82] In contrast to cats with GI illness, clinically healthy cats have much higher concentrations of bacteria in the duodenum and jejunum.[83,84]

Puppies and kittens lacking normal microflora at birth derive their microflora from exposure to their dam and littermates or from their environment by 2 to 3 weeks of life.[85] Studies performed using 16S rRNA gene PCR methods have shown that the composition of the intestinal microflora may change with age in dogs and cats, with Enterobacterales and enterococci decreasing in abundance with age in cats, and lactobacilli and enterococci decreasing in abundance with age in dogs.[86,87] Another study that used 16S rRNA gene PCR showed that the microbial diversity in dogs tended to decrease as dogs aged.[88] Changes in diet, nutritional status, and physiologic state of the host may influence the proportions of residing bacteria.[2,89] Small intestinal bacterial overgrowth (SIBO) in dogs is a condition thought to result from dysbiosis, and is most commonly associated with exocrine pancreatic insufficiency, ileus, malabsorption of nutrients, and deficiency of sIgA. The diagnosis of SIBO is a topic of debate, because it has traditionally been defined as proliferation of small intestinal bacteria to concentrations > 10^5/mL, which have now been identified even in healthy dogs.[90] The term "intestinal dysbiosis" is far more common in dogs, and refers to an alteration of the intestinal microbiota independent of bacterial numbers.

In general, the important phyla that make up the intestinal microbiota in dogs and cats are Fusobacteria, Bacteroidetes, and Firmicutes. Proteobacteria and Actinobacteria are the two other major taxa present. Some of the more important genera are *Fusobacterium*, *Lactobacillus*, *Streptococcus* (dogs) and *Enterococcus* (cats), *Clostridium, Prevotella*, and *Bacteroides*.

Use of 16S rRNA gene pyrosequencing has shown that the stomach of healthy dogs is primarily occupied by Proteobacteria (99.6%), with a predominance of *Helicobacter*. The remaining organisms belong to the Firmicutes, primarily *Lactobacillus*.[82] The duodenum and upper jejunum primarily harbor aerobes and facultative anaerobes. The main phyla of the duodenum in dogs are Firmicutes (approximately 45%), Proteobacteria (approximately 20%), and Bacteroidetes (approximately 10%).[82,91] Prevalent orders in duodenal fluid have included Clostridiales and Lactobacillales, with only low numbers of the anaerobes Fusobacteriales and Bacteroidales.[92] In the jejunal mucosa, the ratio of Firmicutes to Proteobacteria appears to change, with one study showing 47% of the microbiome to be Proteobacteria (primarily Gamma Proteobacteria) and 15% to be Firmicutes; the remaining phyla were Spirochaetes (15%), Actinobacteria (11%), Bacteroidetes (6%), and Fusobacteria (4%).[93] In jejunal fluid, Clostridiales and Lactobacillales remained prevalent, but Enterobacterales and Fusobacteriales were identified in greater concentrations than in duodenal juice.[93] In colonic contents, Proteobacteria have diminished dramatically (comprising < 2% of organisms; this includes *E. coli*) and the population is dominated by Fusobacteria, Bacteroidetes, and Firmicutes, in even distribution.[93] The same phyla are found in canine fecal specimens, although the distribution has varied among studies; in most studies, Firmicutes have comprised a significant proportion of organisms, especially clostridia.[94] The maximum numbers of microorganisms and the greatest biodiversity are found in the large intestine when compared with the small intestine.[92] A single gram of feces contains 10^{11} to 10^{12} organisms and 15,000 to 36,000 different species.[95,96] The concentration of many anaerobes is reduced in the feces during diarrhea because these organisms normally require intestinal stasis and low oxygen tension for growth.

The composition and concentration of the intestinal microflora is altered in dogs with GI disease. For example, in one study of dogs with acute diarrhea, episodes of diarrhea were associated with increased abundance of Clostridiales (especially *Clostridium perfringens*) and enterococci.[97] In dogs with inflammatory bowel disease (IBD), one study showed reduced species richness and a higher proportion of Enterobacterales;[91] another found a greater proportion of Proteobacteria and a lower abundance of Clostridia.[98] Dogs with chronic enteropathies (food-responsive, antibiotic-responsive, or immunosuppressant-responsive) are also significantly more likely to have positive dysbiosis indices when compared with healthy dogs.[5] Although treatment of dogs with immunosuppressant-responsive enteropathies (IBD) results in clinical improvement, microbial dysbiosis may persist.[99]

The effect of intestinal disease on the GI microbiome in cats has also been examined, although relatively few studies exist. In addition, studies that have examined the microbiome of healthy cats have had

somewhat conflicting results, with different percentages of the major phyla (Firmicutes, Bacteroides, Actinobacteria, and Proteobacteria) varying between individuals and being influenced by age and diet.[100,101] A study that used Illumina sequencing showed that cats with chronic enteropathies (IBD and alimentary small cell lymphoma) had reduced fecal bacterial population diversity when compared with healthy cats, with an increase in Enterobacterales and Streptococcaceae and a decrease in abundance of organisms that belonged to the phyla Firmicutes and Actinobacteria (*Bifidobacterium*) and *Bacteroidetes*.[102] There were no detectable differences between cats with IBD and cats with small cell lymphoma.

The prevalence and diversity of fungal organisms in the GI tract of dogs and cats has had limited study. The most abundant phylum in both healthy dogs and dogs with acute diarrhea in one study that used pyrosequencing was Ascomycota (approximately 98%), followed by Basidiomycota (1%).[103] In both groups, the most abundant genus was *Candida*, the primary species being *Candida natalensis*. In another study that used similar methodology, Ascomycota was the most abundant phylum in dogs and the only phylum identified in cats.[104] In that study, the most abundant genus in dogs was *Nacaseomyces* and in cats were *Saccharomyces* and *Aspergillus*.

The Effect of Diet on the Microbiome

Dietary composition can impact the diversity and abundance of different bacterial species in the microbiome. In one study, feeding a raw food diet to dogs was associated with increased abundance of Proteobacteria and Fusobacteria in the fecal microbiota; in dogs fed a commercial diet, Firmicutes were more abundant.[89] It is important to consider the differences in the macronutrient composition of raw and commercial diets, because the increased fiber and carbohydrate in a commercial extruded diet can impact the microbiota significantly. A prebiotic is defined as a "nondigestible food ingredient which beneficially affects the host by selectively stimulating the growth of and/or activates the metabolism of one or a limited number of health-promoting bacteria in the intestinal tract."[105] A variety of prebiotics have been added to dog and cat diets in order to promote GI health. The most common prebiotics studied are fructans, although other prebiotics such as mannans, lactosucrose, and lactulose are also being evaluated. Short-chain fructooligosaccharides (scFOSs) are polymers of glucose that have been added to commercial diets as a source of soluble fiber. They occur naturally in plants or mammalian milk, or are synthesized from fermentation. Chicory root is one example of a naturally occurring source of scFOS. Other natural sources rich in soluble fiber are oat bran or wheat pulp. scFOSs are not digested by the mammalian small intestine, and they reach the colon intact. There they are fermented by anaerobic bacteria such as *Bifidobacterium* spp. or lactobacilli into short-chain fatty acids such as acetate, propionate, and butyrate. These anaerobic organisms proliferate and inhibit growth of other potentially pathogenic microbes such as *Clostridium* species and *E. coli.* Fructan supplementation attenuated some of the pathologic responses to experimental *Salmonella* challenge of weanling pups.[106] In general, studies evaluating the effect of dietary supplementation with scFOS have shown an increase in fecal bifidobacteria and lower fecal clostridia numbers in dogs.[94] However, these studies relied upon traditional culture methods to identify and quantify relative proportions of bacteria. When 16S rRNA gene pyrosequencing was used to assess the effect of a diet that contained beet pulp on fecal microbiota in dogs, the abundance of Clostridia increased within the Firmicutes and the abundance of the phyla Actinobacteria and Fusobacteria decreased.[107] The appearance of butyrate-producing bacterial species that may possess anti-inflammatory effects was also noted. Administration of a scFOS or pectin-based diet to cats was associated with an increase in the abundance of *Bifidobacterium* and *Lactobacillus*, respectively, when compared with a control diet.[108] In this study, genus-specific PCR assays were used to amplify bacterial DNA.

Probiotics

Probiotics are viable microorganisms that, when administered orally in adequate amounts, confer a health benefit on the host. Enterococci, lactobacilli, and bifidobacteria—normal colonic inhabitants—have often been administered after antimicrobial treatment, intestinal infections, weaning, stress, or dietary changes in an attempt to reestablish the intestinal microbiota. Many of these microorganisms become transient constituents of the enteric microflora. In humans, these bacteria have been administered in the form of yogurt, cheese, and milk products, and efforts have been made to include these in canine and feline diets. Theoretical benefits of probiotics include the production of antibacterial substances (bacteriocins) and competitive inhibition of pathogen and toxin adherence to the intestinal epithelium, reestablishment of enteric microflora after antimicrobial treatment, enhancement of host innate immunity, regulation of host immune responses, and regulation of intestinal epithelial cell functions. Synbiotics are combinations of prebiotics and probiotics.

A number of studies addressing the role of probiotics in the management of canine and feline diarrhea have been published to date, with most studies evaluating the efficacy of this therapeutic modality for the management of acute diarrhea, and results have been mixed depending on the type of probiotic and the underlying disorder being managed. The effect of probiotics in both healthy dogs and those with enteropathies have been published, with mixed results. Two studies were randomized, placebo-controlled clinical trials of dogs with food-responsive enteropathy.[109,110] In one of those studies, all of the dogs clinically improved when placed on an elimination diet. However, they showed no specific changes in the inflammatory cytokine patterns or any specific benefit of a probiotic.[109] In the second study,[110] dogs with acute diarrhea, with or without vomiting, were divided into placebo or probiotic groups. The probiotic formulation consisted of a mixture of live strains of *Lactobacillus, Bacillus*, and *Pediococcus* species. The mean time from treatment to resolution of the diarrhea was 1 day shorter in the probiotic group. Administration of *Lactobacillus kefiri* to dogs, a species found in kefir, had no impact on fecal IgA concentrations or the composition of the microbiome.[111] Several publications have described beneficial effects in prospective studies of a probiotic that contains four strains of *Lactobacillus*, three strains of *Bifidobacterium*, and *Streptococcus salivarius* subsp. *thermophilus.* Treatment of dogs with IBD with this probiotic in one randomized study appeared to have the same effect as treatment with metronidazole and prednisone, with improvement in clinical and histopathological scores.[99] In another multicenter study, dogs with IBD were randomized to receive treatment with diet and prednisone alone; or diet, prednisone, and the eight-strain probiotic.[112] There was rapid clinical remission in both groups over 60 days despite no improvement in inflammation assessed histopathologically; dogs treated with diet and prednisone alone had an increase in *Bifidobacterium* spp. using FISH on endoscopic biopsies, and those treated with the probiotic had an increase in *Lactobacillus* spp. Treatment of healthy dogs with this 8-strain probiotic preparation as a dietary supplement for 60 days resulted in a decrease in the abundance of *C. perfringens* and an increase in the abundance of *Bifidobacterium* and *Lactobacillus* spp. when compared to a control group fed the diet alone.[113] Treatment of healthy dogs and dogs with food-responsive diarrhea with a synbiotic that contained *Enterococcus faecium*, FOS, and gum arabic had no impact on fecal microbiota diversity or richness.[114] Additional studies are warranted in dogs to further assess the immunomodulatory effects of probiotics and to evaluate their safety.

There are fewer publications pertaining to probiotic use in cats, and one randomized, placebo-controlled study in 217 shelter cats administered the probiotic, *Enterococcus faecium* SF68 or placebo, showed that the percentage of cats with diarrhea ≥ 2 days was significantly lower ($P = 0.03$) in the probiotic group (7.4%) when compared with the placebo group (20.7%).[115] One study showed that a microencapsulated probiotic formulation that contained three *Lactobacillus* species—*Bifidobacterium bifidum*, *Enterococcus faecium,* and *Saccharomyces cerevisiae*—was able to modulate the fecal microbiota of healthy cats by increasing lactic acid bacterial counts.[116] A mixture of FOS and gum arabic was used for encapsulation. Treatment of laboratory-reared cats with amoxicillin-clavulanic acid for 7 days with or without *Enterococcus faecium* strain SF68 for 14 days was associated with decreased microbiome diversity in both groups, with no detectable differences between groups.[117] However, the probiotic-treated cats had improved diarrhea scores when compared with the cats treated with amoxicillin-clavulanic acid alone.

Fecal Microbiota Transplantation

FMT can be infused by various methods, including nasogastric tube, nasojejunal tube, upper tract endoscopy (esophagogastroduodenoscopy), colonoscopy, or retention enema, and has been used to treat dysbiosis associated with a wide array of disorders in humans. The therapeutic modality has recently received attention for treatment of refractory chronic enteropathies and acute diarrheas in dogs and cats. A fresh fecal specimen is collected from a healthy donor dog or cat, mixed with saline or another isotonic solution, filtered to remove particulate matter, and administered by endoscopy into the colon or enema. Repeated treatments may be given on a regular basis (such as every 3 to 5 days or even on a weekly basis). An optimum method of preparation, dose, or dosing frequency has not been established. Apparent clinical responses to treatment have occurred in animals that were refractory to traditional medical therapies.[118,119] In one report, the fecal microbiome of a recipient dog converted to that of the donor after multiple treatments, with a dramatic decrease in the abundance of Proteobacteria and increase in the abundance of Fusobacteria.[118] As in humans, randomized prospective studies are required to evaluate the efficacy of FMT to treat enteropathies in dogs and cats. Although complications associated with FMT are extremely infrequent in people, the risk of infectious hazards needs to be taken seriously, particularly in recipients who are severely immunocompromised. A recent report of infection with extended-spectrum beta-lactamase (ESBL)-producing *E. coli* in two human patients following FMT underscores the importance of comprehensive screening of donors and of the material to be transplanted.[120] Both of the ill recipients had severe underlying diseases – cirrhosis with hepatic encephalopathy in one and hematologic dysplasia treated by means of hematopoietic-cell transplantation in the other. Both patients also had concomitant and previous use of antibiotics that were broadly active against gut luminal bacteria, which may have diminished the microbiota that normally provide resistance to introduced pathogens. Both recipients developed severe infections following FMT and one of the patients died after they received FMT capsules from the same donor. It is readily apparent that FMT may carry risks that can only be identified after the fact, and improved screening of FMT donors and of the material to be transplanted should help reduce the risks of infections by known pathogens. It is highly probable that as the use of FMT is broadened in veterinary medicine and more compromised patients are treated, complications may be more frequently observed.

Bacterial Translocation

The GI tract is a known reservoir of microorganisms, which under certain circumstances can spread via the portal circulation or intestinal lymphatics to extraintestinal sites, including the mesenteric lymph nodes, liver, spleen, and pancreas, and to other organs by systemic circulation. In one study of 50 clinically healthy entire females undergoing ovariohysterectomy, a variety of aerobic and anaerobic bacterial species could be isolated using culture from the mesenteric lymph nodes of 26 dogs; in most dogs a single isolate was obtained.[121] Corresponding peripheral venous and portal venous blood cultures yielded a gram-positive coccus and a coagulase-negative *Staphylococcus* species from the peripheral blood of one of the dogs. It is highly plausible that the prevalence of bacterial translocation in healthy dogs is even higher than that documented in this study given the limitations and insensitivity of routine bacterial culture compared to molecular-based methods. In the human literature, bacterial translocation has been divided into "healthy" translocation, whereby bacteria and fragments of bacteria (DNA, LPS, peptidoglycan, flagellin) are continuously presented to the reticuloendothelial system in the liver and serve to promote host immunity. In contrast, "pathologic" bacterial translocation occurs when significant numbers of bacteria are able to cross a damaged intestinal barrier in a sustained manner and cause or contribute to disease (Fig. 125.5).

Pathologic bacterial translocation occurs with conditions of reduced mucosal perfusion; these can result from systemic hypotension, decreased peristalsis (such as with intestinal obstruction or ileus), intestinal resection, abdominal trauma, burns, abdominal radiation therapy, pancreatitis, and obstructive biliary disease. Paradoxically, antimicrobial therapy has been shown to promote bacterial translocation in mouse models.[122] Administration of glucocorticoids or NSAIDs can result in reduction in GI mucus production, a normal protective defense of the bowel against bacteria. In one study of 448 humans undergoing laparotomy in the United Kingdom, bacterial translocation was detected in 15% of patients, with the main species isolated being *E. coli*.[123] Furthermore, 41% of patients that had evidence of bacterial translocation developed septic complications, compared with only 14% of those that did not have evidence of bacterial translocation. Furthermore, gut microbes were responsible for the majority of septic events. Bacteria may translocate via transcellular or paracellular pathways; paracellular translocation of bacteria and LPS is facilitated by disruption of tight junctions. Currently the best approach to prevention of bacterial translocation is early treatment of the underlying condition, and the use of intraoperative antimicrobial drugs during contaminated procedures (see Chapter 76). A number of treatments, such as dietary modification with antioxidants, prebiotics, probiotics, and vitamin D have been suggested to reduce the impact of chronic translocation of bacteria and LPS in humans with chronic disease states by working to improve the integrity of the mucosal barrier.[124]

PATHOPHYSIOLOGIC MECHANISMS OF INFECTIOUS DIARRHEA

Enteropathogenic organisms, unlike resident and nonpathogenic transient microflora, have acquired means of overcoming the host defense mechanisms and the inhibitory properties of the normal microflora. Adherence factors (e.g., somatic pili) that permit intestinal pathogens to establish infection also allow them to attach to, multiply on, and colonize the intestinal mucosa. Some pathogenic bacteria that cause diarrhea remain on the mucosal surface and produce potent enterotoxins that disrupt fluid flux across the intestinal mucosa. Others are able to penetrate intact epithelial cells, producing inflammatory damage in the underlying mucosa. Enteric viruses damage the intestine by replicating within and destroying selected populations of epithelial cells. Often, multiple mechanisms are involved. Various mechanisms by which microorganisms produce intestinal injury are covered in relevant chapters on enteropathic viruses and bacteria in this book.

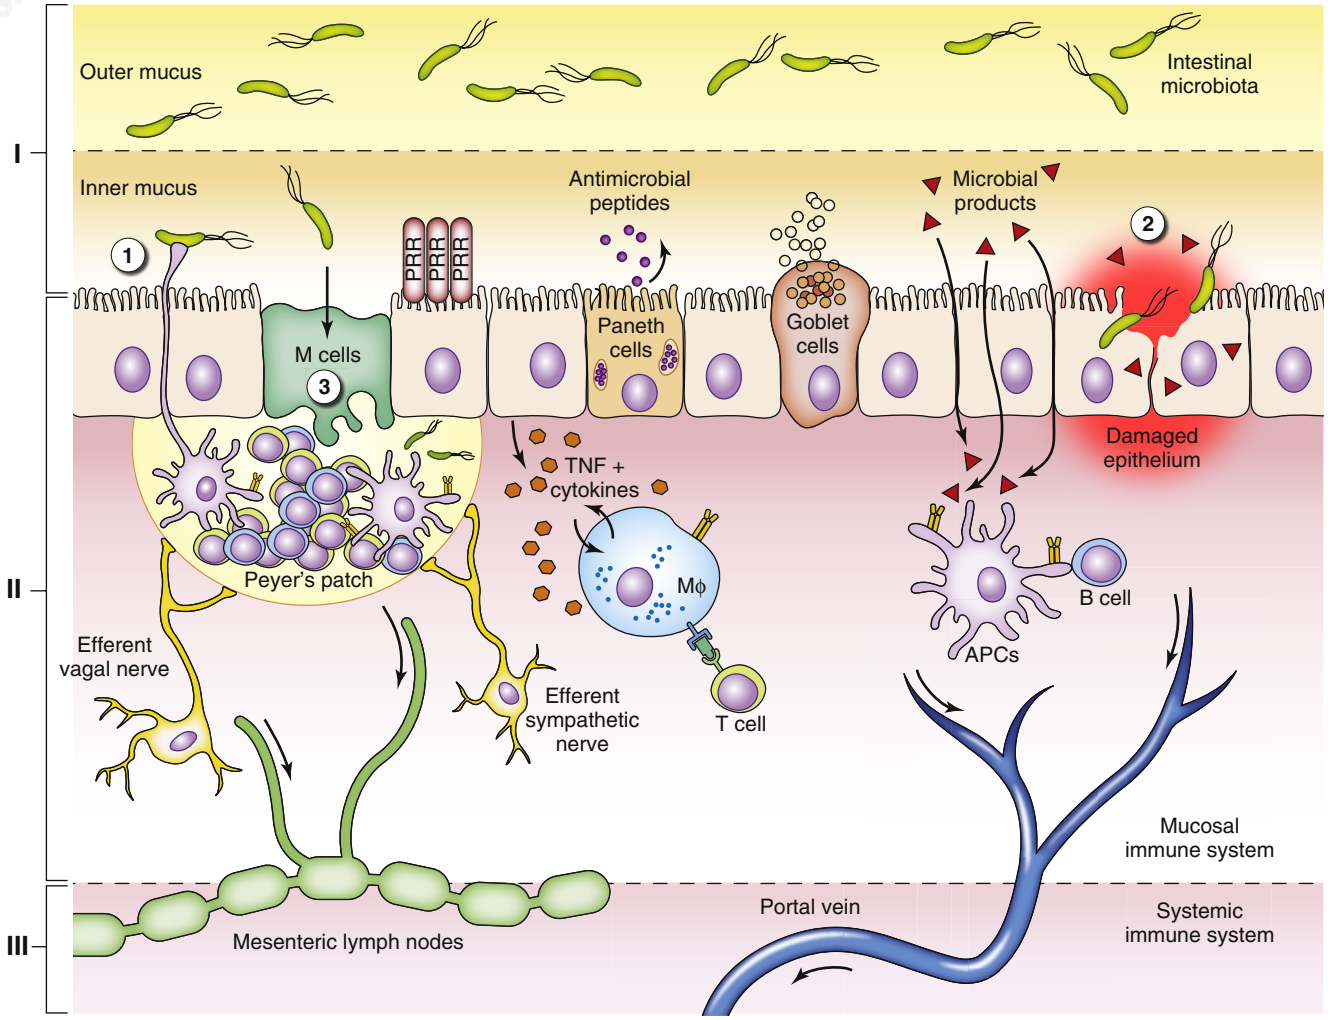

Fig 125.5 Compartments and key players involved in mediating pathological bacterial translocation (BT) and the associated host response. Three different routes *(1–3)* of BT can be separated: (1) direct sampling of luminal bacteria by dendritic cells via processes between epithelial cells, not affecting tight junction function; (2) injured/inflamed epithelium with dysfunctional epithelial barrier; and (3) M-cells overlying Peyer's patches as specialized cells providing access of microbial products to antigen-presenting cells. Moreover, three different levels of barriers (I–III) against bacterial translocation are shown: (I) lumen and secretory component (e.g., inner and outer mucus layer, antimicrobial peptides) of gut barrier; (II) mechanical epithelial barrier and the gut-associated lymphatic tissue (GALT) beneath with response elements to BT (e.g., TNF and other proinflammatory cytokines) and autonomic nervous system; (III) systemic immune system as a third barrier in case of spreading of bacteria beyond mesenteric lymph node including hematogenous (portal venous) and lymphatic (thoracic duct) route of delivery. *PRR*, pattern recognition receptors. (From Wiest R, Lawson M, Geuking M. Pathological bacterial translocation in liver cirrhosis. *J Hepatol.* 2014;60:197-209.)

DIAGNOSIS OF ACUTE INFECTIOUS GASTROENTERITIS

Diagnosis of many enteropathogenic infections is notoriously challenging because many organisms are present in both healthy and sick dogs and cats. When outbreaks of diarrhea occur, testing specimens from multiple affected and unaffected animals is recommended, because an organism is more likely to be the cause of illness when found in more than one animal and when more prevalent in diarrheic than nondiarrheic animals. Examination of fecal smears from a wet-prep may be useful when positive for *Tritrichomonas blagburni* or *Giardia* spp., but this is a highly insensitive diagnostic approach. Many veterinary diagnostic laboratories offer "GI panels" which comprise a combination of diagnostic tests for organisms that have the potential to cause diarrhea. An understanding of the limitations of each of the assays included in these panels is critical for proper interpretation. For example, some panels include culture on selective media for *Salmonella* and *Campylobacter* and ELISA assays that detect clostridial toxins; some are panels that combine fecal flotation for parasites with special stains for *Giardia* (e.g., direct FA) or *Cryptosporidium* (e.g., direct FA, acid fast stains); and others are PCR-based assays that detect clostridial toxin genes or the DNA of multiple different enteric viral, bacterial, and protozoal pathogens. It should be emphasized that the detection of bacterial DNA does not equate with infection, and that the detection of toxin genes does not equate with expression of that gene. Collection of a sufficient quantity of fresh feces is important, with the amount required depending on the assay being performed. The laboratory (or laboratory's website) should be consulted for information on the correct specimen type, quantity, and handling and transport conditions. Specific pathogen chapters in this book also include information on specimen collection and handling to optimize diagnostic yield.

TREATMENT OF ACUTE INFECTIOUS GASTROENTERITIS

Fluid and electrolyte administration is probably one of the most important therapeutic strategies for the management of the diarrheic animal. Fluids should be given intravenously when severe shock and hypotension, obtundation, or persistent vomiting or ileus accompanies the diarrheic episode. Animals with less severe manifestations of disease can receive subcutaneous fluids. When finances preclude hospitalization and dehydration is mild, acute diarrhea without vomiting can sometimes be treated successfully with specific oral fluid preparations.[125] Oral fluid therapy is based on the observation that glucose is actively absorbed by the normal small bowel and sodium is carried with it in an approximately equimolar ratio. Solutions containing glucose or sodium, either alone or in an imbalanced ratio of a decreased concentration, are not effective in reversing fluid and electrolyte flux across the intestinal mucosa. In one study, an oral rehydration solution designed for dogs (Hydrolyte, Advanced Nutritional Support, Elka Park, NY) was used to treat dogs with acute hemorrhagic diarrhea.[125] Dogs were offered the solution every 4 hours, the volume was calculated based on estimated dehydration, maintenance requirements, and estimated ongoing losses. Two-thirds of the dogs voluntarily consumed the solution, and the cost of treatment was significantly lower for this group than dogs treated with IV fluids.

Antimicrobials are rarely indicated for treatment of acute gastroenteritis. They should only be used when episodes of diarrhea or vomiting are accompanied by signs of systemic illness, including fever, severe lethargy, and impending shock, and the presence of leukopenia or leukocytosis with a marked left shift. These findings suggest sepsis secondary to translocation of microbes or their toxins. Use of antimicrobials to treat uncomplicated diarrhea may be harmful, altering the intestinal microbiome deleteriously, reducing competitive exclusion of pathogenic species by nonpathogenic commensals, and selecting for resistant bacterial populations. Treatment of healthy dogs with metronidazole for 14 days was associated with a reduction in richness of the fecal microbiome with increased abundance of Proteobacteria and decreased abundance of Fusobacteria and Bacteroidetes (assessed using 16S rRNA gene PCR-Illumina sequencing). Furthermore, disturbances in the population persisted for 4 weeks after the drug was discontinued.[6] When indicated, antibacterial therapy should be combined with supportive care measures such as dietary modification, fluid therapy, and antiemetics. In addition to complicated diarrhea with suspected bacterial translocation, antimicrobial treatment is indicated for antibiotic-responsive chronic diarrhea and granulomatous colitis. Antibiotic-responsive chronic diarrhea (ARD) and acute hemorrhagic diarrhea syndrome (AHDS) are described in the following section; information on granulomatous colitis can be found in Chapter 63.

ACUTE HEMORRHAGIC DIARRHEA SYNDROME

AHDS (previously known as hemorrhagic gastroenteritis [HGE]) is a syndrome characterized by acute onset of profuse, mucoid, bloody diarrhea, sometimes (80% of cases) with vomiting. The name of the syndrome was changed because of the frequent lack of gastric involvement. Acute hemorrhagic diarrheal syndrome associated with *Clostridium perfringens* infection has primarily been described in small-breed dogs between 2 and 4 years of age (see Chapter 64). Affected dogs are often lethargic, dehydrated, and may show evidence of abdominal pain on palpation. The syndrome is also marked by hematologic findings that include relative polycythemia, with a normal or low plasma protein concentration, and coagulation test results suggestive of DIC and occasionally, acute oliguric renal failure.

The pathogenesis of AHDS is unknown, but many clinical and laboratory findings are similar to those produced in dogs by experimental administration of bacterial endotoxin or enterotoxins with resultant DIC. Allergic, hereditary, autoimmune, and infectious causes for AHDS have been proposed. Currently it is believed that most cases may result from clostridial overgrowth and production of the pore-forming toxin NetF by *C. perfringens*.[126,127] The prevalence of positive PCR results for the *NetF* and *NetE* genes in dogs with AHDS (48%) was significantly higher than in healthy control dogs (12%) and dogs with parvovirus enteritis (0%).[128] Other pathogens may also play a role. For example, in one report of a dog that was seen for hemorrhagic diarrhea and found to have severe acute protein-losing enteropathy, mucosally invasive enterococci were identified in intestinal biopsies using FISH.[129]

Diagnosis of the syndrome of AHDS is based on historical, clinical, and laboratory findings, and exclusion of other causes. The detection of *Clostridium perfringens* type A strains that encode the pore-forming toxin NetF also suggests AHDS, but these strains can be found in healthy dogs and negative results do not exclude a diagnosis of AHDS.

Rehydration and diuresis with polyionic isotonic fluids are the most important components of treatment. Prognosis is good, with most dogs recovering within 48 hours, although stool consistency may take 7 to 10 days to normalize. Antimicrobial therapy is not warranted for most of these dogs, unless there are signs of systemic illness, including fever, impending shock, marked neutropenia, or neutrophilia with a left shift, or unless the patient is immunocompromised (chemotherapy for cancer, poorly controlled diabetes). One study showed no difference in outcome for dogs with AHDS lacking signs of sepsis when clavulanic acid-amoxicillin was used as part of treatment when compared with no antimicrobials.[130] The drugs of choice for the management of *Clostridium perfringens*-associated diarrhea include amoxicillin or metronidazole, and antimicrobials are typically administered for < 7 days.

ANTIBIOTIC-RESPONSIVE CHRONIC DIARRHEA IN DOGS (TYLOSIN-RESPONSIVE CHRONIC DIARRHEA)

Chronic or intermittent diarrhea of small intestinal character that responds to tylosin therapy has been described in dogs.[131,132] Affected dogs are usually middle-aged, large-breed dogs. The diarrhea is chronic or intermittent in nature, and typically watery, mucoid, or bloody in consistency. The frequency of defecation varies markedly depending on whether the diarrhea is associated with the small or large bowel. In addition, borborygmus and flatulence are common with a low prevalence of vomiting, weight loss, or hyporexia. Diagnostic investigation is important to rule out underlying causes for these signs and to help confirm the diagnosis of ARD (a diagnosis of exclusion). Treatment of dogs with ARD utilizing anthelmintics, antiprotozoals, anti-inflammatories, immunosuppressives, probiotics, prebiotics, other antimicrobials, pancreatic enzymes, or dietary modifications is typically unrewarding. The presence of known enteropathogenic bacteria has not been detected. The presence of an as-yet undiscovered tylosin-susceptible enteropathogen or an anti-inflammatory effect of tylosin have been speculated as possible reasons for response to treatment.[132] Tylosin causes a marked alteration in the bacterial flora of dogs, with an increase in fecal enterococci and lactobacilli, and a probiotic effect has most recently been suggested as its mechanism of action.[93,131] The recommended dose for tylosin is 5 to 10 mg/kg PO q12 to 24h for an initial period of 4 weeks.[133] If signs relapse at this stage, then a longer course of therapy may be required. Many cases require long-term or lifelong therapy to maintain remission of signs. Alternative therapeutic strategies including administration of probiotics or FMT are currently being investigated. For further information on tylosin see Chapter 10.

PANCREATITIS AND PANCREATIC ABSCESSES

Pancreatitis in dogs and cats is usually noninfectious in etiology, and secondary bacterial infection of the pancreas is rare. Nevertheless, infectious diseases should remain on the differential diagnosis list as possible etiologies when a diagnosis of suspected pancreatitis is made, especially when signs of other organ involvement exist or when response to conventional treatment is poor. In dogs, pancreatitis can be caused by *Leptospira* spp. and fungi such as *Cryptococcus neoformans*, often as part of a more widely disseminated infection. *Toxoplasma gondii* can also cause pancreatitis. *Enterococcus hirae* enteropathy was associated with ascending cholangitis and pancreatitis in a kitten.[134] Pancreatic abscesses are usually sterile and treatment requires surgical intervention and drainage.[135,136]

Use of antibacterials in dogs and cats with pancreatitis is controversial. In animals with noninfectious necrotizing pancreatitis, local intestinal damage as a result of spillage of pancreatic enzymes and decreased intestinal perfusion can cause bacterial translocation from the intestine to the diseased pancreatic tissue, with the potential for secondary bacterial infection. Bacterial infection may also occur as a result of infection that ascends the pancreatic ducts. In cats, experimental inoculation of pancreatic ducts with *E. coli* resulted in infection with concurrent pancreatitis, whereas bacteria were cleared in cats with healthy pancreatic tissue.[137] When antimicrobial therapy was started 12 hours after inoculation, infection developed in 73% of animals receiving no antibacterials and in none of the cats receiving antibacterials. In dogs with intestinal colonization by genetically labeled *E. coli*, organisms had spread to the pancreas and mesenteric lymph nodes after experimentally induced pancreatitis.[138]

If antibiotics are used, they should be capable of penetrating damaged pancreatic tissue and have activity against enteric bacteria. Parenteral administration is typically required because affected animals are usually vomiting or have evidence of nausea, and decreased GI perfusion may impair bioavailability. Drugs that reach adequate concentrations in inflamed pancreatic tissue that could be considered are clindamycin, metronidazole, a fluoroquinolone, or third-generation cephalosporins.

BACTERIAL PERITONITIS AND INTRA-ABDOMINAL ABSCESSES

ETIOLOGY AND PATHOGENESIS

Bacterial peritonitis can be classified as primary, secondary, or tertiary/recurrent secondary. Primary bacterial peritonitis, or spontaneous bacterial peritonitis, is an uncommonly reported scenario where there is no identifiable intraperitoneal source of infection or history of a peritoneal penetration.[139,140] This type of infection appears to be more common in cats than in dogs. In 56% of reported canine cases of primary bacterial peritonitis and 100% of feline cases, bacterial culture yielded only one isolate with the majority of organisms in both species being gram positive.[139] Although the pathophysiology is not entirely elucidated, the most common route of infection is believed to be hematogenous spread. Infection may also follow dissemination by the lymphatic route, or transmural migration from the GI or genitourinary (GU) tract. Because primary bacterial peritonitis is uncommon in dogs and cats, risk factors have not been identified. Primary bacterial peritonitis occurs with greater frequency in humans with impaired immune systems, alcoholic cirrhosis, nephrotic syndrome, malignancy, and acute viral hepatitis.[141-143]

Secondary bacterial peritonitis is the most common type of bacterial peritonitis. In approximately 60% of dogs and cats, it results from leakage of commensal bacteria from the GI tract due to either postsurgical wound dehiscence or rupture or perforation of the GI tract.[144,145] Rupture and perforation may occur as sequelae to gastric dilatation-volvulus, perforating ulcers, intestinal mass lesions, or a foreign body. Generalized secondary bacterial peritonitis or localized secondary peritonitis potentially with intra-abdominal abscess formation may also follow pancreatitis, penetrating abdominal wounds, ischemic intestinal injury (e.g., intussusception, foreign bodies, torsion) (Fig. 125.6), rupture of viscera (gallbladder, pyometra, urinary tract), and surgical contamination. Bile salts, along with gastric mucin, hemoglobin, and barium have the potential to enhance the severity of peritonitis. Idiopathic purulent mesenteric lymphadenitis or lymph node abscessation may be infectious or noninfectious with 50% of cases from one case series yielding positive bacterial cultures.[146]

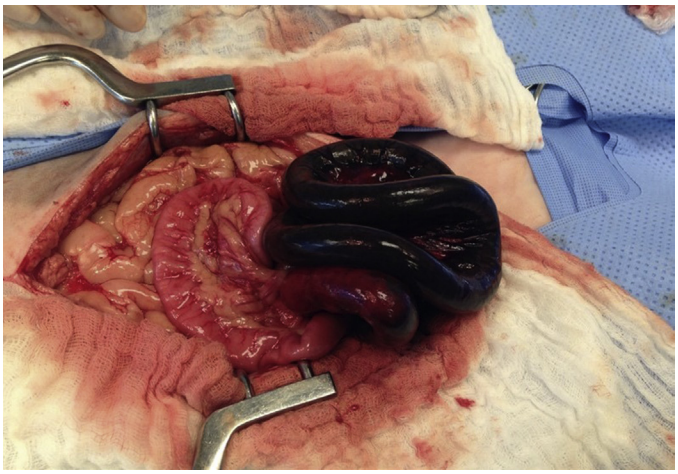

Fig. 125.6 Ischemic injury secondary to partial mesenteric torsion in a cat. Though no perforation was identified in the intestine, *E. coli*, *Enterococcus* sp., and anaerobes were cultured from a peritoneal swab.

Tertiary peritonitis may be defined as intra-abdominal infection that persists or recurs 48 hours following successful and adequate surgical source control. There is uncertainty in the human and veterinary literature how best to diagnose and treat this disease process; however, it is associated with nosocomial or resistant infections in human medicine. True tertiary peritonitis is rarely reported in the veterinary literature. However, some studies describe patients that have failed treatment for secondary septic peritonitis as having recurrent septic secondary peritonitis following a perceived successful surgical source control.[147,148] This description could fit the definition of tertiary peritonitis. Dogs that were at risk for recurrent secondary peritonitis were those that had lower serum albumin concentrations, higher PCVs, and septic peritonitis of GI origin, especially when GI foreign bodies were present.[148]

Bacterial species involved in peritonitis often reflect the normal flora of the GI tract. Secondary bacterial peritonitis is commonly polymicrobial.[149,150] Mixed aerobic-anaerobic infections, with up to four different bacterial species, occur in more than 50% of affected dogs and cats.[139,149] *Escherichia coli* is the most common isolate from both dogs and cats, followed by *Enterococcus* and *Clostridium* spp.[139,149,151] Other isolates include staphylococci, streptococci, *Pseudomonas aeruginosa* or *Acinetobacter* spp., a variety of anaerobes, gram-negative Enterobacterales (*Proteus, Citrobacter, Serratia, Klebsiella,* or *Enterobacter* spp.), *Actinomyces* spp., or, in cats, *Pasteurella multocida*.[152,153] In one study, a greater proportion of dogs with primary peritonitis had gram-positive bacterial infections than dogs with secondary peritonitis.[139] Uncommonly, *Candida albicans* can be isolated, especially if there is a history of antibiotic treatment.[154,155]

CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

The most common clinical signs in dogs and cats with bacterial peritonitis are lethargy, anorexia, vomiting, and diarrhea, although clinical signs can be quite variable. Weakness and collapse can also occur in animals with septic shock. Diarrhea and vomiting may result from intestinal hypermotility or ileus or may be secondary to underlying intestinal disease.

Physical examination findings may include dull mentation, fever, dehydration, mucosal pallor, abdominal pain, thin body condition, abdominal enlargement, and a palpable fluid wave due to fluid accumulation.[139,149,156] Peritoneal fluid generally cannot be detected on physical examination until the volume reaches greater than 10 mL/kg.[157] Tachypnea or tachycardia may be present; however, some affected animals, and especially cats, show none of these signs. More than one-third of cats lack any evidence of abdominal pain.[149,156] Signs of septic shock may be present, including tachycardia, tachypnea, weak pulses, and injected mucous membranes in dogs, or hypothermia and bradycardia in cats (see Chapter 123).

DIAGNOSIS

Preoperative diagnosis of bacterial peritonitis is based on abdominal imaging findings, cytologic examination of peritoneal fluid, and aerobic and anaerobic bacterial culture of the fluid.

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Panel, and Urinalysis

Qualitative and quantitative abnormalities in leukocytes are common with septic peritonitis; however, they are generally nonspecific. Anemia of inflammatory disease is common. Depending on severity of disease, an increase or decrease in neutrophils may be present along with a regenerative or degenerative left shift.[158] Thrombocytopenia may be present in animals with septic shock and DIC.[159] Changes on the serum chemistry panel include electrolyte and acid-base abnormalities and/or hypoalbuminemia due to inflammation or third-space losses. Mild to moderate increases in serum liver enzyme activities may be detected. Hypoglycemia or hyperglycemia may be detected and hyperbilirubinemia can be present.[139,149] In patients with vomiting and diarrhea pre-renal azotemia may be present. Azotemia may be post-renal in animals with a ruptured urinary tract. Several abnormalities may be present on blood gas analysis depending on severity of disease. Increased serum lactate concentration has received the most attention in the veterinary literature.

Clotting Function

Although not indicated in all dogs with septic peritonitis, a subset of dogs and cats that develop DIC as a sequela to bacterial peritonitis may have PT or APTT prolongation, increased plasma D-dimer or fibrin degradation product concentrations, and/or decreased plasma antithrombin concentration, therefore coagulation panel evaluation may be considered in dogs with bacterial peritonitis.

Diagnostic Imaging

Imaging of the abdomen should ideally take place prior to abdominocentesis to avoid iatrogenic pneumoperitoneum and the inadvertent misdiagnosis of ruptured abdominal viscera.

Plain Radiography

Abdominal radiographs in dogs and cats with diffuse septic peritonitis may show loss of serosal detail potentially indicating free peritoneal fluid, presence of free gas, identification of foreign material, segmental dilation of bowel, or the presence of abnormal organ enlargement. Oral administration of a contrast agent may be used to better identify GI foreign bodies, ileus, or evidence of perforation. Barium should not be used as a GI contrast agent when there is concern for perforation as it can contribute to peritonitis.

Sonographic Findings

Findings on abdominal ultrasound examination include focal or diffuse hyperechogenicity of the mesentery and the presence of even small quantities of ascites. The echogenicity of the ascites will differ depending on its cellularity. Evidence of underlying disease may be present, such as an intestinal mass or foreign body. Though nonspecific, corrugation of the small intestine with or without increase in intestinal wall thickness has been associated with peritonitis. Focal bowel ischemia and associated localized peritonitis can also be detected with ultrasound. The presence of pneumoperitoneum; a dilated, air-filled stomach or bowel loops; or severe abdominal pain may interfere with complete ultrasound examination of some patients.

Advanced Imaging

Although not routinely used for the evaluation of septic peritonitis in veterinary patients, abdominal CT scans are the imaging modality of choice in humans with acute peritonitis. Its lack of routine use in veterinary medicine may be due to availability, cost, or the need for general anesthesia. In veterinary patients, a CT scan is most useful in cases of penetrating abdominal wounds secondary to trauma or focal abscessation.

Analysis of Peritoneal Fluid

Specimens for cytologic examination from animals with peritonitis may be collected by blind or ultrasound-guided abdominal paracentesis or diagnostic peritoneal lavage (DPL). With the increased availability and sensitivity of ultrasound to detect and guide collection of small quantities of undiluted intra-abdominal fluid, DPL is now uncommonly performed. Ascites fluid should be collected in a sterile EDTA tube for cytologic examination, and a sterile red top tube for aerobic and anaerobic bacterial culture and susceptibility testing.

Ascites fluid from dogs and cats with bacterial peritonitis is typically a modified transudate or exudate, although fluid from dogs with primary peritonitis may be more likely to be a modified transudate or transudate.[139] Fluid analysis from most animals with peritonitis reveals a high protein concentration and an increased erythrocyte and total nucleated cell count (usually >500 cells/μL and up to 160,000 cells/μL). There is typically a predominance of neutrophils that may have a degenerate appearance, and foreign material and/or intracellular and extracellular bacteria may be seen. The presence of intracellular bacteria is generally considered diagnostic for bacterial peritonitis. The presence of bile pigments suggests the hepatobiliary system is the origin of peritonitis.

Because absence of bacteria does not rule out bacterial peritonitis, submission of fluid for culture is essential to guide appropriate antimicrobial therapy, especially with the rise in prevalence of antimicrobial resistance.[149,160] Although it is preferable to submit specimens after therapeutic lavage at surgery, one study showed that culture results were the same regardless of whether samples were collected before or after therapeutic lavage.[161]

In addition to cytologic examination and culture of ascites fluid, other tests may be performed on the fluid to better characterize the type and source of the peritonitis. Comparing blood glucose and lactate concentrations to that of the abdominal fluid has proven to be useful to diagnose dogs with septic peritonitis. A blood-to-fluid glucose difference greater than 20 mg/dL was 100% sensitive and 100% specific for a diagnosis of bacterial peritonitis in one study of dogs and cats.[152] A peritoneal fluid lactate level greater than 2.5 mmol/L had 100% sensitivity and 91%

TABLE 125.2 Interpretation of Results of Peritoneal Fluid Analysis

Chemical Analysis	Septic Peritonitis	Uroperitoneum	Chyloperitoneum	Bile Peritonitis
Glucose (mg/dL)	< 50			
Ratio Fluid:Serum Concentration				
Glucose	< 0.05×			
Creatinine		Fluid > 2.4×		
Potassium		Fluid >1.4×		
Triglycerides			Fluid >3×	
Bilirubin				Fluid > 2×

specificity for diagnosis a septic effusion in dogs; however, this was not repeatable in cats.[162] Another report examined a variety of biomarkers as predictors of septic peritonitis in dogs.[163] Glucose, the chemokine CCL2, IL-6, IL-10, and lactate were found in significantly higher concentrations in peritoneal fluid than in serum, and serum lactate concentration was the most useful predictor. Lactate and glucose concentrations should only be used as a guide to help predict septic peritonitis in dogs that have not recently undergone an exploratory celiotomy, which has the potential to create similar perturbations based on studies in healthy research animals.[164] No single cut-off offers 100% sensitivity and specificity for distinguishing septic from nonseptic peritonitis. Measurement of fluid concentrations of creatinine, potassium, and total bilirubin and comparing these concentrations to those in serum can be helpful for identifying uroperitoneum or bile peritonitis (Table 125.2).[165]

TREATMENT

Antimicrobial Drugs

Intravenous antimicrobial drugs should be initiated as soon as a patient has been diagnosed with septic peritonitis. While waiting for culture and susceptibility test results, a knowledge of whether cocci or rods are present may be considered to help tailor antibiotic therapy. Empiric antimicrobial therapy can also be selected based on the probable source of infection, if one is suspected. However, because most infections are polymicrobial, and unculturable anaerobes may be present, initial therapy should be broad-spectrum, with activity against gram-positive and gram-negative bacteria, as well as anaerobes and aerobic bacteria. Suggested empiric antibiotic options for septic patients are outlined in Chapters 122 and 123. De-escalation of the type of antimicrobial may be considered when bacterial culture and susceptibility results are available.

Surgery

The standard treatment for secondary bacterial peritonitis is emergent exploratory laparotomy with surgical source control and proper antibiotic therapy; however, without proper surgical debridement, lavage, and drainage, it is unlikely that antimicrobial therapy alone will be successful. It is recommended that the patient is hemodynamically stable prior to anesthesia and surgical exploration. Surgical exploration for primary bacterial peritonitis may not be indicated; however, diagnosis of these conditions may require exploratory surgery.

Surgery should be performed via a standard ventral midline celiotomy from xiphoid to pubis. The entire peritoneal cavity should be explored in a systematic fashion. The source of the bacteria should be removed, in most cases, or repaired. The use of monofilament suture is generally recommended whenever possible. Placement of omentum adjacent to the surgical area (intestinal resection and anastomosis) or abscess cavity should be considered to enhance blood flow and lymphatic drainage. Copious peritoneal lavage with warm isotonic saline should be continued until the fluid returning via suction is clear (suggested 200 to 300 mL/kg). It is recommended, though not required, that a closed suction drain, such as a Jackson-Pratt drain, be placed.[166] Open peritoneal drainage is only recommended in cases of severe visceral contamination or when a planned re-exploratory surgery is required.[167] Likewise, there are reports of the use of vacuum-assisted peritoneal drainage in the veterinary literature. At this time, open drainage and vacuum-assisted drainage have not been shown to result in superior outcomes to closed suction drains and both carry significant added expense and a second anesthetic event to ultimately close the abdomen.[168] However, randomized, prospective, clinical trials regarding the need for and the optimal type of drain in patients with septic peritonitis are lacking in veterinary medicine.

Supportive Care

Patients with bacterial peritonitis often require intensive supportive care and monitoring regarding fluid replacement, cardiovascular stability, and electrolyte derangements. Additionally, transfusion, nutritional support, and analgesics are all important factors for consideration in patients with bacterial peritonitis. Use of surgically placed gastrostomy tubes for enteral nutrition is recommended and was associated with a low rate of complications.[169] Though essential for successful outcome in these patients, discussion of these topics is outside the scope of this chapter and the authors refer readers to other texts. Additionally, anesthetic protocols for patients with septic peritonitis is outside the scope of this chapter; however, a recent retrospective article on intraoperative lidocaine constant rate infusions indicated significantly greater short-term survival than in dogs that did not receive lidocaine intraoperatively.[170]

PROGNOSIS

Survival rates of 32% to 87% have been reported in dogs with secondary peritonitis.[139,151,159,166,168,170] Survival rates of 44% to 70% after surgery have been reported for cats.[139,149,156,171] In the author's experience hospitalization times vary greatly; however, most range from 3 to 10 days. When death occurs, it usually results from septic shock, DIC, lack of source control, or multiple organ dysfunction; prolonged hospitalization is often due to pancreatitis and/or ileus. Negative prognostic indicators identified in dogs with bacterial peritonitis include a diagnosis of primary as opposed to secondary peritonitis,[139] and preoperative anemia, leukocytosis, or hypoproteinemia.[172] Hypoproteinemia (<5 g/dL) and hypoalbuminemia (< 2.5 g/dL) has been correlated with an increased risk of leakage after intestinal anastomosis and resultant peritonitis;[173] however, these findings have not been consistent among studies.[174] Lower serum albumin concentration and increased PCV were risk factors for recurrent secondary peritonitis in one study, as was a GI source

of peritonitis, especially foreign bodies.[148] Dogs with a foreign body were 7 times more likely to require a second surgery than those with GI sepsis occurring for reasons other than a foreign body.[148] Postoperative administration of glucocorticoids has been identified as a risk factor for death in dogs with septic peritonitis.[173] Low preoperative median serum ALT activity (56 U/L for surviving cats compared with 179 U/L for nonsurvivors) was the only positive prognostic indicator in one study of cats with peritonitis.[149] Significant differences between ALT and gamma-glutamyl transferase values were noted between survivors and nonsurvivors in dogs.[145] In another study, a high plasma lactate concentration was a negative prognostic indicator in cats with bacterial peritonitis.[156] In a retrospective study of 83 dogs with septic peritonitis, admission plasma lactate concentrations were also correlated with survival.[175] Admission plasma lactate concentrations > 4 mmol/L yielded a sensitivity of 36% and a specificity of 92% for nonsurvival. Because these prognostic factors were determined using retrospective studies with different populations and treatments, it is difficult to make firm conclusions, especially in the face of conflicting results between studies.

Survival rates of dogs with recurrent secondary peritonitis have been reported to be 44%. One study did not identify any significant prognostic indicators for dogs with recurrent peritonitis.[147] The survival rate of cats with recurrent or tertiary bacterial peritonitis is unknown. Intestinal anastomotic and enterotomy dehiscence rates remains around 10% in the literature in dogs with and without septic peritonitis and remains an important factor to discuss with owners prior to GI surgery.[174-177]

TABLE 125.3 Common Pathogens Encountered During Abdominal Surgical Procedures[178]

Location of Operation	Common Pathogen
Esophageal, gastroduodenal	Enteric gram-negative rods Gram-positive cocci
Colorectal	Enteric gram-negative rods Anaerobes Enterococci
Hepatobiliary	Enteric gram-negative rods Enterococci Clostridia
Genitourinary	Enteric gram-negative rods Enterococci
Penetrating trauma	Gram-negative rods Gram-positive cocci *Actinomyces/Nocardia*

MANAGEMENT OF SURGICAL CONTAMINATION

Surgical contamination and spillage of organ contents can often be anticipated, and a knowledge of the normal enteric flora can assist in appropriate choice of prophylactic antibiotics (Table 125.3). Spillage of intestinal contents in dogs and cats can be minimized by appropriate isolation of bowel loops and stomach with laparotomy pads and appropriate use of an assistant and suction. Although previously advocated in experimental models of septic peritonitis, intra-abdominal instillation of antimicrobials and disinfectants (e.g., povidone-iodine) is not recommend and can lead to chemical peritonitis. Sterile saline used alone (without systemic antimicrobials) to lavage the abdominal cavity as described above has been unsuccessful in consistently resulting in negative bacterial cultures, despite its diluting effect on the spilled material.[153]

CASE EXAMPLE

Signalment

"Colby," a 2-year-old male golden retriever from Davis in northern California.

History

Colby had a 3-week history of waxing and waning lethargy and inappetence that had worsened the week before examination. One week before examination at the University of California, Davis VMTH, he was examined at an emergency clinic. Abnormalities found on bloodwork were a leukocytosis (22,820 cells/μL) due to a mature neutrophilia (20,470 cells/μL); the serum chemistry panel was unremarkable. Abdominal radiographs showed decreased detail in the caudal abdomen secondary to small volume of effusion or peritonitis, and gastroenteritis was suspected. Colby was discharged with instructions to feed a bland, low-fat diet.

Physical Examination

General: Bright, alert, responsive, with adequate hydration; T: 101.5°F (38.6°C), HR: 80 beats/min with strong, symmetrical pulses. Respiration was panting, pink mucous membranes, CRT 2s, weight 29 kg, BCS 5/9. The remainder of the physical examination indicated no clinically significant abnormalities. There was mild dental calculus; the abdomen was soft and nonpainful, with no palpable masses; a rectal examination revealed some evidence of liquid stool.

Laboratory Findings

A CBC revealed a leukocytosis (21,750 cells/μL; RR, 6000–13,000 cells/μL) with 18,270/μL mature neutrophils (RR, 3000–10,500 cells/μL), and 870 bands/μL with slight toxicity. The serum biochemistry panel revealed only mild hypochloremia 107 mmol/L (108–118 mmol/L), hypocalcemia 9.5 mg/dL (9.7–11.5 mg/dL), hypoglycemia 63 mg/dL (64–123 mg/dL), hypoalbuminemia 2.9 g/dL (3.0–4.4 g/dL), and hyperglobulinemia 4.0 g/dL (1.8–3.9 g/dL). A urinalysis was unremarkable, Spec cPL® (IDEXX Laboratories) within reference range, and serum resting cortisol concentration 1.3 μg/dL.

Imaging Findings

Abdominal ultrasound: In the mid descending colon there is focal severe thickening of the colonic wall. An adjacent thick-walled, fluid and gas-filled structure, extending toward midline, is confluent with the colonic wall and gas is seen tracking through the colonic wall and into this adjacent structure. The surrounding mesentery is hyperechoic and there is a small volume of echogenic fluid surrounding the colon, adjacent small bowel, and mesentery. The remainder of the colon as well as the small intestinal tract and stomach are within normal limits. There are multiple severely enlarged, rounded, hypoechoic to heterogenous lymph nodes between the abnormal portion of the colon and the left kidney. A more caudal colic lymph node is also enlarged and hypoechoic. The spleen contains multiple small, hypoechoic nodules. The prostate is hyperechoic and large, consistent with the intact status of the patient.

Impressions: Focal colonic thickening and perforation with adjacent abscess formation; differentials include perforating foreign body, perforating neoplasia, or fungal infection. The adjacent mesentery and fluid may represent septic or sterile peritonitis. Severely abnormal adjacent lymph nodes may be reactive, but are concerning for metastatic or round cell neoplasia. Splenic nodules have a typically benign appearance, although metastatic or disseminated round cell neoplasia is not excluded.

Cytology Findings

Cytologic examination of an ultrasound-guided fine-needle aspirate of an enlarged lymph node in the caudal abdomen: A markedly expanded population of large lymphocytes is present. These cells have a small amount of deeply basophilic cytoplasm.

CASE EXAMPLE—cont'd

Nuclear chromatin is finely stippled and prominent nucleoli are observed, and there are many mitotic figures. The lymphocytes are CD79a positive, CD3 negative using immunostaining.

Diagnosis

B-cell lymphoma, high grade.

Treatment

Surgery was recommended to address the colonic perforation and associated abscess. Preoperatively, Colby was treated with intravenous fluids and parenteral ampicillin-sulbactam, enrofloxacin, maropitant, and methadone. Exploratory laparotomy was performed and the colonic mass was resected. The abdomen was lavaged and a closed suction drain was placed.

Microbiologic Testing

Sample: purulent fluid from colonic mass.

Direct smear: moderate numbers small gram-negative rods, very small numbers thin filamentous gram-negative rods, very small numbers large gram-positive rods.

Aerobic culture: very small numbers hemolytic *E. coli* (susceptible to all antimicrobials tested) and fastidious gram-negative rods. Anaerobic culture: large numbers *Bacteroides* spp./*Prevotella* spp. (β-lactamase negative), *Peptostreptococcus anaerobius* and *Fusobacterium nucleatum* (β-lactamase negative).

Diagnosis

Localized secondary septic peritonitis secondary to ruptured colonic large B-cell lymphoma.

Outcome

After the surgery, Colby was treated with L-asparaginase for lymphoma. He recovered for 5 days in hospital and was subsequently discharged. Ten days after the surgery, he continued chemotherapy with the Medical Oncology Service. Histopathology of the mass was consistent with completely excised colonic B-cell lymphoma with serosal perforation and mucosal ulceration.

Comments: In this case, spillage of colonic contents was contained by the mesentery and omentum, leading to a localized septic peritonitis. Colby recovered uneventfully from surgery with appropriate antibiotic therapy and supportive care, and experienced complete remission with chemotherapy (CHOP—cyclophosphamide, doxorubicin, vincristine, and prednisone). Three years later (at the time of writing), he remains in remission.

Hepatobiliary Infections

Jane E. Sykes, Sina Marsilio, Stanley L. Marks

KEY POINTS

- The liver and biliary tree contain a complex immune defense system that protects the body against bacteria that enter from the portal system, through arterial channels, or that ascend the biliary tree. Diseases that disrupt these processes can predispose to infection.
- Bacteria that most commonly cause hepatobiliary infections are *Escherichia coli*, *Enterococcus* spp., and anaerobes; less often other gram-negative aerobes, *Streptococcus* and *Staphylococcus* spp. are involved.
- Several viruses, atypical bacteria, protozoa, fungi, and helminths also can cause hepatobiliary infections in dogs and cats.
- Major clinical signs of bacterial cholangitis or cholangiohepatitis are inappetence, lethargy, fever, vomiting, diarrhea, abdominal pain, and icterus.
- Ultrasound is a relatively sensitive tool for imaging the hepatobiliary system and can be used to guide collection of specimens for cytologic examination and culture.
- Treatment includes antimicrobial drugs and supportive care for hepatobiliary disease; cholecystectomy may be required when biliary tract obstruction is severe, gall bladder mucocele is present, there is rupture of the biliary tract, or cholelithiasis.

HEPATOBILIARY INFECTIONS

Hepatobiliary infections include a variety of viral, bacterial, protozoal, or fungal infections that can spread hematogenously to the liver as part of a systemic infection; ascending infections of the biliary tree; and possibly bacterial translocation from the portal circulation (Table 126.1). The focus of this chapter is bacterial infections of the biliary tree; hepatic abscesses are considered in a separate section that follows. The main mechanism thought to be involved is ascending infections of the biliary tree, although hematogenous spread and bacterial translocation from the portal system are other proposed mechanisms.[1,2] Ascension of bacteria occurs when normal hepatic defense mechanisms are overwhelmed (Box 126.1). Those mechanisms include the mechanical barrier presented by the sphincter of Oddi, the flushing action of bile, antibacterial effects of bile salts, and local immune defenses as described in the following text (IgA, mucus, Kupffer cells). Inflammatory bowel disease, neoplasia, inflammatory liver disease, biliary obstruction, and systemic immunosuppression can all interfere with these mechanisms and predispose to infection. An understanding of normal hepatobiliary defense mechanisms can facilitate improved understanding of the pathogenesis and treatment of hepatobiliary infections.

NORMAL HEPATOBILIARY DEFENSE MECHANISMS

Kupffer Cells

Hepatic Kupffer cells comprise the largest compartment of tissue macrophages in the body, representing 80 to 90% of the total fixed macrophages and approximately 35% of the nonparenchymal liver cells.[3,4] Residing mainly within the lumen of hepatic sinusoids and adherent to endothelial cells by long cytoplasmic processes, Kupffer cells are most numerous in the periportal area (zone 1, see later) where they offer first-line defense against bacteria, endotoxin, and microbial debris delivered from the GI tract.[3] A number of other immune cells also participate in the hepatic innate immune response by patrolling sinusoids, including natural killer cells and γδ-T cells.[3]

Activation of Kupffer cells by endotoxin and other signaling molecules is mechanistic to their protective and disease-producing effects. Kupffer cells possess both Fc and C_3 receptors and phagocytize a wide variety of opsonized and nonopsonized particulates.[3] Kupffer cells express complement receptor of the Ig superfamily (CRIg), which is a receptor for C_3. This can directly bind lipoteichoic acid, a pathogen-associated molecular pattern associated with gram-positive bacteria, without the need for complement activation.[3]

Normally, hepatic Kupffer cells efficiently clear endotoxin to attenuate systemic exposure. Endotoxin extraction is enabled by LPS-binding glycoproteins on hepatocytes that facilitate transfer to high-affinity LPS receptors on Kupffer cells. Contact with LPS activates Kupffer cells directly via TLR signaling or indirectly by triggering complement activation. On exposure to endotoxin, activation of Kupffer cells initiates a multitude of signaling pathways resulting in a spectrum of inflammatory responses.[4] However, there is a degree of "endotoxin tolerance" that results from constant, low-level exposure of the liver to endotoxin.[5,6]

Because enteric bile acids bind and inactivate endotoxin, patients with extrahepatic bile duct occlusion or severe intrahepatic cholestasis with impaired enterohepatic bile acid circulation have higher risk for endotoxin translocation.[7] Dogs with induced chronic liver disease associated with intrahepatic portal hypertension and acquired portosystemic shunts develop significantly greater endotoxin concentrations in portal venous, hepatic venous, and caudal vena cava blood, compared to healthy control dogs.[8]

On activation, Kupffer cells release superoxide radicals, hydrogen peroxide, nitric oxide, hydrolytic enzymes, and eicosanoids (prostaglandins and leukotrienes) that can assist in antigen destruction. They also release a large number of immunoregulatory and inflammatory cytokines, including Il-1, Il-6, TNF-α, platelet-activating factor, transforming growth factor-β, and IFN-γ. Kupffer cells associated with zone 1 are larger, more phagocytic, and generate greater amounts of TNF-α, Il-1, prostaglandin E, and lysosomal enzymes. Less-active Kupffer cells are associated with zone 3; these exhibit greater cytotoxic activity to

TABLE 126.1 Infectious Agents Capable of Causing Liver Disease in Dogs and Cats

Organism Type	Example
Viruses	CAdV-1 FCoV (FIP) FCV
Bacteria	Gram-negative Enterobacterales, especially *Escherichia coli* but also *Klebsiella pneumoniae, Serratia marcescens, Enterobacter* spp., *Salmonella* spp. *Pseudomonas aeruginosa, Acinetobacter* spp., and gram-positive cocci, especially *Enterococcus* spp., but also *Staphylococcus* spp., *Streptococcus* spp. Anaerobes, especially *Clostridium* spp. but also *Bacteroides* spp. Curved or spiral-shaped bacteria, especially *Campylobacter* spp., possibly *Helicobacter* spp. *Listeria monocytogenes* *Actinomyces* spp. *Nocardia* spp. *Bartonella* spp. (peliosis hepatis) (dogs) *Brucella* spp. *Mycobacterium* spp. (e.g., *M. avium, M. bovis*) *Leptospira* spp. *Neorickettsia helminthoeca* (dogs)
Protozoa	*Neospora caninum* *Toxoplasma gondii* *Cytauxzoon felis* (cats) *Leishmania infantum* (primarily dogs)
Fungi	*Histoplasma* spp. *Cryptococcus neoformans* *Blastomyces* spp. *Coccidioides* spp. *Candida albicans* *Aspergillus* spp. *Prototheca* spp.
Helminths	Migrating ascarids *Platynosomum illiciens* (cats) *Mesocestoides* spp. *Echinococcus* spp.

BOX 126.1 Mechanisms Contributing to Infection of the Hepatobiliary System

- Reduced mechanical cleansing of the biliary tree
- Impaired biliary IgA production or enteric delivery
- Enhanced intestinal bacterial translocation
- Impaired Kupffer cell activation and/or microbial phagocytosis
- Reduced humoral immune responses
- Impaired neutrophil function
- Disruption of tight junctions between hepatocytes
- Increased access to hepatic lymph as occurs in intrahepatic portal hypertension

some stimuli and are more easily activated. Nitric oxide released by Kupffer cells mediates a wide variety of physiologic events, including vasodilation, neutrophil chemotaxis, and adhesion of neutrophils to vascular endothelium (response to bacteria or endotoxin).[9] As potent inducers of inflammatory cytokines, Kupffer cells are implicated in pathologic events resulting in liver injury.[10] Later, during the course of an infection, other cells including hepatocytes, T lymphocytes, and immigrating phagocytes (monocytes and neutrophils) contribute cytokines to the inflammatory process. Kupffer cells have been shown to be critical in T cell priming in the liver.[3] In addition, sophisticated imaging techniques have shown T cells to populate the liver from secondary lymphoid organs, adhere to platelets, crawl along sinusoids, and interact with liver sinusoidal endothelial cells. When they encounter a pathogen, they secrete IFN-γ to eradicate the infection.[3]

Biliary Epithelial Cells (Cholangiocytes)

Cholangiocytes (biliary epithelial cells) in larger bile ducts express the polymeric IgA receptor (secretory component) that localizes secretory IgA (S-IgA) to the ductal system. Uptake from the basolateral side of the cholangiocyte is followed by transport to the luminal ductal surface, where the secretory component is cleaved from but secreted with S-IgA into bile. Cholangiocytes from larger intrahepatic bile ducts, septal bile ducts, interlobular bile ducts, and bile ductules express TLRs that bind a variety of ligands including bacterial molecules, double-stranded messenger RNA (mRNA), LPS, and flagellin. In the presence of inflammatory cytokines, cholangiocytes also can activate the (proinflammatory) NF-κB pathway. Cholangiocytes also produce the antimicrobial peptides defensin and cathelicidin, part of the innate immune system, that defend the biliary tree against gram-positive and gram-negative bacteria, mycobacteria, fungi, and viruses. Expression of cathelicidin in biliary epithelium is enhanced by exposure to endogenous and therapeutic bile salts (e.g., ursodeoxycholic acid). In biliary inflammation, cholangiocytes also recruit CD4+ T cells as well as immature dendritic cells to provide defense against antigenic and microbial challenge. Cholangiocytes also express a variety of leukocyte and vascular adhesion molecules that can facilitate tissue-specific leukocyte migration, slowing leukocyte circulation near damaged epithelium and trafficking cells to the targeted site of injury. Expression of antigen-presenting molecules on cholangiocytes also may contribute to local immune defense.

Bile

Secretory IgA is the major immunoglobulin in bile; IgG and IgM are present in much smaller quantities. Bile contains approximately twice the concentration of S-IgA as found in the upper intestinal fluid.[11] Bile and IgA each influence the enteric bacterial population (type, number of organisms, and enterocyte adherence). Normal physiologic choleresis mechanically clears the biliary pathways of microbial organisms and particulate debris. This function is thwarted in cholestatic disorders. A normal biliary-enterobacterial cycle permits rapid elimination of bacteria that have entered the biliary system where locally produced IgA prevents epithelial invasion.[12,13] Bile salts also have antibacterial action. In health, tight junctions between hepatocytes (abutting canaliculi) resist bacterial entry into canalicular bile.

Experimental models have helped clarify the physiologic significance of enteric portal bacteremia. Infusion of 10^5 to 10^7 bacteria into the splenic vein of normal adult cats significantly retards bile flow and causes bacterobilia within 30 minutes. However, in the presence of extrahepatic bile duct obstruction, only modest bacterial inocula (10^3) lead to bacterobilia within the same time frame. As bacteria enter sinusoidal blood, some are phagocytized (Kupffer cells and neutrophils) and killed while others remain viable entering bile.[14] Experimental studies confirm that any cause of cholestasis can augment development of bacterobilia, including the cholestasis resulting from endotoxemia. The presence of bacteria within choleliths also can sustain

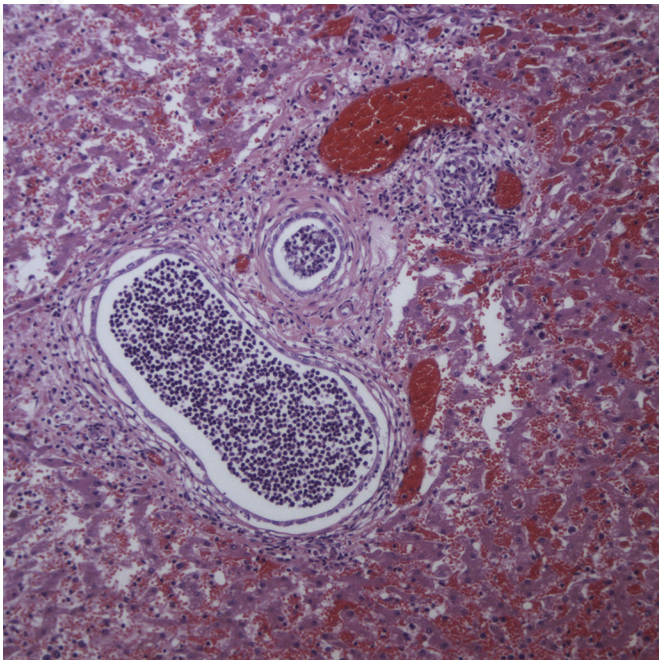

Fig. 126.1 Histopathology showing severe, acute neutrophilic cholangitis in a 20-year-old female spayed domestic shorthair. *Escherichia coli* was isolated from the liver in large numbers at necropsy. Other concurrent diseases found at necropsy were pulmonary adenocarcinoma and moderate multifocal glomerulonephritis.

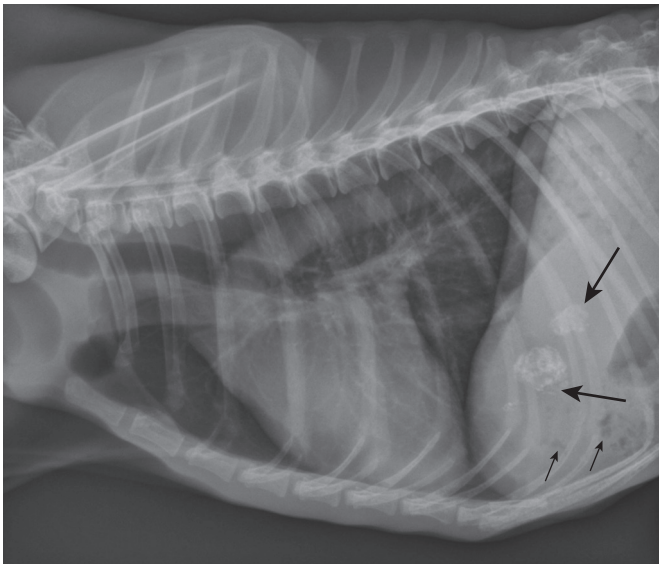

Fig. 126.2 Lateral thoracic radiograph from a 4-year-old male neutered Chihuahua with a 3-month history of vomiting, lethargy, weight loss, and progressive icterus. Within the viewable abdomen, multiple irregular mineral opacities are present in the region of the gall bladder *(large arrows)*. In this region, there are also multiple small irregular gas opacities *(small arrows)*. A diagnosis of necrotizing cholecystitis and secondary bile peritonitis was made based on ultrasound and abdominal fluid analysis. Exploratory laparotomy revealed multiple choleliths, and a cholecystectomy was performed. Histopathology revealed severe, subacute to chronic, transmural suppurative and necrotizing cholecystitis.

bacterial infections in the biliary tree.[15] Enteric organisms in bile may dehydroxylate and deconjugate bile acids, generating membranocytolytic forms that are capable of provoking cholestasis, oxidant cell injury, and cell apoptosis.

Transient or episodic portal bacteremia likely explains the unexpected isolation of bacterial organisms from liver or bile in animals with illnesses thought not to be primarily bacterial in origin, especially if specimens are collected after surgical manipulations of visceral structures. A discussion of bacterial translocation can be found in Chapter 125.

Bacterial infections can lead to suppurative cholangitis/cholangiohepatitis, cholecystitis, choledochitis, and cholelithiasis.[16-23] *Cholangitis* is inflammation of intrahepatic bile ducts, whereas *cholangiohepatitis* is inflammation of the bile ducts that has spread to the adjacent liver parenchyma. The use of the term "cholangitis" (rather than "cholangiohepatitis") has been recommended by the WSAVA Liver Diseases and Pathology Standardization Research Group, because inflammatory disruption of the limiting plate to involve hepatic parenchyma is not a consistent feature and if present, is usually an extension of a primary cholangitis. For these reasons, the term "cholangitis" will be used from this point onwards.

In cats, cholangitis has been classified histologically as *neutrophilic cholangitis, lymphocytic cholangitis*, or *chronic cholangitis associated with liver fluke infestation*.[24] Neutrophilic cholangitis may be further subclassified as acute or chronic depending on the presence of fibrosis, fibroplasia, or bile duct proliferation.[25] Neutrophilic cholangitis is thought to develop as a result of ascending bacterial infection from the GI tract, which may occur secondary to IBD and/or pancreatitis (Fig. 126.1); however, a study evaluating the utility of FISH for the detection of bacteria in feline inflammatory liver disease observed intrahepatic bacteria located predominantly within portal vessels and venous sinusoids, or the hepatic parenchyma near the capsule. This spatial distribution of bacteria within the livers of cats with inflammatory liver disease is inconsistent with an ascending bacterial infection from the GI tract, and more consistent with the translocation of enteric bacteria across the mucosal barrier into the portal circulation.[1] In contrast, bacteria that are localized within the bile ducts are more likely to have ascended secondary to pancreatic and hepatobiliary reflux in the face of intestinal inflammation, pancreatitis, and biliary disease (triaditis) as a consequence of the common entry of the pancreatic and common bile ducts into the intestine. Not all cats with cholangitis have histologic evidence of associated pancreatitis or IBD; studies have indicated that the prevalence of triaditis in cats with cholangitis is 32 to 50%.[26] Cats with acute cholangitis tend to be younger than those with chronic cholangitis.[25,27] Retrovirus infection does not appear to be a predisposing factor. The cause of lymphocytic cholangitis is unclear, although it is thought to be an immune-mediated condition.[28] Chronic cholangitis associated with liver fluke infestation is rare and is primarily reported from regions with subtropical climates such as the southeastern United States and Hawaii, but disease can occur in nonendemic areas in traveled cats. Although several different fluke species may be involved, the most prevalent appears to be *Platynosomum illiciens* (see Chapter 118).[29]

Choledochitis is inflammation of the common bile duct, whereas *cholecystitis* is inflammation of the gall bladder, and may or may not be associated with cholangitis or choledochitis. In some instances, necrotizing and/or emphysematous cholecystitis can occur, which may lead to perforation of the gall bladder wall and septic bile peritonitis. *Cholelithiasis* is stone formation within the biliary tree. In some instances, cholelithiasis or neoplasia of the biliary tree may predispose to cholangitis and necrotizing cholecystitis (Fig. 126.2).[20,21] Alternatively, it has been suggested that bacterial cholecystitis may predispose to stone formation through bacterial deconjugation of soluble bilirubin glucuronide to insoluble unconjugated bilirubin and glucuronic acid.[19]

Culture of bile is more sensitive than culture of liver parenchyma in both dogs and cats with hepatobiliary disease. In one large study, approximately 30% of biliary cultures were positive in dogs and cats, whereas hepatic cultures were positive in 14% of cats and 5% of dogs.[23] In cats, more than 80% of biliary cultures yielded a single bacterial species, whereas multiple bacterial species were isolated from approximately 50% of dogs. Bacterial species isolated from cats include anaerobes, a variety of Enterobacterales, *Enterococcus*, *Streptococcus*, or *Staphylococcus* species.[1,16,23,25] Dogs are most commonly infected with *E. coli*, *Enterococcus* spp., and/or anaerobes, primarily *Bacteroides* and *Clostridium* species.[17-21,23,30-32] *Staphylococcus* spp., other gram-negative aerobes (*Klebsiella, Enterobacter*, *Citrobacter,* and *Pseudomonas aeruginosa*), and *Streptococcus* spp. may also be isolated from dogs, and *Helicobacter* spp. have also been implicated as a cause of chronic hepatitis in dogs and possibly cats (see Chapter 66).[24,33] *Salmonella* in cats and *Campylobacter* in dogs may also cause cholecystitis. Although rare, emphysematous cholecystitis in dogs and cats is usually caused by *Clostridium* spp. or *E. coli*.[34]

CLINICAL FEATURES

Clinical Signs and Physical Examination Abnormalities

The most common clinical signs of hepatobiliary infection in both dogs and cats are lethargy, inappetence, vomiting, weight loss, and diarrhea, although subclinical infections can also occur.[16,17,22,25,27,30,35] Signs may be chronic, acute, and rarely peracute.[17,36] Peracute disease can occur with necrotizing cholecystitis and rupture of the gall bladder wall, and may be associated with clinical signs of septic shock. Hypersalivation may be evident in cats with neutrophilic cholangitis.[16] Physical examination may reveal fever, lethargy, dehydration, icterus, and thin body condition, with or without pain on palpation of the abdomen. Hepatomegaly may also be identified.[25] Some animals may be tachycardic or tachypneic.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

The CBC may show leukocytosis due to a neutrophilia, increased numbers of band neutrophils, and occasionally monocytosis.[16-18,22,25,27,36] Cats with neutrophilic cholangitis have higher segmented and band neutrophil counts compared to cats with lymphocytic cholangitis.[24] Some cats with neutrophilic cholangitis may be leukopenic with or without a left shift.[16,25] Lymphopenia and/or anemia may also be present.

Serum Biochemical Tests

Dogs with cholangitis or cholecystitis typically have increased activities of ALT, ALP, and gamma-glutamyl transferase (GGT), and hyperbilirubinemia.[30,31] At least 50% of cats with cholangitis have mild to moderate increases in the activity of ALT and/or ALP (usually < 1000 U/L). Increased activity of GGT is usually documented; however, some cats with cholangitis may have normal ALT, ALP, and GGT activity.[25] Hyperbilirubinemia is present in approximately two-thirds of cats. Along with higher neutrophil counts, cats with neutrophilic cholangitis have higher activities of ALT and higher total bilirubin concentration than cats with lymphocytic cholangitis.[24] Electrolyte abnormalities may be present secondary to GI losses in animals with vomiting or diarrhea.[16,27] Hypocholesterolemia, hyperglobulinemia, and hypoalbuminemia are uncommonly identified. Hypercholesterolemia may be present in dogs with cholestasis or bile duct obstruction, but is uncommonly present in cats.[18,20,22] Despite the differences observed in hematological and biochemical parameters in cats with neutrophilic versus lymphocytic forms of cholangitis, there is tremendous overlap in laboratory findings between the two forms of cholangitis, and caution should be heeded in relying upon the laboratory results to differentiate these forms of cholangitis.

Urinalysis

Urinalysis may be unremarkable or show evidence of bilirubinuria.[16,18,37]

Coagulation Profile

Coagulation abnormalities such as prolongations of PT and PTT may be present in dogs and cats with hepatobiliary infections, either secondary to impaired absorption of vitamin K secondary to biliary obstruction, or potentially as a result of liver dysfunction.[17,27]

Diagnostic Imaging

Plain Radiography

The most common finding on abdominal radiography of dogs and cats with cholecystitis and cholangitis is hepatomegaly, which may be variable.[22,27] Uncommonly, single or multiple radiopaque choleliths are visible, although choleliths may also be radiolucent (see Fig. 126.2).[18-20,35] Linear mineralization of the biliary tree has been described in some animals with cholelithiasis,[35] whereas other animals may reveal no abnormalities. Emphysematous cholecystitis is characterized by the presence of gas in the liver in the region of the gall bladder. Loss of abdominal detail may be present if gall bladder rupture and septic bile peritonitis has occurred.[17]

Sonographic Findings

Ultrasound examination provides important information and can influence decision-making in animals with cholangitis.[31] Findings on ultrasound in dogs and cats with cholangitis are similar and include hepatomegaly, normal or abnormal hepatic echotexture with a homogenous or heterogenous increase in echogenicity, prominent portal vasculature, ascites, a thickened and hyperechogenic gall bladder wall, and sediment within the gall bladder.[16-18,22,24,25,31,38,39] The gall bladder wall may also appear irregular and contain polypoid mass lesions. Abdominal pain in the right cranial quadrant may be evident during the procedure. Choleliths may occasionally be identified within the biliary tract as hyperechoic masses or linear structures with acoustic shadowing.[35] Distention of the biliary tract may be evident, sometimes with tortuosity of the cystic and common bile duct (Fig. 126.3).[16,17,38] Concurrent evidence of pancreatic and/or intestinal wall disease may be present in cats.[25] Ultrasound cannot be used to differentiate neutrophilic from lymphocytic cholangitis in cats. Intramural gas may be identified in animals with emphysematous cholecystitis (Fig. 126.4). Rupture of the gall bladder may also be detected using ultrasound, which is an indication for emergency surgery.[31] However, one study of 219 dogs with gall bladder mucoceles suggested that the sensitivity of abdominal ultrasound for detection of gall bladder rupture was low, only 56% (95% CI, 40–71%), whereas the specificity was 92% (95% CI, 85–96%).[40]

Microbiologic Tests

Cytologic Examination

Cytologic examination of bile collected by percutaneous ultrasound-guided cholecystocentesis (or intraoperative cholecystocentesis) may reveal increased numbers of degenerate neutrophils, small and/or large

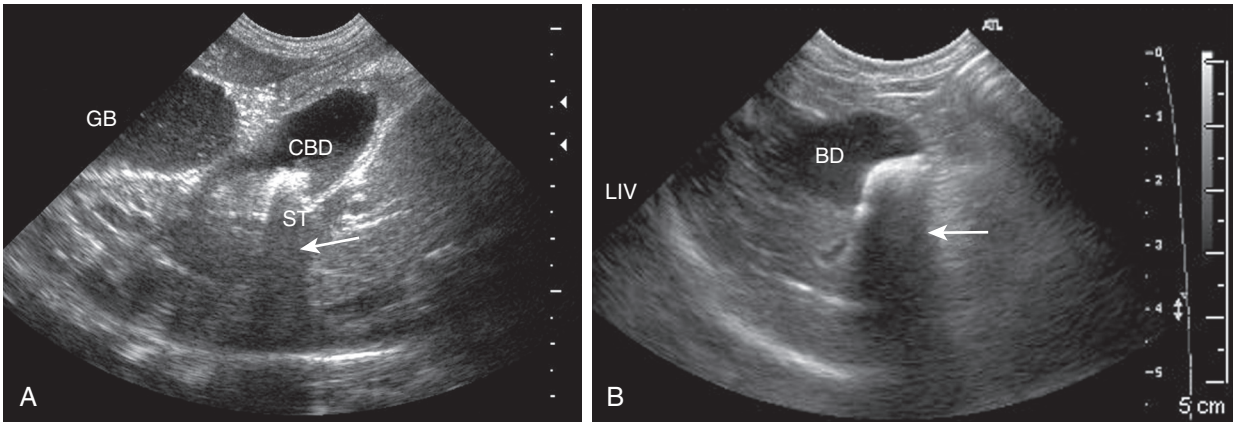

Fig. 126.3 (A) Ultrasonographic image showing a mineralized cholelith with acoustic shadowing *(arrow)* in a cat with neutrophilic cholangitis (*CBD*, distended common bile duct; *GB*, gall bladder; *ST*, stone). (B) Ultrasonographic image showing mineralized choleliths with acoustic shadowing *(arrow)* in a cat with neutrophilic cholangitis; a distended intrahepatic bile duct *(BD)* is observed to the left of the acoustic shadow. Choleliths may have led to septic inflammation or formed subsequent to infection. A cholecystectomy was performed to remove the stones, and, with antimicrobial therapy, complete recovery was achieved.

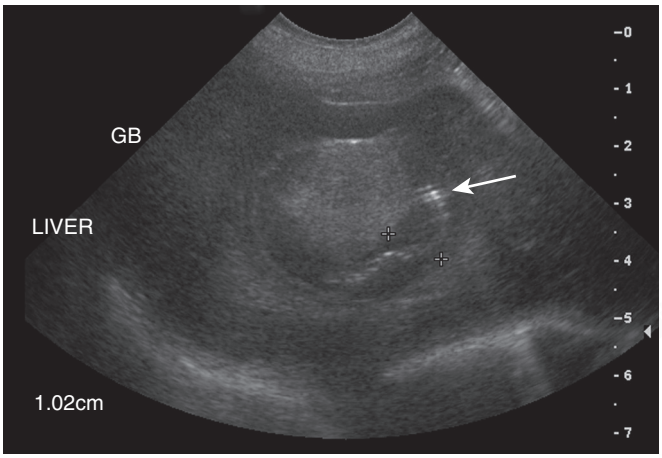

Fig. 126.4 Abdominal ultrasound image of the gall bladder of a 6-year-old female spayed American Eskimo dog with emphysematous cholecystitis. The gall bladder (*GB*) wall is markedly thickened (1 cm), is diffusely hypoechoic, and the gall bladder contains homogenous sludge. Multiple hyperechoic foci were identified tracking throughout the wall *(arrow)*. The hepatic parenchyma immediately adjacent to the gall bladder was poorly characterized because of a large amount of markedly hyperechoic inflamed mesentery within the cranial abdominal region.

mononuclear cells, and in some cases, a mixed or monomorphic bacterial population.[16,30] Identification of multilobular nuclear remnants, representing degenerate neutrophils, may be the only evidence of an inflammatory response owing to the detergent effects of bile on cell membranes. Thus, in biliary sepsis, bacterial organisms are commonly observed in biliary debris, with or without a well-defined exudative response. Examination of only the liquid partition of bile may fail to disclose bacterial organisms readily identified in the heavier biliary sediment. Thus, cholecystocentesis performed with the objective of identifying bacterobilia should include sampling of both nonparticulate and sediment portions. Standard protocol consists of introducing a 22-G needle (attached to an extension set, three-way stopcock, and 10-mL syringe) through the ventral or ventrolateral portion of the liver into the gall bladder. Cats and dogs are either heavily sedated or placed under general anesthesia for the procedure. Sampling should be done to completely empty the gall bladder to minimize postcentesis bile leakage and to optimize collection of dependent sediment. It is possible that percutaneous drainage of infected bile may also have a therapeutic benefit, although this requires further study.

Culture

Aerobic and anaerobic bacterial culture should be performed on bile collected by ultrasound-guided or intraoperative cholecystocentesis or liver biopsies. An approximately 22% isolation frequency of fastidious anaerobes among isolated bacteria from cats justifies submission of specimens for anaerobic culture.[41] Bile is more likely to yield positive results; however, bacteria are best retrieved from bile in which the gall bladder has been nearly completely emptied (3–5 mL in cats). The sensitivity of culture was also improved by combining tissue, bile, and crushed choleliths for inoculation.[41,30] Although it is generally accepted that bile is sterile in healthy dogs and cats,[2,42] transient cytologic and microbiologic evidence of bactibilia has been identified in healthy dogs.[43] Liver tissue from healthy dogs and cats can also harbor a variety of enteric bacterial species.[1,44] Thus, the results of bile culture should be interpreted in light of clinical and cytologic findings. Antibiotic resistance among bacteria isolated from the bile of dogs and cats with cholecystitis and cholangitis has been described in several studies, and so culture and susceptibility testing is suggested whenever possible.[23,31] When cholecystocentesis is undesirable because of concerns for gall bladder rupture (see Cytological Examination), blood cultures may be useful, although the utility of blood culture in dogs and cats with cholecystitis has not been studied. In human patients, bile cultures are positive in 50 to 95% of patients with acute cholecystitis, and blood cultures are positive in 30 to 40% of patients.[45]

Pathologic Findings

Neutrophilic cholangitis in cats varies considerably on histopathology in severity, chronicity, and the extent of associated hepatic parenchymal involvement.[25,37] FISH has been used to identify bacteria within the hepatobiliary system in cats; bacteria were more likely to be identified in portal vessels, venous sinusoids, and parenchyma (12 of 13 cats) than the bile duct (1 of 13 cats).[1] Concurrent hepatic lipidosis may also be present. In a small percentage of affected cats, complete or partial biliary obstruction may be identified as a result of inflammation, neoplasia, or cholelithiasis. Other findings in affected cats include acute or chronic pancreatitis (65% of cats in one study), and/or inflammatory bowel disease or intestinal lymphoma (46% of

cats).[25,26] Histopathology of the gall bladder wall in both dogs and cats with cholecystitis may reveal mucosal and glandular hyperplasia, and thickening and neutrophilic or lymphoplasmacytic inflammation of the gall bladder wall.[18,22,25]

Choleliths in cats are most often composed of calcium carbonate, although they also may comprise a mixture of cholesterol, calcium bilirubinate, and calcium carbonate.[18,20] In dogs they are often composed of calcium bilirubinate, bilirubin, or a mixture of bilirubin and cholesterol. Aged female small-breed dogs (dachshunds, poodles, miniature schnauzers) were predisposed to cholelithiasis in one study.[19]

TREATMENT

Treatment of cholangitis and cholecystitis typically consists of supportive care and antibiotic administration. Dogs and cats with necrotizing or emphysematous cholecystitis require cholecystectomy. Cholecystectomy could also be considered to prevent recurrence of cholelithiasis in animals with chronic cholecystitis. Cholecystectomy, biliary stenting procedures, and/or biliary diversion surgery may be required for animals with obstructive processes such as cholelithiasis, biliary neoplasia, or obstructive cholangitis.[19,20] Because cholecystotomy or biliary diversion surgery often results in dehiscence and septic bile peritonitis if bacterial cholecystitis or choledochitis is present, cholecystectomy has been recommended for dogs with cholelithiasis as opposed to cholecystotomy.[19] When compared with other surgical biliary procedures, cholecystectomy has been associated with good clinical outcomes in dogs and cats, but any condition that requires biliary surgery carries a guarded prognosis.

Antimicrobial Drug Treatment and Supportive Care

Empirically administered antibiotics should target gram-negative enteric bacterial species, *Enterococcus* spp., and anaerobes and be concentrated in bile. Cytologic examination of bile was shown to correlate well with culture results in one study and can be used to guide initial therapy.[46] Suitable antibiotics include ampicillin-sulbactam or clavulanic acid-amoxicillin, or a fluoroquinolone with metronidazole, although resistance to clavulanic acid-amoxicillin or enrofloxacin has been documented among biliary isolates from dogs and cats.[22] Based on the results of cultures from 248 dogs and cats evaluated for hepatobiliary disease, it was concluded that broad-spectrum empirical coverage could be achieved with a combination of a fluoroquinolone, penicillin, and metronidazole (reduce dose by 50% in cats with hepatobiliary disease), or a fluoroquinolone combined with clavulanic acid-amoxicillin or clindamycin.[23] Again, because resistance can occur, culture and antimicrobial susceptibility results should then be used to adjust treatment. In human patients, specific treatment of *Enterococcus* spp. biliary infections may not be necessary when other concurrent bacterial infections are being managed, as the *Enterococcus* spp. infection tends to resolve when the other infections are treated.[45] Supportive treatments that should be considered include IV crystalloid fluids with or without colloids, glucose supplementation, antiemetics (e.g., maropitant, ondansetron), nutritional support by parenteral or enteral means (with a restricted fat diet), ursodiol, S-adenosylmethionine, and parenteral vitamin K supplementation.

PROGNOSIS

The prognosis for cats with neutrophilic cholangitis is fair to good, with mean survival times greater than 1 year.[16,27] Poor outcomes may be related to the presence of underlying disease that contributes to mortality such as neoplasia.[20,27] Among 168 cats with suppurative cholangitis-cholangiohepatitis syndrome, infection (as identified by IHC), and the presence of gram-positive bacteria by culture in conjunction with positive IHC, were associated with a significantly shorter long-term survival time of 283 days following diagnosis.[41] The presence of septic bile peritonitis was associated with mortality in one study of dogs that underwent extrahepatic biliary surgery; over 50% of dogs with septic bile peritonitis died.[21] In another study, 9 of 23 dogs with necrotizing cholecystitis died.[17]

HEPATIC ABSCESSES

Hepatic abscesses are uncommon in dogs and very rare in cats.[47,48] They may be associated with ascending bacterial infection of the biliary tree, translocation of portal bacteria, or hematogenous spread of bacteria to the liver, although the source of bacteremia in some animals is unclear. Because bacteria can be found in the liver of healthy dogs, abscessation may also develop when these bacteria proliferate secondary to compromise of normal defenses (such as hepatic necrosis).[44] Affected animals are typically middle aged to older,[47,48] and the mean age of affected dogs or cats is 10 years. The abscesses may be acute or chronic, single or multiple, and macroabscesses or microabscesses may form. Pancreatitis, diabetes mellitus, other hepatobiliary diseases, neoplasia, colonic surgery, cholelithiasis, or chronic phenobarbital or glucocorticoid administration have been involved in the histories of affected dogs.[48–50] Migrating plant awn foreign bodies may also be an underlying cause.[50] Concurrent conditions reported in cats have included IBD, pancreatitis, hepatobiliary neoplasia, chronic cholecystitis, colonic surgery, or congestive heart failure.[47] Many affected cats have concurrent bacteriuria.

The most common bacterial species isolated from hepatic abscesses in both dogs and cats is *E. coli*. In dogs, other species have included *Klebsiella pneumoniae*, *Staphylococcus*, and *Clostridium* species. In cats, *Bacteroides*, *Enterococcus*, and *Streptococcus* spp. have been isolated, often in mixed infections with *E. coli*. Blood cultures are also often positive.[47,48] Clinical signs and laboratory abnormalities are similar to those for other hepatobiliary infections, except that severe illness and signs of septic shock are often present. Evidence of bleeding diatheses may be present. Marked neutrophilia or neutropenia, bandemia, toxic neutrophils, anemia, lymphopenia, and thrombocytopenia may be present on the CBC. Hypoalbuminemia and coagulation abnormalities are common.[47,48] Abdominal radiographs may be unremarkable or they may show hepatomegaly or a hepatic mass effect, poor abdominal serosal detail, and/or pneumoperitoneum if abscess rupture has occurred (Fig. 126.5). Thoracic radiography often reveals interstitial, bronchiolar, or alveolar lung infiltrates,[47,48] which may result from associated embolic or aspiration pneumonia. Ultrasonographic examination of the abdomen reveals one or more hypoechoic, anechoic, or heteroechoic hepatic masses, with or without peritoneal effusion. In some cases, gas may be evident within the masses (see Fig. 126.5).

Antemortem diagnosis usually relies on cytologic examination of ultrasound-guided fine-needle aspirates of these masses, which reveals large numbers of degenerate neutrophils. Abscesses may also be discovered during exploratory laparotomy (e.g., in dogs and cats with bacterial peritonitis). Culture and susceptibility of aspirates of the liver abscesses, free peritoneal fluid, and/or blood should be performed. Effective treatment of solitary abscesses relies on appropriate antimicrobial drug treatment together with complete or partial liver lobectomy, or abscess drainage and omentalization. With the exception of microabscesses, antimicrobial drug therapy alone is often ineffective. Aggressive supportive care in an intensive care unit may be required. Initial antimicrobial drug treatment should be broad spectrum, after which it should be adjusted based on the results of culture and susceptibility testing. Mortality rates of 79% and 50% have been reported for cats and dogs, respectively.[47] The prognosis appears to be especially poor when multiple hepatic abscesses are present.[47,48]

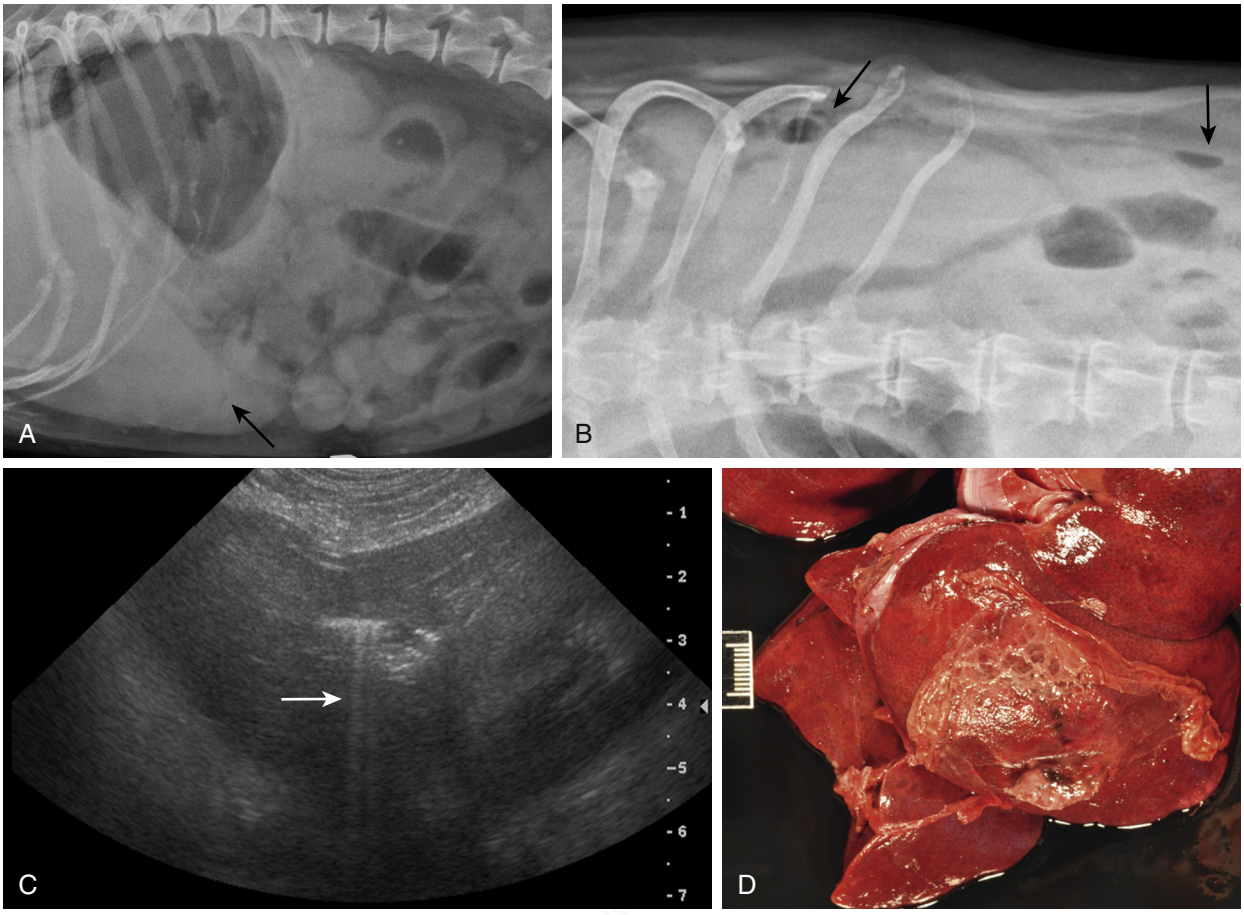

Fig. 126.5 Ruptured hepatic abscess. (A) Right lateral abdominal radiograph from a 15-year-old male neutered dachshund with acute onset of vomiting and diarrhea secondary to a ruptured hepatic abscess. There is a diffuse loss of serosal detail as well as free peritoneal gas present throughout the abdomen. The liver is enlarged. There are multiple small rounded gas opacities present over the ventral and right aspects of the liver *(arrow)*. Multiple small intestinal loops contain gas and fluid, some of which measure at the upper limits or over the upper limit of normal. (B) Free peritoneal air can be seen clearly *(arrows)* using a horizontal beam view. (C) Comet-tail artifact *(arrow)* due to the presence of gas within the liver on ultrasound examination. (D) Hepatic abscess from the same dog at necropsy.

CASE EXAMPLE

Signalment

"George," a 16-year-old male neutered domestic shorthair from northern California.

History

George was evaluated for a 2-day history of vomiting and progressive lethargy and inappetence. The owners reported that the vomiting occurred six times at the onset of illness and was associated with apparent abdominal pain, but had since resolved. The day he became ill, he was seen at an emergency clinic where a CBC showed only a mild left shift (479 band neutrophils), a chemistry panel showed mild hypokalemia (3.1 mmol/L, reference range 3.6–4.9 mmol/L), and a total serum T4 concentration was markedly increased (10.2 μg/dL, reference range, 1.1–3.3 μg/dL). Recurrent pancreatitis and hyperthyroidism were initially suspected and George was treated with subcutaneous lactated Ringer's solution (200 mL, SC, q24h), mucosal buprenorphine (0.2 mg/kg, PO, q8h to q12h), and ondansetron (0.2 mg/kg, PO, q12h). However, because George became inappetent and lethargic, he was returned for re-evaluation the following day.

Other past pertinent medical history: George had been diagnosed with pancreatitis 8 months previously. He was also diagnosed with a biliary cystadenoma via ultrasound at that time. He had been hospitalized for 9 days and treated with jejunostomy tube feeding. Since then, he had been well until this recent onset of illness.

Physical Examination

Body weight: 6.1 kg.

General: Quiet, alert, hydrated. T = 103.8°F (39.9°C), pulse = 240 beats/min, respiratory rate = 32, mucous membranes pink and moist, capillary refill time 1 s.

Eyes, ears, nose, and throat: Palpable thyroid nodule.

Integument: Full, clean haircoat.

Musculoskeletal: Body condition score 5/9. Ambulatory with normal gait.

Cardiovascular: Gallop sound with no murmurs or arrhythmias auscultated. Femoral pulses strong and synchronous.

Respiratory: Eupneic with soft breath sounds in all lung fields.

Genitourinary/GI: Soft, mildly painful abdomen. The bladder was small.

Other systems, including peripheral lymph nodes: No clinically significant findings.

Continued

CASE EXAMPLE—cont'd

Imaging Findings

Abdominal ultrasound: The margins of the kidneys were irregular and there was decreased corticomedullary distinction. In the region of the left limb of the pancreas, the mesentery was markedly hyperechoic and hyperattenuating. There was diffuse thickening of the muscularis layer of the small bowel. There was no evidence of mesenteric lymphadenomegaly. There was a small amount of free anechoic peritoneal fluid.

Thoracic radiographs: The cardiac silhouette appeared mildly enlarged. There was a mild bronchointerstitial pattern throughout the thorax. There was poor serosal detail within the viewable, cranial abdomen.

Outcome

George was treated supportively for pancreatitis with IV fluids (lactated Ringer's solution, 20 mmol/LKCl at 15 mL/h), buprenorphine (0.06 mg, IV, q6h), famotidine (0.5 mg/kg, IV, q12h), and ondansetron (0.5 mg/kg, IV, q12h). His temperature normalized, but he showed no interest in food or his surroundings. Cytologic examination of an ultrasound-guided liver aspirate on day 2 of hospitalization showed moderate vacuolated hepatocytes and mild mixed inflammation. Laboratory testing was re-evaluated, and an echocardiogram was performed on the third day of hospitalization in preparation for anesthesia and placement of an esophageal feeding tube. The echocardiogram was unremarkable and the gallop sound was suspected to result from a systolic click. New findings on the CBC were mild, nonregenerative normocytic, normochromic anemia (HCT 29.9%, RR, 30–50%), with a WBC of 11,580 cells/μL (4,500–14,000 cells/μL), 4053 neutrophils/μL (2,000–9,000 cells/μL), bandemia (3,242 cells/μL) without evidence of toxicity, and circulating metamyelocytes (232 cells/μL). Findings on the serum biochemistry panel included a bicarbonate of 24 mmol/L (15–21 mmol/L), calcium of 8.3 mg/dL (9.0–10.9 mg/dl), BUN of 20 mg/dL (18–33 mg/dL), creatinine of 0.8 mg/dL (1.1–2.2 mg/dL), glucose of 114 mg/dL (63–118 mg/dL), total protein of 5.3 g/dL (6.6–8.4 g/dL), albumin of 2.0 g/dL (2.2–4.6 g/dL), globulin of 3.3 g/dL (2.8–5.4 g/dL), ALT of 57 U/L (27–101 U/L), AST of 46 U/L (17–58 U/L), ALP of 26 U/L (14–71 U/L), GGT of < 3 U/L (0–4 U/L), cholesterol of 109 mg/dL (89–258 mg/dL), and total bilirubin of 0.4 mg/dL (0–0.2 mg/dL). Urinalysis showed a specific gravity of 1.015; pH 7.0, protein 25 mg/dL, no bilirubin, 25 erythrocytes/μL hemoprotein, 1–3 WBC/HPF, 1–6 RBC/HPF, and many lipid droplets. Serum vitamin B12 and folate concentrations were 383 ng/L (279–1254 ng/L) and 7.5 ng/mL (10.4–20.7 ng/mL), respectively.

Because of the severely left-shifted neutrophil count, bacterial cholecystitis was suspected. Findings on abdominal ultrasonography were unchanged from the previous examination. Ultrasound-guided cholecystocentesis was performed while George was under anesthesia for esophagostomy tube placement, and a small volume of the scant ascites was also collected.

Microbiologic Testing

Cytologic examination (bile): Smears had light blue backgrounds and contained a moderate amount of unidentified material. Nucleated cells were not found, but there were many short, plump coccobacilli observed. Most of the bacteria were in large clusters, but a few groups were in chains. During detailed evaluation, no inflammatory cells were recognized. Interpretation: possible severe sepsis.

Peritoneal fluid analysis: Grossly the fluid was pink and cloudy, and it had a yellow, clear supernatant. The total protein concentration was 2.8 g/dL and there were 100,000 RBC/μL. There were 5,380 nucleated cells/μL, with 70% nondegenerate neutrophils, 6% small and well-differentiated lymphocytes, 7% foamy macrophages, and 17% eosinophils. No infectious agents were identified.

Aerobic and anaerobic bacterial culture (bile): Large numbers of *Enterococcus faecium*. No anaerobes were cultured. The isolate was susceptible to clavulanic acid-amoxicillin (≤ 4 μg/mL), ampicillin (≤ 0.25 μg/mL), penicillin (0.12 μg/mL), chloramphenicol (≤ 4 μg/mL), doxycycline (≤ 2 μg/mL), and imipenem (≤ 1 μg/mL); had intermediate susceptibility to erythromycin (1 μg/mL); and was resistant to rifampin (> 2 μg/mL).

Aerobic and anaerobic bacterial culture (ascites): Very small numbers of *Enterococcus faecium*. The antibiogram was identical to the isolate from the bile.

Diagnosis

Bacterial cholecystitis and peritonitis caused by *E. faecium*; pancreatitis and secondary hepatic lipidosis. Hyperthyroidism. A concurrent chronic enteropathy was also likely present in light of the ultrasound changes (thickened muscularis layer) with concurrent hypocobalaminemia and hypofolatemia.

Treatment

Medical treatment with ampicillin-sulbactam (30 mg/kg, IV, q8h) and enrofloxacin (5 mg/kg, IV, q24h) was commenced on day 3 of hospitalization, before the results of culture and susceptibility were available. Treatment was also continued with IV fluids, buprenorphine, omeprazole, ondansetron, and nutritional support via the esophagostomy feeding tube with a slurry of a commercially available gastroenteric diet (Purina ProPlan Veterinary Diets EN Gastroenteric Feline Formula, q4h). Surgery was considered, but because George was medically stable, a decision was made to continue medical treatment with close observation and serial CBC and abdominal ultrasound examinations. Within 12 hours of antibiotic treatment, George was brighter. A repeat abdominal ultrasound showed no changes with the exception of mildly enlarged and hypoechoic mesenteric lymph nodes. The CBC showed persistent nonregenerative anemia (HCT of 26.4%), 10,181 moderately toxic neutrophils/μL, 5,553 bands/μL, 185 metamyelocytes/μL, and a normal platelet count (305,000/μL). On day 5 of hospitalization, abdominal ultrasonography showed a decrease in the amount of ascites. The enrofloxacin was discontinued when the results of culture and susceptibility became available. On day 6, the CBC showed a stable HCT, 9,366 moderately toxic neutrophils/μL, 2,810 bands/μL, and no metamyelocytes. A serum chemistry panel was unremarkable and the total bilirubin had decreased to 0.1 mg/dL. On day 8, George began eating a small amount of food on his own and the CBC showed further improvement with 6,048 neutrophils/μL with no evidence of toxicity, 336 bands/μL, and a mild monocytosis (896 cells/ μL). He was discharged from hospital the following day with instructions to continue tube feeding, ondansetron (0.3 mg/kg, PO, q24h), omeprazole (1 mg/kg, PO, q12h), and amoxicillin-clavulanic acid (15 mg/kg, PO, q12h). At a recheck 1 week later, the owner reported that George had been doing well at home, although he had vomited three times over the course of the week. Physical examination was unremarkable, apart from the thyroid nodule and evidence of mild weight loss (body weight, 5.6 kg compared with 5.9 kg at discharge). A CBC showed a HCT of 30%, 10,592 neutrophils/μL, and 132 bands/μL. A serum chemistry panel was within normal limits and the total T4 concentration was 8.2 μg/dL. Treatment with methimazole (1.25 mg q12h) was initiated for the hyperthyroidism, but because of continued vomiting, this was discontinued after three doses. George's demeanor and appetite continued to improve. A week later he was eating canned and dry food on his own with no vomiting, a CBC showed no abnormalities, and the antibiotics were discontinued. The esophagostomy feeding tube was removed 3 weeks later, and methimazole was reinstituted, after which his T4 normalized. George was still doing well at follow-up 6 months later.

Comments

In this cat, cholecystitis and bacterial peritonitis were diagnosed based on cytologic and microbiologic analysis of bile and peritoneal fluid. However, there were no ultrasonographic abnormalities within the biliary tract, and cytologic evidence of infection in the peritoneal fluid was absent. Pancreatitis or an underlying chronic enteropathy may have predisposed the cat to ascending infection of the biliary tract, or infection may have occurred secondary to bacterial translocation. The lack of an inflammatory reaction in the bile was unusual, but it may have resulted from marked neutrophil disruption in a toxic environment. Isolation of the same bacterial organism from both the bile and the peritoneal fluid and the rapid clinical response to antibiotic treatment suggested that *Enterococcus* played a role in disease in this cat, although the clinical signs and hematologic abnormalities may also have resulted from severe pancreatitis and suspected hepatic lipidosis. Surgery was postponed because the peritonitis appeared to be very mild, and there was a concern that it could exacerbate the pancreatitis. Fortunately, the cat made a complete recovery.

Infections of the Genitourinary Tract

Jodi L. Westropp, Jane E. Sykes

KEY POINTS

- Causes: The most common cause of genitourinary tract infections is *Escherichia coli*, but other gram-negative bacteria, staphylococci, and streptococci may also be involved. Anaerobic bacterial infections are rare causes of genitourinary tract infections, but may be involved in pyometra.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: No signs, or dysuria, hematuria, or pollakiuria may occur with lower UTI. Acute pyelonephritis, prostatitis, and pyometra may be accompanied by fever or abdominal pain. Lethargy, inappetence, vomiting, or diarrhea may occur with sepsis. Pyometra may be accompanied by abdominal distention and/or a vaginal discharge. Prostatitis may be accompanied by dyschezia, dysuria, and a purulent or hemorrhagic urethral discharge.
- Differential Diagnoses: Feline idiopathic/interstitial cystitis, bladder neoplasia, or cystolithiasis (bacterial cystitis); toxicity, leptospirosis, and fungal or protozoal pyelonephritis (pyelonephritis); pregnancy, mucometra, or hydrometra (pyometra); benign prostatic hyperplasia, paraprostatic cysts, and prostatic neoplasia (prostatitis).
- Human Health Significance: MDR uropathogens might have the potential to colonize human patients.

INTRODUCTION

Infections of the genitourinary tract include sporadic bacterial cystitis, recurrent bacterial cystitis, pyelonephritis, renal abscesses, prostatitis, epididymitis and orchitis, metritis, pyometra, and potentially bacterial vaginitis. Lower UTI can also be caused by *Candida* spp. (see Chapter 85), and some fungi, especially molds such as *Aspergillus* spp., can infect the upper urinary tract leading to fungal pyelonephritis (see Chapter 86). This chapter focuses on bacterial infections of the urogenital tract; information on infections by other types of pathogens such as protozoa and nematodes can be found in other respective chapters in this book. UTI and genital infections can occur separately or concomitantly. Terminology regarding lower UTI has been addressed in the 2019 guidelines regarding diagnosis and management of bacterial UTI in dogs and cats by the ISCAID.[1] *Sporadic bacterial cystitis* (formerly known as uncomplicated UTI), in which a bacterial infection in the bladder results in inflammation and associated lower urinary tract signs (stranguria, pollakiuria, hematuria, and dysuria), is a common reason for veterinary visits and antimicrobial administration. This often occurs in otherwise healthy nonpregnant females and to a lesser extent, castrated males and cats. While possible, comorbidities such as endocrinopathies, intervertebral disc disease, and urinary stones are rarely identified in this group. Generally, animals with sporadic bacterial cystitis have had known or suspected UTI fewer than three times in the last 12 months. Complicated bacterial cystitis has also been described in dogs and cats; however, it is often difficult to determine if the bacterial cystitis is truly uncomplicated; underlying predispositions may be present.

In human medicine, *recurrent bacterial cystitis* implies three or more bacterial cystitis events within a 12-month period, or more than two events in a 6-month period; the same definition has been adopted in veterinary medicine.[1] In this case, predisposing patient factors are often identified, such as immune suppression, kidney disease, hypercortisolism, diabetes mellitus, urolithiasis, neoplasia, micturition disorders, ectopic ureters, and other anatomic abnormalities such as urethral strictures or cystic diverticulum.[2] While clinical cystitis can occur secondary to these conditions, these co-morbidities also have been associated with subclinical bacteriuria (SBU). Recurrent bacterial cystitis may reflect refractory (or persistent) infection, relapsing infection, or reinfection (Table 127.1). Without the use of molecular techniques (e.g., pulsed-field gel electrophoresis), it may not be possible to distinguish between relapsing infection and reinfection if the same bacterial species is isolated repeatedly, because a different strain may be present. *Enterococcus* spp. and *Pseudomonas* spp. may be more commonly found in dogs with persistent or recurrent UTI than dogs with simple uncomplicated UTI.[3] Some bacteria such as *Escherichia coli* can invade and form microcolonies within the uroepithelial cells (Fig. 127.1),[4] which may contribute to persistent infection in the face of antimicrobial treatment. Bacteria may also be able to form biofilms in association with the bladder wall ("deep-seated" infections), or on

TABLE 127.1 Factors that May Predispose to (or Contribute to) Development of Bacterial Cystitis or Subclinical Bacteriuria in Dogs and Cats

Dogs	Cats
Recessed vulva with concurrent perivulvar pyoderma	Perineal urethrostomy
Diabetes mellitus	Hyperthyroidism
Hyperadrenocorticism	Diabetes mellitus
Renal failure	Chronic kidney disease
Urinary catheterization	Micturition abnormalities (urinary incontinence or urinary retention)
Ectopic ureters	Urinary catheterization
Micturition abnormalities (urinary incontinence or urinary retention)	Urolithiasis
Tube cystostomy	Urinary neoplasia (rare)
Immunosuppressive drug treatment	
Urethrostomy	
Urolithiasis	
Urinary neoplasia	

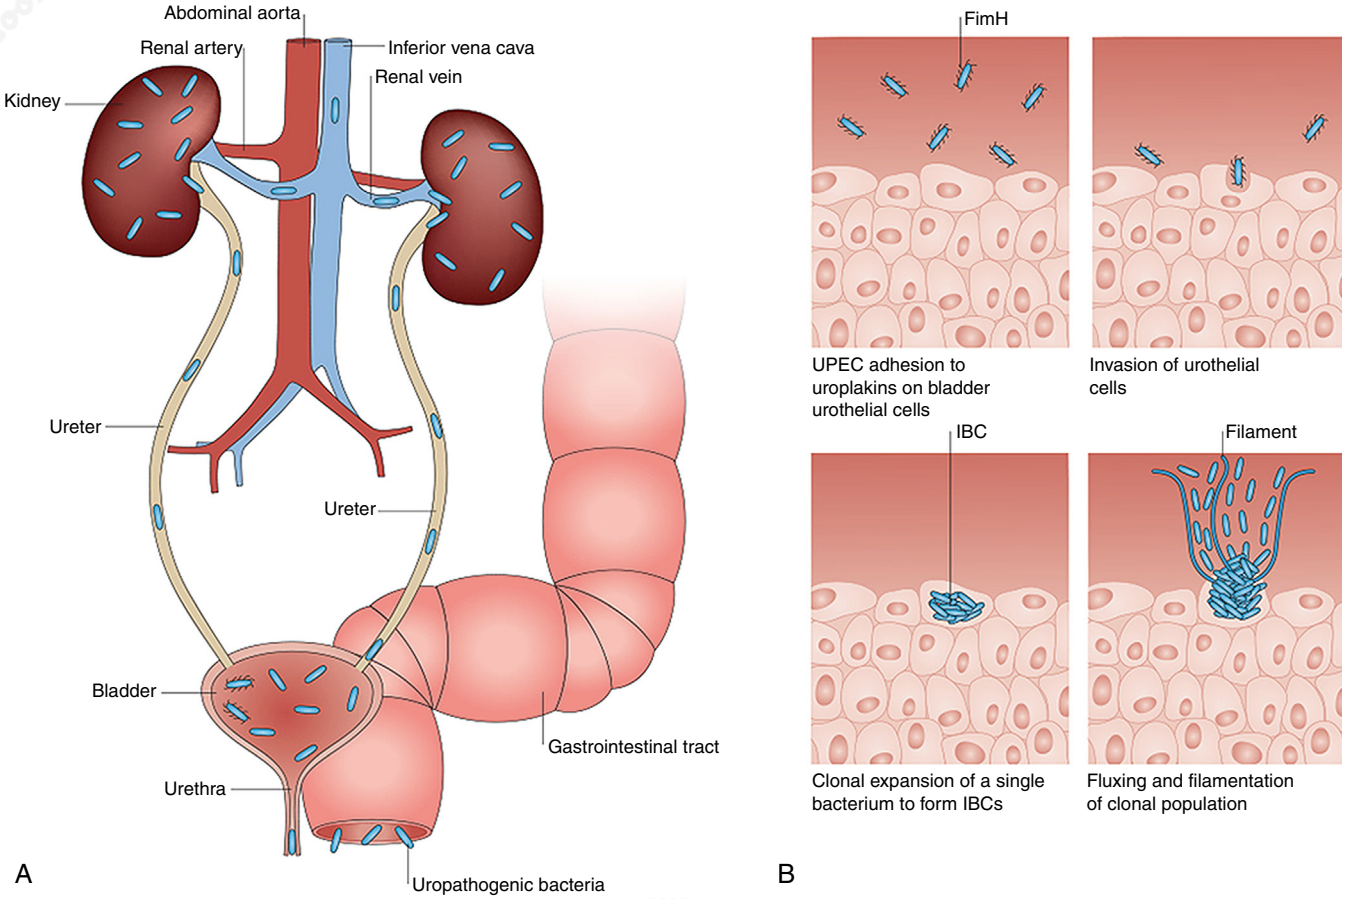

Fig. 127.1 Pathogenesis of urinary tract infection by uropathogenic *Escherichia coli* (UPEC). (A) UPEC colonizing the gastrointestinal tract, perineum, or vagina ascend into the urinary bladder to cause cystitis, which may be accompanied by lower urinary tract signs. They can also ascend into the kidneys to cause pyelonephritis. (B) In the urinary bladder, individual bacteria adhere to and invade superficial urothelial cells in a FimH-dependent manner. There they undergo clonal expansion to form biofilm-like intracellular bacterial communities (*IBCs*), where they can evade normal host mechanical and immunologic clearance mechanisms. Bacteria then form filaments that flux out of the cells into the bladder urine, where they then bind to adjacent cells and begin a new infection cycle. (From Klein RD, Hultgren SJ. Urinary tract infections: microbial pathogenesis, host-pathogen interactions and new treatment strategies. *Nat Rev Microbiol.* 2020;18:211–226.)

urinary implants such as stents and urinary catheters. *Escherichia coli* isolated from the urinary tract of dogs have been reported to frequently form biofilms; 52.6% of isolates were capable of forming biofilms in one study. Because no clinical distinguishing feature was found, biofilm formation should be considered whenever *E. coli* bacterial UTI is diagnosed. Biofilm formation was actually associated with greater susceptibility to antimicrobial drugs, suggesting that the antimicrobial tolerance may not be related to the presence of a resistance gene, but further studies are needed.[5] The use of antimicrobial-coated urinary catheters may reduce biofilm formation.[6]

Pyelonephritis can result when bacteria ascend into the renal pelvis and parenchyma from the lower urinary tract (see Fig. 127.1); less commonly, hematogenous spread to the kidney occurs. A single bacterial species (most often *E. coli*) is isolated from the urine of approximately three quarters of dogs with pyelonephritis, with two species isolated in 8% of dogs and three species from only 2% of dogs. Pyelonephritis may be acute or chronic. Strains of *E. coli* that cause pyelonephritis have greater ability to adhere to cells than strains that cause cystitis. Adhesins located on the tip of *E. coli* fimbriae adhere to glycolipid residues on tubular, collecting duct and bladder epithelial cells. In humans with pyelonephritis, both P and type I fimbriae appear to be important in colonization of the renal pelvis (Fig. 127.2).[7,8] Other *E. coli* virulence factors associated with pyelonephritis include hemolysin, cytotoxic necrotizing factor, the iron scavenger aerobactin, and a serum protease known as Sat. Fimbriae are also important in the pathogenesis of *Proteus* spp. pyelonephritis.[9] The medulla is more sensitive to colonization than the cortex, possibly owing to impaired host defenses in a high-osmolality, low-pH and low–blood flow milieu. Organisms adhere to pelvic and distal and proximal tubular epithelium, and have been observed intracellularly. Considerable renal injury results from the inflammatory response to infection. Aggregation of neutrophils within capillaries and induction of vascular spasm by bacterial toxins and/or cytokines can contribute to renal ischemia.

These infections should not be confused with SBU (also referred to as asymptomatic bacteriuria or ASB in humans). This term is used to describe the presence of bacteria in the urine, as determined by a positive bacterial culture in the absence of lower urinary tract signs (LUTS). The term "subclinical UTI" could be applied to dogs and cats if cytologic evidence of infection (e.g., pyuria or hematuria) is present,[10] but in human patients, the term SBU is used even in the presence of these abnormalities. SBU is commonly identified in dogs and cats, especially those with underlying endocrinopathies, kidney disease,

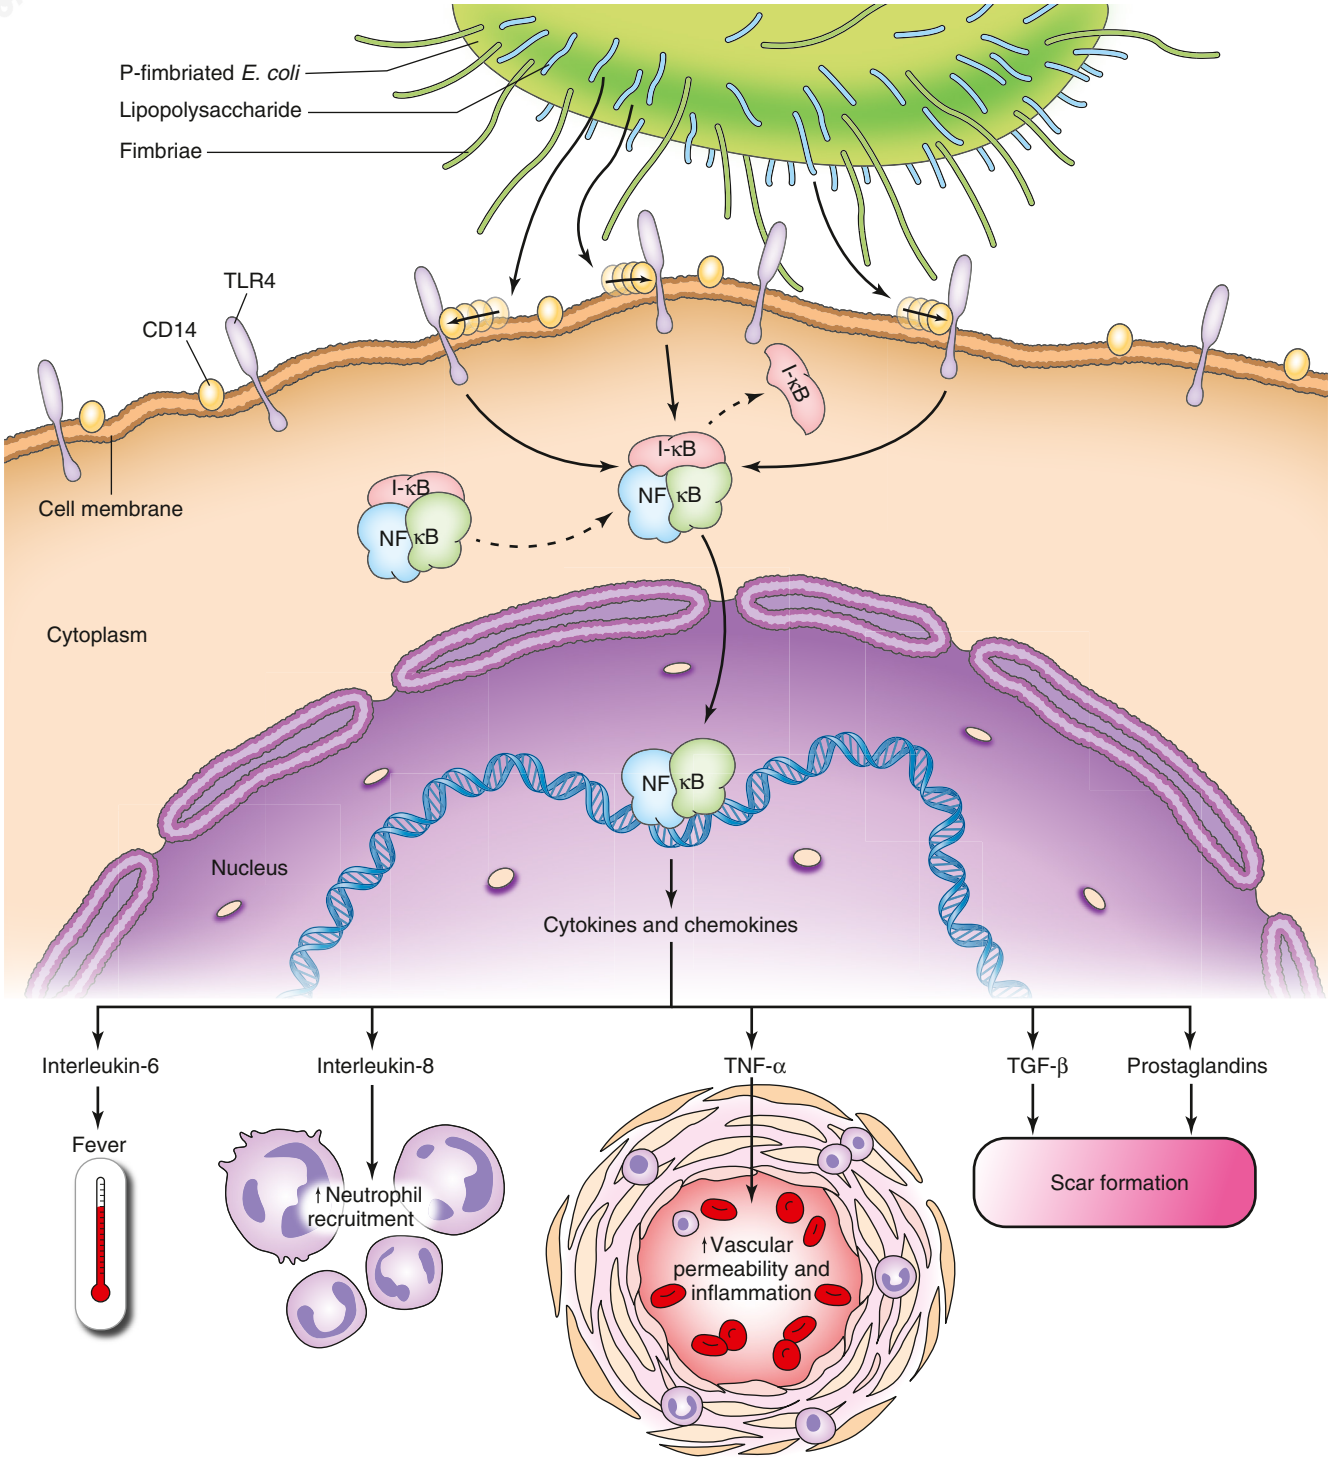

Fig. 127.2 Pathogenesis of acute pyelonephritis. *Escherichia coli* invades uroepithelium, facilitated by the presence of fimbriae. Bacterial lipopolysaccharide binds CD14 and activates toll-like receptors (*TLR4*). As a consequence, nuclear factor-κB (NF-κB) migrates into the cell nucleus and stimulates the transcription of inflammatory mediators that lead to fever, neutrophil recruitment, and increased vascular permeability. (Modified from Morello W, La Scola C, Alberici I, et al. Acute pyelonephritis in children. *Pediatr Nephrol.* 2016;31:1253–1265.)

micturition disorders, as well as dogs treated with glucocorticoids or cyclosporine.[11–15] In dogs evaluated in a primary care setting, bacteriuria was documented in 23 (12.7%) of 181 nonproteinuric specimens and 23 (8%) of the 286 proteinuric specimens. Of these 46 positive specimens, 31 were from dogs with SBU.[16] In a retrospective study that included 182 dogs with CKD, 33 (18.1%) had a positive aerobic bacterial urine culture. The highest prevalence of positive cultures was found for dogs with SBU (45%), with *E. coli* as the most frequently observed isolate.[17] In one study of dogs treated with glucocorticoids for dermatologic disorders, 18% of 127 dogs had bacteriuria in the absence of clinical signs, whereas none of 94 dogs that had not received glucocorticoids had bacteriuria.[15] SBU has a prevalence of 10%–13%

in cats; females were 21 times more likely to have a positive culture than male cats.[18] The extent to which antibiotic treatment is important in dogs or cats with SBU is not clear (see Treatment).

PATHOPHYSIOLOGY

Infections of the genitourinary tract usually follow impairment of normal host defenses and invasion by bacteria that are part of the normal flora (see Fig. 127.1). Less commonly, infection results from hematogenous spread to urogenital organs secondary to bacteremia. Specific pathogens such as *Leptospira* spp., *Borrelia* (*Borreliella* [incertae sedis]) *burgdorferi*, and *Leishmania* spp. that injure the kidneys secondary to systemic infection are described in Chapters 68, 69, and 96.

In healthy dogs and cats, bacteria are not found in upper urinary tract or prostate gland. In anestrus and diestrus, the uterus is also a sterile environment. The vagina, vestibule, prepuce, and distal urethra have a resident microflora. Normal flora should also be considered when results of aerobic bacterial cultures of urine, semen, or the preputial area are interpreted. In humans, recurrent infections can be associated with alterations in the normal vaginal microbiome, which is an important factor in host defense against pathogenic organisms. The resident microflora competes with pathogenic bacteria for nutrients and can interfere with adherence of pathogenic bacteria to vaginal epithelial receptors. Lactobacilli isolated from the vagina of dogs showed antimicrobial activity against *Proteus mirabilis, Staphylococcus aureus,* and *E. coli*.[19] The most common canine vaginal isolates reported in the dog are *E. coli* and *Staphylococcus pseudintermedius*. Vaginal lactic acid-producing bacteria were reported less often, with *Enterococcus canintestini* being the most common.[20]

Other factors that prevent bacterial colonization of the bladder include the glycosaminoglycan layer that covers bladder transitional epithelium, frequent voiding, the normal urethral microflora, antimicrobial properties of urine, an appropriate host immune response, and a functional urethral sphincter. Commensal bacteria that reside in the distal urethra, prepuce, and vagina invade opportunistically when these mechanisms are disturbed. The most common pathogen involved in all genitourinary tract infections is *E. coli*, which has a particular propensity to adhere to epithelial cells of the genitourinary tract. Others include coagulase-positive and coagulase-negative staphylococci; *Enterococcus* spp.; other aerobic gram-negative bacilli such as *Klebsiella, Proteus*, *Enterobacter,* and *Pseudomonas aeruginosa*; *Corynebacterium* spp.; streptococci; and mycoplasmas. Anaerobic bacteria are also found in the genital tract of female dogs, and may contribute to pyometra and metritis. In addition to impaired host defenses, a variety of bacterial virulence factors may impact the nature of the organisms that ultimately invade tissues and cause disease. The importance of virulence factors in uropathogenic *E. coli* infections is described in Chapter 53.

UPPER AND LOWER URINARY TRACT INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Sporadic bacterial cystitis is commonly diagnosed in dogs. Although mixed bacterial infections can occur, the vast majority of these infections involve a single bacterial species.[21] The most common uropathogen isolated is *E. coli*, which accounts for approximately 50% of all isolates, followed by *Staphylococcus*, *Proteus*, *Klebsiella*, *Enterococcus*, and *Streptococcus* spp. Mycoplasmas have also been isolated from dogs with bacterial cystitis, although their clinical significance has been unclear because they are usually isolated from dogs that have other disorders of the lower urinary tract, such as underlying neoplasia or cystolithiasis. Spayed females and older dogs are at increased risk for infection; the mean age at diagnosis is 7 to 8 years.[3,21] As a result of breakdown in host defense mechanisms, systemic disorders such as acute or chronic kidney disease, hyperadrenocorticism, diabetes mellitus, and systemic neoplasia also predispose dogs to bacterial colonization of lower urinary tract. However, in many of these cases, SBU may be present and treatment with antimicrobials is not warranted (see later) (Table 127.2).

TABLE 127.2 Definitions Applied to Urinary Tract Infections

Term	Definition
Subclinical bacteriuria	Presence of bacteria in the urine as determined by a positive bacterial culture, in the absence of LUTS. Differentiation from subclinical UTI may be difficult
Sporadic cystitis	Bacterial infection of the lower urinary tract associated with compatible clinical signs
Complicated bacterial cystitis	UTI that occurs in the presence of an anatomic or functional abnormality or comorbidity that predisposes to persistent UTI, recurrent infection, or treatment failure
Recurrent bacterial cystitis	Three or more episodes of UTI during a 12-month period
Relapsing UTI	Isolation of the same microorganism within 6 months of apparent clearance of the infection with treatment in between positive cultures
Re-infection	Isolation of a different microorganism within 6 months of apparent resolution of a previous infection

LUTS, lower urinary tract signs; *UTI,* urinary tract infection.

In contrast, bacterial cystitis is less common in cats. Most young cats with LUTS have disorders such as feline idiopathic/interstitial cystitis (FIC), which are not associated with bacterial infection. The prevalence of sporadic cystitis in cats ranges from just 1% to 3%.[22–24] However, other studies have reported a higher prevalence of bacterial cystitis; 44/134 (33%) of cats with obstructive and nonobstructive feline lower urinary tract disease had bacteriuria from the Norwegian School of Veterinary Science.[25] As in dogs, *E. coli* is the most common pathogen. Other potential uropathogens in cats include *Streptococcus*, *Staphylococcus*, *Enterococcus*, *Klebsiella*, and *Pasteurella*, and *Enterobacter*.[13,21,26] Mycoplasmas are very rarely isolated from the urine of cats.[26]

While bacteriuria (clinical or subclinical) in cats is more often recognized in older cats, co-morbidities such as diabetes mellitus and CKD were reported to be associated with UTI. The prevalence of "UTI" in cats with diabetes mellitus is 11%–13%.[11,13] At referral institutions, positive aerobic bacterial urine cultures were found in 17% and 22% of cats with CKD, and 22% and 12% of cats with hyperthyroidism.[11,26] Other factors that may predispose cats to bacteriuria are breed (Persians or Abyssinians), female sex, older age, and lower body weight,[13,24,26] although some of these risk factors may also be associated with the co-morbidities mentioned above. Most recently, the prevalence of subclinical bacteriuria in cats with hyperthyroidism was reported to be low, and this did not differ from a euthyroid control group, suggesting no increased risk and no clinical benefit in routinely

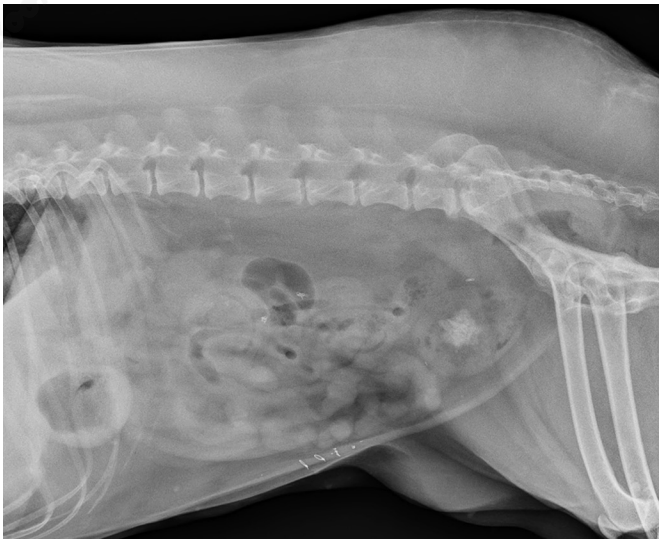

Fig. 127.3 Lateral abdominal radiograph from a 10-year-old female spayed miniature schnauzer with emphysematous cystitis and a large, irregular cystic calculus. Irregular gas densities can be seen throughout the bladder. *Escherichia coli* was cultured from a urine specimen that was obtained by cystocentesis.

performing urine cultures as a screening diagnostic in hyperthyroid cats.[27]

Uncommon forms of bacterial cystitis in dogs and cats are *encrusting cystitis* and *emphysematous cystitis*. Encrusting cystitis is caused by the gram-positive bacterium *Corynebacterium urealyticum*. Urease production by this organism leads to precipitation of large amounts of struvite and calcium phosphate within the bladder and along the bladder and urethral mucosa, and in some cases within the ureters and renal pelvis.[28–31] Most animals with *C. urealyticum* infections have severe LUTS and underlying co-morbidities such as urinary retention, urolithiasis, or ectopic ureters. Antimicrobial resistance is common and treatment should be implemented based on susceptibility testing. Use of an acidifying diet is warranted and endoscopic or surgical urothelial debridement may be required.

Emphysematous cystitis is characterized by the production of gas by bacteria within the bladder wall (Fig. 127.3). The most common cause is *E. coli*, but *Clostridium* spp. may also be involved.[32,33] The majority of dogs and cats that develop *E. coli* emphysematous cystitis have co-morbidities. In one study, diabetes mellitus was reported in 33% of 27 dogs, neurologic disease in 26%, and adrenal disease in 19%.[32] In diabetics, gas production may result from fermentation of glucose to gas products by *E. coli*. In the absence of glucose, proteins such as albumin may be fermented to gas. Emphysematous cystitis caused by *Clostridium perfringens* occurs in the absence of diabetes mellitus.[33,34]

CLINICAL FEATURES

Clinical Signs

Clinical signs of bacterial cystitis can include LUTS such as dysuria, hematuria, stranguria, and pollakiuria. Some clinical signs might be less apparent, such as subtle urinary incontinence or licking of perivulvar or prepucial area. Owners might also complain of foul-smelling urine. Cats may urinate outside the litter box (periuria or inappropriate urination). In some dogs, such as those with neurologic disorders like paraplegia, it can be difficult to ascertain if the animal is exhibiting signs of discomfort from the infection. Short-term treatment (see later) can be considered and the dog's clinical response closely monitored. Rarely, lethargy may accompany sporadic cystitis, but fever and hyporexia are not present.

Acute or acute-on-chronic pyelonephritis may result in decreased appetite, lethargy, variable fever, hematuria, and clinical signs of uremia, such as vomiting and diarrhea. Polyuria and polydipsia may also be present, or dogs with advanced disease may be anuric. Dogs and cats with chronic pyelonephritis may show no signs, or show only polyuria and polydipsia.

Physical Examination Findings

Physical examination findings in dogs or cats with bacterial cystitis may be unremarkable, or there may be mild urine staining of the perineum. Some dogs may present with urinary incontinence and evidence of urine scalding or a strong ammonia-like odor may be present. Underlying disorders that predispose to bacterial cystitis may also be apparent (such as a recessed vulva and associated vulvar fold dermatitis).

Occasionally, abdominal pain may be detected on palpation of the abdomen of dogs or cats with bacterial cystitis, but more often this is seen with acute pyelonephritis or when concurrent prostatitis is present. The bladder is often small in dogs or cats due to persistent inflammation and associated frequent voiding (pollakiuria); a thickened bladder wall may also be palpated. If a large, turgid bladder is present in dogs or cats with a UTI, urethral obstruction due to neoplasia, calculi, encrusting cystitis, or proliferative urethritis (PU) should be suspected. Fever is not present in dogs and cats with infections localized to the lower urinary tract, and is variable in dogs and cats with pyelonephritis. Dogs and cats with severe pyelonephritis may show evidence of lethargy, dehydration, and signs of severe sepsis or septic shock (e.g., tachycardia or bradycardia, tachypnea, prolonged capillary refill time).

DIAGNOSIS

Diagnosis of sporadic bacterial cystitis or pyelonephritis is based on the clinical signs present, laboratory abnormalities, imaging findings, and culture of urine. Most cases of acute pyelonephritis arise from ascension of the fecal-derived organisms. Acute pyelonephritis with *E. coli* (at least in children) is associated with type 1 and type P pili, with the latter more frequently identified. Renal scarring is noted in children due to activation of NF-κB, which perpetuates the inflammatory response, fever, and neutrophil recruitment (see Fig. 127.2).[35] The presence of fever or leukocytosis in addition to a positive bacterial urine culture should increase suspicion for concurrent bacterial pyelonephritis; prostatitis or pyometra should also be considered (see relevant sections later in this chapter). Ultrasound examination findings also can support the diagnosis and assist in the identification of predisposing disorders such as neoplasia, anatomic abnormalities, or the presence of calculi or foreign material. At a minimum, collection of urine by cystocentesis followed by complete urinalysis (with sediment examination) and quantitative aerobic bacterial urine culture are recommended to confirm the presence of bacterial UTI for dogs or cats with signs of lower urinary tract disease.[1,10] Additional diagnostics are indicated for animals that have recurrent LUTS or those with systemic signs such as fever, weight loss, or inappetence. The owners of animals that are diagnosed with a suspected sporadic bacterial cystitis should always be advised that other predisposing underlying disease may be present.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Animals with infections localized to the lower urinary tract typically have no hematologic or serum biochemistry abnormalities. The diagnosis of pyelonephritis can be difficult. Animals with pyelonephritis may have

mild anemia, leukocytosis due to a neutrophilia, increased band neutrophils, and monocytosis. A degenerative left shift, toxic neutrophils, and thrombocytopenia may also be present. The serum biochemistry panel may show azotemia. Due to the potential for renal scarring and other complications in children with acute pyelonephritis, various novel biomarkers have been evaluated to identify early kidney injury. These include CRP, IL-6, IL-8, plasma neutrophil gelatinase-associated lipocalin (NGAL),[36] kidney injury molecule-1 (uKIM -1)[37] and procalcitonin (PCT).[38] Several of these biomarkers may be useful for predicting and possibly managing acute pyelonephritis, but none are clinically available in veterinary medicine at this time. The latter (PCT) is intriguing because it is an early and reliable marker of serious bacterial infections and sepsis.[39] SDMA can be a useful marker of glomerular filtration rate (GFR) in cats and dogs and is used for screening for early detection of kidney injury. Like many of the biomarkers, it is not specific for pyelonephritis,[40] but is clinically available. Other markers such as cystatin C, NGAL, and homocysteine have also been investigated in dogs.[41]

Hypoalbuminemia and electrolyte abnormalities may be present in dogs or cats with pyelonephritis. However, pyelonephritis may be present in animals with normal CBC and serum biochemical panels. While research is underway to identify biomarkers specific for renal parenchymal infection, currently the clinician must collate all physical examination, imaging, and biochemical findings and decide if treatment for pyelonephritis is warranted.

Urinalysis

The urinalysis is usually the initial screening test for dogs with LUTS. Of 52 private practices in Denmark evaluating 151 dogs with LUTS, the veterinarian performed a urine dipstick 99% of the time and sediment examination in 80%. Only 56% of those samples were submitted for culture.[42] Findings on the urinalysis in dogs and cats with UTI can include isosthenuria, pyuria, hematuria, proteinuria, and bacteriuria. Animals with pyelonephritis may have cylindruria, and small amounts of glucose may be present in dogs with altered proximal tubular function. However, the urinalysis may also be unremarkable, even in dogs and cats with pyelonephritis. Infections with urease-producing bacteria such as staphylococci, *Proteus* spp., and *C. urealyticum* may be associated with a high urine pH and the presence of struvite crystals. The urine protein to creatinine ratio (UPCR) in dogs with pyelonephritis may be increased as a result of renal tubular or glomerular injury. However, an elevated UPCR may be noted in dogs with sporadic cystitis as well as those with SBU.[16] In patients with a high suspicion of pyelonephritis but negative urine culture, blood cultures and/or nephropyelocentesis should be considered.

Coagulation Profile

Evidence of coagulation abnormalities may be present in animals with severe pyelonephritis that develop severe sepsis or septic shock (see Chapter 123).

Diagnostic Imaging

Plain Radiography

Dogs or cats with sporadic bacterial cystitis alone generally have no radiographic abnormalities. The bladder of animals with pollakiuria may be small. Emphysematous cystitis is characterized by the presence of radiolucencies within the bladder lumen and/or in association with the bladder wall (see Fig. 127.3). Radiopaque cystic or renal ("staghorn") calculi may be visible in dogs with struvite calculi secondary to infections with *Staphylococcus* spp. or *Proteus* spp. (Fig. 127.4).

Renomegaly may be present with acute pyelonephritis, or the kidneys may be small and irregular in dogs or cats with chronic pyelonephritis.

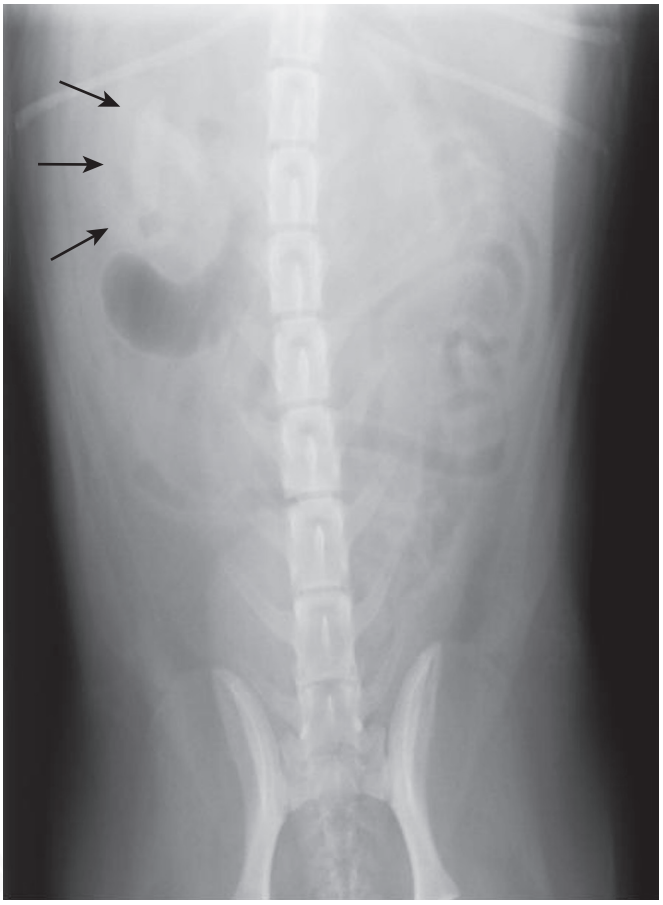

Fig. 127.4 Dorsoventral radiograph of a 6-year-old female spayed shih tzu mix with a urinary tract infection caused by *Proteus mirabilis* and *Enterococcus faecalis* and nephrolithiasis. An opacity ("staghorn" calculus) occupies the right renal pelvis *(arrows)*.

Sonographic Findings

Ultrasound examination of the urogenital tract is a noninvasive method to obtain information about the extent and severity of disease and underlying causes such as neoplasia, calculi, or foreign bodies. It does not permit visualization of the entire urethra, and urethral abnormalities (e.g., evidence of PU) may be overlooked in some animals if only ultrasound is used for imaging purposes. Ultrasound examination of the bladder may be unremarkable or show a mild to moderately thickened bladder wall in dogs or cats with bacterial cystitis. Increased echogenicity of the urine may be present. Rarely the bladder wall is severely thickened (Fig. 127.5). Animals with emphysematous cystitis may have a hyperechoic bladder wall with acoustic shadow artifacts. Shadow artifacts may also occur as a result of the presence of cystic calculi.

Dogs or cats with pyelonephritis may have a normal abdominal ultrasound examination, or blunting of the renal papilla, pyelectasia, irregularity of the renal contour, and evidence of hydronephrosis (Fig. 127.6). However, renal pelvic dilatation can occur in animals with normal renal function, diuresis, and outflow tract obstruction, and there is considerable overlap in the extent of dilatation between groups.[43] Dogs and cats with severe pyelonephritis may have hyperechoic material within the renal pelvis, or the renal pelvis may be anechoic and contain hyperechoic debris.[44] Sometimes the surrounding mesentery is hyperechoic, and perinephric anechoic fluid may be present due to localized peritonitis.

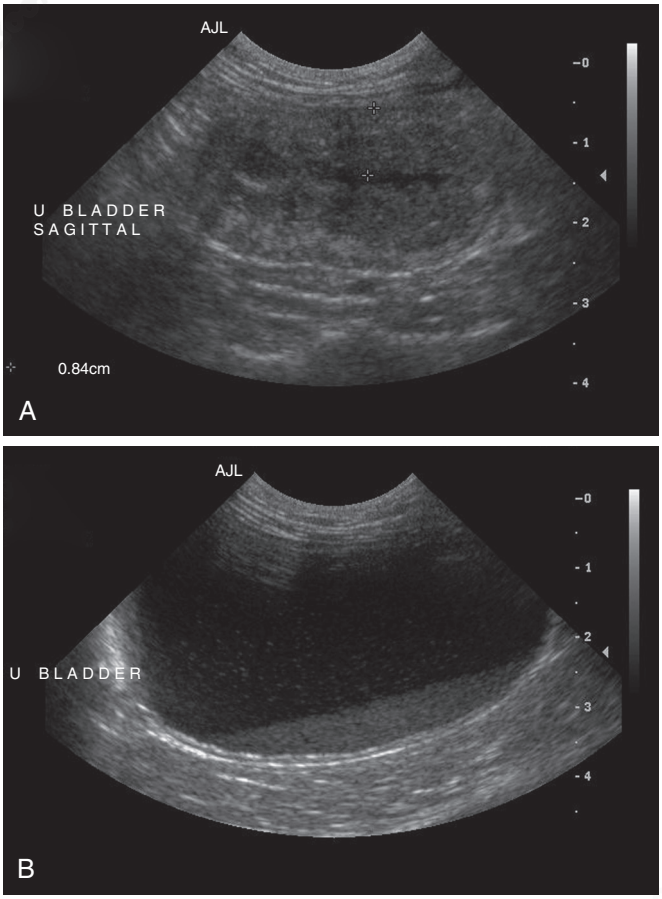

Fig. 127.5 Ultrasound images of the bladder of an 18-year old female spayed domestic shorthair cat with diabetes mellitus, generalized osteoarthritis, a myelopathy, and recurrent urinary tract infection (UTI). The cat had severe lower urinary tract signs (hematuria, pollakiuria, and stranguria) and UTI with a hemolytic *Escherichia coli* was diagnosed. (A) The bladder wall is markedly thickened. (B) Resolution of bladder wall thickening after treatment with marbofloxacin for 3 weeks, which also resolved the clinical signs.

Other nonspecific findings in pyelonephritis can include increased renal cortical echogenicity, and decreased corticomedullary definition. The diagnosis of pyelonephritis should not be made solely based on ultrasonographic findings.

Contrast Radiography and Cystoscopy

Intravenous contrast urography was utilized to identify renal pelvic enlargement and assist in the diagnosis of pyelonephritis, but has largely been replaced by abdominal ultrasonography for this purpose, which is less invasive and can be an excellent tool to identify predisposing factors such as uroliths, diverticuli, neoplasia, and polypoid cystitis. While cystoscopy can be considered for select patients with recurrent UTI, it is not often recommended for women when other imaging such as ultrasonography is normal,[45] and cystoscopy performed solely for recurrent UTI in women was reported to be low yield.[46] In 163 women with recurrent UTI, cystourethroscopy rarely (3.8%) identified a unique lesion (i.e., pertinent uroendoscopic finding) that was not previously identified by ultrasound (111 women) or contrast CT (22 women).[47] In dogs with recurrent UTI, non-specific cystourethroscopic and vaginoscopic findings such as mucosal edema, lymphoid follicles and vestibulovaginal septal remnants were noted in 45/53 (85%) dogs, but no comparisons were made in this study between endoscopic and ultrasonographic findings.[48] In addition, this study did not determine if these findings were clinically relevant or related to the LUTS for which the dog was being evaluated. Preliminary data in dogs with recurrent UTI found that cystoscopy findings were in agreement with the ultrasonographic findings in 26/30 (87%) dogs evaluated.[49] In dogs, cystoscopy can be considered if bladder or urethral biopsy is indicated for histopathology. Culture of the bladder or urethral tissue can be considered, as well as techniques such as FISH when the possibility of a deep-seated infection exists, as bladder wall infection may not be associated with positive urine cultures in some dogs.[50] Furthermore, five dogs with PU had negative urine and tissue cultures when FISH was positive. There was no association detected between the type of urethral inflammation and the results of urine and tissue culture or FISH.[51] However, if obtaining biopsy specimens for culture, it is ideal to collect these when the dog has a negative urine culture and not receiving antimicrobial therapy, which can be difficult

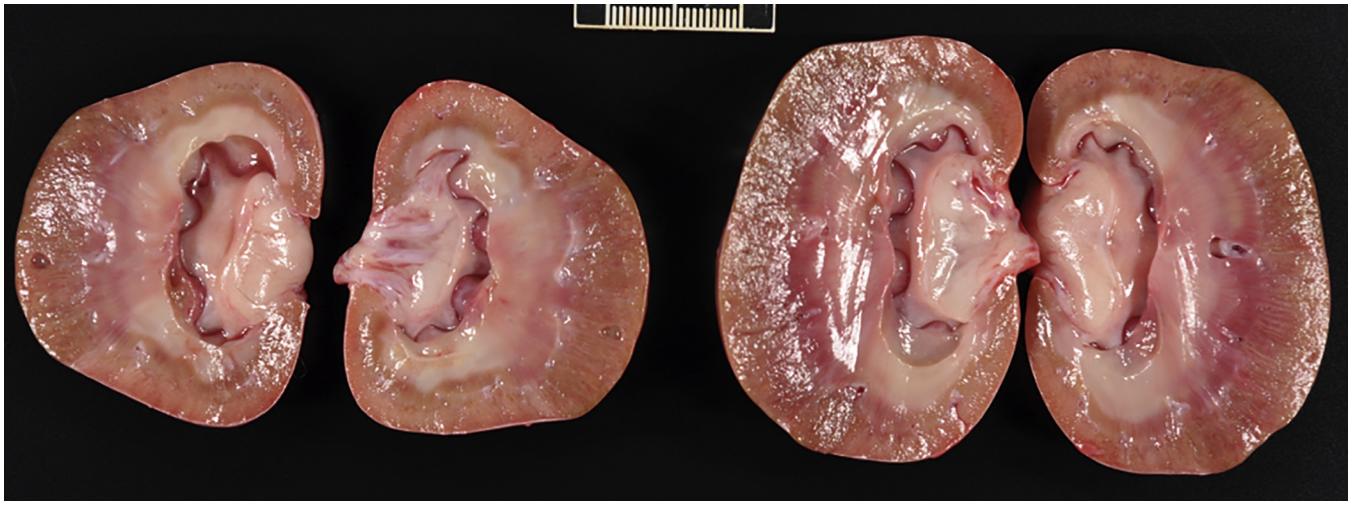

Fig. 127.6 Kidneys of a 2-year-old male neutered German shepherd with diabetes mellitus and chronic pyelonephritis secondary to *Klebsiella pneumoniae* infection. The kidneys are bilaterally asymmetrical; the right kidney is larger than the left. There are several small, cortical subcapsular cysts, and the kidneys have an irregular conformation with markedly shrunken poles. The renal parenchyma at the poles is markedly collapsed from the capsule to the pelvis and the pelvis is uniformly dilated. (Courtesy of University of California, Davis, Veterinary Anatomic Pathology Service.)

to achieve in some patients. Contrast cystourethrography can also be useful for diagnosis of anatomic abnormalities, particularly urethral lesions, when cystoscopy is not available.

Microbiologic Tests

Isolation and Identification

Quantitative aerobic bacterial culture and susceptibility testing is strongly recommended for dogs or cats with UTI before starting antimicrobial drugs, because of the possibility of antimicrobial drug resistance, which has been well recognized among *E. coli* strains isolated from dogs and cats with genitourinary tract infections.[52,53] It is especially warranted in dogs and cats with recurrent UTI that have received previous antimicrobials for UTI treatment. Isolates from dogs that had received amoxicillin, doxycycline, or enrofloxacin 30 days before culture results were obtained were significantly more likely to be resistant than those from dogs that did not receive those antimicrobials before urine cultures were obtained.[2] Guidelines for diagnosis of bacterial UTI in dogs and cats have been published.[1,10] Ideally, urine should be collected by cystocentesis; if this is not possible or contraindicated (e.g., coagulopathy or lower urinary tract neoplasia), urethral catheterization can be considered. Although any pathogens isolated from specimens collected by cystocentesis are likely significant, the presence of $> 10^3$ CFU/mL of bacteria is unlikely to result from skin contamination alone. If specimens are collected using catheterization, colony counts that exceed $> 10^4$ CFU/mL for male dogs and $> 10^5$ CFU/mL for female dogs are considered clinically significant.[1,10] Free-catch (midstream voiding) specimen collection is not recommended for dogs or cats because it is highly susceptible to contamination. Aerobic bacterial urine culture from a specimen collected by cystocentesis confirms the presence of bacterial infection in animals with LUTS. Culture can also help to differentiate reinfection from relapse should a UTI return.[1,10] Culture of a single organism from a mucosal swab collected from a site such as the urethra does not imply disease causation because commensal bacteria may be isolated in pure cultures from healthy dogs and cats. Specimens for culture and susceptibility testing should be refrigerated immediately and submitted to the laboratory as soon as possible. The results of culture for specimens that reach the laboratory > 24 hours after collection should be interpreted with caution because false-negative and false-positive test results can occur. For dogs and cats with recurrent UTI that undergo surgery, culture of a bladder wall biopsy or cystoliths can be considered, but a decision to treat should be based on the presence of clinical signs.

Inexpensive urine "paddles" have been marketed for in-house veterinary diagnosis of UTI, which consist of two different types of agar on either side of a plastic paddle (see also Chapter 3, Fig. 3.6). The media are inoculated with urine collected by cystocentesis and the paddles are then incubated and examined daily for growth; sensitivity and specificity of this POC test was 97.3% and 98.6%, respectively; however, the paddles do take approximately 24 hours before results are available to interpret.[54] A rapid immunoassay (RapidBac Vet, Silver Lake Research, Azusa, CA, USA) is also marketed as a POC test for detection of bacteriuria in cats and dogs with a 90% sensitivity and 96.6% specificity reported when applied to a small number of specimens. Of 200 canine urine samples, 38 (19%) were considered associated with a UTI based on the urine collection method and signifiicant bacteriuria. For these samples, the sensitivity and specificity of the rapid immunoassay was 97.8% and 98.8%, respectively. The agreement with the reference laboratory was considered substantial.[55] In another study of 22 urine specimens from dogs, sensitivity and specificity were 73% and 91%, respectively; for specimens with over 1000 CFU/mL of bacteria identified using culture, sensitivity and specificity were 80% and 91%, respectively.[56] Assay results are available in 20 minutes. These POC tests can be useful screening tools for patients with LUTS when client finances do not permit submission of specimens to a microbiology laboratory for culture. If positive results are obtained, ideally a urine specimen should then be submitted to a microbiology laboratory for culture and susceptibility testing in order to select the most appropriate antimicrobial drug. If performed in-house, bacterial culture should only be performed in clinics with appropriate laboratory facilities, proper BSL containment and waste management, and adequately trained personnel.[10]

If a urinary catheter is present, culture should be performed if clinical signs of infection are present (e.g., hematuria, suspected bacteremia).[10] The catheter should be removed and cystocentesis performed after the bladder is allowed to fill with urine. Alternatively, the catheter could be removed, replaced with a new catheter if necessary, and a urine specimen collected through the new catheter after removal of several milliliters of urine to clear the catheter. Urine culture should never be submitted from specimens collected from the urine bag because it is likely to yield growth of organisms forming biofilm on the bag or catheter; there is no indication to culture the catheter tip.

Bacteria cultured from the urine are usually those involved in pyelonephritis, when pyelonephritis is present. However, a negative urine culture does not rule out pyelonephritis. Pyonephrosis, a collection of sloughed urothelium and inflammatory cells in the dilated renal collecting system, is a complication that can be caused by partial or complete ureteral obstruction with concurrent upper tract infection. The diagnosis of pyelonephritis can be challenging clinically. Ultrasound-guided nephropyelocentesis can be considered when renal pelvic dilation is present to obtain urine for culture, but this is not usually required for effective treatment of pyelonephritis. Blood cultures should also be considered in animals with acute pyelonephritis, especially when signs of severe sepsis are present.

Laboratories that perform susceptibility testing for uropathogens should adhere to local guidelines for test performance and reporting (such as the Clinical and Laboratory Standards Institute [CLSI] in North America and the European Committee on Antimicrobial Susceptibility Testing [EUCAST] in Europe) (see Chapter 3). Breakpoints for systemic infections also apply to UTI. However, provided renal function is normal, many antimicrobials achieve much higher concentrations in urine than they do in serum. Therefore, use of some antimicrobials may eradicate the UTI despite predicted resistance. This is especially true for treatment of staphylococcal UTI with penicillins and cephalosporins. Urinary breakpoints are available for ampicillin or amoxicillin in dogs (≤8 μg/mL), amoxicillin-clavulanate in dogs and cats (<8/4 μg/mL), and nitrofurantoin. These should only be used when infection is confined to the lower urinary tract.

Pathologic Findings

Pathologic findings in dogs with bacterial cystitis and pyelonephritis depend on the chronicity of the infection, the underlying cause, and the uropathogens present. Acute infections are associated with a dense neutrophilic infiltrate on histopathology and intralesional bacteria may be identified. Chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates.

TREATMENT AND PROGNOSIS

Treatment of UTI consists of: (1) removal or management of the underlying cause of infection and (2) antimicrobial treatment. Treatment with antimicrobial drugs alone without attention to an underlying cause frequently leads to recurrent infection and selection for resistant bacteria. Because of the increasing prevalence of MDR *E. coli* and staphylococci in dogs and cats with UTI, provided the

TABLE 127.3 Suggested Initial Treatment for Stable Dogs or Cats with Genitourinary Tract Infections Pending Culture and Susceptibility Results

Disease	Drug	Dose (mg/kg)	Route	Interval (hours)
Bacterial cystitis or pyometra	Amoxicillin OR	11–15	PO	8
	Trimethoprim-sulfadiazine OR	15[a]	PO	12
	Clavulanic acid-amoxicillin	12.5–25	PO	8
Pyelonephritis, prostatitis	Enrofloxacin OR	20 (dogs)	PO	24
	Marbofloxacin OR	2.7–5.5	PO	24
	Orbifloxacin	7.5	PO	24

[a]Based on trimethoprim plus sulfadiazine concentration.
See Chapter 123 for options for severe sepsis.

patient is stable and sepsis is absent, consideration should be given to delaying antimicrobial drug treatment until the results of culture and susceptibility are available. This is especially true for dogs and cats with recurrent UTI that have a history of antimicrobial drug treatment. Empiric treatment while awaiting the results of culture and susceptibility could be considered to relieve discomfort if present in dogs that have not received previous antimicrobial treatment. The use of NSAIDs can be considered (with extreme caution in cats) to relieve clinical signs while pending susceptibility testing. When pyelonephritis or sepsis is present or suspected, treatment should commence immediately with broad-spectrum antimicrobials that have activity against MDR gram-negative bacteria (see Chapter 123).

Sporadic Bacterial Cystitis

Published guidelines provide detailed recommendations for treatment of sporadic cystitis.[1] In most situations, rational choices for initial treatment of sporadic cystitis include amoxicillin or trimethoprim-sulfonamide (Table 127.3). Amoxicillin-clavulanic acid could be considered if regional susceptibility trends suggest a high (>10%) prevalence of β-lactamase production by uropathogens isolated.[1,10] However, evidence of a need for clavulanic acid is lacking and may not be necessary due to the high urinary concentrations of amoxicillin that are achieved in most animals. Trimethoprim-sulfonamides are an excellent option, but do have a greater association with adverse events such as hepatotoxicity, and immune-mediated diseases. Resolution of clinical signs (i.e., clinical cure) is the goal of therapy, rather than elimination of bacteriuria. Once culture and susceptibility results are available, the initially chosen antimicrobial drug should either be continued (if a clinical response has occurred) for a total of 3 to 5 days or switched to an alternative drug (if clinical cure has not been achieved) with activity against the pathogen isolated and that enters urine in high concentrations. A treatment duration of 3 to 5 days has been recommended by the ISCAID Antimicrobial Working Group; however, 10 to 14 days of treatment is still routinely prescribed.[1,10] While there are numerous studies evaluating and supporting short-course therapy for UTI in humans, studies in the veterinary field are lacking. One study showed that treatment of dogs that had sporadic cystitis with high-dose enrofloxacin (20 mg/kg) for 3 days was not inferior to treatment with clavulanic acid-amoxicillin for 14 days (see Table 127.3).[57] Another study of dogs with naturally occurring UTI that evaluated short durations of treatment with trimethoprim-sulfonamide compared with longer duration of treatment with cephalosporins found that no significant difference in the microbiologic or clinical cure rates were reported between the two groups in short- or long-term (>30 days) evaluation, but long-term treatment cure rates were low in both groups.[58]

Recurrent Bacterial Cystitis

Investigation of an underlying cause is strongly recommended in animals with recurrent UTI. For animals where reinfections are confirmed (i.e., recurrent infections with differing bacterial strains or species), a thorough evaluation for micturition disorders (urinary incontinence or urine retention), perivulvar inflammation and infection, or predisposing systemic abnormalities should be performed.

Care should be taken not to overinterpret the finding of a recessed vulva. While the incidence of bacteriuria improved in 19 of 22 dogs after vulvoplasty, 59% of those dogs had perivulvar dermatitis which also improved. Moreover, 14 of 34 dogs had signs such as urinary incontinence, and perivulvar dermatitis at an older age suggesting multiple contributing factors for recurrent infections. While 16 dogs with UTI and hooded vulva improved clinically (i.e., decreased recurrence of UTI) after episioplasty, 3 of 16 had concurrent cystic calculi, and 12 of 16 dogs had concurrent perivulvar dermatitis, which also resolved.[59]

For animals with a relapsing infection (i.e., recurrent UTI with the same pathogen strain), the pathogen susceptibility should be reviewed, as well as the antimicrobial dose and duration. A thorough investigation for a nidus of infection (e.g., urinary calculi, polyp or deep-seated infection) should be considered. Referral to an internal medicine specialist should be considered for further diagnostic tests, including advanced imaging. Antimicrobial drugs should be selected on the basis of culture and susceptibility test results, and preference should be given to drugs that are excreted in the urine in active form. If excreted in the urine, drugs with intermediate susceptibility could be used to treat UTI that is resistant to other appropriate drug choices; however, a higher dose (for concentration-dependent antimicrobials) or dosing frequency (for time-dependent antimicrobials) should be considered. Nitrofurantoin should be considered for UTI that is resistant to other oral antimicrobial drugs that are excreted in the urine and only administered when the infection is isolated to the lower urinary tract. Nitrofurantoin should never be used to treat prostatitis or pyelonephritis due to poor tissue penetration. When mixed infections are present, antimicrobial drug treatment ideally should be directed at all organisms present. In mixed infections that involve *Enterococcus* spp., the *Enterococcus* spp. infection will typically resolve when other organisms present are successfully treated.[10] There is no evidence to suggest that longer antimicrobial treatment duration (10 to 14 days) is needed for animals with recurrent UTI. The primary objective for treatment is clinical cure (resolution of clinical signs); microbiologic cure is not always achievable in some patients with co-morbidities that cannot be corrected. Longer courses (14 days) can be considered for some relapsing infections, particularly for suspected deep-seated infections. Aerobic bacterial urine culture could be considered 5 to 7 days after initiating treatment, but if clinical cure is achieved, a change in treatment may not be warranted even if a positive bacterial culture is documented. If no clinical signs are present, management should be as for SBU (see later).

As mentioned earlier, urolithiasis in the urinary tract can serve as a nidus for infection and reason for relapsing infections, particularly in dogs. Stone removal is advised if appropriate (bladder, urethral stones) and consideration for a ureteral stent or subcutaneous ureteral bypass in patients presenting with ureteral obstruction. In

dogs presenting with suspected struvite urolithiasis, dissolution with a calculolytic diet and concurrent antimicrobials (in dogs) should be prescribed. Traditionally, antimicrobials are recommended for the entire dissolution protocol in dogs. Shorter courses of antimicrobial therapy combined with a calculolytic diet may be efficacious; an induced canine struvite model provided limited evidence for struvite dissolution without antimicrobials[60]; however, dissolution will likely take longer utilizing this strategy. In one study, the target urinary pH appeared appropriate for struvite dissolution (pH = 5.9–6.1) at day 45 in dogs with struvite urolithiasis following only 7 days of antimicrobial administration during the first week combined with a calculolytic diet. However, radiographic evidence of struvite dissolution was not provided.[60] At this point, no definitive guidelines exist for the timing and duration of antimicrobial therapy in humans[61] or dogs with struvite uroliths. Future studies should consider this to improve antimicrobial stewardship. Recommendations for shorter course therapy have been suggested for dogs.[1] Regardless of the strategy implemented, patients should be re-evaluated on a regular basis and treatment adjusted based on clinical findings using diagnostic imaging and laboratory findings (serum chemistry, urinalysis, urine culture).

There is no evidence that direct instillation of antimicrobials, antiseptics, glycosaminoglycans, or dimethyl sulfoxide (DMSO) directly into the bladder via a urinary catheter is effective for treatment of recurrent UTI. These compounds are rapidly eliminated from the bladder during micturition and may be locally irritating, which may predispose further to infection with drug-resistant bacteria. Approaches that have been used to prevent recurrence are detailed in the Prevention section.

Subclinical Bacteriuria

In humans, there is abundant support that antimicrobial treatment is not warranted for ASB. No evidence of an association between SBU and risk of sepsis, pyelonephritis, or other complications exists. Data in veterinary medicine are limited. Of 67 nonazotemic cats that had urine cultures performed on five occasions over 3 years, the presence of SBU in cats did not adversely impact survival even though antimicrobial treatment was withheld.[18] In cats with CKD, no difference was noted in the frequency of CKD progression between cats with UTI and those with SBU or no positive urine culture. However, the impact of not treating SBU on progression of CKD or survival could not be assessed because in this group, all cats received antimicrobial treatment. When nine healthy dogs with SBU were followed for 3 months, four had persistent bacteriuria and four transient; none developed signs during this period.[62] Of 47 chronically paralyzed dogs that lacked pelvic limb pain perception, 35 had at least one positive urine culture and 13 dogs had recurrent bacteriuria.[63] Bacteriuria was not associated with survival, but the differences in antimicrobial treatment between the two groups were not clear. However, resistant bacterial isolates were cultured from 46% of dogs with recurrent positive urine cultures.

Treatment for humans with concurrent diabetes mellitus and ASB is not recommended; the authors do not advocate screening or treatment of SBU in dogs with stable diabetes mellitus or those with hypercortisolism. Identifying clinical signs of bacterial cystitis in some patients can be difficult (e.g., paralyzed dogs); if the clinician or owner is concerned for poor quality of life, a short course (3 to 5 days) of antimicrobials can be considered and the clinical signs charted during the course of therapy.

While both UTI and SBU have been described in cats and dogs that have implants such as subcutaneous ureteral bypass devices or ureteral stents,[64] whether SBU should be treated with antimicrobials requires additional study. These devices are prone to colonization with bacterial biofilms, and bacteriuria can be difficult to eradicate. Treatment should be implemented if azotemia has progressed (and no other underlying cause for the progression has been documented) and serum creatinine or SDMA re-evaluated. If no improvement is noted, further antimicrobial treatment may not be indicated.

Animals with SBU should be evaluated for potential underlying causes of SBU that need to be addressed. If no underlying conditions are evident, treatment for SBU is not warranted. The authors advise treatment for SBU only for patients that are undergoing a urologic intervention (e.g., cystotomy or laser ablation for ectopic ureter) and at least once for dogs with SBU associated with *Staphylococcus* cystitis due to its association with struvite urolithiasis. Treatment is also indicated for SBU when there is an associated new or progressive azotemia, and the response to antimicrobial therapy monitored (clinical signs, severity of azotemia). Finally, urine cultures and treatment are indicated, despite a lack of LUTS, in animals where systemic infection is suspected.

Pyelonephritis

Treatment of dogs with acute pyelonephritis should be initiated immediately, without waiting for culture and susceptibility test results. Cytologic examination of stained urine sediment may assist in initial selection of an antimicrobial drug (i.e., based on the presence of rods versus cocci). The use of a fluoroquinolone that is excreted in the urine in active form (i.e., not difloxacin) has been recommended for gram-negative bacterial pyelonephritis, provided regional susceptibility data do not show widespread resistance to fluoroquinolones.[1,10] The dosage used may need to be altered depending on the severity of renal impairment. If combination treatment is initiated and antimicrobial susceptibility test results show susceptibility to only one drug, the other drug should be discontinued. In older veterinary literature, treatment durations of 4 to 6 weeks have been recommended for pyelonephritis, but a shorter duration is likely adequate, as is recommended in human medicine. Treatment for 10–14 days is recommended by the ISCAID Working Group. Oral antimicrobial therapy is justified for animals that are otherwise systemically healthy and have a normal fluid intake without vomiting. Intravenous antimicrobials should be administered to animals that are febrile, dehydrated, hyporexic, and/or vomiting. Dogs with acute pyelonephritis may require hospitalization and supportive care with IV fluids and other medications used to treat acute kidney injury or sepsis. The patient should be re-evaluated and serum creatinine, urinalysis, and an aerobic bacterial urine culture are recommended 1 week after completion of the antimicrobial treatment. The clinical and biochemical response should be evaluated. If a microbiologic cure is not documented, the clinician should be certain the patient was evaluated properly for underlying disorders (e.g., uroliths) and decide if the isolate is associated with ongoing pyelonephritis or SBU and treated accordingly. Underlying co-morbidities should be addressed if possible.

PREVENTION AND NON-ANTIMICROBIAL THERAPIES

Prevention of lower UTI involves identification and reversal of underlying causes of disease, such as vulvar fold dermatitis or congenital abnormalities such as ectopic ureter. Urinary catheterization should only be used when necessary, and intermittent catheterization is preferred to indwelling catheterization. If indwelling catheterization is required, a closed sterile collection system should always be used, and the catheter should be removed as soon as it is no longer required, because the risk of ascending infection increases with every day the catheter is left in place. Treatment of catheterized animals with antimicrobial drugs may increase the risk of bacterial infection,[65] so catheterized animals should only be treated with antimicrobial drugs when

necessary, and they should not be used in an attempt to prevent urinary catheter infection. Routine antimicrobial treatment after catheter removal is not indicated unless clinical signs of UTI develop, because colonization that follows catheterization is cleared once the catheter is removed and host defenses are restored.

Many treatments for prevention of UTI in dogs and cats with a history of recurrent disease have been considered. Currently, there is no evidence that urinary adjunct treatments such as antiseptics (e.g., methenamine), or nutritional supplements such as cranberry juice extract are effective in dogs or cats. There are numerous alternative/adjunct therapies that have been investigated for the prevention and treatment of recurrent bacterial cystitis in humans as well as animal models such as NSAIDS, estrogen compounds, intravesical glycosaminoglycans, cranberry extract, and live biotherapeutic products.[66] The efficacy of cranberry extract for treatment of recurrent UTI in women has been mixed. At the time of writing, the most recent placebo-controlled studies have shown no significant effect; however, patient selection appears critical. A reduction in UTI recurrence has been reported in other studies,[67] although it has not appeared to be as effective in patients with other co-morbidities. While cranberry has been shown to prevent adherence of *E. coli* strains in *in vitro* canine studies, no significant difference was noted in dogs with intervertebral disc disease to reduce the risk of UTI or SBU compared with placebo.[68]

Live biotherapeutic products appear promising for treatment of recurrent UTI and have the potential to reduce the need for antimicrobial therapy. Intravesicular administration of *E. coli* ASB strain 83972 in human beings with recurrent UTI reduced the symptoms of UTI and protected some patients from recurrent UTI after serial catheterizations. In a recent veterinary pilot study, intravesicular administration of ASB *E. coli* strain 212 to dogs with recurrent UTI resulted in complete or nearly complete clinical cures in four of nine dogs, and three had microbiologic cures at 2 weeks; one of these dogs had SBU after treatment (in addition to ASB *E. coli* 212) and did not require antimicrobial therapy. Long-term follow-up urine cultures were only available for two dogs. ASB *E. coli* 212 (as determined by PFGE analysis) was isolated 60 days after bacterial instillation and these two dogs remained free of LUTS for more than 6 months. Three of the four dogs had the ASB strain isolated from their urine at day 14. Further studies are underway to investigate treatment with this live biotherapeutic compared to antimicrobial administration in a larger population.[69]

PUBLIC HEALTH ASPECTS

Dogs and cats with UTI have a potential to act as a source of MDR bacteria for humans. Similarities between uropathogenic *E. coli* isolates from dogs and those from humans have been identified,[70,71] but differences also exist.[72] Owners of pets with MDR UTI should always wash their hands after handling their pets, wear gloves when medications are administered, and pets should be taken to urinate away from other people and animals.

ORCHITIS, EPIDIDYMITIS, AND PROSTATITIS

ETIOLOGY AND EPIDEMIOLOGY

Orchitis and epididymitis may occur in association with UTI in intact male dogs, but is rare. Infection with *Brucella canis* should always be suspected in dogs with epididymitis (see Chapter 71). *Escherichia coli* accounts for most cases of bacterial prostatitis in dogs, but occasionally other gram-negative and gram-positive organisms, including atypical organisms such as *Mycoplasma* spp. and *Brucella* spp., are involved. Bacterial prostatitis is extremely rare in cats.[73]

CLINICAL FEATURES

Pathophysiology and Clinical Signs

Bacterial prostatitis in dogs may be acute or chronic. It often accompanies benign prostatic hyperplasia or prostatic neoplasia, most likely as a result of ascending infection secondary to altered urinary defense mechanisms. Prostatitis should be suspected in any intact male dog that develops a UTI. Dogs with bacterial prostatitis may show infertility, fever, lethargy, decreased appetite, weight loss, LUTS, purulent or hemorrhagic urethral discharge, abdominal pain, and sometimes a stiff gait. Tenesmus, vomiting, and diarrhea may also occur in some dogs. Acute bacterial prostatitis can be accompanied by severe sepsis or septic shock (see Chapter 123). Formation of prostatic abscesses may be followed by abscess rupture and peritonitis. Dogs with chronic prostatitis may be lethargic or have no clinical signs of illness.

Physical Examination Findings

Dogs with acute bacterial prostatitis may exhibit pain on palpation of the prostate. The prostate may be normal in size and shape, or enlarged or irregularly shaped. Fluctuant regions may be palpated if abscesses are present. Palpation of genitourinary structures should always be performed cautiously when acute bacterial prostatitis is suspected so that rupture of prostatic abscesses does not occur. Hemorrhagic or purulent discharge may be seen around the urethral orifice. Dogs with severe acute prostatitis may be dehydrated, febrile, obtunded, and show other signs of severe sepsis or septic shock (e.g., tachycardia or bradycardia, tachypnea, prolonged CRT). Intact male dogs with bacterial orchitis or epididymitis may have testicular enlargement, hyperemia, and pain on palpation of the testicles. This may sometimes be present in association with prostatitis.

DIAGNOSIS

Diagnosis of prostatitis is based on clinical signs, laboratory abnormalities, imaging findings, and culture of urine or prostatic secretions. Measurement of serum canine prostate specific esterase (CPSE) has been proposed as a biomarker for prostatic disease in dogs[74]; such biomarkers may ultimately be useful to help distinguish benign prostatic hyperplasia from bacterial prostatitis.

Laboratory Abnormalities

Animals with acute prostatitis may have mild anemia, leukocytosis due to a neutrophilia, increased band neutrophils, and monocytosis. A degenerative left shift, toxic neutrophils, and thrombocytopenia may also be present. Hypoalbuminemia and electrolyte abnormalities may be present, or there may be evidence of organ dysfunction in dogs with septic shock. Hyperglobulinemia may be present in dogs with chronic prostatitis. The urinalysis may reveal abnormalities consistent with UTI.

Diagnostic Imaging

Plain and Contrast Radiography

Plain radiography is of limited value for diagnosis of bacterial prostatitis. Dogs with benign prostatic hypertrophy (BPH) or prostatic abscesses may have prostatomegaly, with ventral and cranial displacement of the bladder (defined as a prostate diameter > 70% of the distance between the pubis and the sacral promontory).[75] Prostatic mineralization can rarely accompany chronic bacterial prostatitis in intact dogs, but when present in a neutered dog, mineralization strongly supports the presence of prostatic neoplasia.[76] Extravasation of contrast material into the prostate during retrograde contrast cystourethrography supports a diagnosis of prostatitis or prostatic neoplasia.

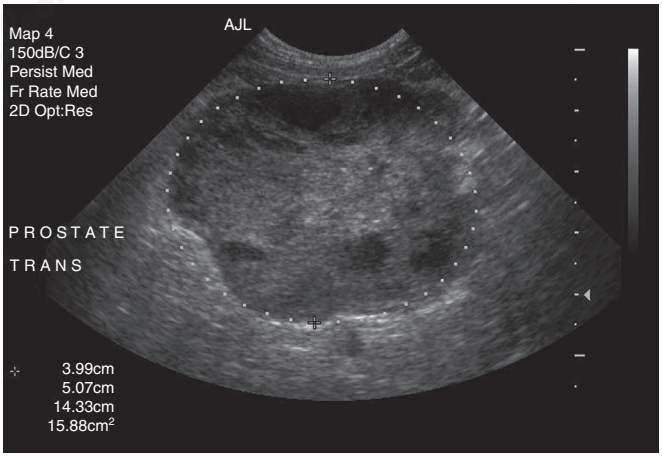

Fig. 127.7 Ultrasound image of the prostate of a 12-year-old intact male beagle dog that had acute prostatitis due to *Escherichia coli* and associated bacterial peritonitis. The dog was seen for acute onset of anorexia and vomiting and had 2,254 neutrophils/μL, 1,160 band neutrophils/μL, mild hypoalbuminemia (2.4 g/dL; reference range, 2.9–4.2 g/dL), increased serum alkaline phosphatase activity (1,338 U/L; reference range, 15–127 U/L), and increased serum total bilirubin concentration (0.5 mg/dL, reference range, 0–0.4 mg/dL). The prostate was significantly increased in size on sonographic examination and contained multiple hypoechoic nodules. There was a small quantity of ascites, which was predominantly localized in the caudal abdomen in the region of the prostate. Hemolytic *E. coli* was isolated from urine and from a prostatic aspirate. The owners elected euthanasia. Acute prostatitis and peritonitis were confirmed at necropsy.

Sonographic Findings

Sonographic abnormalities in dogs with prostatitis include prostatic irregularity, mixed echogenicity, and focal accumulations of anechoic or hypoechoic fluid, with distance enhancement (prostatic cysts or abscessation) (Fig. 127.7).[77]

Microbiologic Tests

Isolation and Identification

Many dogs with prostatitis shed bacteria into the urine; therefore, bacteria cultured from the urine are usually those involved in prostatitis (for collection methods, see Isolation and Identification section for UTI, earlier). Prostatic involvement should be suspected in any intact male dog with bacterial UTI. However, a negative urine culture does not rule out the possibility of prostatitis, and occasionally the organisms isolated from the urine may differ from those isolated from the prostate.

Collection of prostatic fluid via ejaculation, prostatic wash, or aspiration of the prostate or prostatic cysts is also recommended for diagnosis of bacterial prostatitis, particularly if the patient is refractory to treatment, neoplasia is suspected, or the urine culture is negative, and the prostate findings are suggestive for infection on ultrasonography. Aspirates of the prostate for culture and cytology (if clinically indicated) can be done in dogs with acute and chronic prostatitis; however, dogs with acute prostatitis may require sedation for patient comfort. The presence of large numbers of bacteria (>10^5 CFU/mL) together with an inflammatory response suggests infection. Cytologic examination and culture of ultrasound-guided aspirates of prostatic abscesses has been used to assist diagnosis, but there is a risk of localized peritonitis when abscessed tissues are aspirated.

Pathologic Findings

Dogs with acute prostatitis may have infiltrates of neutrophils with or without intralesional bacteria in the prostate on histopathology. Chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates. In some cases, prostatic hyperplasia or abscess formation are identified.

TREATMENT

Data are limited regarding the treatment duration for acute bacterial prostatitis, but 4 weeks of treatment with appropriate antimicrobials is recommended. For dogs with sepsis, parenteral antimicrobial administration initially may be required. If inflammation is severe, any drug appropriate for treatment of UTI may still penetrate the prostate in the acute phase.

Drug penetration is impaired in dogs with chronic prostatitis because of the blood-prostatic fluid barrier. Drugs that effectively cross the prostatic barrier of dogs include enrofloxacin, ofloxacin, marbofloxacin, trimethoprim, and chloramphenicol. Drugs such as the penicillins, cephalosporins, aminoglycosides, and tetracyclines are not able to cross an intact blood-prostate barrier and should be avoided, particularly in cases of chronic prostatitis. Ciprofloxacin should not be administered due to its variable GI absorption. Fosfomycin can be considered if an MDR gram-negative organism is isolated. Organisms may persist within the prostate of dogs with chronic prostatitis despite appropriate antimicrobial drug treatment. Because trimethoprim-sulfamethoxazole and chloramphenicol are more likely to be associated with adverse effects when administered for prolonged periods, a fluoroquinolone such as enrofloxacin is the drug of choice for initial treatment of gram-negative bacterial prostatitis. If the MIC of the organism is between 0.5 and 1.0 μg/mL, the highest dose of enrofloxacin is recommended (20 mg/kg, q24h). Clindamycin may be a reasonable choice for dogs with gram-positive bacterial prostatitis. Treatment of dogs with chronic prostatitis should continue for at least 6 weeks. Cure may not be possible without castration.

Surgical castration is recommended for dogs with prostatitis and can be considered as soon as the dog is stable to undergo anesthesia and surgery. The efficacy of drugs that cause prostatic involution, such as finasteride, is not clear, but finasteride enhanced the resolution of infection in a rat model of chronic prostatitis when administered with a fluoroquinolone.[78] Prostatic abscesses and paraprostatic or large intraprostatic cysts must also be addressed and treated using ultrasound-guided drainage or surgically if necessary. Castration and antimicrobial drug treatment alone does not effectively resolve prostatic abscesses.

Follow-up should consist of a return visit for examination 7 to 10 days after initiating treatment, and aerobic bacterial urine culture should be considered at this time if a positive urine culture was initially present. A return visit and examination should also be performed 1 week after discontinuation of treatment, at which time physical examination, urinalysis, urine culture, and prostatic fluid cytology and culture should be performed. Where available, prostatic ultrasound may also provide useful information at these follow-up times, and if possible, should be performed 1 week after discontinuation of antimicrobial drugs.

PREVENTION

Routine castration reduces the risk of prostatitis, although prostatitis can still occur in neutered animals.

VAGINITIS, METRITIS, AND PYOMETRA

ETIOLOGY AND EPIDEMIOLOGY

Bacterial vaginitis in adult bitches is usually secondary to an underlying disorder such as neoplasia, foreign bodies (e.g., grass awn), or seen

Fig. 127.8 Uterus of an 11-year-old female Pomeranian with pyometra during ovariohysterectomy. The left uterine horn was severely dilated and fluid-filled. (Courtesy of University of California, Davis, Veterinary Anatomic Pathology Service.)

concurrently with UTI or anatomic abnormalities such as strictures. Puppy vaginitis is thought to be a consequence of immaturity, rather than bacterial infection.

Metritis results from ascending infection of the uterus. It usually occurs shortly after parturition (e.g., within a week), or after obstetrical procedures, and may be associated with clinical signs of lethargy, fever, decreased appetite, and purulent vaginal discharge.

Pyometra is an accumulation of pus within the uterus (Fig. 127.8). The pathogenesis of pyometra is incompletely understood. However, in contrast to metritis, pyometra most often seems to occur as a result of increased serum progesterone concentrations, which cause cystic endometrial hyperplasia (CEH), impaired immune function, and decreased uterine contractility. The end result for at least some dogs and cats is opportunistic bacterial invasion, most often by *E. coli* strains that have virulence factors typical of uropathogenic isolates.[70,79] Bacterial biofilm may contribute to resistance to host immune defenses and antimicrobial drugs.[80] Other organisms that cause pyometra are similar to those that cause UTI, with the exception that anaerobes are more often involved, usually in mixed infections with other bacteria. CEH is not an absolute requirement for development of pyometra, and some animals with CEH never develop pyometra. Exogenous estrogen administration (used to treat mismating), as well as exogenous progesterone administration, have also been associated with pyometra.[81] Rarely, pyometra occurs in conjunction with uterine neoplasia.[82,83] Emphysematous pyometra has been reported in dogs but is uncommon; less than 10 cases have been reported in the literature.[84–87] Etiologic agents in emphysematous pyometra have included *C. perfringens*, *Citrobacter diversus*, and *P. aeruginosa*.

In dogs, pyometra usually occurs in diestrus, but it can occur in anestrus. Affected dogs are usually middle-aged to older, intact female dogs (mean age around 7 to 9 years), but pyometra has been reported in dogs as young as 8 months of age. Older dogs are likely to develop pyometra as a result of chronic and repeated exposure to progesterone with progressive cycles, whereas younger dogs may develop pyometra as a result of treatment of mismatings with estrogens. Pyometra is prevalent in regions where routine ovariohysterectomy of dogs is not widely performed; it has been estimated that 19% of all intact bitches develop pyometra before 10 years of age.[88] In a study from Scandinavia, breeds of dogs with increased risk included collies, rottweilers, Bernese mountain dogs, Cavalier King Charles spaniels, English cocker spaniels, and golden retrievers.[89,90] Bitches that have never been pregnant are at increased risk for development of pyometra compared with those that have had litters, but false pregnancy does not influence the risk for pyometra in dogs. In cats, CEH also seems to underlie pyometra. Cats with pyometra are generally > 3 years of age (mean, 5 years), but pyometra may occur in cats of any age.

CLINICAL FEATURES

Clinical Signs

Clinical signs of pyometra in dogs usually occur 2 to 10 weeks after estrus or breeding, but occasionally occur as long as 15 weeks after estrus (mean, 7 weeks). In both dogs and cats, clinical signs may be acute or chronic, and include lethargy, polyuria and polydipsia, vomiting, weight loss, decreased appetite, diarrhea, fever, and abdominal pain. Cats may have an unkempt haircoat. However, some dogs or cats show no signs of illness. Animals with *open-cervix pyometra*, the most common form of pyometra (>60% of dogs), usually have purulent vaginal discharge. The discharge may have a fetid odor, be mucopurulent, purulent, or contain blood. Dogs or cats with *closed-cervix pyometra* do not have vaginal discharge, but abdominal distention may be present. Animals with closed pyometra are more likely to have severe signs of systemic illness than those with open pyometra.[91] In one study, sepsis was more likely to occur in dogs with closed-cervix pyometra (77% of 39 dogs) than in dogs with open-cervix pyometra (51% of 71 dogs).[91] Concurrent glomerular and tubulointerstitial disease may also contribute to signs of polyuria and polydipsia.[92] In some dogs or cats, pyometra may be accompanied by severe sepsis or septic shock (see Chapter 123). Peritonitis may occur secondary to rupture of the uterus when disease is severe. Dogs with leukopenia were 18-fold more likely to have peritonitis as a complication of surgery than those that were not leukopenic.[93]

Stump pyometra is an uncommon form of pyometra. It sometimes occurs after remnants of the ovaries are inadvertently left in place after ovariohysterectomy, but this is not always identified. Stump pyometra occurs most commonly in dogs, but has been reported in the cat.[94] Clinical signs are similar to animals with pyometra. In addition, stump pyometras can contribute to recurrent lower UTI. When evaluated by ultrasound, the uterine stump was enlarged in a small group of dogs treated with estriol for urinary incontinence, without apparent adverse systemic effects.[95]

Physical Examination Findings

Purulent vaginal discharge, sometimes with a putrid odor, may be present in animals with bacterial vaginitis or open pyometra. Fever may be present in some dogs and cats with pyometra, and is more likely in closed-cervix pyometra. Abdominal pain may be present on palpation of the abdomen, which should always be performed cautiously when pyometra is suspected so that rupture of the uterus does not occur. Dogs and cats with severe pyometra may be lethargic, dehydrated, and show signs of severe sepsis or septic shock.

DIAGNOSIS

Diagnosis of vaginitis, metritis, and pyometra is based on signalment and history, clinical signs, laboratory abnormalities, imaging findings, and, in some cases, culture of the urine or uterine contents obtained during surgery.

Laboratory Abnormalities

Acute metritis or pyometra (especially closed-cervix pyometra) may be associated with anemia, leukocytosis due to a neutrophilia, increased band neutrophils, degenerate left shifts, toxic neutrophils, and monocytosis, especially if the cervix is closed.[91] Thrombocytopenia and signs of organ dysfunction (such as azotemia, increased serum ALP activity, and coagulation abnormalities) may be detected in dogs with severe sepsis or septic shock. Azotemia may also reflect the presence of concurrent pyelonephritis. Hypoalbuminemia and electrolyte abnormalities such as low serum sodium-to-potassium ratios may be present.[96,97] Dogs and cats with chronic pyometra may have few laboratory abnormalities; some animals with chronic pyometra may be hyperglobulinemic. On urinalysis, there may be abnormalities consistent with UTI. UPCRs may be increased as a result of renal tubular or glomerular injury.[92]

Diagnostic Imaging

Plain Radiography

Radiographic changes in dogs with pyometra consist of the presence of a large, coiled or tubular mass in the caudal and mid-abdomen, which displaces the small intestine cranially and dorsally. However, the uterus may not be visible in dogs with open pyometra. Differentiation of pyometra from pregnancy may require ultrasound examination. Localized or generalized loss of abdominal detail may be present in dogs with peritonitis secondary to uterine or prostatic rupture.

Sonographic Findings

Ultrasound is the imaging technique of choice for diagnosis of pyometra and differentiation of pyometra from pregnancy. However, it may not effectively distinguish pyometra from mucometra or hydrometra. Dogs with pyometra have an enlarged uterus, which is immediately dorsal to the bladder. The uterus may be thin-walled and distended with echogenic intraluminal fluid, or have a thickened wall with anechoic areas due to glandular proliferation and enlargement (CEH).[98] Assessment of uterine blood flow may help to distinguish pyometra from CEH, one study showing that dogs with pyometra had significantly higher uterine blood flow than dogs with CEH or healthy dogs.[99] In one dog with emphysematous pyometra, the uterus had a homogenously hypoechoic wall and was distended with gas, in contrast to the layered wall of the adjacent colon.[87] Stump pyometra may be recognized as a hypoechoic structure that is located dorsal and caudal to the urinary bladder (Fig. 127.9). It is important to record any concurrent estrogen exposure or administration when interpreting the uterine stump size in dogs. The maximum uterine height/aorta ratio was greater in dogs receiving estriol for urinary incontinence when compared with healthy dogs not receiving estrogen therapy. While this structure appeared ultrasonographically abnormal in these dogs, no clinical consequences were noted.[95]

Microbiologic Tests

Isolation and Identification

Bacteria cultured from the urine are usually those involved in pyometra, although a negative urine culture does not rule out the possibility of pyometra, and occasionally the organisms isolated from the urine differ from those isolated from the uterus. Fine needle aspiration of the uterus is contraindicated because of the risk of uterine rupture. Usually, the bacteria involved are initially identified through culture of urine. Cystocentesis should always be performed with ultrasound guidance in animals suspected to have pyometra to avoid inadvertent perforation of the uterus. For animals with open pyometra, culture of a swab specimen that has been collected from the cranial aspect of the vagina could be considered, but the identity of the bacteria cultured may or may not be the same as those present within the uterus; therefore, this approach is not recommended. Tissues removed surgically can be submitted for culture and susceptibility testing, and this should be done despite the administration of broad-spectrum antimicrobial drugs before surgery, because these drugs are unlikely to penetrate pus within the uterus. If possible, both anaerobic and aerobic bacterial cultures should be performed for dogs or cats with pyometra. Blood cultures could be considered when signs of severe sepsis are present.

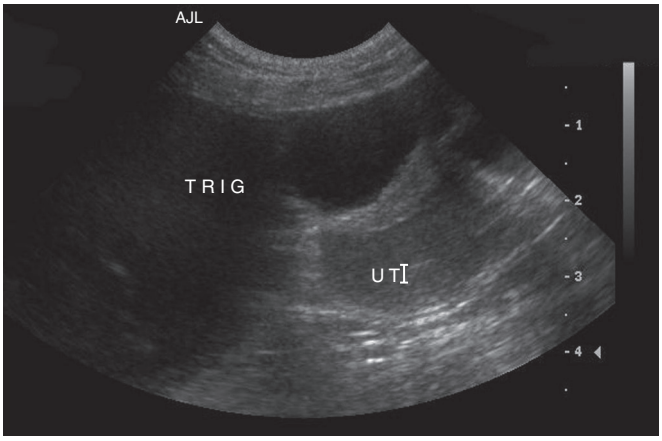

Fig. 127.9 Ultrasound image of the bladder and uterine stump in a 3-year-old female spayed mixed-breed dog that had vaginal discharge with a putrid odor due to a stump pyometra. An oval shaped structure (*UT*) that contained flocculent material is present within the pelvic inlet caudal to and dorsal to the anechoic urinary bladder. A cystic structure is seen in the region of the left ovary which represented a left ovarian remnant.

Pathologic Findings

As for other urogenital infections, acute pyometra is associated with a dense neutrophilic infiltrate on histopathology (Fig. 127.10) and intralesional bacteria may be identified; chronic infections may be associated with histiocytic or lymphoplasmacytic infiltrates. CEH (expansion of the endometrium with hyperplastic, dilated to cystic glands) and corpora lutea may also be identified.

TREATMENT AND PROGNOSIS

The overall prognosis for dogs with pyometra is good, with one study reporting an overall mortality rate of 10%, when euthanasias are included, to as low as 1% for surgically treated cases.[93] Sick dogs or cats with metritis or pyometra should be treated aggressively with IV fluids and broad-spectrum parenteral antimicrobial drugs that have activity against gram-negative bacteria and anaerobes, such as a combination of clindamycin and a fluoroquinolone. Ovariohysterectomy is strongly recommended for animals with pyometra, and may need to be performed on an emergency basis to resolve sepsis or septic shock. Caution is required to avoid rupture of a distended or friable uterus during surgery, because this has been associated with increased mortality (<10% to around 50%). Risk factors for peritonitis in one study were leukopenia and abnormal rectal temperature.[93] Laparoscopic approaches have been described,[100] but these should be reserved for uncomplicated cases. Reevaluation should be performed 1 week after discharge from hospital, and should include physical examination, a CBC,

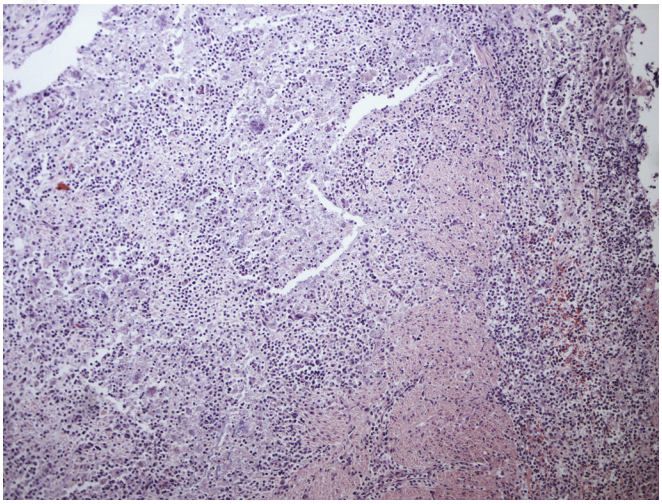

Fig. 127.10 Histopathology of the uterus from a 7-year-old female poodle with pyometra. The dog was seen for vomiting, inappetence, obtundation, nystagmus, collapse, and abdominal distention. The owner elected euthanasia. Severe, chronic, suppurative metritis with uterine perforation and septic peritonitis was found at necropsy. Aerobic and anaerobic bacterial culture of the abdominal fluid yielded mixed growth that consisted of *Escherichia coli* and a nonenteric gram-negative aerobic bacterial species, a *Bacteroides levii*-like anaerobe, *Bacteroides fragilis*, *Prevotella heparinolyticus*, *Fusobacterium nucleatum*, and *Peptostreptococcus anaerobius*. Hematoxylin and eosin stain.

biochemistry panel, and urinalysis. Usually, there is a rapid response to treatment and hematologic and biochemical abnormalities resolve within this time period. The white cell count may increase dramatically after surgery before it returns to normal. Antimicrobial drug treatment should be continued for 7 to 10 days after ovariohysterectomy.

In conjunction with antimicrobial drug treatment, medical treatment with natural or synthetic prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which causes lysis of the corpora lutea, to expel uterine contents may be possible for dogs with open pyometra that are young (<6 years of age), and otherwise in good health (Table 127.4). Medical treatment for pyometra alone is not recommended for dogs that are systemically unwell, and the possibility of pregnancy must first be ruled out with ultrasound. Medical treatment is also less attractive for dogs with closed pyometra because: (1) it risks uterine rupture; (2) it is less effective than in dogs with open pyometra; and (3) dogs are often systemically unwell. However, it has been used with success in some dogs. Medical treatment is most likely to be successful in dogs that are in late diestrus (>5 weeks after the end of estrus). Improvement is generally not evident for at least 48 hours, and adverse reactions such as restlessness, hypersalivation, panting, vocalization, vomiting, diarrhea, mydriasis, and fever are common with $PGF_{2\alpha}$, so treatment should be given in the morning on an empty stomach, hospitalization and observation is recommended for at least 4 hours after the injection (or throughout the treatment period in dogs with closed pyometra), and the dose should be carefully calculated and be appropriate for the product used. Signs of shock may develop in some dogs treated with $PGF_{2\alpha}$. Walking dogs for 20 to 40 minutes after drug administration (while adverse effects occur) may lessen the adverse effects and also promotes close observation.[101] The severity of signs tends to decrease with each injection administered. Serial abdominal ultrasound examinations are recommended every 2 days during treatment for dogs with closed pyometra to evaluate for peritonitis. $PGF_{2\alpha}$ can also be used to treat postpartum metritis.

TABLE 127.4 Published Treatment Protocols for Medical Therapy of Pyometra in Dogs and Cats[101–104]

Drug	Dose[a]
Natural $PGF_{2\alpha}$ (Lutalyse)	0.1 mg/kg SC once (day 1), 0.2 mg/kg SC once (day 2), 0.25 mg/kg SC q24h (days 3 to 7)
Aglepristone	10 mg/kg SC once on days 1, 3, 6, and 9
Aglepristone and cloprostenol	Aglepristone: 10 mg/kg SC once on days 1, 2, and 8 Cloprostenol: 1 μg/kg SC for 5 days on days 3 through 7

[a]Day 1 = day of diagnosis.

Aglepristone (RU534) is a progesterone receptor antagonist that is available in Europe for treatment of pyometra. Aglepristone appears to be a safe and effective alternative to $PGF_{2\alpha}$ in both dogs and cats.[102] Addition of low-dose cloprostenol (a synthetic $PGF_{2\alpha}$ derivative) to aglepristone in one study increased the success rate in dogs with open pyometra from 60% to 84%.[103] Aglepristone (10 mg/kg SC) has been administered at 0, 1, and 6 days after diagnosis. A modified protocol where aglepristone is administered at 0, 2, 5, and 8 days after diagnosis, together with a relatively short (6 days) duration of clavulanic acid-amoxicillin therapy was effective in all of 47 dogs, without the need for ovariohysterectomy, compared with 89% of 26 dogs using the traditional protocol.[104] No recurrence was noted in a 24-month follow-up period, and approximately 80% of dogs subsequently whelped.

All dogs treated medically should be re-evaluated 2 weeks after treatment. If signs of pyometra persist, culture of a swab specimen obtained from the cranial vaginal vault should be performed to determine if resistance to antimicrobials is present, and treatment should be repeated a second time or surgery performed. The measurement of serum progesterone to monitor effective treatment is not necessary because it does not change treatment recommendations. After successful treatment, the dog or cat should be bred at each subsequent cycle until pregnancy occurs. The chance that subsequent pregnancy will occur is over 80%, and the vast majority of dogs that respond go on to have more than one litter. Once the dog or cat is no longer required as a breeding animal, it should be neutered.

PREVENTION

Routine ovariohysterectomy reduces the risk of pyometra, although stump pyometra can still occur in neutered animals. There is no known treatment for CEH. Use of estrogens to treat mismatings is not recommended.

CASE EXAMPLE

Signalment

"Molly," a 6-year-old female spayed shih tzu mix from Sacramento, CA.

History

Molly was brought to the University of California, Davis VMTH for evaluation of recently diagnosed nephrolithiasis and hematuria. Three weeks previously, Molly's groomer noted blood on the towel she had been sitting on. The owners subsequently observed blood in Molly's urine and took her to their local veterinary clinic. There had been no stranguria, polyuria, polydipsia, or change in the frequency of urination. Blood work was performed in the clinic; the hematocrit was 56.5% and thrombocytopenia (86,000 platelets/μL) was present. A urine dipstick analysis revealed 2+ protein, a pH of 8, hematuria, and pyuria. The urine SpG was 1.014. A 3-cm opacity in the right renal pelvis that was consistent with a nephrolith was found on abdominal radiographs (see Fig. 127.4). The kidneys had a mildly irregular shape but were normal in size. Treatment with amoxicillin was initiated (23 mg/kg, PO, q12h for 10 days). After 12 days, the dog was evaluated for dental prophylaxis. A CBC showed a hematocrit of 50% and persistent thrombocytopenia (51,000 platelets/μL). An abdominal ultrasound (performed by a mobile board-certified veterinary radiologist) showed a 2.9-cm right renal pelvic calculus and a 7-mm left renal pelvic calculus. The kidneys were normal in size but had a mildly irregular shape. There was moderate thickening of the apical wall of the urinary bladder, with small (4 mm) apical polyp formation. Moderate flocculent suspended debris was present within the urine and multiple very small sand-like calculi were present. All other organs evaluated were within normal limits.

Other Medical History

There had been no history of vomiting, diarrhea, coughing, sneezing, or trauma. Molly had traveled frequently to Oregon and Nevada. There had been no change in her water consumption. She was fed a stone dissolution diet (Royal Canin Urinary SO), which had been prescribed 4 years ago when crystals were seen in her urine on urinalysis, as part of a wellness examination. She was also occasionally fed dog treats. She had been vaccinated for CDV, CAdV, CPV, and rabies; and *Bordetella bronchiseptica*, CCoV, leptospirosis, and Lyme disease. She was treated with imidacloprid and ivermectin for flea and heartworm prophylaxis, respectively, each month.

Physical Examination

Body weight: 10.8 kg.

General: Bright and alert, hydrated. T = 101.6°F (38.7°C), HR = 128 beats/minute, RR = 32 breaths/minute, mucous membranes pink and moist, CRT < 1 second.

Eyes, ears, nose, and throat: Mild epiphora bilaterally. There was mild dental calculus and gingivitis. Otherwise no clinically significant abnormalities were detected.

Integument: Abdomen clipped from previous ultrasound examination with healing clipper wounds. There was a 1-cm ecchymosis on the ventral abdomen.

Musculoskeletal: BCS 7/9. Ambulatory with normal gait.

Cardiovascular: Sinus arrhythmia. No murmurs auscultated. Femoral pulses strong and synchronous.

Genitourinary/GI: Soft, mildly painful abdomen. The bladder was moderate sized. Rectal examination was unremarkable. There was no vulvar discharge and no evidence of perivulvar dermatitis. A slightly recessed vulva was present.

Other systems, including peripheral lymph nodes: No clinically significant findings.

Laboratory Findings

CBC: HCT 49.1% (40%–55%), MCV 70.3 fL (65–75 fL), MCHC 35.0 g/dL (33–36 g/dL), nRBC 1/100 WBC, WBC 10,200 cells/μL (6,000–13,000 cells/μL), neutrophils 7,140 cells/μL (3,000–10,500 cells/μL), band neutrophils 102 cells/μL, lymphocytes 1,632 cells/μL (1,000–4,000 cells/μL), monocytes 816 cells/μL (150–1,200 cells/μL), platelets 12,000 platelets/μL (150,000–400,000 platelets/μL), MPV 21.6 fL (7–13 fL). Slight anisocytosis and many macroplatelets were reported on smear evaluation.

Serum chemistry profile: Sodium 148 mmol/L (145–154 mmol/L), potassium 4.0 mmol/L (3.6–5.3 mmol/L), chloride 111 mmol/L (108–118 mmol/L), bicarbonate 23 mmol/L (16–26 mmol/L), phosphorus 3.6 mg/dL (3.0–6.2 mg/dL), calcium 10.1 mg/dL (9.7–11.5 mg/dl), BUN 12 mg/dL (5–21 mg/dL), creatinine 0.9 mg/dL (0.3–1.2 mg/dL), glucose 92 mg/dL (64–123 mg/dL), total protein 6.1 g/dL (5.4–7.6 g/dL), albumin 3.4 g/dL (3.0–4.4 g/dL), globulin 2.7 g/dL (1.8–3.9 g/dL), ALT 42 U/L (19–67 U/L), AST 16 U/L (19–42 U/L), ALP 85 U/L (21–170 U/L), cholesterol 257 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.013; pH 8.0, 2+ protein (SSA), 1+ bilirubin, 4+ hemoprotein, no glucose, no ketones, >100 WBC/HPF, 30–50 RBC/HPF, no crystals or casts, many rods, rafts of atypical transitional cells, many degenerated cells.

Coagulation panel: PT 9.9 seconds (7.5–10.5 seconds), PTT 8.4 seconds (9.0–12.0 seconds), fibrinogen 395 mg/dL (90–255 mg/dL).

Microbiologic Testing

Direct smear of urine: Moderate numbers of gram-negative rods and gram-positive cocci were visualized.

Aerobic bacterial urine culture and susceptibility (cystocentesis specimen): 10^5 CFU/mL *Proteus mirabilis*, *P. mirabilis* (non-swarming strain), and *Enterococcus faecalis*. Both *Proteus* spp. were resistant to ampicillin (≥256 μg/mL) but susceptible to clavulanic acid-amoxicillin (4 μg/mL), cephalexin (8 μg/mL), chloramphenicol (≤16 μg/mL), enrofloxacin (≤1 μg/mL), tetracycline (64 μg/mL), and trimethoprim-sulfamethoxazole (≤4 μg/mL). The *E. faecalis* was susceptible to ampicillin, clavulanic acid-amoxicillin (≤2 μg/mL), chloramphenicol (≤16 μg/mL), enrofloxacin (≤1 μg/mL), and tetracycline (16 μg/mL).

Diagnosis

Proteus mirabilis and *E. faecalis* cystitis and suspected pyelonephritis with nephrolithiasis, with possible secondary ITP.

Treatment

Molly was treated with enrofloxacin (7 mg/kg, PO, q24h). The following day her platelet count had increased to 31,000 platelets/μL, and by day 3 of treatment it was 64,000 platelets/μL. After 7 days of treatment, a CBC showed a neutrophil count of 5,700/μL, no band neutrophils, and the platelet count was 79,000 platelets/μL. A urine culture obtained by cystocentesis at this time showed 10^4 CFU/mL of *E. coli* and *E. faecalis*. The *E. coli* was resistant to ampicillin, cephalexin, enrofloxacin, tetracycline, and trimethoprim-sulfamethoxazole, but susceptible to clavulanic acid-amoxicillin (64 μg/mL). The susceptibility of the *E. faecalis* had not changed, with the exception that the MIC for tetracycline was 32 μg/mL. Treatment was changed to clavulanic acid-amoxicillin (23 mg/kg, PO, q12h). When re-evaluated 3 weeks later, she had no clinical signs of illness. A CBC showed only mild thrombocytopenia (146,000 platelets/μL, with an MPV of 12.6 fL). However, bacteria and large numbers of WBCs were still present in the urine sediment, the urine pH was 8.0, and *E. coli* with the same susceptibility pattern was again isolated from the urine. An extended panel showed susceptibility to amikacin (≤4 μg/mL) and imipenem-cilastatin (≤1 μg/mL), but resistance to cefazolin, cefoxitin, cefpodoxime, cephalothin, gentamicin, marbofloxacin, orbifloxacin, and ticarcillin-clavulanic acid. The dosage of clavulanic acid-amoxicillin was increased to 23 mg/kg, PO, q8h. The diet was changed to a stone dissolution diet. After an additional month, urinalysis findings were unchanged and the same *E. coli* was again isolated from the urine. The platelet count was 244,000 platelets/μL and a biochemistry panel was unremarkable. Abdominal radiographs and ultrasound showed no evidence of nephrolithiasis, but multiple small, rounded mineral opacities were present in the region of the right ureter.

Antimicrobial drug treatment was ultimately changed to amikacin (15 mg/kg, SC, q24h) 2 weeks later because an *E. coli* was isolated that was resistant to

CASE EXAMPLE—cont'd

clavulanic acid-amoxicillin. Kidney values were monitored every 2 weeks during amikacin treatment to evaluate for nephrotoxicity. The urine then became sterile and ultrasound examination showed disappearance of all urinary calculi over a 2-month period, after which antimicrobial drug treatment was discontinued and the diet was changed to a maintenance diet. Because of the recessed vulva and the dog's excess body condition, a weight loss program was discussed with the owner. Molly was diagnosed with a subclinical *Enterobacter aerogenes* UTI 2 months later, which was broadly susceptible to antimicrobial drugs and treated with enrofloxacin. The platelet count was within the reference range. Further evaluation for underlying conditions predisposing to recurrent UTI (contrast cystourethrography and cystoscopy), followed by vulvoplasty if no other abnormalities were detected, were offered to the owners but further treatment and evaluation was not pursued. The dog remained alive, untreated, and without clinical signs 4 years later, at which time hematology and biochemistry panel results were unremarkable, but MDR *E. coli* was repeatedly isolated from the urine.

Comments

This is an interesting case of bacterial cystitis and pyelonephritis associated with struvite nephrolithiasis, and probable secondary ITP. The struvite urolithiasis was likely secondary to the *P. mirabilis* infection. Months of antimicrobial treatment were necessary because of bacterial sequestration within urinary calculi. This may have explained continued isolation of bacteria from the urine in the face of antimicrobial drug treatment, although ultimately resolution of the *E. coli* infection quickly followed the change in antimicrobial drug choice. Meropenem would have been another appropriate choice based on the susceptibility of the organism isolated, but is often reserved for life-threatening infections in human patients. Fortunately, dissolution of the nephroliths occurred with antimicrobial and dietary therapy, and surgery to remove infected uroliths was not required. Continued UTI was a likely sequela in this dog in the absence of successful identification and treatment of an underlying cause. Although treatment of the UTI was necessary during nephrolith dissolution, treatment of the subclinical *E. aerogenes* infection may not have been necessary.

Ocular Infections

Jean Stiles

KEY POINTS

- Infections of the eye can involve the ocular surface and adnexal structures, intraocular structures, or both.
- Infections of the ocular surface and adnexal structures often result from invasion by commensals when normal barriers are disrupted, and include infectious blepharitis, conjunctivitis, keratitis, dacryocystitis, and orbital infection.
- Intraocular infections may arise secondary to local injury or occur as part of a systemic process. A large number of viruses, bacteria, fungi, protozoa, and helminths can cause intraocular disease. Sometimes ocular abnormalities are the only outward clinical manifestation of systemic infectious disease.
- Examination of specimens from ocular tissues or ocular fluids can facilitate diagnosis of ocular infectious diseases, and may assist in the diagnosis of systemic infections.
- Treatment of ocular disorders typically involves topical administration of antimicrobials and anti-inflammatory drugs, as well as specific therapy that is directed at underlying causes. Systemic antimicrobial drugs or glucocorticoids are occasionally required.

INFECTIONS OF THE OCULAR SURFACE AND ADNEXA

ETIOLOGY, EPIDEMIOLOGY, AND PATHOGENESIS

Most surface bacterial infections follow other debilitating conditions that potentiate the pathogenicity of organisms that are indigenous to the ocular surface. Despite the fact that all dogs probably have indigenous bacteria in their conjunctival cul-de-sac, bacterial isolation rates of between 46% and 91% have been reported from apparently healthy dogs (Table 128.1). Variations in the type and frequency of isolates may be a result of geography, culture technique, breed, and season. Fungi are isolated from the conjunctival sac of 10 to 22% of dogs.[1,2]

Cats have a relatively lower prevalence of cultivable bacteria in their conjunctival sacs.[3] Bacteria or mycoplasmas have been isolated from 34% of conjunctival specimens and 25% of lid margin specimens. In one study of 50 cats (100 eyes), no organisms were isolated from 42% of the cats, bacteria were isolated from the conjunctival sacs of 34% of cats (47% of eyes), and fungi were isolated from 26% of the cats (14% of eyes) (Table 128.2). No anaerobes were isolated.[4]

Abnormalities that contribute to local nidi of infection, such as those of the nasolacrimal (NL) system and meibomian glands or structures adjacent to the eye (ears, lip folds), should be sought and corrected to overcome persistent or recurring infection. Control of the resident ocular flora of clinically healthy animals is maintained by rinsing of the ocular surface with tears and blinking, which directs tears into the NL system. Tears also contain IgA and other antibacterial substances such as lactoferrin and lysozyme. Competitive interactions among the indigenous flora keep the numbers of organisms lower, whereas disrupting this balance may cause an overgrowth of one species. Conditions that damage the ocular surface, such as keratoconjunctivitis sicca (KCS), ultraviolet or other radiation, immune suppression, and trauma can allow indigenous bacteria to adhere and proliferate to produce disease. To become established, bacteria must adhere, replicate, and then invade the tissue. Invasion subsequently incites inflammation. Tissue damage results from a combination of pathogen toxins and enzymes such as collagenase, elastase, and cathepsins that are liberated by the neutrophilic response.[5] Bacteria that produce proteolytic enzymes such as *Pseudomonas aeruginosa* typically cause rapidly progressive "melting" corneal ulcers.

CLINICAL FEATURES AND TREATMENT

Blepharitis

Dogs

Blepharitis (inflammation of the eyelids) can develop secondary to bacterial, fungal, or parasitic infection. Blepharitis can result from other dermatologic diseases, and sometimes may occur in conjunction with ocular diseases, such as conjunctivitis. Allergic skin disease was the most common underlying cause in 102 dogs from Germany with blepharitis (52% of dogs), followed by infectious/parasitic disease (22%), autoimmune disease (18%), and neoplasia (5%).[6] Brachycephalic breeds were at risk for blepharitis when compared to the hospital population. Infectious diseases were demodicosis, leishmaniosis, and dermatophytosis. Parasitic infection of the eyelids was always accompanied by periocular dermatitis. Secondary bacterial infection of the eyelids may occur with any of these conditions, as well as with KCS. *Staphylococcus* spp. can cause primary blepharitis and can also generate a hypersensitivity reaction. Pruritis can lead to self-trauma, which exacerbates the blepharitis. In a 2020 study, *Staphylococcus pseudintermedius* was isolated from 38 (40%) of 72 dogs and 24 cats with conjunctivitis/blepharitis, keratitis, or uveitis, and 3 (8%) of the 38 isolates were methicillin-resistant; 2 of the isolates were from dogs with conjunctivitis/blepharitis.[7]

Clinical features of blepharitis include eyelid swelling, erythema, skin ulceration, chalazia (granulomatous foci of inflammation along meibomian glands), pruritis, and ocular discharge (serous or purulent) (Fig. 128.1).

Treatment of bacterial blepharitis should include cleansing the skin with a povidone-iodine solution (1:50 dilution) and application of a broad-spectrum ophthalmic antibiotic ointment to affected skin and the eye q6-8h. If the skin is very inflamed, a product that contains an antibiotic and dexamethasone is indicated. Severe blepharitis may require systemic antibiotic therapy such as a cephalosporin

TABLE 128.1 Bacteria Isolated from the Conjunctival Sacs of Apparently Healthy Dogs[50,51]

Organism	% of Positive Specimens[a]
Staphylococcus spp.	57–70
Coagulase-positive	24–45
Coagulase-negative	46–55
Streptococcus spp.	6–43
Nonhemolytic	12–51
α-Hemolytic	4–34
β-Hemolytic	2–7
Corynebacterium spp.	30–75
Undifferentiated	11
Corynebacterium pseudodiphtheriticum	9
Corynebacterium xerosis	13
Neisseria spp.	26
Undifferentiated	4
Neisseria catarrhalis	9
Neisseria pharyngis	4
Neisseria sicca	3
Neisseria caviae	3
Neisseria lactamica	3
Neisseria flavescens	3
Pseudomonas spp.	14
Moraxella spp.	7
Bacillus spp.	6–18

[a]Percentages are based on the numbers of animals from which organisms were isolated.

TABLE 128.2 Bacterial and Fungal Isolates from Ocular Tissues of Apparently Healthy Cats[3,4]

Location	Organism	% of Positive Specimens[a]
Conjunctiva	*Staphylococcus spp.*	27
	Corynebacterium spp.	1.3–5
	Bacillus spp.	3–5
	Streptococcus spp.	2–2.5
	Mycoplasma	0–5
	Fungal isolates	13
Lids	*Staphylococcus spp.*	23–28
	Streptococcus spp.	0–2
	Bacillus spp.	2–5
	Corynebacterium spp.	1.6

[a]Percentages are based on the numbers of animals from which organisms were isolated.

Fig. 128.1 Blepharitis in a dog. Note swelling, erythema, and ulceration of eyelids. Purulent ocular discharge is present at the medial canthus.

and possibly anti-inflammatory doses of an oral glucocorticoid. Oral prednisone at anti-inflammatory to immunosuppressive doses was not found to influence tear production in healthy dogs and those with histamine-induced conjunctivitis.[8] Any underlying condition that can be identified should be addressed. Failure of severe blepharitis to respond to antimicrobial therapy should prompt specimen collection for culture and susceptibility testing.

Canine juvenile pyoderma or cellulitis, which typically develops in puppies aged 3 to 16 weeks, often involves the conjunctiva and eyelids (Fig. 128.2). Four of the 102 dogs in the German study had juvenile cellulitis as the underlying cause of blepharitis.[6] Although the cause is unknown, the response to treatment suggests it to be immune-mediated. Pustules and pyogranulomatous inflammation develop in the eyelids, face, and ears. Conjunctivitis is usually present. Mandibular lymphadenomegaly is common. Puppies may be febrile and have generalized malaise. Swelling of joints or metaphyses may also be observed. Diagnosis is based on age, history, and clinical signs. Prednisolone (1 mg/kg PO q12h) should be administered for 2 to 3 weeks. An oral antibiotic may be used if skin infection is suspected. A topical preparation such as neomycin-polymyxin B-dexamethasone q6-8h is indicated for conjunctivitis. Lesions typically improve within a few days of beginning therapy and resolve completely within 3 weeks.

Cats

Cats appear relatively resistant to bacterial blepharitis, except when they have a traumatic injury and resulting bacterial invasion. This type of injury most commonly occurs in cat fights and can involve the head and eyelids. Abscesses near the eyelids should be drained and appropriate systemic antibiotics administered. *Leishmania infantum* can cause blepharitis in cats in endemic areas.[9]

Conjunctivitis

Dogs

Bacterial conjunctivitis can be a primary condition or secondary to another ocular condition such as KCS, entropion or trichiasis, CDV infection, parasites (e.g., *Thelazia* spp.), trauma, or foreign bodies. Primary bacterial conjunctivitis typically occurs for unknown reasons and in some cases is secondary to an insult that is no longer apparent or is merely an overgrowth of resident conjunctival microflora. Clinical signs are purulent discharge and conjunctival hyperemia with mild to moderate discomfort. Diagnosis should be based on cytologic examination of the exudate and identification of bacteria and neutrophilic inflammation. Because bacterial overgrowth occurs when tear production is low, KCS should be ruled out based on a normal Schirmer tear test result. Culture and susceptibility testing should be performed, especially if the response to therapy is poor or the problem is recurrent. A complete ocular exam, including a Schirmer tear test, fluorescein staining of the cornea, fluorescein evaluation of NL duct patency, and a search for a foreign body in the conjunctival sac and behind the third eyelid, should be performed. Therapy should include a broad-spectrum topical antibiotic such as bacitracin-neomycin-polymyxin B or tobramycin q6h until resolution.

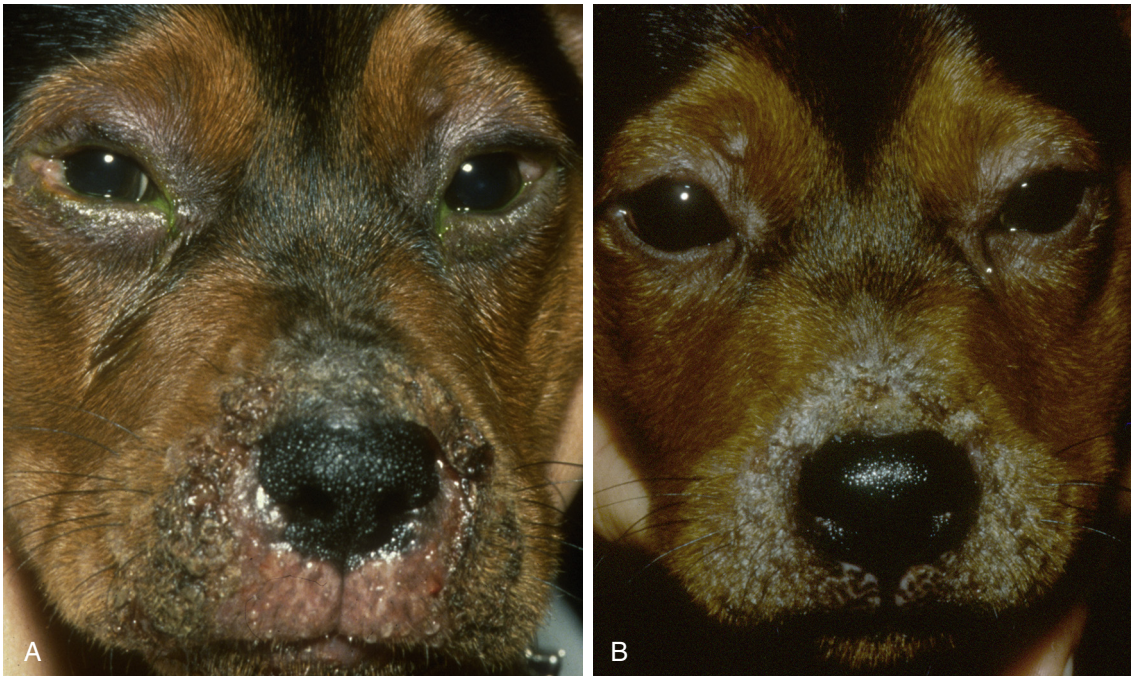

Fig. 128.2 Juvenile pyoderma in a puppy. (A) Ulcerative pyogranulomatous dermatitis of the muzzle and eyelids is evident, including conjunctivitis. (B) Appearance of lesions 2 weeks after being treated with oral prednisolone and cephalexin.

Viral conjunctivitis in dogs has been associated most often with CDV infection (see Chapter 22). The first sign of distemper is often a bilateral conjunctivitis with a serous to mucopurulent ocular discharge. Lacrimal adenitis may result in reduced tear production, which in turn results in more profound signs of conjunctivitis, corneal ulceration, and pain. The KCS typically resolves over several weeks in dogs that recover. Treatment should include regular cleaning of the eye, application of a broad-spectrum topical antibiotic to help prevent secondary bacterial infection, and, if KCS is present, topical cyclosporine or tacrolimus along with artificial tears.

CHV has been documented as a cause of severe conjunctivitis and ulcerative keratitis in a group of 3- to 4-month-old laboratory dogs following recovery from uncharacterized upper respiratory tract disease.[10] In a study of adult dogs experimentally infected with CHV using an ocular route, only self-limiting mild conjunctivitis was noted.[11] In client-owned dogs with and without idiopathic conjunctivitis, CHV or CAdV-2 were found in 23.3% of affected dogs and 0% of clinically healthy dogs.[12] Topically applied 1% prednisolone acetate solution did not reactivate latent herpes virus infection;[13] however, systemic administration of prednisolone at immunosuppressive doses resulted in reactivation of ocular illness and shedding of virus.[14] If CHV is suspected or documented as a cause of conjunctivitis, a topical antiviral agent should be used (see Table 9.5) (see also Chapter 24). Topical 1% trifluridine, topical 0.5% cidofovir, and topical 0.15% ganciclovir gel have been shown to be effective.[15–17]

Fig. 128.3 Neonatal conjunctivitis in a 7-day-old kitten. Purulent discharge was evident as the medial-most aspect of the eyelids was opened. *Pasteurella multocida* was cultured. Virus isolation was negative.

Cats

Neonatal conjunctivitis can occur in cats secondary to bacterial or viral infection. If infection occurs before the opening of the eyelids, at approximately 10 days of age, purulent material accumulates, causing a characteristic distended appearance to the adherent eyelids. In such cases, the eyelids should be opened by inserting a small scissor blade at the medial canthus and gently sliding it along the lid margins. Copious purulent discharge usually follows (Fig. 128.3). The exudate can be submitted for cytologic examination as well as bacterial culture and PCR assays for respiratory pathogens to aid in identification of pathogens that may be present. A broad-spectrum topical antibiotic should be used several times daily. A topical antiviral agent should also be used in cases suspected to be caused by FHV-1 (see Chapters 9 and 34 and Table 9.5).

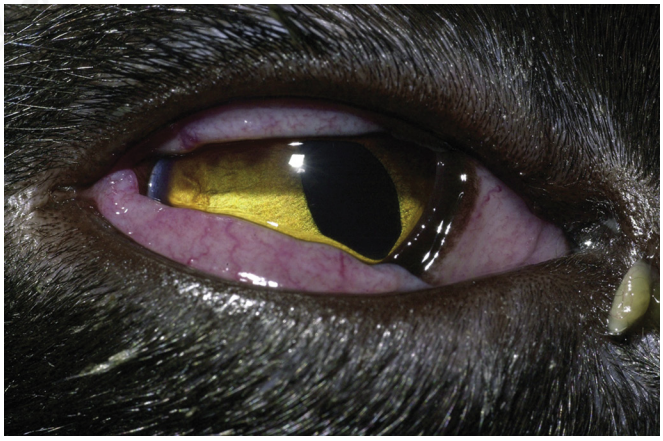

Fig. 128.4 Conjunctivitis in a cat caused by FHV-1. Note the hyperemia, chemosis, and purulent ocular discharge.

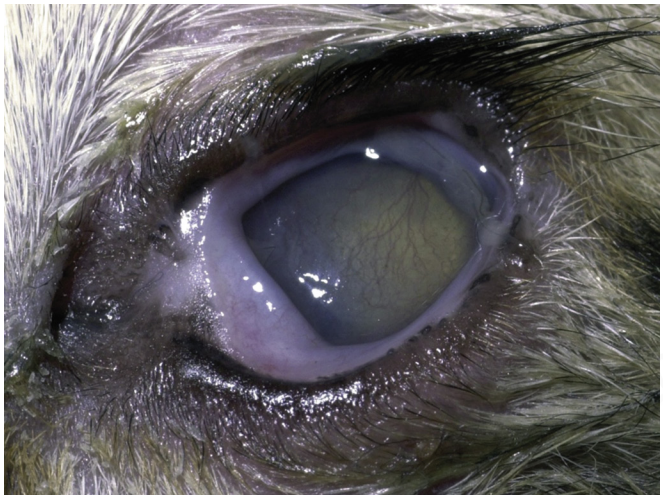

Fig. 128.5 Chronic symblepharon in a kitten secondary to FHV-1 infection. Note circumferential conjunctival adhesions and corneal vascularization.

FHV-1 is a frequent cause of ocular disease in cats. Young cats with respiratory tract disease generally have conjunctivitis with marked conjunctival hyperemia, chemosis, and serous to purulent ocular discharge (Fig. 128.4). Cats typically recover in 2 to 3 weeks. In severe cases of FHV-1 conjunctivitis, the risk of symblepharon, or adhesions of the conjunctiva to itself or the cornea, is high (Fig. 128.5). Symblepharon occurs when areas of conjunctival and corneal epithelial ulceration are present as a result of the cytopathic nature of FHV-1. Symblepharon may lead to permanent visual impairment, and an attempt to break these adhesions early should be made. After application of topical anesthesia, a cotton-tip swab or small forceps can be used to break adhesions and strip off cellular debris and fibrin. This process may need to be repeated frequently until the conjunctivitis has resolved. A topical or oral antiherpesvirus drug should be administered (see Table 9.5). In addition to general supportive care, the eyes should be cleansed frequently and a broad-spectrum topical antibiotic applied to minimize secondary bacterial infection as the conjunctival surface sloughs. Once infected, cats become latent carriers of FHV-1 and may have recurrences of ocular disease, including conjunctivitis and corneal ulcers. Many cats have transient episodes of conjunctivitis, with conjunctival hyperemia, serous or purulent ocular discharge, and blepharospasm. Mild cases that are self-limiting may not require treatment. If the conjunctivitis is painful or lasts more than a few days, antiviral therapy should be instituted.

Fig. 128.6 Severe conjunctivitis in a cat associated with feline calicivirus infection.

Cats can develop chronic conjunctivitis associated with FHV-1 infection.[18] When conjunctivitis becomes chronic, the inflammation needs to be treated. Glucocorticoids should not be used because of the potential to exacerbate an underlying FHV-1 infection. A topical NSAID such as diclofenac used concurrently with a topical antiviral drug such as cidofovir appears to be both effective and safe.

IFN-α and IFN-ω have significant inhibitory effects on FHV-1 *in vitro* at relatively high doses (see Chapter 9).[19,20] High doses of topical IFNs have been used with some success in human ocular herpetic infections.[21,22] However, in a study of naturally occurring viral keratoconjunctivitis in cats, treatment with high dose (10^6 U/mL) IFNs-α and -ω q12h for 14 days failed to lessen severity or duration of clinical signs.[23] In general, studies to date have not supported a beneficial effect of IFNs for treatment of feline herpesvirus infections.[24]

The use of oral famciclovir for treating FHV-1 in cats has become more common. The drug appears to be safe at least for a short course (2 to 3 weeks), although the optimum dose remains unclear, and safety in kittens has not been determined. A retrospective study compared the clinical effects of dosing at either 40 or 90 mg/kg q8h in cats naturally infected with FHV-1.[25] While both groups showed improvement, cats in the high-dose group had greater improvement in a shorter period of time. Reduced shedding of FHV-1, but no difference in reduction in clinical signs, was noted in shelter cats treated with either 30 mg/kg or 90 mg/kg PO q12h for 7 days when compared with untreated cats.[26] Treatment of FHV-1 infections is described in detail in Chapter 34.

Feline calicivirus (FCV) is also a common cause of conjunctivitis in cats, particularly those in shelter or multicat environments. Conjunctivitis caused by FCV is indistinguishable from that caused by FHV-1 and may be severe in some cats (Fig. 128.6) (see Chapter 35). No antiviral drugs are available, so supportive care is required.

Chlamydia felis typically causes conjunctivitis in young adult cats (see Chapter 49) (Fig. 128.7). The clinical appearance of chlamydiosis is indistinguishable from conjunctivitis caused by FHV-1, and the two organisms may be present simultaneously. Chlamydial conjunctivitis can sometimes be successfully treated with topical tetracycline ointment applied to both eyes q6h until a week after resolution of clinical signs. Oral doxycycline may be preferred to clear the organism from extraocular tissues such as the intestinal tract, reproductive tract, and visceral organs. Results of one study indicated that oral doxycycline at 10 mg/kg per day for at least 28 days was necessary to ensure elimination of the organism from tissues.[27] *Hartmannella vermiformis,* an amebic

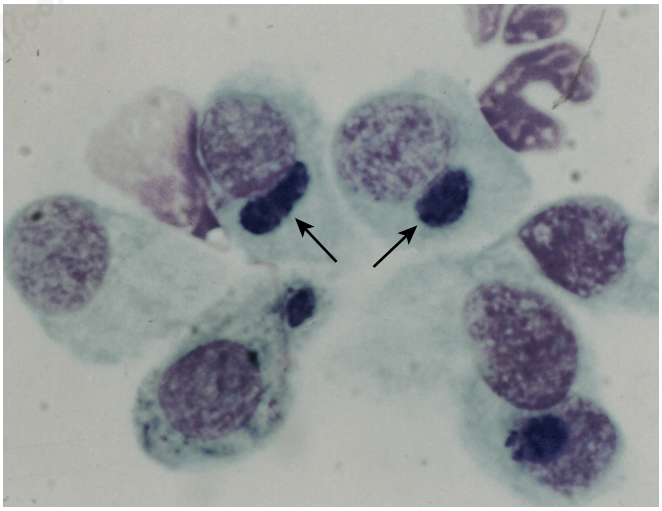

Fig. 128.7 Intracytoplasmic *Chlamydia felis* inclusions (*arrows*) in conjunctival epithelial cells of a cat with conjunctivitis (Giemsa stain, ×330).

endosymbiont that contains the *Chlamydia*-like agent *Neochlamydia hartmannellae,* has been isolated in greater prevalence from the ocular surfaces of cats with keratitis or conjunctivitis than from those of clinically healthy cats.[28] However, in another study, the prevalence of the organism did not differ between similar groups of cats.[29] The clinical significance of this organism is unknown (see Chapters 49 and 105).

Mycoplasma felis has been variably implicated as a cause of conjunctivitis in cats. Some studies have recovered *Mycoplasma* species as resident microflora from feline conjunctiva, whereas others have not. Similarly, experimental infections of clinically healthy, young cats have produced conjunctivitis in some studies[30] and not in others. *Mycoplasma* organisms may require a stressor such as co-infection with FHV-1 to cause disease. One study reported a slightly higher percentage of cats with conjunctivitis to have positive PCR results for *Mycoplasma* spp. DNA (9.6%) as compared to FHV-1 (6.7%) or *C. felis* (3.2%) DNA.[31] Suspected mycoplasma conjunctivitis should be treated as for chlamydiosis.

Keratitis

Dogs

Viral keratitis in dogs can be caused by CHV (see above) and CAdV-1. Bacterial keratitis in dogs develops after corneal ulceration or a traumatic wound. Resident bacterial flora inhabiting the ocular surface are those most likely to invade a corneal wound. This can lead to ulcerative keratitis or a corneal abscess. *Staphylococcus* and *Streptococcus* spp. are especially common, although infections with gram-negative bacteria may also develop. In one study of 476 dogs with ulcerative keratitis from the USA, bacteria isolated were *Staphylococcus* spp. (32%, primarily *S. pseudintermedius*), *Streptococcus* spp. (19%, primarily *Streptococcus canis*), and *Pseudomonas aeruginosa* (8%); MDR bacteria comprised 20% of the isolates and increased in prevalence from 2016 to 2020 from 5% to 34%.[32]

Bacterial keratitis usually incites a visible neutrophilic response, characterized by a yellow-to-white cellular infiltrate within the cornea. Vascular growth into the cornea also occurs but usually does not begin for several days after injury and infection. Blood vessels originate from the limbus and grow at a rate of approximately 1 mm/day toward the site of infection. Rapid corneal destruction can occur. Invading bacteria and neutrophils can release proteases and collagenases, which contribute to corneal melting (Fig. 128.8). Increased cyclo-oxygenase-2 expression has been documented in all corneal

Fig. 128.8 (A) Infected corneal stromal ulcer in a dog. Note the purulent (white to yellow colored) corneal infiltrate, vascularization, and conjunctival hyperemia. (B) Keratoconus due to corneal melting secondary to an infected corneal ulcer. Note corneal edema, purulent infiltrate, and abnormal corneal contour.

layers of affected dogs, suggesting a possible role for antiprostaglandin therapy as a treatment for inflammatory keratitis.[33] Fungal keratitis, which can have a similar clinical appearance, is less common but can be caused by penetrating injuries with plant material or prolonged topical treatment with antibiotic or glucocorticoid therapy. *Candida* spp., *Aspergillus* spp., and a variety of other molds have been implicated[34,35]; in one case report, infection with *Malassezia pachydermatis* was described.[36] Both bacterial and fungal infections can lead to corneal perforation.

Diagnosis of infectious keratitis is based on clinical findings, cytology, and culture. Fluorescein staining is used to detect epithelial loss. All corneal ulcers that are progressive or involve the stroma should be cultured. For specimen collection, a mini-tip Culturette swab with a sterile saline-moistened tip should be used to gently swab the ulcer bed. After application of topical proparacaine, a flattened spatula, the blunt end of a scalpel blade, or a cytology brush should be used to gently scrape the ulcer edge in order to obtain a specimen for cytologic examination. With bacterial keratitis, neutrophils are the predominant cell type, and bacteria can be numerous, few, or not visible. Initial antimicrobial drug selection can be based on whether cocci or rods are present. Until culture results are known, broad-spectrum antibacterial drugs should be used. A combination of chloramphenicol and a fluoroquinolone has been recommended for infected corneal ulcers.[32] To achieve broad-spectrum bactericidal activity, compounding may be required (Tables 128.3 and 128.4). Frequency of application is critical. In a rapidly progressive corneal ulcer, topical antibiotics should be applied q1-2h. To reduce the likelihood of corneal melting, serum or

plasma (autologous, homologous, or heterologous) should be applied topically q1-2h for anti-collagenolytic effect.[37,38] These blood products should be maintained in a sterile fashion and kept refrigerated. Systemic antibiotics are usually not indicated unless the cornea has a penetrating wound. Topical atropine can be used q12-24h daily if miosis is present, although it should not be used in dogs with KCS or glaucoma.

If fungal keratitis is documented or suspected, it should be treated with the application of a topical antifungal agent q2-3h. Topical 1 to 2% miconazole, 1% itraconazole, or 1% voriconazole solutions have been effective in treatment of keratomycosis in dogs (see Chapter 86).[35,36,39,40] Deep corneal ulcers in danger of perforating respond best to surgical therapy, such as placement of a conjunctival flap.

Ocular surfaces should be cleaned of discharges frequently to remove neutrophils and their proteolytic enzymes. If tear production is inadequate, topical cyclosporine or tacrolimus q12h and artificial tears several times daily should be administered to supplement and stimulate lacrimation. Closing the lids or placing a third eyelid flap should be avoided. These procedures limit drug contact with the cornea, impair discharge drainage, and increase the temperature of the environment, thus promoting bacterial growth, fungal growth, or both. They also prevent monitoring of the healing process. Systemic NSAIDs can provide analgesia and aid in the treatment of uveitis associated with deep corneal ulcers.

Cats

Bacterial keratitis in cats may develop secondary to corneal ulceration (including that initiated by FHV-1) or traumatic wounds. Appearance, diagnosis, and treatment are the same as for the dog. Fungal keratitis in cats is rare but can be treated in the same way as fungal keratitis in dogs.[41]

TABLE 128.4 Fortified and Compounded Topical Antibacterial Solution Preparations

Gentamicin (Fortified)	
Gentamicin injectable (50 mg/mL)	6 mL
Artificial tears	24 mL
TOTAL	30 mL
Final concentration = 10 mg/mL (1% solution)	
Or	
Add 2 mL of injectable gentamicin (50 mg/mL) to the 5-mL bottle of commercial ophthalmic gentamicin solution (0.3%). Final concentration: 14 mg/mL (1.4% solution). Shelf life: 30 days	
Amikacin	
Amikacin injectable (250 mg/mL)	4 mL
Artificial tears	26 mL
TOTAL	30 mL
Final concentration = 33 mg/mL (3.3% solution)	
Or	
Remove 2 mL from a 15-mL squeeze bottle of artificial tears and discard. Add 2 mL of injectable amikacin (50 mg/mL). Final concentration: 6.7 mg/mL (0.67% solution). Shelf life: 30 days	
Ampicillin	
Mix a 125-mg vial ampicillin with sterile saline or artificial tears to a concentration of 20 mg/mL	
Cefazolin	
Remove 2 mL from a 15-mL squeeze bottle of artificial tears and discard. Reconstitute a 500- or 1000-mg vial of cefazolin with sterile saline to a concentration of 250 mg/mL. Add 500 mg of the reconstituted cefazolin (2 mL) to the bottle of artificial tears. Final concentration: 33 mg/mL (3.3% solution). Shelf life: 14 days. Keep refrigerated	
Cephalothin	
Remove 6 mL from a 15-mL squeeze bottle of artificial tears and save. Add the 6 mL of tear solution to a 1000-mg vial of cephalothin. Add the entire 1000 mg of the reconstituted cephalothin (6 mL) to the bottle of artificial tears. Final concentration: 67 mg/mL (6.7% solution). Keep refrigerated	
Ticarcillin	
Reconstitute a 1-g vial of ticarcillin with 10 mL of sterile saline. Add 1.0 mL (100 mg) of this solution to a 15-mL squeeze bottle of artificial tears. Final concentration: 6.7 mg/mL (0.67% solution). Shelf life: 4 days. Keep refrigerated	
Tobramycin (Fortified)	
Add 1.0 mL of injectable tobramycin (40 mg/mL) to a 5-mL bottle of commercial ophthalmic tobramycin solution (0.3%). Final concentration: 9.2 mg/mL (0.127% solution). Shelf life: 30 days	
Vancomycin	
Remove 9 mL from a 15-mL squeeze bottle of artificial tears and discard. Reconstitute a 500-mg vial of vancomycin with 10 mL of sterile saline. Add the entire 500 mg of reconstituted vancomycin (10 mL) to the bottle of artificial tears. Final concentration: 31 mg/mL (3.1% solution). Shelf life: 4 days. Keep refrigerated

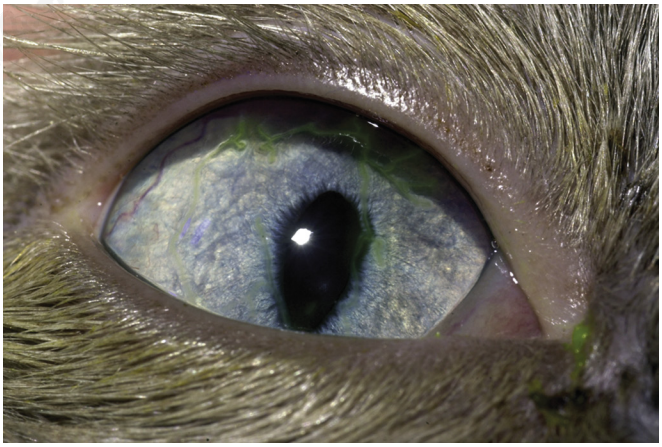

Fig. 128.9 Corneal dendritic ulceration in a cat associated with FHV-1 infection (fluorescein stain).

Fig. 128.10 Stromal keratitis without corneal ulceration in a kitten associated with FHV-1 infection. Note the corneal vascularization, corneal edema, and conjunctival hyperemia.

Corneal ulceration and keratitis that occur in association with FHV-1 infection are very common and begin with invasion of the corneal epithelium by the virus.[42] The most common corneal abnormality is punctate or linear (dendritic) epithelial ulcers (Fig. 128.9), which may quickly enlarge to form geographic superficial ulcers. Conjunctivitis usually accompanies corneal ulceration.[18] Mechanical debridement of any loose corneal epithelium with a cotton-tipped swab and treatment with a topical or oral antiviral agent are recommended. A topical antibiotic should also be used for bacterial prophylaxis. Grid keratotomies should not be performed in cats because this allows the virus greater access to the corneal stroma and appears to increase the risk of corneal sequestration.[43]

FHV-1 infection may also be associated with stromal keratitis in cats, which may occur with or without corneal ulceration.[44] Corneal vascularization and cellular infiltrate, often accompanied by chronic discomfort, are typical signs (Fig. 128.10). Antiviral agents alone may not improve the keratitis. Topical anti-inflammatory agents may be needed, although glucocorticoids should be avoided. Nonsteroidal topical agents such as diclofenac, and/or 0.2% cyclosporine ointment, can be used in conjunction with an antiviral agent such as cidofovir. Topical glucocorticoids predispose cats to the development of corneal ulceration and sequestration when FHV-1 is present. Topical IFN has been used in humans with herpetic keratitis and can also be considered (see Conjunctivitis in cats).

Corneal sequestration can follow chronic corneal ulcers or keratitis caused by FHV-1 in any breed of cat, but Persian and Himalayan cats are predisposed (Fig. 128.11). Corneal sequestration has occurred in cats experimentally infected with FHV-1 after topical glucocorticoid treatment, and in cats treated with grid keratotomy.[43,45] The condition is characterized by an area of corneal degeneration with a brown to black discoloration. Lesions vary from pinpoint sequestra to those that occupy more than half the cornea. Vascularization and ocular pain may be intense or absent. Like stromal keratitis, sequestra can be one of the most serious and potentially blinding sequelae of FHV-1 infection. Most ophthalmologists recommend keratectomy followed by a graft (corneal or conjunctival) as treatment for sequestra.

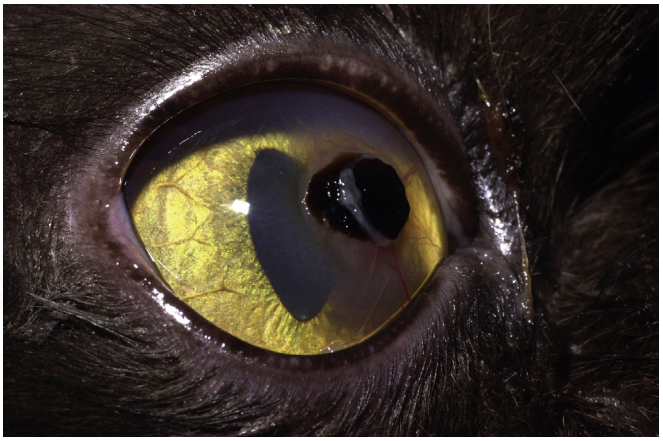

Fig. 128.11 Corneal sequestrum in a cat. Note the black plaque and corneal blood vessels.

Dacryocystitis

Dacryocystitis, or inflammation of the NL system, is usually associated with bacterial infection (Fig. 128.12). Nasolacrimal foreign bodies such as plant material are frequently the inciting cause. Dacryocystitis is less common in cats than in dogs. Clinical manifestations of dacryocystitis include conjunctival hyperemia, especially of the ventral conjunctival sac; purulent ocular discharge; and epiphora. Blepharospasm may or may not be present. Palpation of the skin near the medial canthus may elicit pain and exudation of pus from the lacrimal puncta. Swelling or draining tracts in the skin near the medial canthus may also be identified.

The NL system should be flushed and purulent debris submitted for culture and susceptibility testing. Dacryocystorhinography may be necessary to identify foreign bodies or cystic structures within the NL system. If foreign bodies cannot be flushed from the system, surgical removal using dacryocystotomy may be required. Other, less invasive approaches have more recently been successful, including ultrasound-guided foreign body removal using alligator forceps inserted through the upper puncta[46] and lacrimoscopic removal.[47]

After NL flushing, a broad-spectrum topical antibiotic solution should be used q4-6h. Systemic antibiotics are usually not required if the infection is confined to the NL system. Repeated flushings may be needed to maintain patency. The NL duct can also be stented to establish and maintain patency. Stricture of the NL duct can occur with dacryocystitis, leading to chronic epiphora.

Orbital Infections

Bacterial infection of the orbit is common, especially in dogs. Fungal infections have also been reported in both dogs and cats (see Systemic Mycoses). Bacterial infection of the orbit generally has a fairly rapid onset compared with the slow progression of clinical signs seen with

Fig. 128.12 Dacryocystitis in a dog. Purulent ocular discharge is present, particularly at the medial canthus.

orbital neoplasia. Typical clinical signs of orbital abscess and cellulitis include periorbital swelling, exophthalmos, elevation of the nictitating membrane, conjunctival hyperemia, and pain on palpation of periorbita or when opening the mouth (Fig. 128.13). Swelling of the oral mucosa behind the last molar tooth is evident in some animals. Corneal ulceration and blindness due to exposure keratopathy and optic nerve damage, respectively, can also occur.[48]

Infectious agents may gain access to the orbit by several routes, including through the oral mucosa behind the last molar tooth, from the frontal sinus through breakdown of the medial orbital bone, by extension from tooth root abscesses, from penetrating wounds or foreign bodies of the skin or oral cavity, and through hematogenous spread from distant sites of infection.

Orbital bacterial abscesses are best diagnosed with ultrasonography. Abscesses appear as a hypoechoic area posterior to the globe (Fig. 128.14). Foreign bodies are often best visualized using ultrasonographic examination. Fungal granulomas appear hyperechoic and are not readily differentiated from neoplasia. CT or MRI may be helpful for determining the extent of infection; MRI was most often used in one retrospective study of retrobulbar cellulitis or abscesses in dogs.[48]

Drainage of orbital abscesses should be established when possible. Because only soft tissue separates the oral cavity from the ventral orbit in the dog and cat, an incision through the tissue behind the last molar can be used to access the orbit. A sterile small mosquito forceps or blunt probe should be advanced into the orbit, using gentle probing—not grasping—to attempt to enter the abscess cavity. Any purulent material should be submitted for cytologic evaluation and cultured for aerobic and anaerobic bacteria. Pending culture results, broad-spectrum systemic antibacterial therapy should be instituted. *Escherichia coli* was the most frequently isolated bacterial species in the retrospective study described earlier (9/14 isolates).[48] In other studies, anaerobes were more often isolated. Nonsteroidal agents should also be administered for analgesia and to reduce inflammation. The prognosis for bacterial orbital abscesses is generally good, whereas the prognosis for orbital fungal infections is more guarded. Occasionally, increased intraocular pressure may be so severe it can lead to irreversible blindness.[49]

DIAGNOSIS

The decision to culture the ocular surface should be made early in the examination before eye medications have been administered and

Fig. 128.13 Orbital abscess in a cat. Note the periorbital swelling, exophthalmos, and elevated third eyelid. Purulent nasal discharge is also present, an infrequent finding.

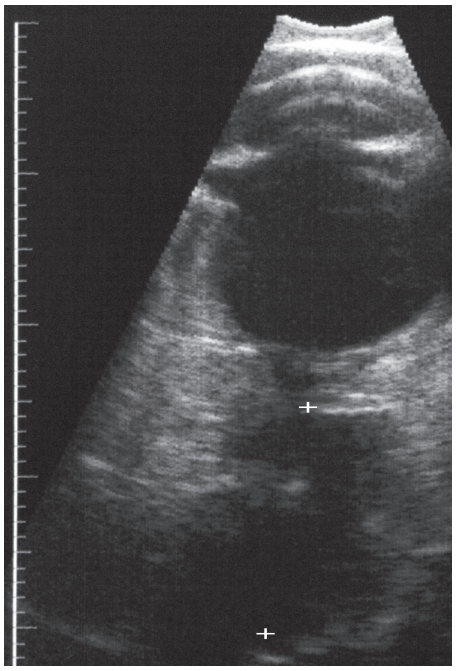

Fig. 128.14 Ultrasound image of retrobulbar abscess in a cat. Markers (+) delineate two sides of a hypoechoic structure (abscess) posterior to the globe.

manipulations performed. The use of a moist or calcium alginate swab can increase sensitivity.[50,51]

Cytologic examination of conjunctival and corneal scrapings is an important and rapid diagnostic aid. Excessive ocular discharges should be removed before scraping. Topical proparacaine should then be applied and the appropriate surface scraped with a small, flat spatula or the blunt end of a scalpel blade. Collected material should be gently spread onto glass slides and air dried. The slides can be stained with modified Giemsa or Wright stain for cytologic evaluation and Gram

staining to evaluate the type of bacteria that might be present. Slides can also be made for direct IFA staining for CDV, FHV-1, and *C. felis*.

An alternate technique is to roll a small, nylon bristle brush applicator (Microbrush, Microbrush International, Grafton, WI) over the appropriate surface and then onto a slide (Fig. 128.15). Preparations made with this method have fewer cells that are dispersed better on the slide and have less crushing artifact.[52,53] This method is less traumatic and easier to perform on cats and small dogs with tight lid-globe conformations.

Small snip biopsy specimens of the conjunctiva can be readily obtained after using cotton-tipped swabs soaked in a topical anesthetic and holding it on the area to be excised for a minimum of 60 seconds. These small pieces of tissue should be spread out on a piece of paper before they are placed in fixative. Tissue should also be collected for testing using nucleic acid–based assays such as PCR; this can be submitted immediately or frozen pending the results of histopathology.

Fig. 128.15 Nylon bristle brush used to obtain a conjunctival cytology specimen.

INTRAOCULAR INFECTIONS

ETIOLOGY AND PATHOGENESIS

Intraocular bacterial infections may be exogenous or endogenous in origin. The source of an exogenous infection from a penetrating ocular injury may be obvious from the history and appearance of the eye, but injury may also be inapparent, such as a self-sealing cat claw injury through the conjunctiva and sclera. Infections that arise from exogenous sources are usually unilateral, whereas endogenous infections may be bilateral or unilateral.

Local Injury

All recent penetrating ocular injuries should be considered infected and treated aggressively with broad-spectrum antibiotics and anti-inflammatory drugs, topically and systemically, until susceptibility data are obtained. Topical fluoroquinolones, especially ofloxacin, moxifloxacin, and gatifloxacin, have excellent corneal penetration and achieve therapeutic levels in the anterior segment against a wide variety of bacteria.[54] In suspected or confirmed bacterial endophthalmitis, a topical fluoroquinolone should be used every 1 to 2 hours.

Aqueous humor centesis in order to obtain specimens for cytologic examination and culture is safe when performed properly and can yield specific information to guide future therapy (see section on Diagnosis). Aqueous centesis is not as sensitive as vitreous centesis for detection of bacteria in endophthalmitis; consequently, a negative culture result from an aqueous specimen does not rule out infection.[55] The finding of nondegenerate neutrophils may indicate a sterile purulent inflammation such as that occurring with phacoclastic uveitis caused by lens capsule rupture. The prognosis for eyes with endophthalmitis is guarded. Many such eyes develop glaucoma, and enucleation is a common outcome.

Systemic Diseases

The eye is often a target organ in systemic infections. In some cases, ocular disease can be the primary owner complaint or the only sign evident in a systemic disease process. Recognition of systemic involvement is essential for prognostication and adequate therapy. Conversely, thorough ocular examination is indicated in any animals with systemic disease, because it may provide rapid diagnostic clues and prognostic information. If infectious agents access the eye, it is usually via the uveal or vascular tract. Typically, infectious agents or immune complexes become established in the uvea, producing chorioretinitis, anterior uveitis, or panuveitis.

Canine Distemper

In addition to conjunctivitis and lacrimal adenitis, CDV often produces multifocal, nongranulomatous chorioretinitis that does not usually cause blindness (see Chapter 22). As with CNS signs, whether chorioretinitis develops likely depends on the viral strain and immune competency of the host. In one study, dogs with all neurologic forms of distemper had an overall prevalence of chorioretinal lesions of 41%, but 83% of the dogs with chronic leukoencephalopathy syndromes had chorioretinal lesions.[56] Acute focal lesions in the tapetum or nontapetum have gray to white, hazy or ill-defined borders (Fig. 128.16).[40] Chorioretinal scars resulting from distemper virus infection have sharply demarcated borders, are hyperreflective in the tapetum ("gold medallion lesions"), and are depigmented in the nontapetum. Histologically, retinal changes are characterized by degeneration of the retina with perivascular cuffing in some instances. Lesions may include focal or diffuse degeneration of ganglion cells, proliferation of retinal pigment epithelium, atrophy of photoreceptors, disorganization of retinal layers, focal gliosis, and distemper inclusion bodies in glial cells. The most serious clinical ocular problem associated with CDV infection is optic neuritis, which results in acute onset of bilateral blindness and mydriasis.[57] If inflammation extends rostrally to the optic disc, ophthalmoscopic signs of peripapillary hemorrhages and edema, retinal vascular congestion, and elevation of the disc are observed (Fig. 128.17). If the neuritis remains retrobulbar, the diagnosis is made by exclusion (e.g., blind eyes with mydriasis and normal retinal function as tested by electroretinography). The optic neuritis can be isolated, prodromal, or occur in conjunction with other CNS signs. Distemper-associated blindness also may occur with inflammation of the occipital cortex or optic radiations, but pupillary light reflexes are normal under such circumstances.

Canine Adenovirus-1 Infection

CAdV-1 infection (see Chapter 23) has been estimated to produce ocular lesions in approximately 20% of dogs recovering from natural infections. The condition is bilateral in 12 to 28% of affected dogs. The most visible ocular lesion is stromal corneal edema ("blue eye") resulting from immune-complex deposition and associated inflammatory damage to the corneal endothelium (see Fig. 23.4). Fluid distention of the cornea can cause bullae to form. If the bullae rupture, corneal ulceration occurs. Occasionally, a dog has signs of uveitis (blepharospasm, miosis, hypotony, and aqueous flare) 1 to 2 days before the corneal edema is evident,

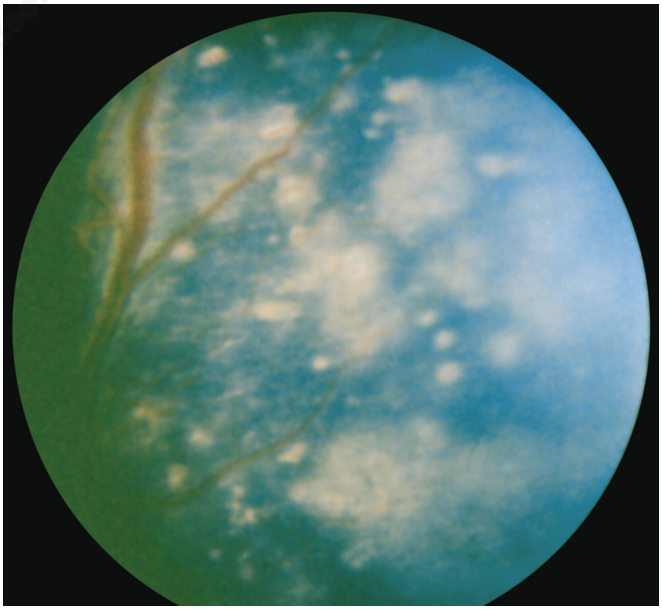

Fig. 128.16 Multifocal acute distemper lesions in the non-tapetal fundus of a dog. Active lesions are recognized by their white cellular infiltrates with hazy borders.

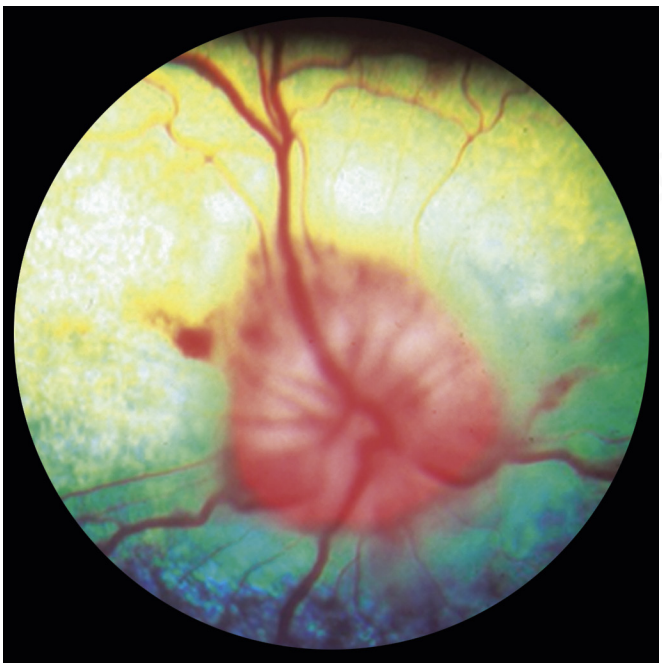

Fig. 128.17 Optic neuritis characterized by swollen and hyperemic optic disc, peripapillary hemorrhages, and loss of vision.

although most dogs do not demonstrate discomfort. Corneal edema may be focal or generalized and is usually transient. In some instances, the edema is permanent or may require several months to clear. A marked hypotony combined with altered corneal rigidity may result in a keratoconus. Other causes of corneal edema, such as congenital persistent pupillary membranes, glaucoma, corneal ulceration, and uveitis from other causes, should be ruled out.

Canine Herpesvirus Infection

Infection of adult dogs with CHV results in conjunctivitis and keratitis as described earlier in this chapter. In addition, neonatal CHV infection has been associated with a bilateral panuveitis with keratitis, synechiae, cataracts, retinal necrosis and disorganization, retinal atrophy and dysplasia, and optic neuritis and atrophy.[58]

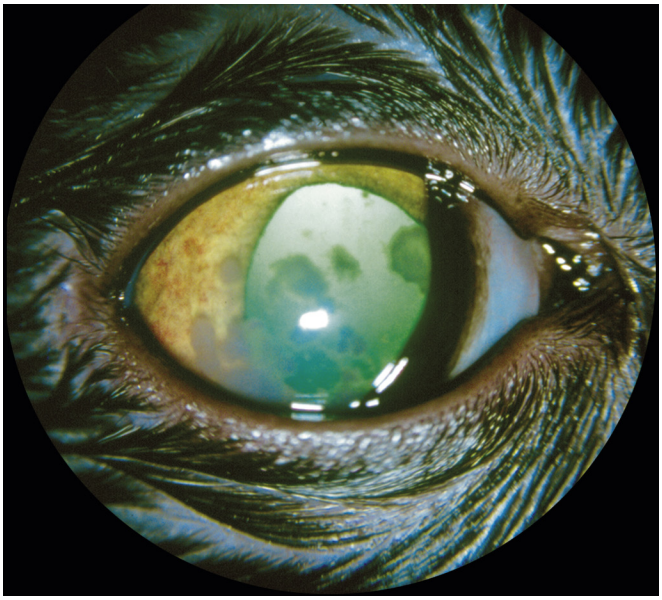

Fig. 128.18 Anterior uveitis with large keratic precipitates in a cat with feline infectious peritonitis.

Feline Infectious Peritonitis

The most common ocular manifestation of infection with FIP virus is bilateral granulomatous anterior uveitis, often accompanied by chorioretinitis (see Chapter 31). Frequently, large keratic precipitates and a fibrinous exudate are found in the anterior chamber (Fig. 128.18). Pyogranulomatous vasculitis, the hallmark of the disease's pathogenesis, may be evident on examination of retinal vessels (Fig. 128.19). Retinal hemorrhages and detachments may also develop. Ocular disease is more common with noneffusive FIP and may be the only sign. The use of PCR for feline coronavirus RNA on aqueous humor specimens may be helpful for diagnosis of uveitis due to FIP when positive, but sensitivity was only 36% in one study.[59] Immunocytochemistry for detection of viral antigens in aqueous humor macrophages was not recommended because of the potential for false-positive results. Topical treatment of ocular disease with glucocorticoids is supportive, and new antiviral drugs (GS441524 and remdesivir) offer promise for improved outcomes. Ocular disease may be temporarily ameliorated, but it usually recurs if the systemic disease worsens.

Feline Leukemia Virus Infection

Ocular disease in FeLV infection primarily results from FeLV-associated lymphoma (see Chapter 32). Neoplastic lymphocytes can often be found in the uveal tract as a result of hematogenous spread. Cats with ocular lymphoma may initially show signs of mild uveitis, including miosis, aqueous flare, and keratic precipitates. As the disease progresses, the iris becomes greatly thickened and distorted with the infiltration of tumor cells. Lymphoma may also initially appear as a mass within the iris in the absence of clinical signs of uveitis (Fig. 128.20). Glaucoma is a common sequela because tumor cells infiltrate the iridocorneal angle. Aqueous centesis may be helpful for diagnosis, because neoplastic lymphocytes readily exfoliate into the aqueous humor. Aggressive treatment of cats with ocular lymphoma with topical (e.g., prednisolone acetate) and systemic glucocorticoids, as well as systemic therapy with chemotherapy can result in improvement. Lymphoma may also manifest as orbital masses, with associated exophthalmos and an elevated third eyelid. Treatment for this form of

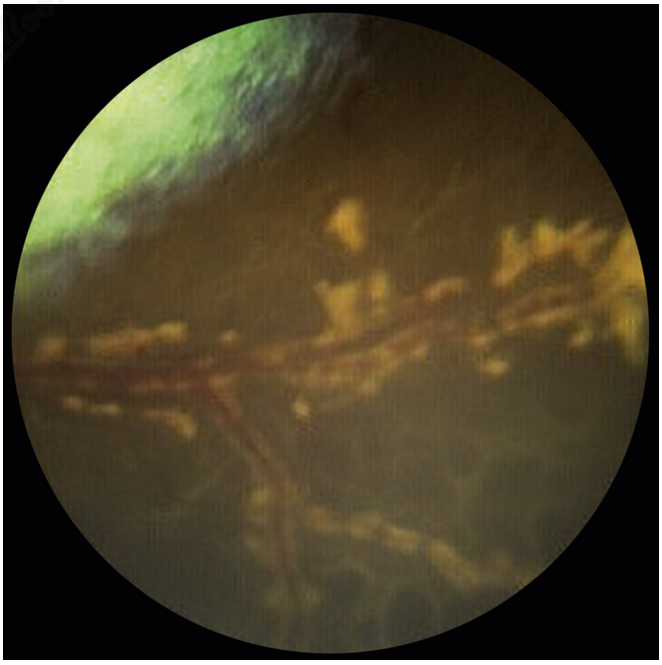

Fig. 128.19 Chorioretinitis and retinal perivascular inflammatory sheathing in a cat with feline infectious peritonitis.

Fig. 128.20 Ocular lymphoma causing iridal masses in a cat infected with feline leukemia virus.

lymphoma should include chemotherapy and possibly orbital radiation therapy. Pupillary abnormalities, including dynamic anisocoria, have been noted in some cats with FeLV infection, as have retinal hemorrhages associated with thrombocytopenia.[60]

Feline sarcoma virus (FeSV) is a naturally occurring variant of the FeLV that has incorporated one of several oncogenes. Experimentally, the virus has caused uveal melanoma when injected into the anterior chamber of cats. Using PCR on formalin-fixed globes with uveal melanoma, one study found FeLV-FeSV DNA in 3 of 36 specimens, suggesting a possible role of the virus in tumor formation.[61] In another study of 10 globes with uveal melanoma, FeLV was not detected by PCR or immunohistochemistry.[62]

Feline Panleukopenia

Although cerebellar hypoplasia is the most common clinically apparent abnormality in cats with feline panleukopenia, kittens infected in the prenatal or neonatal period may also have retinal dysplasia and optic nerve hypoplasia or dysplasia (see Chapter 30).

Feline Immunodeficiency Virus Infection

Ocular inflammation has been associated with FIV infection in both experimentally and naturally infected cats. Anterior uveitis is most commonly reported, but conjunctivitis, pars planitis, and chorioretinitis have also been described. Ocular inflammation may result from direct viral damage, secondary immune-mediated phenomena, or opportunistic infection. In a histopathologic study of the eyes of 19 infected cats, 16 cats had lymphoplasmacytic inflammation of the iris and ciliary body.[63] Secondary opportunistic infections with FHV-1, *C. felis,* and *T. gondii* should always be considered in FIV-positive cats with ocular disease. In an experimental study of chlamydial conjunctivitis, co-infection with FIV markedly prolonged the duration of clinical signs and led to chronic conjunctivitis.[64]

If another infectious disease can be identified in an FIV-positive cat, it should be treated as specifically as possible. Uveitis that is associated with FIV infection can be a chronic problem that requires symptomatic treatment. For long-term use, a topical NSAID is preferred for treatment because use of glucocorticoids risks exacerbation of ocular FHV-1 infections. However, oral prednisolone may be required for treatment of chorioretinitis.

Ehrlichiosis

Ocular lesions occur frequently in dogs with canine monocytic ehrlichiosis (see Chapter 44). The most common lesions include unilateral or bilateral anterior uveitis characterized by conjunctival and episcleral hyperemia or hemorrhage, miosis, aqueous flare, hypopyon, keratic precipitates, hyphema, synechiae, and/or hypotony. Glaucoma can occur secondary to chronic anterior uveitis (Fig. 128.21). Signs of posterior segment inflammation can include chorioretinitis, serous retinal detachment, retinal hemorrhage, and optic neuritis. Evidence of a swollen optic disc and peripapillary hemorrhages on fundic examination suggests optic neuritis (see Fig. 128.17). In a retrospective study of 90 dogs, bilateral uveitis was the most common ocular abnormality.[65] In 30 of the 90 dogs, ocular disease was the only clinical finding; 60 dogs had systemic signs.

Anterior uveitis has also been seen in dogs naturally infected with *Ehrlichia chaffeensis*.[66] In an experimental study of dogs infected with *E. canis, E. chaffeensis*, or *Ehrlichia ewingii,* histologic examination of the eyes showed uveitis only in dogs infected with *E. canis*.[67] The lymphocytic inflammatory infiltrate was most intense in the ciliary body, becoming less intense in the choroid, iris, and retina, respectively.

Rocky Mountain Spotted Fever

Ocular lesions are frequently associated with *Rickettsia rickettsii* infection and primarily arise as a consequence of vasculitis (see Chapter 46). Lesions include conjunctival hyperemia, subconjunctival hemorrhage, hyphema, anterior uveitis, iris hemorrhage, retinal hemorrhage, retinal edema, and retinal perivascular inflammatory cell infiltrate (Fig. 128.22).[68] Lesions tend to be bilateral in affected dogs but may not be symmetrical. Fluorescein angiography in experimentally infected dogs demonstrated increased retinal vascular permeability beginning on day 6 after infection and 2 days after the onset of pyrexia.[69] Venules were affected twice as frequently as arterioles, and smaller vessels were affected more frequently than larger primary vessels. Retinal vascular lesions in this study paralleled the progression of fever, leukopenia, thrombocytopenia, and prolongation of activated partial thromboplastin time during the second week after infection.

The ocular signs of RMSF resemble those of canine ehrlichiosis. Although ocular hemorrhages are the most common ophthalmic sign of RMSF, hemorrhage can also occur with ehrlichiosis. Although

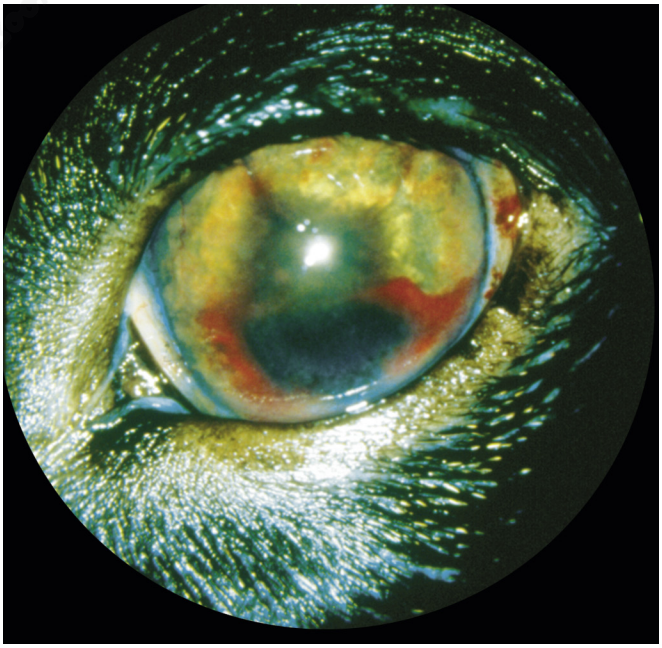

Fig. 128.21 Anterior uveitis with hyphema in a dog with *Ehrlichia canis* infection. Iris bombe and glaucoma are present.

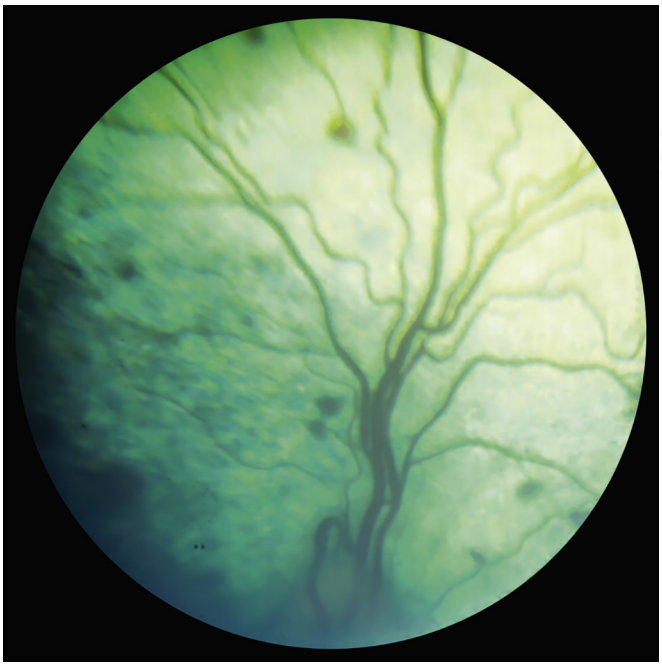

Fig. 128.22 Multifocal retinal hemorrhages in a dog with Rocky Mountain Spotted Fever.

exceptions occur, intraocular hemorrhages and inflammatory cell infiltrates tend to be less dramatic in RMSF than ehrlichiosis.[70]

Brucellosis

Brucella canis infection has been associated with unilateral or bilateral anterior uveitis or panuveitis, endophthalmitis, retinal detachment, and intraocular hemorrhage (see Chapter 71). Ocular involvement is often severe and blinding. A retrospective study of the prevalence of ocular lesions among dogs examined for brucellosis at veterinary schools in the United States and Canada found that 38 of 313 (14.2%) dogs had ocular involvement.[71] Testing for *B. canis* should be performed in dogs with unexplained uveitis or ocular hemorrhage. The prognosis for resolution of uveitis associated with brucellosis with treatment is guarded. A report of three dogs with brucellosis described resolution of unilateral endophthalmitis in each and apparent systemic clearing of the organism with a long-term multidrug treatment protocol (mean of 96 weeks) that included enrofloxacin, doxycycline, streptomycin, and rifampin.[72]

Lyme Borreliosis

In humans, ocular lesions associated with *B. burgdorferi* infection have been well described.[73,74] Uveitis is the primary manifestation, but neuro-ophthalmic disorders and surface inflammations such as episcleritis and keratitis have also been reported. Ocular manifestations are more likely to be seen in late-stage disease. A clear association between ocular disease in dogs and *B. burgdorferi* infection has not been made.

Leptospirosis

Leptospires incite vasculitis, making the eyes a potential target organ (Chapter 68). Although leptospires have been found in the eyes of infected dogs, the paucity of reports of uveitis associated with canine leptospirosis in the literature probably does not reflect the true prevalence of disease.[75] In horses and humans, the development of uveitis often occurs months after acute infection. This likely represents a delayed hypersensitivity reaction between cell-bound antibodies and persistent leptospiral antigens in the eye. Bilateral panuveitis and retinal detachments were described as the only sign of infection in a dog in association with a serovar Canicola infection.[76] Testing for leptospirosis should be included in a workup for a canine uveitis even if systemic signs are not present.

Bacteremia

Bacteremia that occurs in association with conditions such as infective endocarditis, discospondylitis, UTI, or pyometra may be associated with uveitis as a result of hematogenous spread of bacteria to the eye. If endophthalmitis secondary to bacteremia is suspected, a fluoroquinolone antibiotic should be used topically several times daily in addition to systemic antibiotic therapy. Fluoroquinolones will penetrate a normal cornea and reach therapeutic levels in the anterior segment of the eye. In addition, a topical glucocorticoid such as prednisolone acetate should be used several times daily to suppress inflammation.

Tetanus and Botulism

Ocular signs are among the most common early clinical manifestations of tetanus in the dog (Chapter 72) and were among the first signs noticed by the owner in 45% of dogs in one study.[77] Abnormalities included enophthalmos, third-eyelid protrusion, squinting, swollen eyelids, or a "strange facial expression." Miosis is the most common pupillary abnormality on physical examination. However, mydriasis may also occur (Fig. 128.23).

In botulism, autonomic nervous system dysfunction accounts for ocular abnormalities. These include mydriasis with sluggish pupillary light reflexes and a decreased palpebral reflex. Ocular surface disease such as conjunctivitis and corneal ulceration may occur if the palpebral reflex is absent, leading to lagophthalmos. Decreased tear production may also occur secondary to diminished parasympathetic nerve function to the lacrimal glands. In animals with lagophthalmos and/or tear deficiency, generous use

Fig. 128.23 Localized tetanus causing bilateral third-eyelid protrusion in a dog. The dog's pupils were mydriatic.

of artificial tear products should be incorporated with other treatments to avoid ocular surface drying.

Bartonellosis

Ocular complications in humans infected with *Bartonella henselae* include Parinaud's oculoglandular syndrome, neuroretinitis, and retinochoroiditis (Chapter 70).[78] In both naturally and experimentally infected cats, *B. henselae* DNA and a specific antibody have been detected in the aqueous humor, and a role of *Bartonella* in anterior uveitis has been hypothesized.[79] In a study of 366 cats with and without uveitis, the prevalence and magnitude of serum antibody titers to *B. henselae* were not higher in cats with uveitis, suggesting that serum antibody testing cannot determine whether uveitis in a cat is caused by *B. henselae*.[80] A similar lack of correlation was found between *B. henselae* isolation from blood or positive serum antibody titer results in cats with uveitis.[81] A review of our current understanding of the role of bartonellosis in feline uveitis indicates little evidence to date that this disorder is a significant cause of uveitis in cats, although further study is needed.[82] *Bartonella vinsonii* subsp. *berkhoffii* was suspected as a cause of uveitis and choroiditis in one dog,[83] but whether *Bartonella* spp. can cause ocular disease in dogs remains unknown.

Mycobacteriosis and Nocardiosis

Granulomatous to pyogranulomatous chorioretinitis, optic neuritis, and anterior uveitis may occur in disseminated mycobacterial[84-86] and nocardial infections (Sykes, unpublished observations) (Chapters 60 and 61). Granulomatous lesions have also been noted in the conjunctivae and corneas of infected cats.[87,88]

Systemic Mycoses

Systemic mycoses caused by fungi endemic to North America are frequently associated with a pyogranulomatous to granulomatous posterior uveitis. Anterior uveitis accompanies chorioretinitis in many cases. Ocular involvement occurs in up to 52% of blastomycosis cases.[89] Ocular lesions always include chorioretinitis, which may vary from a focal granuloma in the fundus to widespread subretinal infiltrates of organisms and granulomatous inflammation with retinal detachment (Fig. 128.24A).[90] Anterior uveitis is common with extensive posterior segment disease, although the organism is not usually found in these tissues or in aqueous humor aspirates. Secondary glaucoma is a frequent complication (Fig. 128.24B). Ocular involvement with histoplasmosis is relatively uncommon in dogs,[91] but is often recognized in cats and includes granulomatous chorioretinitis, retinal detachment,

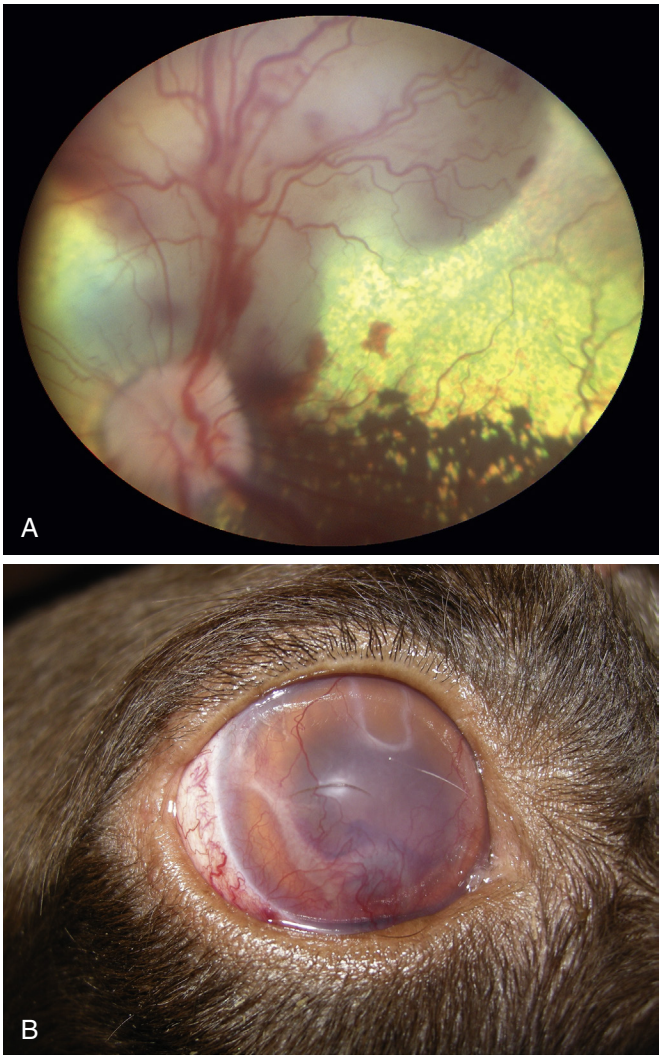

Fig. 128.24 (A) Large subretinal granuloma and retinal hemorrhages in a dog with blastomycosis. (B) Anterior uveitis and glaucoma in a dog with blastomycosis.

anterior uveitis, and secondary glaucoma.[92] Ocular adnexal structures, such as the nictating membrane and conjunctiva, may also be involved in histoplasmosis.[93] Antigen testing may be negative in animals with localized ocular disease.[94] In coccidioidomycosis, ocular lesions are similar to those of blastomycosis (granulomatous chorioretinitis, retinal detachment, anterior uveitis, and secondary glaucoma). Organisms are found predominantly in the choroid. Limited data exist regarding the prevalence of ocular lesions in dogs and cats with coccidioidomycosis; they appear to be less common than with the other endemic mycoses described here.

Chorioretinitis with granulomatous inflammation and retinal detachment is the most common manifestation in cryptococcosis; anterior uveitis is rare. Tapetal lesions are often dark gray to black in color, in contrast to the whitish appearance of most fungal granulomas (Fig. 128.25). Optic neuritis may also develop, and ocular disease is often recognized in association with cryptococcal meningitis.

Clinical signs in cats with sino-orbital aspergillosis (see Chapter 86) include exophthalmos, corneal drying with possible ulceration secondary to lagophthalmos, ocular discharge, oral cavity ulceration, pain on opening of the mouth, and nasal discharge if the infection involves the nasal cavity or sinuses.[95] Brachycephalic cats (especially Persians) appear to be predisposed. Surgical therapy alone,

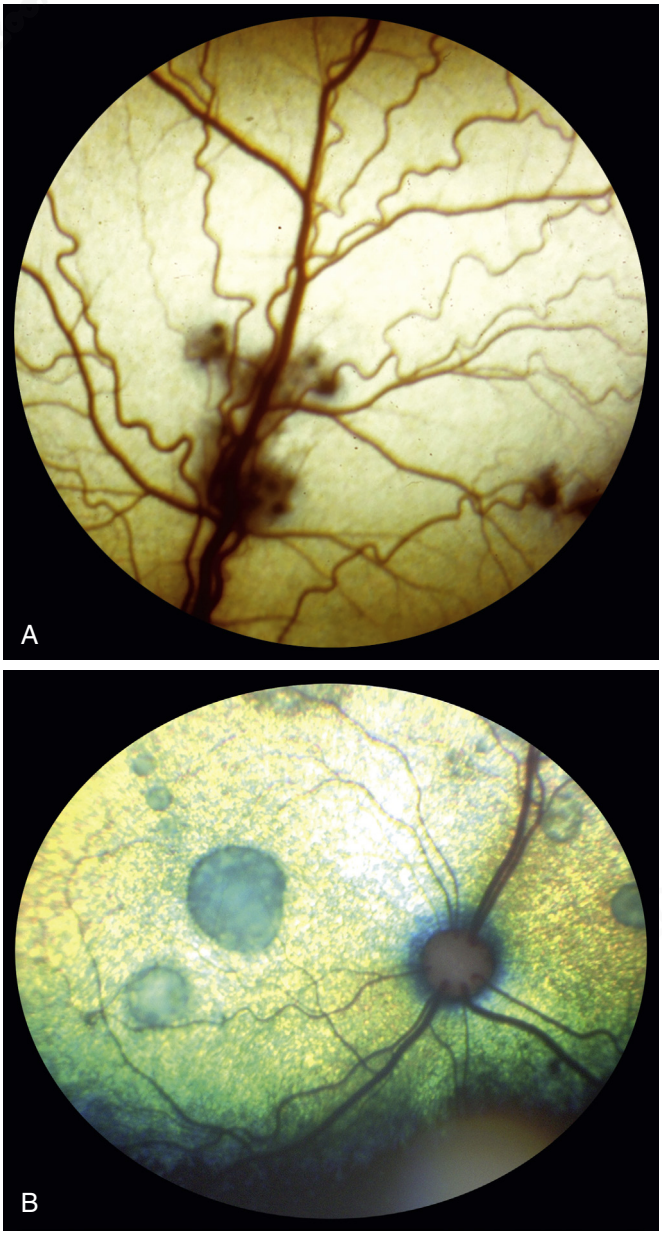

Fig. 128.25 Multifocal subretinal granulomas in a dog (A) and a cat (B) with cryptococcosis.

including orbital exenteration, has not typically been successful. In one report, a cat was successfully treated with posaconazole after surgery and treatment with itraconazole (ITZ) and amphotericin B failed.[96] In dogs (especially German shepherd dogs), disseminated aspergillosis may also cause fungal endophthalmitis. In such cases, chorioretinitis, retinal detachment, and anterior uveitis are common (Fig. 128.26).

Chorioretinitis or endophthalmitis that appears pyogranulomatous to granulomatous should heighten the suspicion for a systemic mycosis. Associated systemic signs of fever and respiratory, skeletal, dermatologic, or CNS involvement are often present. Vitreal centesis in an eye with endophthalmitis may be helpful for diagnosis when other lesions are not present.

In many instances the ocular inflammation worsens initially with systemic antifungal therapy because of the immune reaction to the dying organisms, which can threaten vision. Short-term use of oral

Fig. 128.26 Panophthalmitis causing retinal detachment and hemorrhage in a mixed-breed dog with disseminated aspergillosis.

prednisolone at a dose of 1 to 2 mg/kg per day is recommended to dampen this reaction.[97] If anterior uveitis is present it should be treated as outlined in the section on Topical Therapy. Glaucoma is not uncommon with severe ocular involvement and should be appropriately treated.

Enucleation of blind eyes has been proposed as a means of eliminating a nidus of fungal infection that may cause relapse. Although it is justifiable to remove a blind, painful eye (such as one with intractable glaucoma), enucleation is not indicated in an animal that has been effectively treated for fungal disease and has a comfortable but blind eye.

Protothecosis

More than 50% of dogs with protothecosis have ocular involvement,[98] whereas ocular lesions have not been reported in cats (Chapter 90). Most dogs with ocular lesions also have systemic signs such as diarrhea, but in some instances systemic signs are not evident. Lesions include a granulomatous chorioretinitis, often with retinal detachment, that is similar in appearance to those associated with systemic mycoses.[99] Anterior uveitis is often present as well. Diagnosis is often possible by cytologic examination of specimens collected by vitreous centesis.

Toxoplasmosis

The most prominent ocular lesion in dogs and cats with toxoplasmosis is choroiditis with extension into the retina (Chapter 93).[100] These lesions typically appear as multifocal dark gray infiltrates in the tapetal fundus and fluffy white infiltrates in the nontapetal fundus. Anterior uveitis also occurs, and *T. gondii* bradyzoites and tachyzoites have been identified histopathologically in the irides and ciliary bodies of systemically affected cats.[101]

It is possible that *T. gondii* may incite immune-mediated uveitis in the absence of systemic disease. Several mechanisms have been proposed, including homing of activated immune cells to ocular tissues, molecular mimicry, circulating antigens or immune complexes from nonocular sites of parasite replication, and a nonspecific increase in immune response.[100,102] In kittens experimentally infected *in utero* or

in the early neonatal period, chorioretinitis and anterior uveitis developed without other evidence of clinical illness.[103]

Toxoplasma gondii–specific antibodies can be measured in aqueous humor. Antibody levels can be compared with serum levels through use of the Witmer-Goldman coefficient, or C-value. C-values greater than 3 suggest intraocular antibody production and may be more helpful than serum titers alone in diagnosing ocular toxoplasmosis. Aqueous humor can also be evaluated by PCR for the presence of *T. gondii* DNA.[104,105]

Neosporosis

Although puppies with neosporosis typically die or are euthanized because of neuromuscular signs, ocular lesions are present in some dogs (Chapter 94). Retinitis is the primary ocular lesion with extension into the choroid (retinochoroiditis). A mild anterior uveitis was also reported.[106]

Encephalitozoonosis

In many animals, including rabbits, blue fox, and mink, cataract formation with uveitis is the most common clinical problem that results from *Encephalitozoon cuniculi* infection (Chapter 92).[107-109] Vertical transmission allows the parasite to enter the lens during fetal development.[110] In one report of 11 domestic cats with cataract and uveitis, *E. cuniculi* infection was documented by serology, cytology, and PCR on aqueous humor and lens material[111] (Fig. 128.27). All cats were successfully treated with oral fenbendazole for 3 weeks in addition to undergoing phacoemulsification to remove the lens and anti-inflammatory therapy for uveitis.

Leishmaniosis

Ocular and periocular lesions associated with leishmaniosis were reported in 25% of 105 infected dogs in one study.[112] In 15% of the dogs in the study, ocular lesions were the only clinical sign. Ocular signs may include anterior uveitis, conjunctivitis, keratoconjunctivitis, periocular alopecia, diffuse blepharitis, posterior uveitis, orbital cellulitis, and optic neuritis (Fig. 128.28). In a study of 127 shelter dogs and 132 client-owned dogs in an endemic area of Italy, blepharitis predominated in shelter dogs, whereas anterior uveitis was more common in client-owned dogs.[113] In a histopathologic study of the eyes from 60 dogs from Spain with confirmed leishmaniosis, the predominant inflammatory pattern was granulomatous.[114] The organism was identified by immunohistochemical staining in 27% of globes. *Leishmania* parasites were identified in conjunctiva, cornea, iris, ciliary

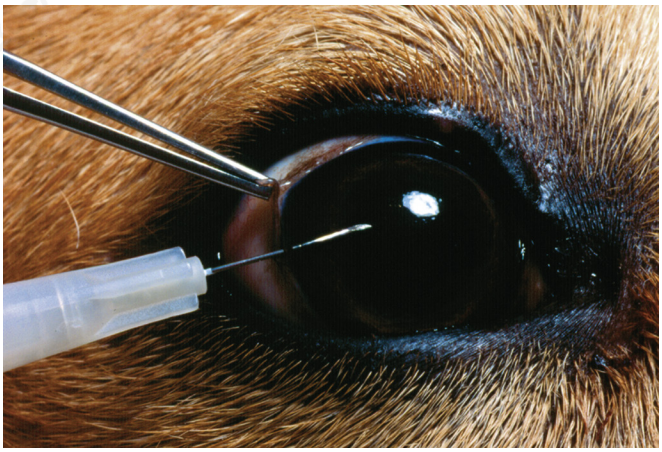

Fig. 128.29 Aqueous centesis in a dog. A 27-gauge to 30-gauge needle enters at the limbus, avoiding the iris and corneal endothelium.

Fig. 128.30 Vitreous centesis in a dog. A 22-gauge to 25-gauge needle enters 6 mm posterior to the limbus and is directed slightly posterior and toward the center of the globe.

body, choroid, and optic nerve sheath. In dogs with blepharoconjunctivitis, scraping and cytologic examination can reveal the presence of amastigotes.

DIAGNOSIS

Aqueous Centesis

Aqueous centesis can be performed using heavy sedation or general anesthesia. A 27- to 30-gauge needle on a tuberculin syringe should be used with the "seal" broken so that movement of the plunger is smooth. Topical proparacaine should be used even with sedation. A cotton-tip swab soaked in proparacaine should be held at the site of centesis for 60 seconds before insertion of the needle. Typically the easiest location to access is the lateral limbus. Small forceps should be used to hold the conjunctiva close to the limbus to fixate the globe and apply counterpressure to the needle. The needle should enter the cornea just rostral to the limbus and parallel to the plane of the iris (Fig. 128.29). The iris, lens, and corneal endothelium should be avoided. Unless the anterior chamber is collapsed, the volume that can be removed from the dog is about 0.3 mL and from the cat is about 0.5 mL. The needle should be withdrawn slowly and a sterile cotton-tipped swab held over the site, because aqueous will leak for a brief time. An aliquot of the aspirated aqueous should be submitted in a plain tube for culture and susceptibility testing, and the remaining aliquot placed in a small EDTA tube to be centrifuged for cytologic examination. If fibrin is present or iris adhesions of less than a few days' duration are present, 25 µg of tissue plasminogen activator (tPA) may be injected to dissolve clots and break synechiae.[115]

Vitreous Centesis

Centesis of the vitreous cavity has more potential complications than aqueous centesis and is usually reserved for eyes that have lost considerable visual function. Choroidal hemorrhage and retinal tears are the two most likely complications. Topical proparacaine is not completely effective in anesthetizing the sclera; thus general anesthesia is recommended. A 22-gauge needle with a 3-mL syringe should be used. The site of entry should be 6 mm caudal to the limbus in the dorsolateral quadrant. Forceps are used to apply counter pressure, and the needle point is aimed posteriorly away from the lens and toward the center of the vitreous cavity (Fig. 128.30). The needle should be short (0.5 inch) so that it does not inadvertently pass completely across the vitreous humor and tear the opposite retina.

TABLE 128.5 Intraocular Penetration of Antibacterial Agents in the Non-inflamed Eye

	PENETRATION BY ROUTE		
Agent	**Systemic**	**Topical**	**Subconjunctival**

NA, not available in a form for route of administration; *NR*, not recommended because of retinal toxicity.

Approximately 0.5 mL of vitreous humor can be removed for culture and cytologic examination.

TREATMENT

Ocular infection and inflammation can be treated using topical, subconjunctival, intraocular, or systemic medications. The route of

administration selected depends on the location, severity of the infection, and the drug being administered. The eye has three barriers to drug penetration: the intact cornea for topical penetration and the blood-aqueous and blood-retinal barriers for systemic drug penetration. In general, drugs with a differential solubility in water and lipids and small molecular size are better able to penetrate these barriers. Inflammation or ulceration weaken these barriers to variable degrees and allow better penetration. The ability of antibiotics to penetrate the normal eye varies by drug and route (Table 128.5). The vitreous humor is a large, rather inert structure, resulting in low drug levels by any route of drug administration except direct intravitreal injection, in which the vitreous humor acts as a depot for the relatively slow release of the drug.

Topical Administration

Depending on the drug and whether the cornea is ulcerated, topical therapy may provide adequate drug concentrations only on the surface or as deep as the iris and ciliary body. Epithelial defects of 25 to 50% of the surface area increase drug penetration into the corneal stroma and aqueous humor nine-fold, but larger defects do not produce an additional increase.[116] Other variables that influence drug concentrations following topical administration are the frequency of application, drug contact time, drug concentration, and formulation. Solutions are generally easier to apply to a painful eye than ointment and, therefore, are preferred in terms of compliance. Although medications with high drug concentrations may have improved absorption, they can also increase reflex lacrimation and become diluted by osmotic influx of fluid from tissues.

When solutions are used, one drop (about 30 to 50 µL) of a preparation in the affected eye(s) is adequate. Multiple or rapidly repeated instillations of the same or different preparations simply increase the rate of loss through the NL system or mutually dilute each preparation, thereby reducing the availability of each drug. Waiting an interval of at least 5 minutes between instillation of different drugs is required to allow reflex tearing to subside and prevent dilution of the previous drop.

Treatment of routine surface infections of the conjunctiva or prophylactic antibacterial therapy of corneal ulcers should include topical broad-spectrum antibiotics such as neomycin-polymyxin B-gramicidin that are not used systemically. This rationale reduces exposure of bacteria to drugs that may be beneficial for systemic therapy (and hence reduces selection for resistant bacteria) and avoids sensitization of a patient to a topical antibiotic that might have potential in systemic therapy. Some animals develop an allergic reaction to topical neomycin, particularly when used chronically. Anaphylactic reactions in cats after administration of topical bacitracin-neomycin-polymyxin B preparations have been reported.[117] Most cases have been fatal, so this product is not recommended in cats.

Regardless of cause, treatment of uveitis requires anti-inflammatory therapy. Topical potent glucocorticoids such as 1% prednisolone acetate and 0.1% dexamethasone alcohol (the form present in neomycin-polymixin B-dexamethasone suspension) penetrate the corneal barrier well and achieve therapeutic levels in the anterior segment. Prednisolone and dexamethasone in the phosphate forms do not penetrate the cornea as well and should not be used for the treatment of uveitis. Topical NSAIDs such as diclofenac and flurbiprofen penetrate an intact cornea well and can also be used for treating uveitis. Topical NSAIDs have less potent anti-inflammatory effects and thus are better suited for treatment of mild uveitis. They can also be used in conjunction with a topical glucocorticoid for an additive effect. The frequency of use of a topical anti-inflammatory agent is dictated by the severity of the uveitis, ranging from 2 to 6 or more times daily for mild and severe uveitis, respectively.

Subconjunctival Administration

Subconjunctival administration of antibiotics or anti-inflammatory drugs is used primarily for anterior segment disease and can achieve therapeutic intraocular levels of medication. The major limitations of subconjunctival injections are drug irritation and ocular manipulation. The means by which a subconjunctivally injected drug reaches the interior of the eye are controversial, but direct diffusion through the sclera, which has no epithelial barrier as the cornea does, and leakage through the needle hole with topical absorption have been demonstrated. Except for long-acting drugs, most others must be readministered at 12- to 24-hour intervals to maintain therapeutic levels. Typically, a single injection of a subconjunctival drug is administered, followed by topical agents, systemic agents, or both.

Drugs should be injected under the bulbar conjunctiva, not the palpebral conjunctiva. The dorsal 12 o'clock position is easiest to access. Adequate topical anesthesia is required. A proparacaine-soaked cotton-tip swab should be held at the injection site for at least 60 seconds. The conjunctiva should be lifted with a small forceps to allow for proper needle placement. A 25-gauge needle should be used to slowly inject the drug. In many animals, this can be accomplished without sedation. In both dogs and cats a volume of 0.2 to 0.5 mL can be administered, creating a bleb that resolves in a few hours.

While significant posterior segment drug concentrations can be obtained when injecting near the equator of the globe, the subconjunctival route achieves inadequate concentrations for bacterial infections of the vitreous. Subconjunctival dosages vary by agent (Table 128.6).

TABLE 128.6 Concentrations and Dosages of Locally Used Ocular Antibacterial Agents[a]

Agent	Topical	Subconjunctival	Intravitreal
Amikacin	10 mg/mL	25 mg	0.4 mg
Ampicillin	50 mg/mL	50–150 mg	5 mg
Bacitracin	10,000 U/mL	5000 U	—

Systemic Administration

The systemic route of therapy is indicated in cases of chorioretinitis and optic neuritis, because topical or subconjunctival application does not result in therapeutic drug concentrations in these tissues. Many drugs are unable to cross the blood-retinal or blood-aqueous barrier, although some agents have good ocular penetration (see Table 128.5). However, most drugs administered systemically do penetrate the eye when it is inflamed and the normal ocular barriers are disrupted. Of the systemically administered antifungal azole compounds, fluconazole

has optimal penetration of the eye and CNS, but also is the least active azole. Itraconazole has also been effective in many animals for treating systemic mycoses such as blastomycosis with ocular involvement, and may be effective when treatment with fluconazole fails.

Some systemically administered medications may be associated with ocular adverse effects. Some cats receiving systemic enrofloxacin (oral or injectable) have developed acute retinal degeneration and permanent blindness.[118,119] This has been most notable in cats receiving greater than the recommended dose of 5 mg/kg per day. However, even lower doses may cause retinal degeneration in some cats, particularly older or debilitated animals with compromised renal function, and all systemically administered fluoroquinolones should be viewed as potentially retinotoxic in cats. However, pradofloxacin was shown to have no retinal toxicity in young healthy cats at 6 and 10 times the therapeutic dose.[120] This drug is preferred for cats when treatment with fluoroquinolones is indicated.

Treatment of moderate to severe anterior uveitis or posterior uveitis should include the use of an oral anti-inflammatory drug. Prednisone or prednisolone has the most potent effect and should be used in cases of optic neuritis, moderate to severe chorioretinitis, or retinal detachment caused by posterior uveitis. In cases of anterior uveitis without posterior segment involvement, an oral NSAID may be adequate and will also provide an analgesic effect.

Adjunctive Treatments

In addition to specific therapy, standard nursing care involves cleansing the ocular surface and lids with warm, moist wipes. Systemic analgesic drugs such as the synthetic opioid tramadol can be beneficial in treating ocular pain and can be safely used in conjunction with an oral glucocorticoid or NSAID. Topical atropine minimizes ocular pain from ciliary and iridal muscle spasm and helps prevent synechiae; however, atropine should not be used if KCS, glaucoma, or iridocorneal angle compromise are present. Injection of 25 μg of tPA into the anterior chamber is an effective and dramatic means of breaking down adhesions and dissolving fibrin clots if given within 3 to 7 days of formation. Once the clot is organized, drug efficacy is lost. If active or recent bleeding has occurred in the eye, intraocular rebleeding may occur after injection of tPA. Injections may be repeated if necessary. Injection of tPA into the vitreous humor is not as safe because of retinal toxicity.

Intraocular Administration

Intracameral or intraocular injection of antibacterial drugs is a heroic and effective means of obtaining high levels of intraocular antibiotics for the treatment of bacterial endophthalmitis. If vision is to be preserved, the decision to use the intracameral route must be made early to avoid rapidly devastating inflammation to delicate intraocular structures. Because culture and susceptibility testing results are not available for a few days, a broad-spectrum bactericidal antibiotic is usually selected. The use of intravitreal vancomycin has been common in human medicine for the treatment of bacterial endophthalmitis after injury or intraocular surgery. Prudent use of vancomycin is recommended to reduce selection for vancomycin-resistant enterococci, which represent a significant threat to human and animal health.

CASE EXAMPLE

Signalment

"Max," a 10-year-old male neutered bichon frise from northern California.

History

Max was evaluated by the University of California-Davis Veterinary Ophthalmology Service for a fleshy pink mass that had been noticed by his groomer on the outer corner of his left eye a week before the time of evaluation. The mass did not appear to be painful or pruritic, and Max had otherwise been eating well and was bright and alert. Max had been diagnosed a year previously with small B-cell lymphoma, which at that time had been detected in the right conjunctiva, peripheral lymph nodes, and GI tract. The lymphoma was treated with a combination chemotherapy protocol (cyclophosphamide, doxorubicin, vincristine, prednisone). A month later he developed a left-sided superficial corneal ulcer that was initially treated with neosporin-polymixin-bacitracin ointment, but subsequently ruptured and was treated with a conjunctival pedical flap. Topical cyclosporine and ocular lubricant were also prescribed for decreased tear production in the left eye, but because of persistently decreased tear production at a 3-month recheck, topical tacrolimus was also added. Since then, he had done well and was considered to be in complete remission. Max was up to date on vaccinations and was receiving monthly heartworm and ectoparasite prophylaxis medications.

Current Medications

Topical cyclosporine (2%, 1 drop q12h OS), tacrolimus (0.03%, 1 drop q12h OS), ocular lubricant (q6-8h OD), prednisone 1 mg/kg PO q24h.

Ophthalmic Examination

Body weight: 4.5 kg.

Eyes were open and appeared comfortable. There was moderate mucoid discharge OS. Face symmetrical, globe position and movements were normal OU. Pupil size was midrange OD. There were anterior synechia OS and the pupil could not be fully assessed due to large conjunctival flap and corneal opacity. Pupillary light reflexes (direct and consensual) were intact. The menace response was intact OU, there was a dazzle reflex, and palpebral reflexes were complete OU. Patient behaved as if sighted.

OD: Iris atrophy and nuclear sclerosis were present. All other findings were within normal limits.

OS (Fig. 128.31A): There was mild to moderate hyperemia of the third eyelid with mild diffuse thickening of the third eyelid. Mild diffuse conjunctival hyperemia and chemosis was present. There was a 7 mm × 3 mm × 3 mm smooth raised pink conjunctival mass arising from the temporal bulbar conjunctiva just posterior to the ventrotemporal limbus. The conjunctival pedicle flap was integrated into axial cornea. It appeared to be well perfused, densely pigmented, and fibrotic with extension of melanin and fibrosis forming a 2- to 3-mm rim around the incorporated flap. The anterior chamber was clear. There was a focal anterior synechia temporally. The visible iris and limited fundoscopic examination appeared normal.

STT (mm/min): OD-15, OS-5

Intraocular pressures (mmHg-rebound): OD-14, OS-10

Fluorescein stain: OU-no retention

Biopsy Procedure: Tetracaine was applied to the ocular surface OS and lidocaine 2% gel was applied to the affected conjunctiva. The conjunctiva adjacent to the mass was grasped with forceps and scissors were used to excise the conjunctival mass. Light pressure with a 4 × 4 gauze over closed lids was applied for hemostasis. Erythromycin ointment was applied OS at the conclusion of the procedure. The tissue was cut in half and submitted for histopathology and aerobic/anaerobic bacterial culture.

Histopathology Findings

The submucosa was markedly expanded by an abundant population of predominantly large foamy macrophages and plasma cells admixed with fewer neutrophils and Mott cells. Macrophages often contained phagocytosed cells, karyorrhectic debris, and occasional coccobacilli. Vascular profiles were cuffed by moderate numbers of lymphocytes and plasma cells. Gram staining revealed

CASE EXAMPLE—cont'd

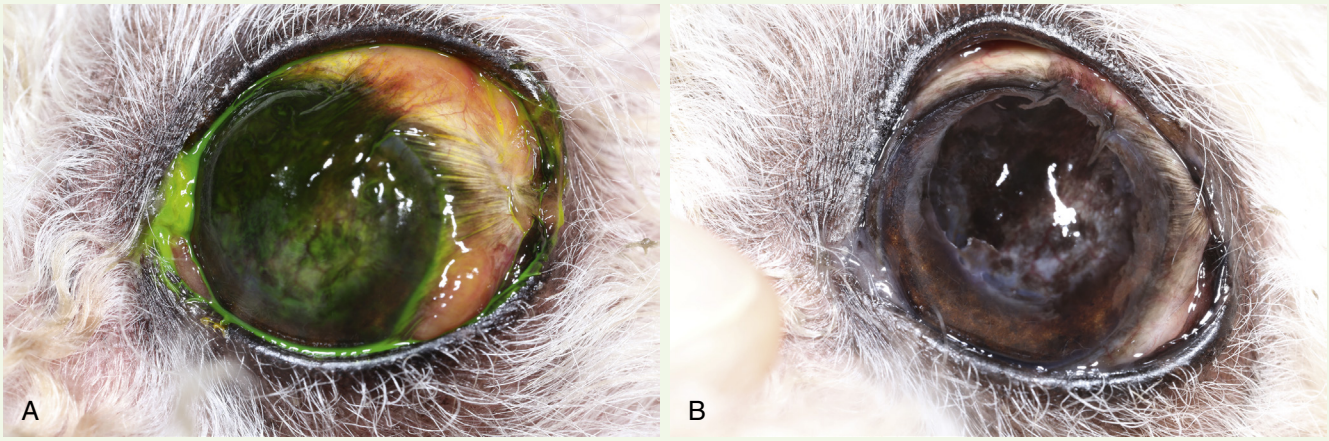

Fig. 128.31 Left eye of a 10-year-old dog with mycobacterial conjunctivitis. (A) There is a pink fleshy mass on the ventrotemporal aspect of the globe. A conjunctival pedicle graft is also present that arises from the dorsotemporal aspect of the globe. Fluorescein stain has been applied. (B) After treatment with surgical excision and topical ofloxacin, topical gentamicin, and oral doxycycline. (Courtesy of University of California-Davis Veterinary Ophthalmology Service.)

small numbers of gram-positive cocci and rare gram-negative rods scattered within histiocytes and occasionally extracellularly. Acid-fast staining revealed intrahistiocytic bundles of fibrillar to rod-shaped bacteria that were strongly acid-fast-positive. These organisms were also visible using Warthin-Starry silver stain.

Aerobic and Anaerobic Bacterial Culture

Very small numbers of mixed growth including methicillin-resistant *Staphylococcus pseudintermedius* (susceptible only to aminoglycosides, chloramphenicol, rifampin, vancomycin) and *E. coli* (susceptible to aminoglycosides, amoxicillin-clavulanic acid, ceftazidime, chloramphenicol, tetracyclines, imipenem, fluoroquinolones).

Diagnosis

Mycobacterial conjunctivitis.

Treatment

Doxycycline, 10 mg/kg PO q24h, topical gentamicin ophthalmic ointment OS q8h, and ofloxacin (0.3% ophthalmic solution, 1 drop OU q8h) in addition to continuing the other medications. At a recheck examination 1 month later, conjunctivitis had resolved and there was no evidence of mass recurrence (Fig. 128.31B). Antimicrobial treatment was discontinued. At an examination 4 months later there was still no evidence of recurrence, although the owners reported a brief period of inappetence a week before that visit. However, a month after that, Max stopped eating and began to lose weight, and the owners elected euthanasia. Necropsy was not performed.

Comments

This dog developed mycobacterial conjunctivitis, a rare infection of the ocular adnexal structures, which was likely secondary to immunosuppressive disease or medications. The lack of mycobacterial growth in culture suggests that a slow-growing or unculturable mycobacterial species was responsible, such as *Mycobacterium avium*. Bacteria cultured were likely secondary invaders and should have been inactivated with the topical antibacterial medications.

The owner was offered additional diagnostic tests to identify the *Mycobacterium* species present and determine whether there was evidence of more widespread infection, but declined. Such tests could include mycobacterial culture at a mycobacterial reference laboratory, species-specific PCR assays on paraffin-embedded biopsy tissue, and a minimum database with thoracic radiographs and abdominal ultrasound examination.

Possible reasons for the decline of this dog after treatment were recurrence of lymphoma, systemic mycobacterial disease, or another unrelated illness.

Miscellaneous Infections and Inflammatory Disorders of the Central Nervous System

Andrea Tipold, Marc Vandevelde, Renee Barber, Jane E. Sykes

KEY POINTS

Prion Diseases and Feline Spongiform Encephalopathy

- First Described: Feline spongiform encephalopathy was first recognized in 1990, but prion diseases of sheep and goats have been recognized since the 1700s and 1800s.
- Cause: Prions are small infectious agents that are resistant to inactivation by heat, formalin, glutaraldehyde, alcohol, and radiation. Infectivity is associated with a host-encoded protein, the prion protein (PrP). The mechanism of transmissible spongiform encephalopathy (TSE) involves a misfolding of the normal prion protein (PrP^c) to a new heat-resistant protein.
- Affected Hosts: Cats, humans, and a variety of other mammalian species.
- Geographic Distribution: Primarily Europe, but cases have occurred sporadically worldwide.
- Mode of transmission: The TSEs are transmissible to other animals, at least under experimental conditions. Routes of natural transmission of TSEs involve oral ingestion, skin scarification, or congenital transmission. For example, scrapie has been consistently found in the placentas of ewes. Infection has spread iatrogenically through contaminated biologic products and likely through other veterinary procedures or feeding practices.
- Major Clinical Signs: Adult cats, slowly progressive neurologic signs, behavioral changes, gait abnormalities, hypersensitivity.
- Differential Diagnoses: Degenerative diseases, neoplasia, other infectious and inflammatory diseases of the CNS.
- Human Health Significance: During the outbreak of bovine spongiform encephalopathy (BSE) in the United Kingdom, a new variant of Creutzfeldt-Jakob disease (vCJD) occurred in humans. The disease has also been reported in other countries. vCJD affected primarily young adults and was suspected of being caused by ingestion of contaminated cattle products. Not all humans are equally susceptible to the development of spongiform encephalopathy. Transmission of the agent through blood transfusions or organ donation remains a concern.

Bacterial Meningitis and Meningoencephalomyelitis

- Cause: Bacterial meningoencephalomyelitis is caused by a variety of pyogenic bacteria that enter the CSF spaces or the CNS parenchyma. Organisms are usually opportunistic microflora or enter tissues as a result of environmental contamination of penetrating objects or spread of an infection from other organs.
- Affected Hosts: Dogs and cats of all ages are affected.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Bacteria can spread to the meninges from: (1) sites of infection in the nasal sinuses, retrobulbar tissues, or middle or inner ear when host immune defenses are compromised; (2) sites of traumatic focal penetration; (3) sites of infection in adjacent venous sinuses or bony structures; or (4) via hematogenous arterial dissemination.
- Major Clinical Signs: Meningitis: fever, reluctance to move, stiff gait, and muscle spasms are the most common clinical signs. Paraspinal hyperesthesia and progressive neurologic dysfunction are progressive features. Meningoencephalomyelitis: additional signs of brain and/or spinal cord lesions.
- Differential Diagnoses: Meningoencephalomyelitis caused by nonbacterial microorganisms and immune-mediated causes should be considered. Myeloid or lymphoid neoplasias may cause similar focal, multifocal, or diffuse signs of inflammation.
- Human Health Significance: None. The organisms that cause bacterial meningoencephalomyelitis are indigenous microflora or environmental contaminants. Precautions should always be taken in collecting or handling CSF potentially laden with microorganisms during diagnostic medical procedures.

Inflammatory Neurologic Diseases Previously of Suspected Infectious Origin

- First Described: Granulomatous meningoencephalitis, necrotizing encephalitis, and feline poliomyelitis were first described in the 1950s–1980s. Nonsuppurative encephalitis was reported in Ireland in 2002 and steroid-responsive meningitis-arteritis was described in 1981.
- Cause: Unknown, but uncultivable infectious agents have been suspected.
- Affected Hosts: Granulomatous meningoencephalitis, necrotizing encephalitis, greyhound nonsuppurative encephalitis and steroid-responsive meningitis-arteritis all occur exclusively in dogs. Feline poliomyelitis has been reported in domestic and wild felids.
- Geographic Distribution: Some conditions have limited distributions, whereas others can be found worldwide.
- Mode of Transmission: Mostly unknown.
- Major Clinical Signs: Depending on the localization of the lesion—spinal cord or intracranial signs, or signs may be multifocal. Cervical rigidity, and in some diseases fever can occur.
- Differential Diagnoses: The main differential diagnoses are neoplasia and a variety of infectious diseases of the CNS (viral, bacterial, fungal, protozoal, and parasitic).
- Human Health Significance: None.

PRION DISEASES AND FELINE SPONGIFORM ENCEPHALOPATHY

ETIOLOGY, EPIDEMIOLOGY AND PATHOGENESIS

Feline spongiform encephalopathy (FSE) belongs to the transmissible spongiform encephalopathies (TSEs; Table 129.1),[1] a group of neurodegenerative diseases in humans and animals characterized by a very long incubation time and degeneration of the CNS with vacuolation of the neuropil and nerve cells.[2] The infectious agent is small and resistant to inactivation by heat, formalin, glutaraldehyde, alcohol, and radiation. Infectivity is associated with a host-encoded protein, the so-called prion protein (PrP). PrP is widely distributed in the CNS, peripheral nerve, neuroendocrine and lymphatic tissues, and many other organs.[3] It is involved in neuronal development and function and in the prevention of cell death. The mechanism of TSE involves a misfolding of the normal prion protein (PrP^c) to a new heat-resistant protein known as PrP^{Sc} or PrP^{res} (*Sc* stands for scrapie, the oldest known spongiform encephalopathy [SE] in small ruminants; *res* stands for resistant to protease digestion). In its new conformation, the PrP^{Sc} is protease resistant and hence accumulates in the tissue. Misfolding of the PrP can also occur spontaneously and sporadically through genetic mutations in the PrP gene, leading to hereditary SEs, which are exceedingly rare in humans. Once formed, the modified, abnormal PrP is thought to induce additional copies of itself by interacting with normal PrP. Thus, the belief holds that this misfolded protein itself becomes an infectious agent, the prion.[3,4] The prion theory is a revolutionary concept in biology, and many questions remain. Prions are unique because they can be both inherited and infectious.

The PrP^c gene is highly conserved among different animals; however, knockout mice devoid of the protein develop normally with mild neuronal abnormalities. The presence of an abnormal PrP in the CNS is devastating. PrP^{Sc} is insoluble and aggregates as amyloid fibrils in infected brain tissue where deposits (amyloid plaques) can be observed in some SEs. Accumulation of aberrantly folded PrP^{Sc} fibrils is central in the pathogenesis of these diseases.[3] Accumulation leads to astrocytic proliferation, microglial cell activation, loss of synapses, and finally to neuronal cell death by apoptosis.[2] However, PrP^c also appears to play an important role in neurotoxicity.[5]

The TSEs are transmissible to other animals, at least under experimental conditions (intracerebral inoculation), even from sheep to pigs.[6,7] Routes of natural transmission of TSEs involve oral ingestion, skin scarification, or congenital transmission. For example, scrapie has been consistently found in the placentas of ewes,[8] and in a cheetah maternal transmission was suspected.[9] Infection has spread iatrogenically through contaminated biologic products and likely through other veterinary procedures or feeding practices.[6]

During the incubation period (following mucosal exposure), which has been studied in small rodents, PrP^{Sc} accumulates on the membranes of follicular dendritic cells (FDCs) in local lymphoid tissue.[2] A crucial phase of neuronal invasion likely occurs at the interface of FDC and nerve endings in secondary lymphoid organs.[10] From the lymphoreticular tissues at the site of experimental inoculation, the prion is thought to gain access to the peripheral nervous system through local nerve endings, although the exact mechanism of transfer is unclear.[10] From there, the prion migrates to the CNS. Following exposure by ingestion, PrP^{Sc} may enter the gut-associated lymphoid tissue, then enter nerve endings in the intestinal tract, and migrate to the CNS by means of the vagus nerve. In bovine spongiform encephalopathy (BSE), there seems to be some replication in tonsils,[11] but spread appears to occur by way of the autonomic nervous system of the gut, specifically the vagus nerve to the medulla oblongata.[10,12]

Scrapie, the classic TSE of small ruminants, has been recognized for approximately 275 years. Since that time, other SEs have been recognized in humans and animals. TSEs became notorious in the late 1980s as a result of the BSE outbreak in the United Kingdom,[13] where scrapie has been endemic for centuries. BSE was spread by animal protein concentrates including scrapie-infected sheep in cattle feed. The agent present in these meats was no longer being properly inactivated because of changes in the production procedures. As a result, the scrapie agent probably became adapted to a new host and established BSE in bovines with major epidemic consequences.[14] However, BSE was not restricted to the United Kingdom. Recycling of imported live animals, processed beef, or livestock food supplements from the United Kingdom sparked new small-scale epidemics in most European countries. The United States had no reported indigenous cases because it banned the importation of beef from the United Kingdom beginning in the mid-1980s, and minimal sheep-derived products have been processed for use in feed for other animals.[15] However, cases in cattle have occurred in Canada, and two of these cattle were exported to the United States. Some infected cattle have been detected in Japan. The incidence of BSE is approaching zero in all European countries as a result of measures taken by the European Union.

FSE was first recognized during the BSE epidemic in the United Kingdom.[1] Based on strain-typing experiments, FSE is undoubtedly caused by the BSE agent.[16] Cats were probably infected by ingesting BSE-contaminated feed.[17] Cats cannot be experimentally infected by the scrapie agent directly as they can by BSE and Creutzfeldt-Jakob disease (CJD) agents, which indicates an adaptation to the new hosts.[18] The first cases of FSE were diagnosed in the early 1990s.[17,19] The outbreak was attributed to consumption of beef products contaminated by CNS tissues from infected animals.

In addition to the United Kingdom, single cases of FSE have been described in several European countries, and also worldwide.[20–23]

TABLE 129.1 Transmissible Spongiform Encephalopathies of Humans and Animals

Disease	Host[a]	First Recognized
Creutzfeldt-Jakob disease	Humans	1920
Kuru	Humans (New Guinea)	1957
Gerstmann-Straussler-Scheinker syndrome	Humans	1928
Fatal familial insomnia	Humans	1986
Variant Creutzfeldt-Jakob disease (bovine SE in humans)	Humans	1996
Sporadic familial insomnia	Humans	1999
Scrapie	Sheep	1730
	Goats	1872
Transmissible mink encephalopathy	Mink	1947
Chronic wasting disease	Mule deer	1967
	Elk	1979
Bovine SE (mad cow disease)	Cattle (Europe)	1985
SE	Eland, oryx, greater kudu (Africa)	1989
Feline SE	Domestic cats (Europe)	1990
	Exotic cats	1992
SE of captive primates	Monkeys	1996

[a]Geographic location in parentheses when restricted to a specific area.
SE, spongiform encephalopathy.

Captive wild species of Felidae such as lions *(Panthera leo)*, tigers *(Panthera tigris)*, cheetahs *(Acinonyx jubatus)*, and pumas *(Felis concolor)* that were fed bovine tissues have also been affected with BSE.[24,25] The number of affected cats being reported annually has sharply decreased. TSE has not been documented in the dog, most probably because of a few changes in the sequence of endogenous PrP.[26,27]

CLINICAL FEATURES

Because of the long incubation time of TSEs, the signs of FSE are observed only in adult cats (peak incidence at age 5 years). The neurologic signs develop progressively over several weeks to months and are characterized by behavioral changes such as aggressiveness and fear. Gait abnormalities include ataxia and inaccurate landing while jumping. Affected cats are hypersensitive to tactile stimulation. No focalization of the neurologic signs occurs. The disease is invariably progressive and fatal.

DIAGNOSIS

The suspicion for FSE is based on geographic location, the age of the animal, and the clinical signs. From a diagnostic standpoint, a variety of neurologic conditions have to be considered. No specific laboratory findings are present in cats with FSE. Laboratory diagnosis of TSE is based on immunohistochemical detection of the protease-resistant PrP^{Sc} in tissues obtained by biopsy or at necropsy. Tissue is subjected to proteinase K digestion to destroy PrP and selectively retain PrP^{Sc}. Several monoclonal and polyclonal antibody commercial test kits are available.[28,29] Species differences exist in reactions to these commercially available tests. In scrapie, PrP^{Sc} can be demonstrated in lymphoid tissues such as the tonsils or third eyelid.[30] Given that no replication of the BSE agent occurs in lymphatic tissues, laboratory diagnosis is possible only on brain material after slaughter. In cats, extraneural PrP^{Sc} accumulation appears to be inconsistent so that obtaining CNS tissue at necropsy has been the only absolute means of confirmation when other test results are negative.[31,32] A protein misfolding cyclic amplification technique was highly sensitive in detecting PrP^{Sc} in a cheetah.[33] Deposition was found throughout the CNS, lymphoreticular, and other tissues suggesting widespread spread of the agent throughout the body. In recent years, new assays have been developed that are based on conversion of recombinant PrP to PrP^{Sc} by PcP^{Sc} in body fluids or tissue homogenates (known as real-time quaking-induced conversion assays) (Fig. 129.1).[34] Application of these assays to CSF specimens has been useful for antemortem diagnosis of Creutzfeld-Jacob disease in humans.

Pathologic Findings

As in all other TSEs, the pathologic findings in FSE are highly characteristic. The changes consist of vacuolation in the neuropil and neurons in a bilaterally symmetric distribution, especially in the thalamus, basal ganglia, and cerebral cortex (Fig. 129.2A). Immunocytochemistry for PrP^{Sc} reveals accumulation of PrP in affected areas (Fig. 129.2B). Advanced cases have neuronal loss and gliosis. Advanced lesions are more commonly observed in human patients because affected animals are often euthanized in early stages of the neurologic disease. No inflammation is present. The neuropathologic profile varies after experimental chronic wasting disease infection.[35,36]

TREATMENT

Treatments used for TSEs must be able to cross the blood-brain barrier. A variety of compounds have been used including polyene antimicrobials,[37] analogues of Congo red, quinacrine, chlorpromazine, and inhibitors of peptide synthesis. Efforts are underway to discover more effective compounds, but to date, treatment of human SEs is largely supportive.[38] Active and passive immunization using recombinant PrP^{c} and antibodies to PrP^{c} could have some merit. TSEs are similar to Alzheimer's disease in which neurodegeneration is accompanied by massive deposition of amyloid-β-protein, and some reduction in progression occurs when immunotherapy is used. Because the incidence of TSE in humans has not risen at all as a result of the BSE epidemic that is now at its end, TSEs remain exceedingly rare diseases. Vaccine development is therefore unlikely.

PREVENTION

All TSEs are fatal diseases. Prevention of exposure is the most important control measure. Although transmitting an SE from one species to another orally is generally difficult, nonbovine species were found to be infected with BSE in the United Kingdom.[16] BSE in these other species undoubtedly resulted from oral exposure. Scrapie-infected sheep were processed into meat and bone meal supplements being fed to cattle, and tissue from sick animals was recycled through the animal food supply. However, further spread in the bovine population in Europe has been prevented by banning the feeding of animal proteins to ruminant species, and finally to all farm animals. The BSE epidemic has ended and FSE has therefore largely disappeared. Although BSE has been nearly eradicated, scrapie remains a challenge because it is a transmissible disease. Because susceptibility to scrapie is genetically controlled, PCR has been used to detect alleles of scrapie-susceptible sheep to assist selection for breeding of scrapie-resistant animals.[39]

PUBLIC HEALTH ASPECTS

In 1996, during the outbreak of BSE in the United Kingdom, a new variant of CJD (vCJD) arose in humans there.[40,41] The disease has also been reported in other countries, including the United States, often in association with a history of residence in the United Kingdom. A total of 232 cases have been reported worldwide, and although the epidemic is nearing its end, surveillance efforts continue.[40] In contrast to classical ("sporadic") CJD, vCJD affected primarily young adults and was suspected of being caused by ingestion of contaminated cattle products. Molecular typing efforts suggest that the vCJD agent is similar to the BSE agent.[42,43] Not all humans are equally susceptible to the development of SE. A higher prevalence of disease is associated with homozygosity for a polymorphism at codon 129 of the PrP gene.[3]

Transmission of the agent through blood transfusions or organ donation remains a concern. Although BSE is the only zoonotic prion disease that has been recognized to date, concerns remain about the possibility of new prion strains arising that may be capable of crossing the species barrier.[44]

BACTERIAL MENINGITIS AND MENINGOENCEPHALOMYELITIS

ETIOLOGY AND EPIDEMIOLOGY

Bacterial infections can spread into the meningeal spaces and subsequently the parenchyma of the CNS from natural orifices such as the nasal sinuses, retrobulbar tissues,[45–47] and middle or inner ear.[48,49] Bacteria that proliferate in middle or inner ear infections can enter the cranial vault and produce cranial meningitis or subdural abscess formation (empyema) and, frequently, with brain parenchymal involvement, central vestibular dysfunction.[50–53] Bacteria can also enter the

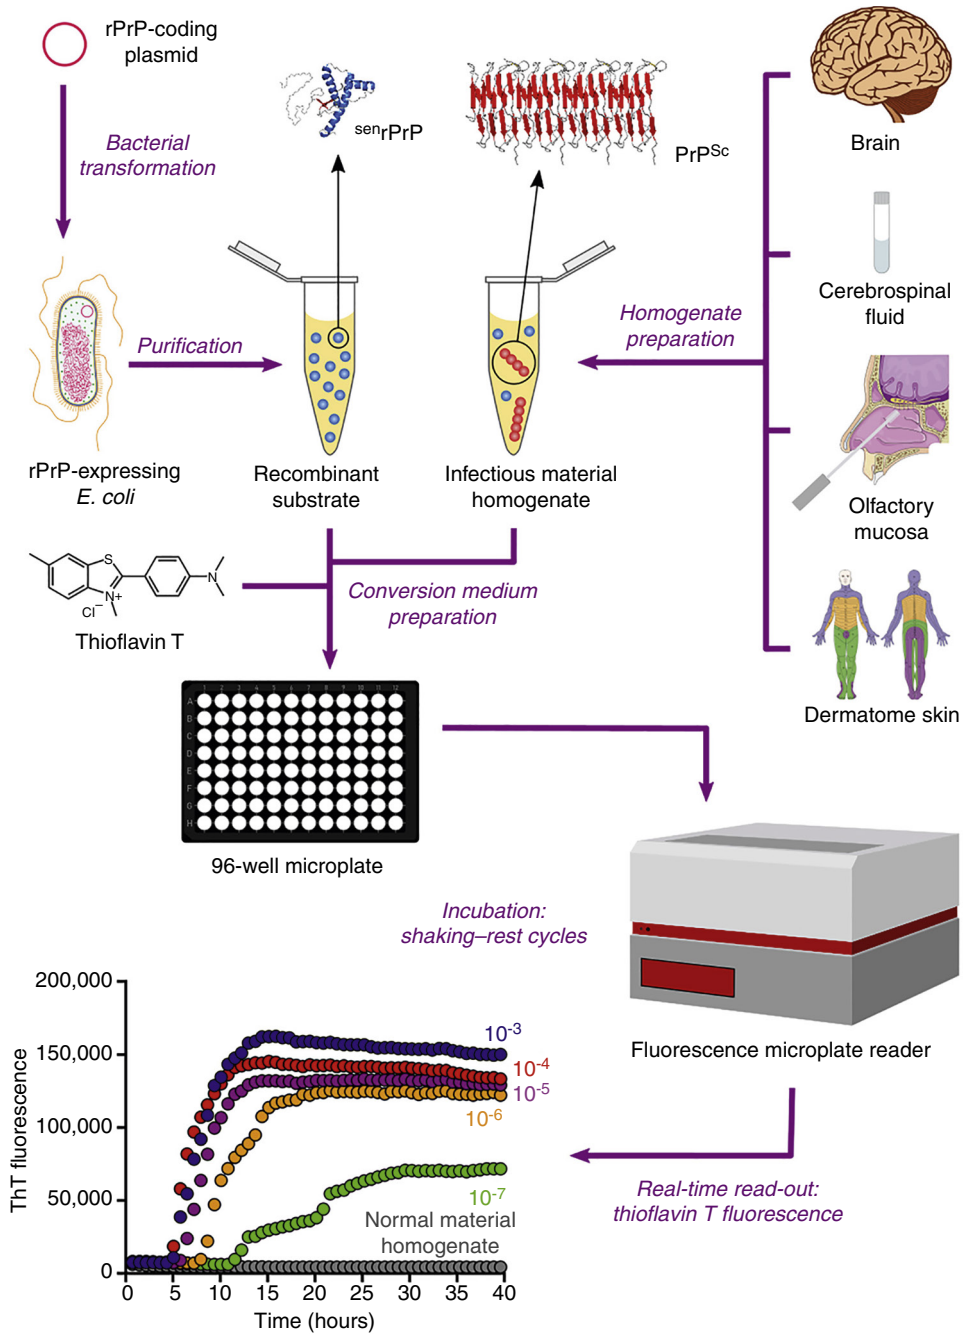

Fig. 129.1 Real-time quaking-induced conversion (RT-QuIC). Recombinant PrP (*rPrP*) is expressed in *Escherichia coli* and purified as folded protease-sensitive rPrP (*^{sen}rPrP*). Suspected infectious material (brain sections, cerebrospinal fluid, etc.), which may contain heat-resistant PrP (*PrP^{Sc}*), is mixed with ^{sen}rPrP, buffer, and thioflavin T (a fluorescent probe). The mixture is loaded into a microplate and then incubated in a fluorescence microplate reader. If PrP^{Sc} is in the sample, it triggers formation of PrP^{Sc} aggregates. The equipment records thioflavin T fluorescence emission during incubation, revealing the kinetics of aggregate formation. Sigmoidal growth in fluorescence indicates a positive transmissible spongiform encephalopathy diagnosis. If there is no PrP^{Sc} in the specimen, no fluorescence is emitted (*normal material homogenate*). (From Ascari LM, Rocha SC, Goncalves PB, et al. Challenges and advances in antemortem diagnosis of human transmissible spongiform encephalopathies. *Front Bioeng Biotechnol.* 2020;8:1228.)

meningeal spaces through traumatic focal penetration (foreign bodies or bite wounds),[54,55] spread from sites of infection in adjacent venous sinuses or bony or cartilaginous structures, or spread via hematogenous arterial dissemination.[56,57] Vascular spread, a common pathway of entry, can result in lodgment of bacteria in the endothelial cells of capillaries or the choroid plexus, which results in bacterial invasion of the parenchyma of the CNS or colonization of the CSF, respectively. Associated vascular necrosis may be followed by hemorrhagic necrosis. In the CSF, bacteria have adequate nutrients and a paucity of phagocytes and immunoglobulin, and they can proliferate, which produces a progressive inflammatory process that can readily spread along CSF pathways.

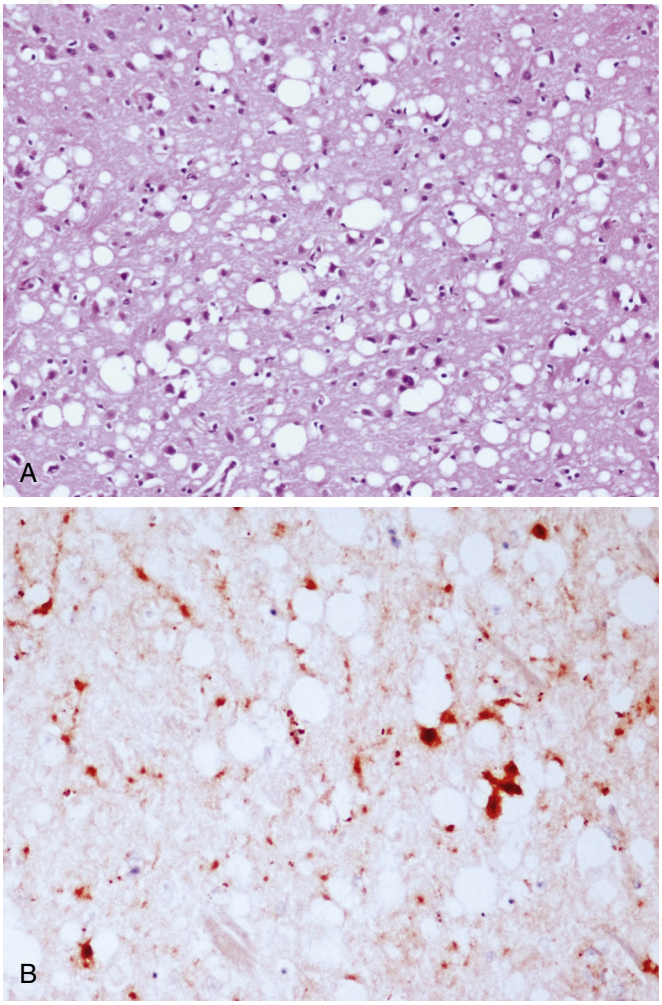

Fig. 129.2 Feline spongiform encephalopathy. (A) Area in the thalamus with many small and large vacuoles in the neuropil (hematoxylin and eosin stain, ×100). (B) Area with spongiform change. Punctate and plaque-like deposits *(red)* of the protease-resistant PrP (immunocytochemical staining with polyclonal anti-PrP; avidin biotinylated enzyme complex technique, ×250).

Bacteria that cause meningoencephalomyelitis in dogs or cats are varied and can include aerobic, microaerophilic, and anaerobic species. Staphylococci, streptococci, *Salmonella* spp., *Pasteurella* spp., *Actinomyces* spp., *Nocardia* spp., and a variety of anaerobic bacteria have been isolated.[50,58–62]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

On entry into the CSF, bacteria can replicate to a moderate degree before they trigger a host protective response, because the immune response in this area is slow. The immune response of the host, rather than virulence of the pathogen, is usually responsible for most of the subsequent pathologic events. TLRs, which are present on astrocytes, neurons, microglia, and oligodendrocytes, initiate innate recognition of the microorganisms. TLR signals initiate the release of a wide variety of proinflammatory mediators including reactive intermediates, cytokines, and chemokines within the CNS tissues and CSF spaces.[63] Within the nervous tissue, inflammatory processes lead to increased expression of inflammatory cytokines such as TNF-α; thus, higher CSF concentrations of TNF-α and IL-12 have been used to distinguish bacterial from aseptic meningitis in humans.[64–66] Immunologic damage to bacteria leads to the release of breakdown products into the CSF and local CNS tissue. This further stimulates the release of cytokines and prostaglandins, which are chemotactic for leukocytes and contribute to meningeal and ependymal inflammation. Subsequent inflammation leads to vascular injury and vascular thrombosis; tissue inflammation, edema, hemorrhage, and necrosis; and increased CNS pressure within the confines of the dura mater and bony spaces. Inflammatory processes may also lead to adhesions and obstruction to CSF flow, resulting in obstructive internal or external hydrocephalus.[67]

In the rare situation of pure meningitis, hyperesthesia from nerve root irritation is an important clinical sign. The gait of animals with meningitis is often choppy and stiff. With progression or direct parenchymal destruction of the spinal cord and brain parenchyma, focal, multifocal, or diffuse neurologic deficits can occur. Manifestations of intracranial deficits include gait abnormalities, central vestibular signs, abnormal placing reactions, seizures, behavioral abnormalities, and progressive decline in mental status until coma occurs.

Physical Examination Findings

Elevated rectal temperature may be found on examination because of fever, as well as excessive muscular exertional activity. Extraneural signs may occur and depend on the site of primary infection. Animals with meningitis may walk with a short stiff or cautious stride. Often the back of affected dogs is arched and the neck is outstretched with low head carriage. Paraspinal and extremity hyperesthesia is present with limb and spinal manipulation. When inflammation is confined to the meninges, postural reactions that involve motor responses are often stilted. As the inflammation involves the CNS parenchyma, deficits in sensory and motor responses such as delayed placing reactions, paresis, and ataxia can be observed. Cranial nerve deficits are often seen on neurologic examination. Further signs of cerebral dysfunction include signs such as altered mentation (depression, aggression) or seizures. Myotatic and flexor reflexes may be difficult to elicit because of increased muscle tone from the animal's extreme tenderness and unwillingness to relax. Loss of reflex function occurs if spinal nerves or gray matter become damaged in the inflammatory process.

DIAGNOSIS

The differential diagnosis for bacterial meningoencephalomyelitis includes noninfectious CNS disease such as neoplasia, or other infectious diseases caused by viruses, rickettsiae, fungi, protozoa, algae, and helminths (Table 129.2).[68,69] FIP is probably the most common cause of meningoencephalomyelitis in cats.[70,71] When parenchymal neurologic dysfunction is apparent, then protozoal meningoencephalomyelitis and meningoencephalomyelitis of unknown origin (MUO) should be considered. Frequently, more localized hyperesthesia associated with upper or lower motor neuron deficits can be observed with epidural empyema, discospondylitis, or paraspinal osteomyelitis. Steroid-responsive meningitis-arteritis (SRMA) in dogs can mimic all the signs of bacterial meningitis.[72] Diseases associated with myositis (such as American canine hepatozoonosis and leptospirosis) can also produce clinical signs that resemble those of meningitis.

Laboratory Abnormalities

Although there are no hematologic or biochemical abnormalities that are specific for bacterial meningitis, the CBC may reveal leukocytosis, often with a left shift, especially if the process that leads to the meningitis resulted from hematogenous spread; however, an absence of neutrophilic leukocytosis is common in dogs or cats with meningitis.[60]

TABLE 129.2 Examples of Infectious Agents That Can Cause Meningitis in Dogs and Cats[a]

	Dogs	Cats
Viruses	Canine distemper virus Arboviruses Suid herpesvirus 1 (pseudorabies)	Feline infectious peritonitis virus Borna disease virus Suid herpesvirus 1 (pseudorabies)

[b]Uncertain role in meningitis in dogs or cats.
[c]Via dissemination or cribriform plate destruction as a result of extension of nasal cavity disease.

Serum chemistry abnormalities are variable and nonspecific and can include increased ALT and ALP activities, hyperglycemia, and variable changes in serum electrolytes.

Definitive diagnosis of bacterial meningoencephalomyelitis requires evaluation of the CSF. Precautions should be taken not to remove too much fluid if CSF pressures could be increased. If imaging capabilities are available, they should be performed and evaluated before CSF removal since they may reveal evidence of increased intracranial pressure. However, findings on medical imaging should not be used to eliminate CNS inflammatory disease, because CSF findings have a high sensitivity for its detection.[73] Abnormalities found on CSF analysis in animals with bacterial meningitis usually consist of marked neutrophilic pleocytosis (Fig. 129.3), and CSF protein concentration is increased. CSF protein concentration (often > 100 mg/dL) and leukocyte numbers (usually > 100 cells/μL) tend to be greatest in suppurative meningitis (especially of infectious origin) as compared with other CNS diseases; however, the electrophoretic patterns of the proteins are not specific for a diagnosis.[74] Neutrophils generally predominate; however, especially in chronicity or with concurrent antimicrobial use, monocytes, lymphocytes, or eosinophils may be observed. In human bacterial meningitis, glucose levels in the CSF are reduced because of bacterial and inflammatory cell utilization, and lactic acid levels may be increased. In dogs, CSF glucose concentrations cannot be used as a distinct marker to differentiate bacterial meningitis from other inflammatory CNS diseases, especially from SRMA (which is usually accompanied by severe pleocytosis). In dogs, low CSF glucose concentrations seem to be associated with elevated CSF cell counts, rather than bacterial metabolism.[75] Finding organisms in the CSF on cytologic examination is exceedingly rare, and isolation of organisms in culture is also uncommon despite their visible presence on histopathologic examination.

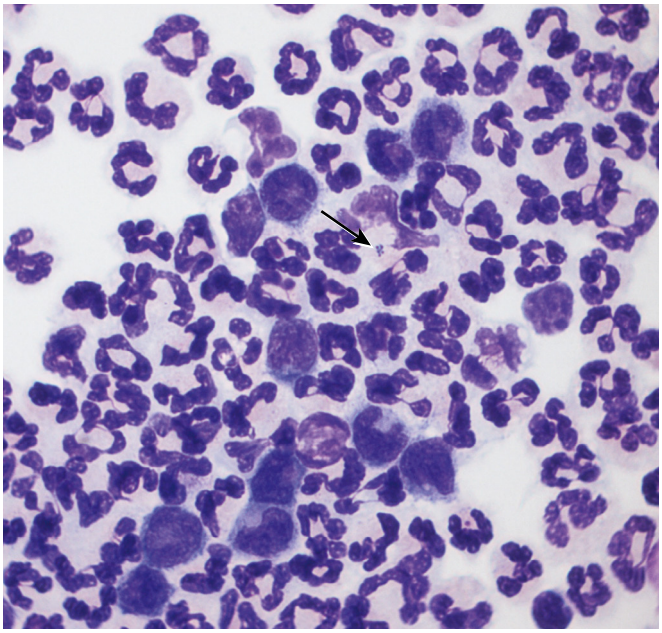

Fig. 129.3 Cytologic appearance of cerebrospinal fluid (CSF; cytospin preparation) in a 3-year-old male neutered Labrador retriever with bacterial meningitis. There is a large population of nondegenerate to moderately degenerate neutrophils. Many of the neutrophils contain intracellular cocci to pleomorphic short rod-shaped bacteria found in pairs and small aggregates *(arrow)*. Moderate numbers of foamy macrophages and reactive lymphocytes are also present. CSF analysis revealed a total protein of 402 mg/dL (reference range, <25 mg/dL), 100 red blood cells/μL, and 5,200 white cells/μL, 92% of which were neutrophils.

Diagnostic Imaging

Plain Radiography

Plain radiographic findings are unremarkable in dogs or cats with bacterial meningitis unless a bacterial osteomyelitis of paraspinal or cranial bones or discospondylitis are part of the infectious process. Bulla radiography is a valuable procedure for animals with suspected otogenic sources for their CNS infection; however, advanced imaging procedures are preferred when available.

Computed Tomography

CT of the brain or spinal cord in dogs or cats with bacterial meningitis may reveal contrast-enhancing lesions on the meningeal or ependymal surfaces. Focal areas of enhancement in areas of abscess formation or edema may also be present. In one puppy with suspected staphylococcal meningitis, CT imaging revealed external hydrocephalus.[67]

Magnetic Resonance Imaging

Purulent exudates that cover the CNS tissue may be visualized by MRI in animals with meningitis using T2-weighted (T2W) sequences while suppressing the signal from CSF (high fluid-attenuated inversion recovery [FLAIR]) (Fig. 129.4A). This method results in enhancement of signal intensity found in the meninges.[76] In more advanced cases, using postcontrast T1-weighted images, meningeal or parenchymal enhancement (signal hyperintensity) may be evident.[77] Occasionally, plaque-like densities are found that compress nervous tissue, which represent abscesses. Lentiform-shaped extra-axial collections of fluid have been described in cases of empyema.[78]

Microbiologic Tests

The main microbiologic assays used for diagnosis of bacterial meningitis in dogs and cats are aerobic bacterial culture and PCR assay of CSF. False-negative results occur because organism numbers in the CSF of dogs and cats are often low. Depending on the sensitivity of the PCR assay used and the viability of the bacteria in the specimen, culture may be positive when PCR results are negative, and vice versa.

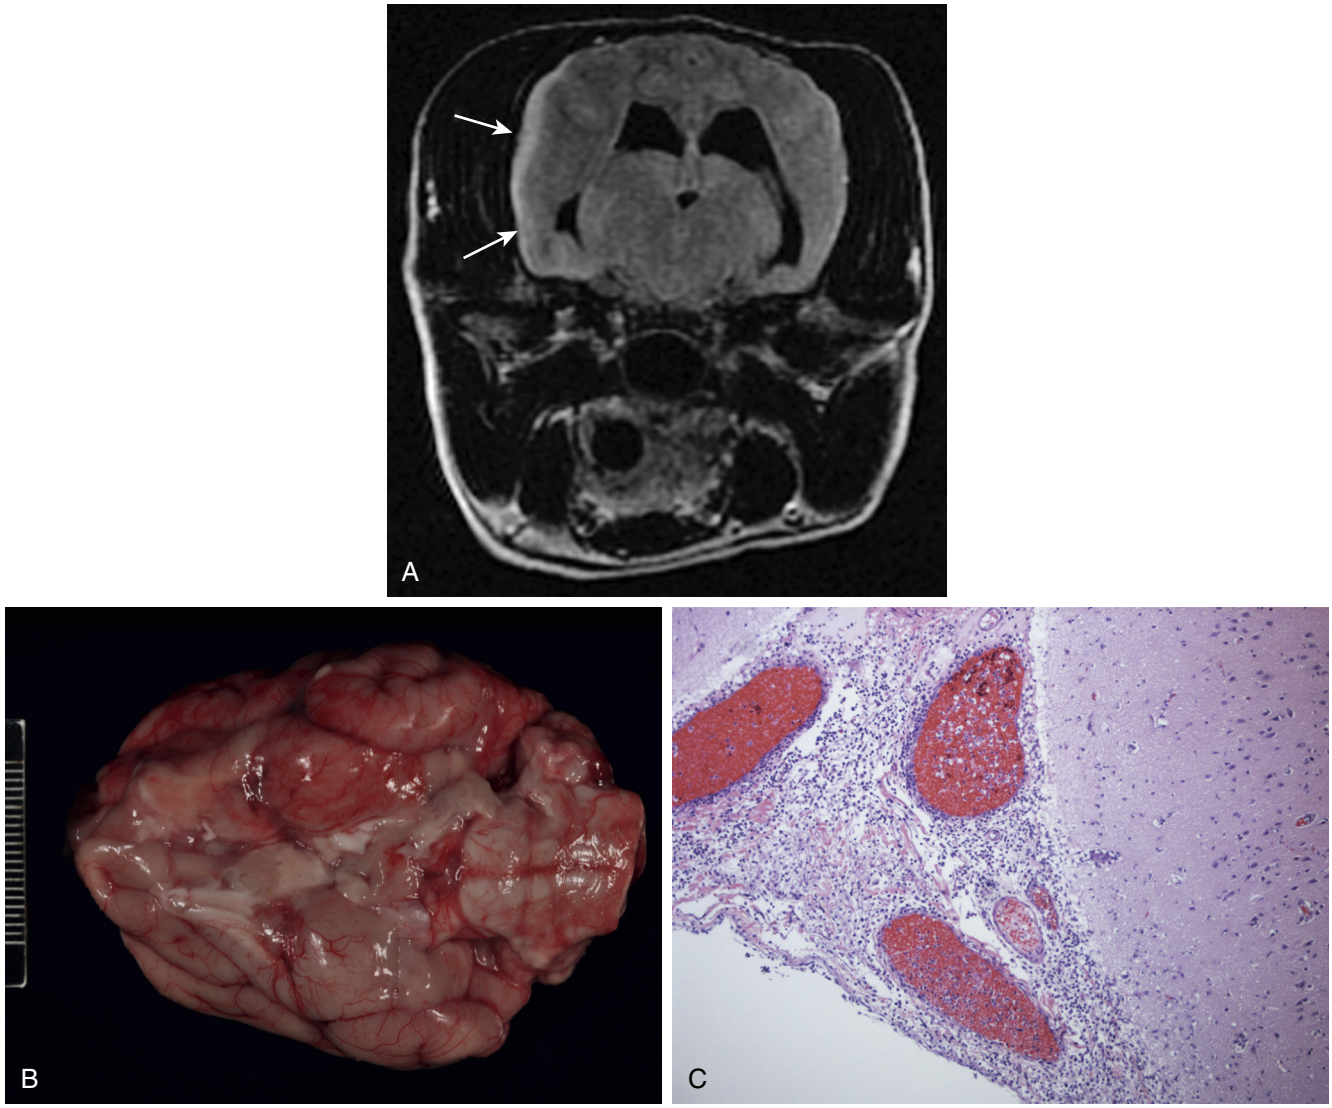

Fig. 129.4 Clinical images from a 4-year old female spayed Yorkshire terrier with bacterial meningitis. The dog had a 12-hour history of hypersalivation, generalized seizures, and vomiting. Small numbers of *Corynebacterium* spp. were isolated in culture from the meninges. (A) Magnetic resonance imaging (FLAIR image). There is marked hyperintensity of the meninges on the left side *(arrows)*. (B) Gross pathologic findings. Ventral aspect of the brain. Purulent material covered the cerebellum and left cerebral cortex and pooled on the floor of the calvarium. The right cerebral vasculature was markedly engorged *(shown)*. Cerebellar herniation was also found *(not shown)*. (C) Histopathologic appearance of meningitis. The meninges and Virchow-Robin spaces are expanded with inflammatory cells. The diagnosis was chronic, suppurative meningitis. Hematoxylin and eosin stain, 100× magnification. (Courtesy of University of California, Davis, Veterinary Anatomic Pathology Service.)

Bacterial Isolation and Identification

Bacteria may be isolated using routine aerobic and anaerobic bacterial culture media and conditions. At least 0.5 mL of CSF should be submitted for aerobic and anaerobic bacterial culture if possible. Organisms are uncommonly cultured from CSF because of their low number and the small amounts of fluid that are typically available; however, when successful, subsequent susceptibility testing assists in appropriate antimicrobial drug selection. Because of the infrequency of positive culture results despite the histopathologic presence of organisms at necropsy,[60] empiric antibacterial therapy should be employed based on a suspected site of origin of infection (see Antimicrobial Treatment, later).

Molecular Diagnosis Using Nucleic Acid–Based Testing

Sensitive and specific real-time PCR assays for detection of bacteria in the CSF have been described.[79] However, as with culture methods, their sensitivity is low. Broad-spectrum bacterial PCR assays have been used to document bacterial infection of the CSF in human medicine,[80] as well as multiplex PCR panels that are designed to simultaneously test for a number of different pathogens capable of causing meningitis or encephalitis.[81] Real-time PCR panels are widely available from commercial veterinary diagnostic laboratories for detection of CNS pathogens in CSF specimens from dogs and cats; however, the clinical sensitivity and specificity of many of the individual assays in these panels have not always been well studied. Results should always be interpreted in light of other clinical findings and diagnostic tests.

Pathologic Findings

Gross Pathologic Findings

At necropsy, sites of infection in animals with bacterial meningoencephalomyelitis may be found in organs outside the CNS, such as the skin or mucous membranes, respiratory tract, internal organs, external or middle or inner ear, or ocular tissues. Gross pathologic findings in the CNS are generally minimal in dogs or cats with early inflammatory changes. As the infection progresses in the parenchyma, the meninges may appear congested and nervous tissue parenchyma may be discolored or opaque (Fig. 129.4B). Focal accumulations of pus may occasionally be observed in the meningeal spaces or adjacent nervous tissue. In late stages, ischemic infarction of CNS tissue may occur as a result of severe vascular inflammation and necrosis. Because of vascular damage, necrosis is often hemorrhagic. Occasionally, obstructive hydrocephalus occurs if the inflammatory process occludes the mesencephalic aqueduct.

Histopathologic Findings

Microscopic findings in bacterial meningoencephalomyelitis consist of a suppurative inflammatory response that is prominent in the meningeal spaces and the penetrating sulci that contain blood vessels (Virchow-Robin spaces), with or without brain parenchymal involvement (Fig. 129.4C). With tissue Gram stains, bacteria may be observed within inflammatory cells, blood vessels, or neural tissues, in association with inflammation of the meninges and adjacent neural parenchyma.

TREATMENT

Antimicrobial Treatment

Because of the low sensitivity of culture and/or PCR assays in bacterial meningitis and the turnaround time involved, treatment must be instituted following the neurologic examination and availability of the results of CSF analysis (Table 129.3). The earlier appropriate antimicrobial therapy is administered, the better the chance that parenchymal damage will be minimized. Anti-inflammatory agents have been recommended, with some caution and on a temporary basis, to reduce intracranial pressure. Almost all drugs, either ionic or lipid-soluble, penetrate acutely inflamed meninges. However, as the inflammation subsides, only lipid-soluble drugs are effective. Where parenchymal abscesses are present, antibacterial drugs may not effectively penetrate affected tissue. In these cases, neurosurgical drainage is required in addition to systemic antibacterial therapy. One case report described the use of CT to guide drainage of a brainstem abscess in a cat on an emergency basis.[82]

Anti-Inflammatory Therapy

In addition to antimicrobial therapy, control of the immune response and resultant inflammation in CNS tissues is critical when intracranial or intraspinal pressures are elevated. Control of CNS edema is usually achieved with targeted dosages of glucocorticoids; however, therapy must be judicious since these medications are immunosuppressive and nonspecific in their effect on the host.[83]

Other Supportive Care Measures

Dogs with severe hyperesthesia may benefit from pain management and NSAIDs. Anticonvulsant medications may be needed for animals with seizures. Other supportive care measures, such as those required for hydration and nutrition, should also be considered.

PROGNOSIS

The prognosis for dogs with early acute bacterial meningoencephalomyelitis is good if minimal CNS parenchymal tissue is damaged. With severe parenchymal damage, long-term treatment might be necessary; prognosis varies depending on clinical signs and the extent of tissue destruction.

PREVENTION

Bacterial meningoencephalomyelitis is a result of exogenous or endogenous factors that allow bacterial organisms to gain access to the CNS. Although these insults cannot be completely prevented, injuries or lesions that occur close to the cranial or paraspinal spaces potentially predispose to CNS infection. Animals with wounds or infections in these areas or with systemic bacteremia should be treated appropriately, then monitored closely for CNS signs, and placed on judicious antimicrobial therapy if meningoencephalomyelitis is highly suspected or documented. Although the signs of bacterial meningoencephalomyelitis are confused with those of immune-mediated CNS disease,

TABLE 129.3 Antibacterial Drugs That Penetrate Central Nervous System Tissues and Fluids[a]

High	Intermediate	Low
Trimethoprim-sulfonamide, chloramphenicol, doxycycline, metronidazole	Third-generation penicillins, third-generation cephalosporins, fluoroquinolones	Penicillin, first-generation cephalosporins, aminoglycosides, clindamycin

[a]During acute inflammation, penetration is adequate for most drugs; however, as treatment progresses and inflammation subsides, the penetration becomes limited.

continued use of immunosuppressive drugs may lead to detrimental progression of a bacterial disease process.

PUBLIC HEALTH ASPECTS

There are minimal, if any, public health risks associated with bacterial meningitis in dogs or cats—that is, unless veterinary staff inadvertently inoculate themselves with organisms being collected for culture or PCR assays. *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*, which cause contagious respiratory disease and subsequent complicating hematogenous-origin meningitis in humans, do not readily infect dogs or cats.

NEUROLOGIC DISEASES OF SUSPECTED INFECTIOUS ORIGIN

The conditions described below are suspected to be caused by insidious infectious agents or immune aberrations in response to one or more stealth pathogens. The CNS is a frequent site of localization of pathogens evading host immune responses. In clinical practice, a diagnosis of MUO may be used for some of the described diseases since histologic features cannot be identified during routine clinical testing.[84–87] Unfortunately, a variety of terms have been used in the literature including "meningoencephalitis of unknown etiology" and "noninfectious inflammatory diseases of the CNS," so a common language is still missing.

GRANULOMATOUS MENINGOENCEPHALOMYELITIS AND NECROTIZING ENCEPHALITIS

Granulomatous Meningoencephalomyelitis

Granulomatous meningoencephalomyelitis (GME) has been reported in dogs in the United States,[69,88–90] Australia,[91] New Zealand,[92] Japan,[93] and several European countries (Vandevelde M, unpublished observations). It is a relatively common condition and is an angiocentric, nonsuppurative, mixed monocytic/lymphoid inflammatory process, predominately affecting the white matter of the brain and spinal cord.[89,90] Three forms of the disease have been described—disseminated, ocular, and focal; the disseminated form is the most common.

Despite its recognition as a clinical entity for over 40 years, the underlying cause and mechanism of disease production remains unclear. Genetic, autoimmune, infectious, neoplastic, and even toxic causes have been theorized. In some studies, female dogs were at greater risk for GME than male dogs; this finding is similar to other autoimmune demyelinating diseases including multiple sclerosis and experimental autoimmune encephalitis.[94] However, in another more recent study from Wisconsin, although more females than males were affected, this difference was not significant when compared to a control dog population.[95] Young to middle-aged dogs are often affected, and GME is uncommon before the age of 2 years. Smaller breeds, especially poodles, small terriers, Pekingese, and Maltese, appear to be predisposed,[88,96] although one case-control study found no breed predisposition.[95] In the latter study, more cases occurred in the spring.

GME has been proposed by some to be a DTH reaction with an autoimmune basis, supported by a predominance of major histocompatibility complex class 2 and CD3+ T cells.[97] Other investigators also noted a predominance of CD3+ T cells and a complete absence of the CD79 (B-cell marker) immunoreactivity in four cases of GME.[98] Positive immunoreactivity to IL-17 on T cells, macrophages, and microglia also has suggested an autoimmune pathogenesis, as this cytokine is often involved in the pathogenesis of other autoimmune disorders.[99] Anti-astrocytic antibodies and anti-transglutaminase 2 antibodies also have been identified in the CSF of dogs with GME.[100,101] The complete immunologic profile of GME and whether CNS autoantibodies are the cause or consequence of inflammation remain to be elucidated.

Despite the conventional view that GME is a disorder of immune dysregulation, some veterinary neuropathologists suggest that at least some cases of GME may be lymphoproliferative disorders, with features of both inflammation and neoplasia.[102] Focal GME is particularly similar to neoplasia, because lymphocytes within the perivascular cuffs often have variable degrees of pleomorphism and mitotic indices.[103] It is unclear whether the abnormal lymphocytes within brain lesions (and sometimes also CSF) are reactive inflammatory cells or representative of a true neoplastic population.

Potential viral, bacterial, and protozoal infectious triggers for GME have also been studied using PCR-based methods.[104–106] Borna disease virus was reported in dogs with meningoencephalitis in Japan and Switzerland and has been proposed as a causative agent for GME.[107,108] Borna disease virus, however, is unlikely to be a common etiology for GME given its predilection for CNS gray matter. Other investigators have demonstrated positive IHC for West Nile, CPIV, and encephalomyocarditis viruses in severe lesions of dogs with meningoencephalitides of presumed unknown origin.[109] The significance of these observations is unclear because the positive IHC may be caused by antibody cross-reactivity with endogenous proteins, as has been described with measles infections and in dogs with West Nile virus infection.[110,111] GME is most likely a nonspecific immunologic response, and multiple environmental triggers (including microbial antigens) and genetic factors are likely to play roles in the etiopathogenesis.

Necrotizing Encephalitis

Necrotizing encephalitis (NE) includes necrotizing meningoencephalitis (NME) and necrotizing leukoencephalitis (NLE). Historically referred to as "pug dog encephalitis" and "necrotizing encephalitis of Yorkshire terriers" respectively, these conditions have now been reported in various toy breeds including the pug, Maltese, Chihuahua, Yorkshire terrier, Pekingese, West Highland white terrier, Boston terrier, Japanese spitz, and miniature pinscher.[112]

Pedigree information on a large cohort of pug dogs is suggestive of a strong familial inheritance pattern for NME.[113] Disease in pugs and Maltese terriers has been strongly associated with the dog leukocyte antigen (DLA) II complex on chromosome 12 (the canine equivalent of MHCII); associations with loci on other chromosomes have also been found.[114] This association with DLAII supports an aberrant immune response as the underlying cause of disease.[115]

Although it is tempting to consider NME and NLE as distinct entities, these disorders may represent a spectrum of CNS injury with similar pathogeneses. Histopathologic differences among the NEs may result from minor genetic differences among dog breeds, modifying genes, and/or variations in antigenic exposures.

In general, attempts at virus isolation from dogs with NME have been unsuccessful. PCR screening of NME-affected brains for an extremely diverse group of DNA and RNA viruses has failed to identify viral nucleic acids.[106,113] A viral trigger for NE via molecular mimicry or the possibility that a pathogen is present in the CNS (but at undetectable levels) in the presence of a self-perpetuating immune response remain possible.

CLINICAL FEATURES

Granulomatous Meningoencephalomyelitis

In acute GME, clinical signs develop rapidly over the course of 1 to 10 days, and without treatment, it is rapidly progressive and fatal. Clinical

signs also may develop more slowly over a period of 1 to 4 months. Signs are associated with the site of most extensive damage, or may be multifocal. Signs can include ataxia, dysmetria, paresis, and paralysis, and changes in mental status, with confusion, lethargy, and coma. Cranial nerve dysfunction may also be observed.

In the acute stage of the disease, more than 50% of animals have fever, and many exhibit paraspinal discomfort on palpation or signs of cervical pain.[90,116] Central vestibular signs are common, and seizures also may be observed. Clinical signs alternatively may suggest a space-occupying mass referring to a single site of involvement, most frequently the posterior fossa, with brainstem and cerebellar signs. Cerebral or spinal signs sometimes predominate. An ocular form of GME, previously called ocular reticulosis, occurs with acute unilateral or bilateral blindness and ophthalmoscopic evidence of optic neuritis.[88,117]

Necrotizing Encephalitis

The onset of neurologic signs associated with NME varies from 6 months to 7 years of age and most commonly occurs in young dogs, with a mean age of 29 months.[118] In comparison, NLE typically manifests between 4 months and 10 years of age, with a mean age of onset of 4.5 years.[119] In general, signs associated with NE typically are rapidly progressive and most commonly include seizures, depression, circling, vestibulocerebellar signs, visual deficits, and ultimately death.

DIAGNOSIS

Because histologic confirmation is required for definitive diagnosis of GME and NE, "MUO" is typically used in the list of differential diagnoses after further examinations as described here. The diagnostic approach should include consideration of potential infectious causes of inflammatory brain disease, and appropriate serologic or nucleic acid–based assays. Testing for pathogens listed in Table 129.2 should be considered based on the history, geographic location, and clinical signs. PCR assays can be used on CSF or brain biopsies in an attempt to determine an underlying infectious cause of inflammatory brain disease before starting treatment.

Laboratory Abnormalities

Laboratory abnormalities in GME and NE are nonspecific. Neutrophilia may be present in the acute phase of GME.[116] In the CSF, marked pleocytosis with cell counts of 100 to several thousand leukocytes/μL is usual. Mononuclear cells predominate, but a mixed pleocytosis can also be observed with varying numbers of neutrophils.[120] Cytologic examination of the CSF may reveal large anaplastic mononuclear cells with abundant lacy cytoplasm,[88] and up to 20% macrophages. Protein concentrations as high as 1,119 mg/dL have been reported (mean 163.2 ± 25 mg/dL).[120] CSF analysis results are abnormal in most dogs with NE, with a predominantly mononuclear pleocytosis (usually 90–600 cells/μL) and an increased protein concentration (usually 50–200 mg/dL).[121]

Diagnostic Imaging

MRI is the preferred imaging technique for dogs with suspected inflammatory brain disease. Lesions in both GME and NE are hyperintense on T2W and FLAIR images, and variably isointense to hypointense on T1W images, and have irregular margins (Fig. 129.5). Both gray and white matter may be affected.[102] Contrast enhancement on T1W images is variable. In some cases of GME, MR images may not reveal any abnormalities.[122] In the uncommon focal form of GME, mass lesions can be detected with CT and MRI.[102] Lesions associated with NME include asymmetric, multifocal prosencephalic lesions affecting the gray and white matter.[123] Loss of gray and white matter demarcation also may be discernible.[123] In NLE, multiple, asymmetric bilateral prosencephalic lesions mainly affecting the subcortical white matter have been described on MRI.[124] NLE lesions often include multiple cystic areas of necrosis. Among the most commonly affected breeds (Yorkshire terrier, French bulldog, pug dog, and Chihuahua), even breed-specific MRI characteristics of NE in dogs have been described.[125] Digital analysis of MRI images (texture analysis/radiomics) may be helpful for differentiating neoplastic and inflammatory brain lesions in dogs.[126] PET has been used on a limited basis in an attempt to distinguish NME from other inflammatory brain diseases.[127,128]

Pathologic Findings

Lesions seen on advanced imaging do not differentiate MUO from neoplasia or infectious encephalitis, so definitive antemortem diagnosis requires histopathologic examination of brain tissue. Brain biopsies can be collected using stereotactic methods that are guided by advanced imaging or an open (free-hand) technique.[129,130] Brain biopsy is associated with some risk, with one study estimating a 6% mortality and 29% with an MRI-guided free-hand technique.[129] In some cases, definitive diagnosis is made at necropsy.

In GME, lesions are found in the meninges, brain, and spinal cord, especially in the cervical segments. White matter often is more severely affected than gray matter. Although the lesions are disseminated, the cerebral hemispheres, the midbrain, and the region around the fourth ventricle are most frequently involved. The lesions, which are strictly associated with the vasculature, consist of perivascular cuffing of monocytes, lymphocytes, plasma cells, and sometimes a few neutrophils and mast cells (see Fig. 129.5). The formation of eccentrically situated nodular foci of macrophages within these cuffs is a characteristic finding in GME. The cuffs can be distinguished in three degrees of severity: small disseminated perivascular lesions, small granulomas resulting from the confluence of several perivascular cuffs, and large focal coalescing granulomas. Additionally, necrosis of the neuropil, mitosis in the perivascular cuffs, and edema may be observed. Tryptase-positive mast cells can be found in perivascular cuffs. Dogs with the acute disease have significantly more mast cells than dogs with chronic disease.[131] Special stains can be applied to help rule out potential infectious agents, and unfixed tissue should also be submitted for nucleic acid–based testing.

Histologic findings in NE are characteristic and include diffuse meningitis, choroiditis, and encephalitis, with lesions predominating in the cerebrum (Fig. 129.6). Perivascular and meningeal inflammatory infiltrates consisting of lymphocytes, plasma cells, histiocytes, and macrophages have a strong tendency to invade the adjacent parenchyma. Extensive compact subpial and subventricular lesions are present and may extend deep into the underlying brain tissue, with unusually intense microglial proliferation and destruction of tissue. In some areas, frank cerebrocortical necrosis occurs. The cerebral white matter also is severely affected, with marked perivascular cuffing and gliosis. In some areas, leukomalacia with liquefaction and cavitation of the tissue is noted.

TREATMENT

No specific therapy for GME or NE exists, although improvement frequently has been observed in GME cases after administration of glucocorticoids with or without additional immunosuppressive agents. Because glucocorticoid therapy provides only temporary improvement in many cases, a second immunosuppressive drug may also be required. Options include procarbazine, cytosine arabinoside, leflunomide, mycophenolate mofetil, cyclosporine, and lomustine.[102] In a study using prednisolone alone, or in combination with lomustine, the response to both regimens was no different.[132] Use of a combination

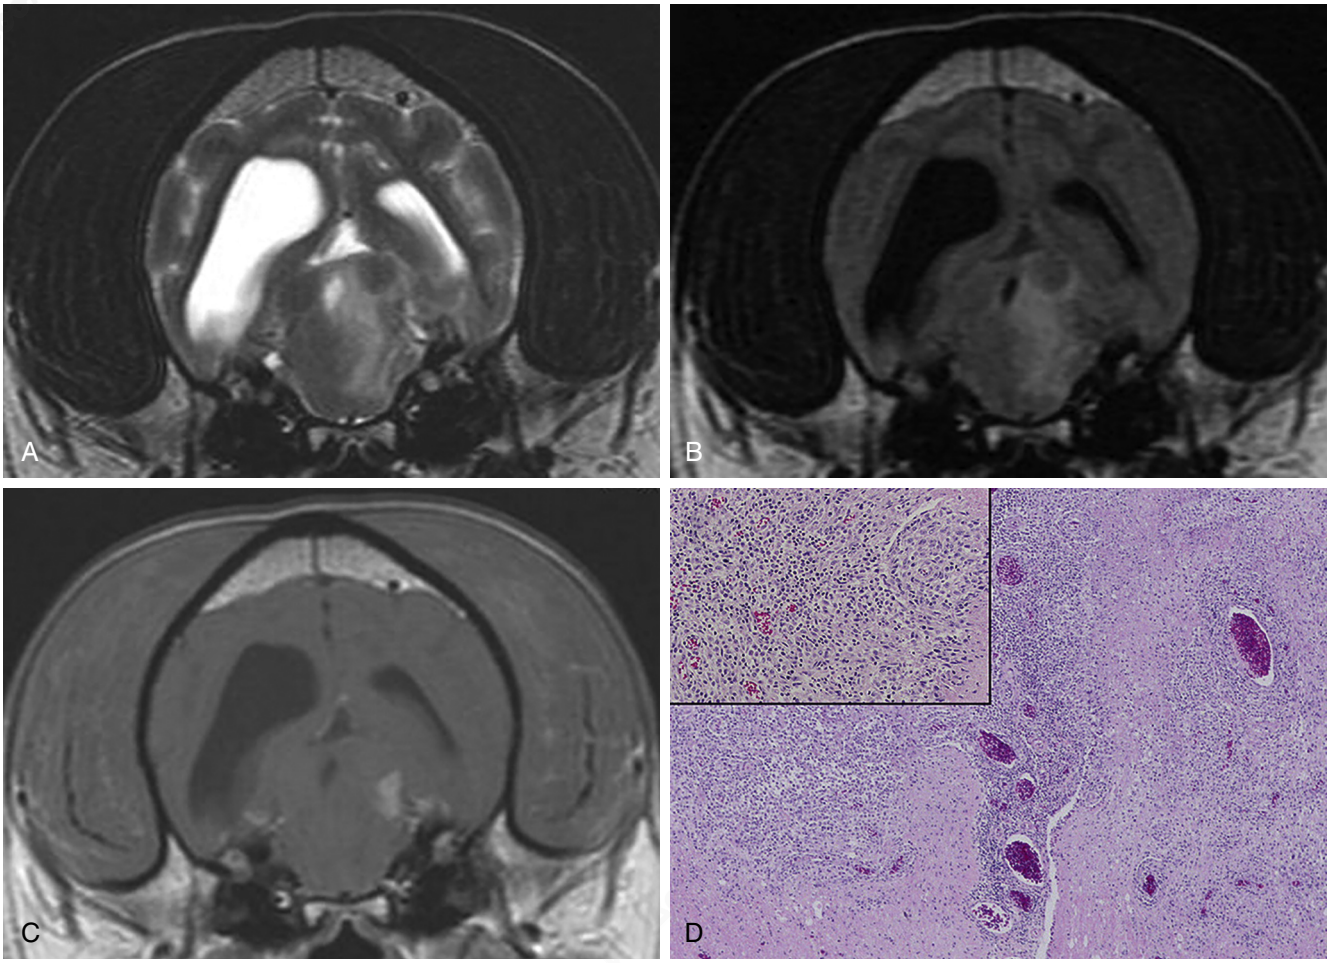

Fig. 129.5 Focal granulomatous meningoencephalomyelitis with ventriculomegaly. (A) Transverse T2-weighted (T2W) magnetic resonance image at the level of the midbrain, caudal colliculi, and cerebral cortex. Diffuse and right-sided hyperintensity involving the central gray substance, brachium of caudal colliculus, reticular formation, medial lemniscus, and mass effect of the mesencephalic aqueduct. (B) Transverse, T2W FLAIR image at the same level as in (A). Edema in the right midbrain is more conspicuous as a result of suppression of signal intensity in the mesencephalic aqueduct. (C) Transverse T1W image at the same level as in (A) after intravenous administration of a gadolinium-based contrast medium. The lesion displays variable contrast enhancement. (D) Hematoxylin and eosin staining of multifocal perivascular infiltrates consisting of macrophages, histiocytes, plasma cells, and lymphocytes. There is whorling of mixed cell infiltrates around blood vessels *(see inset)*. Original magnification x100; inset x400. (Courtesy of Gayle C. Johnson, DVM, PhD, Columbia, MO. Reprinted from Coates JR, Jeffery ND. Perspectives on meningoencephalomyelitis of unknown origin. *Vet Clin North Am Small Anim Pract*. 2014;44:1157–1185.)

of an immunosuppressive dose of prednisone and cytosine arabinoside is often used; the cytosine arabinoside is given for 2 consecutive days every 3–6 weeks on an outpatient basis. The reader is referred to the Suggested Reading list for detailed protocols.

Anticonvulsants may be needed to control seizures associated with inflammatory forebrain lesions. Glucocorticoid monotherapy does not alter the course of this NE in confirmed cases, and seizures may be refractory to anticonvulsants. However, use of anticonvulsant drugs may still prolong survival time.[118]

PROGNOSIS

The prognosis for dogs with GME is generally guarded given that many dogs develop progressive neurologic signs despite treatment, but some dogs may survive for several months.[94,122] Treatment should be attempted if possible because treated dogs have a significantly increased survival time than untreated dogs. Dogs that survive the first month appear to have an increased chance of surviving longer than a year. MRI features seem to help in establishing prognosis: loss of cerebral sulci and brain herniation were associated with a guarded prognosis.[133]

PUBLIC HEALTH ASPECTS

There is no public health significance of these conditions.

GREYHOUND NONSUPPURATIVE MENINGOENCEPHALITIS

Greyhound nonsuppurative meningoencephalitis was initially described in dogs from three different kennels in southern Ireland in 2002,[134] and cases continue to be reported from throughout the British Isles and

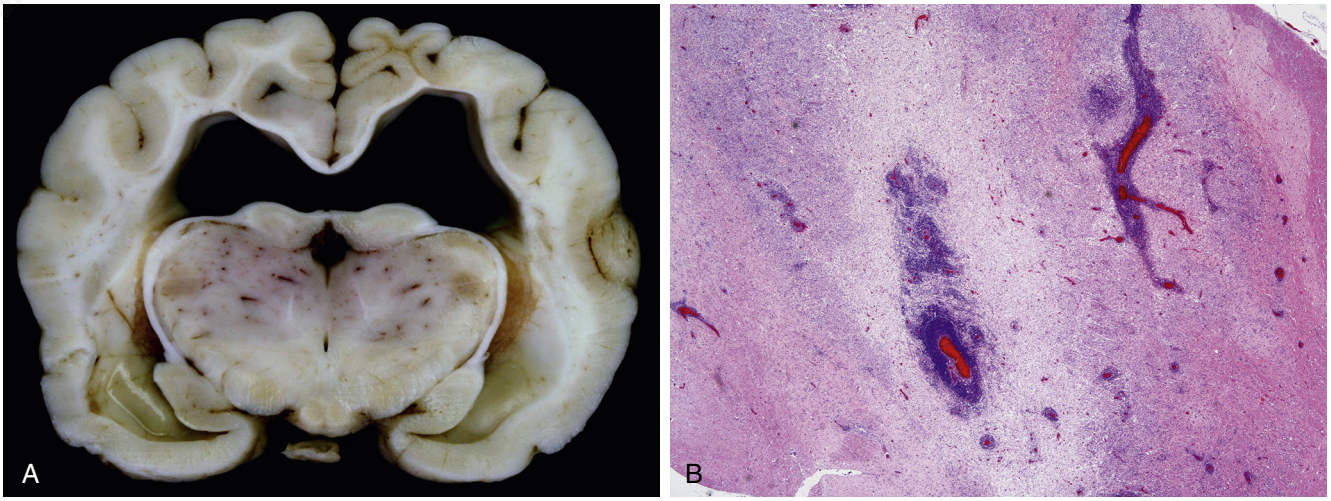

Fig. 129.6 Pathology of necrotizing encephalitis. (A) Brain of a 4-year-old intact female Yorkshire terrier. There is extensive necrosis in the dorsal subcortical white matter (with yellow discoloration) and marked atrophy with ventricular enlargement on the right side. (B) Histopathologic section of the brainstem of a 3-year-old French bulldog: there is a large area of necrosis of the nervous parenchyma with massive perivascular cuffing and intense diffuse infiltration of inflammatory cells in the necrotic tissue. Hematoxylin and eosin stain.

predominantly from Ireland.[135] The disease affects young greyhounds, usually less than 12 months of age, and frequently several littermates are affected. No evidence of underlying infectious causes has been found, but gene expression studies suggested that viral infection or autoimmunity may be involved in the pathogenesis.[136] Neurologic signs may be acute or chronic and progressive in onset and include altered mentation, head tilt, ataxia, recumbency, circling, and blindness. On MRI, lesions in four dogs predominantly affected the olfactory lobes, frontal and frontotemporal gray matter, and caudate nuclei, and were T2W hyperintense, T1W hypointense, with minimal or no contrast enhancement.[135] Histopathology reveals encephalitis with mononuclear perivascular cuffing, especially in the caudate nucleus, cortical cerebral gray matter, and periventricular gray matter of the rostral aspect of the brainstem. Results of a search for a wide range of known infectious agents has been negative.[137]

FELINE POLIOMYELITIS

Poliomyelitis in domestic cats was first reported in North Africa and Ceylon in the 1950s. Additional cases have since been described in North America and Europe.[138–140] A clinically and pathologically similar condition occurs in large Felidae (lions and tigers) held in captivity.[141,142] The disease occurs sporadically in domestic cats, but outbreaks have occurred among captive lions and tigers.[141,142] Pathologic findings indicate that poliomyelitis in cats is caused by a virus, but a search for known viruses has been unsuccessful.[142] Borna disease in cats is morphologically and clinically distinct from feline poliomyelitis, and has a different geographic distribution, so Borna virus is unlikely to be the cause.

Feline poliomyelitis has a slow onset and clinical signs progress over weeks to months. In many instances, the neurologic signs stabilize, and some animals may recover. Immature and adult cats appear to be susceptible. The predominant signs are defects in locomotion, including paresis, ataxia, and depressed placement reactions. Lower motor neuron involvement is characterized by muscle atrophy and decreased reflexes. Hyperesthesia in the thoracic and lumbar areas is apparent in some cases. Rarely, seizures, cerebellar signs, and pupillary abnormalities occur.

On histopathology, disseminated inflammatory lesions are found in the brain and spinal cord. The spinal cord and medulla oblongata are most severely affected. The lesions consist of perivascular mononuclear cuffing, gliosis, and neuronal degeneration, with the latter being most obvious in the ventral horns of the spinal cord. In chronic cases, there is minimal inflammation but substantial neuronal loss and intense astrogliosis in the cord. As a result of neuronal damage, marked diffuse Wallerian degeneration of the lateral and ventral columns also occurs, resembling a primary degenerative disorder.

Treatment is supportive. Contact between unaffected cats and those suspected to have the disease should be avoided. The prognosis is not always unfavorable because large Felidae have been known to recover.[141]

STEROID-RESPONSIVE MENINGITIS-ARTERITIS

SRMA is an immune-mediated condition of young dogs (usually < 2 years of age) that primarily involves arteries and meninges of the CNS, and one of the most common inflammatory disorders of the CNS in dogs. It has also been referred to as "beagle pain syndrome," "necrotizing vasculitis," and "sterile suppurative meningitis." In some cases, the disease occurs in combination with polyarthritis. A breed predisposition has been noted in Bernese mountain dogs, boxers, beagles, Nova Scotia duck tolling retrievers, golden retrievers, wire-haired pointing griffons, and basset hounds.[143] However, other medium- to large-breed dogs may be affected. There is no apparent sex predisposition.

A variety of studies have supported an immune-mediated pathogenesis for SRMA. Findings have included infiltration of the meninges by B cells and plasma cells, and the presence of T cells in vessel walls. Markedly increased IgA concentrations have been detected in CSF and serum, and there is an increased B cell to T cell ratio in the blood. A large portion of T cells are activated, suggesting the presence of a superantigen.[144,145] A Th2 response predominates based on an increased expression of IL-4 and reduced Th1 cytokines (IL-2 and INF-γ); other cytokines that predominate are IL-17 over a Th17-skewed immune response,[146] vascular endothelial growth factor, transforming growth factor 1, and IL-6.[147] All attempts to identify a causative infectious

agent have failed. Invasion of neutrophils is facilitated through upregulation of lymphocyte antigen CD11a and matrix metalloproteinases.[148,149] Uncontrolled IgA synthesis may be the result of immune dysregulation.

Classically, clinical signs are episodic and recurrent and include cervical pain of acute onset, reluctance to move, stiff gait, resistance to neck manipulation, paraspinal hyperesthesia, and high rectal temperature. Chronically affected animals develop neurologic deficits consistent with a multifocal or spinal cord lesion; paresis, ataxia, strabismus, and anisocoria have been described. In some cases, spontaneous bleeding in the subarachnoidal space may occur; in one dog, this led to acute nonambulatory tetraparesis.[150]

Hematologic findings include a predominantly neutrophilic leukocytosis, often with a left shift.[144] The CSF may be turbid, blood tinged, or xanthochromic from hemorrhage occurring in the subarachnoidal space. Neutrophilic pleocytosis (up to several thousand cells per microliter), a high CSF protein concentration, and erythrophagocytosis are apparent in acute cases. With chronicity, mononuclear cells may predominate in the CSF. Simultaneous demonstration of high IgA levels in serum and CSF supports the diagnosis with a high sensitivity (approximately 90%), but low specificity.[151] In addition, acute-phase proteins, including CRP, have been shown to be elevated in the serum and CSF of dogs with SRMA.[152,153]

CT or MRI may reveal contrast enhancement of the meninges; evidence of extramedullary hemorrhage has also been reported.[150] In a few instances at necropsy, subarachnoid hemorrhages may be found extending over the entire length of the meninges of the spinal cord and brainstem. In chronic disease, fibrous thickening of the spinal meninges may be noted grossly. Histopathologic changes consist of necrotizing arteritis of medium- and small-sized arteries and associated leptomeningitis, predominantly in the spinal cord and to a lesser degree in the brainstem (Fig. 129.7). Chronic lesions include proliferative changes of the vascular intima with stenosis and adventitial fibrosis. Occasional vessels may be thrombosed. Extraneural arteritis is more frequently noted in affected beagles, particularly in the extramural coronary arteries and myocardium.

Spontaneous remission has been observed in some dogs. In contrast to GME and NE, the response to glucocorticoid treatment is usually dramatic. Prednisone is given as a long-term treatment starting at an immunosuppressive dose (1–2 mg/kg, PO, q12h), then tapering. Response to treatment and follow-up examinations determine the treatment protocol. The use of second immunosuppressive agents such as azathioprine[143] or cytosine arabinoside[154] may allow reduction in the prednisone dose in order to minimize glucocorticoid adverse effects. Older dogs that have experienced frequent relapses that were insufficiently treated with glucocorticoids and that have high concentrations of IgA in the CSF seem to require a longer duration of therapy and have a less favorable prognosis. Long-term treatment studies have shown relapse rates of 60% to 16%; the relapse rate with a prednisone-azathioprine protocol was 19%.[143] One study identified pathogenic involvement of the endocannabinoid system in SRMA, a potential target for new treatment strategies.[155]

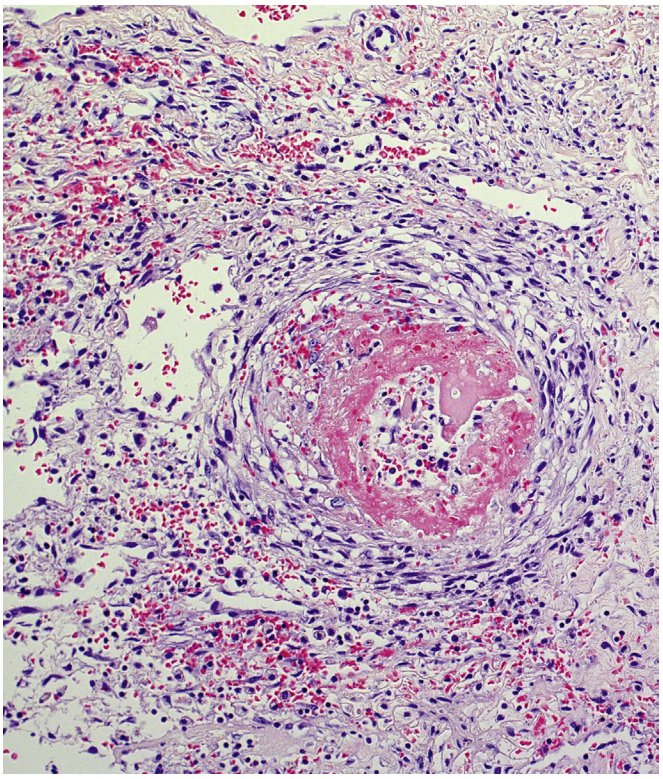

Fig. 129.7 Histopathology of cervical spinal cord meninges from a 2-year-old female intact mixed breed dog with steroid-responsive arteritis-meningitis: A large artery with acute hyaline necrosis and intense infiltration by inflammatory cells. The meninges also display diffuse infiltration by inflammatory cells and hemorrhage. Hematoxylin and eosin stain.

CASE EXAMPLE 1

Signalment

"Maxie," a 6-year-old female Birman cat from Bern, Switzerland.

History

Maxie was evaluated by the neurology service at the University of Bern in Switzerland in June 2001. Several weeks before examination, the cat started to drink large quantities of milk, but refused water. Two weeks before examination, Maxie became progressively reluctant to have her head touched, became easily startled, and exhibited short episodes of walking in circles, ataxia, and hypersalivation. The cat had been purchased as a kitten from a local Swiss breeder, and was fed commercial cat food as well as fresh bovine and turkey meat supplemented with vitamins and minerals. The cat had traveled to other countries including England in order to participate in cat shows. She had had regular contact with other cats and a dog. The cat had had several healthy litters. Vaccinations were up to date and she was FeLV antigen negative. Treatment with glucocorticoids and vitamin B by the referring veterinarian did not improve the cat's condition.

Physical and Neurologic Examination Findings

Routine physical examination revealed no abnormalities. The cat was excited and disoriented. There was a continuous fine head and ear tremor. The cat exhibited bilateral vestibular ataxia with frequent episodes of walking in circles while hypersalivating. All postural reactions were delayed. Pupils were dilated but responsive. Menace response was strongly diminished bilaterally. There was a pronounced hyperesthesia of the head region and the cat reacted strongly to sound. Spinal reflexes were normal. A diffuse cerebral lesion with partial involvement of the brainstem was suspected. The differential diagnoses included toxic metabolic and infectious diseases.

Laboratory findings

A CBC, serum chemistry panel, and urinalysis did not reveal any abnormalities.

Occipital CSF puncture was performed under general anesthesia. Cell count and protein content were within the normal range.

(Continued)

CASE EXAMPLE 1—cont'd

Electroencephalography
EEG was performed under general anesthesia. EEG tracings revealed a generalized iso-electrical course as well as sporadic spindles of medium amplitude and episodes of slower activity.

Treatment and Outcome
The cat was hospitalized and treated with 2 mg/kg phenobarbital IV q12h. The seizures were suppressed but the cat became increasingly obtunded. The owner requested euthanasia.

Neuropathologic and Microbiologic Examination
Histopathologic examination revealed marked vacuolization of the neuropil particularly in the cerebral cortex, thalamus, and brainstem. Spongiform change was most intense in the basal nuclei. In several gray matter areas, there was intracytoplasmic neuronal vacuolation and diffuse astrogliosis. Immunocytochemical staining with anti-PrP antibodies revealed accumulations of PrP in affected areas.

Diagnosis
Feline spongiform encephalopathy.

Comments
The clinical findings in this case were similar to those in cats described in the literature. However, although rapid onset of neurologic signs is typical, rapid progression as seen in this cat is unusual. Metabolic causes were unlikely based on the normal laboratory findings, and the normal CSF was not consistent with viral, bacterial, protozoal, or fungal infection. Against the background of the BSE epidemic in Europe and the much smaller FSE epidemic in its wake at the time this case was evaluated, the history and all clinical findings raised suspicion for FSE. MRI may have been helpful for antemortem diagnosis, but this imaging technique was not yet widely used in veterinary clinics at the time of the FSE epidemic.

The most likely source of infection in this case was ingestion of contaminated feed. It is possible that the cat may have been exposed to contaminated cat feed while in the United Kingdom, but in view of the long incubation time (5 years or more) the cat could have been exposed at home to specified bovine risk materials, which were first banned from animal consumption in April 1996 in Switzerland. FSE is no longer diagnosed in Europe. However, the disease may one day reemerge, as SEs continue to occur in other animal species.

CASE EXAMPLE 2

Signalment
"Jake," a 10-month-old male Weimaraner from north Georgia, USA.

History
Jake was evaluated for a 2-week history of reluctance to move, in association with anorexia and fever. He had been treated with oral enrofloxacin and clindamycin for 2 days; however, the signs of discomfort returned 2 days after medication was discontinued. Jake also had a history of external ear inflammation and pruritic skin disease for the previous month. The dog was up to date on routine vaccinations, lived indoors and outdoors, and traveled outdoors locally with the owner.

Physical Examination
The dog was alert, but held his head down with his neck extended. He was reluctant to stand or walk, and appeared painful when his head was elevated or lifted; however, no further discomfort could be elicited by more caudal paraspinal palpation. T = 103.5°F (39.7°C), HR = 110 beats/minute, RR = 30 breaths/minute, with shallow breathing. BCS was 3/9 and body weight was 31 kg. Mild erythema of the external ear canals was present and small amount of yellow-colored exudate was noted in the ear canals bilaterally. With the exception of the neurologic examination, no other abnormalities were detected.

Neurologic Examination
The dog held its neck extended and head down and walked with a short, stiff gait. Placing reactions were present in all limbs, but initiation and follow-through were stilted. In lateral recumbency, the dog did not relax, and myotatic reflexes were difficult to elicit because of excessive muscle tone. Discomfort was elicited by paraspinal palpation and application of traction on the extremities or with deep muscle palpation. No deficits in cranial nerve responses or reflexes were observed.

Imaging Findings
Cervical spinal radiographs without anesthesia showed no detectable abnormalities.

Laboratory Findings
Hematologic and biochemical findings: The only abnormality of the CBC was a low MCV (65.5 fL; reference range 66–77 fL) and mild leukocytosis (13,200 cells/μL; reference range 5,100–13,000 cells/μL). Serum ALP activity was increased (267 IU/L; reference range 13–122 IU/L). No abnormalities were found on urinalysis.

Arthrocentesis: Synovial fluid was pink and hazy. Nucleated cell count was slightly increased (3.2×10^3 cells/μL in the stifle joint). Nondegenerate neutrophils predominated; no intracellular inclusions or LE cells observed. Impressions: Mild purulent inflammation.

CSF analysis findings (specimen collected from cisterna magna): Clear, RBC = 26 cells/μL, WBC = 462 cells/μL (reference range, <5 cells/μL), total protein 72.6 mg/dL (reference range, 15–35 mg/dL). Differential cell count: Lymphocytes 4%, macrophages 18%, neutrophils 78%, occasional RBC, no bacteria observed in this specimen. Impressions: Marked purulent inflammation.

Microbiologic Testing
Aerobic bacterial culture (CSF): Negative. Anaerobic culture was not done.

Outcome
The dog was treated with chloramphenicol (35 mg/kg, IV, q8h) for 5 days and was then discharged on oral therapy for 3 weeks. The dog made a complete recovery from the signs when monitored for over 1 year.

Diagnosis
Meningitis (antibacterial-responsive) caused by suspected unidentified bacterial organisms.

Comments
Bacterial meningitis was suspected in this dog based on the history, clinical signs, laboratory findings, and response to chloramphenicol. Systemic spread of infection from a hematogenous route was suspected based on some of the inflammatory indicators in the hematologic and biochemical profile and evidence of mild suppurative polyarthritis that was found. The original treatment with enrofloxacin and clindamycin may have been subtherapeutic since it was short-lived and may not have penetrated the CNS tissues and fluids as well as chloramphenicol. Furthermore, IV dosing with chloramphenicol for the first days of therapy allowed for very high levels of drug in the CNS (although the use of chloramphenicol is controversial because of the potential for adverse effects in humans). Although an organism was not observed or isolated, bacterial infection was suspected based on the dramatic response to antibacterial therapy alone. In bacterial meningitis of dogs and cats, organisms are not often identified by cytologic or cultural examination of CSF. Response to antibacterial therapy should be considered presumptive evidence of bacterial infection.

Hereditary and Acquired Immunodeficiencies

Urs Giger, Krystle L. Reagan

KEY POINTS

- Immunodeficiencies are a large heterogeneous group of hereditary (primary immunodeficiencies) and acquired (secondary immunodeficiencies) disorders of host immunity that are associated with an increased risk of infection.
- Immunodeficiencies can arise through disturbances in antigen-specific defense mechanisms mediated by lymphocytes, the nonspecific defense system (which includes phagocytes, plasma proteins, and physical barriers), or both.
- The exact pathogenesis of many canine and feline immunodeficiencies remains unknown, but the molecular defects for several hereditary immunodeficiencies have been elucidated.
- A few hereditary immunodeficiency disorders are prevalent within certain breeds of dogs and cats, whereas others have been described once and may exist only in research animal colonies. Some appear transiently in the dog population, then disappear because of screening and informed breeding.
- A definitive diagnosis of immunodeficiency often requires specific immune testing in addition to routine laboratory tests, and therapeutic interventions are limited.

INTRODUCTION

Immunodeficiencies can be divided into primary and secondary forms depending on whether they are inherited or acquired (Table 130.1).[1–3] Certain clinical features can suggest immunocompromise (Box 130.1). Specific organisms and medical conditions often implicated in immunocompromised hosts are listed in Box 130.2. A definitive diagnosis often requires specific immune testing in addition to routine laboratory tests, and therapeutic interventions are limited.

HEREDITARY OR PRIMARY IMMUNODEFICIENCIES

Many genetically determined immune defects have been described in dogs, whereas only a few are known in cats. With few exceptions, they occur rarely and are summarized in Table 130.2; some are discussed later in this chapter in more detail. They can be broadly classified according to defects of the specific or nonspecific immune system as well as combinations thereof. The innate immune system should be functional at birth and available on short notice to protect the host from invasion by all sorts of organisms. It includes physicochemical barriers, phagocytes, complement and other plasma proteins, and natural killer cells. Congenital barrier defects particularly involve the skin and mucous membrane surfaces and are associated with infections of specific organs; such infections can become systemic. A variety of hereditary skin diseases are being further defined and other immunodeficiencies are being recognized. Ehlers-Danlos syndrome, which leads to fragile, hyperextendable skin in many dogs and cats as well as the myxedematous skin and immunodeficiencies of sharpeis, predispose to pyoderma, whereas ciliary dyskinesia in dogs increases susceptibility to rhinosinusitis and pneumonia. Similarly, X-chromosomal and other ectodermal dysplasias are associated with skin problems as well as mild immunodeficiencies.

Disorders of the phagocytic system involve defects of neutrophils and monocytes as well as the complement system and can lead to pyogenic and granulomatous infections. The granulomatous reaction can occur when neutrophils malfunction and mononuclear cells are recruited. A wide variety of bacteria (e.g., staphylococci, *Escherichia coli, Klebsiella, Enterobacter*) are usually involved, most of which represent resident microflora or pathogens of relatively low virulence. Recurrent infections of the skin, respiratory tract, and oral cavity are common, and intermittent bacteremia and overwhelming sepsis are also seen. Multisystemic amyloidosis, vasculitis, and immune-complex diseases are complications that can occur as a result of chronic recurrent or persistent infections. Cyclic hematopoiesis and leukocyte adhesion deficiency (LAD) are examples of serious quantitative and qualitative phagocytic defects, respectively.

The specific immune system can be divided into humoral and CMI systems and includes lymphocytes, immunoglobulins, and cytokines. Deficiencies of B cells or humoral immunity affect the production of immunoglobulins and lead to increased susceptibility to pyogenic bacterial infections. Deficiencies of T cells or CMI are associated with viral and fungal infections, but intracellular bacterial infections may also occur. Animals with cellular immunodeficiencies may have smaller thymic and tonsillar tissues as well as intestinal and peripheral lymph nodes and decreased numbers of circulating lymphocytes.

The severity of immunodeficiency varies among defects. Infections may be systemic or restricted to a particular organ system such as the skin or respiratory tract. Some immunodeficiencies in neonates lead to overwhelming infections and death within the first few days to weeks of life, whereas others, such as morphologic leukocyte changes, are not consistently associated with any noticeable predisposition to infection. Chédiak-Higashi syndrome in smoke-colored Persian cats is characterized by abnormally large eosinophilic granules in polymorphonuclear leukocytes. It causes no immunodeficiencies, but leads to a bleeding tendency resulting from a platelet storage pool disease.[4] Similarly, Birman cats with acidophilic granulation of neutrophils and dogs and cats with various lysosomal storage diseases (e.g., mucopolysaccharidosis, gangliosidosis, mannosidosis) have granulation or

TABLE 130.1 Features of Immunodeficiency Diseases Based on the Underlying Defect

Defect	Susceptibility to Specific Infections	Diagnostic Tests to Confirm Defect
Ciliary dyskinesia	Respiratory infections	Electron microscopy of cilia
Ehlers-Danlos syndrome	Skin injury and infections	Histopathology and electron microscopy of skin
B-cell dysfunction	Pyogenic bacteria, *Giardia* spp.	Globulin, serum electrophoresis, tetanus antibody response
T-cell dysfunction	Bacterial sepsis, mycobacteria, *Candida* and *Pneumocystis* spp.	Thymic radiographs, skin testing delayed hypersensitivity, CD4 and CD8 cell quantification
Granulocyte dysfunction	Streptococci, *Pseudomonas*, *Nocardia*, *Candida*, and *Aspergillus* spp.	Neutrophil count, phagocytosis assays, molecular genetic tests[a]
Complement	Pyogenic bacteria	CH50 assay, molecular genetic tests

[a]Specific breed-specific genomic DNA mutation/variant tests are available for several hereditary defects.

BOX 130.1 Major Clinical Signs of Immunodeficiency Disorders

Recurrent infections, chronic and protracted course of infection, or both
Infection with common nonpathogenic (opportunistic) or aberrant infectious agents
Severe and often atypical infectious disease manifestations
Delayed, incomplete, or absent response to antimicrobial therapy
Adverse reactions to attenuated live virus vaccines

BOX 130.2 Infectious Agents and Medical Problems Associated with Immunocompromise

Opportunistic Pathogens

Viruses: Feline herpesvirus-1, feline infectious peritonitis virus, feline calicivirus, canine papillomavirus, canine herpesvirus
Bacteria: *Mycoplasma haemofelis, Citrobacter* spp., *Escherichia coli, Enterobacter* spp., *Klebsiella pneumoniae, Mycobacterium* spp., *Nocardia* spp., *Proteus* spp., *Pseudomonas aeruginosa, Serratia marcescens, Staphylococcus pseudintermedius*
Fungi: *Aspergillus* spp., *Candida* spp., *Cryptococcus* spp., *Histoplasma* spp., *Blastomyces* spp., *Coccidioides* spp., *Mucor* spp.
Protozoa: *Pneumocystis* spp., *Toxoplasma gondii, Neospora caninum, Cryptosporidium* spp., *Giardia* spp., *Tritrichomonas* spp., *Isospora* spp.
Mites: *Demodex canis, Ododectes* spp., *Notoedres* spp.

Medical Problems

Recurrent skin infections
Recurrent mucosal infections
Neonatal sepsis and mortality
Reactive amyloidosis
Vasculitis, arteritis, polyarthritis
Recurrent bacteremia
Granulomatous infections
Chronic hypersensitivity reactions
Autoimmune diseases
Persistent intracellular rickettsial or bacterial infections
Disproportional leukocytosis
Persistent lymphopenia

vacuolation of leukocytes without being immunocompromised; frequently they also exhibit a lymphocytosis. The Pelger-Huët anomaly, which is characterized by hyposegmentation of granulocytes, causes no immunodeficiency in animals despite the fact that the leukograms of affected dogs and cats reveal the most severe left shift with a normal leukocyte count and no toxic changes. In foxhounds, *in vitro* chemotactic response of these neutrophils was mildly diminished, whereas in basenjis no functional abnormalities have been found.[5–7]

Although an increased susceptibility to opportunistic infections develops, the type of infection varies depending on the immune system defect present. A few immunodeficiency disorders predispose animals to unusual infectious agents. Miniature dachshunds appear to be predisposed to *Pneumocystis* pneumonia (see Chapter 89), and German shepherd dogs and Hungarian vizslas may be prone to systemic aspergillosis and other systemic mold infections.[8,9] Golden and Labrador retrievers that had high serum antibody titers to *Borrelia* (*Borreliella*) *burgdorferi* were more likely to have glomerulonephritis.[10] Miniature schnauzers and basset hounds have an increased susceptibility to systemic avian mycobacteriosis, and possibly other specific infections like candidiasis.[11] Boxer dogs and German shepherds have been the predominant breeds reported with the cutaneous mycobacterial disease known as canine leproid granuloma syndrome.[12,13] Great Danes, boxers, border collies, German shepherds, Dalmatians, and Doberman pinschers (Australia)[14] and American cocker spaniels (United States)[15] have been overrepresented in retrospective studies of cryptococcosis. Boxers and French bulldogs are predisposed to granulomatous colitis secondary to adherent and invasive *E. coli*.[16] A genetic predisposition to demodicosis has been proposed in various canine breeds and families within breeds. The predisposition to develop FIP has also been suggested to have a genetic basis, more commonly in some purebred cats like Birmans. Mechanisms that predispose different breeds to specific infections remain unknown, but have been elucidated for some, such as miniature schnauzers and systemic *Mycobacterium avium* complex (MAC) infection caused by a *CARD9* variant.[11]

The mode of inheritance of primary immunodeficiencies has not yet been determined in all cases. Autosomal recessive transmission, with affected males and females born to healthy parents is usual, but a few exceptions exist. The Pelger-Huët anomaly is inherited as an autosomal dominant trait. Ectodermal dysplasia of German shepherds (but not other ectodermal dysplasias) caused by a ectodysplasin (ED) 1 gene defect, and severe combined immunodeficiency (SCID) caused by two different mutations in the common γ-chain of the IL-2 receptor in basset hounds and Cardigan Welsh corgis, are X-chromosomal recessive disorders. Thus, only males are affected, and the dams and one half of the dam's female littermates are carriers. Granulomatous colitis of boxer dogs appears to result from mutations in the gene that encodes neutrophil cytosolic factor (NCF) 2, which encodes the cytosolic subunit, $p67^{phox}$ of NAPDH oxidase.[16] Thus, the breed, sex, age of onset, type of infections, and other special characteristics can suggest a particular immunodeficiency. Furthermore, it follows that within a breed, the immunodeficiency is typically caused by the same defect and mutation, whereas different breeds can have mutations in the same or different genes.

DIAGNOSIS

Suggestive signs of infection (see Box 130.1) develop in animals with a primary immunodeficiency generally early in life. Despite receiving colostrum during the first day of life, clinically affected animals can have illness during the neonatal to juvenile period and can develop recurrent

TABLE 130.2 Hereditary or Primary Immunodeficiencies of Dogs and Cats

Disease (Synonym)	Inheritance	Breeds	Defect	Characterization
Barrier Defects				
Ciliary dyskinesia (immotile cilia syndrome)	AR	Many[a]	Functional and morphologic cilia abnormalities CCDC39, AKNA, NME5	Rhinosinusitis, bronchopneumonia with bronchiectasis, situs inversus, breed-specific DNA mutation test
Neutrophil Defects				
Bactericidal neutrophil defect	U	Doberman pinscher	Unknown	Upper respiratory infections, reduced bactericidal activity, ciliary dyskinesia not excluded
Cyclic hematopoiesis (cyclic neutropenia)	AR	Collie (gray), basset hound	Hematopoietic growth factor defect AP3B1	Severe neutropenia every 12–14 days, reactive amyloidosis, DNA mutation test
Chronic idiopathic neutropenia	U	Rottweiler	G-CSF deficiency	Recurrent fever, sepsis, polyarthritis, pyoderma
Leukocyte adhesion deficiency	AR	Irish setter, red and white setter, domestic medium-hair cat	CD11/18 deficiency β-chain (CD18) deficiency	Severe leukocytosis, infection with limited pus formation, lack of neutrophil adhesion, DNA mutation test
Pelger-Huët anomaly	AD	Australian shepherd, foxhound, other dog breeds, domestic shorthair cats	Unknown	No immunodeficiency, hyposegmented granulocytes
Leukocyte granulation	U	Birman cats	Unknown	No immunodeficiency, acidophilic granules
Complement component 3 deficiency (C3 deficiency)	AR	Brittany spaniel	C3 deficiency	Pyogenic infections, lack of C-mediated phagocytosis in colony of dogs with neuromuscular disease
Chédiak-Higashi syndrome	AR	Persian cats	CHS1/LYST	No immunodeficiency, large granules in phagocytes, bleeding tendency
Reactive (AA) amyloidosis	U	Abyssinian cats	Unknown	Reactive (AA) amyloidosis, renal failure
Increased susceptibility to *Pneumocystis* pneumonia	AR	Dachshund, King Charles spaniel	Unknown	*Pneumocystis*
Increased susceptibility to systemic mycobacteriosis/candidiasis	AR	Miniature schnauzers, bassets	CARD9 defect in miniature schnauzers, unknown in basset	Systemic mycobacteriosis, DNA mutation test (miniature schnauzers)
Susceptibility to fungal and rickettsial infections; pyoderma	U	German shepherd	Possible macrophage or T-cell defect	Severe ehrlichiosis, Rocky Mountain Spotted Fever, disseminated aspergillosis, deep pyoderma
Immune vasculitis, amyloidosis	U	Sharpei, Abyssinian cats, Oriental shorthair cats	Elevated IL-6	Arthritis, amyloidosis, renal failure, hepatic rupture, hypoproteinemia
Lethal acrodermatitis	AR	Bull terrier	MKLN1	Zinc deficiency, hyperkeratosis
Increased susceptibility to parvoviral infection	U	Rottweiler, Doberman pinscher	Unknown	Parvovirus infection
Vaccine-exacerbated immune disturbance	U	Akita, Weimaraner	Unknown	Variable meningitis, polyarthritis, amyloidosis
Humoral Immune Defects				
X-linked severe combined immunodeficiency (X-SCID)	XR	Basset hound, Cardigan Welsh corgi	Common γ-chain of IL-2 and other cytokines	Severe bacterial and viral infections, no IgG and IgA, deficient lymphocyte blastogenesis, DNA mutation test
SCID	AR	Jack Russell terrier	DNA-protein kinase catalytic subunit	Severe serum immunoglobulin deficiency, hypoplasia of lymphoid tissues, DNA mutation test
SCID	AR	Frisian water dog	RAG1 gene defect alters antigen recognition	Severe IgM, IgG and IgA deficiency and lymphopenia, DNA mutation test
Combined immunodeficiency	U	Sharpei	T-cell and B-cell defects, low IL-6 and IL-2	Skin, respiratory, and gastrointestinal infections
Thymic abnormalities and dwarfism	U	Weimaraner	Unknown	Reduced growth, thymosine responsive
Hypotrichosis congenita with thymic aplasia	AR	Birman	FOXN1	Nude kittens with lethal immundeficiency

In addition to the listed syndromes, bone marrow dyscrasias have been described in miniature and toy poodles and transient hypogammaglobulinemia in Samoyeds, but less is known of these disorders.

[a]For example, springer spaniel, old English sheepdog, English setter, West Highland white terrier, pointer.

AD, autosomal dominant; *AR*, autosomal recessive; *G-CSF*, granulocyte colony-stimulating factor; *IL*, interleukin; *U*, unknown; *XR*, X-linked recessive.

and overwhelming infections that lead to severe debilitation and death before 1 year of age. Some animals, but typically not all, in a litter may be affected, whereas the parents are usually clinically healthy. A genetic predisposition to infection is less commonly noted after 1 year of age (e.g., leishmaniosis in foxhounds and MAC in miniature schnauzers and basset hounds). Furthermore, animals with hereditary immunodeficiencies may have other special clinical manifestations. Hypersensitivity reactions can occur and reflect an overall dysregulation of the immune system caused by a lack of one or more components or a chronic antigen stimulation from inadequate clearance of infections. Chronic systemic infections may also impair growth. Characteristic coat color dilutions and increased tendency for surface bleeding are seen, for example, in collies with cyclic hematopoiesis, Persian cats with Chédiak-Higashi syndrome, and Weimaraners with an incompletely defined immunodeficiency. Nude Birman kittens and ectodermal dysplasia are associated with a complete lack or loss of hair and either severe or minimal predisposition to infection, respectively.

Results of a CBC, serum chemistry panel, and urinalysis can suggest a specific immunodeficiency. Results of differential leukocyte count and microscopic evaluation of a blood smear are most important. Some breeds, such as greyhounds, have low reference values for blood leukocyte counts. Neutropenia can be transient (e.g., cyclic hematopoiesis, parvovirus infection), or can be persistent (e.g., cobalamin malabsorption defects or sepsis). Lymphopenia may be observed in dogs with T-cell disorders or SCID. Although leukocytosis often accompanies infection, defects in leukocyte adhesion and egress from blood circulation at sites of infection can be associated with disproportionately high leukocytosis for the degree of infection as seen with hereditary LAD or with concurrent glucocorticoid usage. Careful review of a blood smear can reveal leukocyte abnormalities such as granulation and vacuolation resulting from lysosomal storage diseases or Chédiak-Higashi syndrome,[17] acidophilic granulation of leukocytes in Birmans,[18] phagocytized microorganisms, or toxic leukocyte changes that suggest overwhelming bacterial infections.

Serum globulin concentrations are generally increased with chronic infections. Low or normal globulin levels in infected animals can suggest major external losses or diminished production from a humoral immune defect. Indeed, specific immunoglobulin deficiencies have been recognized in dogs. Serum protein electrophoresis may identify a γ-globulin deficiency, but immunoelectrophoresis is required to detect the class and degree of immunoglobulin deficiency. Maternally derived antibodies can only be absorbed during the first day of life and influence the serum values during the first few weeks. Only IgM can be synthesized very early in life (neonatal period), whereas the development of IgA can be delayed for months. Thus, it is important to compare values with data from age-matched controls. Serum titers against specific antigens can be measured, followed by evaluation of the antibody response to vaccination against particular agents. However, despite the antibody titer, cellular immunity is not being assessed. Biopsy specimens of lymph nodes can reveal disorganization with loss of germinal centers and normal paracortical lymphocytes. Decreases in plasma cell populations can also be evident.

T-cell or combined immunodeficiencies cause defective CMI responses, which may be manifested as prolonged allograft rejection times and decreased delayed-type hypersensitivity (DTH) reactions to skin testing.[19] Reduced *in vitro* lymphocyte stimulation results can also be caused by a primary lymphocyte defect or by infection.

The identification of the nature of microbes that infect an animal is important for diagnostic as well as therapeutic reasons. Antibody titers can be used to assess response to vaccines and humoral immunity. Histopathology and cytology can assist in characterization of the architecture, morphology, maturation, and function of the immune system, including barrier systems. In ciliary dyskinesia, morphologic abnormalities of cilia may be identified by electron microscopy. Functional studies using nuclear imaging or on respiratory epithelial biopsy specimens are also indicated.

Characterization of immunodeficiencies may require special leukocyte studies. Flow cytometry can be used to differentiate between T and B cells, determine T and B cell ratios, "bacterial killing reaction," and the presence or absence of leukocyte adhesion proteins (CD11/18) or IL-2 receptors. Lymphocyte function studies include lymphocyte stimulation and plaque-forming assays that assess immunoglobulin production. Phagocyte function studies assess leukocyte adhesion, migration, chemotaxis, phagocytosis, "respiratory burst," and bactericidal activity. Functional assays must generally be performed on fresh (collected within 24 hours) blood cells and compared simultaneously with a preferably age- and breed-matched control. Infection can impair *in vitro* lymphocyte function and enhance phagocyte function. Therefore, control of infection before studying leukocyte function is preferred.

A variety of hereditary immunodeficiencies have been characterized at the molecular genetic level. This permits simple screening of affected animals or those potentially at risk. Because genetic variants (mutations) are typically breed specific, these DNA screening tests may be applied within a breed not only for detection of infected immunodeficient animals but also those potentially at risk to infection and carriers.

TREATMENT AND PREVENTION

Successful control of infection in immunodeficient animals depends on the type of infection as well as the type and severity of the immune defect. In immunocompromised patients, early and aggressive antimicrobial therapy is indicated even for mild infections with agents that are considered nonpathogenic in immunocompetent hosts. Because of the immunodeficient host's potential inability to kill infectious organisms, cidal antimicrobials are recommended for treatment if available.

Few practical treatments exist for animals with hereditary immunodeficiencies. Dogs with hereditary cobalamin malabsorption can be successfully administered parenteral cobalamin every 2–4 weeks.[20] In experimental studies, bone marrow transplantation and gene therapy corrected several canine leukocyte defects and dogs with cyclic neutropenia.[21–23] Granulocyte colony-stimulating factor (G-CSF) has been used to increase neutrophil numbers in dogs with cyclic neutropenia and G-CSF deficiency. Fresh whole blood can be transfused repeatedly to animals with overwhelming infections and neutropenia or neutrophil dysfunction, but the effect is very transient. Plasma transfusions or immunoglobulin (hyperimmune serum) injections can temporarily support animals with humoral immunodeficiencies. However, these products should not be used in animals with complete IgA deficiency, because they can experience anaphylactic reactions to the foreign IgA protein. No commercial canine or feline γ-globulin is available, and the human γ-globulin preparations do not target animal-specific infections and can cause allergic reactions on repeated use.

If an acquired immunodeficiency is present and can be corrected, the infection is often easily controlled. Administration of immunosuppressive agents should be withheld during treatment of infection, and any underlying disorder should be treated if possible. Immunocompromised animals with an infection, where the cause of immunosuppression cannot be corrected, generally have a guarded to poor prognosis. Despite aggressive antimicrobial therapy, their infections can be difficult to control, leading to overwhelming infections, protracted courses, and recurrences.

SPECIFIC HEREDITARY OR PRIMARY IMMUNODEFICIENCIES IN DOGS

Primary Ciliary Dyskinesia

Primary ciliary dyskinesia, also known as immotile cilia syndrome, is caused by various functional and ultrastructural ciliary abnormalities that include lack of outer or inner dynein arms, abnormal microtubular

pattern, random ciliary orientation, and electron-dense cores in the basal body. Because of impaired mucociliary clearance, affected animals have recurrent bacterial rhinitis, sinusitis, and bronchopneumonia with bronchiectasis. Poorly motile or immotile live sperm results in male infertility. Although evidence is lacking, dysfunction of ependymal cilia can cause hydrocephalus and otitis media. The lack of coordinated cilia motility during embryogenesis is responsible for a 50% prevalence of concurrent situs inversus in some forms of primary ciliary dyskinesia. The clinical triad of rhinosinusitis, bronchiectasis, and situs inversus is known as Kartagener's syndrome.[24–26]

Primary ciliary dyskinesia is inherited by an autosomal recessive trait. It represents a heterogeneous group of defects that have been described in more than a dozen breeds.[27] Clinical signs typically begin at a young age, and recurrent respiratory infections lead to death or euthanasia before 1 year of age. However, a few dogs appear clinically healthy for months to years.[28]

A diagnosis of ciliary dyskinesia is reached through documentation of absent ciliary clearance of technetium-99m-labeled microaggregated albumin that is placed through a catheter into the nasal cavity or the tracheal bifurcation; biopsy of ciliated mucosae with ultrastructural analysis using electron microscopy; and *in vitro* motility studies.[29,30] Induction of ciliogenesis can also be determined by use of *in vitro* cell culture.[30] A likely causative mutation in the *NME5* gene encoding a sparsely characterized protein associated with ciliary function has recently been found in Alaskan malamutes with ciliary dyskinesia.[31] A deletion was found in the *AKNA* gene, encoding the AT-hook transcription factor, of rough collies with recurrent inflammatory pulmonary disease similar to ciliary dyskinesia. A mutation in the *CCDC39* gene has been found in Old English sheepdogs with axonemal disorganization and abnormal ciliary beating.[32]

Chronic recurrent respiratory infections have been observed in related Irish wolfhounds.[33,34] In wolfhound puppies, the disease begins with a serous rhinitis that later becomes catarrhal to hemorrhagic with turbinate ulceration and destruction. Pneumonia and generalized lymphadenomegaly are apparent in later stages. Although the disease is responsive to antimicrobial treatment, it can progress in intervening periods. Ciliary dyskinesia has been identified in some wolfhounds but has not been a consistent feature of the disease. Serum IgA levels were reduced in some dogs, but bronchoalveolar lavage fluid had high IgA concentrations in tested dogs, which can relate to their inflammatory response to infection.[33]

Cyclic Hematopoiesis

Cyclic hematopoiesis is characterized by a periodic production and maturation defect of hematopoietic cells in the bone marrow.[35] In human patients, the cycle is 21 days, but in dogs, severe neutropenia (<1,000 cells/μL) occurs every 12 to 14 days and lasts for 3 to 4 days (cyclic neutropenia syndrome). Serial blood counts are used to make a definitive diagnosis unless a molecular test is performed. During periods of neutropenia, dogs are very susceptible to bacterial infection. Clinical illness appears at 6 to 8 weeks of age with regular recurrence of bacterial infections. The condition culminates in sepsis or systemic amyloidosis and death from organ failure before 1 year of age. The condition may be accompanied by gingival bleeding from an associated platelet storage pool disease. Affected collies have a silver gray or light beige to tan coat color, and secondary hormonal cycling has been observed.[36]

Cyclic hematopoiesis was the first reported canine immunodeficiency observed and has only been described in hypopigmented collies, hence the term gray collie syndrome. It is inherited as an autosomal recessive trait, but no case has been reported since the 1970s outside of the research colony in this breed. Experimentally, bone marrow transplantation corrects this syndrome, including the coat color dilution. Injections of G-CSF also abolish the cycling. The defect in collie dogs is associated with a homozygous mutation of the gene encoding the dog adaptor protein complex 3 β-subunit that directs trans-Golgi export of transmembrane cargo proteins to lysosomes.[37,38] Mutations in a leukocyte elastase have been identified in humans with a similar syndrome.[35]

Leukocyte Adhesion Deficiency

LAD, originally described as canine granulocytopathy syndrome in Irish setters and cattle and more recently (2017) a cat,[51] is referred to as canine, feline or bovine LAD (or CLAD, FLAD, or BLAD).[39] It results from the absence of a family of three leukocyte integrins.[40–43] These proteins are heterodimers (CD11a-d/CD18) with a specific α-chain (CD11a-d) and a common β-chain (CD18). In LAD, the β_2-subunit is missing (CD18 deficiency), resulting in a lack of surface expression and function of all leukocyte integrins. CD11b/18 (CR3) is the most critical integrin because it is the receptor that binds leukocytes to C3bi and ICAM-1 on activated endothelium, thereby mediating tight adhesion of leukocytes (Fig. 130.1). When this is deficient, granulocytes are unable to marginate and destroy microorganisms, which is associated with an impaired inflammatory response despite marked leukocytosis (Fig. 130.2A). Furthermore, the *in vitro* lymphocyte stimulation response is reduced. A missense *ITGB2* mutation substituting a cystine with a serine has been identified in affected Irish setters and red and white setters.[40,44–48]

Dogs with LAD have a severely increased susceptibility to bacterial infections. Signs of pyogenic infections develop during the first weeks to months of life, are often recurring, and are poorly responsive to antibacterials. Omphalophlebitis and gingivitis are often the first infections and might be followed by pyoderma, pododermatitis, thrombophlebitis, pneumonia, pyometra, osteomyelitis (especially craniomandibular and metaphyseal), and fatal sepsis. Pups are often stunted or have poor body condition.[49,50] Infection sites exhibit minimal inflammation and pus formation despite a most severe persistent leukocytosis of 25,000 to 500,000/μL (Fig. 130.2B). Regional lymphadenomegaly and poor wound healing are commonly noted. Long-term therapy with bactericidal antibacterials is required.

LAD has been reported in Irish and red and white setters worldwide and is autosomal recessive. LAD due to other CD18 mutations also has been documented in Holstein cattle, humans, and one cat.[51] The diagnosis in dogs is currently made by mutation-specific DNA testing.[44,47,48,52] Carrier dogs also can be detected by genetic testing which helped to practically eliminate the disease in the affecteed breed populations.[40] In the past, demonstration of neutrophil adherence defects and deficiency of leukocyte glycoproteins CD11/CD18 by flow cytometry analysis were used (Fig. 130.2C,D). If LAD is suspected in another dog breed, leukocyte flow cytometry for CD18 is still a broad and simple screening test.

Hematopoietic stem cell transplantation of CD18+ donor cells and gene therapy can reverse the defect.[12] Mixed chimeric hematopoietic stem cell transplantation from a histocompatible littermate reversed clinical signs in an affected dog.[53]

Complement C3 Deficiency

Complement factor C3 deficiency was found in a colony of Brittany spaniels with spinal muscular atrophy.[54–56] Affected dogs have defective chemotaxis and bacterial phagocytosis from a complete deficiency of C3 (0.1%) and less than 1% plasma complement activity. The immunodeficiency is generally mild and animals live until adulthood, but serious infections can occur, including pneumonia, pyoderma, sepsis, pyometra, and septic arthritis. Affected dogs can develop renal failure with amyloidosis. This is an inherited autosomal recessive disorder, and a diagnosis can be reached by documenting a lack of serum complement activity or mutation test. However, this defect has not been noted outside the research colony.

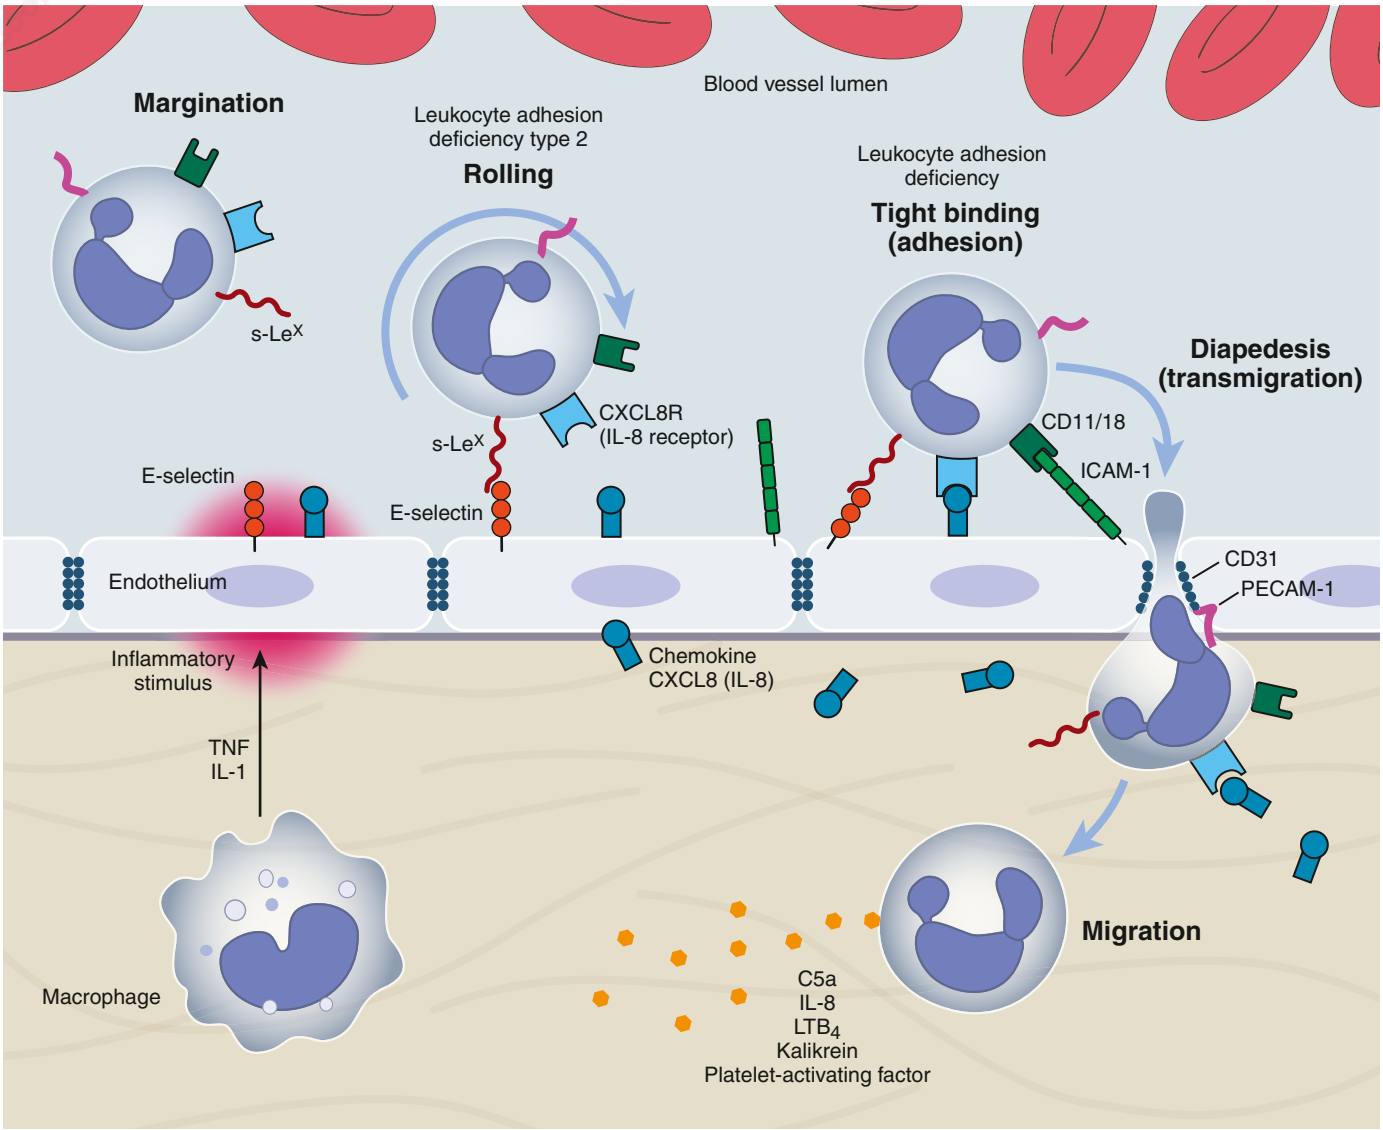

Fig. 130.1 Role of CD11/18 integrins in leukocyte migration to sites of infection.

Selective Cobalamin Malabsorption

Chronic neutropenia and megaloblastic anemia have been described in giant schnauzers, beagles, Australian shepherds, Komondors, and border collie pups.[57–59] Affected animals fail to thrive and often show lethargy, inappetence, and cachexia but are only rarely predisposed to infection accompanied by fever, lameness, or diarrhea. Blood smears show neutropenia with hypersegmented neutrophils. Affected animals have very low serum cobalamin concentrations and marked methylmalonic aciduria. A cobalamin ileal receptor defect was documented in the CUBAM complex, either due to a mutation in amnionless or cubulin.[20,59] Treatment with parenteral administration of cobalamin once or twice monthly is highly effective,[20,58] but does not resolve the very mild proteinuria.

Trapped Neutrophil Syndrome—Hereditary Neutropenia in Border Collies

Chronic neutropenia and recurrent bacterial infections have been found in certain lines of border collies in Australia and New Zealand.[60] This autosomal recessive trait (trapped neutrophil syndrome) is associated with stunted growth by 2 weeks of age and fever, anorexia, diarrhea, and lameness by 2 months of age. Metaphyseal osteomyelitis is seen radiographically, and neutropenia ($<3 \times 10^3$ cells/μL) is consistently found. Bone marrow cytologic abnormalities include granulocytic hyperplasia with a shift to the right, suggesting that the developing cells cannot enter the systemic circulation. A DNA test has been offered to screen border collies.[61,62] Puppies respond poorly to antimicrobial therapy and eventually succumb to systemic infections.

X-Linked Severe Combined Immunodeficiency

X-linked SCID (X-SCID) is characterized by a failure of humoral immunity and CMI.[63–65] It develops in various animal species when lymphocyte precursors fail to differentiate into mature lymphocytes. In dogs, defects in the γ^c chain lead to deficiency of several cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21).[66] Although profound deficiencies are found in T-cell function, some B-cell activities are preserved.[67] For example, canine X-SCID B cells are capable of producing IgM but do not class-switch to the production of IgG after mitogen stimulation. The shared usage of a γ^c chain by these cytokines explains the profound immunologic abnormalities and the impaired IgG response.[68] The ability of lymphocytes to bind to IL-2 and proliferate is severely impaired, and the development of thymocytes is drastically reduced, with an increased proportion of CD4-/CD8-thymocytes.[69,70] Serum IgG and IgA concentrations are low, but IgM values are normal.[71] Because of the

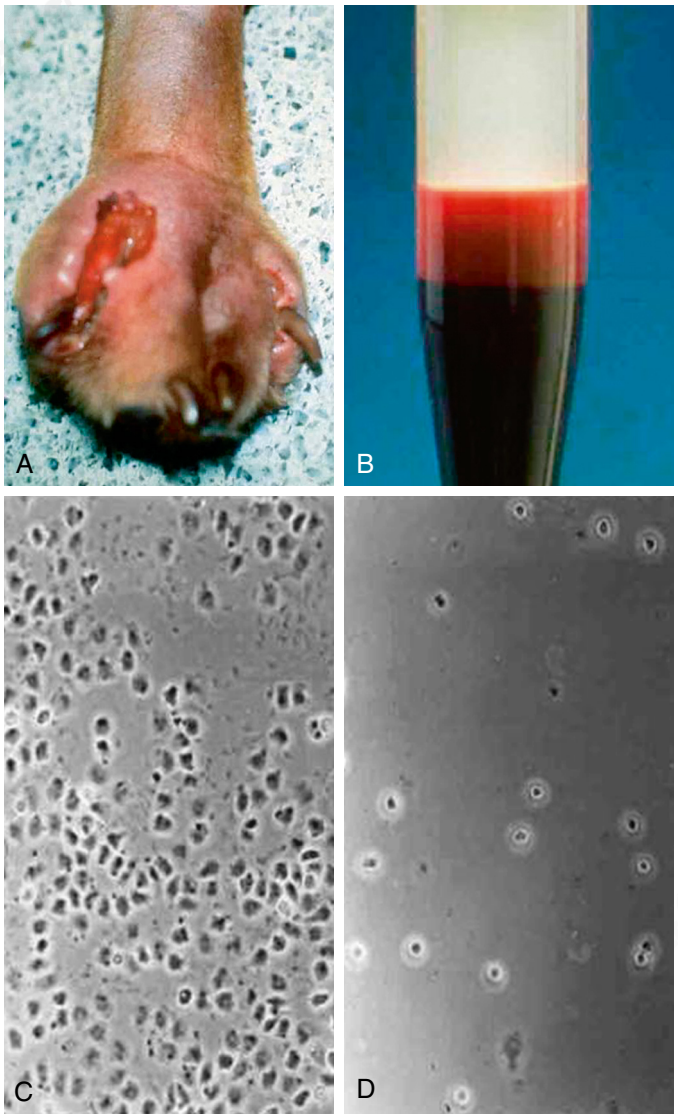

Fig. 130.2 Leukocyte adhesion deficiency in the Irish setter. (A) Lesion showing lack of pus formation. (B) Severe leukocytosis (180,000 cells/μL) as seen in visible buffy coat. Decreased neutrophil adhesion to plastic in control dog (C) and affected dog (D). (Courtesy of Teaching File, University of Pennsylvania, Philadelphia.)

X-chromosomal recessive mode of inheritance, male dogs are affected, whereas females (the dams and some littermates of those affected) are carriers. The Cardigan Welsh corgi and the basset hound have different mutations in the gene encoding the γ-chain that is common to the IL receptors in affected male basset hounds and Cardigan Welsh corgis, but both are restricted to a research colony.[63,72–74]

After the decline of maternal immunity, affected male dogs develop bacterial skin, GI, and respiratory infections (Fig. 130.3). Puppies fail to thrive and generally die within a few months. The most characteristic clinical features are a lack of lymph nodes, tonsils, Peyer's patches, and thymus. Affected basset hounds can develop vaccine-induced distemper. If they survive, affected puppies are poor doers and die by 5–6 months of age. They can survive in germ-free environments.[3] A diagnosis is reached by histopathology, immunologic testing, or molecular genetic testing (bassets and corgis); however, these mutations appear to have been eliminated from breeding populations other than those in research colonies. Bone marrow

transplantation from unaffected littermates and gene therapy were experimentally effective in re-establishing normal T- and B-cell function in affected dogs.[21,67,75]

Autosomal Recessive Severe Combined Immunodeficiency

SCID has been identified in Jack Russell terriers that has an autosomal recessive mode of inheritance, similar to that in CB-17 mice and Arabian foals.[76] A faulty V(D)J recombination and complete deficiency of DNA-PKcs activity result from reduced expression of the DNA-PK catalytic subunit.[76,77] Affected dogs experience severe lymphopenia, agammaglobulinemia, thymic dysplasia, and peripheral lymphoid aplasia. They typically succumb to opportunistic and vaccine-induced infections by 2–4 months of age.[76]

Autosomal recessive SCID has also been identified in Frisian water dogs in South Africa and the Netherlands. A nonsense mutation alters the RAG1 protein which is important in antigen recognition by humoral and cellular mechanisms. Affected pups have severe lymphopenia and undetectable serum immunoglobulin concentrations, and die or are euthanized due to infections at 8 to 12 weeks of age.[77] Dogs develop diarrhea at 7–8 weeks of age that responds to antibacterial therapy. However, progressive neurologic signs including seizures, vestibular ataxia, and blindness ensue. Histiocytic myocarditis and hepatitis was identified in some dogs at necropsy.

Selective IgA Deficiency

Various forms of selective IgA deficiency have been described in several breeds, including beagles,[63,78] sharpeis,[79] German shepherds,[80] and others,[81] but the mode of inheritance remains unknown. The defect may be either an inherited primary defect or may arise secondary to pathologic changes within the intestinal mucosa. Serum IgA concentrations may be completely absent or markedly reduced and only very slowly developing over the first year of life. Complete deficiencies are found in sharpeis, and partial deficiencies have been found in beagles and German shepherds.[82] For diagnosis, serum IgA concentrations need to be compared with those of age-matched controls. Reduced concentrations of IgA have been found in duodenal explant cultures of some German shepherd dogs that had serum IgA values within reference limits.[83] Such assays may be more reliable than serum concentrations but are not as available for routine diagnostic purposes. Reduced secretory IgA concentrations have also been found in bronchial

secretions of affected dogs.[81] IgA-deficient dogs can have positive rheumatoid factor, anti-IgA antibodies, or both, and can be predisposed to hypersensitivity and autoimmune diseases. IgA deficiency in German shepherds is not linked to their predisposition to disseminated aspergillosis, which may relate to a cell-mediated defect.[84] Although affected dogs have large polyclonal increases in serum IgG concentration, it is not directed against *Aspergillus terreus*.

Lethal Acrodermatitis in Bull Terriers

Also known as "zincers" among bull terrier breeders, the lesions of lethal acrodermatitis are similar to those of zinc deficiency in dogs, but do not respond to zinc supplementation. Affected dogs have lower plasma IgA concentrations than clinically healthy dogs.[85] The syndrome is characterized by hyperkeratosis and parakeratosis and thymus and lymph node hypoplasia, which is associated with increased susceptibility to infection, failure to thrive, and abnormal hepatic proteomic patterns.[85–87] Growth retardation, hard and cracked footpads, pyoderma around body orifices, and aggressive to unresponsive behavior are hallmark features and become apparent at a few weeks of age. Affected dogs die or are euthanized before 6 months of age. A *MKLN1* splicing defect has been recently identified and serves as screening test for this common trait in bull terriers.[88]

Susceptibility to *Mycobacterium avium* Complex Infections in Miniature Schnauzers and Basset Hounds

Increased susceptibility to *Mycobacterium avium* infection has been recognized in miniature schnauzers and basset hounds (see Chapter 61). A *CARD9* deletion has been identified in miniature schnauzers but not yet in bassets. Miniature schnauzers related to a sire born in 1986 developed progressive disseminated MAC infections at young adult age that were unresponsive to multidrug antimicrobial therapy, which led to death or euthanasia. All MAC-infected miniature schnauzers worldwide are homozygous for the mutant *CARD9* allele which results in a defective intracellular signaling pathway.[11] Occasionally, these miniature schnauzers may also develop candidiasis which is typically seen in humans with *CARD9* variants. Bassets do not seem to have a *CARD9* mutation.

Uncharacterized Breed-Associated Immunodeficiencies

Apparent breed predispositions to specific infectious diseases also have the potential to reflect underlying hereditary immunodeficiency. However, other factors also have the potential to result in breed-associated infections. For example, leishmaniosis has been identified in English and American foxhounds in the United States (see Chapter 96),[6,89] babesiosis occurs in lines of pit bulls and greyhounds (see Chapter 97), and boxers and Rhodesian ridgebacks appear to be more susceptible to neosporosis. In these cases, although a genetic susceptibility may play a role, transplacental transmission and use of these breeds for hunting or fighting practices (babesiosis) also contribute to the apparent breed predisposition.

Doberman Pinschers

Neutrophil dysfunction has been described in a family of Doberman pinschers; one young dog had chronic recurrent respiratory tract infections.[33] Oxygen radical formation and bactericidal activity of neutrophils were reduced despite normal phagocytosis of bacteria. The specific defect was not identified, and although ciliary morphology appeared normal, functional studies were not performed, so ciliary dyskinesia was not ruled out. Affected Doberman pinschers develop clinical signs of respiratory tract infections at a few weeks of age that respond to antibacterials, but prognosis is guarded.

German Shepherds

An apparent increase in susceptibility to ehrlichiosis, RMSF, pythiosis, aspergillosis, other invasive mycoses, and deep pyoderma has been described in German shepherds.[8,90,91] These predispositions likely involve different immune defects that have yet to be defined. Affected dogs with deep pyoderma have pruritus with lesions distributed primarily over the lumbosacral region.[92] *Staphylococcus pseudintermedius* is most commonly cultured from the lesions. Proposed mechanisms for this susceptibility include cell-mediated immunodeficiency associated with serum inhibitors or defective helper T cells, and hypersensitivity reactions to staphylococci.[90,91,93,94]

Miniature Dachshunds

Certain lines of miniature dachshunds are predisposed to *Pneumocystis* pneumonia by 1 year of age (see Chapter 89). Affected miniature dachshunds have hypogammaglobulinemia, with decreased serum IgA, IgG, and IgM concentrations; decreased lymphocyte transformation to phytohemagglutinin and pokeweed mitogens; and absence of B cells and presence of T cells in lymphoid tissues (stained by CD3 and CD79a cell markers).[95] The molecular defect remains unknown. This predisposition also occurs in cavalier King Charles spaniels that seem to have lower serum IgG concentrations[27]; however, additional genetic and immunologic studies in those dogs are not available.

Sharpeis

In addition to the severely abnormal skin structure, which leads to a barrier failure, two distinct syndromes have been characterized in the sharpei—one involving combined antibody and CMI defects and the other involving renal amyloidosis and swollen joints.

The combined immunodeficiency syndrome may have been confused with the selective IgA deficiency described in this breed. Juvenile to adult dogs develop recurrent infections involving respiratory, skin, and gastrointestinal asystems.[96] Chronic bronchitis, gastroduodenal or colonic ulceration, diarrhea and vomiting, adult-onset pyoderma, demodicosis, and bacterial and fungal otitis may occur. In addition, dogs are predisposed to GI neoplasia, lymphoma, and other malignancies. Single or multiple immunoglobulin class deficiencies are observed in dogs, with IgM deficiency and decreased IL-2 synthesis predominating. Dogs with GI signs or malignancy typically have had reduced serum IgM concentrations. Decreased lymphocyte stimulation test results were found in most of the dogs, suggesting a combined T- and B-cell defect.[96] In addition, peripheral blood mononuclear cells (PBMCs) had reduced expression of IL-6.

Recurrent fever of unknown origin and swelling of the tibiotarsal joints are the clinical signs of another immune-based syndrome in sharpeis, known as "sharpei fever" or "sharpei hock."[97–100] Sharpeis have been strongly selected for thick and heavily folded skin. Altered sequences within the hyaluronic acid synthase gene have been found in affected dogs.[101] Fragmentation of hyaluronan following its accumulation in the thickened skin is thought to trigger an inflammatory reaction. The lameness can be monoarticular or involve multiple joints, usually affecting the tibiotarsal joints and occasionally the carpus. Predominant mononuclear cell polyarteritis and cellulitis, with or without synovial inflammation, can develop. Clinical signs of renal failure—a result of amyloid deposition in the kidney—and nephrotic syndrome eventually develop. A majority of affected dogs have amyloid deposition in the renal medulla; 60% to 80% have glomerular amyloidosis or membranous glomerulitis.[100] Polydipsia, polyuria, weight loss, dehydration, ascites, and peripheral edema can occur. Thromboembolism can be a sudden complication in some dogs with the nephrotic syndrome. Radiographic changes are soft tissue swelling with periarticular bone erosion and bone production. Recurrent fever,

joint pain, and swelling often resolve within 24 hours.[99] Postpartum metritis has developed in intact females and can be another inflammatory feature of this illness.[100] Hyperglobulinemia and increased serum IL-6 concentrations are found in affected dogs.[102] The syndrome resembles familial Mediterranean fever, a human hereditary disorder characterized by polyserositis and reactive amyloidosis. Treatment with colchicine early in the course of disease can reduce amyloid deposition in humans and has been proposed for affected dogs.

Rottweilers

In one report, a litter of rottweiler pups either died before 6 months of age from systemic inflammatory disease or subsequently developed chronic inflammatory skin disease.[103] Serum IgA and IgG concentrations were low. Secondary lymphoid tissues had reduced numbers of CD3+ T cells, although some were found within foci of B-cell follicles. Irregularities were found in plasma cell development, and plasma cells were absent from all mucosal and cutaneous sites. In inflammatory lesions, macrophages expressing major histocompatibility complex (MHC) class II molecules were present. Related unaffected dogs had reduced serum IgA concentrations; however, the spectrum of the defect in affected dogs suggests a more complex underlying defect. Rottweilers have also been considered more susceptible to parvovirus infection, oral papillomatosis, and nasal and systemic fungal infections; however, it is uncertain whether these abnormalities are interrelated.

Weimaraners

At least two distinct immunodeficiency syndromes have been observed in Weimaraners. One syndrome was reported only once, and was associated with growth hormone deficiency with dwarfism, wasting, and thymic hypoplasia.[104,105]

The second syndrome, which is similar to the common variable immunodeficiency syndromes described in humans, involves recurrent bacterial infections and inflammatory conditions in young Weimaraners, which often become systemic.[2,106–109] Some dogs outgrow their condition and do not show signs later in life. Clinical signs of those with recurrent disease start at a few months to young adult and are characterized by lethargy, anorexia, intermittent fever, lymphadenomegaly, pyogranulomatous disease, large abscesses in muscle, stomatitis, osteomyelitis, surface bleeding, and coat color dilution. Some dogs have diarrhea or vomiting. Hyperesthesia of long bones or joints (Fig. 130.4), a predisposition to local injection site reactions, and recurrent urinary infections or pyoderma have also been observed. Some dogs later develop polyarthritis or meningitis. Although dogs may respond favorably to select antibacterial therapy and/or immunosuppressive drug therapy, recurrence of systemic inflammatory disease can occur. While an immunologic deficiency is suspected, inconsistencies exist in the immunologic studies performed on these dogs. Neutrophilia, which is often marked with a left shift, has been observed. Decreased neutrophil phagocytosis of opsonized bacteria and chemiluminescence as well as slightly low serum IgG and IgM concentrations have been reported in some dogs with increased amounts of circulating immune complexes (CICs).[110] In other reports, reduced serum IgG, IgA, and IgM have been observed with no increase in CICs.[109] The lack of CICs in most reports suggests that primary decreased production rather than secondary immunoglobulin consumption is responsible for the defect. No specific diagnostic tests are available. Despite antibacterial and supportive therapy, prognosis is guarded. Some Weimaraners also appear to have an increased tendency to develop hypertrophic osteodystrophy (HOD), which has been associated with a postvaccination reaction. Whether this predisposition is only associated with this immunodeficiency syndrome is uncertain.[109] Dogs that develop HOD respond most favorably to anti-inflammatory doses of glucocorticoids, and the syndrome may be triggered by attenuated live distemper vaccination (see Chapter 20).[111]

SPECIFIC HEREDITARY OR PRIMARY IMMUNODEFICIENCIES IN CATS

Leukocyte Adhesion Deficiency

LAD (see dogs earlier for more details) was described in an adult domestic medium-haired cat with severe leukocytosis and milder signs of infection and inflammation. The disorder was associated with a β_2-integrin mutation, but not in any other cats.[51] If LAD is suspected in a cat, leukocyte flow cytometry for CD18 expression can be used for diagnosis; the gene mutation may be different and thus genetic testing is not useful.

Hypotrichosis Congenita with Thymic Aplasia

Hypotrichosis congenita with thymic aplasia is a defect that is characterized by the birth of nude athymic kittens with severe immunodeficiencies, kittens that are similar to nude research mice. This lethal syndrome has been recognized in Birmans and is autosomal recessively inherited. A deletion in *FOXN1* has been identified and can be used to screen the breed (Fig. 130.5).[112,113]

Other Defects

Abyssinians are predisposed to systemic reactive AA amyloidosis, but clinical signs are caused by renal dysfunction. A genetic basis is suspected. This syndrome is similar to amyloidosis in sharpeis and familial Mediterranean fever in humans. Splenic inflammatory diseases, often related to secondary infections from immunodeficiencies, are responsible for the amyloid deposition in reactive amyloidosis. However, in some affected cats, concurrent inflammatory disease is not detected.[114] Generalized amyloidosis has also been observed in Siamese and Oriental cats, but clinical features and amyloid protein composition differ (mostly hepatic involvement).[115,116]

A syndrome of unknown cause in ragdoll kittens is characterized by fatal infections in the neonatal to weaning period.[117] Vaccination with attenuated live feline panleukopenia vaccine may have accelerated their death. Some kittens died of panleukopenia at a younger age. By weaning, others developed numerous systemic fatal infections. Thymic, splenic, and lymphoid hypoplasia were observed in these affected kittens.

Fig. 130.5 Nude Birman kittens with congenital hypertrichosis with thymic atrophy. (Courtesy of Margret Casal, University of Pennsylvania, Philadelphia, PA.)

Neutrophil abnormalities have been observed in Birman cats with leukocyte granulation,[118] and domestic shorthaired cats with the Pelger-Huët anomaly (Fig. 130.6).[119] However, clinical immunodeficiencies with these defects have not been recognized. Historically, Persian cats with Chédiak-Higashi syndrome,[4,17] had more of a bleeding tendency and color dilution (smoked) than infections, and a large duplication was found in lysosomal trafficking regulator ((CHS1/LYST)). Loss of thymic mass has been observed in cats with GM1 gangliosidosis.[120,121]

ACQUIRED OR SECONDARY IMMUNODEFICIENCIES

Acquired or secondary immunodeficiencies encompass states of a transiently or permanently impaired immune system during or after an underlying disease condition or exposure to toxic agents. Secondary immunodeficiencies occur more commonly than primary immunodeficiencies, and, depending on the type and severity of the immunosuppression, opportunistic infections may result in localized or systemic disease.

Secondary immunodeficiencies can impact the innate or adaptive immune systems. Anatomic barrier disturbances, such as desquamation of skin or damage to the mucociliary escalator of respiratory epithelium, are types of acquired immunodeficiencies. These can also result from administration of immunosuppressive agents, exposure to toxins, nutritional deficiencies, and specific disease processes, including metabolic disorders, neoplasia, and some infectious diseases (Box 130.3). Certain infections, particularly retroviral diseases in cats, directly impair the immune system, predisposing the animals to secondary bacterial, fungal, or protozoal infections. For example, cats infected with FIV harbor more diverse fungal microflora on the hair and mucosal surfaces than noninfected cats.[122] FeLV-infected cats are also more likely to have clinical illness with hemotropic mycoplasma infections than noninfected cats.[123]

Puppies and kittens are particularly vulnerable to infections because of their incompletely developed immune systems. Transfer of maternally-derived antibody (MDA) from colostrum takes place in the first day of life and provides humoral protection during the initial weeks of life in small animals.[124,125] Failure of this transfer can lead to immunodeficiency and susceptibility to some infections. A transient hypoglobulinemia occurs after the decline of MDAs in the plasma and before immunocompetency, and this increases susceptibility to various infections.[126]

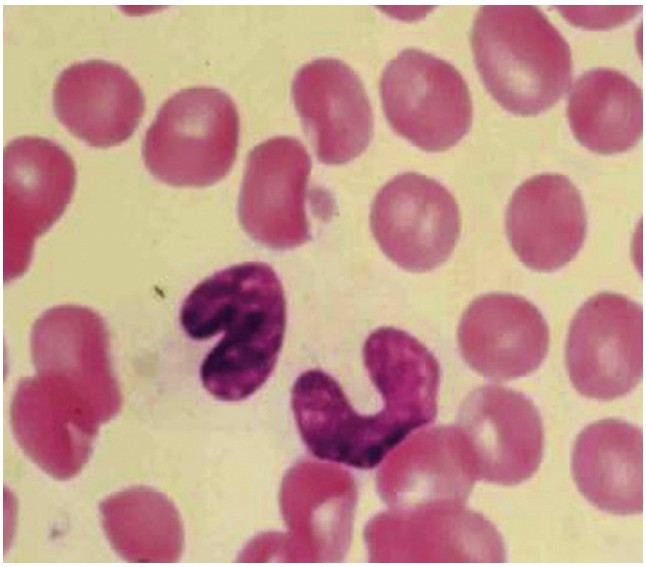

Fig. 130.6 Pelger-Huët anomaly in cat with hyposegmentation of nucleus. Despite morphologic changes, no clinical immunodeficiency was observed. (Wright stain, ×1000). (Courtesy of Teaching File, University of Pennsylvania, Philadelphia, PA.)

SPECIFIC SECONDARY OR ACQUIRED IMMUNODEFICIENCIES

Acquired or secondary immunodeficiencies can develop at any time as a result of an interference with host defense mechanisms.[127,128] Immune defects secondary to infectious diseases, metabolic disturbances, intoxications, nutritional deficiencies, and drug therapies[129,130] have been reported (Table 130.3 and see Box 130.3).

Infectious Diseases

Canine Distemper

CDV infection causes a chronic and profound inhibition and impairment of cellular and humoral immune functions characterized by lymphopenia and immunosuppression, rendering animals susceptible to opportunistic infection (see also Chapter 22). Immunosuppression is due to early virus-mediated lymphocytolysis in the spleen, lymph nodes, thymus, bone marrow, mucosa-associated lymphoid tissue (MALT), tonsils, and hepatic Kupffer cells.[128] CD4+ T cells are preferentially depleted during the acute phase, followed by CD8+ T-cell depletion.[131] In addition, CDV affects antigen presentation and lymphocyte maturation by a poorly understood mechanism.[132,133]

CDV infects cells of the immune system via viral H protein binding to CD150 (signaling lymphocyte activation molecule), a molecule expressed on B and T cells, monocytes, and mature dendritic cells.[134] The viral V protein is essential for rapid viral replication in T cells and antagonizes IFN-α, TNF-α, IL-6, IFN-γ, and IL-2 in the acute phase of infection.[134] Furthermore, viral infection leads to a diminished antigen presentation and altered dendritic cell and B-cell maturation within germinal centers. Subsequent plasma cell formation and immunoglobulin formation are reduced.[132] Thus, long-lasting immunologic abnormalities persist after viral clearance from the peripheral blood leukocytes.

Persistent suppression of CMI in neonatal puppies infected with CDV can be detected by decreased lymphocyte stimulation test results and decreased synthesis of T-cell–dependent antibodies (IgG and IgA). If thymic hypoplasia results from *in utero* infection, IgM levels may be reduced during the postnatal period. Transient depression of CMI has been reported in puppies that are infected with virulent CDV.

TABLE 130.3 Acquired Defects in Phagocyte Function

Disease	Mechanism	Site of Infection	Infecting Organisms	Predisposing Factors
Uremia	Decreased phagocytosis	Catheter sites, lungs, urinary tract, blood	Staphylococci, aerobic gram-negative organisms	Peripheral vascular disease
Diabetes mellitus	Increased adherence, variable chemotaxis, decreased phagocytosis and respiratory burst	Lungs, urinary tract, catheter sites, eyes, bone	Staphylococci, Enterbacterales, filamentous fungi	Hyperglycemia, total parenteral nutrition, skin ulcers, urinary catheterization
Hepatic cirrhosis	Increased adherence with decreased chemotaxis and phagocytosis	Urinary tract, lungs, blood, soft tissues	Staphylococci, Enterbacterales, other enteric organisms	Urinary catheterization
Systemic lupus erythematosus	Increased adherence, decreased chemotaxis, decreased phagocytosis	Lungs, blood	Gram-positive bacteria, mycobacteria, opportunistic organisms	Immunosuppressive therapy
Burns	Decreased chemotaxis and phagocytosis	Wounds, urinary tract, blood, lungs	Staphylococci, aerobic gram-negative organisms, yeasts	Extensive burns, age extremes
Traumatic injuries	Decreased chemotaxis and phagocytosis	Wounds, urinary tract, blood, lungs	Staphylococci, aerobic gram-negative organisms	Old age

Modified from Engellich G, Wright DG, Hartshorn KL. Acquired disorders of phagocyte function complicating medical and surgical illnesses. *Clin Infect Dis*. 2001;33:2040–2048.

BOX 130.3 Causes of Acquired or Secondary Immunodeficiencies

Age Related
- Impaired colostrum uptake
- Transient hypoglobulinemia associated with decline of maternal antibodies
- Weakened immune system in the very young and old

Organ Disorders
- Hyperadrenocorticism
- Hypothyroidism
- Diabetes mellitus
- Hepatic insufficiency
- Splenectomy
- Malnutrition
- Cancer, particularly hematopoietic neoplasia

Barrier Impairment
- Burns
- Invasive or indwelling catheters
- Endoscopic devices
- Splenectomy
- Aspiration of body cavities (i.e., cystocentesis)
- Pulmonary diseases
- Gastrointestinal diseases
- Skin diseases

Immunosuppressive Infections
- Feline leukemia virus infection
- Feline immunodeficiency virus infection
- Feline coronavirus infection
- Feline and canine parvovirus infection
- Canine distemper
- Canine retrovirus infection
- Demodicosis
- Ehrlichiosis
- Anaplasmosis
- Protracted bacterial infections
- Leishmaniosis
- Bartonellosis

BOX 130.3 Causes of Acquired or Secondary Immunodeficiencies—Cont'd

Physical, Chemical, or Drug-Induced
- Whole-body irradiation
- Myelosuppressive drugs
- Cytotoxic agents
- Griseofulvin
- Estrogens (dogs and ferrets)
- Immunosuppressive therapy (i.e., glucocorticoids, cyclosporine)
- Antibacterial- or antacid-induced alteration of intestinal microflora

Nutritional Disorders
- Vitamin A deficiency
- Vitamin E deficiency
- Vitamin D deficiency
- Protein-caloric restriction
- Zinc deficiency

Affected dogs can develop secondary bacterial bronchopneumonia, including *Bordetella bronchiseptica*. Other opportunistic infections reported in dogs with CDV include toxoplasmosis, salmonellosis, nocardiosis, and generalized demodicosis.[128]

Canine Parvovirus Infection and Feline Panleukopenia Virus Infection

CPV and FPV have an affinity for replicating in rapidly dividing cells, including crypt cells of the GI tract and lymphoid tissue, resulting in severe lymphopenia and immunosuppression (see Chapters 29 and 30). This combination of anatomic barrier destruction of the GI tract and leukopenia in immunologically naïve hosts leads to an increased risk of secondary bacterial infections.

In addition to virus-induced destruction of WBC precursors in the bone marrow, massive sequestration of neutrophils within the inflamed GI tract occurs resulting in both a lymphopenia and granulocytopenia. Mild depression of lymphocyte function has also been observed as a result of parvoviral infection.[135] Parvovirus-infected dogs and cats are at increased risk for bacterial translocation from the GI tract and bacteremia, leading to overwhelming sepsis.

In utero infection can lead to permanent suppression of CMI and thymic atrophy. Dogs that recover from CPV infections have had a higher prevalence of UTIs than age-matched control pups. Disseminated candidiasis has been reported in animals with parvovirus.[136] Infection with CPV has also been associated with development of postvaccinal canine distemper encephalitis.[137] There is little known about immunodeficiency that develops in cats with FPV infection, other than that associated with panleukopenia.

Canine and Feline Coronavirus Infection

Opportunistic infections are rarely reported with either enteric FCoV or FIPV infection. However, FIPV is associated with a profound, virus-induced panlymphopenia and hypergammaglobulinemia (see Chapter 31). The virus does not infect lymphocytes, so the mechanism of lymphocyte depletion is unclear, although it may be related directly to TNF-α–induced apoptosis or indirectly to the infection of antigen-presenting cells, specifically dendritic cells.[138,139]

A highly virulent strain of CCoV has been reported to cause severe systemic illness and induce a lymphopenia.[140] Depletion of the CD4+ T-cell population was observed 1 month PI in an experimental model.[141]

Feline Leukemia Virus Infection

FeLV is associated with antiproliferative (myelosuppressive) and proliferative (neoplastic) diseases of the lymphohematopoietic system, and both forms are associated with immunodeficiencies primarily due to reduced CMI competence (see Chapter 32). A reduction in CD4+/CD8+ T-cell subset ratios has been shown to develop in FeLV-infected cats.[142] FeLV-infected cats have impaired T-cell–mediated immunity as characterized by reduced *in vitro* lymphocyte stimulation, prolonged retention of cutaneous allografts, and impaired response to delayed hypersensitivity skin testing.[143–145] Lymphopenia and thymic atrophy can be observed in infected cats.[128] Secondary hyperglobulinemia and complement depletion have also been recognized.[146,147] Persistent neutropenia and decreased neutrophil microbicidal activity can also be observed as the disease progresses.[148] A panleukopenia-like syndrome can develop in cats that are co-infected with FeLV and FIV.[149]

The transmembrane viral envelope peptide p15E can mediate some of the immunosuppression.[150] This viral protein inhibits B- and T-cell function, alters monocyte morphology and distribution, and has been associated with impaired cytokine production and responsiveness.[143–145] FeLV-infected cats have increased susceptibility to concurrent infection with other organisms and severity of disease caused by those organisms, such as commensal bacteria, pathogenic fungi, hemotropic *Mycoplasma* spp., and FIP.

Feline Immunodeficiency Virus Infection

Cats naturally infected with FIV may develop fever, variable neutropenia, and chronic infections of the skin and mucosal surfaces (see Chapter 33). Experimentally inoculated cats develop generalized peripheral lymphadenopathy and transient neutropenia followed by a disease-free period that may last years. FIV infection of the bone marrow can cause blood leukopenias and myelodysplasia even in cats without clinical signs.[151] Studies of FIV infection have identified several mechanisms of innate and adaptive immune dysfunction. Defective natural killer cell proliferation and cytotoxic function occurs in chronically FIV-infected cats, and this may be due to low levels of key cytokines such as IL-2 and IL-15.[152,153] Neutropenia due to apoptosis,[154] dendritic cell dysfunction, and dysregulation of multiple cytokines have been described (e.g., decreased TNFα, IL-1, IL-2, IL-6, and IL-12 and increased IL-10 and TGF-β).[155–157] Depletion of CD4+ T cells is characteristic of the adaptive immune defect and occurs by several mechanisms including apoptosis, anergy, and thymic atrophy. Further adaptive immune dysregulation occurs due to inappropriate activation of regulatory CD4+/CD25+ T cells which in turn downregulate CD4+ and CD8+ T cells.[158–160] Alterations in the phenotype of CD8+ and other lymphocytes eventually lead to immunodeficiency.[161]

Opportunistic infections eventually occur as immunodeficiency progresses, and can include bacterial infections of the oral cavity, chronic skin infections, FCV infection, toxoplasmosis, hemotropic mycoplasma infection, and systemic fungal infections.[162–167] Affected cats tend to have increased severity of disease caused by these pathogens. Compared with noninfected cats, *Cryptococcus* spp. and *Candida albicans* are isolated more frequently from the oropharyngeal mucosa of FIV-infected cats, and *Microsporum canis* are isolated more frequently from the skin.[168]

Canine Monocytic Ehrlichiosis

Infection with *Ehrlichia canis* can be divided into acute and chronic stages (see Chapter 44). No secondary immunosuppression has been associated with acute canine ehrlichiosis.[169] Dogs with chronic ehrlichiosis can develop a marked lymphocytosis and hyperglobulinemia with antibody titers to *E. canis* occasionally exceeding 1:1,000,000. Some dogs develop pancytopenia due to bone marrow failure, and secondary bacterial infections can be attributed to neutropenia in those cases. Alternatively, some dogs can develop opportunistic infections in the absence of neutropenia; the mechanism underlying this has not been fully elucidated. These opportunistic infections, all of which rely on a robust CMI, include leishmaniosis, viral papillomatosis, generalized demodicosis, neosporosis, and opportunistic fungal infections, implying alterations in the CMI occur during chronic ehrlichiosis.[128,170,171] *In vitro* studies demonstrate downregulation of MHC class II molecules in cells infected with *E. canis*.[171] German shepherd dogs are overrepresented in cases of ehrlichiosis[172] and appear to experience a greater degree of suppression of CMI during infection than other breeds.[173] Evaluation of blood lymphocytes from dogs naturally infected with *E. canis* demonstrate higher numbers of cytotoxic T cells and lower numbers of B cells compared with healthy control dogs; however, their potential immunosuppressive effects remain unknown.[174] In fact, one study failed to demonstrate the suppression of CMI or humoral immunity in experimentally infected dogs up to 4 months PI.[169]

Canine Leishmaniosis

Dogs with leishmaniosis are prone to secondary infections and occasionally neoplasia, especially hematopoietic tumors.[175] The *Leishmania* surface protein gp63 mediates entry into macrophages and promotes survival of the parasite through inhibition of the respiratory burst and apoptosis. *Leishmania* can also decrease macrophage function and antigen presentation by inhibition of MHC class I and II molecule expression, inhibition of chemotaxis, and interference with IL-12 transcription.[176] *Leishmania* organisms promote tolerance upon infection of *in vitro* cultivated hepatic macrophages, which is reversed with leishmanicidal drug application.[177] Generalized demodicosis has been described in dogs with leishmaniosis and was associated with an absence of CD3+ cells in dermal lesions suggesting a CMI deficiency.[178]

Fungal Infections

Fungal pathogens including *Aspergillus*, *Candida*, and *Cryptococcus* spp. are capable of causing immunosuppression.[179–181] *Cryptococcus* possesses several virulent factors that suppress or orchestrate the immune response to favor fungal growth and persistence. The capsular polysaccharide inhibits phagocytosis and can interfere with leukocyte transmigration by causing these cells to shed selectin.[182] Cryptococcal urease shifts the CMI to a nonprotective Th2 immune response and promotes immature dendritic cell accumulation within the lung tissue by upregulating IL-10 production and regulatory T-cell accumulation.[183–185]

Hemophagocytic Syndrome

Pathologic proliferation of the mononuclear phagocyte system can either result from infectious diseases or contribute to immunologic dysfunction and signs of debilitation, weight loss with anorexia, splenohepatomegaly, and relapsing fever in dogs or cats.[186–188] In dogs with hemophagocytic syndrome, parvovirus infection or lymphoid or myelomonocytic leukemia and lymphoma have been described; however, the association is not understood.[189] Dogs with infection-associated hemophagocytic syndrome appeared to have better 1-month survival rates than dogs with immune-associated and idiopathic hemophagocytic syndrome.[190]

Metabolic Disturbances

Many biochemical processes that occur in noninfectious disease states interfere with normal immune mechanisms. Failure of neonates to ingest colostrum, and dysproteinemias such as multiple myeloma, are both associated with impaired humoral immune system function. Decreased complement concentration has been noted with endotoxemia and malnutrition.

Newborn puppies and kittens experience a hypothermic state during the first week of life that suppresses T-cell function. A decline in CMI in older animals may increase their susceptibility to infectious and neoplastic disorders.[191] This decline in CMI is characterized by decrease in B-cell percentages and depressed lymphocyte stimulation by various mitogens *in vitro*, with male dogs more profoundly affected than females.[192]

Protein and caloric restriction has resulted in premature thymic atrophy and decreased cell-mediated, humoral, and phagocytic responses in animals. In contrast, overfed, obese dogs have impaired T-cell function and upregulated inflammatory cytokine expression.[193,194] Ingestion of organohalogenated compounds in contaminated environments caused a reduction of serum antibody titer responses of puppies to various inoculated antigens.[195]

Vitamin E and selenium deficiencies in dogs have been associated with decreased *in vitro* lymphocyte responsiveness, decreased serologic response to vaccination, and increased susceptibility to infection with opportunistic pathogens.[196,197] The deficit can be accentuated by excessive intake of polyunsaturated fats (strong oxidants that counteract the effects of vitamin E). Vitamin E deficiency causes the animal to produce a suppressor serum factor capable of decreasing lymphocyte responsiveness to antigenic stimulation. Vitamin A deficiency can cause immunosuppression and opportunistic infections similar to those associated with vitamin E deficiency.[198] Vitamin D is important in the regulation of the innate and adaptive immune systems, and deficiency has been noted with some infections including atypical mycobacterial infection in cats.[199] Zinc deficiency during prenatal and neonatal periods can result in impaired CMI responses and thymic atrophy.

Poorly regulated or untreated diabetes mellitus in dogs is associated with weaker neutrophil adherence than in controlled diabetic and nondiabetic dogs.[200] Diabetic dogs have an increased prevalence of UTIs[201–203] and hepatic abscesses.[204] Intestinal lymphangiectasia is associated with depressed CMI because of lymphopenia.[205] Endogenous or exogenous hyperadrenocorticism is associated with a high prevalence of bacteriuria, and mechanisms have been proposed including decreased neutrophilic chemotaxis or enhanced bacterial growth in urine due to glucosuria or decreased urine osmolality.[206] Splenectomized dogs and cats are prone to clinical babesiosis, hemotropic mycoplasma infections, and bacteremia.[207]

Neutropenia

Severe neutropenia increases the risk of bacterial infection, and several infectious agents can result in neutropenia. Broadly, neutropenia can result from decreased production or increased demand with several specific causes (Box 130.4), and can range from mild to severe.[208–210]

BOX 130.4 Acquired Causes of Neutropenia

Pathologic Demand (i.e., sepsis, peritonitis, pyometra, pneumonia)

Drug-Associated
- Albendazole
- Cephalosporin
- Chemotherapy (i.e. cisplatin, carboplatin, chlorambucil, cyclophosphamide, mitoxantrone, vincristine)
- Chloramphenicol
- Diethylstilbestrol
- Methimazole
- Phenobarbital
- Phenylbutazone
- Trimethoprim/sulfamethoxazole

Bone Marrow Failure
- Aplastic marrow
- Bone marrow necrosis
- Myelophthisis
- Myelodysplasia

Infectious Agents

Dogs: Ehrlichiosis
Cats: FeLV infection, FIV infection
Dogs and cats: Parvoviral infections, histoplasmosis

Immune-Mediated
- Immune-mediated neutropenia

Primary immune-mediated neutropenia, associated with circulating antineutrophil antibodies, has also been observed in dogs and cats.[210–212] Despite the circulating neutropenia, animals have adequate or high numbers of proliferating neutrophil precursors in the bone marrow. Circulating neutrophils are typically nondegenerate and lack toxic change (which might be seen with other causes of neutropenia, such as sepsis), unless secondary bacterial infection has occurred. Rapid increases in neutrophil numbers, usually within a few days, are observed after glucocorticoids are administered. Secondary bacterial infections appear to be uncommon in animals with primary immune-mediated neutropenia when compared with neutropenias associated with other causes, such as myelosuppressive drugs.

Immunosuppressive and Myelosuppressive Therapy

Immunosuppression can be induced during treatment for immune-mediated diseases, neoplasia, or organ transplantation. Use of glucocorticoids, cyclosporine, mycophenolate, or leflunomide has been associated with an increased risk of opportunistic infections. Glucocorticoid administration increases the risk of UTI in dogs treated chronically (more than 6 months).[213,214] In one case series of 169 feline renal transplant patients being treated with cyclosporine, infection was the second most common cause of death after acute rejection of the transplant.[215] Bacterial infections were the most common, followed by viral, fungal, and then protozoal infections. Disseminated toxoplasmosis and opportunistic cutaneous fungal infections have also been reported in animals administered cyclosporine.[216–218] Recovery of T-cell function occurred within 4 days of discontinuation of cyclosporine in healthy research dogs treated for 1 week at 10 mg/kg q12h.[219]

Fever

Amy E. DeClue

KEY POINTS

- Fever may be associated with infectious, inflammatory, immune-mediated, and neoplastic disease.
- True fever is associated with a rise in the hypothalamic set point, and body temperature is increased by enhanced heat production and conservation.
- Fever of unknown origin (FUO) is defined as persistent or recurrent fever which is not responsive to treatment and for which a cause is not easily determined.
- Major endogenous pyrogens are cytokines such as IL-1β, IL-6, and TNF-α. These act to increase synthesis of prostaglandin E2 which acts on thermoregulatory neurons to raise the hypothalamic set point.
- The diagnostic approach to FUO requires consideration of a large number of differential diagnoses and a staged diagnostic investigation with thorough and repeated physical examinations.
- Therapeutic trials should be a last resort as they have the potential to mask underlying disease, contribute to adverse outcomes, and result in unnecessary expense.

Fever is a common clinical finding in patients with infectious, inflammatory, immune-mediated, or neoplastic disease. In many of these patients, fever is accompanied by other more specific or localizing clinical signs, and the cause of the fever is determined with simple diagnostic tests. In some cases, the cause of the fever is not readily apparent, but it resolves spontaneously or in response to empiric therapy, often with antibacterial drugs. In a further small subset of animals, the cause of fever is not easily determined and not therapeutically responsive, and the problem becomes persistent or recurrent. Such cases of fever of unknown origin (FUO) present a particular diagnostic challenge in both human and veterinary medicine.[1-5] This chapter outlines the pathophysiology of fever and presents an approach to the small animal patient with FUO.

ETIOLOGY OF FEVER OF UNKNOWN ORIGIN

Although fever is frequently associated with infectious diseases, the same response can be elicited by many inflammatory, immune-mediated, or neoplastic disorders, some medications and several miscellaneous disorders. Because the list of differential causes for FUO is extensive, grouping these causes into broad categories based on the underlying disease process is useful. Table 131.1 shows the causes of FUO divided into infectious and parasitic diseases, Table 131.2 summarizes inflammatory and immune-mediated causes of FUO, and neoplastic and miscellaneous causes are listed in Table 131.3. Similar tables are used in the diagnostic approach to FUO in humans. In the human medical literature, the causes of FUO are typically distributed as follows: 17% to 35% are infectious, 10% to 20% are neoplastic, 24% to 36% are inflammatory, 3% to 15% are miscellaneous, and up to 51% are undiagnosed.[5] *In general, bacterial infections are not the most common cause of fever in dogs or in cats.* In cats, fever often results from viral infection (FeLV, FIV, feline respiratory viruses, FCoV). In dogs, neoplasia and immune-mediated disease are the more common causes of fever than infectious causes. In a study of 101 dogs with fever, 22% of dogs had immune-mediated disease, 22% had primary bone marrow abnormalities (usually hemic neoplasia, but many had myelodysplasia), 16% had infectious diseases, 10% had neoplasia outside the bone marrow, 12% had miscellaneous inflammatory conditions, and 20% had pyrexia of unknown origin, where the underlying disease was never identified.[6] Variation among case series may reflect referral bias and geographic location of the study. Published case series are also exclusively or predominantly canine.[6,7] Fever needs to be distinguished from hyperthermia and dysthermia; dysthermia results from damage to the brain (hypothalamus) and is usually accompanied by other CNS signs.

PATHOGENESIS

Body temperature is determined by the set-point of the hypothalamic thermoregulatory center. Thermoregulation depends on sensory information from external and internal thermoreceptors and on physiologic and behavioral effector mechanisms that control heat production and heat loss. Body heat is lost through the skin and the respiratory tract and can be gained by transfer from the environment or generated by muscle activity or body fat catabolism. Body temperature is decreased by panting, cutaneous vasodilation, seeking shelter, and remaining inactive. In a cold environment, body temperature is maintained by shivering, postural changes, piloerection, and cutaneous vasoconstriction. In a normal animal, these mechanisms balance heat loss and heat gain and keep the body temperature as close as possible to the normal hypothalamic set-point.

In true fever, the hypothalamic set-point increases, and body temperature is increased by enhanced heat production and conservation. Heat gain and heat loss mechanisms now act to maintain body temperature at the new set-point. In nonfebrile hyperthermic conditions, the hypothalamic set-point is *not* altered, and increased body temperature is the result of increased and unregulated heat gain or heat production or impaired heat loss. Examples of nonfebrile causes of hyperthermia include heat stroke, exercise-induced hyperthermia, malignant hyperthermia, seizure activity, and hypermetabolic disorders. Hyperthermia of this type can progress to multiorgan-dysfunction syndrome caused by an interplay among circulatory disturbances, hypoxia, increased

TABLE 131.1 Infections Associated with Fever of Unknown Origin

Type of Infection	Examples
Systemic bacterial	Infective endocarditis (D), bacteremia from inapparent focus (B)
Localized bacterial	Infective endocarditis (D), pyelonephritis (B), prostatitis (D), pyometra (including stump pyometra) (B), pyothorax and bronchopneumonia (B), pancreatitis (D), visceral abscess or cholangiohepatitis (B), peritonitis (B), septic meningitis (B), septic arthritis (B), osteomyelitis (B), discospondylitis (B), tooth root abscess (B), deep pyoderma (B), other abscesses or cellulitis (B). The possibility of migrating foreign bodies should be considered
Specific bacterial	Leptospirosis (D), Lyme borreliosis (D), brucellosis (D), hemoplasmosis (B), mycobacterial infection (B), bartonellosis (B), plague (B), tularemia (B), mycoplasma and L-form infections (B), relapsing fever borreliosis (D), disease caused by certain virulent GI pathogens, such as salmonellosis (B), ehrlichiosis (B), anaplasmosis (B), neorickettsiosis (D), actinomycosis (D), nocardiosis (B)
Viral	FeLV infection (C), FIV infection (C), feline panleukopenia (C), feline infectious peritonitis (C), feline calicivirus infection (C), feline herpesvirus-1 infection, canine distemper virus infection (D), canine parvovirus infection, canine influenza virus infection (D)
Fungal/algal	Blastomycosis (B), cryptococcosis (B), coccidioidomycosis (B), histoplasmosis (B), disseminated candidiasis (D), aspergillosis (D), pythiosis (D), protothecosis (D), pneumocystosis (D)
Protozoal	Toxoplasmosis (B), neosporosis (D), hepatozoonosis (B), babesiosis (B), leishmaniosis (B), cytauxzoonosis (C), trypanosomiasis (D), sarcocystosis (D)

B, both dog and cat; *C,* predominantly cat; *D,* predominantly dog.

TABLE 131.2 Inflammatory and Immune-Mediated Diseases Associated with Fever of Unknown Origin

Type of Disease	Examples
Immune-mediated	Systemic lupus erythematosus (D, rare in C), idiopathic immune-mediated polyarthritis (B), rheumatoid arthritis (D), polymyositis (B), steroid-responsive meningitis-arteritis (D), vasculitis (B), immune-mediated hemolytic anemia (D), immune-mediated thrombocytopenia (D), sterile nodular panniculitis (D), drug reactions (B)
Inflammatory	Pancreatitis (B), hypereosinophilic syndromes (B), lymphocytic cholangitis (C), panosteitis (D), hypertrophic osteodystrophy (D)

B, both dog and cat; *C,* predominantly cat; *D,* predominantly dog.

TABLE 131.3 Neoplastic and Miscellaneous Diseases Associated with Fever of Unknown Origin

Type of Disease	Examples
Solid tumors	Several, including hepatic tumors, gastric tumors, lung tumors, bone tumors, metastatic disease, and any necrotic tumor (B)
Hematopoietic tumors	Lymphoma (B), leukemia (B), myeloma (B), malignant histiocytosis (B)

B, both dog and cat; *C,* predominantly cat; *D,* predominantly dog.

metabolic demand, cytotoxicity of high temperature, and activation of inflammatory and coagulation cascades.[8]

Fever is mediated by the action of pyrogens (Fig. 131.1). Exogenous pyrogens (infectious agents and their products such as LPS, tumors, drugs, and toxins) stimulate inflammatory cells to release endogenous pyrogens (cytokines such as interferons, IL-1β and IL-6, and TNF-α), and this leads to induction of cyclooxygenase 2 activation of the arachidonic acid cascade, with enhanced synthesis of prostaglandin E_2 (PGE_2). PGE_2 is synthesized by hypothalamic vascular endothelial cells and acts on thermoregulatory neurons to raise the hypothalamic set-point. The cytokine RANKL (receptor activator of nuclear factor kappa-B ligand), which is a member of the TNF superfamily, may also be involved in thermoregulation.[9] The thermoregulatory set-point is located in a rich vascular network called the organum vasculosum laminae terminalis in the preoptic rostral hypothalamus, which possesses little if any blood-brain barrier. Endothelial cells within this region are thought to release arachidonic metabolites themselves, and then metabolites of cyclooxygenase such as PGE_2 are thought to diffuse the short distance to the hypothalamic neurons and induce fever. PGE_2, which itself is not neurally active, can induce production of cyclic adenosine monophosphate or other neurotransmitters, which, in turn, raises the temperature set-point of the body. Additional evidence suggests that the thermoregulatory center may also be stimulated via vagal fibers that respond to release of cytokines locally released in tissues.[10] PGE_2 may also be released peripherally by hematopoietic cells in response to activation of TLR4 by bacterial LPS.[9] The increase in set-point is thought to protect the body from infection. Febrile-range temperatures have been shown to enhance the neutrophil respiratory burst; the release of neutrophils from the bone marrow; the recruitment of neutrophils to tissues; natural killer cell cytolytic activity; and the activity of macrophages and dendritic cells, with upregulation of major histocompatibility complex (MHC) Class I and MHC Class II molecules.

Cats are especially sensitive to drug-induced hyperthermia, which can result from drugs such as opioids (including buprenorphine, oxymorphone, hydromorphone) or ketamine.[11] In some cases, rectal temperatures may exceed 107°F (41.7°C). The mechanism of opioid-induced fever in cats is not fully understood.

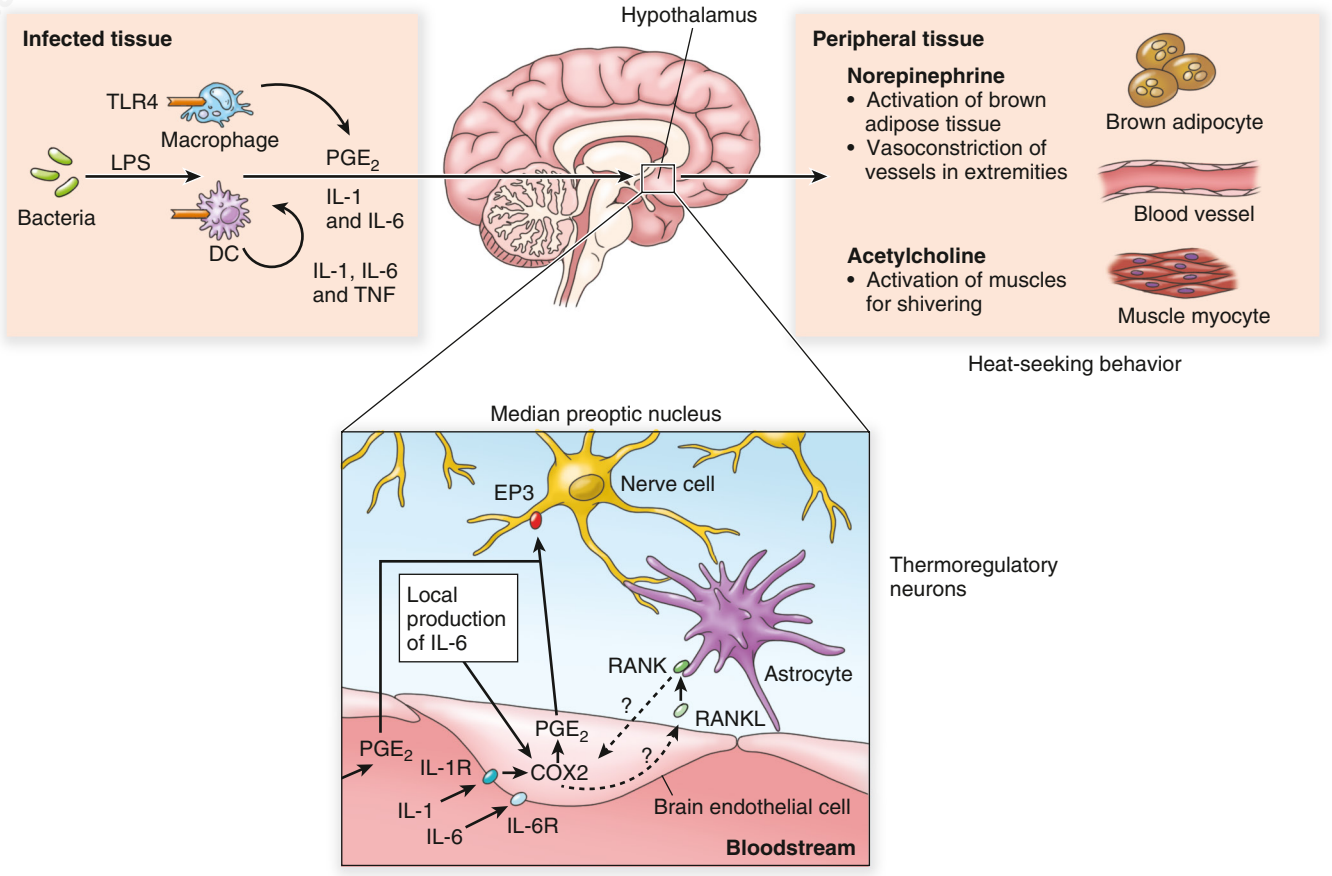

Fig. 131.1 Pathogenesis of fever. The recognition of damage-associated molecular patterns (DAMPs) or pathogen-associated molecular patterns (PAMPs), such as LPS, by TLRs and other pattern recognition receptors drives the activation of dendritic cells *(DCs)* and macrophages. These innate immune cells release prostaglandin E_2 *(PGE_2)* as well as pyogenic cytokines *(IL-1, IL-6,* and *TNF)* that act systemically to induce fever. IL-6 acts downstream of IL-1 in the median preoptic nucleus region in the hypothalamus to induce the synthesis of cyclooxygenase 2 *(COX2)*, the enzyme responsible for production of additional PGE_2. PGE_2 is the major pyogenic mediator of fever. Receptor activation of NF-κB *(RANK)* expressed by astrocytes also acts via the COX2-PGE_2 pathway to induce fever. It is not known exactly how this pathway interacts with the IL-6 pathway. Neurons that express PGE_2 receptor 3 *(EP3)* trigger the sympathetic nervous system to trigger norepinephrine release, which raises body temperature by increasing thermogenesis in brown adipose tissue and inducing vasoconstriction, which reduces heat loss. Additionally, acetylcholine contributes to fever by stimulating muscle myocytes to induce shivering. (Reprinted from Evans SS, Repasky EA, Fisher DT. Fever and the thermal regulation of immunity: the immune system feels the heat. *Nat Rev Immunol.* 2015;15:335-349.)

Another example of drug-induced hyperthermia is serotonin syndrome, which in humans is triggered by medications such as certain migraine medications, antidepressants, and ecstasy. It has also been reported in dogs with 5-hydroxytryptophan toxicosis.[12] These medications cause hyperthermia through both neuromuscular effects (muscle cramping) and a direct effect on the hypothalamus. A number of molecules can influence the hypothalamic neurons, including serotonin, norepinephrine, dopamine, acetylcholine, and prostaglandins.

Factors That Modify Fever

In some cases, fever may be masked by factors such as extremes of age, immunosuppression (e.g., immunosuppressive drugs, hyperadrenocorticism, severe malnutrition), or NSAID treatment. Renal failure can also mask a fever, because uremic toxins are considered to be endogenous cryogens; they are thought to act on the hypothalamus to reduce the set-point, although the true pathogenesis is unclear. Research into this phenomenon was stimulated by the finding that human patients that underwent dialysis often experienced an increase in rectal temperature.[13] Uremic hypothermia has been documented in dogs and cats undergoing intermittent hemodialysis, and appears to be more common in cats.[14] In this study, for dogs post dialysis, rectal temperature decreased by 0.05°F for every 1 mg/dL unit increase in serum creatinine concentration.

CLINICAL SIGNS

Rectal temperatures of 103°F to 105.5°F (39.5°C to 40.8°C) are typically identified in FUO patients and can be associated with nonspecific signs such as anorexia, lethargy, arthralgia, and dehydration.

Body temperatures above 106°F (41.1°C) can rapidly lead to CNS damage and subsequent CNS signs, disseminated intravascular coagulation and evidence of bleeding diathesis, metabolic derangements,

TABLE 131.4 Causes of Fever of Unknown Origin Grouped by Body System or Region

Body System Or Region	Appropriate Diagnostic Tests	Examples
Blood and hematopoietic	Ophthalmic examination, CBC, serum chemistry panel, urinalysis, bone marrow aspirate, bone marrow biopsy, serum protein electrophoresis, FeLV and FIV tests, vector-borne disease serology, blood culture	Leukemia, myeloma, bacteremia, drugs, ehrlichiosis, granulocytopathy, hypereosinophilic syndromes, hemotropic mycoplasmosis, babesiosis, cytauxzoonosis, metastatic neoplasia
Lymphoid	Lymph node palpation, lymph node cytology, lymph node biopsy	Lymphoma, lymphadenitis, salmon poisoning disease, plague, FIV, bartonellosis?
Cardiovascular	Auscultation, radiography, electrocardiography, echocardiography, pericardiocentesis, blood culture, biopsy, *Bartonella* serology and culture	Endocarditis, pericarditis, vasculitis
Respiratory	Radiography, transtracheal or endotracheal wash, fine-needle aspiration, biopsy, ultrasonography, bronchoscopy, bronchoalveolar lavage, CT, thoracoscopy	Bronchial foreign body, fungal or bacterial pneumonia, neoplasia
Nervous system	Fundic and neurological examination, radiography, myelography, CT, MRI, muscle biopsy, CSF analysis	Toxoplasmosis, neosporosis, fungal infection, steroid-responsive meningitis-arteritis, FIP
Musculoskeletal	Radiography, arthroscopy, blood culture, arthrocentesis, synovial membrane biopsy, bone biopsy, ANA	Immune-mediated polyarthritis, myositis, panosteitis, discospondylitis
GI	Rectal examination, fecal cytology, rectal cytology, fecal culture (*Salmonella*), radiography, barium contrast studies, ultrasonography, oral and dental radiographs, pancreatic lipase immunoreactivity, trypsin-like immunoreactivity, endoscopy, laparoscopy, exploratory surgery, biopsy	Neoplasia or abscess anywhere in GI tract, pancreatitis, fungal disease, hepatobiliary or splenic infection
Urogenital	Urinalysis, urine culture, prostatic wash and ejaculate cytology and culture, radiography, ultrasonography, IV pyelography, cystography, cystoscopy, vaginoscopy, cytology, biopsy, *Brucella* serology/blood culture	Prostatitis, stump pyometra, pyelonephritis, orchitis
Pleural or peritoneal cavity	Radiography, ultrasonography, fluid analysis, cytology, microbial culture, biopsy	Pyothorax, FIP, peritonitis, neoplasia
Skin	Physical examination, cytology, biopsy, microbial culture, ultrasound, fistulography	Abscess, fungal infection, nodular panniculitis, vasculitis, actinomycosis, nocardiosis, mycobacteriosis

ANA, antinuclear antibody.

Adapted with permission from Lunn KF. Fever of unknown origin: a systematic approach to diagnosis. *Compend Contin Educ Pract Vet.* 2001;23:976-992.

and death. Such temperatures are typically associated with hyperthermia, rather than fever. When the rectal temperature is mildly increased (< 104°F), animals that appear otherwise systemically well and active are more likely to be hyperthermic than febrile, especially if the weather is warm or the animal has a history consistent with hyperthermia (e.g., traveled in a hot car). The rectal temperature should be retaken after 20 to 30 minutes of being indoors in a cool, quiet environment to determine if the high rectal temperature is clinically relevant. In contrast to fever, hyperthermia is not responsive to treatment with antipyretics.

DIAGNOSIS

Fever (pyrexia) is defined as an increase in body temperature above 102.5°F (39.1°C) in dogs and cats, although fever is typically associated with body temperature above 103°F (39.4°C). Rarely does body temperature exceed 106°F (41.1°C). In human medicine, the following criteria are used to define FUO:

1. Prolonged fever of > 3 weeks' duration associated with vague, nonspecific signs of illness.
2. Temperature more than 1.5°F above normal on several occasions.
3. Diagnosis uncertain after 1 week of hospitalization involving repeated physical exams and routine laboratory tests.

With the availability of faster and more accurate diagnostic tests, and changing models of care (more outpatient care), this definition has changed and the requirement for a week of hospitalization is no longer considered essential.[5]

In veterinary medicine, some practitioners are quick to assign the term "FUO." Multiple definitions of FUO have been used in veterinary medicine without a clear consensus definition. FUO in both human and veterinary medicine can be most usefully defined as fever that does not resolve spontaneously in the period expected for self-limited infection and the cause of which cannot be ascertained despite considerable diagnostic effort.[1] In veterinary medicine, this diagnostic effort typically includes a complete history and physical examination, CBC, chemistry, urinalysis, aerobic bacterial urine culture, plain radiographs of the thorax and abdomen, and abdominal ultrasound examination.

Development of a Diagnostic Plan for FUO

Although some patients with FUO may have uncommon infectious, inflammatory, adverse drug reaction or neoplastic diseases, many patients are ultimately found to have an unusual or early manifestation of a common disorder. Therefore cases must be approached in a systematic fashion that allows for the detection of any potential cause of fever while avoiding unnecessary testing and minimizing invasive testing. A diagnostic plan for FUO may be based on consideration of the disease process, as outlined in Tables 131.1, 131.2, and 131.3. Similar tables are used for the approach to diagnosis of FUO in people.[5,15] A complementary approach is summarized in Table 131.4, in which the causes of FUO are grouped according to anatomic or body system location. Fever may also be classified as "high-grade" (> 104°F) or "low-grade" (≤ 104°F).

BOX 131.1 Good Practice Points in the Management of Fever of Unknown Origin

- Ensure a thorough history, meticulous examination, and baseline investigation panel (CBC, serum chemistry panel, and urinalysis) have been done
- Return to the history and physical examination at regular intervals
- Consider noninfectious causes of a fever early on in the patient's journey (this is especially important in dogs; consider viral causes of a fever in cats)
- Avoid giving empirical antimicrobial or glucocorticoid trials
- Be cautious with the interpretation of some serological tests as some perform poorly with high false-positive and false-negative rates
- Do not perform serological testing if there is no history of exposure to the pathogen you are testing for
- Ensure the client is aware that diagnostic tests may need to be repeated because findings can change over time, and that there is a possibility of no diagnosis being made

The presence of a high-grade fever can raise suspicion for viral infections, gram-negative and some gram-positive (e.g., *Streptococcus* spp.) infections, and diseases such as salmon poisoning disease, plague, and tularemia. High-grade fevers are uncommon for pathogens that replicate slowly, such as mycobacteria or fungi; or those that evade the immune system ("stealth" pathogens), such as *Bartonella* spp.

By combining a disease process and anatomic approach, the clinician can develop a comprehensive diagnostic plan for any FUO patient. In addition to including appropriate diagnostic tests, the diagnostic plan should follow a sequence that is both logical and flexible. The typical diagnostic plan will begin with tests that are safe, simple, inexpensive, easy to interpret, and high yield. Every abnormal result has to be carefully considered; the more tests that are done, the greater the number of false leads that can appear. "Good practice points" for approach to diagnosis of FUO in humans have been outlined,[5] and these can be adopted for FUO in dogs and cats (Box 131.1). A staged approach can be used to guide the selection of diagnostic tests, and examples are outlined in Box 131.2.

The results of stage 1 tests in the FUO patient will determine the tests to be performed at the next stage. If the fever has not been localized, more specialized procedures can also be introduced. Stages 2 and 3 require the repetition of earlier tests and introduce the need for advanced imaging and more invasive procedures. Ideally, the selection of the tests used in stage 3 will be based on abnormalities detected in stages 1 and 2.

An important aspect of staged testing in the FUO patient is the need to repeat the early, less invasive, and less expensive tests frequently enough to detect new changes. In animals with acute illness, fever may develop a day or two before the appearance of lesions, so withholding extensive diagnostic testing and simply repeating physical examinations should be considered in animals with a recent onset of fever to avoid wasting client financial resources and creating undue stress for the patient.

The key is not to rigidly follow a predetermined and fixed diagnostic plan but rather to review and modify the plan as new results become available. For example, if repeated CBCs demonstrate developing pancytopenia, a bone marrow aspirate and biopsy should be performed early in the diagnostic plan and not reserved for stage 3.

BOX 131.2 Staged Approach to the Diagnostic Evaluation of the Patient with Fever of Unknown Origin

Stage 1
Detailed history
Complete physical examination (repeat frequently)
Fundic examination
Neurologic examination
CBC
Serum chemistry profile
FeLV and FIV serology (cats)
Thyroxine (T4) (cats)
Complete urinalysis
Aerobic bacterial urine culture
Thoracic and abdominal radiographs

Stage 2
Repeated physical examinations
Repeat additional stage 1 tests as indicated
Referral to a specialist
Blood cultures
Arthrocentesis
Abdominal ultrasound
Bone marrow aspiration and biopsy (if unexplained cytopenia)
Lymph node aspiration
Other tissue or fluid aspirates as indicated
Fecal culture for *Salmonella* spp. (if diarrhea present)
Echocardiography (if murmur present)
Long bone and joint radiographs
Infectious disease immunoassays or PCR panels as indicated
Antinuclear antibody (only if indicated by clinical signs)

Stage 3
Repeat stage 1 and stage 2 tests as indicated
Referral to a specialist
Echocardiography (if no murmur present)
Dental radiographs
Bone marrow aspirate (with or without biopsy)
Bronchoscopy and bronchoalveolar lavage
Cerebrospinal fluid analysis
Computed tomography
Magnetic resonance imaging
Laparoscopy
Thoracoscopy
Endoscopy
Arthroscopy
Biopsies as indicated
Exploratory surgery
Scintigraphy
Trial therapy

Tests recommended in each staging column are listed in increasing order of expense or risk to animal. These tests are not indicated for initial workup and may be considered appropriate with successive workups. Adapted with permission from Lunn KF. Fever of unknown origin: a systematic approach to diagnosis. *Compend Contin Educ Pract Vet.* 2001;23:976-992.

Client Communication

The management of the FUO patient demands flexibility, dedication, and patience from both the clinician and the client. By definition, patients with FUO will already have undergone several basic diagnostic tests, and some may have received one or more courses of antimicrobial therapy. Clients may be frustrated by the failure to reach a diagnosis or the continuation of the patient's clinical signs. Good client communication is vital to the successful resolution of the FUO case. The clinician should explain that many diagnostic tests, including repeated tests, may be necessary to reach a diagnosis, that test results

BOX 131.3 Differential Diagnosis for Antibacterial-Unresponsive Fever

Viral infections—especially young animals, e.g., CDV, FIP, FHV-1, FCV
Fungal infections
Protozoal infections
Antibiotic-resistant bacterial infections
Immune-mediated disease
Neoplasia
Pancreatitis
Central fever (dysthermia due to CNS disease)

often change over time to become more revealing, and that the process can be time-consuming and expensive. However, clients should also be reassured that a diagnosis is reached in most cases, that many causes of FUO may be treatable or even curable, and that the fever itself is rarely harmful to the patient.

History

The patient history should include details of geographic location, *any* travel history, environment and lifestyle (e.g., indoor vs. outdoor, history of wildlife exposure or ingestion, boarding, plant awn exposure, digging behavior), recent adoption from a shelter or rescue environment, other animals in the household and when they were introduced, and the possibility of exposure to ticks or other vectors. All of these factors will influence exposure to specific microorganisms. The medical history should cover diet (especially whether raw food diets are fed), vaccinations (antigens and timing), heartworm and other parasite treatment and prevention, the administration of any other medications, previous medical problems, trauma, and previous surgeries (including whether implants may be present). The response to past therapies used for the fever problem should be noted. A failure to respond to antibacterial drugs can help to narrow the differential diagnosis list (Box 131.3), and a previous response to antibacterials may suggest an underlying, inadequately treated bacterial infection or bacterial infection in association with a foreign body. Clients should be carefully questioned about the patient's urination and defecation habits and the presence of clinical signs such as lameness; neck, back, or abdominal pain; skin lesions; masses, or swellings; weakness; exercise intolerance; coughing; nasal discharge; and dyspnea. Any previous medical records should be thoroughly reviewed as the client may not be aware of or recall prescribed medications, vaccines, or procedures.

Physical Examination

All body systems should be examined in detail, and a complete physical examination should be repeated at each hospital visit for outpatients. Repeated and thorough physical examinations are one of the simplest and most rewarding things that can be done to localize the problem. Asking another clinician in the practice to perform a second physical examination may also be helpful. Inpatients should be examined twice daily. The physical examination should include careful cardiac and lung auscultation and regular and thorough examination of the oral cavity and rectum, bones and joints, lymph nodes, and skin. Thorough palpation of the entire surface of the skin, including examination of the foot pads and interdigital spaces should be performed, in an effort to identify skin lesions or painful regions of the body. Detection of a cat bite abscess or cellulitis by means of a thorough physical examination can avoid unnecessary diagnostic tests. An effort should be made to visualize as much of the oral cavity as possible. This is especially important in cats, because oral ulcerations due to viral respiratory pathogens may be located only at the base of the tongue. Musculoskeletal and neurologic examinations may reveal spinal pain or subtle neurologic deficits in dogs with discospondylitis. Repeated ocular examinations, including a fundoscopic examination, should not be overlooked because they may provide evidence of infectious, inflammatory, or neoplastic disease. Given that fever can often wax and wane in FUO, the pattern of fever in an individual patient should be determined by serial measurement of body temperature. In veterinary medicine, this measure is not of any value in elucidating the underlying cause, but it is important in monitoring the response to any subsequent therapy.

Laboratory Findings

Complete Blood Count and Serum Chemistry Panel

Fever is often accompanied by neutrophilia or a stress leukogram, and serum chemistry tests are frequently nonlocalizing in FUO patients. However, any abnormalities detected on these tests should be used to direct further testing. The CBC should always be accompanied by examination of a blood smear so as to determine blood cell morphology and look for microorganisms. Automated CBCs should be verified by manual counts. Thrombocytopenia may be a clue to an underlying vector-borne disease or immune-mediated thrombocytopenia. Neutropenia may be: (1) secondary to bacterial infection, in which case it is usually accompanied by toxic changes and bandemia, (2) an underlying cause of secondary bacterial infection and fever (e.g., because of marrow disease), or (3) an immune-mediated problem (i.e., immune-mediated neutropenia, which is uncommon to rare).[16,17] When neutropenia exists and neutrophils appear mature and nontoxic, marrow disease or immune-mediated neutropenia should be considered. For unclear reasons, dogs with immune-mediated neutropenia rarely seem to develop secondary bacterial infections.

Urinalysis and Urine Culture

Because FUO may be associated with focal urogenital infections (e.g., prostatitis, pyelonephritis), urinalysis and aerobic bacterial urine culture are mandatory in the evaluation of fever patients. Urine specimens should be obtained by cystocentesis and submitted for bacterial culture and susceptibility testing, regardless of the appearance of the urine sediment. However, because subclinical bacteriuria may be unrelated to the problem causing fever, at the same time, care should be taken not to overinterpret the finding of a positive urine culture (see Chapter 127). With the exception of *Candida*, which can cause infections localized to the urinary tract, funguria generally indicates a systemic fungal infection. However, candiduria in the presence of fever is suggestive of disseminated candidiasis.

Diagnostic Imaging

Plain Radiography

Thoracic and abdominal radiographs should be obtained during the first stage of evaluation of the FUO patient. These radiographs may provide early evidence of neoplastic disease or suggest infectious disease such as viral, bacterial, or fungal pneumonia. Attention should also be paid to each rib and the vertebral column on thoracic and abdominal radiographs for evidence of osteomyelitis or discospondylitis. In the second or third stages of diagnosis, complete spinal, long bone, joint, and dental radiographs should be considered.

Ultrasonographic Examination

A complete abdominal ultrasound examination should include examination of the liver, gall bladder, bile duct, gastrointestinal tract, spleen, pancreas, kidney, urinary bladder, prostate, uterus, abdominal lymph

nodes, and adrenal glands. When lesions are present, other regions that can be investigated by ultrasonography include the thorax (particularly in the presence of effusions or masses), the retrobulbar area, and any other peripheral mass lesion or swelling. Ultrasonography can also facilitate minimally invasive acquisition of fine-needle aspirates or biopsies.

Echocardiography

Ultrasonographic examination of the pericardium, myocardium, endocardium, heart valves, and great vessels is essential in the evaluation of the patient with FUO and a heart murmur, particularly if the murmur is of recent onset, which might suggest infective endocarditis (IE) (see Chapter 122). Because IE can occur in the absence of a murmur, should other attempts to localize a cause of fever fail, echocardiography could be considered even in dogs that do not have a murmur. The results of echocardiography should be interpreted in light of the patient's signalment, clinical signs, and blood culture results. Echocardiographic evaluation is especially important in medium to large breed dogs because these breeds are overrepresented and IE is more common in dogs than in cats.[18,19]

Advanced Imaging

Advanced imaging modalities should be regarded as third-stage tests in the evaluation of the FUO patient and used when clinical signs have been localized to a particular body system. For example, CT is useful for detecting certain pulmonary lesions and for examining the nasal cavity, tympanic bullae, and pharynx. MRI is often used in evaluation of the CNS.

Nuclear medicine has provided several techniques that can be used to visualize infection or inflammation in human patients.[20] Scintigraphic imaging can demonstrate many of the steps involved in the inflammatory process and can, therefore, potentially localize some causes of FUO. For example, leukocyte infiltration of tissues can be visualized with indium-111 or technetium-99m–labeled neutrophils.[21] Other techniques in nuclear medicine include the use of radiolabeled human immunoglobulin, or gallium-67, which binds to transferrin in the blood, to nonspecifically demonstrate areas of increased fluid extravasation associated with enhanced vascular permeability in inflammation. Positron emission tomography (PET) with fluorine-18 fluorodeoxyglucose is an imaging technique used to identify areas of increased glucose metabolism such as tumors and infectious or inflammatory lesions. The combination of PET with computed tomography (PET/CT) allows for anatomic localization of the lesion which enhances diagnostic value of this technique in patients with FUO.[22,23]

Cytologic and Histopathologic Examination

Fine-needle aspirates are usually simple and safe to obtain, and touch preparations or impression smears can also be made from ulcerated lesions or discharge material. Cytologic examination of these specimens is relatively inexpensive and, depending on the skill of the clinician, can sometimes be performed in-house. For example, if blastomycosis is suspected, repeated aspirates from lymph nodes or skin nodules can be examined for *Blastomyces* organisms because they are relatively easy to identify (see Chapter 80). Ultrasound, fluoroscopy, or CT can be used to facilitate guidance. Aspirates of fluids such as pleural, pericardial, or peritoneal effusions; CSF; synovial fluid; or bile should also be submitted for bacterial and other cultures. Aspiration of peripheral lymph nodes, even if palpably normal, is recommended in the second stage of diagnostic testing if the source of the fever has not been localized.

Cisternal or lumbar puncture, bronchoalveolar lavage, transtracheal or endotracheal lavage, prostatic wash and ejaculation, and bone marrow aspiration may also be used to obtain specimens for cytologic examination and culture. Biopsy specimens may also be obtained with techniques such as thoracoscopy, laparoscopy, endoscopy, or arthroscopy, or they can be obtained percutaneously, sometimes with guidance from ultrasound or radiography.

Bone Marrow Cytology and Histology

Bone marrow disease is a relatively common cause of FUO. Reported examples include myelodysplasia, lymphoid leukemia, myeloma, hemophagocytic syndrome, and disseminated adenocarcinoma.[6,24,25] Bone marrow aspiration is indicated in the early stages of diagnostic testing if CBCs show unexplained, persistent cytopenias. Investigation of pancytopenia requires the evaluation of both cytology of a bone marrow aspirate and histopathology of a core biopsy. In cats, additional unstained bone marrow cytology smears should also be reserved for FeLV FA testing. Bone marrow aspiration is indicated in the third stage of the diagnostic plan if the FUO has not yet been localized.

Arthrocentesis

Immune-mediated polyarthritis is a common cause of FUO in dogs,[6,7,26] although only 3 of 79 dogs with polyarthritis in one study were examined because of intermittent fever.[26] The condition can be idiopathic (nondeforming and nonerosive), or it can be caused by rheumatoid arthritis or associated with other immune-mediated disorders such as systemic lupus erythematosus or steroid-responsive meningitis-arteritis (SRMA; see Chapter 129). Occasionally, nonerosive immune-mediated polyarthritis can be secondary to infection, drug therapy, or neoplasia.[27] Immune-mediated polyarthritis is rare in cats.[28]

Lameness, joint swelling, and periarticular pain can wax and wane or be inapparent in patients with immune-mediated polyarthritis. Therefore arthrocentesis should be performed in the second stage of evaluation of canine patients with FUO. Because dogs with immune-mediated polyarthritis may have fever as their only clinical sign, collection of synovial fluid by arthrocentesis should be considered. Synovial fluid specimens should be obtained from both carpi and both tarsi if possible. The fluid should be examined for color, clarity, and viscosity and submitted for cytologic examination including a differential cell count and cytologic description. The cells in synovial fluid can degrade and undergo apoptosis, quickly altering the cytologic evaluation. Ideally, joint fluid should be submitted as cytologic slide preparations; if additional fluid is available after slide preparation, that can be submitted as well. Aerobic bacterial and mycoplasma culture or mycoplasma PCR should also be performed if specimen volume is large enough. Bacterial recovery from joint fluid will be enhanced if the joint fluid is incubated in blood culture bottles immediately after collection for 24 hours before bacterial plating.

Cerebrospinal Fluid Analysis

In a retrospective study of fever in dogs, 10 of 66 patients were found to have inflammatory CNS disease.[29] This included seven dogs with SRMA (see Chapter 129). Dogs with FUO and evidence of spinal pain can also have concurrent immune-mediated polyarthritis and SRMA.[30] Therefore arthrocentesis should be considered in dogs in which this form of meningitis is suspected. If joint fluid analysis is unremarkable, CSF analysis should be performed.

Blood Culture

Blood cultures are indicated in all patients with FUO and should be especially considered where there is the presence of a cardiac murmur; spinal, long bone, or joint pain; neutropenia; or a history of immunosuppressive drug administration.

Few prospective studies have been done of blood culture techniques in veterinary patients, although this subject has been extensively

reviewed in the human literature.[31] In human medicine, the likelihood of obtaining a positive culture result is directly correlated with the volume of blood drawn, regardless of whether the blood is obtained as a single blood culture set or divided into several sets over a 24-hour period. In one study, the yield from a 30-mL blood sample was found to be 62% more than that from a 10-mL sample. However, the sensitivity of blood cultures is also improved by obtaining more than one set. For example, in a study of bacteremic humans, 91.5% of bacteremic episodes were detected by the first blood culture set, and 99.3% were detected by the first two sets. Increasing the number of blood culture sets will also increase the specificity of the test because contaminants are unlikely to be present in all sets.

In dogs and cats, blood culture techniques should focus on the collection of adequately large volumes of blood, with less emphasis on the timing or periodicity of the collections. The total volume of blood that can safely be obtained will depend on patient size. If size allows, more than one blood culture set should be obtained to increase the sensitivity and specificity of the test. Detailed information on blood culture technique can be found in Chapter 3.

Serologic Testing

Tests available for the diagnosis of infectious disease include assays for specific antibodies or antigens, as well as molecular tools such as PCR-based assays. Many of these tests are performed on blood specimens; however, other body fluids can be used for detection of certain organisms. For example, urine antigen detection appears to be sensitive for the detection of some fungal diseases.[32] Consideration of the signalment, clinical signs, geographic location, and possible vector exposure of the patient should direct selection of the most appropriate tests. Vaccination history, local disease prevalence, sensitivity, specificity, etiologic predictive value, and positive and negative predictive values must be considered when interpreting the results of any diagnostic test (see Chapter 7). Ensuring that tests are only conducted when there is a reasonable likelihood of the disease in question being present will help to minimize problems associated with poor positive predictive value.

Serologic tests are also available for the diagnosis of certain immune-mediated diseases. Antinuclear antibody (ANA) can be detected in patients with systemic lupus erythematosus. However, diagnosis of this uncommon multisystem disorder requires the demonstration of multiple clinical and immunologic abnormalities and should never be based on a positive ANA assay alone.[33,34] In addition, ANA can be positive in some clinically healthy dogs and in association with other medical conditions. This disorder is more appropriately diagnosed by a combination of radiographic changes indicating an erosive polyarthritis together with joint fluid analysis and possibly synovial membrane biopsy.

In summary, extensive arrays of wide-ranging serodiagnostic tests are not recommended in the investigation of FUO, and the use of panels should be avoided if possible or each result in a panel should be interpreted with care and attention to the meaning of a positive or negative result. Ideally, serologic tests should be used to investigate a diagnosis that is suspected based on other findings.

TREATMENT

The goals of FUO therapy are to treat the underlying cause of the fever and provide supportive care to the patient. Dogs and cats with fever have the potential to develop dehydration as a result of reduced water intake and increased sensible and insensible losses. Intravenous fluid therapy can correct these conditions. While cooling measures (e.g., fans, cool water baths, colonic or gastric irritation) are indicated when body temperature is increased as a result of nonfebrile factors such as heat stroke or prolonged seizure activity, these methods should not be used for true fever unless body temperature exceeds 41.1°C (106°F) and there is concern for CNS damage, and then they should only be used to reduce body temperature sufficiently to avoid CNS damage. Fever is a *regulated* increase in body temperature; therefore any attempts to physically cool the patient will be working against the body's own thermoregulatory mechanisms. Fever is also a protective adaptive response to the effects of infection and can have beneficial effects. External cooling is the treatment of choice for hyperthermia in which core temperature exceeds the thermoregulatory set-point. Thus, when external cooling is used to treat hyperthermia, no opposition of regulatory process takes place in an attempt to increase heat gain, as is the case with fever.

Antipyretic therapies inhibit cyclooxygenase and therefore act centrally to reduce the hypothalamic set-point. However, it is extremely rare that antipyretic medications are needed for dogs or cats with FUO and like steroids, antipyretic medications have many risks such as masking disease, inducing secondary complications and preventing treatment with disease-specific appropriate therapy.

In the editor's experience, the most common cause of true FUO in dogs is immune-mediated disease. Usually, fever in cats resolves spontaneously or an underlying cause is identified.

Trial Therapy

In many cases, the investigation of the FUO patient will achieve a definitive diagnosis, and treatment of the underlying cause will lead to resolution of fever and other clinical signs. However, in some cases of true FUO, a diagnosis is not reached, and in other cases, diagnostic testing is discontinued because of client or patient factors. In these cases, therapeutic trials are undertaken in the absence of a definitive diagnosis. Antibacterial, antifungal, or glucocorticoid therapies are often used in therapeutic trials.

The goals of a therapeutic trial should be to confirm a presumptive diagnosis indirectly, control or cure the underlying disease, and resolve the patient's clinical signs, without inducing intolerable adverse effects or exacerbating an undiagnosed disease.

A therapeutic trial should be planned and monitored as rigorously as the diagnostic plan. It is important to begin with a tentative diagnosis, select safe and appropriate therapies, and implement a careful monitoring program, using predetermined criteria for success or failure of the therapeutic trial. Medication should be used at appropriate doses, and the duration of therapy should be sufficient to detect both the presence and absence of a response, particularly because fever can wax and wane independent of therapy.

Good client communication is essential in developing and monitoring a therapeutic trial, and clients should understand the risks of such an approach. Such risks include the continued progression of an undiagnosed disease if an ineffective therapy is used, development of medication adverse effects or toxicities, and the possibility of exacerbating an underlying infectious disease if immunosuppressive therapy is used. Clients should also understand that some medications, such as antifungals, can be expensive, and that initiating treatment without a diagnosis for diseases that require a long course of therapy may make attempts to make a diagnosis more difficult in the future. The risks and benefits of trial therapy should be carefully considered if the patient is likely to be referred for further diagnostic testing.[29] A therapeutic trial is unlikely to be helpful if the client abandons the plan because of expense, adverse effects, or lack of immediate response to treatment.

Many causes of FUO are inflammatory or immune mediated; therefore glucocorticoids are commonly used in patients with FUO in the absence of a specific diagnosis. Because this approach can be dangerous if infectious disease has not been ruled out first, the patient should be monitored closely for exacerbation or development of new clinical signs. The indiscriminate use of glucocorticoids can also interfere

with future diagnostic testing and future more specific therapies, or worsen prognosis. This practice is a particular concern for patients with neoplasia such as lymphoma or fungal disease. Glucocorticoids can also have nonspecific antiinflammatory effects and may improve the patient's clinical signs without addressing the primary cause of the fever allowing progression of disease to go unnoticed.

Empiric antibacterial therapy is commonly used in small animal patients with fever, often with a successful outcome. Ideally, such therapy should be based on culture and susceptibility testing, although this is not always feasible. In trial therapy for FUO patients, antibacterials should be chosen based on a tentative but specific diagnosis, with consideration of spectrum of activity and an understanding of pharmacokinetics. For example, doxycycline is a reasonable choice if salmon poisoning disease, leptospirosis, or a rickettsial disease is suspected. A significant risk of indiscriminate antibacterial therapy is that it contributes to antibacterial resistance in bacterial populations. Treatment with antibiotics without attempting basic diagnostics should be avoided if possible, because serious abnormalities (especially renal failure) may be present, and if undetected and untreated, these may be life-threatening.

Trial therapy for fungal infections with antifungal drugs is rarely indicated without strong support for an underlying fungal disease. Fungal lesions respond slowly to treatment, antifungal drugs are often expensive, and prolonged treatment is typically required. Therefore the importance of investing client funds to obtain a diagnosis first cannot be overemphasized. Fortunately the advent of fungal antigen tests has facilitated diagnosis because they are relatively inexpensive and can be performed on specimens collected in a minimally invasive manner.

CASE EXAMPLE

Signalment:
"Grover," a 2-year-old male neutered Shetland sheepdog from northern California.

History:
Grover was evaluated by the University of California-Davis veterinary emergency and critical care service for fever. Six days previously, Grover vomited four to six times, and vomited up a plant awn. He was seen at a local veterinary clinic and a physical examination was unremarkable. He was treated with subcutaneous fluids and maropitant on an outpatient basis. Two days later, the owners found him shivering and reluctant to move. He was again evaluated at the local veterinary clinic and his temperature was 104.9°C (40.5°F). A CBC, serum chemistry panel, urinalysis, and thoracic radiographs were unremarkable. He was hospitalized and given IV fluids and ampicillin-sulbactam, and discharged the following day. For the following 2 days, the owners reported that he was eating normally but was quiet and still reluctant to move about the house. The owners took his temperature at home and it was 104.4°C (40.2°F).

Current Medications:
Phenobarbital 60 mg in the morning and 90 mg in the evening; levetiracetam 740 mg q 12h for previously diagnosed epilepsy. Monthly endoparasite prophylaxis (milbemycin oxime and praziquantel).

Other Medical History:
Acquired from a breeder at 9 months of age. Diagnosed with suspected idiopathic epilepsy 1 year ago. Last seizure was a week before the onset of fever.

Physical Examination
Body weight: 13.6 kg.
General: Bright, alert, responsive, hydrated. T = 102.9°C (39.4°F), HR 132 beats/min, RR 60 bpm, BCS 5/9, CRT 1–2 s, mucous membranes pink and moist.
GI and genitourinary: Tense abdomen but no apparent pain, organomegaly, or masses. No other clinically significant findings.

Laboratory Findings
CBC: HCT 40.1% (40–55%), MCV 71 fL (65–75 fL), MCHC 33.9 g/dL (33–36 g/dL), WBC 19,660 cells/μL (6000–13,000 cells/μL), neutrophils 14,015 cells/μL (3000–10,500 cells/μL), lymphocytes 2350 cells/μL (1000–4000 cells/μL), monocytes 1752 cells/μL (150–1200 cells/μL), platelets 231,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 143 mmol/L (143–151 mmol/L), potassium 4.3 mmol/L (3.6–4.8 mmol/L), chloride 105 mmol/L (108–118 mmol/L), bicarbonate 19 mmol/L (20–29 mmol/L), phosphorus 4.9 mg/dL (2.6–6.2 mg/dL), calcium 10.3 mg/dL (9.6–11.2 mg/dl), BUN 19 mg/dL (11–33 mg/dL), creatinine 0.9 mg/dL (0.8–1.5 mg/dL), glucose 83 mg/dL (86–188 mg/dL), total protein 6.3 g/dL (5.4–6.9 g/dL), albumin 3.4 g/dL (3.4–4.3 g/dL), globulin 2.9 g/dL (1.7–3.1 g/dL), ALT 98 U/L (21–72 U/L), AST 72 U/L (20–49 U/L), ALP 236 U/L (14–91 U/L), creatine kinase 103 U/L (55–257 U/L), GGT 4 U/L (0–5 U/L), cholesterol 426 mg/dL (139–353 mg/dL), total bilirubin < 0.2 mg/dL (0–0.2 mg/dL), magnesium 2.2 mg/dL (1.9–2.5 mg/dL).

SNAP 4Dx Plus (IDEXX Laboratories, ME, USA): negative for antibody to *Ehrlichia canis*, *Anaplasma platys, Anaplasma phagocytophilum*, and *Borrelia burgdorferi*. Negative for antigen to *Dirofilaria immitis*.

Imaging Findings
Abdominal ultrasound: Abdominal ultrasound examination of the liver, spleen, pancreas, GI tract, urinary tract, and adrenal glands was unremarkable. However, within the dorsal right abdominal wall, adjacent to the kidney and just deep to the last ribs, there was a gas- and fluid-containing structure. Within this structure there were one to two foreign bodies visualized that appeared to be plant awns.

Diagnosis
Suspected plant awn foreign body abscess.

Treatment
Exploratory surgery was performed using a ventral abdominal approach. This revealed significant swelling on the right side of the body wall under the last rib. The swelling was explored and purulent material as well as three plant awns were found. The area was lavaged and a drain placed to allow continuous suction. Aerobic and anaerobic cultures yielded mixed growth that included a broadly susceptible *Escherichia coli*, small numbers of a viridans streptococcus, and small numbers of *Cutibacterium acnes* (formerly *Propionibacterium acnes*). Grover was discharged on treatment with clavulanic acid-amoxicillin and carprofen. He recovered uneventfully.

Comments
This dog had fever that was associated with systemic plant awn migration. The case illustrates the value of a thorough history (as the dog had recently vomited up a plant awn) and meticulous ultrasound examination for detection of migrating foreign bodies. Plant awns often migrate to sites in the retroperitoneal region and caudal ribs, which warrants careful scanning of these regions in dogs with FUO.

Vaccination Schedules for Dogs and Cats

Jane E. Sykes

The schedules provided below are guidelines for immunization of dogs and cats against major viral and bacterial agents. These assume the availability of client resources and suitable products for immunization. The schedules are based on guidelines written by the WSAVA, AAHA, AAFP and ABCD,[1–11] and information available at the time of writing. These are *general guidelines*, because the vaccine types recommended and the frequency of immunization vary depending on the lifestyle of the pet being immunized, i.e., indoor versus outdoor pets, shelter animals, travel plans, kennel/boarding plans, and underlying disease conditions such as immune-mediated diseases or preexisting infections such as FIV infection. Because these factors may change over time, the vaccination plan for individual pet animals should be decided by the owner at routine annual examinations, after a discussion between the veterinarian and the client regarding the animal's lifestyle in the year ahead and the advantages and disadvantages of vaccination. This discussion should be documented in the medical record. A previous history of vaccine reactions in an individual pet will also affect recommendations for immunization. More research is required to generate optimal recommendations for vaccination of dogs and cats.

Vetbooks.ir

TABLE A.1 Guidelines for Vaccination of Individual Pet Dogs

	INITIAL VACCINATION			
Vaccine	**Age ≤ 16 weeks**	**Age > 16 weeks**	**Subsequent Vaccination**	**Comments**
CPV-2, CDV, CAdV-2 (A; SC); or CPV-2, recombinant CDV, CAdV-2 (A; SC)	6–8 weeks of age, then every 3–4 weeks until no sooner than 16 weeks (16–20 weeks in breeding kennels).	Two doses 3–4 weeks apart are recommended, especially for dogs at high risk of exposure, but one dose is considered protective and is sufficient in dogs seen after 6 months of age.	Consider revaccination at 6 months of age rather than 1 year of age, then every 3 years thereafter. This means an additional visit at 1 year of age for rabies and other annually required vaccines.	Core. Protection after the 12-month booster may be lifelong. The recombinant CDV vaccine may immunize in the face of maternal antibody.
CPV-2 (I; SC)				Not recommended when attenuated live vaccines are available and indicated.
Rabies (I; SC)	One dose not earlier than 12 weeks of age.	One dose.	Administer a single dose within 1 year following the initial dose, regardless of the age at the time the initial dose is administered; then every 3 years thereafter if using a 3-year-labeled vaccine or annually if using a 1-year-labeled vaccine. Local jurisdictions may dictate an alternative protocol.	Core in endemic areas or where required by local regulations.
CPiV (A; SC)	6–8 weeks of age, then every 3–4 weeks until no sooner than 14–16 weeks.	One dose.	Annual or within 6 months of boarding, and at least 1 week before boarding.	Noncore. Use as a monovalent product or in combination with other noncore vaccines for annual boosters.
CPiV, *Bordetella bronchiseptica*, CAdV-2 (A; IN)	One dose as early as 3 weeks of age; consider second dose 2–4 weeks later if initial immunization occurs at < 6 weeks of age.	One dose.	Annual or within 6 months of boarding, and second dose (or booster) at least 1 week before boarding.	Noncore. Potential to provide improved local mucosal immunity over SC products. Mucosal vaccines that contain CAdV-2 are for reduction of respiratory disease due to CAdV-2. Parenteral CAdV-2 vaccines are preferred for protection against CAdV-1.
B. bronchiseptica (I; SC)	Two doses 3–4 weeks apart as early as 6 weeks of age.	Two doses 3–4 weeks apart.	Annual or within 6 months of boarding, and at least 1 week before boarding.	Noncore.
B. bronchiseptica (cell wall antigen extract; SC)	Two doses 3–4 weeks apart starting at 8 weeks of age.	Two doses 4 weeks apart.	Annual or within 6 months of boarding, and at least 1 week before boarding.	Noncore.
B. bronchiseptica (A; IN or oral)	One dose as early as 3 weeks of age for IN vaccines, depending on product label. For oral vaccines, one dose as early as 6 or 8 weeks of age, depending on product label.	One dose.	Annual or within 6 months of boarding, and at least 1 week before boarding.	Noncore. Potential to provide improved local mucosal immunity over SC products. Never administer SC.
Borrelia burgdorferi (I or recombinant; SC)	Two doses 3–4 weeks apart starting at 9–12 weeks of age.	Two doses, 3–4 weeks apart.	Annual. Ideally revaccinate 1 month before the onset of the local *Ixodes* tick season.	Noncore.
Canine influenza H3N8 or H3N2 (I; SC)	Two doses 3–4 weeks apart starting at 6 weeks of age.	Two doses 3–4 weeks apart.	Annual.	Noncore, for dogs at risk of exposure such as co-housed dogs, or before import to certain countries. At the time of writing, canine influenza H3N8 may be extinct in the United States and the prevalence of H3N2 is low.
Leptospira (I; SC)	Two doses 3–4 weeks apart starting at 9–12 weeks of age (or earlier depending on product label).	Two doses 3–4 weeks apart.	Annual. Revaccinate 1 month before the onset of the season if disease occurs seasonally.	Author recommends as core. A 4-serovar vaccine is preferred; breakthrough infections are commonly reported with 2-serovar vaccines.
CCV (I and A; SC)				Not recommended because disease is mild and immunization of unproven benefit.

A, attenuated live; *I,* inactivated whole organism; *IN,* intranasal; *SC,* subcutaneous.

TABLE A.2 Guidelines for Vaccination of Individual Pet Cats

Vaccine	INITIAL VACCINATION ≤ 16 weeks	INITIAL VACCINATION > 16 weeks	Subsequent Vaccination	Comments
FPV, FCV, FHV-1 (A; SC)	6–8 weeks of age, then every 3–4 weeks until no sooner than 16–20 weeks (20 weeks in breeding catteries).[4]	One or two doses 3–4 weeks apart. Two doses are recommended for cats that are at high risk of exposure.	Consider revaccination at 6 months of age rather than 1 year of age, then every 3 years thereafter. This means an additional visit at 1 year of age for FeLV and rabies vaccination.	Core. Provides cross-protection to CPV-2 strains that infect cats.[12] Administration of attenuated live vaccines to pregnant cats and kittens less than 4 weeks of age may cause cerebellar hypoplasia in the neonate. Inactivated vaccines are for pregnant cats (if absolutely necessary) and cats with advanced retrovirus infection. Administer distally in the right thoracic limb, avoiding the interscapular space.
FPV, FCV, FHV-1 (I; SC)	6–8 weeks of age, then every 3–4 weeks until no sooner than 16–20 weeks (20 weeks in breeding catteries).[4]	Two doses 3–4 weeks apart.	Consider revaccination at 6 months of age rather than 1 year of age, then every 3 years thereafter. This means an additional visit at 1 year of age for FeLV and rabies vaccination.	Core. Provides cross-protection to CPV-2.[12] Vaccine of choice for pregnant cats and cats with advanced retrovirus infection. Inactivated FPV vaccines should be avoided for routine vaccination in order to optimize protection against FPV. Administer distally in the right thoracic limb, avoiding the interscapular space. Dual-strain calicivirus vaccines may provide broader cross-protection against FCV than single-strain vaccines.
FCV, FHV-1 +/– FPV (A; IN)	6–8 weeks of age, then every 3–4 weeks until no sooner than 16–20 weeks of age.	One dose.	Yearly.	Intranasal vaccines may be associated with transient upper respiratory signs. Intranasal FPV vaccines may not provide sufficient protection against FPV in contaminated environments. Intranasal vaccines may provide rapid protection against FCV and FHV-1 which may be desirable in high-risk situations.
Rabies (I; SC or recombinant canarypox; SC)	One dose not earlier than 12 weeks of age.	One dose.	Administer a single dose within 1 year following the initial dose, regardless of the age at the time the initial dose is administered; then every 3 years thereafter if using a 3-year-labeled vaccine or annually if using a 1-year-labeled vaccine. Local jurisdictions may dictate an alternative protocol.	Core in endemic areas or where required by local regulations. Provides strong protection. AAFP/AAHA recommends administration as distal as possible in the right pelvic limb.
FeLV (I; SC)	Two doses 3–4 weeks apart starting at 8 weeks of age.	Two doses 3–4 weeks apart.	1 year, then every 2-3 years thereafter when risk is ongoing. For high-risk exposure, consider annual revaccination. Beyond 1 year of age, age-related resistance may provide additional protection.	Noncore.[a] FeLV testing before administration recommended before first administering the vaccine to kittens and if exposure was likely before booster immunization is required. Can provide strong protection.[13] Administration as distal as possible in the left pelvic limb is recommended.
FeLV (recombinant canarypox; SC)	Two doses 3–4 weeks apart starting at 8 weeks of age.	Two doses 3–4 weeks apart.	Annual when risk is ongoing.[b] Beyond 1 year of age, age-related resistance may provide additional protection.	Noncore.[a] Only for FeLV-negative cats (see above). More data are required on relative efficacy and whether it is associated with a reduced risk of injection site sarcomas. Administration as distal as possible in the left pelvic limb is recommended. Conflicting evidence exists in the literature regarding the efficacy and safety of recombinant vaccines when compared with inactivated vaccines.
FIV (I; SC) (where available)	Three doses, 3 weeks apart, starting at 8 weeks of age.	Three doses 3 weeks apart.	Annual.	Not recommended. Vaccination does not provide complete protection, can interfere with interpretation of antibody test results, and PCR is insufficiently sensitive for accurate diagnosis. Antibodies may also be passed to kittens in colostrum and interfere with testing up to 12 weeks of age.

TABLE A.2 Guidelines for Vaccination of Individual Pet Cats—cont'd

Vaccine	INITIAL VACCINATION ≤ 16 weeks	INITIAL VACCINATION > 16 weeks	Subsequent Vaccination	Comments
FIP (A; IN)	Two doses 3–4 weeks apart starting at 16 weeks of age.	Two doses 3–4 weeks apart.	Annual.	Not recommended. Only seronegative cats have the potential to be protected. Benefit and risks currently unclear.
Chlamydia felis (I and A; SC)	Two doses 3–4 weeks apart starting at 9 weeks of age.	Two doses 3–4 weeks apart.	Annual.	Noncore. Provides incomplete protection. Could be used as part of a control program in multiple cat households where infection is confirmed using appropriate diagnostic tests as endemic. Vaccination may be associated with adverse effects and provides incomplete protection.
Bordetella bronchiseptica (A; IN)	One dose as early as 8 weeks of age.	One dose.	Annual, but young cats are most at risk.	Noncore. Provides incomplete protection. Use as part of a control program in multiple cat households where infection is confirmed using appropriate diagnostic tests as endemic. Never administer parenterally.

[a]AAFP/AAHA recommends immunization of all kittens for FeLV.[2]
[b]The ABCD, AAHA/AAFP and WSAVA suggest boosters every 2 to 3 years in view of the significant lower susceptibility of older cats, even with recombinant vaccines; annual vaccination is recommended for cats that have predominantly outdoor activities and have aggressive interactions with other cats.
A, attenuated live; *I,* inactivated whole organism; *IN,* intranasal; *SC,* subcutaneous.

GUIDELINES FOR VACCINATION OF DOGS AND CATS IN SHELTER ENVIRONMENTS

For shelter animals, attenuated live core vaccines apart from rabies should be given before or immediately on entry to the shelter. Optimally, vaccination for CPV and CDV should occur at least 3 days before entry to a shelter environment, but vaccination even hours before entry has the potential to make a difference. When outbreaks of known parvovirus disease or canine distemper are present, vaccines can be administered as early as 4–5 weeks of age, but should not be administered earlier than this because of the possibility of vaccine-induced disease and immunosuppression. In the absence of an outbreak situation, vaccination for these pathogens should be performed no earlier than 6 weeks of age. In a shelter situation, the benefits and risks of vaccination of individual pregnant animals with attenuated live vaccines must be carefully assessed. Vaccination with an inactivated vaccine is probably better than no vaccine for pregnant animals that enter a shelter, but inactivated vaccines should not be administered to other animals in the shelter environment, because the onset of immunity is slower than with attenuated live vaccines. Attenuated live vaccines should be administered if ovariohysterectomy is to be performed during pregnancy. If pregnant animals are not vaccinated, they should be strictly isolated from the rest of the shelter animal population. The use of rapid in-house serologic tests that assess for protective antibody titers may be helpful in this situation (see Chapter 20).

Revaccination should be performed no more frequently than at intervals of 2 to 3 weeks, because administration of an attenuated live vaccine within 3 to 14 days of another immunization attempt can interfere with development of immune responses. Revaccination is most important for pups and kittens younger than 16 weeks of age, and is performed to maximize the chance of immunization as soon as possible after the disappearance of maternal antibody interference. Puppies and kittens should also be physically separated from the rest of the shelter animal population and handled with strict attention to quarantine protocols.

Where affordable, vaccination for respiratory pathogens and leptospirosis is strongly recommended in shelter environments. Intranasal vaccines for respiratory pathogens are advantageous in shelter environments because of the potential for improved local immunity, the possibility of administration to very young animals, more rapid onset of protection, and improved protection in the face of maternal antibody. However, they also have been associated with vaccine-induced upper respiratory disease, which may be more severe in debilitated animals and can be difficult to distinguish from natural infection. In addition, field studies have yet not shown benefit of intranasal over parenteral vaccines for respiratory disease. Mucosal *Bordetella bronchiseptica* vaccines should never be given parenterally. This is an emergency situation that requires immediate treatment. See Chapter 20 for specific instructions on how to manage accidental parenteral administration of these vaccines. Leptospirosis vaccines are bacterins and so require 2 doses, 3-4 weeks apart, to provide protection, with annual re-vaccination. Because leptospires can be shed subclinically in the urine of dogs in shelters, vaccination should nevertheless be considered in an effort to minimize zoonotic transmission.

In endemic areas, if possible, a rabies vaccine could be administered at the time of discharge from the facility.[1] Administration of a 3-year product is preferred, but regardless of the product used, booster immunization must be performed no later than 1 year after the initial immunization. Rabies immunization must be properly documented and a veterinarian must usually be present at the time of immunization. Otherwise, the number of vaccines should be limited to those that can assist control of disease that is confirmed to exist within the shelter. This will avoid excessive immune suppression that may worsen the severity of illness due to other pathogens in the shelter for which vaccines are nonexistent.

TABLE A.3 Guidelines for Vaccination of Dogs in Shelter Environments

Vaccine	INITIAL VACCINATION: Age ≤ 16 weeks	INITIAL VACCINATION: Age > 16 weeks	Recommendations for booster at exit	Comments
CPV-2, CPV, CDV or recombinant CDV (A; SC)	On entry no earlier than 4 weeks of age,[a] then every 2 weeks until no sooner than 16–20 weeks.	Two doses 2 weeks apart recommended, but one dose is considered protective.	Consider revaccination at 6 months of age rather than 1 year of age, then every 3 years thereafter. A visit at 1 year of age is necessary for vaccines requiring annual administration.	Core. Potential to provide strong protection. Do not use in pregnancy. The recombinant CDV vaccine has the potential to immunize pups in the face of maternal antibody, but protection may not be as robust as with attenuated live vaccines.
Rabies (I; SC)	One dose not earlier than 12 weeks of age	One dose.	Administer a single dose within 1 year following the initial dose, regardless of the age at the time the initial dose is administered; then every 3 years thereafter if using a 3-year-labeled vaccine or annually if using a 1-year-labeled vaccine. Local jurisdictions may dictate an alternative protocol. If local regulations or absence of veterinary oversight prevent rabies vaccination at the shelter, adopters should be encouraged to pursue rabies vaccination from another source within 4 weeks of adoption.	Use in endemic areas. Local regulations can dictate the need for rabies immunization or the ability to vaccinate in a shelter.
CPiV (A; SC)	On entry, no earlier than 4 weeks of age,[a] then every 2 weeks until no sooner than 16 weeks.	Two doses 2 weeks apart recommended, but one dose is considered protective.	Annual or within 6 months of boarding, and at least 1 week before boarding with monovalent SC or IN respiratory disease vaccines.	If the SC vaccine is used, it can be administered in shelters in combination with CDV, CPV, and CAdV-2. Administer with a vaccine for *B. bronchiseptica.*
CPiV, *Bordetella bronchiseptica*, CAdV-2 (A; IN or oral) (various combinations)	Two doses 2 weeks apart starting as early as 3 weeks (IN), or based on label recommendations (oral), although one dose may be sufficient.	Two doses 2 weeks apart, although one dose may be sufficient.	Annual or within 6 months of boarding, and at least 1 week before boarding.	Potential to provide improved local mucosal immunity over SC products. Inadvertent administration of mucosal *Bordetella* vaccines SC may cause death.
Canine influenza H3N2, H3N8 (I; SC) (subtypes available alone or in combination at time of writing)	On entry, two doses 3 weeks apart starting at 6 weeks of age.	Two doses 3 weeks apart.	Annual, if risk is ongoing.	For dogs at risk of exposure in shelters in endemic regions of the United States. At the time of writing, whether H3N8 is still circulating in the United States is controversial, and the incidence of H3N2 infection is low.

[a]Vaccination can be performed as early as 4–5 weeks in the face of an outbreak.
A, attenuated live; *I,* inactivated whole organism; *IN,* intranasal; *SC,* subcutaneous.

TABLE A.4 Guidelines for Vaccination of Cats in Shelter Environments

Vaccine	INITIAL IMMUNIZATION: Age ≤ 16 weeks	INITIAL IMMUNIZATION: Age > 16 weeks	Recommendations for booster at exit	Comments
FPV, FCV, FHV-1 (A; SC)	On entry and no earlier than 4 weeks of age, then every 2 weeks until no sooner than 16–20 weeks.[4]	Two doses 2 weeks apart recommended, but one dose is considered protective.	1 year, then every 3 years thereafter.	Potential to provide strong protection against FPV and CPV-2.[12] Use in pregnant queens may be associated with cerebellar hypoplasia in neonates. The use of inactivated FPV/FCV/FHV-1 vaccines in shelters is not recommended.
FPV, FCV, FHV-1 (A; IN) (available with or without FPV)	On entry and no earlier than 4 weeks of age, then every 2 weeks until no sooner than 16-20 weeks.	Two doses 2 weeks apart recommended, but one dose is considered protective.	1 year, then every 3 years thereafter. Annual revaccination may be indicated in contaminated environments.	Does not provide complete protection. Avoid in pregnancy. Intranasal vaccines may be associated with transient upper respiratory signs. The use of IN vaccines to protect against FPV is not recommended in shelters. Use of IN vaccines that contain FPV should be avoided in kittens < 4 weeks of age or pregnant queens. Use of IN vaccines should be accompanied by parenteral attenuated live vaccination for FPV.
Rabies (I; SC)	One dose not earlier than 12 weeks of age	One dose.	Administer a single dose within 1 year following the initial dose, regardless of the age at the time the initial dose is administered; then every 3 years thereafter if using a 3-year-labeled vaccine or annually if using a 1-year-labeled vaccine. Local jurisdictions may dictate an alternative protocol. If local regulations or absence of veterinary oversight prevent rabies vaccination at the shelter, adopters should be encouraged to pursue rabies vaccination from another source within 4 weeks of adoption.	For use in endemic areas. Local regulations may dictate the need for rabies immunization and the ability for shelters to vaccinate.

A, attenuated live; *I,* inactivated whole organism; *IN,* intranasal; *SC,* subcutaneous.

ACKNOWLEDGEMENT

The editor wishes to thank Dr. Richard B. Ford, Laurie Larson, and George Moore for their review of and contributions to portions of this Appendix.

Aujeszky's disease virus or suid (porcine) herpesvirus-1 (SuHV-1), 470
Auranofin, for cryptosporidiosis, 1293
Avian newcastle disease virus infection, 463
Avian origin, influenza virus infections of, 312–317
Azithromycin, 118, 119t
as antiprotozoal, 144t
anti-tuberculosis medications, 725t
for babesiosis, 1211–1212, 1211t
for bartonellosis, 865–867
for borreliosis, 838t
for *Campylobacter* infections, 780t
for canine pyoderma and otitis externa/otitis media, 1555t
for COVID-19, 84t
for cytauxzoonosis, 1224, 1224t
for giardiasis, 1271
for keratitis, 1693t
for leptospirosis, 814–816
for toxoplasmosis, 1157–1158, 1159t
Azole antifungals, 127–133, 128f, 129t–130t, 145
fluconazole, 129t–130t, 132
itraconazole, 129t–130t, 130–132, 131f, 132t
ketoconazole, 128–130, 129t–130t
posaconazole, 129t–130t, 133
voriconazole, 129t–130t, 132–133
Aztreonam, 107

B

B. bronchiseptica, 190
Babesia canis, 1204, 1204f
Babesia conradae, 1206
Babesia gibsoni, 1205–1206
Babesia negevi sp. nov, 1206
Babesia rossi, 1203–1204
Babesia spp., prevalence of, 208t–209t
Babesia vogeli, 1203–1204
Babesia vulpes, 1206
Babesiosis, 1203–1217
canine, 1203–1206
clinical signs and pathogenesis of, 1207, 1207b
large *Babesia* species, 1203–1204, 1205f–1206f
treatment for, 1211–1212, 1211t
unnamed large *Babesia* species, 1204
case example for, 1213b–1214b
clinical features of, 1207–1208
clinical signs of, 1207–1208
diagnosis of, 1208–1211
epidemiology of, 1203–1207, 1204f
etiology of, 1203–1207, 1204f
feline, 1207
clinical signs and pathogenesis of, 1208
treatment for, 1212
immunity and vaccination for, 1212–1213
laboratory abnormalities of, 1208–1209
coagulation testing, 1209
complete blood count, 1208
serum chemistry profile, 1208–1209
urinalysis, 1209
microbiologic testing for, 1209–1210, 1209t
cytologic diagnosis, 1209, 1210f
molecular diagnosis using nucleic acid-based testing, 1210
serologic diagnosis, 1209–1210
pathogenesis of, 1207
pathologic findings of, 1210–1211
physical examination findings of, 1208, 1208f
prevention of, 1213
public health aspects for, 1213–1214
severe, 1208
supportive care for, 1212
treatment for, 1211–1212
antiprotozoal treatment, 1211–1212
Bacillus anthracis, 632–633
Bacitracin, for keratitis, 1693t
Bacitracin/neomycin/polymyxin B, for surgical and traumatic wound infections, 943
Bacteremia, 1604t, 1699. *See also* Sepsis
anaerobic infections and, 659–660
bartonellosis and, 854
clinical features of, 1590, 1591t–1592t
defined, 1603
mycoplasma infections and, 683
periodontitis and, 1644
salmonellosis and, 752
treatment of, 605, 1597, 1598t
Bacteria
non-wild-type strains of, 78
wild-type strains of, 78
Bacterial culture, 21–22, 22f, 168–169
for bacterial meningitis, 1717
of bordetellosis, 672
of *Campylobacter*, 777–778
of *Clostridium tetani*, 897
for prostatitis, 1680
for pyometra, 1682
results, interpretation of, 26
of *Salmonella*, 750–751
specimen types for, 20t
for surgical and traumatic wound infections, 940–942
in tularemia, 919
for urinary tract infections, 1676
Bacterial cystitis, 1669t, 1672
clinical signs of, 1673
physical examination findings in, 1673
recurrent, 1669–1670, 1672t
treatment of, 1677–1678
sporadic, 1669, 1672, 1672t
treatment of, 1677, 1677t
Bacterial identification, 24–26, 24f–25f
Bacterial infections
enteric, 797–801
Anaerobiospirillum spp., 797
Arcobacter spp., 797
Brachyspira spp, 797–798
case example for, 799b–800b
Clostridium piliforme, 798–800, 799f
Lawsonia intracellularis, 798
Plesiomonas shigelloides, 798
Shigella spp., 798
miscellaneous, 948–960
case example for, 956b–957b
clinical features of, 949
clinical signs of, 949
cytologic diagnosis of, 949
diagnosis of, 949–950
epidemiology of, 948–949
etiology of, 948–949
isolation and identification of, 949–950, 949f
molecular diagnosis using nucleic acid-based testing for, 950
pathogenesis of, 949
pathologic findings of, 950, 950f
physical examination findings of, 949
public health aspects for, 950
treatment of, 950
Bacterial isolation
and identification
of rapid-growing non-tuberculous mycobacterial infections, 741
of slow-growing non-tuberculous mycobacterial infections, 738
of mycobacterium tuberculosis complex infections, 731
of salmonellosis, 753
and typing, of enteric *Escherichia coli* infections, 762

Bacterial meningitis, 1712–1718
  clinical features of, 1714
  diagnosis of, 1714–1717, 1715t
    diagnostic imaging in, 1715–1716
    laboratory abnormalities in, 1714–1715, 1715f
    microbiologic tests for, 1716–1717
    pathologic findings in, 1717
  epidemiology of, 1712–1714
  etiology of, 1712–1714
  pathogenesis of, 1714
  physical examination findings in, 1714
  prevention of, 1717–1718
  prognosis of, 1717
  public health aspects in, 1718
  treatment of, 1717
Bacterial pathogens, prevalence of, 206t
Bacterial pneumonia
  in cats, 1625
  in dogs, 1624–1625
Bacterial pyoderma, 1551–1556, 1566b
  clinical features, 1552–1553
    classification, 1552
    physical examination findings, 1553
  diagnosis, 1553–1554
    culture and susceptibility testing, 1553–1554, 1553b
    cytologic examination, 1553, 1553f
    molecular diagnosis using nucleic acid-based testing, 1554
    pathologic findings, 1554
    skin scrapings, 1553
  etiology and epidemiology, 1551–1552
  prevention, 1555–1556
  public health aspects, 1556
  treatment and prognosis, 1554–1555
    systemic antimicrobial drug therapy, 1554–1555, 1555t
    topical treatments, 1554, 1554b
Bacterial translocation, 1648, 1649f
Bactericidal drugs, 75
Bactericidal neutrophil defect, 1730t
Bacteriologic statistics, 74
Bacteriology, types of media used in, 21t
Bacteriostatic drugs, 75
Bacteroides spp., 656, 656t–657t
Baermann assay, of feces, 45–46
Balamuthia mandrillaris infection, 1312–1313, 1315, 1316f
Balantidium coli, 1264t
Barmah Forest virus infection, 490t
Barrier gowns, as barrier nursing precautions, 177
Barrier nursing precautions, 177–178
Bartonella alsatica, 855t
Bartonella bacilliformis, 855t
Bartonella bovis, 855t
Bartonella clarridgeiae, 853–854, 855t, 863–864
Bartonella elizabethae, 855t
Bartonella grahamii, 855t
Bartonella henselae, 853–854, 855t, 863–864
  prevalence of, 206t

Bartonellosis, 853–875, 1700
  and bacteremia, 854
  case example of, 870f, 870b–871b
  in cats, 853–854, 857f
    clinical manifestations, 857, 858f
    diagnosis of, 860–865, 862t
    epidemiology of, 853–854
    pathogenesis of, 854–857, 858f–860f
    pathologic findings in, 864–865, 865f–867f
    prevention of, 867, 868t
  in dogs
    clinical manifestations of, 858–859, 861f
    epidemiology of, 854
    physical examination finding, 859–860, 861f
    prevention of, 867, 868t
  etiology of, 853–854, 854f, 855t
  high-risk individuals and, 222, 225f
  immunity and vaccination, 867
  laboratory abnormalities of, 861–862
  microbiologic tests of, 862–864
  public health aspects, 868–871, 868f–870f, 870b
  treatment and prognosis of, 865–867, 867t
Basidiobolomycosis, 1112
Basidiobolus, 33t
Basidiobolus ranarum, 1112
Baylisascaris procyonis, 1427–1430, 1428t
  life cycle of, 1428–1429
  treatments for, 150t–151t
Baytril Otic Emulsion (Bayer Animal Health), 1564t
Behavioral wellness/enrichment, in kennels, 202
Benzimidazoles
  as antiparasitic drugs, 152
  as antiprotozoal drugs, 140–141
Benznidazole, 145t, 146
  for trypanosomiasis, 1254
Benzodiazepines, for tetanus, 897
Betacoronavirus, 1660
Beta-lactam antibiotics, 103–104, 104f
Bile, in hepatobiliary system, 1661–1663, 1662f
Bile examination, *Platynosomum fastosum* infection (platynosomiasis), 1541–1542
Biochemistry findings, of anaerobic bacterial infections, 661
Biochemistry profile, of lyme borreliosis, 832
Biocides, for staphylococcal infections, 615–616
Biofilm, 613
Biopsy
  intestinal, in cryptosporidiosis, 1292, 1292f
  of skin, in *Malassezia* dermatitis, 981–982, 982f
Biosafety levels (BSLs) set, for diagnosis of laboratory practices, 9t
Bioterrorism risk, tularemia as, 921
Bipolaris, 33t
BISC. *See* Bowenoid in situ carcinoma
Bismuth salicylate, for *Helicobacter* infections, 791t
Bismuth subsalicylate, for gastrointestinal disease, 192
Bite wound infections, 925–937
  advanced imaging for, 928–929
  antimicrobial treatment of, 930–931
    contaminated wounds, 930
    infected wounds, 930–931, 930t
    rabies prophylaxis, 931
  case example for, 934b–935b
  clinical features of, 926–927
    cats, 926–927, 928f–930f
    dogs, 926, 927f–928f
  cytologic examination of, 929
  diagnosis of, 927–929
  epidemiology of, 925–926, 926t
    cats, 925–926
    dogs, 925
Bite wound infections *(Continued)*
  etiology of, 925–926, 926t

Borrelia persica, 825t, 841
Borrelia recurrentis, 825t, 841
Borrelia spielmanii, 825t
Borrelia turicatae, 825t, 832
Borrelia valaisiana, 824–826, 825t
Borreliosis, 824–852
  case example of, 843b–844b
  Lyme
    in cats, 831
    clinical laboratory findings, 832
    clinical signs of, 829–831, 829f–830f
    detection of *Borrelia*e by other techniques, 835
    diagnosis of, 831–835
    diagnosis with molecular methods, 835
    diagnostic imaging of, 832
    in dogs, 830–831, 834t
    epidemiology of, 824–829, 826f, 828f
    etiology of, 824–829, 825t, 828f
    immunity and vaccination, 838–839, 839t
    microbiologic tests of, 832–835
    pathogenesis of, 829–831, 830f
    pathologic findings of, 835, 836f–837f
    prevention of, 840
    public health considerations, 840–841
    treatment and prognosis, 835–838
    vector control, 840
  tick-borne relapsing fever, 840–841
    clinical features of, 841–842
    clinical signs of, 841–842
    diagnosis of, 842–843, 843f
    epidemiology of, 841, 842f
    etiology of, 841, 842f
    pathogenesis of, 841–842
    treatment and prevention, 843–844
Botanicals, as antiparasitic drugs, 157
Botulism, 898, 1699–1700
  case example of, 902b–903b
  clinical signs of, 898–900
  diagnosis of, 900–901, 900t
  diagnostic imaging of, 900
  epidemiology of, 898
  etiology of, 893
  immunity and vaccination of, 901–902
  laboratory abnormalities of, 900
  microbiologic tests of, 900–901
  pathogenesis of, 898–900
  pathologic findings of, 901
  physical examination findings of, 899–900
  prevention of, 902
  public health aspects, 902–903
  treatment and prognosis of, 901
Bowenoid in situ carcinoma (BISC), 478, 480–482, 483f
Brachyspira spp, 797–798
Branched DNA assays, of pathogen detection, 54
Breeding catteries
  for feline calicivirus infection, 450, 451b
  feline respiratory disease control in, 437
Breeding facilities, in infectious disease prevention, 183
Bridging the Veterinary-Human Healthcare Communication Divide, 221b
Broad-range bacterial PCR and sequencing, of L-form infections, 680t
Bronchiectasis
  in cats, 1625, 1627f
  in dogs, 1624, 1624f
Bronchoalveolar lavage specimens, for bacterial culture, 20t
Bronchomalacia, 1624, 1624f
Bronchoscope-guided BAL, 1628–1629
Brown dog tick *(Rhipicephalus sanguineus)*
  as *Ehrlichia canis* vector, 522–523, 524f
  as hepatozoonosis vector, 1230–1231
  as Rocky Mountain spotted fever vector, 556
Brucella abortus, 876
Brucella canis, 877–878
Brucella melitensis, 876
Brucella neotomae, 876
Brucella ovis, 876
Brucella suis, 876
Brucellosis, 876–892, 1699
  canine
    case example of, 890f, 890b–891b
    clinical features of, 877–880, 878f
    clinical signs of, 877–880, 879f

pathogenesis of, 1221, 1221f–1222f
pathologic findings of, 1223–1224, 1223f–1224f
peripheral blood smears, 1222, 1222f–1223f
physical examination findings of, 1221
prevention of, 1226
prognosis of, 1225
public health aspects for, 1226–1227
treatment of, 1224–1225, 1224t, 1225f
Cytochrome P-450, substrates, inhibitors, and inducers of, 129t
Cytokine storm, 1608
Cytologic diagnosis
of anaerobic bacterial infections, 661–662
for bacterial tracheobronchitis, 1628–1629
of *Echinococcus* spp. infections (echinococcosis), 1466, 1468f

Cytologic diagnosis *(Continued)*
in *Hepatozoon americanum* infection, 1242
in *Hepatozoon canis* infection, 1234–1236, 1236f
for *Heterobilharzia americana* infection (heterobilharziasis/canine schistosomiasis), 1531
of *Mesocestoides* spp. infection, 1471–1472, 1473f–1474f
in microsporidiosis, 1142–1143
Paragonimus kellicotti infection (paragonimiasis), 1536
in pneumocystosis, 1121–1122, 1122f, 1122t
for pyothorax, 1634, 1634f
of rangeliosis, 1310, 1311f
Cytologic examination
in aspergillosis-penicilliosis, 1076–1077
for blastomycosis, 991–992, 993t, 996f
in candidiasis, 1063, 1064f
for coccidioidomycosis, 1033t, 1034–1035, 1037f
for cryptococcosis, 1020t, 1021, 1022f
for *Ehrlichia canis* infection, 524
for *Ehrlichia chaffeensis* infection, 530
in entomophthoromycosis and mucormycosis, 1113–1114, 1113f
for feline ehrlichiosis, 534
for fever of unknown origin, 1752
for histoplasmosis, 1007, 1008t, 1009f
in lagenidiosis, 1111
of mycobacterium tuberculosis complex infections, 729, 730f
in pythiosis, 1108
of rapid-growing non-tuberculous mycobacterial infections, 741
of slow-growing non-tuberculous mycobacterial infections, 737, 738f
in trypanosomiasis, 1252–1253
Cytologic findings, of hyalohyphomycosis, 1099, 1100f
Cytologic identification, of disseminated invasive aspergillosis-penicilliosis, 1085
Cytological diagnosis, of nonenteric (free-living) amebiasis, 1314
Cytological examination
of bile, for hepatobiliary infections, 1663–1664
in protothecosis, 1129, 1130f
Cytology
of bordetellosis, 672
in hemotropic mycoplasma infections, 697
of L-form infections, 680t
for surgical and traumatic wound infections, 943
Cytopathic effect (CPE), 7–8
Cytopathologic examination, for sporotrichosis, 1047–1048, 1048f

D

Dalbavancin (Dalvance), 108
Dantrolene, for tetanus, 897
Dapsone
for pneumocystosis, 1124
for rhinosporidiosis, 1136
Daptomycin, 110
Decitabine, 86t
for feline leukemia, 399t
Decoquinate
as antiprotozoal, 143, 144t
for hepatozoonosis, 1243, 1243t
Deep incisional surgical site infection, 941t, 942
Deep pyoderma, 23, 1552, 1552f
Deer tick *(Ixodes scapularis)*
life cycle of, 828f
size of, 827f
Deletion mutant vaccines, 239
Demodex canis, 1381–1382
Demodex cati, 1381–1382
Demodex gatoi, 1381–1382
Demodex injai, 1381–1382
Demodex spp., 1381–1384
diagnosis of, 1382–1383
direct microscopic examination for, 1382–1383, 1383t
epidemiology of, 1381–1382, 1381f
etiology of, 1381–1382, 1381f

DermaPet Malacetic Otic (Dechra), 1564t
Dermatophilosis, 949
Dermatophilus congolensis, 948
Dermatophyte culture, 32
for dermatophytosis, 967–969, 967b, 968f
Dermatophyte test medium (DTM), 35, 967–968
Dermatophytes, 33t, 193
Dermatophytosis, 961–977
case example for, 974b
in cats, 193–194
clinical features of, 962–964
diagnosis of, 964–969, 965t
dermatophyte culture, 967–969, 967b, 968f
dermoscopy, 965, 965t
direct examination (cytologic examination), 965t, 966–967, 966b, 967f
fungal culture, 965t
molecular testing real-time PCR, 965t
skin biopsy, 965t
Wood's lamp examination, 965–966, 965t, 966f, 966b
epidemiology of, 961–962, 962f, 962t
etiologic agent of, 961–962, 962f, 962t
high-risk individuals and, 226–227, 226f
immunity and vaccination for, 973
molecular diagnosis using nucleic acid-based testing for, 969
pathogenesis of, 962–964, 963f
physical examination findings of, 963–964
in cats, 963–964, 963f
in dogs, 964, 964f
prevention of, 973
public health aspects for, 973–975
signs of, 962–964, 963f
skin biopsy for, 967
treatment and prognosis of, 969–973
duration of, 972–973, 972b
environmental control, 971b
systemic antifungal therapy, 970t, 971
topical antifungal drug treatment, 969–970, 970b
Dermoscopy, for dermatophytosis, 965, 965t
Dexamethasone
for blastomycosis, 996
for COVID-19, 84t
DH-82 cell line, 6t
Diabetes mellitus, hereditary immunodeficiencies and, 1738t
Diagnostic assay sensitivity, degrees of, 70f
Diagnostic imaging, for feline ehrlichiosis, 535
3,3′-diaminobenzidine (DAB), 12
Diarrhea
antibiotic-responsive chronic, 1650
giardiasis and, 1265–1267
infectious, 1648
Dicloxacillin, 105t
Dictyocaulus viviparus, 1440
Didanosine, 86t
for feline leukemia, 399t
Diethylcarbamazine, for feline leukemia, 401
Diffuse unilateral subacute retinitis (DUSN), 1423
Diffusely adherent *E. coli* (DAEC), 760t
Diffusion methods, of antimicrobial susceptibility testing, 26–28
Digital PCR, 60, 60f
Dilution methods, of antimicrobial susceptibility testing, 26
Diminazene aceturate
as antiprotozoal, 144, 144t
for babesiosis, 1211t
for cytauxzoonosis, 1224t, 1225
for trypanosomiasis, 1257–1258, 1257t
Dioctophyme renale infection (dioctophymatosis, dioctophymiasis), 1494–1496
clinical features of, 1495
clinical signs of, 1495
diagnosis of, 1495
etiology and epidemiology of, 1494–1495
immunity, 1496
pathogenesis of, 1495
physical examination findings of, 1495
prevention of, 1496
prognosis of, 1496
public health aspects of, 1496
treatment of, 150t–151t, 1496
Diphyllobothrium latum, 1473
eggs of, 1475
life cycle of, 1474f
Diphyllobothrium spp. infection, 1473–1476
clinical signs of, 1475
diagnosis of, 1475
epidemiology of, 1473–1475
etiology of, 1473–1475
laboratory abnormalities of, 1475
microbiologic tests of, 1475, 1475f
pathogenesis of, 1475
prevention of, 1476
prognosis of, 1475–1476, 1476t
public health aspects of, 1476
treatment of, 153t, 1475–1476, 1476t
Dipylidium caninum, 1457–1460
clinical signs of, 1458–1459
diagnosis of, 1459
epidemiology of, 1457–1458
etiology of, 1457–1458
life cycle of, 1458f
morphologic features of, 1458f
pathogenesis of, 1458–1459
prevalence of, 206t–207t
prevention of, 1460
prognosis of, 1459–1460
public health aspects of, 1460
treatment of, 153t, 1459–1460, 1460t
Direct contact transmission, 174
Direct examination (cytologic examination), for dermatophytosis, 965t, 966–967, 966b, 967f
Direct fluorescent antibody (DFA), with rabies, 266, 266t
Direct hybridization, of pathogen detection, 53–54
Direct IFA, 12
Direct immunostaining, in dogs, 279t

Direct observation, 169
Direct saline smear, of feces, 42–43, 43f–44f
Direct smears, microscopic examination of, 21–24, 21f, 21b
  airway specimens, 23
  bacterial culture, 21–22
  blood and intravascular catheters, 22–23
  body fluids, 23

for bite wound infections, 930t
for brucellosis, 888
for *Campylobacter* infections, 780t
for canine parvovirus, 347t
for canine pyoderma and otitis externa/otitis media, 1555t
for *Ehrlichia canis* infection, 529
for feline ehrlichiosis, 535
for hemotropic mycoplasma infections, 698, 698t
for plague, 911t
for *Rhodococcus equi* infection, 629t
for Rocky Mountain spotted fever, 562
Entamoeba histolytica, 1264t
Enteric bacterial infections, 797–801
Anaerobiospirillum spp., 797
Arcobacter spp., 797
Brachyspira spp, 797–798
case example for, 799b–800b
Clostridium piliforme, 798–800, 799f
Lawsonia intracellularis, 798
Plesiomonas shigelloides, 798
prevention of, 754
Shigella spp., 798
Enteric clostridial infections, 766–773
assays for toxin production, 769
bacterial isolation of, 768–769
case example for, 771b
chemistry panel of, 768
clinical features of, 766–768
clinical signs of, 766–768
complete blood count of, 768
diagnosis of, 768–770
diagnostic imaging of, 768, 769f, 769t
epidemiology of, 766, 767f, 767t
etiology of, 766, 767f, 767t
mechanism of toxin action of, 767–768
microscopic examination of, 768
molecular diagnosis using nucleic acid-based testing of, 769
pathogenesis of, 766–768
pathologic findings of, 770
physical examination findings of, 768
prognosis of, 770, 770t
public health aspects for, 770–771
treatment of, 770, 770t
Enteric coccidioses, other, 1304–1305, 1304f
Enteric *Escherichia coli* infections, 759–765, 760t
adherence patterns of, 760f
case example of, 764f, 764b
clinical features of, 759–762
diagnosis of, 762–763
diagnostic imaging of, 762
endoscopic findings of, 762, 762f
epidemiology of, 759
etiology of, 759
immunity and vaccination, 763, 763f
laboratory abnormalities of, 762
microbiologic testing of, 762–763
pathogenesis of, 759–762, 761f
pathologic findings of, 763
Enteric *Escherichia coli* infections *(Continued)*
physical examination findings of, 762
prognosis of, 763
public health aspects, 763–765
treatment of, 763
Enteric protozoal infections, 1263
amebiasis, 1264t
Enteroaggregative *E. coli* (EAEC), 760t
Enterobacter infections, 647
Enterobacterales, 643, 645–647
Enterococcal infections, 597–610, 605t
treatment of, 605
Enterococcus spp., 601–602
Enterocytozoon bieneusi, 1145, 1145t
Enterohemorrhagic *E. coli* (EHEC), 763
Enteroinvasive *E. coli* (EIEC), 760t
Enteropathogenic *E. coli* (EPEC), 760t
Enteropathogenic *Escherichia coli*, 645–646
Enterotoxigenic *E. coli* (ETEC), 760t
Enterotoxigenic *Escherichia coli*, 646
Enterovirus infections, 509, 509t
Entire adult nematodes, of *Dioctophyme renale*, 1495
Entomophthoromycosis, 1095t, 1105–1117, 1108t
case example of, 1114b–1115b, 1115f
clinical features of, 1112, 1113f
cytologic and histologic findings of, 1113–1114, 1113f
diagnosis of, 1113–1114
etiology of, 1112
laboratory and imaging abnormalities of, 1113
prognosis of, 1114
public health aspects of, 1114–1115
treatment of, 1114
Environmental infection control, 178–179
Environmental monitoring, 181–182
Environmentally acquired infections, 219b
Enzootic disease, 65
Enzyme-linked immunosorbent assay (ELISA), 13–14
in *Anaplasma platys* infection, 550
of botulinum, 900
in brucellosis, 882t
for *C. difficile* antigen, 769
in canine parvovirus, 344–345
in cryptosporidiosis, 1291
in feline coronavirus infection, 369–370
in feline leukemia virus infection, 395–396
for feline panleukopenia virus (FPV) infection, 354–355
in leptospirosis, 812–813
for sporotrichosis, 1048
in toxoplasmosis, 1155
in trypanosomiasis, 1254
in tularemia, 920
Eosinophilic bronchopneumopathy, 1624
Epidemic typhus, 565
Epidemiologic triangle, of infectious disease, 64
Epidermophyton floccosum, 961
Epididymitis, 1679–1680
Epi-Otic Advanced (Virbac), 1564t
Epistaxis
for *Ehrlichia chaffeensis* infection, 530
in leishmaniosis, 1184–1185, 1186f
Eprinomectin
as antiparasitic drugs, 155
for heartworm prevention, 152t
Epsiprantel
as antiparasitic drugs, 154
for *Dipylidium caninum* infection, 1459–1460, 1460t
for *Taenia* spp. infections, 1462, 1463t
Equine encephalitides, eastern, 490t, 492f
Equine origin, influenza virus infections of, 316
Erysipelothrix infections, 632, 633f
Erysipelothrix rhusiopathiae, 632

Erysipelothrix tonsillarum, 632
Erythromycin, 119t
  for borreliosis, 838t
  for *Campylobacter* infections, 780t
  for enteric clostridial infections, 770t
  for keratitis, 1693t
  for nocardiosis, 719t
  for *Rhodococcus equi* infection, 628, 629t
Escherichia coli infections, 645–646
  adherent invasive, 646
  enteric, 759–765
    adherence patterns of, 760f
    case example of, 764f, 764b
    clinical features of, 759–762
    diagnosis of, 762–763
    diagnostic imaging of, 762
    endoscopic findings of, 762, 762f
    epidemiology of, 759
    etiology of, 759
    immunity and vaccination, 763, 763f
    laboratory abnormalities of, 762
    microbiologic testing of, 762–763
    pathogenesis of, 759–762, 761f
    pathologic findings of, 763
    physical examination findings of, 762
    prognosis of, 763
    public health aspects, 763–765
    treatment of, 763
  enteropathogenic, 645–646
  enterotoxigenic, 646
  extraintestinal pathogenic, 646

brucellosis control in, 889
community health in, 203
design and layout of, 199–200, 200b
disinfection, sanitation, and pest control in, 201
environmental factors in, 201–202
giardiasis control in, 1271–1272
health monitoring in, 202–203
nutrition in, 202
parasite control in, 202
population density management, 198–199, 199f
record keeping in, 203
segregation of populations in, 200–201, 201b
vaccination of animals in, 202
Keratitis, 1692–1694
in cats, 1693–1694, 1694f
in dogs, 1692–1693, 1692f
treatment of, 1693t
Keratoconjunctivitis sicca, in leishmaniosis, 1184
Ketoconazole (KTZ), 128–130, 129t–130t
for aspergillosis-penicilliosis, 1081
for coccidioidomycosis, 1038
for dermatophytosis, 970t
for *Malassezia* dermatitis, 982–983
for rhinosporidiosis, 1136
for sporotrichosis, 1050–1051
Ketolides, 118–120, 119t
Kirby-Bauer antibiotic testing, 26–28
Kittens, fading kitten syndrome in, 393
KlearOtic (Dechra), 1564t
Klebsiella infections, 646–647, 647f
Kupffer cells, 1660–1661

L

La Crosse virus infection, 490t, 491–492
Laboratory diagnosis, of fungal infections, 31–41
diagnostic methods, 33–37
direct examination, 33, 34f, 34t
interpretation of results, 37–39
organism identification, 35–37, 38f
organism isolation, 37t
specimen collection and transport, 31–33
β-lactamase inhibitor, 105t
Lactoferrin, 95–96
Lactogenic (transmammary) transmission, 1422
Lagenidiosis, 1095t, 1108t, 1110, 1110f
case example of, 1114b–1115b, 1115f
clinical features of, 1110–1111
diagnosis of, 1111
epidemiology of, 1110
etiology of, 1110
imaging findings of, 1111
laboratory abnormalities of, 1111
microbiologic tests of, 1111
pathologic findings of, 1112, 1112f
prognosis of, 1112
public health aspects of, 1112
treatment of, 1112
Lagenidium spp., 1110
Lagochilascaris major, life cycle of, 1430
Lagochilascaris minor, life cycle of, 1430
Lagochilascaris spp., 1430–1431
Lameness, feline calicivirus and, 445
Lamivudine, 86t
Lavage, for pyothorax, 1635
Lawsonia intracellularis, 798
Leishmania amazonensis, 1181
Leishmania braziliensis, 1179, 1192
Leishmania donovani, 1181
Leishmania infantum, 1179
life cycle of, 1180f
Leishmania panamensis, 1181
Leishmania peruviana, 1181, 1192
Leishmania spp., prevalence of, 208t–209t
Leishmania tropica, 1181
Leishmaniosis, 1179–1202, 1702–1703, 1702f
canine, 1181–1192, 1739
bone marrow examination for, 1187
clinical signs of, 1183–1185, 1184f–1185f
complete blood count for, 1186
culture for, 1189
diagnosis of, 1186–1189
diagnostic imaging for, 1187
epidemiology of, 1181–1183, 1182f
examination of other body fluids for, 1187
laboratory abnormalities of, 1186–1187, 1186t
microbiologic tests for, 1187–1189, 1187t
molecular diagnosis using nucleic acid-based testing for, 1188–1189
pathogenesis of, 1183–1185, 1184f–1185f
pathologic findings of, 1189, 1189f
physical examination findings of, 1185, 1186f, 1186t
prevention of, 1191–1192
public health considerations for, 1192
serologic diagnosis of, 1187–1188, 1188f
serum chemistry profile for, 1186–1187
staging of, 1191, 1191t
tegumentary, American, 1192, 1192f
treatment for, 1189–1191, 1190t
urinalysis for, 1187
case example for, 1193b–1194b
feline, 1192–1195
clinical findings of, 1193, 1193f
epidemiology of, 1192–1193
etiology of, 1192–1193
treatment and prognosis of, 1195
global distribution of, 1179–1181, 1180f–1181f
in humans, 1180–1181
Leptospira biflexa, 802
Leptospira interrogans, 802
serogroup, 802, 803t
Leptospira kirschneri, 802, 803t
Leptospira vaccines, 803–804, 817
Leptospiral pulmonary hemorrhage (LPHS), leptospirosis and, 805
Leptospiremia, 804–805
Leptospirosis, 802–823, 1699
antimicrobial drugs of, 814–816, 815t
case example for, 818f, 818b–819b, 819t
in cats, 803–804
clinical features of, 804–806
clinical signs of, 804–806, 805f
diagnosis of, 806–814
coagulation function, 806
complete blood count, 806, 807t
plain thoracic radiography, 810f
serum biochemical tests, 806, 808t–809t
urinalysis, 806–810
in dogs, 803–804
epidemiology of, 802–804, 803f, 803t
etiologic agent of, 802–804, 803f, 803t
high-risk individuals and, 227
immunity and vaccination for, 816–817
machine learning for, 813
microbiologic tests for, 810–813, 811t
culture, 810
darkfield microscopy, 810
molecular diagnosis using nucleic acid-based testing, 813, 814f
serologic diagnosis, 811–813, 812f
pathogenesis of, 804–806, 805f
pathologic findings of, 813–814, 814f–815f
physical examination findings of, 806
prevention of, 817
prognosis of, 814–816
public health aspects for, 817–819, 817b
renal replacement therapy for, 816
reservoir hosts of, 803
supportive care of, 816
treatment of, 814–816
Lethal acrodermatitis, 1730t, 1735
Leukemia, feline leukemia virus and, 389, 398
Leukocyte adhesion deficiency, 1730t
in cats, 1736
in dogs, 1732, 1733f–1734f
Leukocyte granulation, 1730t
Levamisole, for feline leukemia, 401
Levine technique, for wound sampling, 943, 943b
Levofloxacin, 111t
for keratitis, 1693t
L-form infections, 679–681, 679b, 680f–681f, 680t
clinical features of, 679
diagnosis of, 679–680
epidemiology of, 679
etiology of, 679
prognosis of, 680–681
public health considerations of, 681
treatment of, 680–681
Lice, 1324
case example for, 1333f, 1333b–1334b
clinical features of, 1331
diagnosis of, 1331–1332
direct microscopic examination, 1331–1332, 1332f
gross pathologic findings, 1332
laboratory abnormalities, 1332
epidemiology of, 1331
etiology of, 1331
immunity for, 1332
pathogenesis of, 1331
prevention of, 1333
public health aspects for, 1333
treatment and prognosis of, 1332
Lime sulfur dips
for dermatophytosis, 194
for miscellaneous bacterial infections, 950
Lincomycin, 119
for *Rhodococcus equi* infection, 628
Lincomycin hydrochloride, 119t
Lincosamides, 118–120, 119t, 143
Linezolid, 120, 120t
for nocardiosis, 719t
Lions, canine distemper virus in, 460–462
Lipid A backbone, 643
Lipid-soluble drugs, 77
Lipopolysaccharide (LPS), 643
Liposomal AMB (Ambisome), 134
Liquid immersion sterilization, 167, 167t
Liquid specimens, 4
Listeria monocytogenes, 630, 631f
Listeriolysin O, 630–632
Listeriosis, 630–632, 631f
L-Lysine, as antiviral, 91
Local cutaneous reactions, 248–250, 248f–249f
Localized tetanus, 894
Lone Star tick *(Amblyomma americanum)*
as *Ehrlichia chaffeensis* vector, 530
as *Ehrlichia ewingii* vector, 531
Louping-ill virus, 490t, 494–495
Lower respiratory complications, and feline calicivirus infection, 444
Lower urinary tract candidiasis, 1062
Low-level disinfectants, 162
Low-passage cell lines, 5
Lyme borreliosis, 1699
in cats, 831
clinical laboratory findings, 832
clinical signs of, 829–831, 829f–830f
detection of *Borreliae* by other techniques, 835
diagnosis of, 831–835
with molecular methods, 835
diagnostic imaging of, 832
in dogs, 830–831, 834t
epidemiology of, 824–829, 826f, 828f
etiology of, 824–829, 825t, 828f
immunity and vaccination, 838–839, 839t
microbiologic tests of, 832–835

Lyme borreliosis *(Continued)*
pathogenesis of, 829–831, 830f
pathologic findings of, 835, 836f–837f
prevention of, 840
public health considerations, 840–841
treatment and prognosis, 835–838
vector control, 840
Lyme nephritis, 837–838. *See also* Glomerulonephritis
Lymphadenitis, necrotizing, Hendra virus infection and, 462
Lymphadenomegaly, in leishmaniosis, 1184
Lymphocyte T-cell immunomodulator, 95
Lymphoma
feline leukemia virus and, 382, 388–389, 388f, 398
ocular, 1697–1698, 1698f
risk of, in FIV infected cat, 419
Lymphopenia, feline leukemia virus infection and, 391
Lymphoplasmacytic dermatitis, *Cheyletiella* spp. and, 1379
Lynxacarus radovskyi (fur mite, hair clasping mite), 1391, 1391f
Lysine, 87t
Lyssaviruses
classification of, 260
current taxonomy of, 261t

M

Macrocyclic lactones, 154–155, 154t, 158
for canine heartworm disease, 1405t, 1406, 1406f
of ocular nematode infections, 1498
Macrocyclic lactones/doxycycline combinations, for canine heartworm disease, 1406–1407
Macrolides, 118–120, 119t, 143
Macrophage, 1606
Madin-Darby canine kidney cells (MDCK), 6t
Magnetic resonance imaging (MRI)
for bacterial meningitis, 1716, 1716f
for canine distemper virus infection, 279, 279f
for coccidioidomycosis, 1034, 1037f
for cryptococcosis, 1021, 1021f
for feline panleukopenia virus infection, 354
for histoplasmosis, 1007
for rabies, 265–266
Malassezia arunalokei, 979t
Malassezia brasiliensis, 979t
Malassezia caprae, 979t
Malassezia cuniculi, 979t
Malassezia dermatis, 979t
Malassezia dermatitis, 978–986
case example for, 983b–984b
clinical signs of, 979–980, 979f
diagnosis of, 980–982
culture, 981, 982f
cytologic diagnosis, 980–981
molecular diagnosis using nucleic acid-based testing, 981
epidemiology of, 978–979, 979t
etiology of, 978–979, 979t
pathogenesis of, 979–980, 979f
pathologic findings of, 981–982, 982f
prevention of, 983
public health considerations for, 983–984
treatment for, 982–983, 983t
systemic therapy, 982–983
topical therapy, 982
Malassezia equina, 979t
Malassezia furfur, 979t
Malassezia globosa, 979t
Malassezia japonica, 979t
Malassezia nana, 978, 979t
Malassezia obtusa, 979t
Malassezia pachydermatis, 978, 979t
high-risk individuals and, 227–228
Malassezia psittaci, 979t
Malassezia restricta, 979t
Malassezia slooffiae, 979t
Malassezia spp., 33t, 34, 36f, 978
Malassezia sympodialis, 979t
Malassezia verpertilionis, 979t
Malassezia yamatoensis, 979t
Mammomonogamus spp., 1493–1494, 1493f–1494f
Marbofloxacin, 111t
anti-tuberculosis medications, 725t
for bite wound infections, 930t
for canine pyoderma and otitis externa/otitis media, 1555t
for hemotropic mycoplasma infections, 698, 698t
for tularemia, 921t
Maropitant citrate, for canine parvovirus, 347t
Maternal antibody, feline panleukopenia and, 356
Maternal immunity, canine parvovirus vaccination and, 348
Maternally derived antibody (MDA), influence of, 243f
McCoy cell line, 6t
Mediastinal lymphoma, 388, 388f, 398
Mediterranean spotted fever (MSF), 555–556, 563
Medline Plus, Pets and the Immunocompromised Person, 221b
Mefenoxam, for pythiosis, 1110
Meglumine antimoniate, 145t
for leishmaniosis, 1189, 1190t
Melarsomine
for canine heartworm disease, 1405t, 1406
for ocular nematode infections, 1498
Melarsomine dihydrochloride, as antiparasitic drugs, 155
Melarsoprol, for trypanosomiasis, 1257
Melioidosis, 950–951
clinical signs of, 951–952, 952f
diagnosis of, 952–953
antigen-detection ELISA, 953
cytologic diagnosis, 952, 953f
isolation and identification, 952–953
molecular diagnosis using nucleic acid-based testing, 953
pathologic findings, 953, 954f
serologic diagnosis, 953
epidemiology of, 950–951, 951f
etiologic agent of, 950–951, 951f
pathogenesis of, 951–952, 952f
physical examination findings of, 951–952, 952f
public health aspects for, 953–954
treatment and prognosis of, 953
Meningitis, 831
bacterial, 1712–1718
clinical features of, 1714
diagnosis of, 1714–1717, 1715t
diagnostic imaging of, 1715–1716
epidemiology of, 1712–1714
etiology of, 1712–1714
laboratory abnormalities in, 1714–1715, 1715f
microbiologic tests for, 1716–1717
pathogenesis of, 1714
pathologic findings in, 1717
physical examination findings in, 1714
prevention of, 1717–1718
prognosis of, 1717
public health aspects in, 1718
treatment of, 1717
borreliosis and, 830
treatment of, 604–605
Meningoencephalitis
brucellosis and, 879
greyhound nonsuppurative, 1720–1721
mycoplasma infections and, 683–684
treatment of, 604–605
Meningoencephalomyelitis, 1712–1718
Sarcocystis neurona-associated, 1174
2-Mercaptoethanol rapid slide agglutination test (ME-RAST), 877
Meropenem, 108t
for bacteremia, 1598t
for infective endocarditis, 1598t
Mesocestoides spp. infection, 1470–1473, 1471f
clinical signs of, 1471
diagnosis of, 1471–1472
diagnostic imaging of, 1471, 1472f
epidemiology of, 1470–1471
etiology of, 1470–1471
laboratory abnormalities of, 1471
microbiologic tests of, 1471–1472
pathogenesis of, 1471
prevention of, 1472–1473
prognosis of, 1472, 1474t
public health aspects of, 1473
treatment for, 153t
treatment of, 1472, 1474t
Mesocestoides vogae, 1470
Metabolic disturbances, 1740
Metabolome, 1640–1641
Metastatic uterine adenocarcinoma, feline leukemia virus and, 389–390
Metastrongyloid infections, of respiratory tract, 1506–1510
Aelurostrongylus abstrusus infection (Aelurostrongylosis), 1507–1510
Angiostrongylus vasorum infections (Angiostrongylosis), 1516–1520, 1516f
Crenosoma vulpis infection (Crenosomosis), 1511–1513
Filaroides spp. infection (Filaroidosis), 1513–1514, 1513f
of wild felids, 1510–1520
Methicillin, 105t
Methicillin-resistant *Staphylococcus aureus* (MRSA), 612–613
in clinic personnel, 619–620
decolonization, 620–622
high-risk individuals and, 228
infection control in households, 620
pet owners diagnosed with, 620
Methicillin-resistant *Staphylococcus pseudintermedius* (MRSP), 612
Methocarbamol, for tetanus, 897
Methylprednisolone, for hemotropic mycoplasma infections, 698
Metoclopramide, for canine parvovirus, 347t
Metronidazole, 112, 112t
for anaerobic infections, 663–664
for babesiosis, 1211t
for bite wound infections, 930t
for enteric clostridial infections, 770, 770t
for enteric protozoal infections, 1270, 1270t
for *Helicobacter* infections, 791t
for tetanus, 897, 897t
Metronidazole, as antiprotozoal, 141, 141t
Metronidazole benzoate, 112t
Mezlocillin, 105t
Miconazole
for dermatophytosis, 194
for *Malassezia* dermatitis, 983t
Miconazole 1% lotion (generics), 1564t
Microaerophilic bacteria, system for isolation of, 22f
Microbiological tests, of mycobacterium tuberculosis complex infections, 729–731, 729f
Microbiota, 162
Microcirculatory system, organ dysfunction in sepsis, 1610

Microfilaria, testing for, 46–47
Microscopic agglutination tests, in leptospirosis, 811
Microscopic detection, in hepatozoonosis, 1234, 1236f
Microscopic examination, in fungal infections, 33–34, 33t, 34f
Microscopic visualization, in *Ehrlichia* infection, 530
Microsporidiosis, 1139–1150
  case example of, 1146b
  cats, 1141–1142
  clinical features of, 1140–1142
  clinical signs of, 1140–1142
  diagnosis of, 1142–1144, 1143f
  dogs, 1140–1141
  epidemiology of, 1139–1140, 1140f–1142f
  etiology of, 1139–1140, 1142f
  laboratory abnormalities of, 1142
  microbiological tests, 1142–1143
  other species, 1145–1147
  pathogenesis of, 1140–1142
  pathologic findings in, 1143–1144, 1144f
  prevention of, 1145
  prognosis of, 1145
  public health considerations, 1145, 1145t
  treatment of, 1145
Microsporidium spp., 1140
Microsporum canis, 39f, 961–962
Microsporum gypseum, 961–962
Microsporum persicolor, 961–962
Middle ear, bacterial culture and, 20t
Milbemycin oxime
  as antiparasitic drugs, 155
  for *Cheyletiella* spp., 1380
  for heartworm prevention, 152t
  for *Spirocerca lupi* infection, 1491
Miltefosine, 145t, 146
  in leishmaniosis, 1190, 1190t
Miniature dachshunds, immunodeficiencies in, 1735
Minimum bactericidal concentration (MBC), 29
Minimum essential medium (MEM), 6
Minimum inhibitory concentration (MIC), 26, 27f
  breakpoints, definition of, 28–29, 28b, 29f
Minocycline
  for brucellosis, 888
  for *Ehrlichia canis* infection, 527–529
  for nocardiosis, 719t
  for Rocky Mountain spotted fever, 565
  for staphylococcal infections, 616t, 617
Mites, 1378–1398
  case example for, 1392b–1393b, 1393f
  Cheyletiella spp., 1379–1381
    clinical signs of, 1380
    diagnosis of, 1380
    direct microscopic examination for, 1380
    epidemiology of, 1379, 1380f
    etiology of, 1379, 1380f
    gross pathologic findings of, 1380
    immunity of, 1381
    laboratory abnormalities of, 1380
    pathogenesis of, 1379–1380
    physical examination findings of, 1380
    prevention of, 1381
    public health aspects for, 1381
    serology of, 1380
    treatment and prognosis of, 1380–1381
  Demodex spp., 1381–1384
    clinical signs of
    diagnosis of, 1382–1383
    direct microscopic examination for, 1382–1383, 1383t
    epidemiology of, 1381–1382, 1381f
    etiology of, 1381–1382, 1381f
    immunity for, 1384
Mites *(Continued)*
    laboratory abnormalities of, 1383
    pathogenesis of, 1382
    physical examination findings of
    prevention of, 1384
    public health aspects for, 1384
    serology of, 1383
    treatment and prognosis of, 1383–1384
  Lynxacarus radovskyi (fur mite, hair clasping mite), 1391, 1391f
  Otodectes cynotis, 1388–1390, 1389t, 1390f
  Pneumonyssoides caninum (nasal mite), 1390–1391
  Sarcoptes scabiei var. canis, 1384–1387
    diagnosis of, 1385–1386
    direct microscopic examination for, 1385, 1386f
    etiology and epidemiology of, 1384–1385
    gross pathologic findings of, 1386
    immunity of, 1386
    laboratory abnormalities, 1386
    pathogenesis of, 1385
    physical examination findings of
    prevention of, 1386–1387
    public health aspects for, 1387
    serology of, 1386
    treatment and prognosis of, 1386
  Trombiculid, 1391–1394
"Modified transudates", 366
Molds, definition of, 31
Molecular diagnosis
  in aspergillosis, 1086
  in aspergillosis-penicilliosis, 1078–1079

pathogenesis of, 1127–1128
pathological findings in, 1129, 1131f
physical examination findings of, 1128, 1128f
prognosis of, 1130–1131
public health aspects of, 1131
treatment of, 1130–1131
Protozoa, enteric, 1264t
Protozoal diseases
emerging and miscellaneous, 1307–1323
case examples of, 1319b
Protozoal infections, prevalence of, 208t–209t
Pruritus
Cheyletiella spp. and, 1380
intense, in pseudorabies, 471–472
Pseudohyphae, 31, 32f
Pseudomonas aeruginosa infections, 647–649, 648f
virulence factors associated with, 644
Pseudomyiasis, 1347, 1355–1356
Pseudorabies (PRV), 470–476, 472f
in cats, 470–471
clinical features of, 471–472
clinical signs of, 471–472, 472t
diagnosis of, 472–474, 473t
in dogs, 470–471
epidemiology of, 470–471, 471f
etiologic agents of, 470–471, 471f
immunity, 474–475
laboratory abnormalities of, 472
microbiologic tests of, 472–473
pathogenesis of, 471–472, 472t
pathologic findings of, 473–474
physical examination findings of, 472
prevention of, 475
prognosis of, 474
public health aspects of, 475
serologic diagnosis of, 472
treatment of, 474
vaccination for, 474–475
Psychodidae, 1340, 1341f–1342f
Public health aspects, of CDV, 284–286
Pulex irritans, 1326–1327, 1327f
Pulmonary disease
in nocardiosis, 715–716, 717f
in pneumocystosis, 1119, 1119f
Pulmonary nocardiosis, 715–716
Puppies
neosporosis in, 1164
segregation of, in kennels, 201
Pure red cell aplasia (PRCA), feline leukemia virus and, 390
Pyelonephritis, 1670, 1671f, 1673–1675, 1675f
treatment of, 1678
Pyoderma, 1730t
bacterial, 1551–1556, 1566b
classification of, 1552
clinical features, 1552–1553
culture and susceptibility testing for, 1553–1554, 1553b
cytologic examination of, 1553, 1553f
diagnosis, 1553–1554
etiology and epidemiology of, 1551–1552
molecular diagnosis using nucleic acid-based testing, 1554
pathologic findings in, 1554
physical examination findings in, 1553
prevention, 1555–1556
public health aspects, 1556
skin scrapings, 1553
treatment and prognosis, 1554–1555
juvenile, 1689, 1690f
Pyogenic streptococci, 597–598
Pyometra, 1681f
clinical signs of, 1681
closed-cervix, 1681
diagnosis of, 1681–1682
diagnostic imaging in, 1682
laboratory abnormalities in, 1682
microbiologic tests in, 1682
pathologic findings in, 1682, 1683f
epidemiology of, 1680–1681
etiology of, 1680–1681
open-cervix, 1681
physical examination findings, 1681
prevention of, 1683–1685
prognosis of, 1682–1683
treatment of, 1682–1683, 1683t
Pyothorax, 659, 661f, 1632–1637
case example, 1636b
in cats, 1633
clinical signs of, 1633

Pyothorax *(Continued)*
culture for, 1634
diagnosis of, 1633–1634, 1633t
diagnostic imaging for, 1634
laboratory abnormalities in, 1633
microbiologic tests for, 1634
in dogs, 1633
epidemiology of, 1632–1633
etiology of, 1632–1633
mycoplasma infections and, 683
pathogenesis of, 1632–1633, 1633t
physical examination findings of, 1633
prevention of, 1636–1637
prognosis of, 1636
susceptibility testing for, 1634
treatment of, 1634–1635
antimicrobial therapy for, 1635
drainage for, 1635
lavage for, 1635
monitoring in, 1635
surgery for, 1635
Pyrantel pamoate, as antiparasitic drugs, 156
Pyrimethamine
as antiprotozoal, 142, 144t
for hepatozoonosis, 1243, 1243t
in neosporosis, 1168t
for toxoplasmosis, 1157–1158
Pyrogens, 1747
Pythiosis, 1095t, 1106
case example of, 1114b–1115b, 1115f
clinical features of, 1106–1107
cutaneous, 1107, 1107f
diagnosis of, 1107–1109
epidemiology of, 1106, 1106f
etiology of, 1106, 1106f
imaging findings of, 1107
laboratory abnormalities of, 1107
microbiologic tests of, 1107–1109, 1108t
pathologic findings in, 1109
prognosis of, 1109–1110
public health aspects of, 1110
treatment of, 1109–1110
Pythium insidiosum, 33t, 1106
Pythium-associated esophagitis, 1645–1646

Q

Q fever, 582–588
case example of, 586b–587b, 587t
clinical features of, 583–584
diagnosis of, 584, 584t
culture, 584
molecular diagnosis using nucleic acid-based testing, 584
serologic diagnosis, 584
epidemiology of, 582–583, 583f
etiology of, 582–583, 583f
microbiologic tests of, 584
pathogenesis of, 583–584
pathologic findings of, 584, 585f
public health aspects for, 585–587, 585f–586f
signs of, 583–584
treatment for, 584–585
Quality assurance, prevention of, 58–60, 58b
Quarantine, 189–190
Quaternary ammonium compounds, 164–165, 164t
Quinacrine, for enteric protozoal infections, 1270t
Quinolone derivatives, as antiprotozoal, 143
Quinupristin-dalfopristin, 122

R

Rabbit hemorrhagic disease (RHD), 513
Rabies, 211–212, 260–270
clinical features of, 262–265
diagnosis of, 265–267
diagnostic imaging of, 265–266
Rabies *(Continued)*
epidemiology of, 260–262, 263f
etiologic agent of, 260–262, 263f
immunity and vaccination for, 267–268, 268t
infection with, 260
laboratory abnormalities, 265
microbiologic testing of, 266–267, 266t
paralytic stage of, 264–265, 265f
pathologic findings of, 266t, 267, 267f
prevention of, 268
prodromal phase of, 264–265
prognosis of, 267
public health aspects of, 269
signs and their pathogenesis of, 262–265, 264f, 265t
treatment of, 267
virus virion, structure of, 261f
Radiography
for actinomycosis, 707, 708f
for *Anaplasma phagocytophilum* infection, 546
for aspergillosis-penicilliosis, 1073
for bacterial meningitis, 1715
for bacterial peritonitis, 1652
for bacterial tracheobronchitis, 1626–1627, 1626f–1627f
for bartonellosis, 862, 863f
for bite wound infections, 928
for blastomycosis, 991, 994f–995f
for brucellosis, 881, 883f
for canine distemper virus infection, 279
for canine parvovirus infections, 343
for cardiovascular infections, 1594
for coccidioidomycosis, 1034, 1035f–1036f
for cryptococcosis, 1021
for discospondylitis, 1581, 1581f
for feline leukemia virus infection, 394
for feline panleukopenia virus infection, 354
for fever of unknown origin, 1751
for hepatobiliary infections, 1663
for *Hepatozoon americanum* infection, 1241–1242
for *Hepatozoon canis* infection
for *Heterobilharzia americana* infection (heterobilharziasis/canine schistosomiasis), 1531
for histoplasmosis, 1006–1007, 1006f
for lyme borreliosis, 832
for mycobacterium tuberculosis complex infections, 728
for nocardiosis, 716, 717f
for nonenteric (free-living) amebiasis, 1314
for *Paragonimus kellicotti* infection (paragonimiasis), 1535–1536, 1536f
for prostatitis, 1679
for protothecosis, 1129
for pyometra, 1681
for rhinosporidiosis, 1135
for salmon poisoning disease, 574
for salmonellosis, 753
for slow-growing non-tuberculous mycobacterial infections, 737
for sporotrichosis, 1047
for toxoplasmosis, 1153, 1156f
for tularemia, 919
for urinary tract infections, 1674, 1674f
Raltegravir, 89–90
for feline leukemia, 399t
Rangelia vitalii, life cycle of, 1309f
Rangeliosis, 1307–1312
clinical features of, 1308–1309
clinical signs of, 1308–1309
diagnosis of, 1309
etiologic agent and epidemiology of, 1307–1308
immunity and vaccination, 1312
laboratory abnormalities of, 1309
microbiologic tests, 1310
Rangeliosis *(Continued)*
pathogenesis of, 1308–1309
pathologic findings of, 1310–1312, 1312f
physical examination findings of, 1309, 1310f–1311f
prevention of, 1312
prognosis of, 1312
public health aspects, 1312
treatment of, 1312, 1313t
Rapid fluorescent focus inhibition test (RFFIT), 266
Rapid slide agglutination test (RAST), in brucellosis, 882t
Rapid urease testing, in *Helicobacter* infections, 788
Rapid-growing non-tuberculous mycobacterial infections, 739–741
clinical signs of, 740–741
epidemiology of, 739–740
etiology of, 739–740
immunity and vaccination, 741
laboratory abnormalities of, 741
microbiologic tests of, 741
pathogenesis of, 740–741
pathologic findings of, 741
physical examination findings of, 740–741
prevention of, 741
public health aspects, 741
treatment and prognosis of, 741
Reactive amyloidosis, 1730t, 1736
Real-time PCR (qPCR), 55–58, 55f
analysis of, 58
detection chemistries used in, 55–57
probe-based, 56f
validation and optimization of, 57–58
Receiver operating characteristic (ROC) curves, 66f
Receptor blockers, as antivirals, 89
Recombinant DNA vaccines, 239, 241f
Recombinant human erythropoietin (rhEPO), for feline immunodeficiency virus, 422
Recombinant human granulocyte colony-stimulating factor (rHuG-CSF), for feline immunodeficiency virus, 422
Recombinant subunit vaccines, 239
Recombinant Vero-SLAM cells, 6t
Record keeping, in kennels, 203
Recrudescent typhus, 565
Recurrent bacterial cystitis, 1669–1670, 1672t
treatment of, 1677–1678
"Red biliary syndrome", 1208
Reference gene, PCR and, 58
Regenerative anemia, feline leukemia virus and
Regional antibiogram, 74–75
Relative risk, calculation of, 66f
Remdesivir, for COVID-19, 84t
Renal function, antimicrobial drugs and, 78
Renal replacement therapy, for leptospirosis, 816
Reovirus infections, 490t, 492–493
Reproductive disorders, feline leukemia virus infection and, 392–393
Reservoir hosts, 802–803
Resistance-nodulation-cell division (RND) pump, 643
Respiratory infections
bacterial, 1622–1639
pneumonia. *See* Pneumonia
pyothorax, 1632–1637
tracheobronchitis, 1622–1632
with CHV-1, 304
of adult dogs, 301–302
viral, canine, 332–340
canid herpesvirus-1, 332–333, 334f
canine bocavirus, 337
canine hepacivirus, 337–339
canine influenza viruses, 333–335

Respiratory infections *(Continued)*
canine parainfluenza viruses, 335
canine pneumovirus, 335–336
canine reoviruses, 336
canine respiratory coronavirus, 335
case example of, 337b–338b
epidemiology of, 332, 333t
etiology of, 332, 333t
Respiratory system, organ dysfunction in sepsis, 1609
Respiratory tract
nematode infections of, 1505–1527, 1522b–1523b
Metastrongyloid infections, 1506–1510
non-metastrongyloid nematode infections, 1520–1523
non-metastrongyloid nematode infections of, 1520–1523
Eucoleus aerophilus (Eucoleosis), 1520–1523, 1520t, 1522f
Eucoleus boehmi infection (Capillariasis), 1520–1523, 1520t, 1522f
Respiratory tract disease
feline herpesvirus infections and, 431–432, 432f
in multiple-cat environments, 190–191
Retinal lesions, feline panleukopenia virus infection and, 354
Retinitis, feline infectious peritonitis and, 365, 365f
Retrobulbar abscesses, 658, 660f
Retroperitoneal actinomycosis, 705
Retrovirus infections, for cats, 194–195
Reverse transcriptase-polymerase chain reaction (RT-PCR), 58–59
in canine distemper virus infection, 279t
for canine parainfluenza virus, 323t
in feline coronavirus infection, 370–371
RHD. *See* Rabbit hemorrhagic disease
rhEPO. *See* Recombinant human erythropoietin
Rhinoscopy, in aspergillosis-penicilliosis, 1075–1076, 1077f
Rhinosporidiosis, 32, 32f, 1135–1138, 1136f
case example of, 1137b–1138b
clinical features of, 1135
diagnosis of, 1135–1136, 1136f
epidemiology of, 1135
etiology of, 1135
pathogenesis of, 1135
prognosis of, 1136
public health apsects of, 1137–1138
treatment of, 1136
Rhinosporidium seeberi, 1135, 1137f
Rhipicephalus gertrudae, 1360t
Rhipicephalus haemaphysaloides, 1360t
Rhipicephalus sanguineus, 1359, 1360t, 1362, 1366
Rhipicephalus sanguineus sensu lato, 1361t
Rhodococcus equi infection, 627–628, 628f, 629t
Rhodococcus equi pneumonia, 627
Rhodotorula spp., 1065
Rhodotorulosis, 1065–1067
case example of, 1065b–1066b, 1066f
rHuG-CSF. *See* Recombinant human granulocyte colony-stimulating factor
Ribavirin
as antiviral, 89
for feline leukemia, 399t
for hantavirus infection, 508
Richness, definition of, 1640–1641
Rickettsia akari, 564
Rickettsia bellii, 563–564
Rickettsia felis infection, 564–565
Rickettsia massiliae, 564
Rickettsia montanensis, 563–564
Rickettsia parkeri, 563

Screening assays, diagnostic *versus*, 68
Secondary antibody, 12
Secondary immune responses, time course of, 12f
Secondary infections, feline leukemia virus infection and, 391–392, 392f
Second-line drugs, 75–76
Sedatives, for tetanus, 897
Segregation, for respiratory tract disease, 191
Selamectin
as antiparasitic drugs, 155
for heartworm prevention, 152t
Selective IgA deficiency, 1734–1735
Semen examination, in brucellosis, 881, 884f
Semicritical items, 162–163
Sensitivity, calculation of, 66f
Separation, in transmission-based precautions, 178
Sepsis, 1603–1621
case example, 1615b–1616b
definitions of, 1603–1605, 1604t
diagnosis of, 1610–1611
laboratory abnormalities in, 1610–1611
pathologic findings in, 1611
epidemiology of, 1603–1605, 1605t
molecular pathogenesis of, 1605–1608, 1606f, 1608f
organ dysfunction in, 1608–1609
cardiovascular system, 1609
gastrointestinal systems, 1609–1610
hepatic systems, 1609–1610
microcirculatory system, 1610
neurologic dysfunction, 1609
Sepsis *(Continued)*
respiratory system, 1609
urinary system, 1609, 1609b
PIRO system for staging, 1605t
prognosis of, 1615–1617
treatment of, 1611–1615
antimicrobial use in, 1613, 1613b
cardiovascular support for, 1612, 1613t
circulatory support for, 1611–1612, 1612t
gastrointestinal protectants, 1613
high mortality group box 1, 1615
individualized approach to, 1615
nitric oxide for, 1614–1615
nuclear factor-κB inhibitors, 1615
statins for, 1615
strategies for, 1613–1614
toll-like receptor antagonists for, 1615
Sepsis-induced hypoperfusion, 1604t
Sepsis-induced hypotension, 1604t
Septic shock
definition of, 1604t
pathophysiology of, 1606f
Septicemic plague, 908
Serologic testing, 11
for *Anaplasma phagocytophilum* infection, 547
for *Anaplasma platys* infection, 550
for arthropod-borne viral infections, 496
for aspergillosis-penicilliosis, 1077–1078
for bartonellosis, 863–864
for bordetellosis, 672, 672t
for botulinum, 900
for brucellosis, 883–885, 885f–886f
for CAdV-1 infection, 294
for *Campylobacter* infections, 778
for canine distemper virus infection, 279t, 281–282
for canine parainfluenza virus, 322–323, 323t
for canine respiratory coronavirus infection, 327–328
for *Cheyletiella* spp., 1380
for chlamydial infections, 593–594
for coccidioidomycosis, 1033t, 1035–1036
for cowpox virus infection, 468
for coxiellosis, 584
for cryptococcosis, 1022–1023
for *Demodex* spp., 1383
for disseminated invasive aspergillosis-penicilliosis, 1085
for *Echinococcus* spp. infections (echinococcosis), 1467
for *Ehrlichia canis* infection, 525–527
for *Ehrlichia chaffeensis* infection, 530
for *Ehrlichia ewingii* infection, 532
for feline ehrlichiosis, 534–535
for feline foamy virus (FFV) infection, 456
for feline herpesvirus-1 infection, 435
for fever of unknown origin, 1753
for fungal infections, 37
for *Helicobacter* infections, 788–789
for hepatozoonosis, 1236, 1242–1243
for *Heterobilharzia americana* infection (heterobilharziasis/canine schistosomiasis), 1531–1532
for histoplasmosis, 1007
for lagenidiosis, 1111
for leptospirosis, 811–813, 812f
for microsporidiosis, 1143
for neosporosis, 1166–1167
for *Notoedres cati*, 1387
for *Otodectes cynotis*, 1389
for parasites, 49–50, 50f
for plague, 910
for pneumocystosis, 1122
for pseudorabies, 472
for pythiosis, 1108–1109
for Q fever, 584
Serologic testing *(Continued)*
for rabies, 266, 266t
for Rocky Mountain spotted fever, 561
for *Sarcoptes scabiei var. canis*, 1386
for sporotrichosis, 1048–1049
for tetanus, 897
for trypanosomiasis, 1254
for tularemia, 920
Seroreactive (seropositive) blood sample, 11
Serratia marcescens extract, for feline leukemia, 401
Serratia marcescens infections, 647
Serum antibody titer, 12
Serum bactericidal testing (SBT), 29
Serum chemistry profile
for actinomycosis, 706
for American trypanosomiasis, 1252
for *Anaplasma phagocytophilum* infection, 546, 547t
for bacterial peritonitis, 1652
for bacterial tracheobronchitis, 1626
for blastomycosis, 990
for bornavirus infection, 502
for botulism, 900
for brucellosis, 880
for canine distemper virus infection, 278, 278t
for canine parvovirus infections, 343, 344t
for cardiovascular infections, 1593–1594
for coccidioidomycosis, 1034
for cryptococcosis, 1019–1020
for disseminated invasive aspergillosis-penicilliosis, 1084
for dogs with ICH, 294
for *Echinococcus* spp. infections (echinococcosis), 1466
for *Ehrlichia canis* infection, 525
for *Ehrlichia chaffeensis* infection, 530
for enteric *Escherichia coli* infections, 762
for feline infectious peritonitis, 366, 366t–367t
for feline leukemia virus infection, 394
for feline panleukopenia virus (FPV) infection, 354
for fever of unknown origin, 1751
for hepatobiliary infections, 1663
for *Hepatozoon americanum* infection, 1241
for *Hepatozoon canis* infection, 1234, 1237f
for *Heterobilharzia americana* infection (heterobilharziasis/canine schistosomiasis), 1530–1531
for histoplasmosis, 1005–1006
for leptospirosis, 806, 808t–809t
for mycobacterium tuberculosis complex infections, 728
for mycoplasma infections, 684
for nocardiosis, 716
for pneumocystosis, 1121
for prototheocosis, 1128
for pyothorax, 1633
for rangeliosis, 1309–1310
for rapid-growing non-tuberculous mycobacterial infections, 741
for Rocky Mountain spotted fever, 560
for salmon poisoning disease, 573–574, 574t
for salmonellosis, 752
for sepsis, 1610
for slow-growing non-tuberculous mycobacterial infections, 737
for sporotrichosis, 1047
for tetanus, 896
Serum neutralization, 15
Serum protein electrophoresis, for feline infectious peritonitis, 366, 367f
Severe combined immunodeficiency (SCID), 1730t
autosomal recessive, 1734
Severe lymphoplasmacytic stomatitis, in feline immunodeficiency virus, 419f

Severe sepsis, 1604t
Shared vector-acquired zoonoses, 219b
Sharpeis, immunodeficiencies in, 1735–1736
Sharps handling, in infection prevention, 180–181
Shelter facilities
  for feline calicivirus infection, 450
  in infectious disease prevention, 183
Shiga toxin, 645–646
Shiga-like toxins, 644
Shiga-toxin-producing *E.coli* (STEC), 760t
Shigella spp., 798
Short-chain fructooligosaccharides (scFOSs), 1647
Signaling lymphocytic activation molecule (SLAM), 272, 275f
Silver sulfadiazine, for surgical and traumatic wound infections, 943
Simuliidae, 1339, 1340f–1341f
Sinonasal aspergillosis (SNA), 1071–1072
  canine, 1080–1081, 1081f
Sino-orbital aspergillosis, 1072
Sinuscopy, in aspergillosis-penicilliosis, 1075–1076
Skin, 938
  for bacterial culture, 20t
  microscopic examination of, 23
Skin biopsy
  for dermatophytosis, 967, 965t
  in *Malassezia* dermatitis, 981–982, 982f
Skin infections
  bacterial. *See* Pyoderma
  feline leukemia virus infection and, 392
  tissue, 658
Skin lesions
  borreliosis and, 831f
  in lagenidiosis, 1110, 1110f
  in leishmaniosis, 1184, 1184f–1185f
  in phaeohyphomycosis, 1099f
  in protothecosis, 1129
  in pythiosis, 1108
Skin scaling, *Cheyletiella* spp. and, 1380
Skin scrapings, for dermatophyte culture, 32
Slide agglutination test, rapid, in brucellosis, 877, 882t
Slow-growing non-tuberculous mycobacterial infections, 735–739
  clinical features, 736–737
  diagnosis of, 737–738
  epidemiology of, 735–736
  etiology of, 735–736
  microbiological tests of, 737–738
  pathogenesis of, 736–737, 737f
  pathological findings of, 738, 739f
  public health aspects, 739
  treatment and prognosis of, 733t–734t, 738–739
Small intestinal bacterial overgrowth (SIBO), 1646
Small portable medical equipment, cleaning and disinfection of, 168
Socialization areas, in kennels, 200
Sodium hypochlorite (bleach), 164, 164t
Sodium iodide, for sporotrichosis, 1051, 1051t
Soft ticks, 1359
Soft tissue infections, 658
Solid-phase hybridization, of pathogen detection, 53
"Songbird fever", 750
Southern tick-associated rash illness (STARI), 841
Spatial epidemiology, 67–68
Species diversity, definition of, 1640–1641
Specificity, calculation of, 66f
Specimen collection
  in anaerobic infections, 662–663
  transport and, 3–5, 5t
    of fungal infections, 31–33
Spike gene, of PCR, 58
Spinosyns, as antiparasitic drugs, 158
Spirocerca lupi infection (spirocercosis), 1488–1490
  clinical features of, 1490
  clinical signs of, 1490
  diagnosis of, 1490
  etiologic agent and epidemiology of, 1488–1490, 1488f–1489f
  immunity, 1491
  life cycle of, 1489f
  pathogenesis of, 1490
  physical examination findings, 1490
  prevention of, 1491
  prognosis of, 1490–1491, 1491t
  public health aspects of, 1491
  treatment of, 150t–151t, 1490–1491, 1491t
  vaccination, 1491
Spirochetes, microscopic detection of, 835
Spirometra spp. infection, 1476–1480
  clinical signs of, 1477, 1478f
  diagnosis of, 1477
  diagnostic imaging of, 1477
  epidemiology of, 1476–1477
  etiology of, 1476–1477
  laboratory abnormalities of, 1477
  life cycle of, 1476f
  microbiologic tests of, 1477
  pathogenesis of, 1477, 1478f
  prevention of, 1477
  prognosis of, 1477, 1479t
  public health aspects of, 1478–1480
  treatment of, 153t, 1477, 1479t
Splendore-Hoeppli phenomenon, 709–710
Splenomegaly, in leishmaniosis, 1184
Sporadic bacterial cystitis, 1669, 1672, 1672t
  treatment of, 1677, 1677t
Sporothrix, 1043
  transmission of, 1044–1045, 1045f
Sporothrix brasiliensis, 1043–1044, 1044f
Sporothrix schenckii, 33t, 34, 1043, 1044f
Sporotrichosis, 1043–1060
  case example, 1055b, 1056f
  clinical features of, 1044–1047
  clinical signs of, 1044–1045, 1046f
  diagnosis of, 1047–1050
    diagnostic imaging in, 1047
    laboratory abnormalities in, 1047
    microbiologic tests for, 1047–1049
    pathologic findings in, 1049–1050, 1049f–1050f
  epidemiology of, 1043–1044
  etiologic agent of, 1043–1044
  immunity for, 1053–1054
  pathogenesis of, 1044–1045, 1045f
  physical examination findings of, 1045–1047
  prevention of, 1054, 1054b
  prognosis of, 1050–1053
  public health aspects of, 1054–1055
  treatment of, 1050–1053, 1051t
  vaccination for, 1053–1054
Spotted fever group rickettsias. *See also* Rocky Mountain spotted fever
SPUD gene, of PCR, 58
Squamous cell carcinoma
  canine, 480
  feline cutaneous, 482
St. Louis encephalitis virus, 490t
Stable flies, 1340–1341, 1342f–1343f
Staphylococcal infections, 611–626
  case example of, 621f, 621b
  clinical features of, 613–614
  clinical signs of, 613–614, 614f
  coagulase-negative, 611–612
  coagulase-positive, 611
  culture and susceptibility testing for, 615
  cytologic diagnosis of, 615, 615f
Staphylococcal infections *(Continued)*
  diagnosis of, 614–615
  epidemiology of, 611–613
  etiologic agent of, 611–613
  incidence of, 611
  infection control precautions in veterinary clinics, 619
  local antimicrobial therapies for, 618
  methicillin-resistant, 612–613, 620–622
  molecular diagnosis using nucleic acid-based testing for, 615
  pathogenesis of, 613–614, 614f
  perioperative prophylaxis for, 618–619
  physical examination findings of, 613–614, 614f
  prevention of, 618–619
  prognosis of, 615–618
  public health aspects for, 619–620
  Staphylococcus aureus, 612
  Staphylococcus pseudintermedius, 611–612
  Staphylococcus schleiferi subsp. *coagulans*, 612
  systemic antimicrobials for, 616–618, 616t
  topical antimicrobials for, 618
  treatment of, 615–618
Staphylococcal protein A, for feline leukemia, 401
Staphylococcus aureus, 612, 615f
  clinical signs of, 614
  methicillin-resistant, 612–613, 620–622
  pathogenesis of, 614
  physical examination findings of, 614
  public health aspects for, 619–620
Staphylococcus pseudintermedius, 611–612, 615, 620, 1551
  clinical signs of, 614
  methicillin-resistant, 612
  pathogenesis of, 614
  physical examination findings of, 614
Staphylococcus schleiferi subsp. *coagulans*, 612
  clinical signs of, 614
  pathogenesis of, 614
  physical examination findings of, 614
STARI. *See* Southern tick-associated rash illness
Statins, for sepsis, 1615
Stavudine, 86t
Steam sterilization, 165, 166f, 166t
STEC. *See* Shiga-toxin-producing *E.coli*
Sterilization, 162, 175, 175t
  definition of, 163b
  indications for, 162–163
  for surgical and traumatic wound infections, 944
Steroid-responsive meningitis-arteritis, 1721–1724, 1722f

diagnosis of, 895–897
diagnostic imaging of, 896, 896f
epidemiology of, 893–894
etiology of, 893, 894f
immune globulin, 897t
immunity and vaccination of, 898
laboratory abnormalities of, 896
localized *vs.* generalized, 896f
microbiologic tests of, 897
pathogenesis of, 894, 895f
pathologic findings of, 897
physical examination findings of, 894
prevention of, 898
prognosis of, 898
public health aspects, 898
severity classification system for dogs, 898t
supportive care of, 897–898
treatment and prognosis, 897–898
Tetracycline, 120–122, 121t, 122f, 143
for brucellosis, 888
for *Campylobacter* infections, 780t
for *Ehrlichia canis* infection, 529
for feline ehrlichiosis, 535
for feline respiratory disease, 435
for L-form infections, 680–681
for mycoplasma infections, 685
for Rocky Mountain spotted fever, 562
for salmon poisoning disease, 576
for staphylococcal infections, 617
for tularemia, 920–921
Thelazia californiensis, 1497, 1499f
Thelazia callipaeda, 1497
infection, 1498–1499
Thelazia spp. infections, 1498
Thermometers, cleaning and disinfection of, 167
Third-line drugs, 76, 76b
Thoracic actinomycosis, 705
Thoracic radiography
for leptospirosis, 810f
in pneumocystosis, 1121, 1121f
for pyothorax, 1634
in trypanosomiasis, 1252
Three-host hard ticks, 1362
Thrombocytopenia
canine babesiosis and, 1207
feline leukemia virus and, 391
Thrombosis, canine parvovirus and, 342
Thymic abnormalities, 1730t
Thymic lymphoma, 388–389
Ticarcillin, 105t
for keratitis, 1693t
Ticarcillin disodium, 105t
Tick paralysis, 1364
Tick-borne encephalitis, 490t, 493–494, 495f
Tick-borne relapsing fever, 841–844
clinical features of, 841–842
clinical signs of, 841–842
diagnosis of, 842–843, 843f
epidemiology of, 841, 842f
etiology of, 841, 842f
pathogenesis of, 841–842
treatment and prevention, 843–844
Ticks, 1359–1377
case example for, 1374f, 1374b–1375b
clinical signs of, 1364

Ticks *(Continued)*
diagnosis of, 1364–1366
epidemiology of, 1359–1363
etiology of, 1359–1366, 1360t–1361t, 1362f–1363f
hard, 1359–1360
immunity and vaccination for, 1372–1373
laboratory abnormalities of, 1366
pathogenesis of, 1363–1364, 1363f
galactose-alpha-1,3-galactose hypersensitivity reactions, 1363–1364
tick paralysis, 1364
pathologic findings of, 1366, 1366f
physical examination findings **of**, 1364, 1365f
prevalence of, 208t
prevention of, 1373
public health aspects for, 1373–1375
soft, 1359
treatment and prognosis of, 1366–1372, 1367t
Time-dependent killing, 77
Tinidazole
as antiprotozoal, 141, 141t
for enteric protozoal infections, 1270, 1270t
for trichomonosis, 1282
Tissue aspirates, cytologic analysis of, 881
Tissue specimens, microscopic examination of, 23
Tobramycin, for keratitis, 1693t
Tobramycin sulfate, 115t
for keratitis, 1693t
Togaviridae, 489–491, 490t
Toll-like receptor antagonists, for sepsis, 1615
Toltrazuril
as antiprotozoal, 144t, 145
for hepatozoonosis, 1237
Toxascaris leonina, 1427
treatments for, 150t–151t
Toxic shock syndrome, pathophysiology of, 599f
Toxin detection, of botulinum, 900–901
Toxocara canis, 1418–1423
clinical features of, 1421–1422
clinical signs of, 1422
diagnosis of, 1422–1423
diagnostic imaging of, 1422, 1422f
eggs of, 1420f
ingestion, transmission by, 1421
epidemiology of, 1418–1421
etiologic agent of, 1418, 1419f, 1419t
laboratory abnormalities of, 1422, 1422f
life cycle and transmission routes of, 1421f
microbiologic tests of, 1422–1423
paratenic host ingestion, transmission by, 1421
pathogenesis of, 1421–1422
pathologic findings of, 1423, 1423f
physical examination abnormalities of, 1422
prevention of, 1423
public health aspects of, 1423, 1424f
transplacental and transmammary transmission, 1421–1422
treatment of, 1423
Toxocara cati, 1423–1427
clinical features of, 1424–1426
clinical signs of, 1424–1426
diagnosis of, 1426
diagnostic imaging of, 1425f, 1426
epidemiology of, 1424
etiologic agent of, 1423–1424
laboratory abnormalities of, 1425f, 1426
life cycle and transmission routes of, 1425f
microbiologic tests of, 1426, 1426f
pathogenesis of, 1424–1426
pathologic findings of, 1426, 1426f
physical examination findings of, 1424–1426
prevalence of, 206t–207t
public health implications of, 1427
treatment of, 1426–1427
Toxocara malayensis infection, 1430–1431
Toxocara spp., treatments for, 150t–151t
Toxocara tanuki, 1418
Toxocariasis, high-risk individuals and, 229–230
Toxoplasma gondii, 230, 1151
differentiation from *Neospora caninum*, 1167
infection, 204–207, 212
life cycle of, 1152f
merozoites of, 1152f
oocysts of, 1152f
prevalence of, 208t–209t
tachyzoites of, 1152f
tissue cysts of, 1152f
Toxoplasmosis, 1151–1162, 1701–1702
case example for, 1160b
clinical signs of, 1151–1153, 1155f
diagnosis of, 1153–1157, 1156t
advanced imaging, 1153, 1156f
cerebrospinal fluid analysis, 1153
complete blood count, 1153
cytologic diagnosis, 1154–1155, 1157f
fecal flotation, 1155
molecular diagnosis using nucleic acid-based testing, 1157
plain radiography, 1153, 1156f
serologic diagnosis, 1155–1157
serum chemistry profile, 1153
sonographic findings, 1153
urinalysis, 1153
epidemiology of, 1151, 1152f–1154f
etiologic agent of, 1151, 1152f–1154f
high-risk individuals and, 230
immunity and vaccination for, 1158
life cycle of, 1152f
ocular disease and, 1152, 1155f
pathogenesis of, 1151–1153, 1155f
pathologic findings of, 1157, 1158f
prevention of, 1158
prognosis of, 1157–1158, 1159t
public health aspects for, 1158–1160, 1159f
treatment for, 1157–1158, 1159t
traA protein gene, 627
Tracheal collapse, 1624, 1624f
Tracheobronchitis, bacterial, 1622–1632
in cats, 1625
clinical signs of, 1625–1626
diagnosis of, 1626–1630
culture for, 1629–1630
diagnostic imaging in, 1626–1628
laboratory findings in, 1626
microbiologic tests for, 1628–1629
pathologic findings in, 1630
susceptibility testing for, 1629–1630
in dogs, 1624–1625
epidemiology of, 1622–1625
etiology of, 1622–1625
pathogenesis of, 1622–1625, 1623t
physical examination findings of, 1625–1626
prevention of, 1632
prognosis of, 1632
public health aspects of, 1632
secondary, 1623–1624
treatment of, 1630–1632
ancillary supportive therapy for, 1631–1632
antimicrobial drug, 1631
identification and management of underlying causes, 1630–1631
surgery for, 1632
Tracheobronchoscopy, for bacterial tracheobronchitis, 1627–1628, 1629f
Trachipleistophora spp., 1145t
Transdermal moxidectin, for *Cheyletiella* spp., 1380
Transdermal selamectin, for *Cheyletiella* spp., 1380
Transmammary transmission
of *Toxocara cati*, 1425–1426
transplacental and, 1421–1422
Transmission
airborne, 175
contact, 174
routes of, 173–175
vector-borne, 175
Transmission-based precautions, 178
Transtracheal lavage, 1628
Trapped neutrophil syndrome, 1733
Traumatic injuries, hereditary immunodeficiencies and, 1738t
Trematodes, of dog and cat, 1528–1550, 1544t, 1545b
Tresaderm Dermatologic Solution (Boehringer Ingelheim), 1564t
Trial therapy, for fever of unknown origin, 1753–1755
Triatomine bugs, as vector of trypanosomiasis, 1249f
Triazine antiprotozoals, 145
Triazole antifungal drugs, 128
Trichomonads, prevalence of, 208t–209t
Trichomonosis, 1278–1284
case example of, 1282b–1283b
clinical features of, 1279
clinical signs of, 1279, 1281f
diagnosis of, 1279–1281
diagnostic imaging of, 1279, 1281t
etiologic agent and epidemiology, 1278, 1279f–1280f
immunity and vaccination of, 1282
laboratory abnormalities of, 1279
microbiologic tests of, 1279–1281
pathogenesis of, 1279, 1281f
pathologic findings of, 1281
physical examination findings of, 1279
prevention of, 1282
prognosis of, 1281–1282, 1281t
public health aspects of, 1282–1283
treatment of, 1281–1282, 1281t
Trichophyton mentagrophytes, 39f, 961
Trichophyton tonsurans, 961
Trichuris campanula, 1445
Trichuris felis, 1445–1446, 1446f–1447f
Trichuris serrata, 1445
Trichuris spp., 1444
treatments for, 150t–151t
Trichuris vulpis, 1444, 1445f
infestations, treatments for, 1451t
life cycle of, 1446f
prevalence of, 206t–207t
Trifluridine (TFT)
as antiviral, 84t, 87t, 88
for feline herpesvirus-1 infection, 437t
Trimethoprim-sulfadiazine, 114t
for neosporosis, 1168, 1168t
for staphylococcal infections, 616t
Trimethoprim-sulfamethoxazole, 114t
for plague, 910
for *Rhodococcus equi* infection, 629t
for staphylococcal infections, 616t
Trimethoprim-sulfonamide, 113–114, 114f, 114t
for canine pyoderma and otitis externa/otitis media, 1555t
for hepatozoonosis, 1237, 1243, 1243t
for nocardiosis, 718
for pneumocystosis, 1123
for sporadic bacterial cystitis, 1677
for staphylococcal infections, 617
for toxoplasmosis, 1157, 1159t
Tritop Ointment, 1564t
Tritrichomonas, prevalence of, 208t–209t
Tritrichomonas blagburni, 42, 1278, 1280f
life cycle of, 1279f
treatment of, 1281t
Tritrichomonas foetus, 1264t
Trombiculid mites, 1391–1394

True flies (Diptera), 1338
Trypanosoma brucei, 1256
Trypanosoma caninum, 1255–1256
Trypanosoma caninum infection, 1255–1256
Trypanosoma congolense, 1256
Trypanosoma cruzi
  cats, 1251
  dogs, 1251
  epidemiology of, 1248–1249, 1249f
  life cycle of, 1249f
Trypanosoma evansi infection, 1257–1258
Trypanosomiasis, 1248–1262
  African, 1256–1258, 1257f
  American, 1248–1255
    clinical features of, 1250–1251
    diagnosis of, 1251–1254, 1252t
    diagnostic imaging of, 1252, 1253f
    epidemiology of, 1248–1250, 1249f–1250f
    etiology of, 1248–1250, 1249f–1250f
    geographic distribution of, 1256f
    immunity and vaccination of, 1255
    laboratory abnormalities of, 1252
    microbiologic tests of, 1252–1254
    pathogenesis of, 1250–1251
    pathologic findings in, 1254, 1254f
    prevention of, 1255
    prognosis of, 1254–1255
    public health aspects of, 1255
    treatment of, 1254–1255
  case example of, 1258b
Tsetse flies, as vector of trypanosomiasis, 1256, 1256f
Tube agglutination test (TAT), in brucellosis, 882t, 884
Tuberculosis, 725
Tubular lesions, leptospirosis and, 805
Tubulinosema spp., 1145t
Tularemia, 916–924
  biochemistry profile for, 919
  case example for, 922b
  clinical features of, 917–919
  complete blood count for, 919
  cytologic examination of lymph node aspirates for, 919
  diagnosis of, 919–920, 919t
  direct detection of, 920
  epidemiology of, 916–917, 917f–918f
  etiologic agent of, 916–917, 917f–918f
  high-risk individuals and, 230
  immunity and vaccination for, 921
  isolation and identification of, 920
  microbiologic tests for, 920, 920t
  molecular diagnosis using nucleic acid-based testing for, 920
  pathogenesis of, 917–919
  pathologic findings of, 920
  physical examination findings of, 919
  plain radiography for, 919
  prevention of, 921
  prognosis of, 920–921, 921t
  public health aspects for, 921–923, 921f
  serology of, 920
  signs of, 917–919
  sonographic findings of, 920
  transmission cycle of, 918f
  treatment of, 920–921, 921t
  urinalysis for, 919
Tumor necrosis factor (TNF) inhibitors, for feline infectious peritonitis, 373
Tumors, feline leukemia virus and, 388–390, 388f, 398
Tunga penetrans, 1330, 1331f
Tylosin, 119t
  for *Campylobacter* infections, 780t
  for cryptosporidiosis, 1292
  for enteric clostridial infections, 770t
Typhoidal tularemia, 921–922
Typhus, 565–567
  epidemic, 565
  murine, 565
  recrudescent, 565
  scrub, 565
Tyzzer's disease, 799

U

Ulceroglandular tularemia, 921–922

adverse reactions to, 245–250
immune-mediated vaccine reactions, 246–248
injection-site sarcomas, 248–250, 248f–249f
interference with diagnostic test results, 250
local cutaneous reactions, 248–250, 248f–249f
vaccine organism-induced disease, 248
for canine, 3
composition of, 238–241
efficacy and challenge studies, 244, 244t
of exotic carnivores, 251
factors that can affect immune responses to, 241
for feline, 3
handling, 241
requirements for transport of animals, 251
selection, 250–251
storage, 241
types of, 238–241
Vaginal miconazole cream, for dermatophytosis, 970
Vaginitis, 1680–1685
Valacyclovir, 84t, 87
Vancomycin, 108, 109t
for bacteremia, 1598t
for infective endocarditis, 1598t
for keratitis, 1693t
for *Rhodococcus equi* infection, 629t
Vasculitis
feline coronavirus infection and, 363
leptospirosis and, 805
Vector-borne disease panel, 69t
Vector-borne infections, high-risk individuals and, 230
Vector-borne transmission, 175
Vectored vaccines, 239–240
Vectors, control of, 181
Vehicle transmission, 174
Venezuelan equine encephalitis (VEE), 489–490, 490t
Ventilatory status, for bacterial tracheobronchitis, 1626
Vero cells, 6t
Verocytotoxins, 644
Vesicular exanthema, 513
Veterinary personnel, resources for, 221b
VGG. *See* Vaccination Guideline Group
Vidarabine
as antiviral, 84t, 87t, 89
for feline herpesvirus-1 infection, 437t
Videofluoroscopy, for bacterial tracheobronchitis, 1627
Viral infections
canine distemper virus infection, 271–288
case example, 285b–286b
epidemiology of, 271–272
etiology of, 271–272
species spectrum of, 271
emerging and miscellaneous, 507–521
arenavirus infection, 508–509
ebola virus infection, 509–511, 510f
encephalomyocarditis virus infection, 509
enterovirus infections, 509, 509t
foot-and-mouth disease, 512–513, 512f
hantavirus infection, 507, 508f
hepatitis E virus infection, 511–512, 511t
rabbit hemorrhagic disease, 513
sudden acute respiratory coronavirus infections, 513–517, 513t, 514f–515f, 516t–517t
vesicular exanthema, 513
Viral pathogens, prevalence of, 205t
Viral plaques, feline, 480–482
Viral protease inhibitors, for feline infectious peritonitis, 374
Viral V protein, CDV and, 276–277
Virginia opossum, as host of *Sarcocystis neurona*, 1172–1173
Viridans streptococci, 597–598
Virulence assays, of enteric *Escherichia coli* infections, 763
Virus, discovery of, 3
Virus isolation
of arthropod-borne viral infections, 496
CAdV-1 infection and, 294
for canine parainfluenza virus, 323t
for canine parvovirus infections, 345
of canine respiratory coronavirus infection, 327
of CDV, 279–280, 279t
for feline foamy virus infection, 456–457
for feline herpesvirus-1 infection, 434
of feline immunodeficiency virus, 415
of feline leukemia virus, 397
of feline panleukopenia, 355
for poxvirus infections, 468t
in pseudorabies, 473, 473f, 473t
for rabies, 266
Virus virion, rabies, structure of, 261f
Virus-infected cells, inclusions and abnormal cell morphology in, 7f
Vitamin D, for COVID-19, 84t
Vitreous centesis, 1703, 1703f
Vittaforma corneae, 1145t
VlsE and C_6-based assays, for Lyme borreliosis, 833–834
Vomiting and respiratory distress, 246
Voriconazole, 129t–130t, 132–133
for aspergillosis-penicilliosis, 1087
for cryptococcosis, 1024

W
Warts, papillomavirus and, 484
Waste management, 180
Water bowls, disinfection of, 180
Water-soluble antimicrobial drugs, 77
Weimaraners, immunodeficiencies in, 1736, 1736f
Wesselsbron disease, 490t
West Nile virus infection, 490t, 491f, 493, 494f
Western immunoblotting, 14, 15f
for ehrlichiosis, 528t
Wet mounts, for fungal infection diagnosis, 33–34, 35f
Whipworms, 1444–1454
case example of, 1451b–1452b
cats, 1445–1446
clinical features of, 1446–1448
clinical signs of, 1446–1448, 1448b
diagnosis of, 1448–1450, 1449f
dogs, 1444–1445
epidemiology of, 1444–1446
etiologic agent of, 1444–1446
immunity and vaccination of, 1450
laboratory abnormalities of, 1448, 1449t
microbiologic tests of, 1448–1450, 1450t
pathogenesis of, 1446–1448, 1448b
pathologic findings of, 1450, 1450f
physical examination findings of, 1448
prevention of, 1450–1451
prognosis of, 1450
public health aspects of, 1451–1452
treatment of, 1450, 1451t
White blood cell abnormalities, feline leukemia virus infection and, 391
Whole genome sequencing (WGS), 66–67
Whole-agent attenuated live, conventional, 240t
Wild carnivores, hepatozoonosis in, 1231
Window of susceptibility, 242–243
Window of vulnerability, 242–243
Wolbachia pipientis, 1401
Wood tick *(Dermacentor andersoni)*, as Rocky Mountain spotted fever vector, 556, 556f
Wood's lamp examination, for dermatophytosis, 965–966, 965t, 966f, 966b
World Health Organization, 221b
World Organization for Animal Health, 221b
Worms and Germs Blog, 221b
Wound lavage, for surgical and traumatic wound infections, 945
Wound myiasis, 1353–1355
clinical features of, 1353–1354
diagnosis of, 1354
etiologic agents and epidemiology of, 1353
laboratory abnormalities of, 1354
parasitologic tests for, 1354
pathologic findings of, 1354
prevention of, 1354–1355
public health aspects for, 1355
treatment and prognosis of, 1354
Wright stain, of feces, 47
Wright-Giemsa stain, of feces, 47

X
Xenodiagnosis
in parasitic infections, 48
in trypanosomiasis, 1253–1254
X-linked severe combined immunodeficiency (X-SCID), 1730t, 1733–1734, 1734f

Y
Yeast, definition of, 31
Yellow fever virus, 490t

Yersinia enterocolitica, 912–913
Yersinia pestis, 905–915
case example for, 913b–914b
clinical features of, 907–908
computed tomography of, 908, 909f
cytologic demonstration of, 908, 910f
diagnosis of, 908–910
direct immunofluorescent antibody and antigen ELISA assays for, 908–910
epidemiology of, 905–907, 906f–907f
etiology of, 905–907, 906f–907f
immunity and vaccination for, 911
isolation and identification of, 910
laboratory abnormalities of, 908
microbiologic tests for, 908–910, 909t
pathogenesis of, 907–908
Yersinia pestis (Continued)
pathologic findings of, 910, 911f
physical examination findings of, 908
plain radiography of, 908
polymerase chain reaction for, 910
prevention of, 911
public health aspects for, 911–912, 911f–912f
serology for, 910
signs of, 907–908
sonographic findings of, 908
treatment and prognosis of, 910, 911t
Yersinia pseudotuberculosis, 905, 912–913

Z
Zalcitabine, 86t
for feline leukemia, 399t
Zidovudine
as antiviral, 84t, 85–86, 86t–87t
for feline immunodeficiency virus, 422
for feline leukemia, 399t
Zoonoses, 219
from dogs and cats to humans, 219b
legal implications of, for veterinarians, 220–221
mechanisms of transmission of, 219b
occupational and environmental factors increasing risk of, 220
shared vector-acquired, 219b
Zoophilic dermatophyte species, 961
Zygomycosis, 1112

Abbreviations Used Throughout This Book

AAFP	American Association of Feline Practitioners
AAHA	American Animal Hospital Association
ABCD	Advisory Board on Cat Diseases
ACTH	Adrenocorticotropic Hormone
ACVIM	American College of Veterinary Internal Medicine
AE	Alveolar Echinococcosis
AGID	Agar Gel Immunodiffusion
AKI	Acute Kidney Injury
ALP	Alkaline Phosphatase
ALT	Alanine Aminotransferase
AMB	Amphotericin B
APTT	Activated Partial Thromboplastin Time
ARDS	Acute Respiratory Distress Syndrome
ASPCA	American Society for the Prevention of Cruelty to Animals
AST	Aspartate Aminotransferase
AUC	Area Under the ROC Curve
AVMA	American Veterinary Medical Association
BAL	Bronchoalveolar Lavage
BCS	Body Condition Score
BoCV	Bovine Coronavirus
BSAVA	British Small Animal Veterinary Association
BSL	Biosafety Level
BUN	Blood Urea Nitrogen
CAdV	Canine Adenovirus
CAPC	Companion Animal Parasite Council
CBC	Complete Blood Count
CCL	Chemokine Ligand
CCoV	Canine Coronavirus (Enteric or Pantropic)
CD	Cluster of Differentiation
CDC	Centers for Disease Control and Prevention
CDV	Canine Distemper Virus
CE	Cystic Echinococcosis
CFU	Colony-Forming Units
CHV	Canine Herpesvirus
CIRD	Canine Infectious Respiratory Disease
CIRDC	Canine Infectious Respiratory Disease Complex
CIV	Canine Influenza Virus
CK	Creatine Kinase
CKD	Chronic Kidney Disease
CLSI	Clinical and Laboratory Standards Institute
CMI	Cell-Mediated Immunity
CNS	Central Nervous System
CoNS	Coagulase-Negative Staphylococci
CoV	Coronavirus
COVID	Coronavirus Disease
CPE	Cytopathic Effect
CPIV	Canine Parainfluenza Virus
CPnV	Canine Pneumovirus
CPV	Canine Parvovirus[a]
CRCoV	Canine Respiratory Coronavirus
CRFK	Crandell-Rees Feline Kidney Cells
CRI	Constant Rate Infusion
CRP	C-Reactive Protein
CRT	Capillary Refill Time
CSD	Cat Scratch Disease
CSF	Cerebrospinal Fluid
CT	Computed Tomography
DIC	Disseminated Intravascular Coagulation
DLA	Dog Leukocyte Antigen
DNA	Deoxyribonucleic Acid
DOI	Duration of Immunity
dsDNA	Double-Stranded DNA
DTH	Delayed-Type Hypersensitivity
ECG	Electrocardiogram
EDTA	Ethylenediaminetetraacetic Acid
ELISA	Enzyme-Linked Immunosorbent Assay
EMG	Electromyography
EPG	Eggs Per Gram
ESBL	Extended-Spectrum Beta-Lactamase
ExPEC	Extraintestinal Pathogenic *Escherichia coli*
FA	Fluorescent Antibody
FCoV	Feline Coronavirus
FCV	Feline Calicivirus
FDA	Food and Drug Administration (United States)
FECV	Feline Enteric Coronavirus
FeLV	Feline Leukemia Virus
FeMV	Feline Morbillivirus
FFV	Feline Foamy Virus
FHV-1	Feline Herpesvirus-1
FIP	Feline Infectious Peritonitis
FIPV	Feline Infectious Peritonitis Virus
FISH	Fluorescent In Situ Hybridization
FIV	Feline Immunodeficiency Virus
FLAIR	Fluid-Attenuated Inversion Recovery
FNA	Fine-Needle Aspiration
FPV	Feline Panleukopenia Virus
FVRCP	Feline Viral Rhinotracheitis-Calicivirus-Panleukopenia
GGT	Gamma-Glutamyl Transferase
GI	Gastrointestinal
GICA	Gold Immunochromatographic Assays
GMS	Gomori's Methenamine Silver
H&E	Hematoxylin and Eosin
H2RA	Histamine-2 Receptor Antagonist
HCT	Hematocrit
HI	Hemagglutination-Inhibition
HIV	Human Immunodeficiency Virus
HLA	Human Leukocyte Antigen
HPF	High-Power Field
HR	Heart Rate
HSV	Herpes Simplex Virus
IBD	Inflammatory Bowel Disease
ID	Immunodiffusion
IFA	Immunofluorescent Antibody

[a] Refers to CPV-2 variants unless otherwise specified.

Continued

Abbreviations Used Throughout This Book—cont'd

IFN	Interferon
IHC	Immunohistochemistry
Ig	Immunoglobulin
IL	Interleukin
IM	Intramuscular
IMHA	Immune-Mediated Hemolytic Anemia
IMPA	Immune-Mediated Polyarthritis
IN	Intranasal
IRIS	International Renal Interest Society
ISCAID	International Society for Companion Animal Infectious Diseases
ISFM	International Society of Feline Medicine
ITP	Immune-Mediated Thrombocytopenia
IV	Intravenous
LAMP	Loop-Mediated Isothermal Amplification
LPG	Larvae Per Gram
LPS	Lipopolysaccharide
LRS	Lactacted Ringer's Solution
LUTS	Lower Urinary Tract Signs
MALDI-TOF MS	Matrix-Assisted Laser Desorption/Ionization-Time of Flight Mass Spectrometry
MAT	Microscopic Agglutination Test
MCHC	Mean Corpuscular Hemoglobin Concentration
MCV	Mean Corpuscular Volume
MDA	Maternally Derived Antibody
MDR	Multiple Drug Resistant
MDS	Myelodysplastic Syndrome
MHC	Major Histocompatibility Complex
MIC	Minimum Inhibitory Concentration
MIF	Microimmunofluorescence
MLST	Multilocus Sequence Typing
MLV	Modified Live Virus
MPV	Mean Platelet Volume
MRI	Magnetic Resonance Imaging
MRS	Methicillin-Resistant *Staphylococcus*
MRSA	Methicillin-Resistant *Staphylococcus aureus*
MRSP	Methicillin-Resistant *Staphylococcus pseudintermedius*
NAAT	Nucleic Acid Amplification Tests
NF-κB	Nuclear Factor κB
NGS	Next Generation Sequencing
NLM	Neural Larva Migrans
NOD	Nucleotide-Binding Oligomerization Domain
NPV	Negative Predictive Value
NSAIDs	Non-Steroidal Anti-inflammatory Drugs
OD	Oculus Dexter, Right Eye
OIE	World Organisation for Animal Health
OLM	Ocular Larva Migrans
OMP	Outer Membrane Protein
OR	Odds Ratio
OS	Oculus Sinister, Left Eye
Osp	Outer Surface Protein
OU	Oculus Uterque, Both Eyes
PABA	Para-Amino Benzoic Acid
PAMPs	Pathogen-Associated Molecular Patterns
PAS	Periodic Acid-Schiff
PBMC	Peripheral Blood Mononuclear Cell
PBP	Penicillin-Binding Protein
PCR	Polymerase Chain Reaction
PCV	Packed Cell Volume
PET	Positron Emission Tomography
PFGE	Pulsed-Field Gel Electrophoresis
PI	Post-infection
PK-PD	Pharmacokinetic-Pharmacodynamic
PLR	Pupillary Light Reflex
PO	Oral
POC	Point-of-Care
PPE	Personal Protective Equipment
PPI	Proton Pump Inhibitor
PPP	Prepatent Period
PPR	Pattern Recognition Receptor
PPV	Positive Predictive Value
PRN	As Needed
PRV	Pseudorabies Virus
PT	Prothrombin Time
qPCR	Quantitative PCR
QUAT	Quaternary Ammonium Compound
RDW	Red Cell Distribution Width
RBC	Red Blood Cells
RER	Resting Energy Requirement
RMSF	Rocky Mountain Spotted Fever
RNA	Ribonucleic Acid
ROC	Receiver Operating Characteristic
RR	Respiratory Rate
rRNA	Ribosomal RNA
RT	Reverse Transcriptase
RT-PCR	Reverse Transcriptase-Polymerase Chain Reaction
SARS-CoV-2	Severe Acute Respiratory Syndrome Coronavirus-2
SBU	Subclinical Bacteriuria
SC	Subcutaneous
SCC	Squamous Cell Carcinoma
SCT	Sedimentation and Counting Technique
SDMA	Symmetric Dimethylarginine
SIRS	Systemic Inflammatory Response Syndrome
SFG	Spotted Fever Group
SPF	Specific Pathogen-Free
SpG	Specific Gravity
SSA	Sulfosalicyclic Acid
SSI	Surgical Site Infection
STT	Schirmer Tear Test
SuHV-1	Suid Herpesvirus-1
T3SS	Type 3 Secretion System
T6SS	Type 6 Secretion System
TBRF	Tick-Borne Relapsing Fever
TDM	Therapeutic Drug Monitoring

Continued

Abbreviations Used Throughout This Book—cont'd

TIN	Tubulointerstitial Nephritis
TK	Thymidine Kinase
TLR	Toll-Like Receptor
TMS	Trimethoprim-Sulfonamide
TNF	Tumor Necrosis Factor
TNR	Trap-Neuter-Return
TPP	Total Plasma Protein
UPCR	Urine Protein:Creatinine Ratio
URTD	Upper Respiratory Tract Disease
USA	United States of America
USDA	United States Department of Agriculture
UTI	Urinary Tract Infection
UV	Ultraviolet
VLM	Visceral Larva Migrans
VMTH	Veterinary Medical Teaching Hospital
VN	Virus Neutralization
VNTR	Variable Number Tandem Repeats
VRE	Vancomycin-Resistant Enterococci
WBC	White Blood Cells
WGS	Whole Genome Sequencing
WHO	World Health Organization
WSAVA	World Small Animal Veterinary Association
