Cats of all ages may be affected,[31] but young adult cats appear to be at increased risk. In dogs, cryptococcosis is diagnosed predominantly in young adult dogs. In one study, the median age of cats and dogs was 6 and 4 years, respectively.[11] No clear sex predisposition exists. Siamese, birman, and ragdoll cats have been predisposed in Australian studies but were not found to be at risk in the United States.[11,32] Similarly, German shepherd dogs, Doberman pinschers, and great Danes appear to be predisposed in Australia, whereas in the United States, American cocker spaniel dogs were strongly predisposed with an odds ratio of 16.[8,11,31,33,34]

Most cats and dogs with cryptococcosis do not have identifiable underlying immunosuppressive illness. The prevalence of retrovirus infection in cat populations with cryptococcosis does not differ from that in cat populations without cryptococcosis.[11,31] However, some cats

TABLE 82.1 Relationships Between Phenotypes, Genotypes, and Species Belonging to *Cryptococcus neoformans* and *Cryptococcus gattii* Species Complexes

Serotype	Previous Species Name	Molecular Type	AFLP Genotype	New Species Name

		VGIV	7	*C. tetragattii*
		VGIIIc/VGIV hybrid	10	*C. decagattii*
D	*C. neoformans* var. *neoformans*	VNIV	2	*C. deneoformans*
AD		VNIII	3	*C. neoformans/C. deneoformans* hybrid

with cryptococcosis that are co-infected with FeLV appear to respond more slowly to treatment and may be more likely to have relapses.[35] Cats infected with FIV and cryptococcosis did not have an unfavorable prognosis in one study, and several were cured of the infection.[36] Cryptococcosis is occasionally reported in cats treated with immunosuppressive therapy or chemotherapy for malignancy.[11,37] Concurrent opportunistic infections have been reported in other cats (e.g., toxoplasmosis), as well as in dogs (e.g., neosporosis or papillomatosis), suggesting underlying immunodeficiency.[11,38] Administration of glucocorticoids to dogs and cats infected with *Cryptococcus* spp. can lead to the development of disseminated disease.

Cryptococcus neoformans Species Complex

Organisms that belong to the *C. neoformans* SC have a worldwide distribution. They primarily infect human patients who are immunocompromised, especially AIDS patients. The realized environmental niche for *C. neoformans* SC organisms is weathered bird (especially pigeon) guano which provides an alkaline, hyperosmolar, nitrogen-rich environment that allows prolific growth.[39] They can also be found in decaying plant matter in hollows of certain trees.[40] The organism can remain viable for at least 2 years in environments such as pigeon lofts. The majority of human cryptococcal infections result from infection with *C. neoformans* sensu stricto (ss) (VNI).[41] *C. neoformans* ss is the most common *Cryptococcus* species isolated from dogs and cats in southeastern Australia and accounts for more than 70% of infections.[31,32,34] Across the United States, most dogs with cryptococcosis are infected with *C. neoformans* SC organisms, but infection of cats with this species is rare.[11,42]

Cryptococcus gattii Species Complex

Organisms that belong to the *C. gattii* SC are endemic in Australia, New Zealand, Papua New Guinea, Southeast Asia, parts of Latin America, California, Mexico, Hawaii, Central and South Africa, and, to a lesser extent, certain parts of Europe (Austria, Germany, France, Italy, Greece, and Spain).[43,44] Since 1999, an epidemic of infections with *C. gattii* SC has occurred in humans and domestic and wild animals in British Columbia in Canada, especially Vancouver Island, and the Pacific Northwest of the United States, and infections have been occurring in humans at a rate higher than that in other endemic regions.[45–49] The main species identified in this epidemic has been *C. deuterogattii* (molecular types VGIIa and, to a much lesser extent, VGIIb and, in Oregon, also VGIIc). *Cryptococcus deuterogattii* (VGII) can be found on living tree bark (Garry oak, maple, cedar, and pine) and in air, and has also been found in freshwater and seawater. Proximity to areas with soil disturbance was a risk factor for dogs and cats.[48] In California, almost all cats appear to be infected with *C. bacillisporus* (VGIII), with occasional *C. deuterogattii* (VGII) infections.[11,42] The ecologic niche of *C. bacillisporus* (VGIII) in the United States remains somewhat unclear,[49] but it has recently been isolated from the bark of several tree species, including the Canary Island pine, American Sweetgum, Pohutukawa tree, Western Sycamore, and Blue Gum in southern California, as well as from soil in public parks and areas in the Los Angeles and San Diego regions.[50] However, as found for other endemic mycoses, approximately 25% of affected cats are housed exclusively indoors.[11]

In eastern Australia, 20% to 30% of human, feline, and canine cryptococcosis is caused by *C. gattii* SC organisms,[32,38] whereas in Western Australia, approximately 50% of cats and dogs with cryptococcosis are infected with *C. gattii* SC organisms.[8,49] Most *C. gattii* isolates from eastern Australia belong to *C. gattii* ss (VGI), whilst *C. deuterogattii* (VGII) is mostly seen in southwestern and northern Australia.[8,51] *Cryptococcus gattii* ss (VGI) in Australia is very strongly associated with dead plant material in *Eucalyptus* tree hollows.[5,52] Cats in rural environments are at risk of infection. Recently, *C. deuterogattii* (VGII) was identified in two cats with nasal signs[53] and dogs with disseminated disease[54,55] from southeastern Brazil, and *C. bacillisporus* (VGIII) was identified in a cat with a nasal cutaneous lesion from Chile.[56]

In contrast to *C. neoformans* ss, *C. deuterogattii* (VGII) isolates from the Pacific northwest and British Columbia can infect apparently immunocompetent humans.[57] *Cryptococcus bacillisporus* (VGIII) infections have been reported in immunosuppressed humans in southern California.[58] When disease occurs in immunocompetent hosts, it is often characterized by the presence of pulmonary mass lesions (cryptococcomas) and sometimes intracranial cryptococcomas.[59,60] As a result, pulmonary cryptococcomas are more commonly described in human patients infected with *C. bacillisporus* (VGIII) compared with those infected with *C. neoformans* ss.[60]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Based on the small size of basidiospores, the lung is thought to be the primary site of infection in humans. In cats, dogs, and koalas, the nasal cavity may be the primary site of infection (see Fig. 82.1). *Cryptococcus neoformans* ss has been shown to be a transient colonizer of the nasal mucus of cats, dogs, and koalas in Australia,[5,61] whereas *C. gattii* ss can be isolated in sufficient numbers and with sufficient frequency to potentially even be considered part of normal sinonasal flora of koalas in certain environments.[62] Significant pulmonary parenchymal

involvement in these species is rare, although lesions can be detected on pulmonary CT scans and at necropsy. Importantly, the progression of disease from colonization to subclinical disease and clinical disease is best recognized in the koala.[5,62,63] Colonization of the nasal cavity may be followed by development of cryptococcal rhinitis in some (but not all) dogs and cats. However, some nasal cavity involvement may result from hematogenous dissemination, because injection of *Cryptococcus* spp. into the carotid artery of cats can lead to development of lesions on the bridge of the nose. Some localized cutaneous lesions may result from direct cutaneous inoculation (e.g., after a cat scratch), but skin lesions are usually interpreted as the result of dissemination or extension from the nasal cavity.

The pathogenesis of cryptococcosis depends on the size of the inoculum, virulence of the cryptococcal strain, and host immunity. *Cryptococcus* has been aptly described as "a sugar-coated killer with designer genes."[64] *Cryptococcus* has several important virulence factors, including its polysaccharide capsule, laccase (which makes melanin), mannitol, and other enzymes such as phospholipase, urease, and superoxide dismutase.[17,59,65] Capsular polysaccharide is continuously shed into the host's extracellular fluid, which includes blood, urine, and CSF. The capsule inhibits phagocytosis through its negative charge and via blockage of the Fc portion of bound antibodies from interacting with host phagocyte receptors. The capsule also depletes complement and interferes with migration of leukocytes from the bloodstream into infected tissues by causing them to shed selectin.[65,66] It also directly inhibits CMI by causing a shift from Th1 to a Th2 type immune response.[66] The ability of *C. neoformans* SC and *C. gattii* SC organisms to grow at mammalian body temperature is also an important virulence factor and is lacking in other species of *Cryptococcus*. Both *C. neoformans* SC and *C. gattii* SC organisms can undergo phenotypic switching by altering the cell membrane sterol composition and GXM structure allowing the organisms to evade the host immune response.[67]

The incubation period can range from 2 to 13 months.[68,69] Exposure and self-limiting infection may occur in some individuals, with reactivation of viable cryptococci in residual granulomatous foci months or years later with immunosuppressive drug therapy or illness.[59] Because of this delay, a travel history to areas where *Cryptococcus* is highly endemic (such as British Columbia or the west coast of the United States) may be present in animals and humans residing in nonendemic regions. After infection is established within the lung or nasal cavity, the organism can spread hematogenously via macrophages to other sites, particularly the lymph nodes, eye, skin, and CNS (see Fig. 82.1). *Cryptococcus* spp. can cross the capillary endothelium and enter the CNS by traveling within infected macrophages ("Trojan horse" mechanism). Free organisms may also be able to penetrate the blood-brain barrier by penetrating between damaged endothelial cells, or by transcytosis, whereby free organisms cross through capillary endothelial cells into the brain parenchyma, causing meningitis or meningoencephalitis.[30,70] In humans, cerebral cryptococcosis is often associated with increased intracranial pressure, and this probably also occurs in cats and dogs. Spread of infection to the eye, either along the optic nerves from the brain or as a result of hematogenous spread, may result in concurrent cryptococcal optic neuritis and chorioretinitis. In animals with nasal cavity involvement, extension of infection into the brain may also follow osteomyelitis of the cribriform plate or of the ventral wall of the frontal sinus. Middle ear involvement can also occur.[71] Infection also often spreads from the nasal cavity to the mandibular lymph nodes.

Multifocal cutaneous involvement in cats and dogs reflects hematogenous dissemination from the primary site of infection (usually respiratory tract), as do lesions in bone (e.g., digits) or periarticular soft tissues. Primary cutaneous lesions are rare, although occur more frequently in species like the koala, due to direct inoculation from heavily contaminated environments. Dogs infected with *C. neoformans* ss often develop widely disseminated disease, with involvement of sites such as the GI system, pancreas, mesenteric lymph nodes, kidneys, myocardium, and thyroid gland (Fig. 82.3).[11,33,72,73] In contrast, dogs infected with *C. deuterogattii* (VGII) in the United States tend to have isolated caudal nasal cavity cryptococcomas, which can extend through the cribriform plate into the brain (Fig. 82.4). Primary GI tract cryptococcosis is rare but does seem to occur and may be associated with *C. deuterogattii* (VGII).[74,75]

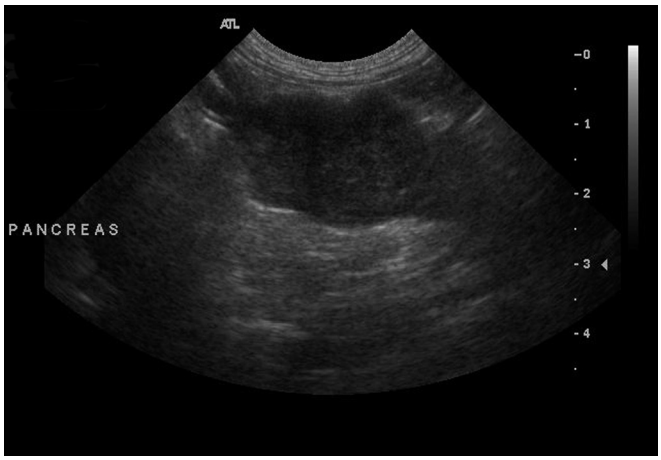

Fig. 82.3 Ultrasound image that shows an enlarged and hypoechoic pancreas in a 7-year-old female spayed basset mixed-breed dog with systemic cryptococcosis caused by *Cryptococcus neoformans* var. *grubii* (molecular type VNI). The dog was evaluated for gastrointestinal signs that were associated with severe cryptococcal pancreatitis and enteritis. The dog's lungs, heart, kidneys, liver, mesenteric lymph nodes, peritoneum, brain, and meninges were also involved at necropsy.

Clinical Features in Cats

Cryptococcosis is often a chronic infection in cats, and affected cats are usually otherwise well but occasionally have mild lethargy and inappetence. Fever is rare, and when it occurs, it tends to be of low grade. Upper respiratory tract signs due to nasal cavity involvement are common including sneezing and nasal discharge which can be mucopurulent, serous, or hemorrhagic in nature. A firm to fluctuant swelling over the bridge of the nose may be present with or without mandibular lymphadenopathy. Single or multifocal ulcerated or nonulcerated cutaneous masses may also be present (Fig. 82.5).[76]

Lower respiratory tract signs such as tachypnea are uncommon but can occur as a result of pleural effusion or severe mediastinal lymphadenomegaly. Neurologic signs vary depending on the location of lesions in and around the CNS (see Physical Examination Findings), and, rarely, cats with CNS involvement lack obvious neurologic signs. Optic neuritis and chorioretinitis develop in as many as one third of affected cats and almost always indicate CNS involvement.

Other signs include peripheral lymphadenomegaly (which may be unassociated with skin lesions and is often asymmetric), lameness due to osteomyelitis or cryptococcal arthritis, and swollen digits. Rarely, involvement of the abdominal lymph nodes, kidneys, lower urinary tract, spleen, liver, thyroid, and salivary glands occurs.

Clinical Features in Dogs

In contrast to cats, dogs frequently develop severe disseminated disease. In one study, 80% of dogs had involvement of multiple anatomic sites, and 50% of dogs had involvement of sites other than the nasal

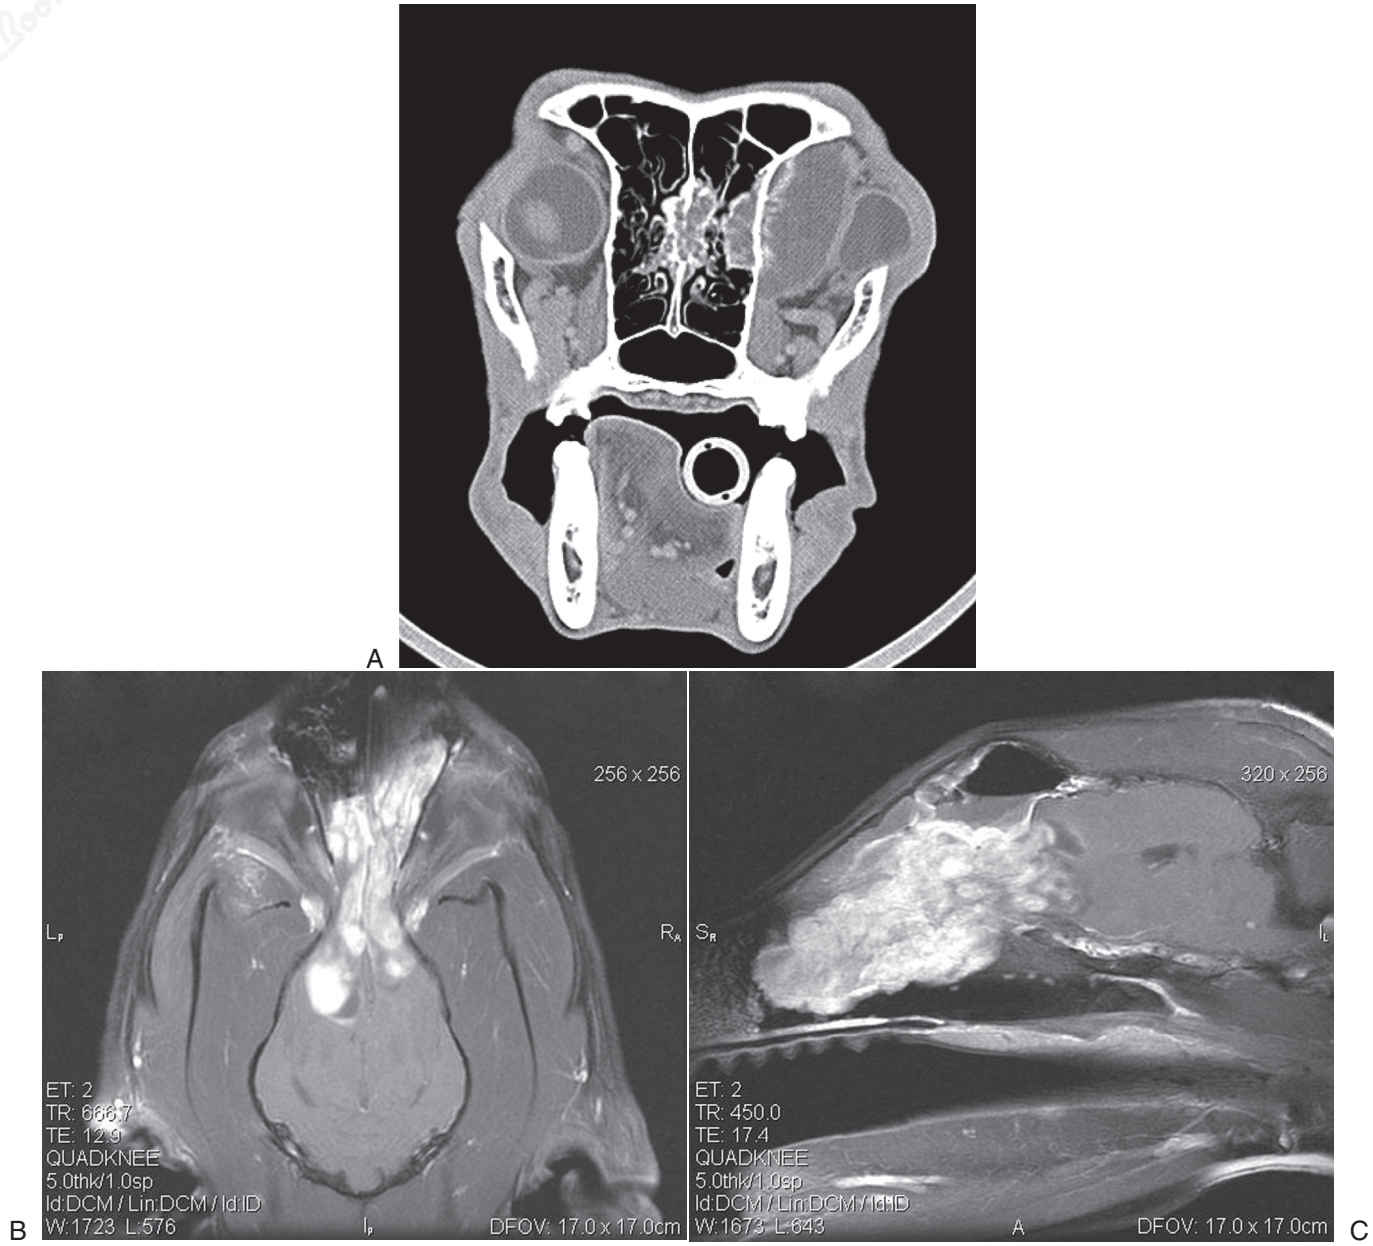

Fig. 82.4 Caudal nasal cryptococcosis in dogs infected with *Cryptococcus gattii*. (A) Computed tomography scan showing a large caudal nasal cavity cryptococcoma at necropsy that invaded the cribriform plate and retrobulbar space in a 5-year-old Doberman pinscher infected with *C. deuterogattii* (*C. gattii* molecular type VGIIa). There is a palisading periosteal response along the lateral margin of the right frontal and lacrimal bones. (B and C) Postcontrast magnetic resonance images of the head of a 2-year-old intact male malamute with a 1-week history of abnormal behavior and seizures. *Cryptococcus* was isolated from the nasal cavity. A large, contrast-enhancing mass is present in the caudal nasal cavity that invades the cribriform plate and extends into the brain. (Courtesy Dr. Stacey Hoffman.)

cavity, skin, lungs, lymph nodes, kidney, eye, and CNS.[11] Weight loss, lethargy, and inappetence are common nonspecific findings. Rhinosinusitis from cryptococcosis may be subclinical in dogs, so its incidence may be underestimated.[11,34] However, sneezing and mucopurulent nasal discharge can also occur. Neurologic signs were present in two thirds of affected dogs from California.[11] Dogs can also primarily show signs of GI or pancreatic involvement, such as vomiting, diarrhea, and abdominal pain.[54,74,75]

Cutaneous involvement is uncommon in dogs but, as in cats, may be a marker for disseminated disease. Although rarely detected antemortem, more than half of dogs have lower respiratory involvement at necropsy.[11] Other clinical signs that are infrequently present in dogs include peripheral lymphadenomegaly or lameness (due to osteomyelitis or arthritis) (Box 82.1).[77]

Physical Examination Findings

Cats

Upper respiratory tract signs are common physical examination findings in cats with cryptococcosis. These include sneezing; snuffling; and mucopurulent, serous, or hemorrhagic nasal discharge that is unilateral or bilateral. In some cats, a fleshy mass protrudes from the nostril. Other cats have one or more firm to fluctuant, ulcerated

Fig. 82.5 Multiple ulcerated skin lesions in a cat from northern California with disseminated cryptococcosis caused by *Cryptococcus gattii* molecular type VGIII.

or nonulcerated, subcutaneous swellings over the bridge of the nose. These swellings may communicate with the frontal sinus or nasal cavity, and palpation of the lesions may reveal crepitus due to subcutaneous emphysema. Cats with nasopharyngeal cryptococcosis develop stertor, stridor, and, occasionally, otitis media. Mandibular lymphadenopathy is often present. Ulcerated or proliferative lesions of the buccal mucosa can also be found. Multifocal skin lesions consist of nodules or masses that are fluctuant to firm, up to several centimeters in diameter, and may ulcerate (see Fig. 82.5).

Neurologic examination abnormalities in cats with CNS involvement include obtundation; atypical behavior; slow menace, palpebral, or pupillary light responses; mydriasis or anisocoria (Fig. 82.6A); twitching or tremors; and seizures, circling, head pressing, ataxia, paresis, abnormal placing reactions, head tilt, nystagmus, and spinal pain.[10] Fundoscopic examination may reveal granulomatous chorioretinitis, exudative retinal detachment, papilledema, evidence of optic neuritis, and/or retinal hemorrhage (Fig. 82.6B). Severe ocular lesions or optic neuritis may result in blindness with dilated and unresponsive pupils.

Dogs

Many dogs with cryptococcosis are lethargic or obtunded because of disseminated disease and/or CNS involvement. When fever occurs, it is typically low grade. Other CNS signs in dogs include absent or slow menace, gag, or pupillary light responses, nystagmus, mydriasis, head tilt, strabismus, anisocoria, facial paralysis, paraparesis, abnormal placing reactions, ataxia, circling, seizures, twitching or tremors, reluctance to open the mouth, absent or decreased segmental reflexes, and, commonly, cervical hyperesthesia.[10,33] Some dogs show signs that resemble those of cervical disc herniation. The most common ocular abnormalities are chorioretinitis, papilledema, evidence of optic neuritis, and retinal detachment. Decreased nasal airflow may be present in dogs with nasal cavity cryptococcomas. Nodules, masses, or ulcers may involve any portion of the integument, and the nose, tongue, buccal mucosa, hard palate, lips, or nail beds.

BOX 82.1 Clinical Signs in Cats and Dogs with Cryptococcosis[a]

Nasal Cavity
Rhinitis (sneezing, nasal discharge), frontal sinusitis, deforming sinonasal disease, nasal planum disease, nasopharyngeal obstruction or dysfunction

Lung and Thoracic Cavity
Nodules (single or multiple), interstitial (miliary) or alveolar (fluffy) infiltrates, mediastinal lymphadenomegaly, hilar lymphadenomegaly, pleural effusion

Central Nervous System
Meningoencephalomyelitis, cryptococcomas of the brain or spinal cord, increased intracranial pressure, hydrocephalus

Skin and Subcutaneous Tissues
Papules, nodules, subcutaneous abscesses, draining lesions, ulcers, digital swellings, peripheral lymphadenopathy

Eye
Papilledema, chorioretinitis, optic neuritis, uveitis (miosis, aqueous flare, hypopyon), endophthalmitis, panophthalmitis

Genitourinary Tract
Prostatitis (prostatomegaly, dysuria), renal abscesses, bladder wall infection, funguria

Bone and Joints
Osteolytic lesions, arthritis

Heart
Myocarditis, pericarditis

Gastrointestinal Tract
Glossitis (lingual swelling, ulceration), gingivitis, gastritis, enteritis, typhlitis, hepatitis, mesenteric lymphadenomegaly, peritonitis, pancreatitis

Endocrine
Thyroiditis, adrenal gland granulomas

Musculoskeletal
Middle ear disease, arthritis, osteomyelitis

[a] Clinical abnormalities vary depending on the *Cryptococcus* species/molecular type, host species (dog versus cat) and level of immunocompromise. For example, widely disseminated disease that involves multiple parenchymal organs is most often seen in young adult, often purebred dogs with *Cryptococcus neoformans* sensu stricto (VNI) infection, resembling that in human AIDS patients. See text for more details.

DIAGNOSIS

Definitive diagnosis of cryptococcosis is usually straightforward and based on evaluation of representative tissue specimens with cytology, culture, and occasionally histopathology, with or without serologic detection of cryptococcal antigen in body fluids (Table 82.2). Suitable specimens include nasal swabs, nasal washings, needle aspirates from mass lesions or enlarged lymph nodes, bronchoalveolar lavage specimens, pleural fluid, CSF, and urine.

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, and Urinalysis

Changes in the CBC, chemistry panel, and urinalysis in animals with cryptococcosis are generally mild and nonspecific. Mild to moderate

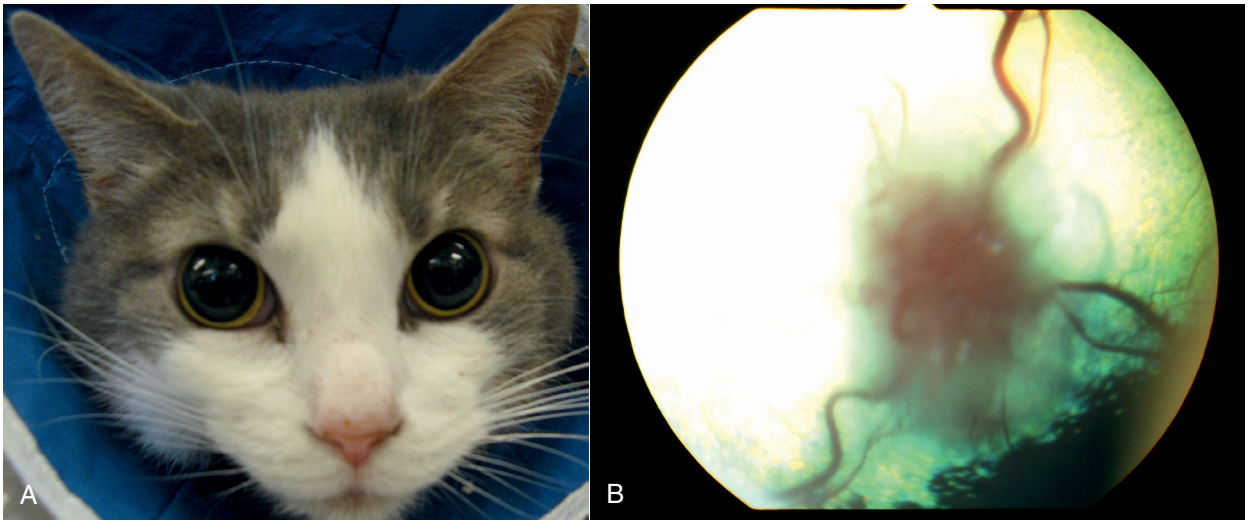

Fig. 82.6 Ocular abnormalities in cats with disseminated cryptococcosis. (A) Bilateral mydriasis in an 8-year-old male neutered domestic shorthair with cryptococcal meningoencephalitis. Fundoscopic examination was within normal limits. (B) Granulomatous chorioretinitis and retinal detachment in another cat with cryptococcosis. TABLE 82.2 Diagnostic Assays Available for Cryptococcosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions or biopsies	*Cryptococcus* organisms	High sensitivity, but occasionally organisms are not visualized (such as in the CSF of some animals with CNS cryptococcosis).
Fungal culture	Aspirates or biopsies of affected tissues, body fluids such as CSF and urine	*Cryptococcus* spp.	Generally sensitive and specific, but false negatives are possible if specimen size is low. Requires several days' incubation. Allows species identification and antifungal drug susceptibility testing.
Cryptococcal antigen latex agglutination tests (LCAT)	Serum, CSF	*Cryptococcus* polysaccharide antigen	Sensitivity and specificity exceed 90%. False negatives can occur in dogs and with localized infections in cats. False positives are generally of low magnitude (<1:200 and usually <1:16). Titers vary between kits.
Immunochromatographic POC assays (IMMY Diagnostics, OK, USA and CryptoPS, Biosynex, Strasbourg, France)	Serum, CSF	*Cryptococcus* polysaccharide antigen	IMMY assay: Sensitivity greater than 90% and specificity 80%–85% on serum specimens in dogs and cats. CryptoPS assay: sensitivity approximately 80% and specificity 95%. Provide results in less than 15 minutes. Not yet validated for CSF in dogs and cats.
Real-time PCR assays	Biopsies, body fluids, aspirates	*Cryptococcus* DNA	Not yet validated in adequate numbers of dogs or cats with cryptococcosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*Cryptococcus* spp. yeasts	High sensitivity, with rare false negatives. Special stains such as Mayer's mucicarmine and immunohistochemical stains facilitate organism detection and identification.

nonregenerative anemia; leukocytosis, often with monocytosis; and eosinophilia are the most common findings. Dogs with disseminated disease may have a neutrophilia with a left shift. The serum biochemical profile reflects specific organ involvement in animals with disseminated disease. Occasionally, cryptococcal yeasts are found on examination of the urine sediment.

Cerebrospinal Fluid Examination

The CSF in cats and dogs with neurologic signs due to cryptococcosis may have an increased protein concentration (usually between 10 and 140 mg/dL in cats, but may be several hundred or rarely more than 1,000 mg/dL in dogs).[10] Leukocyte counts can range from 2 to more than 1000 cells/μL in both dogs and cats. A mixed cellular pleocytosis is generally present, with neutrophils or large mononuclear cells generally outnumbering other cell types. Some dogs have a marked eosinophilic pleocytosis. Cryptococcal yeasts are visible in most but not all animals with cryptococcal meningitis (see Fig. 82.2).[10] Marked deterioration in neurologic status occasionally occurs in animals with CNS cryptococcosis immediately after CSF collection. Many animals have intracranial mass lesions or increased CSF pressure, which can increase the risk of cerebellar herniation following a cisternal tap. Wherever possible, attempts to make a diagnosis with serum antigen testing or collection of specimens from other anatomic sites should be considered as an alternative to diagnosis by CSF analysis.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs and cats are often normal. In some animals, interstitial to alveolar infiltrates or small nodular lesions are present. Occasionally, large pulmonary nodules, hilar lymphadenopathy, a mediastinal granuloma, or pleural effusion are found.[58]

Computed Tomography

In cats with nasal cryptococcosis, CT of the nasal cavity can reveal soft tissue and fluid opacification of the nasal cavity or frontal sinus, peripherally contrast-enhancing mass lesions of the nasal planum, and lysis of the nasal bones or of the cribriform plate.[11] CT was used to document a contrast-enhancing right cranial lung lobe mass that invaded the distal trachea and right mainstem bronchus in a cat from Arizona.[78] In dogs, CT findings in the nasal cavity include peripherally contrast-enhancing mass lesions within the frontal sinuses, caudal nasal cavity, nasopharynx, or the retrobulbar space and associated osteomyelitis (see Fig. 82.4A). CNS abnormalities such as ventricular dilation and intra-axial contrast-enhancing mass lesions have been described in dogs using CT.[10] However, MRI is more sensitive for detection of CNS lesions in human patients,[59] and the same is probably true for dogs and cats.

Magnetic Resonance Imaging

MRI abnormalities in cats with CNS cryptococcosis consist of single or multifocal contrast-enhancing mass lesions that tend to be hyperintense on T2-weighted images and hypointense on T1-weighted images, as well as mild to moderate, diffuse or focal meningeal enhancement.[10] Some cats have lesions that appear fluid-filled on T2-weighted images but have a greater T1-weighted intensity than expected for acellular fluid ("high T2, low T1 lesions"; Fig. 82.7).[10] MRI in dogs may show contrast-enhancing mass lesions that are hyperintense on T2-weighted images and of variable intensity on T1-weighted images, as well as meningeal enhancement (see Fig. 82.4B). Ventriculomegaly and/or cribriform plate osteomyelitis may also be evident.

Sonographic Findings

Over 80% of cats with cryptococcosis have normal abdominal ultrasound examinations. Cats with kidney involvement can have iso- to hypoechoic intraparenchymal mass lesions on ultrasound, with or without associated renal failure. These sometimes involve the renal pelvis. However, cats with renal involvement can also have normal abdominal ultrasound examinations.[11]

Ultrasonographic findings in dogs include intra-abdominal lymphadenomegaly, multifocal gastric and small intestinal thickening, changes suggestive of pancreatitis, renal mass lesions, and/or ascites (see Fig. 82.3).[11,73]

Microbiologic Tests

Cytologic Examination

Cytologic examination can be performed on aspirates, body fluids, or impression smears of biopsy specimens. Romanowsky-type stains, new methylene blue, and Gram stain are all satisfactory for making a cytologic diagnosis. India ink can be used to examine CSF for cryptococcal yeasts, which appear unstained and silhouetted against a black background. India ink staining of CSF has been used in the diagnosis of human cryptococcal infections (Fig. 82.8).[59] However, lymphocytes and fat droplets can sometimes be confused with the organism.

Although cytologic examination of nasal or cutaneous exudates, aspirates, or body fluids for organisms is a rapid and sensitive test for cryptococcosis, negative test results do not eliminate the possibility of cryptococcosis. Generally, organisms are found only by cytologic examination of CSF in 60% to 80% of dogs and cats.[11] If a sufficient index of suspicion exists, additional diagnostic tests such as histopathology, antigen testing, and/or fungal culture are indicated.

Fungal Culture

Cryptococcus spp. are readily cultured from aspirates, exudate, CSF, urine, and tissue specimens. Attempts to culture the organism are recommended whenever possible before treatment is initiated, because isolation confirms the diagnosis, can be used to differentiate *C. gattii* SC from *C. neoformans* SC organisms, and permits antifungal susceptibility testing for cases that subsequently fail to respond adequately to antifungal drug treatment. Some veterinary diagnostic laboratories still report all *Cryptococcus* isolates as *C. neoformans* in the absence of tests to discriminate between *C. neoformans* SC and *C. gattii* SC organisms. If the report lists *C. neoformans* as the isolate, the laboratory must therefore be consulted to determine whether *C. neoformans* SC was differentiated from *C. gattii* SC. However, whether the clinician needs to know whether the isolate belongs to the *C. neoformans* SC or the *C. gattii* SC is debatable because at this time, species identification

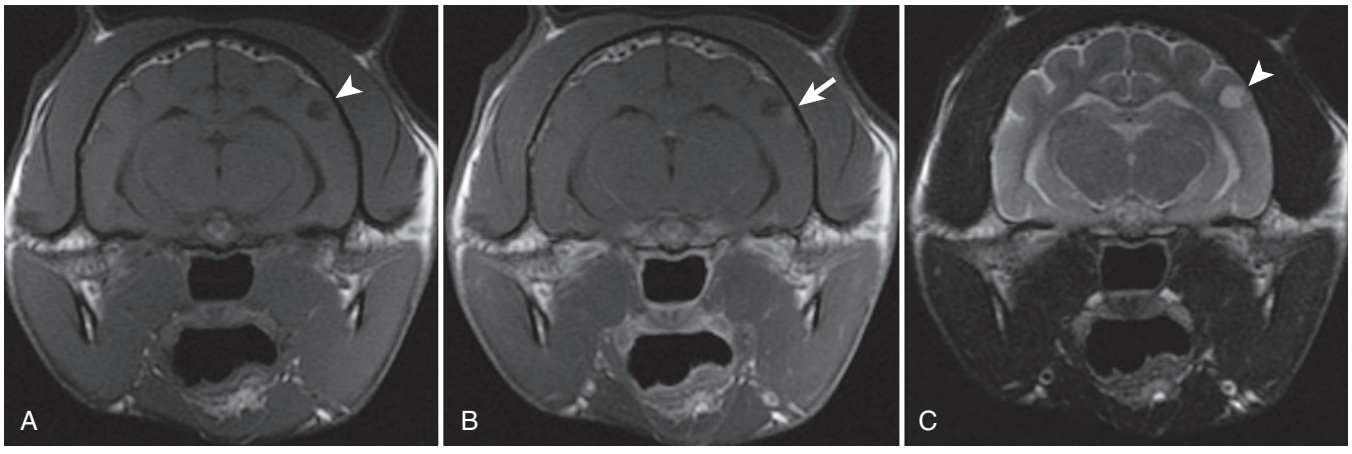

Fig. 82.7 Transverse T1-weighted pre-contrast (A), T1-weighted postcontrast (B), and T2-weighted (C) magnetic resonance imaging of the brain of an 8-year-old male neutered domestic shorthair with cryptococcosis. There is a focal lesion in the gray matter of the right cerebral cortex at the junction of the parietal and occipital lobes *(arrowhead)*. The lesion is T2 hyperintense, T1 hypointense, and rim-enhancing *(arrow)*. These signal characteristics were consistent with a pseudocyst lesion.

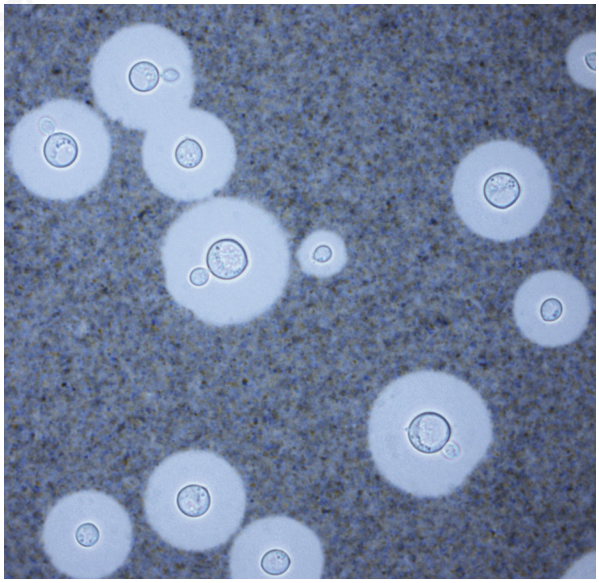

Fig. 82.8 India ink stained preparation of *Cryptococcus gattii* yeasts that had been grown in culture. 1000× oil magnification. (Courtesy Greg Hodges and George Thompson III, University of California, Davis.)

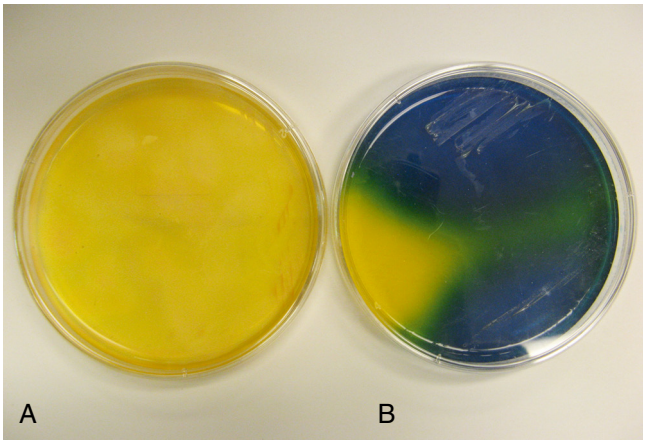

Fig. 82.9 Growth of *Cryptococcus neoformans* (A) and *Cryptococcus gattii* (B) on canavanine-glycine-bromothymol blue agar. *Cryptococcus neoformans* does not grow well in the presence of canavanine and does not utilize glycine, so the medium color remains unchanged. *Cryptococcus gattii* grows in the presence of L-canavanine and utilizes glycine as the sole carbon and nitrogen source, which raises the pH of the medium and causes the bromothymol blue indicator in the medium to turn the agar a vivid cobalt blue color.

does not clearly influence treatment recommendations or prognosis in dogs and cats. If *Cryptococcus* is isolated from a contaminated site such as the nasal cavity, a diagnosis of cryptococcosis should be supported with cytologic or histopathologic evidence of active infection. This is because subclinical colonization occurs in some animals.

Pathogenic *Cryptococcus* species grow on almost all laboratory media, but fungal isolation media (such as Sabouraud's dextrose agar) and incubation temperatures of 25°C or 30°C in addition to incubation at 37°C are preferred when fungi are being considered in the differential diagnosis. Antibiotics are added to the medium for isolation of *Cryptococcus* spp. from contaminated sites, such as the nasal cavity. Colonies usually are visible in 2 to 3 days, but sometimes incubation for up to 10 days is required. Unlike other dimorphic fungi, *Cryptococcus* grows as a yeast, rather than a mold, on routine fungal media and so is less likely to represent a laboratory hazard than organisms that grow as molds. The organisms form white, creamy colonies. Often colonies of the *C. gattii* SC are more mucoid than those of the *C. neoformans* SC. The organism is identified based on its microscopic morphology and either response to biochemical tests in commercial yeast identification kits or MALDI-TOF mass spectrometry (see Chapter 4). Canavanine-glycine-bromothymol blue (CGB) agar is used to differentiate between *C. neoformans* SC and *C. gattii* SC isolates.[79] Unlike *C. neoformans* SC organisms, *C. gattii* SC organisms grow on CGB agar and turn the media a brilliant deep blue (Fig. 82.9). Fungal culture of the CSF is frequently positive in patients with CNS cryptococcosis and should be performed even if the organism cannot be demonstrated cytologically or serologically. Culture of urine specimens collected using cystocentesis is also indicated when cryptococcosis is suspected, even when obvious renal involvement is not present and cytologic abnormalities are not present. Identification of molecular types for epidemiologic purposes requires specialized techniques such as multilocus sequence typing or PCR fingerprinting. However, MALDI-TOF mass spectrometry can also rapidly differentiate between *Cryptococcus* species, and may be used in veterinary clinical microbiology laboratories for this purpose in the future.[80]

Most cryptococcal isolates from dogs or cats are susceptible to amphotericin B (AMB), 5-flucytosine, and azoles. Rarely, resistance to 5-flucytosine and azole antifungal drugs (especially fluconazole) is detected. In general, MICs for fluconazole are higher than those for other azole drugs, and this does not imply resistance *in vivo*. In the human literature, it has been suggested that when the MIC rises during treatment, or if the initial MIC is at least 16 µg/mL for fluconazole, or at least 128 µg/mL for flucytosine, failure of antifungal drug treatment may result from drug resistance.[59] There is evidence that organisms that belong to the *C. gattii* SC may be more resistant to fluconazole than those that belong to the *C. neoformans* SC.[81]

Serologic Testing

Latex agglutination assays (referred to as the latex cryptococcal antigen test [LCAT]) for detection of cryptococcal polysaccharide capsular antigen are widely used for diagnosis of cryptococcosis in veterinary patients and are sensitive and specific.[11,82,83] (Note: the latex agglutination assay offered by Meridian Biosciences is known as the Cryptococcal Latex Agglutination System [CALAS]). Serologic assays detect the antigen of all species in the *C. neoformans* SC and *C. gattii* SC and can be used on serum or CSF. These can provide a rapid diagnosis when organisms cannot be visualized or cultured. When positive, serum cryptococcal antigen assays can be advantageous in animals with neurologic signs when CSF collection is unacceptably risky or if a diagnosis of cryptococcosis is unlikely but requires additional evidence for exclusion.

In human patients, commercial kits typically have at least 90% sensitivity and 97% to 100% specificity.[59] Results have been similar for small animal patients,[11,82,83] although false-negative results may be more common in dogs than in cats.[11] False-positive test results are reduced when test specimens are pretreated in the laboratory with pronase (a proteinase).[59] In human patients, titers below 1:8 can represent false-positive results, although false-positive titers of up to 1:200 have rarely been detected in cats.[11] These cats had other causative etiologies identified that explained their clinical signs. In some cats, these low positive titers may represent subclinical colonization. Attempts to obtain cytologic or histopathologic confirmation of infection in animals with titers of 1:200 or less are recommended.

Antigen titers are frequently extremely high (>1:65,536) in cats and dogs with cryptococcosis, but even a titer of 1:2 can indicate cryptococcal infection.[82] Titer results from different kits vary considerably; therefore, the methodology should not be altered when monitoring the

response to treatment. A good prognosis is indicated by a decrease in antigen titer, whereas a persistent titer after treatment suggests continued infection. Reductions in the titer typically lag behind clinical improvement. No correlation has been found between pretreatment antigen titer and outcome.

Other detection methodologies exist including ELISA assays and immunochromatography. A POC dipstick cryptococcal antigen lateral flow assay (CrAg, IMMY Diagnostics, Norman, OK, USA) is one of the most reliable screening tests in human medicine and has the benefit of providing rapid test results.[84] It has been validated in cats and dogs from Australia with a sensitivity of 92% and 100% and specificity of 81% and 84%, respectively.[85] In the United States, the assay had a sensitivity of 92% and specificity of 93.2% compared with the LCAT when applied to cats and dogs with and without cryptococcosis. Another POC assay (CryptoPS, Biosynex, Strasbourg, France) correctly classified 8/10 tested LCAT-positive specimens and 56/59 LCAT-negative specimens (sensitivity 80%, specificity 94.9%). This latter assay is semiquantitative, with high titer and low titer bands, and offers greater ease of use in practice than the IMMY assay. However, suboptimal sensitivity of this assay when compared with the IMMY assay has also been documented in humans.[86] In animals recovering from cryptococcosis with treatment, sometimes the POC assays were positive when LCAT was negative, so these assays may be more sensitive for monitoring treatment.[87] Use of a combination of POC assays and LCAT may ultimately prove to offer the highest sensitivity for treatment monitoring, but whether this leads to reduced rates of relapse requires further study.

Because the sensitivity of cryptococcal antigen testing is not 100%, cryptococcosis should not be ruled out on the basis of a negative antigen titer alone. This is especially important in dogs, because false negatives are more common in dogs than in cats.[11] False negatives are most common in animals with localized ocular, CNS, or solitary cutaneous lesions. For dogs and cats suspected to have cryptococcal meningoencephalomyelitis that have negative serum antigen titers, CSF should be submitted for cytologic examination, antigen titers, and fungal culture.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays for *Cryptococcus* spp. are offered on a commercial basis by some veterinary diagnostic laboratories. These assays can confirm the presence of *Cryptococcus* DNA in tissues or body fluids when other means fail. However, because a diagnosis of cryptococcosis is usually apparent based on the methods described earlier, PCR is currently not regarded as a routinely useful clinical tool. Because *Cryptococcus* DNA has been detected using PCR assays in small intestinal contents from healthy dogs and dogs with chronic enteropathies,[88] positive results on intestinal biopsies may not reflect cryptococcosis. Similarly, because subclinical nasal cavity colonization can occur, positive results on nasal biopsies may not represent invasive disease. Because false positives also have the potential to occur as a result of contamination in the PCR laboratory, a PCR diagnosis of cryptococcosis should always be supported by cytologic or histopathologic evidence of infection and/or culture of *Cryptococcus* spp. from a normally sterile site.

Pathologic Findings

Gross lesions associated with cryptococcosis vary from gelatinous masses that consist almost exclusively of organisms to well-ordered granulomas or pyogranulomas that typically occur in patients with improved CMI responses. The gelatinous appearance is a reflection of the large amount of capsular polysaccharide present in lesions. In sections stained with H&E, *Cryptococcus* yeasts are faint, eosinophilic, round to oval bodies that are surrounded by a clear halo (the unstained capsule). In fact, the histopathologic lesion is often dominated by the negative staining capsule, sometimes occupying most of the lesion. The organism's cell wall is more easily visualized with PAS, methenamine silver, or Fontana-Masson stain, although the capsule still does not stain well with these methods. With Mayer's mucicarmine stain, the cryptococcal capsule takes on a rose red color, and the organism appears pink against a blue background. Other fungi with similar morphologic features do not stain with Mayer's mucicarmine. Some *Cryptococcus* strains have poorly developed capsules. Infections with capsular-deficient organisms were described in four cats from the United States (Texas and upstate New York) with pyogranulomatous and eosinophilic dermatitis; in some of these cases, it was possible to identify infection with *C. neoformans* ss.[76] If necessary, IHC or the use of molecular methods (PCR) can be used to differentiate *Cryptococcus* from other fungi and molecular methods can provide information on the identity of the species complex present.[89]

Cats

In cats that die or are euthanized as a result of cryptococcosis, histopathology of lesions within the nasal cavity may reveal granulomatous rhinitis. CNS cryptococcosis consists of either meningitis[58] or meningoencephalomyelitis, with single or multiple cerebral granulomas (Fig. 82.10). Extension of infection from the meninges along perforating arteries into the Virchow-Robin spaces can result in cystic collections of yeast organisms sometimes referred to as "soap-bubble lesions" and known as gelatinous pseudocysts.[10] Ocular lesions include pyogranulomatous to granulomatous chorioretinitis, optic neuritis, uveitis, endophthalmitis, panophthalmitis, and retinal separation. Other affected organs include skin and subcutaneous tissues, kidneys, and lymph nodes. Renal granulomas have been found in some cats with disseminated disease. Granulomas can also occasionally be found in the spleen, adrenal glands, thyroid glands, and liver.

Dogs

Dogs that die or are euthanized because of cryptococcosis often have CNS infection, ocular involvement, or widely disseminated disease. The lesions consist of granulomatous or pyogranulomatous meningoencephalitis, sometimes with pseudocyst formation; neuritis of the optic, facial, or vestibular nerves; and pyogranulomatous or granulomatous chorioretinitis. Inflammatory lesions that contain *Cryptococcus* yeasts may also be present in the lungs, nasal cavity, kidneys, pancreas, liver, myocardium, GI tract, and spleen. Less commonly, involvement of the peritoneum, thyroid, tongue, prostate, pleura, joints, mediastinum, urinary bladder, and adrenal gland has been detected at necropsy.

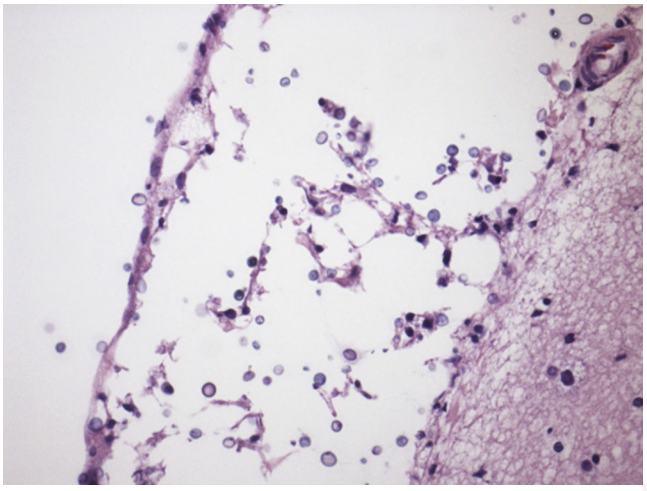

Fig. 82.10 Histopathology showing the meninges of a cat with cryptococcosis. Numerous round yeast organisms occupy the meningeal spaces. Hematoxylin and eosin stain.

TREATMENT

Treatment recommendations for dogs and cats with cryptococcosis have been based on evidence-based studies performed in human patients and clinical experiences; evidence-based studies are lacking for veterinary patients. The most common problems encountered are the high cost of therapy, requirement for multiple hospital visits, and the need for regular medication of pets for a protracted period. Resistance to antifungal medications is not common; however, development of fluconazole and flucytosine resistance has been reported.[90–92] Immunocompromised animals (which may include purebred dogs with no obvious underlying immunodeficiency) are especially likely to have persistent or progressive infection in the face of treatment. In many affected animals, treatment must be continued for years or the life of the animal. Surgical debulking could be considered before treatment for large cryptococcomas to improve drug penetration. However, even large cryptococcomas can resolve with medical treatment alone, and surgery should only be performed if lesions can be easily and safely resected. The reader is referred to Chapter 11 for detailed information on antifungal drugs.

Cats

Cats with localized cutaneous disease can sometimes be treated successfully with azole monotherapy. The initial drug of choice is fluconazole (10 mg/kg, PO, q12h), because of its good penetration of the brain, eye, and urinary tract; low cost; and minimal adverse effects.

Treatment should be continued until there is complete lesion resolution and the cryptococcal antigen titer becomes negative. A fourfold to fivefold reduction in the antigen titer suggests an adequate response. In cats with *C. gattii* ss or *C. neoformans* ss infections, this typically takes 2 to 12 months (median, 4 months),[32] although longer periods of therapy may be required for some cats. For recovered animals that achieve an antigen titer of 0, the titer can be monitored every 3 to 6 months so that any recurrence is diagnosed early. However, in the authors' experience, many cats with *C. deuterogattii* (VGII) and *C. bacillisporus* (VGIII) infections in North America fail to respond completely to fluconazole treatment, antigen titers persist at high levels, and relapse may ultimately occur after an initial treatment response. In some of these cats, treatment with itraconazole (5–10 mg/kg, PO, q24h [capsules] or 3–5 mg/kg, PO, q24h [solution]) can lead to clinical remission. Itraconazole does not have good penetration into the CNS; however, it has been used successfully to treat cryptococcal meningitis.[35,83,93] Ketoconazole has also been used with success when treating *C. deuterogattii* infections from the Vancouver Island region.[2] Serum liver enzyme activities should be monitored monthly during treatment with azole antifungal drugs to monitor for hepatotoxicity (see Chapter 11).

AMB is the most effective anticryptococcal agent. Penetration of the CNS and vitreous is poor, but clinical responses still occur in cats and dogs with CNS and ocular cryptococcosis, presumably because the blood-brain barrier is compromised. A combination of AMB and 5-flucytosine (250 mg, PO, q8h) is considered the optimal therapy for cats (and humans, but not dogs) with CNS cryptococcosis, or for those that fail to respond to azole drugs. Fluconazole can be substituted for 5-flucytosine if 5-flucytosine is unaffordable. However, 5-flucytosine shows synergy when combined with AMB and effectively penetrates the blood-brain barrier. Because resistance can develop rapidly when 5-flucytosine is used alone, it is used chiefly to improve the efficacy of other antifungal drugs.[92] Lipid-complexed AMB preparations are not necessarily more effective but are less nephrotoxic, which may translate into greater efficacy because higher doses can be used, although at a substantially increased cost. In human patients, higher doses of AMB more effectively sterilize the CSF. The reader is referred to Chapter 11 for dosing protocols for various formulations of AMB. Treatment with 5-flucytosine (or fluconazole) and AMB is continued for 2 to 4 weeks (ideally 4 weeks) or until azotemia develops, after which treatment is continued with azole monotherapy. Additional courses of AMB may be required to maintain clinical remission in some cats. Although controlled trials have not been performed, some cats with CNS cryptococcosis have shown apparent response to addition of terbinafine to the treatment regimen when other drugs failed to resolve clinical signs.[94]

Dogs

If affordable to the owner, dogs with disseminated disease or CNS involvement should be treated initially with deoxycholate or lipid-complexed AMB and fluconazole. Dogs treated with flucytosine frequently develop toxic epidermal necrolysis, typically 10 to 14 days after starting therapy, which precludes treatment with flucytosine in this species.[95] Some dogs with CNS involvement respond to azole monotherapy, although residual neurologic signs may persist.[10] Other potential outcomes include incomplete recovery, with persistent active infection despite therapy, or relapse after prolonged clinical remission. In one dog, surgical debridement of an extradural spinal cord granuloma combined with fluconazole treatment controlled spinal cord infection.[96] Again, azoles are fungistatic and rely on a CMI response and phagocytosis to remove cryptococcal yeasts from the host, which may be lacking in some dogs with cryptococcosis. Treatment of a dog with intestinal cryptococcosis with terbinafine was associated with long-term disease resolution when treatment with azoles, surgical debulking, and AMB failed.[73]

Other Antifungal Treatments

Other antifungal drugs that are effective for treatment of cryptococcosis include voriconazole and posaconazole. Both drugs penetrate the CNS and are therefore potentially advantageous for treatment of cryptococcal meningoencephalitis, but urinary concentrations are low. However, virtually all cats and some dogs do not tolerate voriconazole treatment because of GI, neurologic, and cardiac adverse effects.[97,98] In humans, posaconazole[99] is well tolerated, and it has been used to treat other fungal infections without complication in cats (see Chapter 11), so it could be an option for cats with refractory disease.[99] In the future, novel drugs such as the azole isavuconazole may offer promise for treatment of cryptococcal infections in dogs and cats,[100] but pharmacokinetic and toxicity studies will be required before agents used for humans can be considered safe and efficacious.

Supportive Care

Because many cats and dogs with CNS involvement deteriorate clinically during initial treatment with antifungal drugs as a result of the inflammatory response to dying yeasts, anti-inflammatory doses of short-acting glucocorticoids may be necessary to support animals with CNS cryptococcosis for the first few days to weeks of treatment and may increase survival rate at 10 days after initiation of treatment.[10] Deterioration of neurologic status in the first few days of treatment is not a negative prognostic indicator if the animal can be supported through this phase. Supportive care with IV fluid therapy, tube feeding, and antiseizure medications may be necessary. Rarely, dogs or cats require supplemental oxygen because of respiratory involvement.

PROGNOSIS

In general, cats show significant clinical improvement within 1 to 2 weeks of starting therapy. In studies from Australia, around 75% of cats were treated successfully.[8,32] As many as 60% of cats may be cured after an initial course of therapy, although some cats that show an initial favorable response to therapy can relapse, sometimes as long as 10 years after therapy is discontinued.[32] In one study, the median survival time of cats

with CNS cryptococcosis was only 13 days (range, 0–4,050 days), but a median survival time was never reached if cats survived at least 3 days after diagnosis, so supportive care during this phase may be critical.[10]

The prognosis is more guarded for dogs. Six of 11 dogs with cryptococcosis in Australia were treated successfully.[32] In a study from the western United States[9] and another from southwestern Australia,[5] the success rate was lower, around 30%. The median survival time for dogs with CNS cryptococcosis was 7 days (range, 0–3,680 days).[10]

In human patients with cryptococcosis, negative prognostic indicators include underlying immunosuppressive disease or drugs, abnormal mental state, high organism burden at presentation (as defined by large numbers of yeasts in the CSF and/or high antigen titers), and a poor anti-inflammatory response in the CSF (<20 cells/μL).[101] The presence of CNS disease appears to negatively affect outcome in both cats and dogs.[102,103] In dogs and cats with CNS involvement, the presence of altered mental status at first evaluation was associated with increased mortality ($P = .03$).[10]

IMMUNITY AND VACCINATION

Cryptococcosis can occur in apparently immunocompetent or in immunodeficient individuals, although those with deficiencies of CMI are most commonly infected. Production of Th1-type cytokines such as IL-2, TNF-α, and IFN-γ and a granulomatous inflammatory response are important for elimination of infection, and decline in the CD4+ T-cell count to less than 50 to 100 cells/μL correlates well with the risk of infection in HIV-infected humans.[59] No vaccines are available.

PREVENTION

Prevention of cryptococcosis may be possible through avoidance of exposure to ecologic niches of the organism, such as pigeon feces. Nevertheless, cryptococcosis occurs in animals housed exclusively indoors, and widespread exposure and recovery likely occurs in endemic areas.

PUBLIC HEALTH ASPECTS

Cryptococcosis is an important opportunistic fungal infection of humans with AIDS, in particular those who are not treated with highly active antiretroviral therapy. Human infection is acquired from the environment and not by direct contact with infected animals, although intense exposure to avian excrement has been associated with some cryptococcosis cases in HIV-infected humans.[104] Malignancy, chemotherapy, immunosuppressive drug therapy, diabetes mellitus, splenectomy, cirrhosis, or sarcoidosis can also predispose to the disease. Severe meningitis and disseminated infections can develop in immunodeficient patients. Identification of *Cryptococcus* spp. infection or colonization of cats has been proposed as a sentinel for human infection in Italy and Brazil.[53,105]

The organism does not aerosolize from sites of tissue infection, so the disease cannot spread among humans or animals. The major public health significance of infected pets is that cats may act as a sentinel for infection of human beings, because of their susceptibility to infection. In the diagnostic laboratory, culture of *Cryptococcus* is not a significant health hazard, because only the yeast form is grown routinely, and this form does not aerosolize from media. During handling of infected tissues or cultures, precautions should be taken to prevent inadvertent cutaneous inoculation of the organism. Veterinarians should consider patient sedation for procedures that involve FNA in order to avoid inadvertent needle-stick injuries, which have caused localized cutaneous infection in the human health care setting.[106] Because sporotrichosis is a major differential diagnosis for cats with cutaneous lesions, gloves should always be worn and hand hygiene performed when handling cats with suspicious lesions (see Chapter 84).

CASE EXAMPLE

Signalment

"Simon," an 8-year-old male neutered domestic shorthair cat from northern California.

History

Simon was evaluated by the University of California, Davis, VMTH, for a 5-week history of progressive weakness, inappetence, and weight loss. Initially the owners noted that he was reluctant to jump and had a low tail carriage; intermittent episodes of head shaking and sneezing were also noted. He also had episodes of clenching the furniture with his claws. Three weeks before he was brought to the VMTH, Simon was seen at a local veterinary clinic where a physical examination was unremarkable. Broad-spectrum antimicrobial drugs were prescribed (amoxicillin-clavulanic acid and enrofloxacin for 7 days), and he was treated with subcutaneous fluids (lactated Ringer's solution, 150 mL, once). Over the following 5 days his clinical signs lessened, but then anorexia developed. Physical examination 2 days after the onset of anorexia revealed a rectal temperature of 102.5°F (39.2°C) and weight loss (from 3.7 kg at the previous visit to 3.2 kg). A CBC and biochemistry panel showed mild lymphopenia (1,157 cells/μL [reference range, 1500–7000 cells/μL]). Treatment with metronidazole (39 mg/kg, PO, q24h) and prednisone (3 mg/kg, PO, q24h) was instituted. Three days before he was brought to the VMTH, he began panting and vocalizing. The metronidazole was discontinued and the prednisone dose was reduced to 1.5 mg/kg, PO, q24h. The following day, the owners noted that Simon's eyelids were twitching, and he urinated and defecated on himself in the litter box. Clindamycin (6 mg/kg, PO, q12h) was prescribed for suspected toxoplasmosis, and Simon was referred for further evaluation.

Simon had no other previous medical or surgical history apart from being neutered as a kitten. He had access to the outdoors and there were no other cats in the household. There had been no changes in his thirst or urination, no vomiting or diarrhea, and he was last vaccinated at 5 years of age. He had killed a large rat approximately 5 weeks earlier and had not been himself since.

Physical Examination

Body weight: 2.9 kg.

General: Obtunded but responsive, estimated as 5% dehydrated. T = 100.2°F (37.9°C), HR = 200 beats/minute, RR = 60 breaths/minute, CRT < 2 seconds.

Eyes, ears, nose, and throat: Bilateral mydriasis and absent pupillary light reflexes were noted. There was no evidence of nasal discharge and nasal airflow was normal. Mucous membranes were pink and slightly tacky. Fundic examination was within normal limits.

Musculoskeletal: BCS 4/9, ambulatory. The cat had a slow gait with a short stride.

Respiratory: Tachypnea was present with a normal respiratory effort. Normal breath sounds were present on auscultation.

Cardiovascular, GI, genitourinary, and lymph nodes: No clinically significant abnormalities were detected. The urinary bladder was small.

Continued

CASE EXAMPLE—cont'd

Neurologic examination: The cat was mildly obtunded, walked with a crouched stance, and behaved as if nonvisual. Bilateral mydriasis and absent menace and pupillary light reflexes were confirmed. Intermittent horizontal nystagmus with the fast phase to the left was present. Cranial nerve examination was otherwise normal. Placing and hopping reactions were delayed in the left pelvic limb. There was a decreased left patellar reflex, but other segmental reflexes were intact. There was no apparent pain on spinal palpation, but the cat appeared painful when the tail was raised. Neuroanatomic location: multifocal CNS disease.

Laboratory Findings

CBC: HCT 27.2% (30%–50%), MCV 48.3 fL (42–53 fL), MCHC 29.8 g/dL (30–33.5 g/dL), reticulocytes 8,400 cells/μL (7,000–60,000 cells/μL), WBC 12,360 cells/μL (4,500–14,000 cells/μL), neutrophils 11,000 cells/μL (2,000–9,000 cells/μL), lymphocytes 828 cells/μL (1,000–7,000 cells/μL), monocytes 445 cells/μL (50–600 cells/μL), eosinophils 87 cells/μL (150–1,100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 357,000/μL (180,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 150 mmol/L (151–158 mmol/L), potassium 4.3 mmol/L (3.6–4.9 mmol/L), chloride 115 mmol/L (117–126 mmol/L), bicarbonate 19 mmol/L (15–21 mmol/L), phosphorus 5.4 mg/dL (3.2–6.3 mg/dL), calcium 10 mg/dL (9.0–10.9 mg/dl), BUN 21 mg/dL (18–33 mg/dL), creatinine 1.2 mg/dL (1.1–2.2 mg/dL), glucose 136 mg/dL (63–118 mg/dL), total protein 7.5 g/dL (6.6–8.4 g/dL), albumin 3.8 g/dL (2.2–4.6 g/dL), globulin 3.7 g/dL (2.8–5.4 g/dL), ALT 37 U/L (27–101 U/L), AST 28 U/L (17–58 U/L), ALP 8 U/L (14–71 U/L), GGT < 3 U/L (0–4 U/L), cholesterol 177 mg/dL (89–258 mg/dL), total bilirubin < 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.018; pH 7.0; 25 mg/dL protein; no bilirubin, hemoprotein, glucose; rare WBC/HPF, 0 RBC/HPF, few amorphous crystals, few lipid droplets.

ELISA for FeLV antigen and FIV antibody: Negative.

Latex agglutination for *Cryptococcus* antigen (LCAT): Positive at 1:32,768.

Imaging Findings

Plain thoracic and abdominal radiographs: The only abnormality present was mild lateral spondylosis of the caudal lumbar spine.

Abdominal ultrasonography: The liver was mildly enlarged and contained multiple small hyperechoic foci. In the kidneys, mild cortical hyperechogenicity and decreased corticomedullary distinction were present.

Magnetic resonance imaging (brain): Precontrast images showed a well-defined, round T2-hyperintense, T1-hypointense lesion in the gray matter of the right cerebral cortex at the junction of the parietal and occipital lobes (see Fig. 82.7). Postcontrast images showed moderate contrast enhancement of this lesion. There was mild contrast enhancement of the meninges ventral to the right preoptic area. There was moderate, focal contrast enhancement of the gray matter at the lateral aspect of the right pyriform lobe. There was contrast enhancement of the medial aspect of both pyriform lobes adjacent to the hypophysis. Impressions: multifocal contrast-enhancing lesions with T2 hyperintensity and a cystic lesion in the right cerebral cortex.

Cytologic Findings

CSF analysis (cisternal): Protein concentration 29 mg/dL (reference range, <25 mg/dL). The specimen had a moderate increase in cellularity with a low number of erythrocytes. Numerous thick-capsuled yeast organisms with frequent narrow budding forms were noted, consistent with *Cryptococcus* spp. Nucleated cells consisted of nondegenerate neutrophils admixed with low numbers of variably vacuolated macrophages and small lymphocytes. The differential cell count was 83% neutrophils, 7% small mononuclear cells, and 10% large mononuclear cells.

Microbiologic Testing

Fungal culture (CSF): *C. gattii* SC. Multilocus sequence typing revealed that the organism belonged to *C. deuterogattii* molecular type VGIIa.

Diagnosis

C. deuterogattii meningoencephalitis.

Treatment

Simon was treated with deoxycholate AMB (0.25 mg/kg in 30 mL 5% dextrose IV over 30 minutes on Monday, Wednesday, and Friday for five treatments). Before and after this treatment, 0.9% NaCl was administered at twice maintenance rate and kidney analytes were monitored. Flucytosine (62.5 mg, PO, q8h) and prednisone (2.5 mg, PO, q24h) were also administered. An esophagostomy tube was placed for enteral nutrition because of persistent inappetence. By day 7, Simon appeared more alert, pupillary light reflexes and menace responses were present but weak, and nystagmus had resolved. He was discharged from the hospital on day 12, with instructions to continue treatment with fluconazole (50 mg, PO, q12h) and prednisone (2.5 mg, PO, q48h), in addition to esophagostomy tube feeding. On day 24, he was reevaluated for lethargy of several days' duration. Physical examination showed resolution of cranial nerve abnormalities, but delayed hopping reactions in all limbs were present. He was treated with six additional AMB treatments over 2 weeks. He began eating, and the esophageal feeding tube was removed on day 40. Three months after diagnosis, his neurologic signs had almost completely resolved with the exception of occasional tremors, persistent mild placing reaction deficits, and lumbosacral pain. A cryptococcal antigen titer was positive at 1:65,536. The fluconazole was replaced with itraconazole solution (3 mg/kg, PO, q12h). After an additional month, the antigen titer was 1:1024, a serum chemistry profile was unremarkable, and the owners felt that Simon was a normal cat. The prednisone treatment was discontinued thereafter. A year later, the antigen titer was 1:20. At a recheck examination 2 years later, the cat was neurologically normal. The owner declined further antigen testing and chose to continue treatment with itraconazole.

Comments

This cat had CNS cryptococcosis caused by *C. deuterogattii* (molecular type VGIIa), a hypervirulent molecular type that emerged in British Columbia and the Pacific Northwest. The treatment plan was limited by client's financial concerns, which meant that the initial course of AMB and flucytosine treatment was short, and a second course of AMB was required. Subsequently, treatment with fluconazole was associated with limited improvement, but a change to itraconazole was followed by dramatic clinical improvement and reduction in antigen titers.

Coccidioidomycosis and Paracoccidioidomycosis

Polina Vishkautsan, Jane E. Sykes

KEY POINTS

- First Described: *Coccidioides* spp. was first described in 1892 (by the medical student Alejandro Posadas), in a person from Buenos Aires, Argentina, where it was initially mistaken for a protozoan (*Coccidia*).[1]
- Cause: Coccidioidomycosis is caused by *Coccidioides immitis* and *Coccidioides posadasii* (ascomycetes, no known teleomorph).
- Affected Hosts: Primarily humans and dogs, but also a variety of other animals that include cats, domestic farm animal species, and a variety of wildlife hosts.
- Geographic Distribution: Southwestern United States, northern Mexico, and parts of Central and South America (northeastern Brazil, Argentina, Paraguay, and Bolivia). Recently cases have also appeared in eastern Washington in the United States.
- Mode of Transmission: Inhalation of arthroconidia from the environment; rarely cutaneous inoculation.
- Major Clinical Signs: Cough, fever, inappetence, weight loss, tachypnea, increased respiratory effort, lameness, subcutaneous masses or draining skin lesions, lymphadenopathy, neurologic signs, ascites due to right-sided heart failure (pericarditis), ocular lesions (uveitis, chorioretinitis, endophthalmitis).
- Differential Diagnoses: Neoplasia, other deep mycoses, mycobacteriosis, actinomycosis or nocardiosis, toxoplasmosis or neosporosis, systemic immune-mediated disease.
- Human Health Significance: Direct transmission from animals to humans does not usually occur, although sharps injuries or bite wounds from affected animals may be a source of human infection. Dogs are a sentinel for human exposure.

COCCIDIOIDOMYCOSIS

ETIOLOGY AND EPIDEMIOLOGY

Coccidioides spp. are dimorphic, soil-borne fungi that exist in the environment as a mycelium and in tissues (at 37°C) as peculiar structures known as *spherules* (Fig. 83.1). The mycelium consists of chains of haploid, multinucleated, barrel-shaped arthroconidia (or arthrospores) that alternate with smaller, thin-walled, nonviable cells. The arthroconidia remain viable in the soil for long periods. They ultimately fragment from each other and are subsequently aerosolized and inhaled by animal hosts (Fig. 83.2). The inoculum needed for infection can be small, even a few arthroconidia.[2] This can be followed by the development of coccidioidomycosis, a localized pulmonary disease or a serious multisystemic disease if dissemination occurs in the face of an inadequate immune response.

In the environment, *Coccidioides* spp. are distributed in the lower Sonoran life zone, regions characterized by semi-arid to arid soils, low elevations above sea level, and hot summers. The organism has been aptly referred to as "the dust devil."[3] Worldwide, *Coccidioides* spp. are found in the southwestern Unites States, Mexico, and parts of Central and South America, specifically northeastern Colombia, Guatemala, Honduras, Venezuela, northeastern Brazil, the Chaco region in Argentina and Paraguay, and Bolivia (Fig. 83.3). In the southwestern United States, highly endemic regions are the south-central valley of California, especially Bakersfield ("valley fever") and Arizona, especially Tucson and Phoenix.[4] Other affected states in the United States are Utah, Nevada, New Mexico, and southwestern Texas. Since 2010, cases in non-traveled dogs and humans have been reported from Washington state.[5,6] Infections also occur in non-endemic regions in dogs and humans that have a travel history to endemic regions. Over the last two decades, the incidence of coccidioidomycosis in humans and likely also dogs has been on the rise (Fig. 83.4);[7,8] it has been speculated that this may be the result of population growth in endemic areas, climate change, a larger population of immunocompromised humans, and increased recognition and reporting.[9,10]

Two species of *Coccidioides* have been identified— *Coccidioides posadasii* and *Coccidioides immitis.* These appear to cause similar clinical manifestations and have similar antifungal drug susceptibilities, but further studies are required.[11] The geographic range of *C. immitis* is largely limited to endemic regions in California and eastern Washington state, whereas *C. posadasii* is found elsewhere.[7,12] However, there may be some overlap in the distribution of these organisms.[13]

Infection of animals and humans with *Coccidioides spp.* often follows a cycle of moist conditions (required for growth of the organism in the soil), a dry period, then soil disruption, such as that may occur with heavy rainfall, earthquakes, dust storms, prolonged droughts, or construction.[14–16] An association between the presence of *Coccidioides* in the soil and small desert mammal activity has been observed; these rodents may contribute to distribution of the fungus in the soil,[7] and it has been suggested that they may act as reservoirs of the fungus.

Dogs of any breed, age, or sex may be affected, although large-breed, young adult dogs predominate in some case series.[17,18] In dogs seen at the University of California-Davis VMTH, boxers, poodles, pointers, Labrador and golden retrievers, German shepherd dogs, Australian shepherds, Dalmatians, Scottish terriers, dachshunds, and beagles are over-represented when compared with the hospital patient population.[19] When compared with a control population of dogs with diseases other than coccidioidomycosis, risk factors for coccidioidomycosis among dogs seen at the University of California-Davis VMTH were younger age (young adult rather than older adult), digging behavior, and travel to Arizona or the California central valley.[20] In this study, predisposed breeds were viszlas, Dalmatians, weimaraners, greyhounds, English pointers, bull terriers, Brittany spaniels, and

boxers. Risk factors for infection in dogs from Arizona included being housed outdoors during the day rather than indoors, roaming area more than 1 acre, and walking in the desert.[21] Latent infections may also occur in dogs and these can reactivate after treatment with immunosuppressive drugs, such as glucocorticoids and chemotherapeutic agents, including after previous recovery from coccidioidomycosis.

Although not as prevalent as in dogs, coccidioidomycosis also occurs in cats.[22,23] In two separate case series of cats from Arizona, cats ranged in age from 1 to 15 years (median, 5 years in one study and 6.8 years in another) and there was no obvious sex or breed predisposition.[22,23] Many cats were indoor only.[22] Only a small number of affected cats in the combined studies were co-infected with FIV or FeLV. Interestingly, a search of the UC Davis VMTH and pathology database from 1990 to 2015 revealed only one case of feline coccidioidomycosis, and that cat lived in Arizona, which might suggest cats are less susceptible to *C. immitis* infection than to *C. posadasii* infection.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The clinical signs of coccidioidomycosis depend on factors such as the infectious dose and the immune status of the host. Arthroconidia are inhaled and are phagocytosed by alveolar macrophages. They then enlarge into a spherule, which measures 8 to 100 µm in diameter. Hundreds of endospores then develop within the spherule, which are released when the mature spherule ruptures. These attract neutrophils, which leads to a pyogranulomatous inflammatory response. Each released endospore that escapes immune destruction then enlarges into a new spherule, and the cycle continues. Endospores can also revert to mycelial growth when removed from the site of infection. In hosts that are unable to mount an effective immune response, endospores disseminate by lymphatics to tracheobronchial lymph nodes and hematogenously to a variety of body sites. Inoculation coccidioidomycosis can rarely occur, and generally results in lesions that are localized to the site of the wound. In one report, it followed removal of a foxtail from a wound.[24] Cutaneous coccidioidomycosis appears to be predominantly a sequela of disseminated infection, whereas primary cutaneous infection is a rare event.[25]

Most infections in endemic areas are subclinical.[26] Development of clinical signs often follows a subacute to chronic course, with variable and often mild systemic signs such as intermittent fever, lethargy, inappetence, and weight loss.[17,27] Many dogs otherwise appear healthy, with occasional periods of inappetence.[17] Clinical signs may be present for days to years before veterinary attention is sought.[18] Signs of respiratory tract involvement include a harsh cough, increased respiratory effort, tachypnea, and/or exercise intolerance.[18,27] Cough may be chronic and is sometimes associated with gagging or retching; occasionally it results from bronchial compression by enlarged tracheobronchial lymph nodes. Rarely, diffuse pneumonia follows a fulminant course, with signs that resemble acute bacterial pneumonia or septic shock, as reported in immunocompromised human patients.[4]

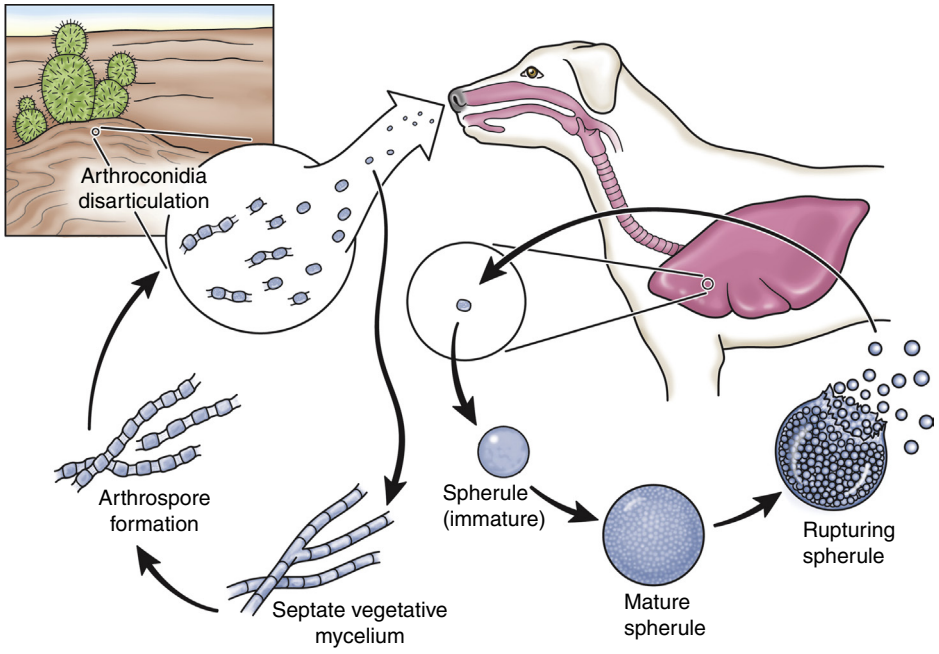

Fig. 83.2 Life cycle of *Coccidioides* spp. Hyphae fragment into arthroconidia, which are inhaled and form spherules in tissues. The spherules rupture and release endospores, which form new spherules. In some dogs, the organism disseminates from the lungs to a variety of other tissues, but especially local lymph nodes, bone, skin, the pericardium, the eye, and the CNS.

A smaller percentage of infected dogs develop disseminated infections. Sites of dissemination often include osteoarticular sites, the CNS, skin, peripheral lymph nodes, eye, reproductive organs (testes, prostate, and the uterus), and the pericardium.[18,19] Rarely, other sites such as the liver, spleen, GI tract, peritoneal cavity, and urinary system are affected.[17] Sometimes dissemination to only one anatomic site is evident; in other dogs multiple sites are involved. A history of respiratory signs may be absent.[17] Bone involvement may manifest as lameness and/or one or more firm swellings associated with the appendicular or axial skeleton. Dogs with skin involvement may have ulcerated skin lesions that drain serosanguinous fluid, or subcutaneous masses (Fig. 83.5).[17,25] Lesions are commonly located on the trunk for both dogs and cats, and in over 50% of cases lesions affect non-appendicular skeletal regions. In most cases, skin lesions should be considered separate sites of dissemination and not necessarily an extension of coccidioidal osteomyelitis.[25] Neurologic signs result from meningoencephalitis or mass lesions and include obtundation, blindness, nystagmus, absent menace reflexes, diminished gag responses, ataxia, abnormal placing reactions, pacing, circling, cervical pain, tetraparesis and seizures.[18,28–30] Ocular manifestations of coccidioidomycosis include chorioretinitis, uveitis, optic neuritis, and endophthalmitis.[18,31,32] Involvement of abdominal organs such as the liver and GI tract can lead to inappetence, vomiting, and/or diarrhea.[17] Pericarditis may lead to signs of right-sided cardiac failure, with ascites and pleural effusion.[17]

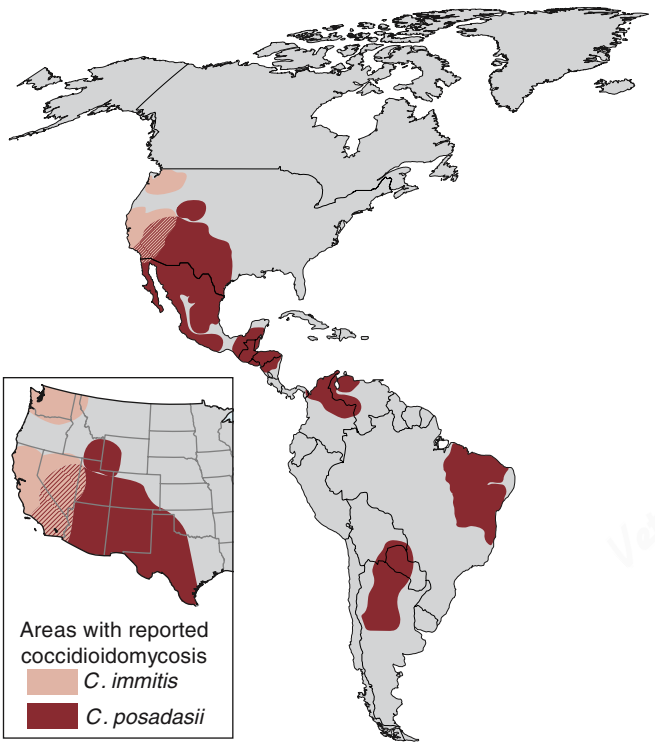

Fig. 83.3 Geographic distribution of *Coccidioides* spp. worldwide. The inset shows the distribution of *Coccidioides* species in southwestern United States. (Adapted from Ashraf N, Kubat RC, Poplin V. Re-drawing the maps for endemic mycoses. *Mycopathologica.* 2020;185:843-865)

Clinical signs in affected cats from Arizona have most often been respiratory signs (cough, tachypnea, dyspnea) and skin lesions, which may be nodular lesions, non-healing ulcers, or plaque-like crusting lesions.[22,25] In addition to those, nonspecific signs of weight loss, inappetence, and lethargy can be commonly seen. Fever and lameness due to bone involvement can also occur; lameness, paresis, or paraparesis was described in 22% of 51 cats in one case series.[22]

Physical Examination Findings

Fever is present in up to two-thirds of affected dogs with coccidioidomycosis (range, 103 to 106°F) on physical examination. Other common findings in dogs are lethargy, weakness, thin body condition or profound muscle atrophy, tachypnea, increased respiratory effort, inducible or spontaneous cough, and/or increased lung sounds.[18] Lameness and firm, often painful bony swellings with associated muscle atrophy may be present in dogs with osteomyelitis.[33] Less often, focal or (very rarely) generalized peripheral lymphadenomegaly, subcutaneous masses or draining skin lesions, or swollen joints are present. Dogs with pericardial coccidioidomycosis may have abdominal distention with a palpable fluid wave, tachycardia, tachypnea, jugular pulses, muffled breath and heart sounds due to pleural effusion, mucosal pallor, prolonged capillary refill time, and weak pulses.[34] Neurologic signs, when present, include seizures, obtundation, apparent blindness, ataxia, nystagmus, spinal pain, circling, and tetraparesis. The most common ocular abnormality is uveitis, but keratitis, conjunctivitis, granulomatous chorioretinitis, optic neuritis, retinal detachment, and endophthalmitis with secondary glaucoma have also been described.[18,31,32]

In cats with coccidioidomycosis, fever was reported in 31% of 48 cats in one study[23] and 8% of 51 cats in another.[22] Skin lesions were present in more than 40% of cats, and included draining skin

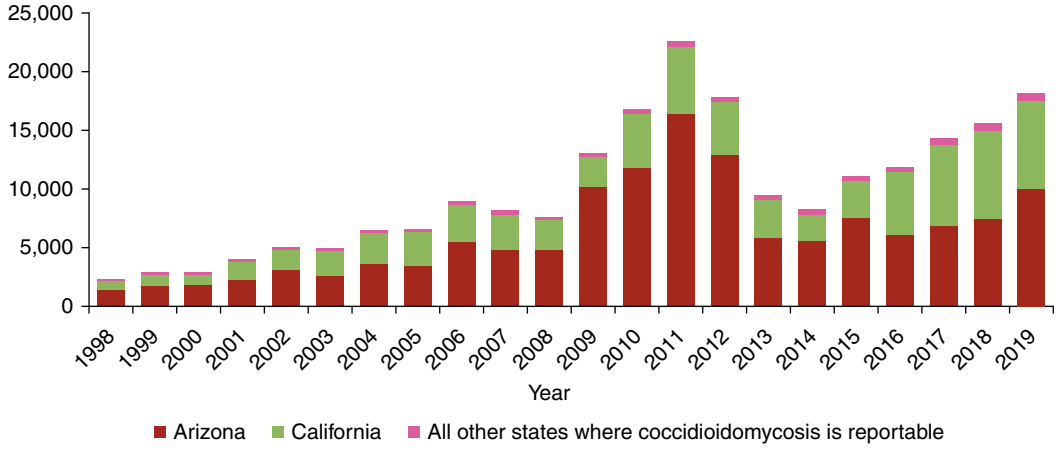

Fig. 83.4 Number of reported coccidioidomycosis cases in humans, 1998–2019. (From Centers for Disease Control and Prevention, Valley Fever (Coccidioidomycosis) Statistics. Available at https://www.cdc.gov/fungal/diseases/coccidioidomycosis/statistics.html.)

Fig. 83.5 Draining skin lesion on the left elbow of a 5-year-old shepherd mix with disseminated coccidioidomycosis. Radiography revealed a mixed productive and destructive lesion of the distal humerus and proximal ulna. Productive lesions of the sixth and seventh ribs were also present. Arthrocentesis revealed suppurative inflammation with no growth on culture. Diagnosis was ultimately made by biopsy of the synovium and serology. The *Coccidioides* antibody titer was 1:64.

lesions, subcutaneous granulomas, plaque-like crusting lesions, and abscesses.[23] Tachypnea or increased respiratory effort was present in 25% of affected cats in one study and in 39% in another; and lameness has been noted in approximately 20% of cats. Ocular abnormalities that include conjunctival masses, periorbital swellings, chorioretinitis, retinal detachment, endophthalmitis, and/or anterior uveitis have been described.[35,36] A small percentage of cats have neurological signs such as hyperesthesia, posterior paresis, seizures, and ataxia. Dissemination to abdominal organs such as the spleen can occur.[37]

DIAGNOSIS

Coccidioidomycosis is usually suspected based on a history of travel to or residence in an endemic region, and consistent clinical signs and radiographic findings. Coccidioidomycosis should be retained in the differential diagnoses for dogs and cats that have formerly lived in or traveled through endemic areas, for the rest of their lives and regardless of whether they have previously shown any sign of infection. Because the disease's geographic distribution is changing as a result of climate change, population shifts, and construction activity, early diagnosis requires a high index of suspicion in the regions where new reports of disease in people and animals become available. The diagnosis can be confirmed with cytologic examination of aspirates or body fluids, serologic assays that detect antibodies to *Coccidioides* spp., histopathology, and/or fungal culture (Table 83.1).

TABLE 83.1 Diagnostic Assays Currently Available for Coccidioidomycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions	*Coccidioides* spherules and/or endospores	Low sensitivity and organisms may be difficult to accurately identify in some specimens. Immature spherules may be mistaken for other fungi or cellular aggregates or debris
Fungal culture	Aspirates or biopsies of affected tissues, body fluids such as CSF or pleural effusion, transtracheal, or bronchoalveolar lavage specimens	*Coccidioides* spp.	Generally sensitive and specific, but false negatives are possible if specimen size is low. Can require several weeks' incubation. A significant laboratory health hazard
Antibody serology (gel immunodiffusion [ID])	Serum, CSF	IgG or IgM antibodies to *Coccidioides* spp.	Sensitivity is close to 100%. Quantification of an IgG antibody titer is possible. Titers decline with successful treatment. In hyperendemic areas, titers as high as 1:16 have the potential to exist in subclinically infected or recovered dogs, so positive serology should be supported with other diagnostic tests for coccidioidomycosis. Serologic results may be negative in early infection or in animals with weak immune responses
Antibody-detection enzyme immunoassays (MiraVista Diagnostics, Indianapolis, IN, USA)	Serum	*Coccidioides* antibodies	Sensitivity of 89% and specificity 97% on serum specimens from dogs when compared with gel ID in one study of dogs from Arizona
Immunochromatographic POC assay (Sõna, IMMY Diagnostics, Oklahoma, USA)	Serum	*Coccidioides* antibodies	Sensitivity of 89% and specificity 100% on serum specimens from dogs when compared with gel ID in one study of dogs from California; agreement of 87.5% when applied to dogs from Arizona (see text). False-negative results may occur with low gel ID titers. Provides results in less than 15 minutes
Serology for *Coccidioides* antigen	Serum, urine	*Coccidioides* spp. galactomannan antigen	Low sensitivity (≤ 20%); false positives can occur in dogs with histoplasmosis or blastomycosis. Not recommended
Real-time PCR assays	Biopsies, body fluids, respiratory lavage specimens, aspirates	*Coccidioides* DNA	Not yet validated in adequate numbers of dogs or cats with coccidioidomycosis; usefulness requires further evaluation
Histopathology	Biopsy specimens from affected tissues, such as bone biopsies	*Coccidioides* spp. spherules	Limited sensitivity in dogs; submission of multiple biopsies is recommended when possible. Often only one or two spherules are visualized. Special stains such as PAS and silver stains facilitate organism detection

Laboratory Abnormalities

Complete Blood Count

CBC findings in dogs with coccidioidomycosis are nonspecific and resemble those of other deep mycoses. Most affected dogs have mild, normocytic, normochromic, non-regenerative anemia and mild leukocytosis. Leukocytosis results from a neutrophilia, occasionally with a left shift and evidence of neutrophil toxicity.[18,34] A monocytosis and lymphopenia may also be present, but in contrast to human infections, eosinophilia is not typically present. Neutrophilia and monocytosis have also been described in affected cats.[22]

Serum Biochemical Tests

Almost all dogs with coccidioidomycosis have hypoalbuminemia, and approximately half of affected dogs and cats have hyperglobulinemia (up to 7.8 mg/dL in one study).[18,22,23] Hypoalbuminemia is usually mild to moderate, but rarely may be more severe (< 1.5 g/dL). Uncommonly, mild hypercalcemia is present. Increased activity of serum ALP may be present in some dogs, possibly as a result of bone involvement.

Urinalysis

The urinalysis in dogs with coccidioidomycosis is often normal, but significant proteinuria (urine protein-to-creatinine ratios as high as 9.5, reference range < 1) has been reported in some dogs.[18] In a series of chronic canine coccidioidomycosis cases, glomerular lesions and proteinuria were documented.[38] Dogs with coccidioidomycosis should be carefully screened for proteinuria to initiate timely treatment. In addition, testing dogs with protein-losing nephropathies that have resided in *Coccidioides*-endemic areas for anti-*Coccidioides* antibodies has the potential to identify an underlying cause.

CSF Analysis

CSF analysis in dogs with CNS coccidioidomycosis usually reveals an increase in protein concentration (generally < 300 mg/dL, reference range < 25 mg/dL), and a mild to moderate increase in the nucleated cell count (usually < 50 cells/μL, reference range < 2 cells/μL).[18] The differential cell count may show mixed, predominantly lymphocytic, mixed mononuclear, or neutrophilic pleocytosis. Organisms are generally not observed.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with disseminated coccidioidomycosis are often unremarkable. The most common radiographic finding in dogs with pulmonary coccidioidomycosis is mild to severe hilar lymphadenomegaly (Fig. 83.6A), which was present in 10 of 19 dogs with coccidioidomycosis from California.[18] Hilar lymphadenomegaly can also be present in affected cats.[22,23] Although hilar lymphadenomegaly may be present as the only finding, most dogs with hilar lymphadenomegaly also have pulmonary infiltrates, which are usually mild to moderate and interstitial. Nodular interstitial, interstitial-alveolar, bronchointerstitial infiltrates, and/or sternal lymphadenomegaly can also be present (see Fig. 83.6B and C).[18,27] Dogs with pericarditis can have cardiomegaly and pleural effusion, with hepatomegaly and decreased abdominal detail. Findings in cats with pulmonary involvement have included bronchial, alveolar, and/or interstitial patterns, consolidation of one or more lung lobes, and less commonly solitary lung nodules or pleural effusion.[22]

Radiographs of affected bones in both dogs and cats with *Coccidioides* osteomyelitis reveal local periosteal proliferation as well as osteolysis and soft-tissue swelling. Lesions can resemble osteosarcomas (Fig. 83.7).[17,22,23,33]

Sonographic Findings

Abdominal ultrasound examination of dogs with coccidioidomycosis is typically unremarkable. Mild hepatosplenomegaly and abdominal lymphadenomegaly have been described in a small proportion of dogs.[18] Dogs with *Coccidioides* peritonitis may have echogenic, elongated plaques on serosal surfaces and peritoneal effusion. Ascites, hepatomegaly, and distended hepatic veins may be evident in dogs with pericarditis and right-sided heart failure.[34]

Echocardiography in dogs with *Coccidioides* spp. pericarditis can reveal thickening and mass lesions of the pericardium, adherence of the pericardium to the epicardium, pericardial and pleural effusion, and evidence of cardiac tamponade (see Fig. 122.3).[34] Detection of pleural effusion using thoracic ultrasound was described in 2 of 51 cats with coccidioidomycosis from Arizona.[22]

Advanced Imaging

Advanced imaging findings in dogs with coccidioidomycosis have not been extensively reported in the literature. Focal, contrast-enhancing intra-parenchymal mass lesions in the brain or osteomyelitis of the skull may be identified on CT of the head.[39] Thoracic CT findings include contrast-enhancing miliary nodular pulmonary lesions; single or multifocal larger nodules or masses; tracheobronchial, sternal, or mediastinal lymphadenopathy; focal regions of alveolar or peribronchial infiltrates; lobar consolidation; pleural or mediastinal thickening; and rarely pleural effusion (Fig. 83.8).

MRI of the brain in dogs with CNS coccidioidomycosis may show focal or multifocal lesions within the brain (Fig. 83.9).[40,41] While human patients typically develop meningitis, mass lesions may be more frequently identified in dogs. When granulomas are present, they can share multiple MRI features with CNS neoplasia or other infectious or inflammatory processes. Mass lesions may have indistinct borders on post-contrast T1-weighted images. The degree of intensity on T1- and T2-weighted images varies greatly.[30] Other findings include ventricular dilation and/or meningeal enhancement. Bilaterally symmetric T2 hyperintense lesions within the frontal lobes, caudate nuclei, and rostral internal capsule, with variable evidence of faint, wispy, contrast enhancement were described in a subpopulation of dogs with CNS coccidioidomycosis from Arizona; schnauzers were overrepresented.[41] Use of other diagnostic tests such as serology or demonstration of the organism are needed for definitive diagnosis of coccidioidomycosis.

Microbiologic Tests (see Table 83.1)

Cytologic Examination

Cytologic examination of aspirates of affected tissues, pleural effusion, or respiratory lavage specimens typically reveals granulomatous or pyogranulomatous inflammation, sometimes with rare multinucleated giant cells, scattered eosinophils, and/or a reactive lymphocyte population. However, occasionally a suppurative inflammatory response predominates. Fungal elements are often not found in fluid specimens. Fluid specimens should be centrifuged and multiple aspirates of masses or lymph nodes should be collected to increase chance of detection. The clinician should alert the laboratory if there is clinical suspicion of coccidioidomycosis since often there are only very few organisms on the slide; because of their large size, they have the potential to be overlooked. Spherules may be visualized as round, deeply basophilic, double-walled, slightly crinkled structures that range in diameter from 8 to 70 μm. Spherules are generally low in number, often associated with cellular aggregates, but often they are not evident or easily identified. Usually their internal structure is not easily discernable, but occasionally endospores are seen in association with ruptured spherules (Fig. 83.10). The endospores are 2 to 5 μm in diameter, are surrounded by a thin, non-staining halo, and have small, round to oval, densely aggregated, eccentric nuclei. Endospores may be found extracellularly or within phagocytes. In one report, endospores were visualized in a fine-needle aspirate from a bone lesion in the absence of spherules.[24]

Because cytology is relatively insensitive for diagnosis of coccidioidomycosis when compared with other deep mycoses, serologic testing for coccidioidomycosis should always be considered when cytology of

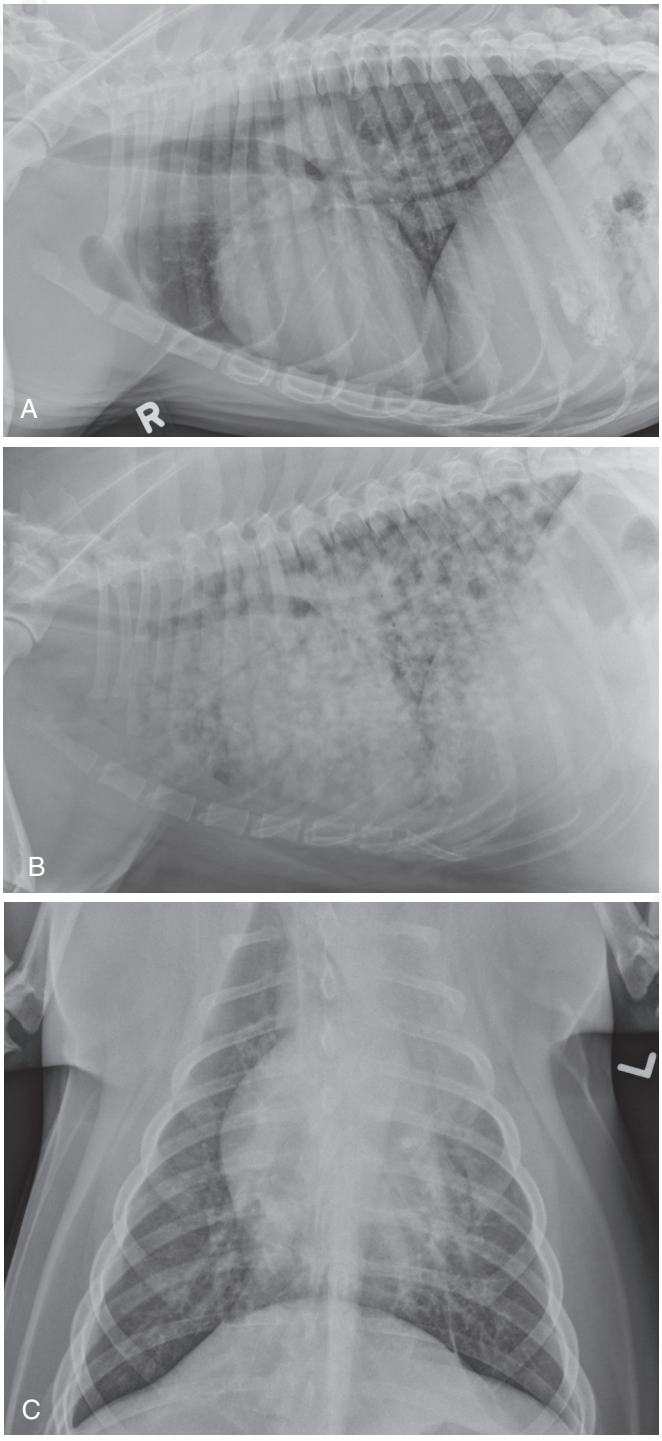

Fig. 83.6 Thoracic radiographic patterns in coccidioidomycosis. (A) Lateral thoracic radiograph from a 7-year-old intact male English pointer that shows severe tracheobronchial lymphadenomegaly and focal pulmonary infiltrates. (B) Lateral thoracic radiograph from a 3-year-old intact female Rottweiler with cough, anorexia, and respiratory distress. There are diffuse nodular and peribronchial infiltrates throughout the pulmonary parenchyma and possible hilar lymphadenopathy. Necropsy revealed necrogranulomatous interstitial pneumonia with intralesional spherules. The spleen, liver, and kidney were also involved. (C) Dorsoventral thoracic radiograph from a 2-year-old female spayed Labrador retriever with cough and inappetence. There is an alveolar pattern in the left cranial lung lobe.

tissue aspirates, body fluids, or lung washes reveals pyogranulomatous, suppurative, or granulomatous inflammation but organisms are not seen, and exposure to *Coccidioides* is possible based on the history.

Serologic Diagnosis

Serologic assays that detect antibodies to *Coccidioides* spp. are important diagnostic tests for coccidioidomycosis because organism detection assays have low sensitivity. Most diagnostic laboratories screen serum specimens with qualitative gel immunodiffusion (ID) assays for IgG or IgM antibodies (see Chapter 2). Detection of IgM (tube precipitin) or IgG (complement fixating) antibodies is reported, depending on the antigen preparation used in the assay. In dogs, IgM is detectable within 2 to 5 weeks of infection, and IgG appears after 8 to 12 weeks.[19] Quantification of an IgG antibody response can then be performed with quantitative ID, whereby serial dilutions of patient serum are subjected to gel ID.[26] In human patients, the complement fixation test is often used for quantification of IgG antibody, but frequent false-positive results have been described with this method in dogs as a result of anticomplementary properties of canine serum.[42] The complement fixation test is positive in most cats with coccidioidomycosis, with titers that range from 1:2 to 1:128.[23]

False-negative serologic test results are extremely rare in dogs with coccidioidomycosis tested at the author's institution,[18,34] but they have been described in dogs from Arizona[42–44] and rarely in cats.[22] False-negative results can occur in early infection and therefore sometimes a follow-up serologic test should be performed a few weeks later if clinical suspicion for coccidioidomycosis still remains. False-negative serologic test results can occur in immunocompromised patients. In people, false-negative results have been reported in forms of disease with a more benign clinical course, such as patients with isolated pulmonary nodules.

Positive antibody titers usually range from 1:2 to 1:256; the median titer was 1:32 in one study.[18] There appears to be no clear correlation between the magnitude of the IgG titer and the severity of illness in dogs. Dogs with active infection can have titers as low as 1:2, and healthy dogs in hyperendemic areas in Arizona can have titers as high as 1:16.[26] As a result, positive titers of 1:16 or lower should always be interpreted in light of clinicopathologic abnormalities and, in hyperendemic areas, other diagnostic tests (such as cytology or histopathology) should also be used to confirm the diagnosis if possible. Rapid antibody-detection assays have been developed, including enzyme immunoassays (EIAs) and an immunochromatographic lateral flow assay (LFA). A commercially available EIA (MiraVista Laboratories, Indianapolis, IN, USA) was evaluated in dogs compared to AGID and determined to have a sensitivity of 89.2% and specificity of 97.2%.[46] Although this assay is rapid compared to conventional gel ID, it requires shipment of specimens to a commercial laboratory, specialized training, and equipment to perform with delays in the time to diagnosis. A POC LFA for detection of antibodies to *Coccidioides* (Sōna LFA, IMMY Diagnostics, OK, USA), which received FDA approval for diagnosis of human coccidioidomycosis, has recently been assessed for the diagnosis of coccidioidomycosis in dogs. In a study from Arizona, an overall agreement of 87.5% was noted between the LFA and conventional gel ID.[47] Another study from the UC Davis VMTH revealed a sensitivity of 89% and a specificity of 100% when compared with conventional gel ID.[48] False negatives were observed in dogs with low gel ID titers, and so confirmatory testing is needed if the clinical suspicion for coccidioidomycosis remains. Otherwise, this assay represents an excellent rapid alternative to conventional gel ID.

A serologic assay that detects *Coccidioides* antigen in urine is available for diagnosis of coccidioidomycosis in human patients, such as in immunocompromised patients that lack the ability to produce significant quantities of antibody. However, preliminary data suggest that

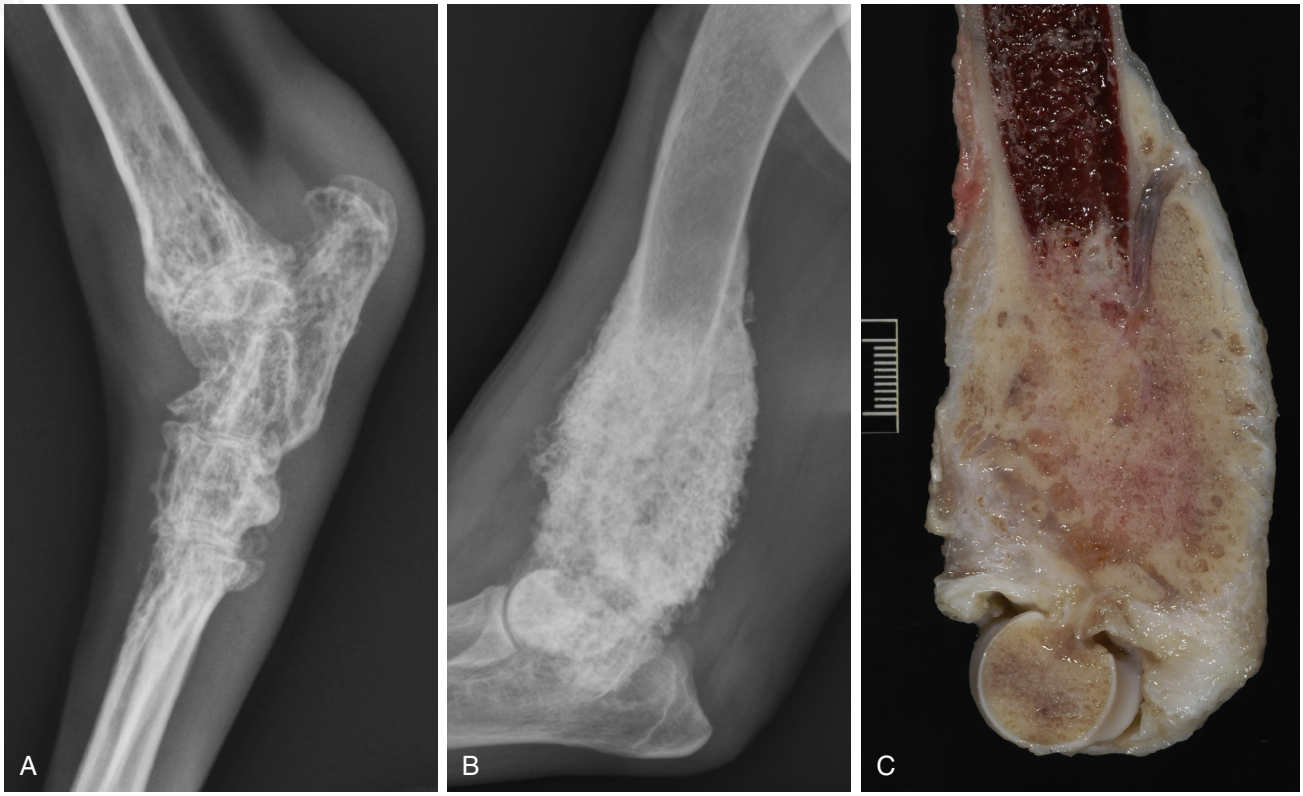

Fig. 83.7 Osteomyelitis caused by *Coccidioides* spp. (A) Left tarsus of a 4-year-old female spayed Dalmatian that was evaluated for signs of right-sided congestive heart failure due to pericarditis. Severe osteolysis is present. (B) Right humerus of a 4-year-old female spayed shepherd mix. There is a mixed productive and lytic lesion of the distal diaphysis of the right humerus. (C) Lesion in (B) at necropsy. (Courtesy of University of California, Davis Veterinary Anatomic Pathology Service.)

Fig. 83.8 CT scan of the thorax of a 2-year-old intact male Labrador retriever with coccidioidomycosis. There are infiltrates in the caudal aspect of the right cranial lung lobe which extend from the mediastinum to the pleural surface. The walls of the right cranial bronchus and associated airways are thickened. Bronchial lymphadenomegaly was also identified.

this assay has unacceptable sensitivity (≤ 20%) for diagnosis of canine coccidioidomycosis when serum, urine, or both specimens are tested, and false-positive reactions occur in a small proportion of dogs with blastomycosis or histoplasmosis.[49]

Fungal Culture

Coccidioides spp. can sometimes be isolated from clinical specimens on routine fungal media in the laboratory, but a negative culture result does not rule out coccidioidomycosis. Growth of a gray-white, downy mold that is tan to brown when visualized through the bottom of the plate usually appears after incubation for several days. The organism can be identified based on its light microscopic appearance, with or without molecular methods. Culture of *Coccidioides* spp. is a serious laboratory health hazard, and should be done by suitably equipped laboratories. The clinician should warn the laboratory of the possibility of dimorphic fungal infection if suspected.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays have been used for rapid detection of *Coccidioides* spp. in respiratory specimens or CSF from affected humans, although sensitivity has been limited.[4,50] PCR assays have also been used in epidemiological studies to identify major growth sites for *Coccidioides* spp. in soil.[51] PCR assays have not yet been widely applied to the diagnosis of coccidioidomycosis in dogs and cats.

Pathologic Findings

Gross pathologic findings in dogs with coccidioidomycosis include mottling and consolidation of the pulmonary parenchyma; single

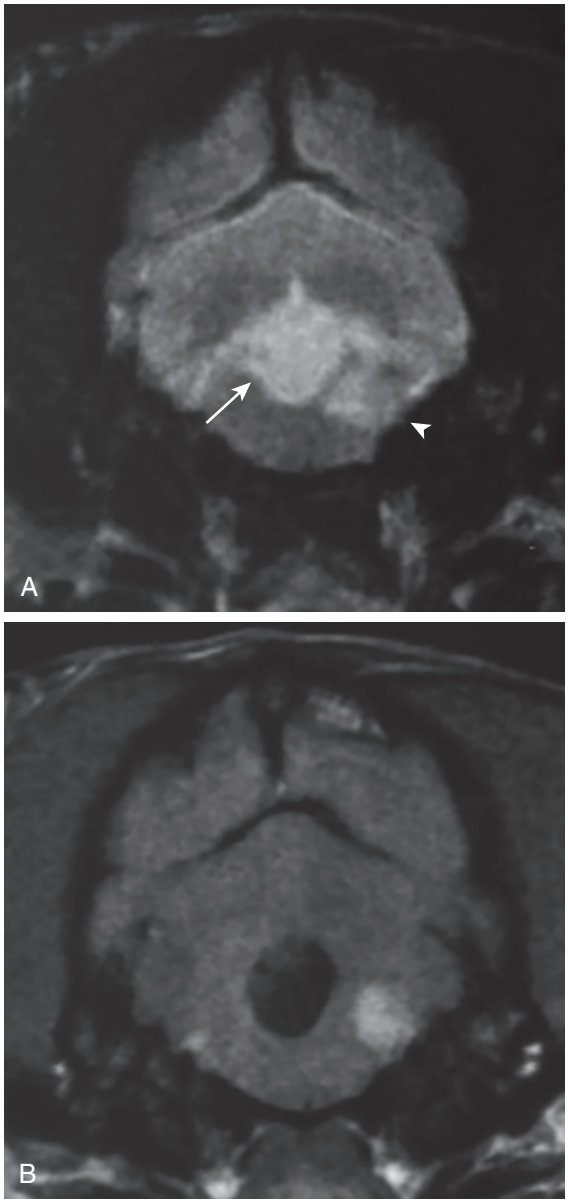

Fig. 83.9 MRI scan of the brain of a 7-year-old male neutered shih tzu with disseminated coccidioidomycosis. (A) A small focus of increased signal intensity on T2-weighting is present in the left lateral aspect of the brainstem *(arrowhead)*. Ventricular dilation is also present *(arrow)*. (B) T1-weighted image after administration of gadolinium. The lesion in the brainstem is contrast enhancing.

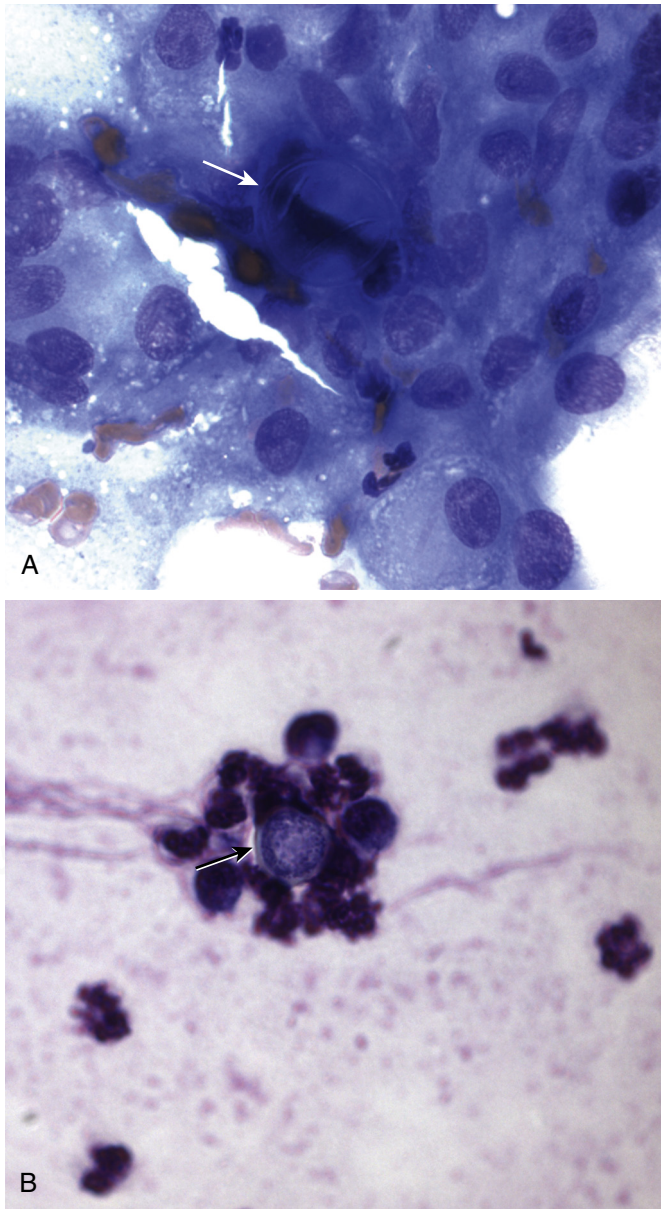

Fig. 83.10 Cytologic appearance of *Coccidioides* spp. spherules. (A) Spherules often appear as deeply basophilic, crinkled, intact, or ruptured ball-like structures *(arrow)*. (B) Sometimes, a refractile spherule wall is appreciated *(arrow)* and endospores are visualized within the spherule as granular material.

or multiple, pale masses, nodular lesions, or emphysematous bullae within the lungs (Fig. 83.11); enlarged and firm tracheobronchial, mediastinal or sternal lymph nodes; plaque-like lesions on the pleura; and pleural and pericardial effusion. The interior of masses or nodules may be firm, caseous, or liquefied. The pericardium and epicardium may be thickened with mass lesions and adhesions between the pericardium and epicardium.[34] Ascites may also be present in dogs with pericarditis. Dogs with disseminated disease may have diffuse muscle atrophy, one or more enlarged peripheral lymph nodes, irregular bony swellings with associated draining skin lesions, and/or evidence of arthritis and synovitis. Meningoencephalitis may be evident as mass lesions within the brain parenchyma, ventricular dilation secondary to obstruction of CSF flow by inflammatory lesions, regional discoloration within the brain, and/or discoloration and thickening of the meninges. Rarely prostatic enlargement, hepatic congestion and friability, multifocal nodular lesions within the myocardium or other parenchymal organs, and ocular lesions are present.

Histopathology of affected tissues reveals large numbers of neutrophils and macrophages and sometimes marked fibrosis, with occasional endosporulating or non-endosporulating spherules. Multinucleated giant cells may be present and can contain spherules.[44] Spherules have a thick wall and endospores may be visualized in mature spherules (Fig. 83.12). Often only one or two spherules are visualized, and in some cases they are not found at all. Use of special stains such as PAS and Gomori's methenamine silver can enhance organism identification within lesions. The presence of large numbers of spherules has been described in some affected cats.[37,52] Histopathologic lesions consistent

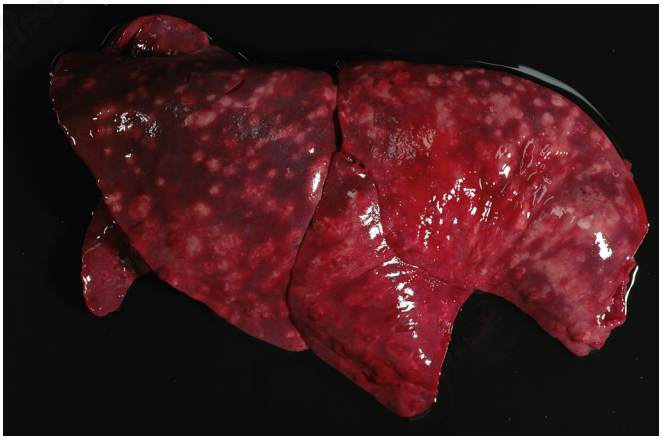

Fig. 83.11 Lungs of the dog in Figure 83.6B. Multiple pale nodules are present throughout the lung parenchyma.

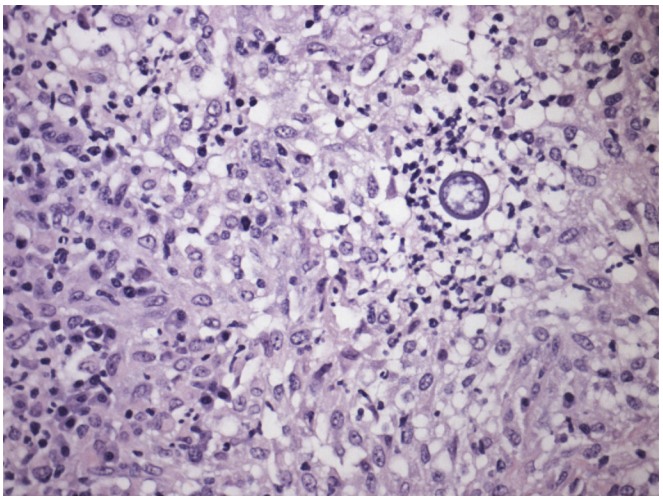

Fig. 83.12 Histopathology of the tarsus of the dog in Figure 83.7A. A single mature spherule is surrounded by a pyogranulomatous inflammatory response. The spherule contains large numbers of endospores.

with immune complex glomerulonephritis were described in dogs with chronic coccidioidomycosis. Many of those dogs had proteinuria.[38]

TREATMENT

Treatment of coccidioidomycosis typically requires a combination of antifungal drug therapy and supportive care; in some cases, surgery is required. Usually a minimum of 6 months of treatment is required.

Antimicrobial Treatment

Animals with coccidioidomycosis can respond well to azole monotherapy with fluconazole or itraconazole. Ketoconazole has been used successfully to treat dogs and cats in the past but is no longer recommended owing to its lower activity and increased rate of adverse effects. Fluconazole is the least expensive azole and may be a better choice than itraconazole for dogs with CNS involvement, because of its superior penetration of the CNS. The dose of fluconazole is 5 to 10 mg/kg PO q12h; for dogs with disseminated or refractory pulmonary disease, doses of 10 mg/kg PO q12h may be required. Occasionally, such high doses can lead to inappetence or diarrhea, especially in the first 1 to 2 weeks of treatment. Itraconazole (5 mg/kg PO q24h) is preferred for animals with bone involvement, based on clinical studies in people,[53] and may be effective in dogs that fail to respond to treatment with fluconazole. In human patients, itraconazole demonstrated a greater response rate in a blinded comparison with fluconazole.[53] Compounded formulations of itraconazole should be avoided. Small dogs are best treated with itraconazole suspension (10 mg/mL), which has higher bioavailability than the capsules (see Chapter 11). If capsules are used, they should be administered with food. If clinical signs do not improve with azole treatment, therapeutic drug monitoring could be considered to ensure serum drug concentrations are adequate. Periodic monitoring of liver enzymes is recommended for animals treated with azole antifungals.

Treatment with deoxycholate or lipid-complexed amphotericin B is recommended either alone or in combination with an azole for dogs with refractory disease or severe disease (see Chapter 11 for dosing protocols). However, studies that compare amphotericin B to azole therapy in dogs have not been performed. Combination therapy with an azole and terbinafine are anecdotally reported as beneficial in some dogs that become refractory to single azole treatment.[25] Controlled studies are lacking. Voriconazole and posaconazole have excellent *in vivo* activity against *Coccidioides* spp. Both have been used to treat refractory coccidioidomycosis in human patients.[4] These have been used to treat affected dogs[54,55] but use has been limited by expense. Voriconazole could be considered for treatment of refractory meningoencephalitis if client finances permit its use, because it has excellent penetration of the CNS.

Nikkomycin Z is a narrow-spectrum anti-fungal drug with potent *in vitro* activity against *Coccidioides* spp. It inhibits the synthesis of chitin, a fungal cell wall component which mammals lack. This drug is currently under development as an orphan drug for the treatment of coccidioidomycosis in people, but its prospects for commercial development are unclear.[56] It has shown efficacy in naturally affected dogs and experimentally infected mice.[57,58]

Surgical Management

Ultimately, some dogs with severe and persistent osteomyelitis require amputation to control the infection, and enucleation may be required for dogs with endophthalmitis. In some situations, spinal surgery is required in cases of discospondylitis or intra-spinal granulomas that cause spinal cord compression.[59,60] Successful treatment of *Coccidioides* pericarditis has been reported after subtotal pericardiectomy and epicardial excision, which should be performed in conjunction with antifungal drug therapy. The perioperative mortality rate in one study was reported as 24%, and the 2-year survival rate after discharge was 82%.[34]

Supportive Care

Other treatments that may be required for dogs with severe pulmonary coccidioidomycosis are similar to those described for blastomycosis, and include oxygen supplementation, nebulization and coupage, drainage of thoracic effusions, nutritional support, anti-inflammatory drugs, and intravenous fluid therapy. Concurrent treatment with glucocorticoids and anti-seizure medications may be necessary to reduce the severity of neurologic signs in dogs with CNS coccidioidomycosis. Topical prednisolone acetate solution and anti-glaucoma agents may be required for dogs with ocular lesions.

PROGNOSIS

The prognosis for resolution for coccidioidomycosis depends on the severity of infection and the extent of dissemination. The duration of treatment ranges from 6 months to many years, and in some cases (such as with bone or CNS involvement), life-long treatment is needed. IgG antibody titers decrease with successful treatment, which in general should be continued until lesions resolve and the titer is 1:2 or lower.

Residual radiographic opacities may be present in some dogs as a result of scar tissue formation. Dogs with localized pulmonary infection have the best prognosis; the prognosis is less predictable for dogs with CNS involvement. Long-term clinical remissions have been described in dogs treated with fluconazole for CNS coccidioidomycosis in two recent reports from Arizona.[40,41] A 2021 report of 45 client-owned dogs with suspected intracranial coccidioidomycosis described a mean duration of follow-up of 22.4 ± 20.5 months.[40] Some dogs with *Coccidioides* osteomyelitis may require life-long azole therapy.[33]

IMMUNITY AND VACCINATION

Immunity to *Coccidioides* spp. depends primarily on cell-mediated immunity, specifically T lymphocytes. No vaccine is currently available commercially for prevention of the disease, but the potential for effective immunization exists because recovered individuals rarely become reinfected. A variety of vaccine strategies have been examined for prevention of human coccidioidomycosis.[3] One candidate is a deletion mutant strain of *C. posadasii* that lacks a homolog of the gene *CPS1*, a virulence factor found in a maize pathogen. Vaccination of mice with this deletion mutant strain has protected mice from lethal infection with *C. posadasii* and *C. immitis*, and a vaccine based on this strain is currently under development for prevention of Valley fever in dogs.[3] An initial challenge study in a limited number of research beagles showed protection from disease following a prime followed by booster vaccination; subcutaneous swelling at the site of vaccination was the main adverse effect.[61] A single vaccination did not result in protection. Should this vaccine be successful, it may be a model for human vaccination.

PREVENTION

Prevention of coccidioidomycosis requires avoidance of hyperendemic areas (especially parts of Arizona and south-central California), which may not be possible. In endemic areas, dogs should be kept away from sites of soil disturbance (such as construction sites), and housed indoors during dust storms; digging should be discouraged. Housing dogs indoors during the day in endemic regions may reduce the chance of infection. Nevertheless, it should be remembered that clinical infections only develop in a minority of exposed dogs.

PUBLIC HEALTH ASPECTS

Coccidioidomycosis is a serious infection in human patients and has similar clinical manifestations to those described in dogs. As noted earlier in this chapter, coccidioidomycosis is considered an emerging infectious disease, and its incidence in people has increased in Arizona and California in the last decade, possibly as a result of population growth, immigration of immunologically naïve people, and construction. In an endemic area, construction and agricultural workers, archeologists, and excavators are at high risk for coccidioidomycosis.[2,4] African American and Filipino patients, as well as patients with AIDS and other causes of immunosuppression and women in the third trimester of pregnancy and immediately post-partum are at highest risk for disseminated disease, which occurs in approximately 1% to 3% of infected humans.[2]

Because of their susceptibility to infection, dogs have been used as a sentinel for human exposure to environmental sources of *Coccidioides* spp. in seroprevalence studies.[20,62] Direct transmission between infected veterinary patients and humans has not been reported. However, fatal disease occurred in a veterinary resident after necropsy of a horse with disseminated disease.[63] Inoculation coccidioidomycosis was reported in a veterinary technician from Arizona after a bite from a cat that was later diagnosed with disseminated disease.[37]

Inoculation coccidioidomycosis also has the potential to occur if sharps injuries occur during aspiration of affected tissues, surgical procedures, or necropsy examinations. Proper sedation or anesthesia should always be used if coccidioidomycosis is suspected in dogs or cats seen at veterinary clinics and the potential for a sharps injury exists. If accidental inoculation occurs, immediate attention should be sought from a physician. Prolonged fluconazole prophylaxis is generally recommended with monitoring of *Coccidioides* serology and liver function tests. Bandaging of skin lesions should be avoided because of a concern for conversion of the organism to a mycelial form in drying organic matter exposed to air, although no documented instances of transmission through exposure to bandages exist. Necropsies should be performed without delay with suitable protective clothing, and the carcasses of animals that die from coccidioidomycosis should immediately be incinerated. For the same reason, burial is not recommended because of the potential for contamination of the environment. Fluconazole prophylaxis is also indicated after accidental laboratory exposure to inocula.[64]

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis is a severe systemic mycosis, almost exclusively of people, endemic in Latin America (Brazil, Argentina, Colombia, Ecuador, and Venezuela). The etiologic agents are organisms that belong to the *Paracoccidioides* species complex, such as *Paracoccidioides brasiliensis* and *Paracoccidioides lutzii*.[65,66] The eco-epidemiological niche of those fungi is not well characterized.[67] The main clinical characteristics in people are development of granulomatous lesions in the lungs, lymph nodes, liver, spleen, and skin.[68] Infections result from inhalation of conidia. *Paracoccidioides* spp. have been rarely recovered from animals. To date, the fungus has been isolated from a variety of avian and mammalian species, including three dogs and a cat.[49,52,69] Serologic studies have shown that other wild animals had contact with the fungus but did not develop signs of the disease. Serologic studies in Brazil showed seroprevalence of 31.6% in cats[67] and 14.8% to 80.5% in dogs.[70] Seropositivity was higher in dogs and cats living in rural areas.[70] There are only three case reports of clinical disease in dogs. The dogs all had peripheral lymphadenomegaly, and variable evidence of other organ involvement (pneumonia, hepatosplenomegaly, epididymitis, or pyogranulomatous dermatitis),[65,69,71] resembling clinical signs described in humans. The organism was found in peripheral lymph nodes using cytologic examination or histopathology and the organism was definitively identified using culture (which can take 20 to 30 days for growth to occur) and/or molecular methods.[65,69,71] In cytologic preparations, the organism is 10 to 20 µm in diameter, oval to elongated in shape, and has a thick cell wall; simultaneous side-by-side budding of two or more daughter cells from the parent cell has led to the description of a "Mickey Mouse" and "pilot-wheel" appearance in the literature (Fig. 83.13A and B).[69] There is a granulomatous inflammatory response, and multinucleated giant cells may be present.[69] On histopathology, the organism may be difficult to distinguish from other fungal pathogens when the characteristic budding pattern is not identified (Fig. 83.13C). Itraconazole is the drug of choice and was associated with good clinical responses in dogs.[65,69,71] Paracoccidioidomycosis was diagnosed in a cat that presented with general systemic and neurologic signs. The cat was treated successfully with fluconazole and amphotericin B.[72] Paracoccidioidomycosis should be considered as a differential diagnosis for dogs and cats that reside within endemic regions, and it should be considered when yeast-like structures that resemble organisms such as *Sporothrix, Cryptococcus,* or *Blastomyces* are seen in tissues on histopathology. Increased awareness of this disease in endemic regions may lead to recognition of more cases.

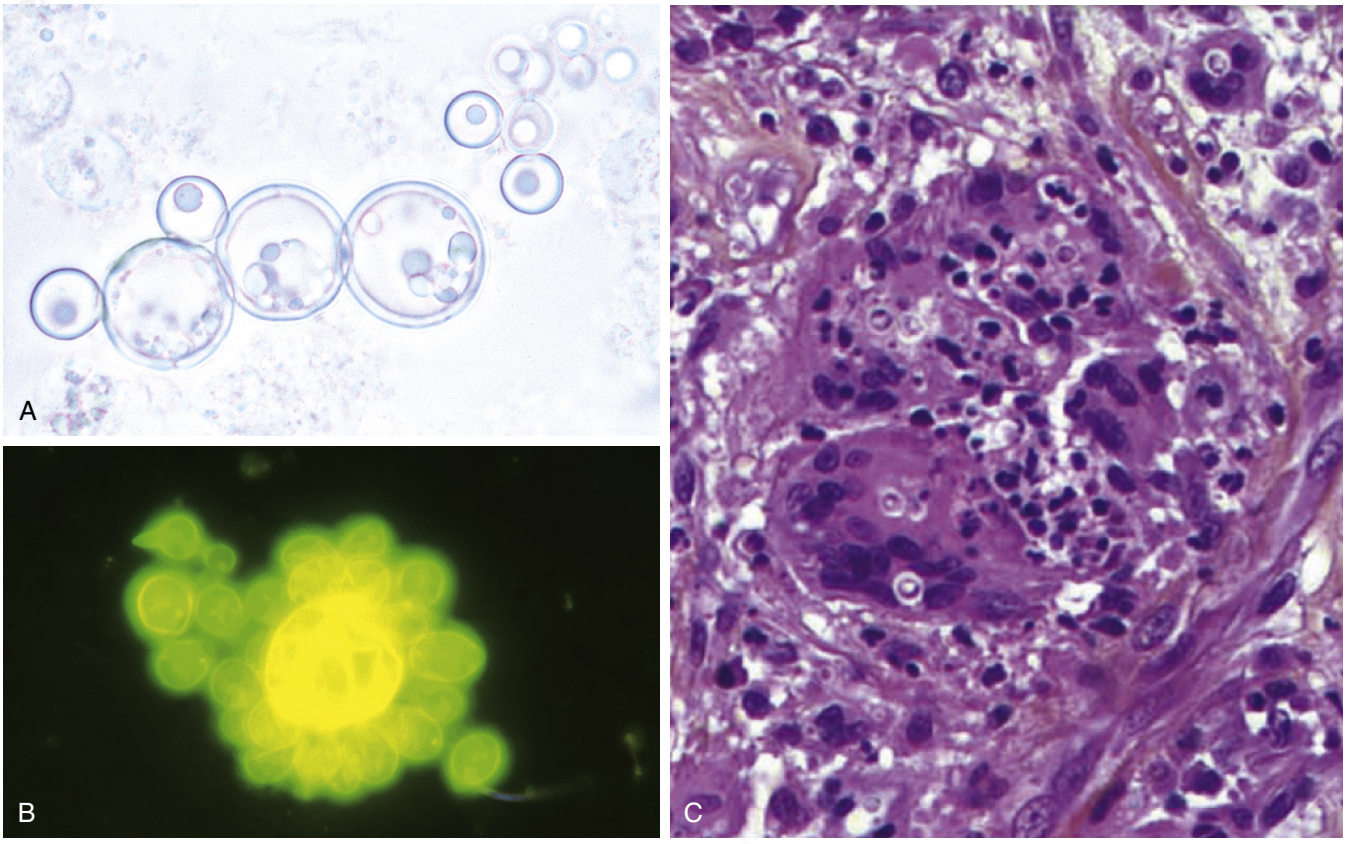

Fig. 83.13 *Paracoccidioides brasiliensis* in specimens from human patients. (A) Multiple budding and variation in cell size are apparent (potassium hydroxide preparation from purulent material, ×1000). Note the "Mickey Mouse" appearance of the organism on the left with two budding daughter cells at the 9 and 1 o'clock positions. (B) Multiple buds surrounding the parent cell are observed in a wet mount from a 36°C culture (calcofluor, ×1000). (C) Histopathologic appearance of yeast cells in tissue demonstrating multiple budding and mononuclear cell infiltration (hematoxylin and eosin stain, ×400). (From Restrepo-Moreno A, Tobón-Orozco AM, González-Marín A. Paracoccidioidomycosis. In: *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 9th ed. Philadelphia: Elsevier; 2020:3211–3221.)

CASE EXAMPLE

Signalment

"Jenny," a 2-year-old female spayed Labrador retriever from Oxnard in southwestern California.

History

Jenny was evaluated for a 2-month history of cough, inappetence, and lethargy. For the first 3 days of illness, the owner noted only an intermittent harsh, nonproductive cough. On day 4 of illness, the dog became lethargic and inappetent, so she was taken to a local veterinary clinic. Thoracic radiographs revealed alveolar infiltrates in the left cranial lung lobe. A diagnosis of bacterial pneumonia was suspected, so Jenny was treated with enrofloxacin (6 mg/kg PO q24h), clavulanic acid-amoxicillin (12.5 mg/kg PO q12h), and metronidazole (8 mg/kg PO q12h) for 2 weeks. After the first week of treatment, there was no improvement, so a long-acting cephalosporin was administered (cefovecin, 8 mg/kg, SC, once). Two days later, treatment with prednisone (0.3 mg/kg PO q12h) was initiated which was followed by only mild improvement in the clinical signs. Jenny's owner then sought a second opinion on day 20 after onset of clinical signs, and *Coccidioides* serology was performed. The titer was positive for IgG at 1:64. The prednisone was discontinued and treatment was initiated with fluconazole (6.7 mg/kg PO q12h). However, after 1 month of treatment, there had been no clinical improvement and thoracic radiographs were unchanged. The fluconazole was substituted with a compounded itraconazole formulation (5 mg/kg PO q12h). However, after an additional 2 weeks of treatment there had been no further improvement in the cough, so the owner sought a third opinion at the University of California, Davis.

According to the owner, Jenny had a poor appetite for dog food but was eating home-cooked chicken, rice, and vegetables. Her activity level had been low. The cough occurred many times throughout the day and was unrelated to exercise and eating. Occasionally she had paroxysms of cough with a terminal retch. Other medical history included canine parvovirus infection when she was 8 weeks old and "kennel cough" when she was 9 months old, which resolved after 10 days. The owners lived in a semi-rural area just north of Los Angeles. The only travel had been to Atascadero further north on the California coast. She was the only animal in the household. There had been ongoing construction around the house to replace a septic system with a sewer, which began approximately 4 to 6 weeks before the onset of clinical signs.

Physical Examination

General: Quiet but alert and responsive, hydrated. T = 102.6°F (39.2°C), P = 100 beats/min, R = 24 breaths/min, CRT = 1 s.

Eyes, ears, nose, and throat: No ocular abnormalities noted. A dilated fundoscopic examination was unremarkable.

Musculoskeletal: BCS 4/9. The dog was ambulatory with no lameness or muscle atrophy.

Cardiovascular, GI, genitourinary, and lymph nodes: No clinically significant abnormalities were detected.

CASE EXAMPLE—cont'd

Imaging Findings

Thoracic radiographs were compared to the two-view thoracic study performed 2 weeks previously, which were available for review. The initial radiographs showed a dense alveolar pattern throughout the left cranial lung lobe and increased opacity in the region of the hilar lymph nodes with splaying of the mainstem bronchi (see Fig. 83.6C). These abnormalities improved slightly in the 10-day recheck interim, but alveolar infiltrates were still present throughout the left cranial lung lobe. There was a persistent, mild, diffuse pulmonary interstitial pattern in the remaining pulmonary parenchyma, which was most severe in the caudodorsal lung fields. This was considered excessive for the age of the patient. The cardiovascular structures were within normal limits.

Microbiologic Testing

Coccidioides serology: Positive by qualitative gel immunodiffusion for complement fixing antibody (IgG), negative for IgM. Quantitative immunodiffusion revealed an IgG titer of 1:128.

Serum itraconazole concentration: < 0.31 μg/mL (undetectable).

Diagnosis

Pulmonary coccidioidomycosis.

Treatment

The itraconazole capsules prescribed at the previous veterinary clinic were examined and found to contain a white powder rather than granules. Treatment was changed to brand name itraconazole (Sporonox), because compounded formulations can be unstable. Instructions were given to administer the itraconazole (5 mg/kg PO q24h) with food to improve absorption. Aspirin was also prescribed (12 mg/kg PO q12h). One month later, Jenny's cough and activity level had improved considerably. A CBC was within normal limits and a biochemistry panel showed hypoalbuminemia (3.3 g/dL, reference range 3.4–4.3 g/dL) and hyperglobulinemia (3.4 g/dL, reference range 1.7–3.1 g/dL). Liver enzyme activities were within reference ranges. Thoracic radiographs showed resolution of hilar lymphadenopathy with persistence of the alveolar infiltrates in the left cranial lung lobe. The IgG antibody titer to *Coccidioides* was 1:64. Three months later the cough had resolved completely, and after 6 months of treatment, there was complete resolution of thoracic radiographic abnormalities and the titer was 1:32. At this point, the owner switched to a generic formulation of itraconazole due to financial concerns. After an additional 3 and 6 months of treatment, the IgG titer was 1:16 and 1:8, respectively, with no further clinical signs. Treatment was continued for an additional 3 months (i.e., total of 15 months of treatment), and the dog remains alive at the time of writing.

Comments

This is an interesting case of pulmonary coccidioidomycosis that occurred outside the hyperendemic central valley region in California. Exposure may have resulted from soil disturbance as a result of sewer work. Because of the low suspicion for the disease, the disease was mistaken for bacterial pneumonia. The owner had limited financial resources, so an extensive respiratory workup (including respiratory lavage with cytology and culture) was declined. When *Coccidioides* serology was positive, fluconazole was prescribed, but there was no improvement. The decision to treat with a compounded formulation of itraconazole was made because of client financial limitations, but serum drug levels with this treatment were undetectable. Fortunately, disease ultimately resolved with a change to a noncompounded formulation, and there was progressive decline in serial IgG titers (which were always performed by the same laboratory). Whether treatment beyond complete resolution of the radiographic abnormalities was necessary is debatable.

Sporotrichosis

Luisa H.M. Miranda, Isabella D.F. Gremião, Sandro A. Pereira, Rodrigo C. Menezes, Tânia M.P. Schubach, Jane E. Sykes

KEY POINTS

- Cause: *Sporothrix* spp. (ascomycetes).
- First Described: *Sporothrix schenckii* was first described in 1896, in Maryland, United States, by Benjamin Schenk.[1]
- Affected Hosts: Infection has been reported principally in humans and cats, as well as in dogs and a variety of other mammalian and avian species.
- Geographic Distribution: Tropical, subtropical, and temperate zones worldwide.
- Route of Transmission: Cutaneous inoculation of conidia or yeasts, or less frequently, inhalation of conidia.
- Major Clinical Signs: Cutaneous nodules or ulcerated skin lesions, lymphangitis, lymphadenomegaly.
- Differential Diagnoses: Other systemic mycoses (especially cryptococcosis in cats), mycobacterial infections, nocardiosis or actinomycosis, cutaneous leishmaniosis, SCC, feline eosinophilic granuloma complex, feline herpesviral dermatitis, abscess, foreign body granulomas.
- Human Health Significance: Many human infections are acquired from the environment, but direct transmission can follow contact between infected cats and humans, and especially cat bites or scratches.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

The fungal genus *Sporothrix* includes a group of thermodimorphic pathogens that cause human and animal infections.[1] These organisms are widespread in nature and have been isolated as a saprobe from senescent or dead vegetation, such as thorns, hay, straw, sphagnum moss, wood, and soil rich in decaying organic matter. *Sporothrix* sp. is most prevalent in warm, tropical, and subtropical climate regions. It grows in the environment or in culture at 25°C as a mycelium and converts to a small budding yeasts in mammalian host tissues or in culture at 37°C. Infectivity may result from selection of strains adapted to grow at temperatures higher than 35°C.[2] Although all *Sporothrix* isolates have in the past been grouped into the single species *Sporothrix schenckii*, multiple genotypes exist that vary in virulence and geographic distribution.[3–6] The classic agent *S. schenckii* now comprises several molecular siblings nested in a clinical clade with *Sporothrix globosa*, *Sporothrix luriei*, and *Sporothrix brasiliensis*,[7] with the latter being the most virulent.[8] The phylogenetically distant environmental species *Sporothrix mexicana*, *Sporothrix pallida*, *Sporothrix chilensis*, and *Sporothrix humicola* are rare agents of sporotrichosis in mammals being nested in the environmental clade.[8–13] However, the epidemiology of the various species of *Sporothrix* is incompletely understood. *Sporothrix brasiliensis* is so far restricted to Brazil, Argentina, and Paraguay.[14,15,16] Two different clusters of *S. schenckii sensu stricto* are prevalent in the Americas and Asia, and in the Americas and Africa, respectively. *Sporothrix globosa* is predominant in Asia and Europe, but rare in the Americas and Africa.[9] *Sporothrix schenckii, S. brasiliensis, S. humicola*,[17] and *S. albicans* have been isolated from cats, and *S. brasiliensis*, *S. schenckii*, and *S. luriei* have been isolated from dogs.[18]

Human sporotrichosis is distributed worldwide and is rare in Europe, with endemic areas in Brazil, Peru, Mexico, South Africa, China, and India. In Latin America, it is the most common subcutaneous mycosis in humans.[19] Feline sporotrichosis has been documented in the United States, Brazil, Mexico, Argentina, Spain, Germany, India, Malaysia, Japan, Australia, Paraguay, Thailand, and United Kingdom.[15,17,20–22] Reported cases of canine sporotrichosis are from the United States, Brazil, Canada, France, and Italy.[23–27] The classic infection results from direct inoculation of the fungus into skin via contact with contaminated plants or soil, or less frequently, by inhalation of conidia. Zoonotic transmission occurs through bites or scratches of animals. Infected cats are the main species implicated in the zoonotic transmission of *Sporothrix*. Additionally, there have been reports of this mycosis following bites or scratches by other animals,[28] such as armadillos, birds, and rodents, although without a significant zoonotic potential.[29] The oral cavity and claws of most animals are suggested to become contaminated from contact with the environment, which would allow the transmission of the fungus percutaneously through scratches or bites. However, the isolation of the agent from the oral cavity and claws has only been reported from cats.[30] Epidemics involving great numbers of people or wide geographic regions are rare and usually related to a common source of infection in the environment such as wood timbers and sphagnum moss.[2,31,32] *Sporothrix schenckii* has primarily been associated with sporadic transmission from the environment to humans, cats, and dogs in developed countries (Fig. 84.1). There were no reports of sporotrichosis epizootics before a cat-transmitted epidemic was reported in Rio de Janeiro, Brazil.[14,33] Between 1998 and 2015, approximately 5,000 human cases were recorded at Evandro Chagas National Institute of Infectious Diseases, Oswaldo Cruz Foundation, Rio de Janeiro, Brazil,[34] and most of them were related to zoonotic transmission by infected cats (Fig. 84.2A and B).[4] Most of the isolates from affected humans in Brazil were *S. brasiliensis*, but *S. schenckii sensu stricto* and *S. globosa* were also isolated.[7] It seems that *S. brasiliensis* is more likely associated with outbreaks of zoonotic sporotrichosis related to transmission by cats (see Fig. 84.1). Since 1998, 244 dogs were diagnosed through 2014[35] and 5,113 cats were diagnosed through 2018 at the same institution,[14] so far representing the largest outbreaks of this mycosis.[33] In Malaysia, cats seem to also take part in the transmission of *S. schenckii sensu stricto* to humans, as around 50% of the human cases from a case series reported a previous episode of scratches or bites from cats. Sporotrichosis due

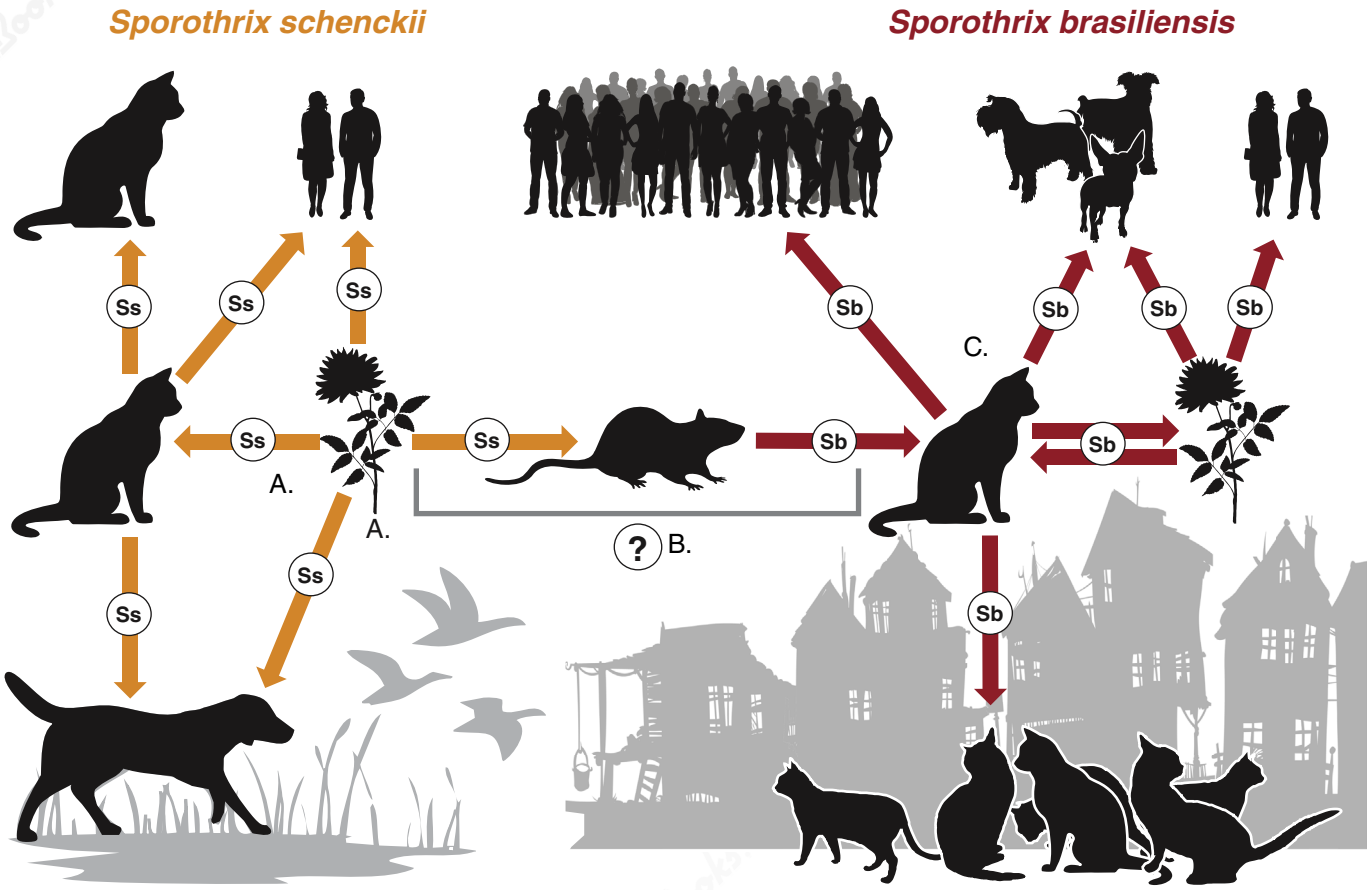

Fig. 84.1 Transmission of *Sporothrix schenckii* and *Sporothrix brasiliensis*. A, *Sporothrix schenckii* (*Ss*) is primarily transmitted through contact with environmental sources. The domestic cat may be infected and also be a source of infection to humans, dogs and other cats, primarily through scratches and bites. B, *Sporothrix brasiliensis* (*Sb*) is primarily a zoonotic pathogen that is transmitted from cats to humans. It is suggested to have shifted from an environment-adapted species to a feline-adapted species. In this scenario, the host-shifting steps are as-yet unsolved, but *Rattus norvegicus* has been hypothesized as a potential passage host (possibly through hunting behavior of cats). C, In the *Sb* zoonotic cycle, cats are the main source of infection for humans, dogs, and other cats, with resulting outbreaks most likely occurring in urban and periurban areas and affecting a larger number of individuals, in comparison with environment-acquired sporotrichosis. Likewise, *Sb*-infected cats may contaminate the environment not only through scratching but also through feces and following decomposition of their carcasses in the environment.

to *S. schenckii sensu stricto* was reported as the third principal cause of death in cats submitted to necropsy examination at a veterinary teaching hospital in Malaysia.[36–45]

Cats are the only species confirmed as a source of infection of *Sporothrix* sp., as demonstrated by isolation of fungus from skin lesions, which are rich in fungi, nasal and oral cavities, and claws of cats with sporotrichosis. The fungus isolation from the oral cavity of apparently healthy cats from Rio de Janeiro that were in contact with affected animals range from 1.5% to 3.6%.[46,47] In addition, in an endemic region in Peru, *Sporothrix* was isolated from the nasal cavity and/or nails of two cats (2.4%) without clinical signs of sporotrichosis.[48] The low prevalence of the isolation of *Sporothrix* spp. from apparently healthy cats suggests they contribute little to the transmission and maintenance of the disease. The mobility of cats in dwellings and surroundings, their habit of scratching vegetation, and their fighting behavior, especially in non-neutered male cats, may improve dispersal of the fungus in the environment.[49,50] Cats can be infected either through the classic route (environmental sources) or through scratches and bites during physical interaction with an infected cat. Direct contact with the exudate from infected cats' lesions is also a potential route of transmission, presumably facilitated by a previous breach in the skin integrity. Cat-to-cat transmission is the main route described in *S. brasiliensis* transmission.[13,14,22,47]

Canine sporotrichosis can be acquired during hunting activities with possible introduction of the organism through thorn injuries or wood splinters. However, in Brazil, the most frequent forms of transmission to dogs were through scratches, bites or contact with exudates from cutaneous lesions of cats.[23] No clear breed or sex predisposition has been identified, and dogs in the Rio de Janeiro epizootic ranged in age from 6 months to 12 years (median, 4 years). Mixed sporotrichosis and cryptococcosis was reported in a dog from Ontario, Canada.[51]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The transmission of *Sporothrix* classically results from cutaneous inoculation of organisms present in the environment, but can also result from inhalation of conidia. The cutaneous inoculation of the pathogen through scratches and bites by infected cats is also described and represents the major route of transmission of *S. brasiliensis*. Direct

Fig. 84.2 Zoonotic transmission of *Sporothrix* spp. following exposure to feline cutaneous lesions. (A) Ulcerated lesions on the left pinna, face, nasal planum, nasal mucosa, and conjunctiva of the owner's cat from Brazil. (B) Ulcerated nodular lesion on the medial canthus of the right eye of the owner, which affected the lacrimal apparatus (fistulized dacryocystitis).

contact with cats that have sporotrichosis (even without a history of a previous break in the skin) can result in transmission.[46] Following inoculation, the fungus can remain in the dermis and subcutaneous tissue at the inoculation site, spread up regional lymphatics and produce lymphangitis and lymphadenitis, or disseminate systemically through blood vessels. The incubation time usually ranges from 3 to 30 days (within 14 days in average) in human and animal sporotrichosis, but can be months.[29] The initial skin lesions are firm subcutaneous nodules that slowly soften, generally draining purulent or hemorrhagic content, and progress to form exudative ulcers with slightly elevated well-defined rims.[23,46]

The optimal interaction of *Sporothrix* PAMPs and innate immunity receptors, such as Toll-like receptors (TLRs), has shown to be determinant for phagocytosis and cytokine production.[52,53] After phagocytosis, the fungus can evade oxidative damage, such as through production of melanin and mutations in stress-activated protein kinases.[54,55] The successful dissemination into host tissues is strongly related to the pathogen's ability of binding to proteins in the extracellular matrix. In this context, cell wall adhesins on the *Sporothrix* surface can bind to fibronectin.[56,57] Organisms that are thermotolerant (able to survive at temperatures closer to body temperature, or 37°C) may be more likely to cause invasive disease.[52,53,58]

The clinical form of the disease is determined principally by the immunologic status of the host, the load and depth of the inoculum, and the virulence of the infecting *Sporothrix* species.[59] *Sporothrix brasiliensis*, the principal species involved in zoonotic transmission and the causative pathogen of feline sporotrichosis in Brazil, is remarkably virulent,[60] and has been associated with disseminated and atypical presentations of sporotrichosis in humans.[61,62]

The classification of clinical forms used for humans includes several forms: lymphocutaneous, fixed cutaneous, mucocutaneous, extracutaneous, and disseminated. More than 50% of human patients develop the lymphocutaneous form and the infection spreads proximally along lymphatics, with formation of multiple secondary nodules that may ulcerate (Fig. 84.3). Among the extracutaneous forms in humans, osteoarticular and pulmonary involvement are the most common.[54,63] Co-infection with HIV and *Sporothrix* may be associated with disseminated cutaneous lesions, systemic sporotrichosis, and hospitalization.[64]

Dogs and cats frequently display more than one of these clinical forms simultaneously. The most common lesions in dogs and cats are cutaneous nodules and ulcers, sometimes with mucosal involvement. Although the cutaneous-lymphatic form is the most frequently seen in humans, this is not the case for cats, and possibly not for dogs.[23,46] In a retrospective study involving 347 cats with sporotrichosis, the cutaneous-lymphatic form was observed in only 19.3% of cats.[46]

Cats are highly susceptible to *Sporothrix* infection. The spectrum of clinical signs ranges from a single or multiple skin lesions to fatal systemic forms due to hematogenous dissemination. Multiple skin lesions in cats can occur because of multiple inoculation sites, self-trauma, grooming,[46] or they can be a manifestation of a systemic infection. Generalized disease is frequently reported in cats with sporotrichosis, with involvement of multiple organ systems.[65,66] The detection of the fungus by histopathologic examination and/or by culture is described in the lungs, heart, spleen, kidneys, lymph nodes, adrenal glands, and liver of naturally infected cats.[66–68] Hematogenous spread may be an early event and it was demonstrated by isolation of *Sporothrix* from the peripheral blood of cats with widespread cutaneous lesions as well as cats in good general condition with localized lesions, even when no clinical signs suggestive of a septic syndrome were observed.[30,69] Fatal disseminated cases are not described in Asia, which is suggested to be due to the lower thermotolerance of *S. schenckii sensu stricto* in comparison with *S. brasiliensis*.[45] Co-infection with FIV does not appear to be a risk factor for dissemination.[69]

The occurrence of respiratory signs may also precede the beginning of the cutaneous involvement and may be observed in cats without skin lesions.[44] The high frequency of these signs, and nasal mucosa and pulmonary lesions in cats with sporotrichosis, as well as the isolation of *Sporothrix* from bronchoalveolar lavage washings and from the lungs of necropsied cats, suggest that the inhalation route of entry may have epidemiologic importance in cats.[66,70]

Physical Examination Findings

The most common clinical signs in dogs and cats are cutaneous lesions. Extracutaneous signs are frequent, and primarily consist of lymphadenomegaly and respiratory signs, such as sneezing, nasal discharge, and dyspnea. Secondary bacterial infection may occur. Other clinical signs that may be observed are anorexia, hyporexia, vomiting, weight loss, and dehydration.[23,46] Hematologic and biochemical alterations observed in dogs and cats are nonspecific.[23,46]

Dogs

In dogs, as in humans, sporotrichosis is essentially a benign disease, although disseminated forms may rarely develop.[71–73] The most

Fig. 84.3 Cutaneous lymphatic form of sporotrichosis on the right arm.

common lesions in dogs are skin nodules and ulcers, with frequent nasal mucosal involvement. Intranasal masses that protrude from the nostrils can be observed.[23,74] The skin lesions may be solitary or multiple and more frequently located on the head, especially on the nose (Fig. 84.4), followed by the limbs and thorax. Skin lesions on the nasal planum were observed in 56.8% of 44 dogs in one study, and 20.5% of dogs had nasal mucosal involvement, with isolated mucosal lesions in 3 (6.8%) dogs. The high frequency of lesions on the muzzle of dogs may be explained by injuries caused by cats that inhabit the same household environments.[23] Rarely, lesions course along lymphatics,[23,65,70,74] when they are usually associated with regional lymphadenomegaly.[23] Osteoarticular sporotrichosis occurs rarely in dogs and may manifest clinically as lameness and synovial effusion.[74,75] Disseminated cutaneous sporotrichosis in association with immunosuppressive therapy has been described in a dog.[76]

Canine sporotrichosis should be clinically differentiated from cutaneous neoplasia, cryptococcosis, histoplasmosis, blastomycosis, coccidioidomycosis, bacterial pyoderma, American tegumentary leishmaniosis, drug eruption, among others.[29,77]

Cats

The most frequent clinical forms of feline sporotrichosis are multiple skin lesions, usually in three or more anatomical sites, with involvement of nasal mucosa. Generally, cats with sporotrichosis exhibit good general health,[46] but lethargy, anorexia, and fever may occur in systemic infection.[78]

Skin lesions are characterized especially by nodules and ulcers. Plaques and tumor-like lesions are also observed.[29] The main affected site for skin lesions is the head (Fig. 84.5), especially the nasal region and the pinna. Other common sites are the distal limbs, digits, and tail, but lesions can also be found elsewhere on the body. Lesions of the conjunctiva (Fig. 84.6), and oral and genital mucosa can also be present in some affected cats. In addition to skin and mucosal lesions, lymphangitis, lymphadenomegaly, and extensive zones of necrosis that expose muscle and bone can be observed.[46]

Extracutaneous signs, particularly respiratory signs (sneezing, dyspnea, and nasal discharge) and nasal mucosa involvement, are frequent. Respiratory signs are observed in 42% of cats, mainly sneezing (39%).[79] Nasal mucosa lesions and respiratory signs can be associated with treatment failure and death.[79,80] The isolation of *Sporothrix* from nasal swab specimens and the occurrence of sneezing may precede appearance of skin lesions in some cases.[44]

Sporotrichosis differential diagnosis in cats includes neoplasia (mainly SCC), feline eosinophilic granuloma complex, bacterial pyoderma, mycobacteriosis, nocardiosis, actinomycosis, cryptococcosis, histoplasmosis, phaeohyphomycosis, American tegumentary leishmaniosis, feline herpesviral dermatitis, and severe allergic diseases (e.g., mosquito bites, flea allergy dermatosis), among others. The coexistence of sporotrichosis and other skin diseases, like neoplasia, eosinophilic

dermatosis, bacterial pyoderma, dermatophytosis, and demodicosis should be considered.[44,81]

DIAGNOSIS

A high degree of suspicion is required for the disease in non-endemic regions. Although clinical signs, patient history, and epidemiologic data can suggest sporotrichosis, definitive diagnosis depends on isolation of *Sporothrix* spp. in culture media. Cytology and histopathology are very useful routine tools for the preliminary diagnosis. IHC, serology and PCR are other options for the diagnosis of sporotrichosis.

Laboratory Abnormalities

Complete Blood Count

In many dogs and cats with sporotrichosis, the CBC is unremarkable. The most common abnormalities are mild anemia and leukocytosis due to a neutrophilia, sometimes with a mild left shift.[46,71] Monocytosis, eosinophilia, lymphocytosis, or lymphopenia may also be present. Approximately 50% of the dogs from the Rio de Janeiro epizootic were anemic, and around 20% had eosinophilia or neutrophilia.[23]

Serum Chemistry Profile

The most frequent serum biochemistry findings in cats and dogs with sporotrichosis are hyperglobulinemia and hypoalbuminemia. Increased liver enzyme activities can occur in affected cats and dogs.[23,46]

Urinalysis

Urinalysis in animals with sporotrichosis usually reveals no clinically significant abnormalities.

Diagnostic Imaging

Plain Radiography

A pulmonary interstitial infiltrate was described in one affected cat.[66] Thoracic radiographs on one dog and five cats seen at the author's teaching hospital revealed no radiographic abnormalities. Radiographs of bones that underlie skin lesions typically reveal only soft tissue swelling; rarely is underlying osteomyelitis detected.

Advanced imaging

CT of the nasal cavity in cats with lesions on the bridge of the nose may reveal masses within the nasal cavity that invade through nasal bones to involve the subcutaneous tissues (Fig. 84.7A and B). Severely thickened turbinate mucosa, an intranasal soft tissue density mass, and focal osteolysis were reported on nasal CT in a dog with signs of nasal cavity disease due to sporotrichosis.[82]

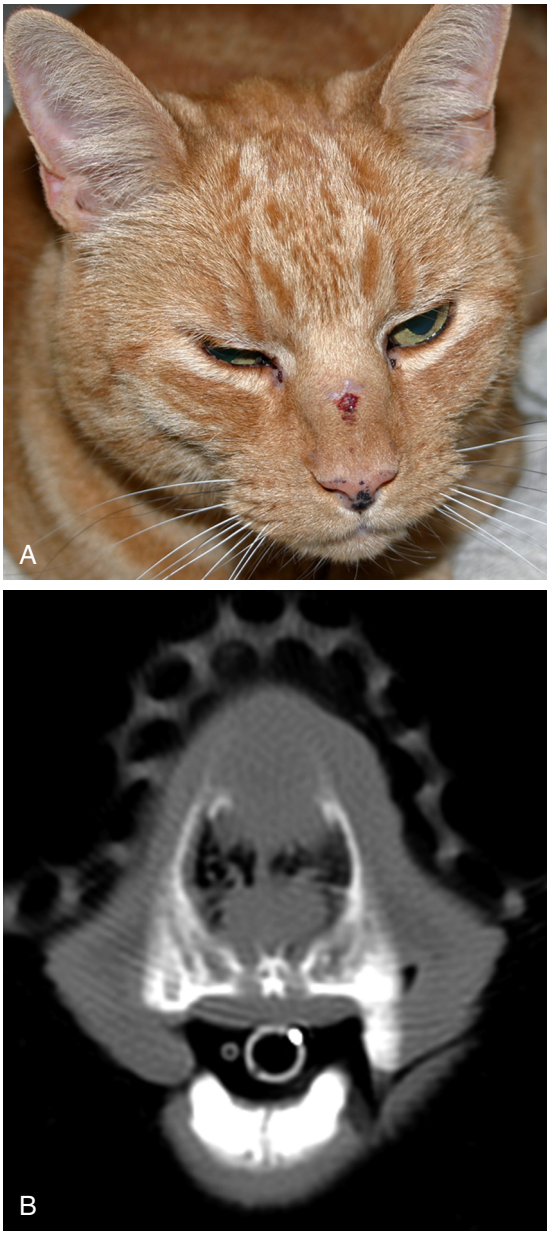

Fig. 84.7 Nasal sporotrichosis with communication to the overlying skin in a 14-year-old male neutered domestic shorthair cat. (A) The cat had a 1-year history of sneezing and a 2-month history of a mass on the bridge of the nose. (B) Computed tomography revealed a nasal cavity mass with nasal bone destruction and involvement of the subcutaneous tissues.

Microbiologic Tests

Specimens to be collected may include swab specimens of the nasal cavities, exudative lesions, and purulent or seropurulent content aspirated from nonulcerated nodular lesions, as well as incisional skin biopsy specimens.[46,83] In cats, swab specimens of exudative lesions are the recommended specimen for diagnosis of *Sporothrix* infection.[46]

Skin biopsies should be obtained from borders of active lesions with a 3- to 4-mm surgical punch. Two tissue specimens can be collected, one fixed in 10% buffered formalin for histopathology and immunohistochemical tests, and the second kept in a sterile glass flask with sterile saline and transported on ice to a diagnostic laboratory for fungal culture, preferentially within 8–10 hours.[59] In dogs, the best results for fungal isolation are from surgical skin biopsy specimens as they are more sensitive than swab specimens of exudative lesions.[23,46]

Suitable specimens for cytopathologic examination include impression smears of ulcerated skin, exudates or biopsy specimens (before placing in formalin), smears of swab specimens, skin scrapings, or fine-needle aspirates of abscesses and nodules.[84–86]

To diagnose dissemination, whole blood can be directly seeded in blood culture flasks.[69] BAL is useful for diagnosis of pulmonary involvement.[70] At necropsy, tissue specimens can be collected for mycology, cytology, histopathology, and immunohistochemical testing.

Cytopathologic Examination

The sensitivity of the cytopathologic examination of skin lesions of cats with sporotrichosis ranges from 79% to 87%.[85,87,88] This method is rapid, practical, and low cost, and a positive result can allow initiation of antifungal treatment while awaiting the results of culture.[87,89] However, despite cytopathology being highly sensitive for diagnosis of feline sporotrichosis, its sensitivity drops drastically after onset of antifungal treatment.[89] In dogs, a sensitivity of 32% was observed.[83,87]

Cytologic preparations stained with Wright or Romanowsky-type or Gomori's methenamine silver (GMS) stains permit good visualization of the yeast cells.[83,86] With Wright or Romanowsky-type staining, *Sporothrix* spp. appear as cigar-shaped to oval or round budding yeasts that are 3–5 µm by 5–9 µm in maximum length, with blue cytoplasm and a single round nucleus surrounded by a nonstaining cell wall (Fig. 84.8).[84,87] These organisms are seen mainly within the cytoplasm of macrophages, and neutrophils and also extracellularly.[76,84,85] *Sporothrix* spp. may be confused with *Histoplasma*, *Cryptococcus*, *Candida*, and *Leishmania* spp., and potentially other protozoan parasites such as *Toxoplasma gondii* and *Neospora caninum*.[29]

Fungal Culture

Fungal culture is the reference standard for the diagnosis of sporotrichosis in animals and humans due to its high sensitivity and specificity. The sensitivity of isolation from skin biopsies exceeds 95% in both dogs and cats.[23,46,65] In addition, fungal culture allows further identification of *Sporothrix* at species level by PCR.[7,8] However, it is time consuming, taking 10 to 15 days to obtain results. Other disadvantages of culture are that false-negative results can occur due to low fungal burden, prior treatment with topical or systemic antifungal agents, inadequate specimen size, deterioration of specimens during transport, and contamination with bacteria.

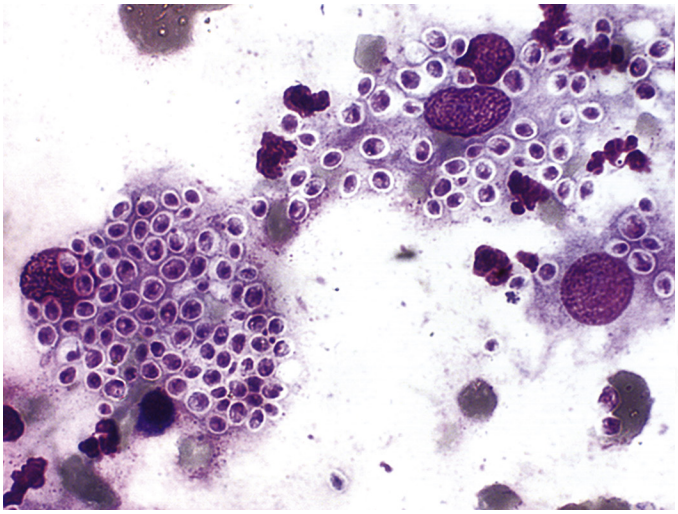

Fig. 84.8 Photomicrograph of impression smear from an ulcerated skin lesion in a cat with sporotrichosis. There are numerous oval to round and occasional cigar-shaped budding yeast-like forms. These have blue cytoplasm with a single nucleus, and are surrounded by a nonstaining cell wall. They are located within macrophages and extracellularly (panoptic stain, ×100).

Clinical material should be inoculated onto Sabouraud's dextrose agar with chloramphenicol and Sabouraud's dextrose agar with chloramphenicol plus cycloheximide and incubated at 25°C to 30°C. Mycelial growth of *Sporothrix* spp. can be observed in 3 to 5 days, although sometimes several weeks of incubation may be required.[58] Typical colonies are initially cream colored, smooth, and moist, gradually becoming dark brown or black, as a result of production of pigmented conidia, (Fig. 84.9A). However, much variation among isolates and even among subcultures of the same isolate can be observed. Various culture media can also influence the color and texture of colonies. Identification depends on the morphologic characteristics of the mycelial form and its conversion to the yeast form on blood agar or brain-heart infusion (BHI) agar plus yeast extract agar when incubated at 37°C. The microscopic characteristics of the mycelial form are slender, hyaline, septate, and branched hyphae measuring 1.5 to 2 µm in width. The conidia arise directly from the hyphae or from the apex of thin conidiophores, with conidia in a flowerlike arrangement. The intensity of colony color is directly proportional to the number of dark brown thick-walled conidia. The yeast phase is pleomorphic, showing oval or cigar-shaped cells and exhibiting single or multiple buds with elongated morphology. The organism can then be identified based on light microscopic appearance of the mold and yeast forms (see Fig. 84.9B and C).

Sporothrix species identification requires subsequent molecular analysis by specialized laboratories.[90] MALDI-TOF has also been successfully applied for the differentiation of *Sporothrix* species.[91]

Antifungal susceptibility testing can be performed, but established breakpoints are not available.

Serologic Diagnosis

ELISAs that detect antibody to *Sporothrix* cell wall antigens have been developed for diagnosis of human and feline sporotrichosis.[92–94] The best results for an ELISA's sensitivity and specificity for the diagnosis of feline sporotrichosis were 96% and 98%, respectively, using *S. schenckii* crude exoantigen, and 90% and 98%, respectively, using a cell wall antigen (SsCBF).[83]

ELISA and immunoblotting suggest 3-carboxymuconate cyclase (a 60-kDa protein in *S. brasiliensis* and a 70-kDa protein in *S. schenckii*) as

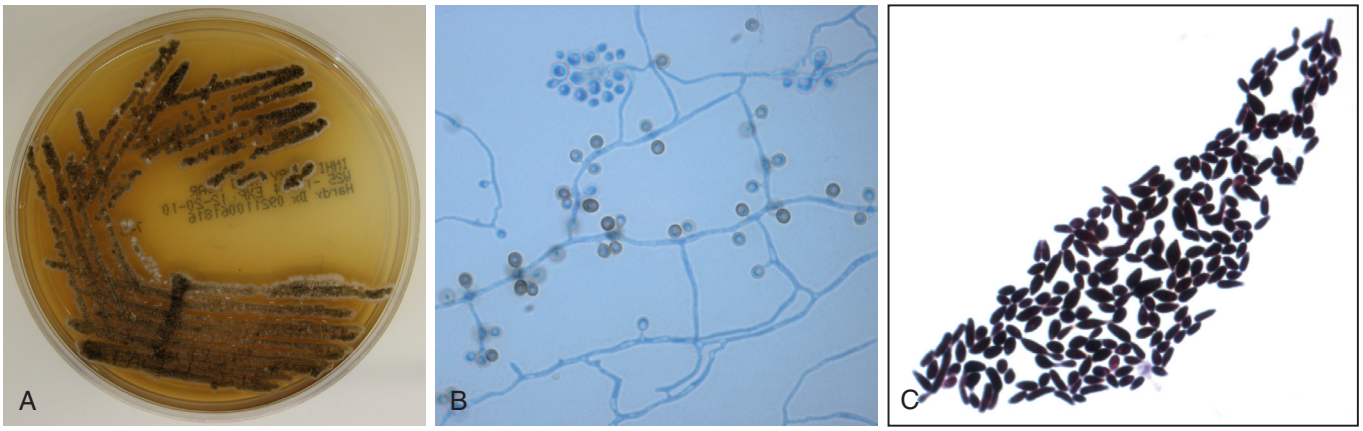

Fig. 84.9 *Sporothrix* sp. growing on laboratory media. (A) The fungus grows on fungal isolation media as a white mold at 30°C with production of pigmented conidia. (B) Using light microscopy, the mold form is characterized by the production of conidia in a flower-like arrangement and occasionally pigmented. Lactophenol cotton blue stain, 1000× oil magnification. (C) At 37°C, the organism converts to the yeast form. Gram stain, 1000× oil magnification.

the immunodominant antigen in feline sporotrichosis and a potential marker for serologic diagnosis. Although these methods do not distinguish between *S. brasiliensis* and *S. schenckii* infections, there is no reactivity when sera from healthy cats or from cats with other infections were used, so specificity appears to be promising.[94]

Recently, the ELISA test using SsCBF was adapted and validated for detecting IgG from sera of cats with sporotrichosis and is currently commercially available in private laboratories in Brazil.[22,95]

Molecular Diagnosis Using Nucleic Acid-Based Testing

Conventional identification methods are time consuming and prone to misidentification since there is an overlap of phenotypic characteristics among the species of *Sporothrix*. Therefore, rapid and accurate identification of *Sporothrix* relies on the use of molecular methods. PCR is an important tool used to identify *Sporothrix* species from animals and humans, especially when isolates are not identified by morphologic and physiologic phenotyping. PCR sequencing targeting the calmodulin gene is most used, but PCR sequencing targeting ITS1/2, large-subunit (LSU) ribosomal DNA, β-tubulin, chitin synthase,[9,96,97] and translation elongation factor[96,98] can also distinguish among species of *Sporothrix*. Recently, more rapid molecular assays that do not need sequencing for identification were developed. These include PCR fingerprinting based on random amplification of polymorphic DNA (RAPD) using the universal primer T3B,[99] amplified fragment length polymorphisms,[98] PCR-restriction fragment length polymorphisms (RFLPs),[100] species-specific PCR,[101] and rolling-circle amplification (RCA).[102–104] A PCR assay targeting the chitin synthase 1 gene was used with success for specific and rapid detection of *Sporothrix* DNA and identification at genus level in a biopsy specimen from a cat with sporotrichosis.[105] A species-specific PCR targeting calmodulin gene sequences has also been described, including its direct application in clinical specimens from cats with sporotrichosis.[101,106] In addition, RCA has been used to successfully detect and identify *Sporothrix* from both clinical and environmental specimens.[102]

Pathologic Findings

Gross Pathologic Findings

In addition to cutaneous and mucosal lesions, the main gross lesions in cats are small whitish nodular lesions measuring approximately 1 mm in diameter on the pleural surface and parenchyma of the lungs, and enlargement of lymph nodes.[65]

Histopathologic Findings

Histopathology of cutaneous lesions of feline and canine sporotrichosis is characterized by ulcerative and variable but usually intense pyogranulomatous inflammatory reaction in the dermis, which can reach the panniculus and subjacent skeletal muscles.[107,108] The inflammatory infiltrate usually reveals a predominance of neutrophils and macrophages, variable number of plasma cells and lymphocytes. Eosinophils and mast cells can be occasionally seen.[74,108,109] Multinucleated giant cells are infrequent in dogs and cats compared with their occurrence in humans.[108–110] The presence of Splendore-Hoeppli phenomenon ("asteroid bodies") around yeasts is commonly described in human infections,[111] but this is not typically observed in dogs or cats.[107,111]

There is a predominance of poorly formed granulomas (poorly delineated) in cutaneous lesions from cats, dogs, and humans with sporotrichosis.[23,107,108,110] Organized granulomas are less common (approximately 11%) in skin lesions of cats (Fig. 84.10) compared with dogs (38%–45%) and humans (38%).[23,107,108,110] Cats tend to have poorly formed granulomas composed of macrophages filled with yeast-like forms and a mild neutrophilic and lymphoplasmacytic surrounding reaction (Fig. 84.11).[108]

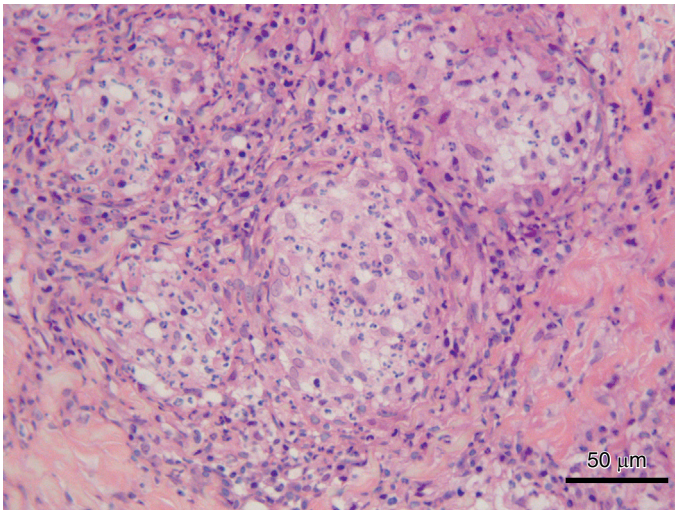

Fig. 84.10 Photomicrograph of a histologic section of a skin lesion of a cat with sporotrichosis showing multiple well delineated suppurative granulomas with a predominance of epithelioid cells (well-formed granuloma) (hematoxylin-eosin stain).

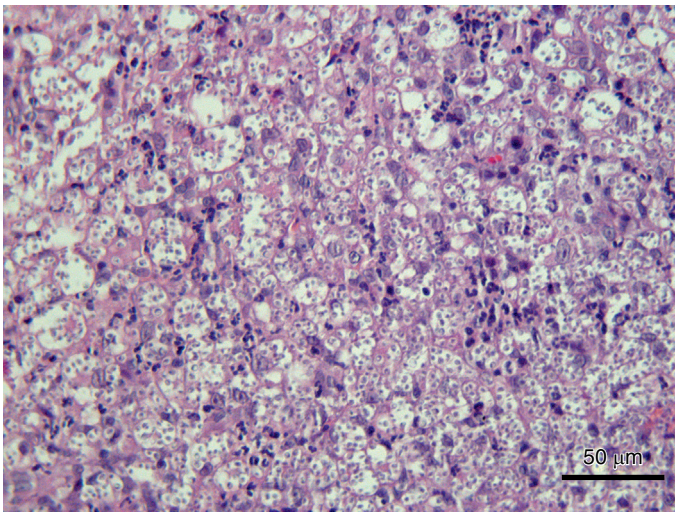

Fig. 84.11 Photomicrograph of a histologic section of a skin lesion of a cat with sporotrichosis showing poorly formed granulomas composed by macrophages filled with yeast-like forms (hematoxylin-eosin stain).

Systemic involvement is common in cats and a pyogranulomatous inflammatory reaction and yeasts can be observed in the lungs, spleen, lymph nodes, liver, kidneys, adrenal glands, eyes,[66–68] skeletal muscles, and tongue. Cats with intranasal sporotrichosis often have severe pyogranulomatous rhinitis with osteomyelitis, osteolysis, and necrosis of hyaline cartilage (Fig. 84.12).[44]

Histopathologic findings are nonspecific and similar to those of other pathogenic fungi and protozoans.[109] Therefore, histochemical stains such as GMS and PAS are needed to highlight *Sporothrix* spp. in tissues.[46,67] *Sporothrix* spp. yeasts are oval or cigar-shaped, range in size from 4 µm to 6 µm, generally exhibit a single bud with a narrow base, and are dark staining using GMS (Fig. 84.13A) and pink using PAS. Pseudohyphae, hyphae, and yeast-like forms with multiple budding are occasionally seen.[39,44,68] Yeast-like forms of *Sporothrix* spp. should be differentiated from those of *Histoplasma* spp., which are smaller (2 µm to 4 µm), do not present cigar-shaped forms, and are usually grouped in clusters inside macrophages.[112]

The yeast-like forms of *Sporothrix* can be seen inside neutrophils, macrophages, giant cells and osteoclasts, or extracellularly in purulent exudate and inflamed areas.[44] In cats with sporotrichosis, the number of *Sporothrix* organisms is usually high and can be detected in 94% of histopathologic examinations of skin biopsies stained by GMS.[46,67,68,108] Higher fungal loads in skin lesions detected by histopathology (GMS) were linked to young age and treatment failure with itraconazole (ITZ), as well as to poorly formed granulomas with fewer inflammatory cells and a longer time for wound healing.[80]

In dogs, as in humans, the yeast-like forms are usually rare, and the fungus is visualized in tissue specimens stained by PAS and GMS in approximately 17% and 44% of cases, respectively.[23,110,113] Use of GMS increases sensitivity when compared with PAS for diagnosis of canine sporotrichosis. Around 58% of cases show a maximum of five fungal elements in multiple histologic sections of skin biopsies.[108,113]

In order to increase the sensitivity of histologic diagnosis in formalin-fixed paraffin-embedded (FFPE) tissues from dogs, IHC is recommended. An IHC protocol using a rabbit anti-*Sporothrix* hyperimmune serum and an avidin-biotin detection system was described for the diagnosis of *Sporothrix* in FFPE skin samples of dogs (Fig. 84.13B) and cats.[113] The sensitivity of this assay was 65% in dogs and 88.6% in cats.[88,113] However, anti-*Sporothrix* antibodies are not commercially available.[114]

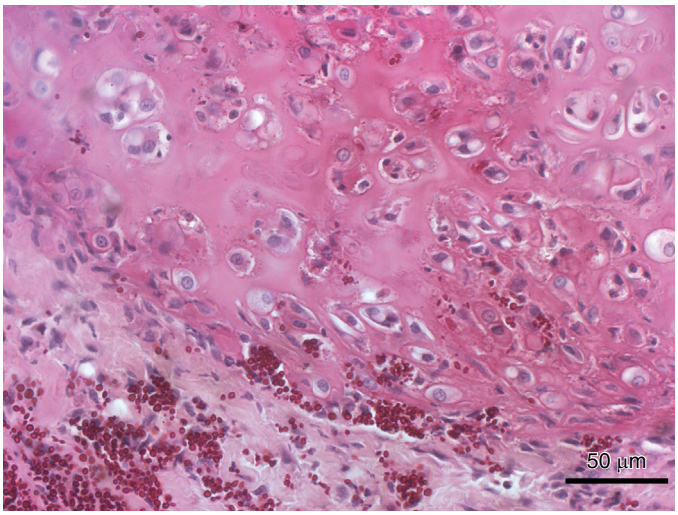

Fig. 84.12 Photomicrograph of a histologic section of the nasal mucosa and associated cartilage from a cat with intranasal sporotrichosis. There is a high load of yeast-like organisms that infiltrate cartilage (periodic acid–Schiff stain).

TREATMENT AND PROGNOSIS

Treatment of dogs and cats with sporotrichosis still represents a challenge for veterinarians.[115] The cost and availability of antifungal drugs vary and this often dictates the choices made.[74]

Antifungal drugs for sporotrichosis include ketoconazole (KTZ), ITZ, potassium iodide (KI), sodium iodide (NaI), terbinafine, fluconazole (FLZ), or AMB. Treatment of animal sporotrichosis should be continued for at least a month after complete resolution of clinical signs. Other therapeutic options are local thermotherapy, cryosurgery, and surgical resection of cutaneous lesions.[116–118] Clinical and biochemical monitoring is strongly recommended,[78] regardless of the prescribed treatment regimen. ITZ is considered the drug of choice in human, feline, and canine sporotrichosis treatment.[2,79,84,118] The recommended dosage of ITZ capsules for the treatment of feline or canine sporotrichosis is given with food to facilitate absorption (Table 84.1).[46,84] ITZ solution permits more accurate dose measurement and improved absorption and bioavailability at the recommended dose so that dosages per unit body weight are lower[46] (see Table 84.1); however, this formulation is not available in some countries. Compounded formulations are not recommended in substitution to the reference drug as they might not be bioequivalent, while generic formulations can be a suitable alternative (see Chapter 11).[22]

Concurrent bacterial infections should be simultaneously treated with an appropriate antibiotic/antibacterial agent.[119] Use of glucocorticoids or any immunosuppressive drug is contraindicated in dogs and cats during and after the treatment of the disease, because the disease can worsen or recur.[78,120] There are risks of fetal malformations associated with the use of KTZ and KI. Administration of any azole, terbinafine,[121] and KI[122] should be avoided during pregnancy.

Treatment response is assessed through clinical evaluation, and cure is defined as complete remission of cutaneous and extracutaneous

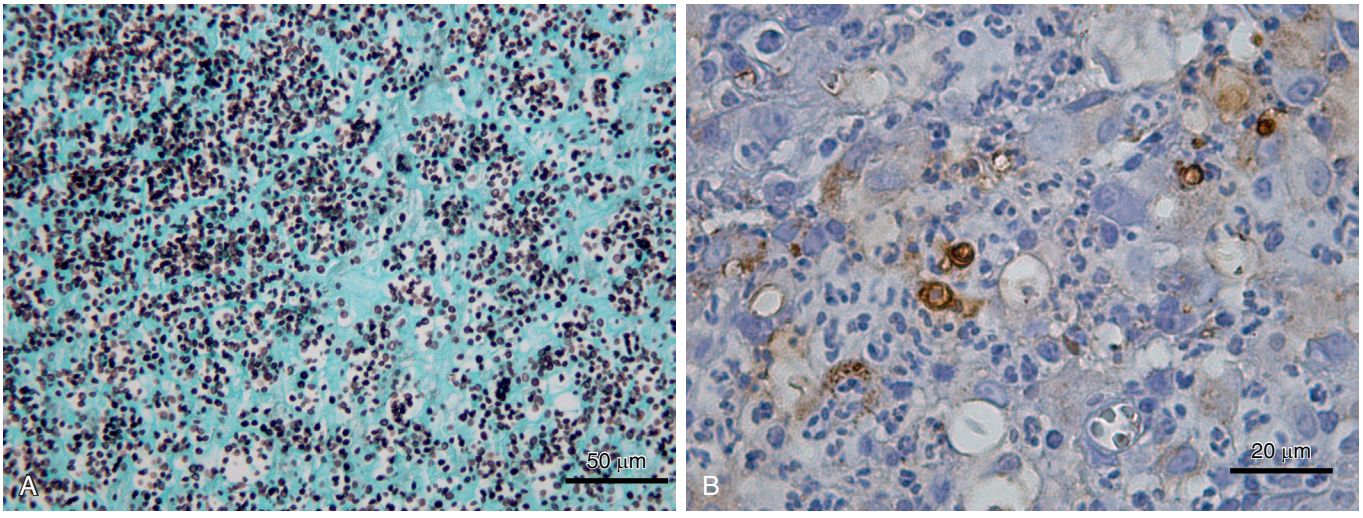

Fig. 84.13 Photomicrograph of a histologic section of a skin lesion of a cat with sporotrichosis following application of special stains and immunohistochemistry. (A) Large numbers of dark staining yeast-like forms are visualized with silver staining (Gomori's methenamine silver stain). (B) Dark brown yeast-like forms of *Sporothrix* are identified using immunohistochemistry using a rabbit anti-*Sporothrix* sp. hyperimmune serum and avidin-biotin detection system.

TABLE 84.1 Recommended Treatment for Sporotrichosis[a]

Drug	Species	Dose (mg/kg)[b]	Route	Interval (hours)
Supersaturated solution of potassium iodide	Dog	40	PO	8
	Cat	10–20	PO	12
Sodium iodide	Cat	10	PO	12
Potassium iodide (KI) capsules	Cat	2.5–20	PO	24
KI + itraconazole capsules	Cat[c]	KI 2.5–5.4	PO	24
	Dog	KI 4.5	PO	PO
Ketoconazole tablets	Dog	5–10	PO	24
	Cat	5–27.0	PO	12–24
Itraconazole capsules	Dog	5–10	PO	12–24
	Cat	5–27.7	PO	12–24
Itraconazole solution	Cat	1.25–3	PO	24
Terbinafine tablets	Cat	30	PO	24
	Dog	30	PO	24
Fluconazole capsules	Cat	10	PO	24

[a]Continue treatment at least 30 days beyond resolution of all clinical signs.
[b]Dose per administration at the specified interval.
[c]Itraconazole 100 mg/day.
PO, oral; *IL*, intralesional administration.

signs. The cooperation and persistence of the owners is instrumental in attempting a successful response to therapy. When sporotrichosis is not treated for an adequate time, it often recurs, usually with respiratory signs.

Importantly, in regions where zoonotic transmission of *Sporothrix* spp. occurs, the treatment of infected cats is one of the main control measures of this mycosis.

Cats

Sporotrichosis is more difficult to treat in cats than in dogs, generally requiring a prolonged period of therapy. Four to six months of treatment are usually necessary for a successful outcome, but in some cats, treatment may last more than a year.[86] Additionally, even when there is remission of clinical signs, fungal clearance cannot be confirmed and recrudescence may occur.[46]

In a retrospective study, the effectiveness and safety of ITZ and KTZ were assessed for the treatment of 773 *Sporothrix*-infected cats[79]: 598 cats received oral KTZ tablets and 175 cats received oral ITZ capsules at dosages listed in Table 84.1. Clinical cure was achieved in 238 (30.8%) cats, 171 (29%) with KTZ and 67 (38%) with ITZ. The median treatment time using either KTZ or ITZ was similar (26 to 28 weeks). Adverse effects were reported in 39.6% of the cats, with a higher occurrence in cats treated with KTZ. Hyporexia was the most frequent adverse effect, followed by vomiting and/or diarrhea. The high prevalence of adverse effects was attributed to the use of higher dosages than those usually employed for the treatment of feline sporotrichosis.[46,78,84] Higher doses were used because of the difficulty in achieving clinical cure with those recommended by the literature.[79] Nevertheless, the doses were similar to those used by other authors for the treatment of cats with systemic mycoses such as coccidioidomycosis and cryptococcosis.[123,124] When adverse GI effects related to KTZ and ITZ were observed, the total daily dose was split in two equal parts and given every 12 hours instead of every 24 hours.[78,84] Because of its effectiveness and safety in cats, ITZ has replaced KTZ in the treatment of feline sporotrichosis.

NaI or KI were otherwise considered the drugs of choice in human and canine sporotrichosis, but serious adverse effects have limited their use, especially in cats. Oral administration of supersaturated potassium iodide (SSKI) was used to treat sporotrichosis in cats, dogs (see Table 84.1 for doses), or humans in the past, before the widespread availability of ITZ. In the treatment of feline sporotrichosis, controversial results have been related with the use of SSKI or supersaturated sodium iodide (SSNaI). Some authors reported clinical cure and others the worsening of clinical condition and death.[125–127] Cats are very sensitive to iodides, and adverse effects can occur such as anorexia, depression, vomiting, hypothermia, hyperthermia, cardiovascular failure, cardiomyopathy, hyperexcitability, muscular spasms, ptyalism, and diarrhea.[128]

The use of KI capsules in lower doses than those previously employed (see Table 84.1) has re-emerged as an effective alternative for the treatment of feline sporotrichosis.[129,130] Because of its extremely bitter taste, a capsule formulation of KI has been used to treat affected cats, with a cure rate of 48% after 4 to 5 months (median time to achieve clinical cure was around 19 weeks).[130] Inappetence occurred in 52% of cats, and a smaller percentage of cats developed weight loss, diarrhea, or vomiting. Increased liver enzyme activities can also occur. The dose range used was 2.5 to 20 mg/kg, PO, q24h (median, 15 mg/kg). The dose was increased in 2.5 mg/kg increments every 5 days from the initial dose. Alterations in thyroid function can be an adverse effect of KI treatment in humans.[131]

Higher cure rates in feline sporotrichosis have resulted from use of a combination of KI capsules and ITZ.[129] The combination allowed the reduction of KI dose (see Table 84.1) compared with KI monotherapy, and led to a cure rate of 96.2% in a prospective cohort study (Fig. 84.14A and B). Dose increments of 2.5 mg/kg at every 30-day period were employed in those cats with worsening or persistence of clinical signs. Adverse effects were observed in 50% of the cats from this study and were managed with temporary treatment interruption and/or the introduction of hepatoprotective therapy with oral silymarin (30 mg/kg, PO, q24h). Clinical adverse effects, such as hyporexia, vomiting, and weight loss, were reported

Fig. 84.14 Feline sporotrichosis during treatment. (A) Cat with multiple skin lesions on the head and thoracic limbs after 6 months of treatment with itraconazole. (B) Clinical cure after 6 additional months of therapy with a combination of itraconazole and potassium iodide.

in 20% of the cats, while a mild elevation in transaminase activities was detected in almost 17% of cats. The occurrence of clinical adverse effect was similar to that described for ITZ monotherapy and lower than that with the use of KI alone. This is likely to be explained by lower doses of KI when combined with ITZ, in comparison with KI monotherapy.[129]

Cats with ITZ-refractory sporotrichosis can be treated with the combination of ITZ and KI, notably when respiratory signs and nasal mucosa lesions are present.[132] The primary indication for AMB is the treatment of sporotrichosis refractory to ITZ.[116] Systemic administration of AMB by the IV route in cats is limited because of its adverse effects, mainly nephrotoxicity and thrombophlebitis.[36,67,127] Intralesional AMB administration in combination with ITZ was used successfully to treat fixed or multifocal cutaneous lesions in cats that were refractory to ITZ alone.[116,133] The solution was prepared by addition of 5 mL of 2% lidocaine and 5 mL of distilled water to a 50-mg vial of AMB (final concentration, 5 mg/mL). A total of 0.5 to 1.5 mL (median 0.7 mL) was administered intralesionally once a week to once every other week, and 73% of the cats were cured. The number of treatment sessions ranged from 1 to 5 (median, 2 treatment sessions per cat). Sterile abscess formation at the site of administration occurred in 15% of cats.[133]

Although terbinafine has been effective for treatment of cutaneous forms of human sporotrichosis,[134] and *in vitro* susceptibility studies have shown promising results,[135] its employment for the treatment of feline sporotrichosis is poorly described[46] and its effectiveness and safety in cats are not known.

FLZ is recommended for lymphocutaneous sporotrichosis in humans when the patient cannot tolerate other agents. In one cat with disseminated sporotrichosis, cutaneous lesions and respiratory signs resolved during treatment with FLZ, although an additional course of treatment was needed following relapse.[74] The effectiveness and safety of FLZ in the treatment of feline sporotrichosis needs to be further clarified.

Surgical resection of a lesion combined with antifungal therapy can be an alternative after failure of antifungal treatment in humans and cats, as long as the anatomic location of the lesions enables surgical intervention.[38,136–138]

Localized hyperthermia has been used as a safe and inexpensive method to treat fixed cutaneous and lymphocutaneous sporotrichosis in human patients and was used as the sole treatment in a cat with localized cutaneous disease.[139] In that case, a thermal bag that reached a temperature of 40°C to 42°C was applied twice daily for 15 minutes. When used alone, this method is not likely to be effective in animals with disseminated disease.

Lastly, cryosurgery was apparently effective in the treatment of 11 cats with sporotrichosis that were concurrently treated with ITZ,[140] initiated prior to the cryosurgical procedure. The treatment length until clinical cure ranged from 14 to 64 weeks (median 32 weeks), after starting ITZ therapy. Although the treatment duration until cure was longer than that reported with other schemes, this protocol can be an option for cats that do not tolerate higher doses of ITZ and in which systemic disease signs are not observed.

Despite the occurrence of treatment failure in cats, clinical cure may be achieved. The likelihood of cure is unrelated to the severity of the initial clinical findings. However, involvement of the nasal mucosa, respiratory signs, and high fungal loads detected by cytologic examination or histopathology in skin lesions are predictors of treatment failure with ITZ.[80,89] Co-infection with FIV does not seem to alter the likelihood of treatment success.[47] Clinical cure following treatment has been observed in the majority of the cats co-infected with FIV or FeLV. Moreover, the difference between the median treatment time to clinical cure in FIV-positive and FIV-negative cats was not statistically significant.[79]

Relapse can occur between 3 and 18 months after discontinuation of antifungal drug therapy. Spontaneous regression of a persistent cutaneous lesion was also described in a cat.[47] In animals with advanced disease, euthanasia may be indicated. This should also be regarded as a management alternative when long-standing clinical stagnation or progressive worsening of clinical condition is observed even under adequate therapeutic protocols. The expensive antifungal therapy and the concerns for zoonotic transmission are additional factors in which euthanasia is to be considered.

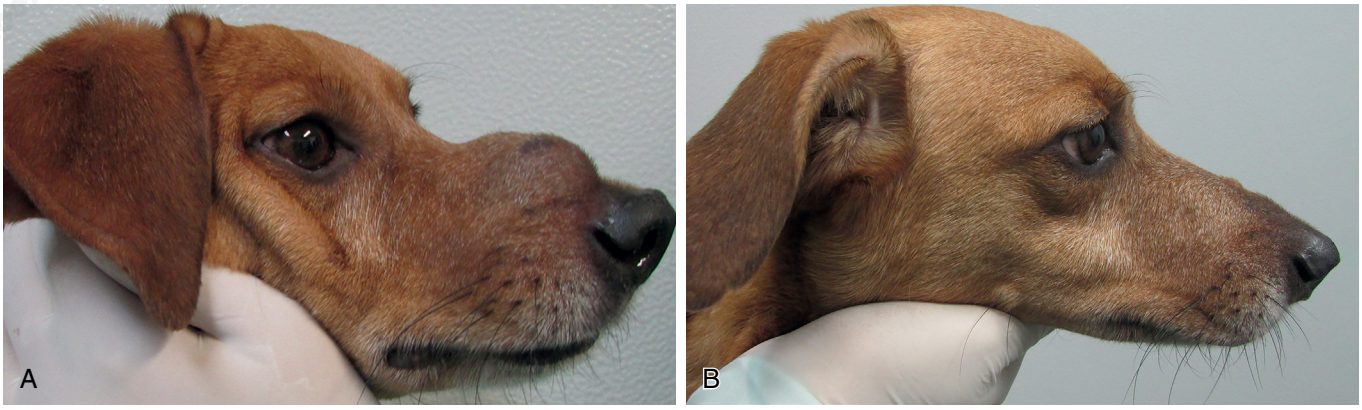

Fig. 84.15 Canine sporotrichosis during treatment. (A) Before treatment is initiated. There is a large subcutaneous mass lesion on the muzzle. (B) Clinical cure after 8 months of itraconazole therapy.

Dogs

Generally, canine sporotrichosis has a good prognosis and is easily treated. Spontaneous regression of cutaneous lesions has been described in a few cases[31] and dogs have remained lesion-free for 1 to 4 years on follow-up examinations.[23]

ITZ capsules can be used to treat canine sporotrichosis (Fig. 84.15A and B) at recommended dosages (see Table 84.1) for 2 to 5 months.[23] Adverse effects include anorexia, vomiting, diarrhea, elevated hepatic enzyme activities, and cutaneous vasculitis (see also Chapter 11).[141–143]

Although KTZ is not the first choice for treatment of canine sporotrichosis, clinical cure was obtained with the recommended dosage in Table 84.1 for 2 to 5 months.[23] Potential hepatotoxicity should be monitored during therapy.[119,144]

The treatment of canine sporotrichosis with oral administration of a SSKI is also described (see Table 84.1), but dogs should be monitored for any signs of iodism (mucopurulent oculonasal discharges, salivation, and weakness). If toxicity occurs, the medication should be discontinued for a week. If the adverse effects are mild, they may not recur, and therapy should then be reinstituted. If the adverse effects recur or the initial reactions were severe, another drug should be considered.[78] Although the effectiveness of KI capsules (see Table 84.1) for treating canine sporotrichosis is poorly known, a successful outcome was described in one dog with no reported adverse effects.[145]

Recently, terbinafine was described for the treatment of sporotrichosis in two dogs, being successful even in the presence of respiratory signs and nasal mucosa lesions. It may be a suitable alternative in animals that do not tolerate ITZ therapy.[146]

IMMUNITY AND VACCINATION

Most of the knowledge on the immune response to *Sporothrix* infection is derived from studies from human sporotrichosis and animal models.

The immune response to *Sporothrix* infection involves both innate and adaptive mechanisms. Elements from the *Sporothrix* cell wall function as PAMPs for recognition by pattern-recognition receptors (PRRs), such as TLRs and C-type lectin receptors (CLRs),[147] expressed by innate immune cells.[148] These contribute to the enhancement of a further adaptive response.[149,150] The generation of oxidative species during phagocytosis in the experimental model is also involved in fungicidal activities.[151]

Whether *Sporothrix* infection leads to a severe or a mild disease clearly is affected by the host's immune response in murine and human studies. Th1-dependent immunity, through $CD4^+$ cells and activated macrophages, persists as a required mechanism in the defense to *Sporothrix*,[152] while the response to more virulent strains of the fungus seem to be Th2-shifted.[153] Recently, Th17 also emerged as an important branch of immune response for fungal clearance in sporotrichosis.[154]

Cellular immunity is also recognized as important in the response to feline infections.[155] Cats with localized sporotrichosis that are in good general condition typically display well-organized granulomatous lesions with a lower fungal burden and a higher percentage of $CD4^+$ cells in their peripheral blood when compared with cats with disseminated sporotrichosis that exhibit a poor general condition. The latter group of cats have poorly organized granulomas and a high fungal burden, in association with a higher percentage of $CD8^{low}$ cells. Although the $CD8^{low}$ cells subset is connected to retroviral infections, such as HIV and FIV[156,157] in humans and cats, respectively, this subset was unrelated to FIV co-infection in the case of cats with sporotrichosis.

Some authors believe that the severity of feline sporotrichosis may be related to immunosuppression caused by co-infection with FIV or FeLV. In a recent study, a poor general condition in cats with sporotrichosis was correlated to FIV co-infection. Likewise, the evaluation of cytokine levels in cats with sporotrichosis revealed IL-10 expression to be significantly higher in FIV co-infected cats and in FeLV progressive infection than in retrovirus-negative cats.[158] Considering IL-10 is a key cytokine in the inhibition of Th1 immunity, its increase is believed to impair the host's optimal antifungal response. Still, severe sporotrichosis is increasingly reported in cats independently of retrovirus co-infection or other apparent immunosuppression, which supports the assumption that this disease develops in a different manner in cats.[46]

Despite the importance of cellular immunity in resolution of fungal infections, a humoral immune response contributes to the overall response in sporotrichosis and fuels further studies for the development of a vaccine.[159] Cell wall components have been studied as a promising source of vaccine candidate antigens. Passive immunization with antibodies to 3-carboxymuconate cyclase antibodies, a 70-kDa cell wall glycoprotein (gp70) that is important for fungal adherence to the extracellular matrix,[160] resulted in a protective effect in mice,[161] even when T-cell–deficient animals were used. Moreover, yeast opsonization with serum against cell wall proteins of *S. schenckii* markedly increases phagocytosis and strongly inhibits the adhesion of the fungus to fibroblasts. In a similar way, the opsonization of the fungus by antibodies anti-3-carboxymuconate cyclase enhanced phagocytic ability of macrophages and elicits the release of proinflammatory

cytokines.[162] Carboxymuconate cyclase has been suggested as an antigen candidate for the further development of an effective vaccine for animal and human use.[94]

Another potential vaccine candidate from *Sporothrix* cell wall is the protein enolase. In conjunction with the adjuvant Montanide™ Pet Gel A (PGA), this protein has been shown to induce a strong Th1 reaction in addition to high antibody levels and decreased fungal load in the liver and spleen.[163] The use of a recombinant enolase-based PGA-adjuvanted vaccine demonstrated a protective effect in mice after challenge with virulent *Sporothrix* species.[164]

Despite the progress made in the past few years on the discovery of potential vaccine candidates, an effective vaccine for preventing sporotrichosis is still not commercially available.

PREVENTION

People handling cats with potential sporotrichosis should follow the biosafety measures listed in Box 84.1.[165] In addition, isolation of sick cats from other animals reared in the same environment is indicated. Care must be taken to avoid cuts or penetrating injuries when working with infected cats, and protective outerwear should be worn. Proper physical restraint or sedation of noncooperative animals must be done to allow complete examination of lesions and the collection of specimens for diagnosis.

Decontamination and cleaning of cages or transport containers can be achieved with sodium hypochlorite (1%), for at least 10 minutes. If possible, sun drying is also beneficial. After contact with infected animals, surfaces should be cleaned and disinfected with sodium hypochlorite solution (1%), for at least 10 minutes, followed by alcohol 70%, using disposable paper towels.[166] Accelerated hydrogen peroxide and polihexametilene biguanide (PHMB) are suitable alternatives to sodium hypochlorite.

An effective and viable therapeutic regimen applied to cats as well as public awareness programs on sporotrichosis prophylaxis are required in endemic areas, encouraging the following: responsible ownership, castration, cremation of dead cats, confinement of cats inside the home, limitation of the number of cats per household, regular cleaning of dwellings, and proper health care for cats. General public health measures such as basic sanitation, regular garbage collection, and cleaning of uninhabited lots are also required.[166]

PUBLIC HEALTH ASPECTS

Sporotrichosis is classically associated with contact with contaminated plants or soil. Individuals with occupational risks are gardeners, florists, forestry workers, agricultural workers, farmers, hunters, fishers, and carpenters. Outbreaks have been reported after common exposure of multiple individuals to a source of contaminated plant material. Laboratory-acquired infections have also been described.[167,168]

Since the 1990s, zoonotic sporotrichosis, related to the direct transmission from infected cats, has emerged as an important alternative route for the infection. The first reported zoonotic epidemic of this mycosis was identified in 1998 in the city and surroundings of Rio de Janeiro, Brazil, and currently this region is considered hyperendemic for zoonotic sporotrichosis. Cases have occurred in an urban area mainly among people of underprivileged socioeconomic level. Taking care of diseased cats is the main factor associated with zoonotic transmission due to contact with infectious lesions and due to the higher risk of suffering scratches and bites when handling these cats.[6] Nearly 85% of affected humans reported contact with sick cats, and more than half of these individuals reported a history of a scratch or a bite. Housewives (30%), students (18%), and veterinarians (5%) were the primary at-risk populations.[5] Immunocompromised humans, such as HIV-infected patients, are a high-risk population and are susceptible to extracutaneous sporotrichosis with involvement of multiple organs.[64,169] Atypical clinical presentations as well as disseminated sporotrichosis in humans have been associated with *S. brasiliensis* infection, with no apparent connection to the host's immune status.[170]

The detection of *Sporothrix* strains on claws and in the oral cavities of cats that are genetically identical to those causing human disease provides evidence that zoonotic transmission can occur through scratches or bites.[171] Isolation of organisms from nasal secretions and cutaneous lesions implies the possibility of transmission through secretions and exudates. In contrast, no human cases were associated with a series of 23 veterinary cases from northern California.[74] This

BOX 84.1 Biosafety Measures for People Handling Cats with Suspected Sporotrichosis

Veterinary Clinics

- Personal protection equipment: disposable gloves, long-sleeved impermeable gowns, closed-toe footwear. In regions where epidemics occur, consider head covers, shoe covers, goggles, and N95 or surgical face masks.
- Hair should be tied back.
- After handling animals or contaminated equipment, remove gloves and wash hands with antiseptic (chlorhexidine, 2%; or povidone-iodine, 1%) and water.
- In case of injury through protective clothing by piercing, cutting, biting, or scratching, the wound must be immediately washed with soap and running water and professional medical advice obtained.
- Use experienced physical or preferably chemical restraint for examination of the animal or collection of specimens for laboratory evaluation.
- Dispose of animal waste in infectious waste labeled bags.
- After euthanasia, animals should be placed in infectious waste labeled bags and, after any necropsy examination, the final destination must be incineration.
- Needles and syringes and other disposable equipment used to collect specimens should be disposed of in labeled biohazard containers.
- Sharp items require approved rigid containers and soft items can be disposed of in infectious waste labeled bags.
- Soiled gauze squares should be treated as biohazardous and disposed of properly.
- Disposable gowns, gloves, and shoe and head covers should be treated as biohazardous and disposed of properly.
- Decontaminate and clean surfaces that were in contact with the animal, its tissues, or fluids using hypochlorite (1%) solution, accelerated hydrogen peroxide, or polihexametilene biguanide (PHMB) for 10 minutes. For impervious horizontal surfaces such as tables, alcohol (70% ethanol) can be applied for additional 10 minutes following a rinse of the hypochlorite solution. For smaller items, sun or ultraviolet (UV) light drying can facilitate decontamination and drying.

Owner

- Use disposable gloves when handling cats.
- Wash hands and arms after handling cats.
- Clothes should be washed in detergent and hot water and sun dried.
- Crate and dishes should be reserved exclusively for the infected pet and disinfected on a regular basis.
- Transport infected animals in plastic carriers instead of wood or cardboard to facilitate cleaning.

remarkable difference in the Brazilian zoonotic epidemic is probably due to the prevalence of the highly virulent *S. brasiliensis* in association with a successful route of transmission driven by cats.[172]

In contrast to feline sporotrichosis, canine sporotrichosis is of minimal zoonotic importance. Dogs are probably not directly involved in the transmission of sporotrichosis in view of the scarcity of yeasts in the lesions and the absence of *Sporothrix* in the oral cavity. In addition, there is no confirmation of human cases associated with transmission by dogs in the Brazilian epidemic.[49] Interhuman transmission is rare.[173,174]

CASE EXAMPLE

Signalment

"Milho," a 2-year-old mongrel intact male cat from Rio de Janeiro, Brazil.

History

Milho was examined at a reference center for diagnosis and treatment of sporotrichosis in Rio de Janeiro because of suspected sporotrichosis. The owner had observed skin lesions on the cat for a month before referral.

Physical Examination

The cat weighed 4.1 kg and was in a good overall condition. Clinical examination revealed multiple ulcerated skin lesions distributed over the face (Fig. 84.16A), nasal region, cervical region, hind limbs and fore limbs, as well as generalized lymphadenomegaly.

Laboratory Findings

Exudates from the ulcerated lesions (pelvic limbs, thoracic limbs, and cervical region) were collected under anesthesia before and during follow-up by sterile swab and seeded on to Sabouraud's dextrose agar, followed by incubation at 25°C. Suspected isolates were subcultivated on potato dextrose agar medium at 25°C for macroscopic and microscopic morphologic studies, and dimorphism (demonstration of both yeast and mold forms) was demonstrated by conversion to the yeast form on BHI agar medium at 37°C. For cytologic examination, impression smears of the same skin lesions were made.

Yeast-like cells were observed on cytologic examination, and *Sporothrix* spp. was isolated and identified from skin lesions using fungal culture. Alterations identified on routine hematology and serum biochemical panels were anemia, leukocytosis, and hypoalbuminemia. The cat was positive for FIV antibody and negative for FeLV antigen (SNAP Combo FeLV/FIV, IDEXX Laboratories, ME, USA).

Treatment

Oral ITZ capsules, at a dose of 100 mg, PO, q24 h (24.4 mg/kg), was prescribed. After 3 months of ITZ therapy, besides worsening of the initial skin lesions (Fig. 84.16B), new skin lesions and nasal mucosal involvement developed, together with respiratory signs (sneezing and nasal discharge).

Sporothrix continued to be isolated from exudates during the 3 months of ITZ monotherapy, and impression smears were still positive after 2 months, though with a progressive decrease in the number of yeasts present.

Due to poor clinical response, KI capsules at the dose of 15 mg, PO, q24h (3.65 mg/kg) were administered, while continuing ITZ (100 mg, PO, q24h). Both drugs were administered with food by the owner.

Two weeks after the ITZ+KI association had been initiated, the cat developed hyporexia. KI treatment was temporarily suspended for 3 days and oral silymarin 30 mg/kg, q24h, was administered. Within this period, the cat began eating normally, and KI was reintroduced at half the dose on alternate days for 15 days. After that, the full KI dose (15 mg, q24h) was again prescribed.

At the first follow-up visit, around 30 days after the introduction of KI, the cat had stopped sneezing and nasal discharge was not observed. Cutaneous lesions were healing, but lymphadenomegaly persisted.

At the following appointment, the owner reported hyporexia and weight loss was documented. A palpable soft mass on the left thoracic region (8 cm diameter) was detected on physical examination, and needle aspiration cytology confirmed abscess formation with polymorphonuclear leukocytes, necrotic cells, and numerous coccoid bacteria. After the drainage of the abscess, oral amoxicillin-clavulanic acid treatment was initiated (25 mg/kg, PO, q12h for 14 days).

Because of the inappetence, treatment with both antifungal drugs was temporarily suspended (15 days for ITZ and 20 days for KI). The drugs were reintroduced as follows: ITZ 100 mg PO q24h, and KI 7.5 mg PO q48h (1.8 mg/kg) for a week, then 15 mg PO q48h for a week, then 15 mg PO q24h. After 3 months of combination therapy, the cat was considered cured with complete healing of skin and mucosal lesions (Fig. 84.16C). After clinical cure, treatment was continued for an additional period of 4 weeks.

Comments

This cat demonstrated progression of clinical signs with the emergence of nasal mucosa involvement, even while receiving ITZ. *Sporothrix brasiliensis* is the most prevalent etiologic agent in Rio de Janeiro, Brazil, and is described as the most virulent among the *Sporothrix* species. A recent study demonstrated that none of the tested strains of *S. brasiliensis* recovered from cats were ITZ resistant.[175] Although antifungal susceptibility tests were not performed in this case, it should be considered that the causative strain may have exhibited some resistance to ITZ, or alternatively, there may have been problems related to absorption of ITZ. Therapeutic drug monitoring could have also been considered, although 100 mg PO q24h is a high dose of ITZ that can be associated with significant adverse effects in cats. Still, the high susceptibility of cats to *Sporothrix* species is not yet understood, but it is believed to be multifactorial.

The decrease in fungal burden during treatment suggests that in spite of the clinical failure, the potential of this cat as a source of infection was probably reduced. The use of KI capsules as a combined therapy led to a favorable outcome. Hyporexia and weight loss were managed as adverse effects of the therapy. However, the coincidental development of an abscess (presumably a cat-bite abscess) may have been the cause of hyporexia when they both occured at the same time.

Candidiasis and Rhodotorulosis

Jane E. Sykes, Krystle L. Reagan

KEY POINTS

- First Described: The identification of *Candida* as a fungal pathogen was recognized in Stockholm around 1840 (Fredrik Berg),[1] but candidiasis was described as far back as around 400 BC by Hippocrates.
- Cause: *Candida* spp. (division Ascomycota, class Saccharomycetes).
- Affected Hosts: Dogs, cats, humans, and a variety of other animal species.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Usually invasion of commensal yeasts secondary to immune suppression.
- Major Clinical Signs: Local dermatitis; otitis externa; keratitis; LUTS; abdominal pain, icterus, and/or ascites due to peritonitis; or severe systemic infections with fever, inappetence, ocular inflammation, lameness due to osteomyelitis, respiratory distress, icterus, vomiting.
- Differential Diagnoses: Other systemic fungal or bacterial infections.
- Human Health Significance: Human infections by *Candida* species result from invasion by normal flora, but human-to-human transmission of *Candida* strains can also occur. The potential for exchange of *Candida* species between animals and humans is not known.

CANDIDIASIS

ETIOLOGY AND EPIDEMIOLOGY

Candida species are yeasts that are typically benign counterparts of the normal GI, urogenital, and cutaneous flora but can invade tissues and cause disease as a result of disruption of normal host defenses. *Candida* species can also be isolated from soil, inanimate objects, and hospital environments. The yeasts are small (3 to 6 μm) and ovoid (blastospores) and reproduce by budding. Budding results in the formation of new yeast cells, pseudohyphae (chains of elongated yeast cells), and true septate hyphae. Disease syndromes caused by *Candida* species that occur in dogs and cats are listed in Box 85.1. More than 200 species of *Candida* exist, but only a few species have been identified as pathogens in dogs and cats (Table 85.1).[2–12] The most commonly isolated species is *Candida albicans,* and only *C. albicans* appears to cause disseminated disease in dogs and cats. However, an epidemiologic shift with increasing numbers of non-*C. albicans*–related infections in animals has been reported.[6,10,12,13] This change has also been documented in humans and is of significant concern as non-*C. albicans* species exhibit higher rates of fluconazole resistance.[14,15]

Local or disseminated infections where *Candida* is present with a mixture of bacterial species can occur. Local infections (such as UTIs) with two different *Candida* species have also been reported.[10,16]

When compared with human patients, candidiasis is uncommonly described in dogs and cats. Predisposing factors in dogs or cats with local or disseminated candidiasis have included diabetes mellitus,[5,10,17] treatment with immunosuppressive drugs or broad-spectrum antibacterial drugs,[10,12,18] a history of GI surgery,[8,11] lower urinary tract disease other than infection (e.g., urinary catheter placement, permanent stomata, atonic bladder),[12] parvoviral infections,[19–21] and/or underlying malignancy.[10,20] Often more than one of these factors is in the history. Disseminated candidiasis has most often been described in dogs, but also occurs in cats.[11,22] Although most animals have underlying immunocompromising conditions, disseminated candidiasis has been described in apparently immunocompetent animals,[23,24] which may reflect an unidentified underlying genetic immunodeficiency. Cats with FeLV or FIV infection do not have higher rates for *Candida* colonization,[25] and those with candidiasis usually test negative for FeLV and FIV.[16]

Analysis of the authors' hospital population suggests that cats are at least as likely as dogs to develop *Candida* UTIs.[16] In other studies, *Candida* species were isolated from the urine of 0.2% of more than 8,000 dogs with UTIs[26,27] and 0.2% of more than 2,000 dogs with persistent or recurrent UTIs.[27] Administration of antibacterial drugs is strongly associated with candiduria in dogs and cats.[12] Lower urinary tract disease other than infection, such as cystostomy tube placement, intermittent urinary catheterization, and perineal urethrostomy, has been reported in the history of some cats and dogs with *Candida* UTIs[6,10,12] and is significantly associated with candiduria in cats.[12] Local mucocutaneous infections can occur at the site of long-term placement of feeding tubes.[3]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

A combination of disruption of normal host barriers and expression of virulence factors are likely necessary to allow *Candida* spp. to invade the host. Administration of antibacterials can lead to alterations in the normal bacterial flora, allowing *Candida* to proliferate.[28,29] Compromise to defenses of the lower urinary tract with urinary catheter placement or alterations to urine flow (e.g., perineal urethrostomies) are risk factors for the development of *Candida* UTIs.[6,12]

Candida can adhere to a variety of tissue components, such as epithelial and endothelial cells, as well as other bacteria and inanimate objects, such as catheters and stents, via integrin-like and carbohydrate adhesion molecules.[30,31] *Candida* yeasts produce many proteins that are associated with infection including hydrolases and heat shock proteins.[23] The yeasts readily form biofilms consisting of extracellular polymeric polysaccharides and budding, pseudohyphal, and hyphal

BOX 85.1 Disease Syndromes Associated with *Candida* Infections in Dogs and Cats

- Keratitis
- Cutaneous candidiasis
- Otitis externa and otitis media
- Urinary tract infections
- Gastrointestinal candidiasis
- Cholecystitis
- Pancreatitis
- Peritonitis
- Disseminated infections

TABLE 85.1 *Candida* Species Associated with Disease in Dogs and/or Cats[2–12]

Species	Clinical Manifestations
Candida albicans	Dermatitis, UTI, otitis externa, keratitis, cholecystitis, disseminated infections
Candida glabrata (formerly *Torulopsis glabrata*)	UTI, feeding-tube site infections, pancreatitis
Candida krusei	UTI, feeding tube site infections
Candida guilliermondii	UTI, dermatitis
Candida parapsilosis	UTI, otitis, dermatitis
Candida tropicalis	UTI, otitis
Candida rugosa	UTI

forms.[32] Biofilm growth is enhanced by availability of carbon sources such as glucose (glucosuric patients) and on some substrates such as latex urinary catheter.[32] Formation of a biofilm confers resistance to antifungal drugs by allowing organisms at the center of the biofilm to slow growth rates, thus making cell cycle–dependent antifungal agents less effective. It also provides a physical barrier against antifungal penetration with the extracellular matrix and promotes the upregulation of drug efflux pumps.[32]

Within tissues, neutrophils are a key defense against *Candida*.[33] *Candida* blastospores are phagocytized and destroyed by neutrophils. Mononuclear cells play a less important role. Reactive oxygen species, hydrolytic enzymes, and antimicrobial peptides contribute to the intracellular destruction of blastospores by neutrophils. Thus, any condition that impairs neutrophil numbers or function, such as neutropenia or diabetes mellitus, predisposes dogs and cats to candidiasis. A large number of other cytokines, complement, dendritic cells, and lymphocytes are also involved in the immune response to *Candida*.[33] The formation of hyphae by *Candida* promotes tissue invasion, which may be followed by life-threatening fungemia and dissemination to multiple organs.[34] This ability of *Candida* to change its morphology ("morphologic dimorphism") is thought to be an important virulence factor.

Lower urinary tract candidiasis may be subclinical or associated with dysuria, stranguria, and/or hematuria. Systemic signs of pyrexia, lethargy, inappetence, and weight loss have also been described in affected dogs and cats,[6] but these signs may result from the presence of other predisposing diseases. Ascending infections may lead to development of *Candida* pyelonephritis.

Cutaneous candidiasis may manifest as erythema, scaling, alopecia, erosions, and crusting, often where disruption of cutaneous or mucocutaneous regions has occurred (such as a previous surgical site or a feeding tube or cystotomy stoma). Persistent disease in the face of systemic or topical treatment with broad-spectrum antibiotics should raise suspicion for candidiasis. Dogs with *Candida* otitis externa often have a history of chronic bacterial otitis externa that has been treated aggressively with systemic or topical antibacterials.

Overgrowth of *Candida* in the GI tract may occur in animals that are immunosuppressed or treated with glucocorticoids and/or broad-spectrum antibacterial drugs. In some cases, invasion of the mucosa into the lamina propria or deeper tissues occurs (e.g., intestinal candidiasis). A *Candida* GI granuloma was diagnosed in a cat after passage of an intestinal foreign body without previous antibacterial drug administration or known cause of immunosuppression.[35] Intestinal candidiasis is occasionally identified at necropsy in puppies that die after treatment for parvoviral enteritis and may be a reason for persistent vomiting, diarrhea, and death despite aggressive fluid and antibacterial drug therapy.[21] *Candida* spp. may also contribute to ulcerative glossitis in puppies with parvovirus infection (Fig. 85.1).

Candida albicans cholecystitis was reported in a 3-year-old cat from upstate New York.[36] Although no clear underlying cause could be identified, the cat had obstructive cholecystitis with what appeared to be an organizing mucocele, and a nematode of unknown identity was discovered in the cat's esophageal feeding tube during hospitalization. Another cat with diabetes mellitus was described with pancreatitis associated with a *Candida glabrata* infection.[37]

Candida peritonitis can occur after intestinal and/or biliary surgery or intestinal perforation secondary to NSAID administration.[8,11,38] Recent treatment with broad-spectrum antibacterial drugs is reported in most dogs that develop *Candida* peritonitis.[38] Mixed infections with *Candida* and intestinal flora may develop. Affected dogs are febrile, have abdominal pain, and may have other GI signs such as vomiting and diarrhea.

Disseminated candidiasis results from hematogenous spread of *Candida* from intestinal, urinary, or possibly corneal or cutaneous sites.[17,39,40] A diagnosis of disseminated candidiasis should be considered whenever *Candida* infections are identified in the eye, skin, or urinary tract of an animal that has (or subsequently develops) severe systemic illness. Clinical signs of disseminated candidiasis in dogs include fever, inappetence, anorexia, weight loss, and a variety of other clinical signs that reflect underlying immunosuppressive disease processes and specific organs involved. The latter can include the pancreas, liver, mesentery, spleen, kidneys, heart, lungs, lymph nodes, and, less often, the bone, intestinal tract, eyes, meninges, thyroid, and/or prostate gland.[5,17,20,23,39–44] Ocular signs in animals with disseminated disease include keratitis and corneal ulceration, uveitis, chorioretinitis, and endophthalmitis.[16,17,41,43] *Candida* keratitis may also occur as a localized process, sometimes secondary to aggressive treatment of corneal ulceration secondary to other disease processes with topical broad-spectrum antibacterial drugs. Thromboembolic disease may complicate disseminated infections. Pulmonary thromboembolism may result in respiratory distress and death.[5,16]

DIAGNOSIS

Laboratory Abnormalities

Laboratory abnormalities in dogs and cats with candidiasis result from the underlying disease process (such as diabetes mellitus or systemic neoplastic disease) as well as the location and severity of the fungal infection. Laboratory abnormalities in dogs or cats with *Candida* UTIs may be absent, or there may be evidence of renal failure with azotemia and isosthenuria. Grossly, urine may contain flocculent white debris. Urinalysis may reveal proteinuria, pyuria, and, in some cases, hematuria and/or *Candida* fungal elements (see Case Example). Dogs and cats with disseminated candidiasis or *Candida* peritonitis frequently have had nonregenerative anemia and mild to marked neutrophilia with bandemia and toxic neutrophil changes (in contrast to other deep mycoses, where hematologic abnormalities are often mild or absent).

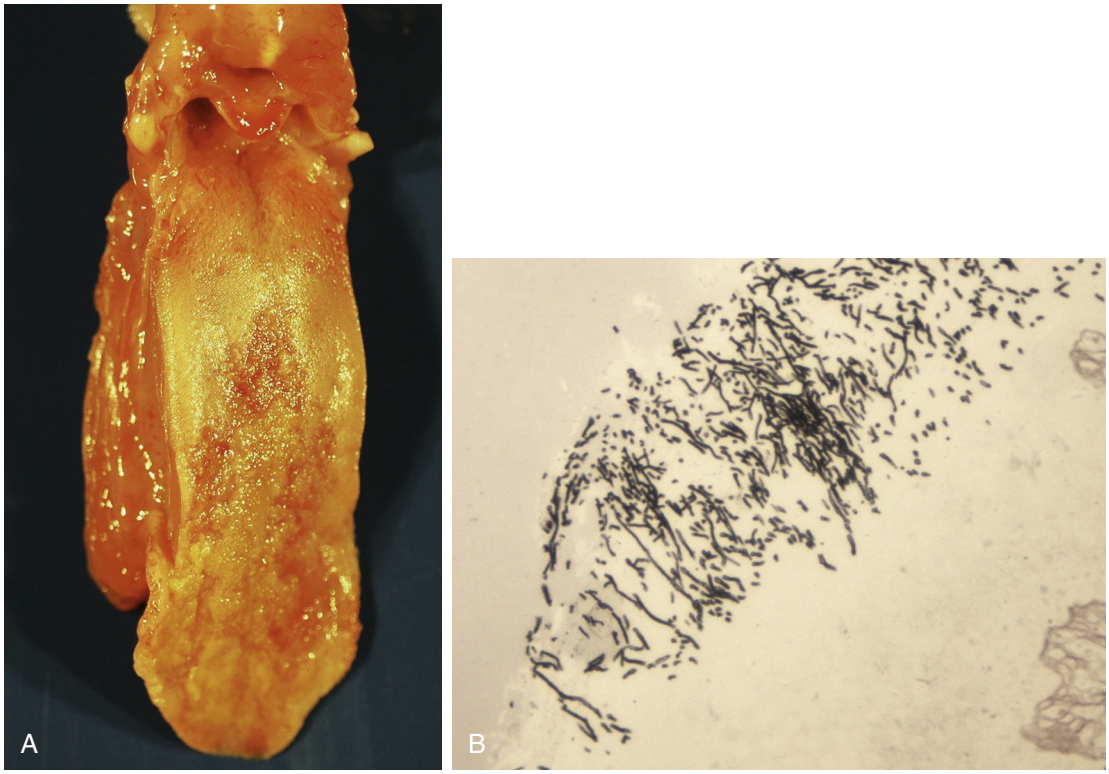

Fig. 85.1 (A) Tongue ulcerations at necropsy in a 2-month-old mixed-breed puppy that was euthanized because of canine parvoviral infection. (B) Histopathology revealed multifocal ulcerative glossitis, pharyngitis, and esophagitis with intralesional yeasts and pseudohyphae. Gomori's methenamine silver stain. (Courtesy University of California Davis Anatomic Pathology Service.)

Lymphopenia may be present as a result of underlying immunosuppressive illness or drug therapy. Some dogs are thrombocytopenic and have coagulation abnormalities consistent with DIC.[5] Findings on the serum biochemistry panel in dogs with disseminated candidiasis are variable and nonspecific but may include metabolic acidosis, moderate to severe hypoalbuminemia, and increased liver enzyme activities. The cat with *Candida* cholecystitis had marked hyperbilirubinemia (up to 33.8 mg/dL) and increased serum liver enzyme activities associated with a concurrent hepatitis.[36]

Diagnostic Imaging

Plain thoracic radiographs in dogs with disseminated candidiasis may be unremarkable or show increased pulmonary interstitial opacity, thoracic lymphadenomegaly, and/or pleural or pericardial effusion.[11,18,23] Abdominal ultrasound examination in dogs with *Candida* peritonitis or disseminated disease may reveal echogenic ascites fluid, mesenteric hyperechogenicity, changes consistent with pancreatitis, abdominal lymphadenomegaly, or increased echogenicity of the renal cortices or hepatic parenchyma. In animals with *Candida* UTIs, fungal balls may be detected as mobile, echogenic, spherical structures without distal acoustic shadowing within the lumen of the urinary bladder.[45]

Microbiologic Tests

Definitive diagnosis of candidiasis requires visualization of the organism within lesions by cytologic or histopathologic examination and confirmation of its identity using culture.

Cytologic Examination

Candida blastospores (5–7 µm), pseudohyphae, and true hyphae (3–5 µm-wide septate hyphae) can be visualized in swab specimens from the ear canal (ear cytology); tape preparations from the skin; urine sediment or other body fluids (Fig. 85.2); or ultrasound-guided aspirates of abdominal lesions.

Fungal Culture

Candida grows on routine bacteriologic media as well as fungal media such as Sabouraud dextrose agar. Creamy white colonies appear within 2 to 3 days, and so isolation of the yeast may be reported when it is present in specimens submitted for aerobic bacterial culture, which are typically incubated only for this period of time. If *Candida* is suspected based on the history, fungal culture (rather than bacterial culture alone) should be requested because *Candida* grows best on fungal isolation media. Because *Candida* can be isolated from the skin and mucous membranes of healthy dogs and cats, infection must be confirmed with cytology or histopathology when *Candida* is isolated from these sites.

Identification of *Candida* isolates is based on morphology and biochemical reactions. Preliminary differentiation of *C. albicans* from other *Candida* species can be made based on the ability of *C. albicans* to produce germ tubes when exposed to serum. MALDI-TOF MS (see Chapter 3) accurately and rapidly identifies *Candida* species[46] and may replace these methods in the future. Isolation of *Candida* allows not only definitive identification but also antifungal susceptibility testing (see Fig. 4.16). This is important for *Candida* because some isolates (especially *Candida glabrata* and *Candida krusei*) can exhibit antifungal drug resistance.

Pathologic Findings

Gross pathologic findings at necropsy in animals with disseminated candidiasis include peritoneal or pleural effusion, enlarged and edematous lymph nodes, congestion and necrotic whitish foci within

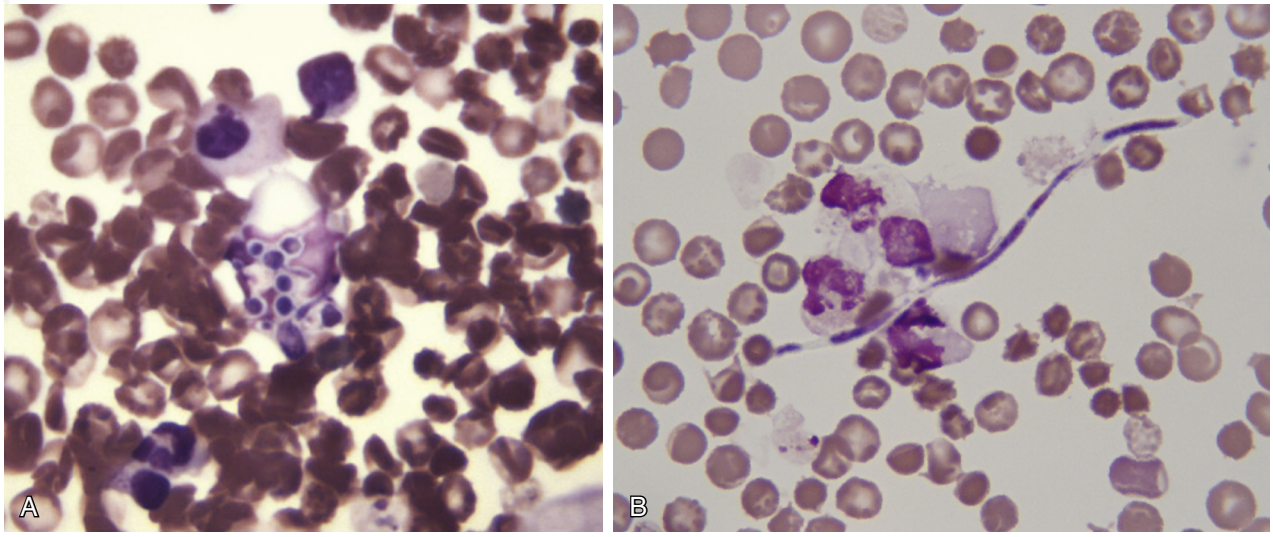

Fig. 85.2 *Candida albicans* within urine sediment from a 5-year-old female spayed Labrador retriever being treated for multicentric lymphoma and acute-onset hematuria. Both budding (A) and filamentous (B) fungal elements are visible. (Courtesy Dr. Barrak Pressler, The Ohio State University. From Bartges J, Polzin D. *Nephrology and Urology of Small Animals*. John Wiley and Sons; 2011.)

affected organs, evidence of tissue thrombosis, and formation of a gray-white or yellow-green fibrinonecrotic layer on affected mucosal surfaces.[5,11,21,23,40,44] Concurrent underlying disease processes are also often identified.

Histopathology of affected tissues reveals yeasts, pseudohyphae, and septate hyphae with an associated inflammatory response that is composed primarily of neutrophils, macrophages, and lymphocytes. Multinucleated giant cells may also be present.[23,40,44] Pseudohyphae and hyphae predominate in invasive infections (see Fig. 4.1). Evidence of blood vessel invasion, thrombosing vasculitis, and infarction may be seen, with multifocal mycotic granulomas in affected organs.[40] The organism is most readily visualized with special stains such as PAS and Gomori's methenamine silver. IHC has also been used to identify *Candida* within lesions.[23,40] When mixed infections with *Candida* and other bacteria are present, tissue Gram stains may reveal bacterial rods and/or cocci in addition to gram-positive fungal elements.

TREATMENT AND PROGNOSIS

Treatment of candidiasis should involve management of underlying immunosuppressive disorders, if possible, and specific antifungal drug treatment. Systemic antibacterial drugs should be discontinued if not clearly indicated, or the spectrum of activity should be narrowed as much as possible.

Cutaneous and corneal infections are usually treated with a combination of topical antiseptics or antifungal medications and systemic antifungal drugs until lesions resolve.[7]

Dogs and cats with candiduria should receive antifungal therapy as many of the underlying risk factors such as permanent urinary tract stomata or neoplasia cannot be easily corrected and ascending pyelonephritis has been reported.[5,10,17] Initial therapy should be with antifungal drugs that achieve high concentrations in the urine, such as fluconazole, for 4 to 6 weeks. Fungal urine culture should be used to confirm resolution of infection. Systemic antifungals alone may be adequate to resolve *Candida* UTIs in some animals, although resolution has been reported in some animals in the absence of antifungal drug therapy.[10]

Persistent infection may result from drug resistance, adverse effects of treatment that necessitate treatment discontinuation, or inadequate drug penetration into fungal masses that line the bladder wall (see Case Example). Intravesicular treatment with 1% clotrimazole may be effective in these cases.[47,48] Under anesthesia, the bladder is catheterized with a Foley catheter, emptied, and then lavaged with sterile saline. The bladder is then filled with 1% clotrimazole solution (e.g., 30 to 50 mL for a cat). The animal is rotated to promote contact of the solution with the uroepithelium, and after the solution has been in the bladder for an hour, the catheter is removed and the animal is allowed to recover. Treatment is continued weekly until *Candida* can no longer be isolated from the urine. Typically one to four treatments are required.[16,48] Ultrasound-guided administration of clotrimazole via cystocentesis to a dog with *Candida* cystitis was described in one report.[47]

Successful treatment of systemic candidiasis in dogs or cats is rarely described. One dog with *Candida* peritonitis was treated successfully by surgical exploration and lavage of the abdomen, placement of an abdominal drain, and IV fluconazole.[8] In addition, aggressive supportive measures were required that included IV fluid therapy, fresh frozen plasma, antiemetics, gastroprotectants, total parenteral nutrition, and antibacterial drugs for a suspected catheter-related infection. Antifungal drugs other than fluconazole used to treat invasive candidiasis in human patients include amphotericin B (AMB) or an echinocandin such as caspofungin,[49] both of which must be administered parenterally.

PREVENTION

Prevention of candidiasis involves avoidance of excessive immunosuppression, as well as discriminate use of antibacterial drugs, which should be tailored to the results of culture and susceptibility whenever possible.[12] Whether *Candida* species carried on the hands of humans can colonize dogs and cats is not known, but routine hand washing and the wearing of gloves when immunosuppressed animals are handled or intravascular devices are placed should minimize the chance of healthcare-associated infections. Although prophylactic antifungal drug treatment has been used to prevent invasive candidiasis in human high-risk groups, the low incidence of candidiasis in

immunosuppressed dogs and cats does not warrant the use of prophylactic antifungal drugs in this group.

PUBLIC HEALTH ASPECTS

Candida species (especially *C. albicans*) are common causes of mucosal disease in humans. Since 2000, *Candida* has also emerged as an extremely important cause of invasive infections owing to the more widespread use of invasive medical devices and immunosuppressive drugs. In hospitalized human patients, *Candida* is reportedly the fourth most common organism isolated from the bloodstream.[50] Although many human infections result from invasion of tissues by commensal yeasts in the face of immune suppression, horizontal transmission of *Candida* and hospital-acquired infections have been described.[51] One *Candida* species of particular concern is *Candida auris*, a highly drug-resistant species of *Candida* that was first reported as a nosocomial pathogen in Japan in 2009 and has subsequently spread worldwide. Whether *Candida* isolates from dogs or cats colonize humans is not known. Zoonotic transmission of *Candida parapsilosis* from dogs was suggested by the authors of a case report that described two human cases of *C. parapsilosis* periorificial dermatitis (one periocular and another perioral).[52] This was on the basis of a history in both cases of volunteering in dog shelters, and historic evidence that dogs can be colonized by *C. parapsilosis*. However, the prevalence of *C. parapsilosis* colonization in dogs from the shelters was not investigated, and no molecular studies were performed to show that isolates colonizing the dogs were the same as those causing the two human infections.

RHODOTORULOSIS

Rhodotorula spp. are saprophytic yeasts within the division Basidiomycota (family Sporidiobolaceae). Previously thought to be nonpathogenic, they are now considered emerging opportunistic pathogens of humans and other animals.[53] *Rhodotorula* spp. are widespread in the environment and can be found in air, soil, lakes, ocean water, dairy products, and fruit juice. They are also commensal inhabitants of the skin, GI, and upper respiratory tracts of mammals, and are common contaminants of hospital surfaces, including endoscopes and dialysis equipment.[53] They may be isolated in low numbers from clinical specimens that may have become contaminated with environmental bacteria or fungi.

Opportunistic infections with *Rhodotorula* spp. in humans are very rare. When they occur, they most often are characterized by fungemia in patients with central venous catheters, including premature neonates, patients with hematologic malignancies, and patients receiving central parenteral nutrition.[53] However, they have also been identified as a cause of meningeal, skin, ocular, peritoneal, and prosthetic infections in humans with other immunocompromising conditions, including treatment with broad-spectrum antibacterials. The most common species isolated from humans is *Rhodotorula mucilaginosa* (approximately 70% of isolates), followed by *Rhodotorula glutinis* (approximately 7%).[54,55] In dogs, there have been fewer than five reports of *Rhodotorula* spp. infection in the literature. Associated conditions were granulomatous epididymitis, funguria, and pneumonia.[6,56,57] Care should be taken not to overinterpret light growth of *Rhodotorula* from potentially contaminated sites as clinically significant infection, especially in the absence of intralesional yeasts and when accompanied by mixed growth of bacterial organisms or other fungal contaminants.

AMB is the most common antifungal agent used for treatment of humans with *Rhodotorula* spp. infections, with a mortality rate of approximately 10%.[53] Although successful therapy with fluconazole has also been reported, *Rhodotorula* spp. are resistant to triazoles and echinocandins *in vitro*.[58] As with candidiasis, treatment of rhodotorulosis should likely include identification, and correction, if possible, of any predisposing local or systemic causes of altered immunity.

CASE EXAMPLE

Signalment

"Lizzie," an 18-year-old female spayed domestic shorthair cat from the San Francisco Bay area (Fig. 85.3A).

History

Lizzie was evaluated by the University of California, Davis, VMTH, for a 12-hour history of dysuria and hematuria. The owner described multiple episodes of urination and defecation outside the litter box with stranguria, hematuria, and tenesmus. Lizzie was also observed repeatedly grooming her perineum. The cat had been diagnosed with diabetes mellitus 10 years previously, and more recently with feline bronchial disease, a thoracolumbar (T3 to L3) myelopathy, generalized osteoarthritis, chronic constipation, bilateral cataracts, CKD, and recurrent bacteriuria (*Streptococcus bovis* group, *Escherichia coli, Enterococcus faecalis,* then *Aerococcus viridans*). She also had a cardiac murmur secondary to dynamic right ventricular outflow tract obstruction. Historic bacteriuria had been treated with a variety of antimicrobial drugs selected based on the results of aerobic bacterial urine culture and susceptibility (most recently doxycycline, but also amoxicillin-clavulanic acid or marbofloxacin in the past). Her current medications consisted of prozinc insulin (3.5 U, SC, q12h), lactulose (2 mL, PO, q12h), a soluble fiber supplement (1 teaspoon with food twice daily), inhaled fluticasone (110-µg puff, q12h), theophylline (12 mg/kg, PO, q24h), and doxycycline (5 mg/kg, PO, q12h). Her most recent blood work (collected 1 month previously) showed a creatinine of 1.8 mg/dL (reference range, 1.1–2.2 mg/dL) and a BUN of 34 (reference range, 18–33 mg/dL), which were similar to values obtained over the course of the previous 5 years. She was an indoor-only cat and was fed a commercial cat food with occasional turkey meat from the delicatessen. Her appetite was good, there had been no weight loss noted, her water consumption was unchanged, and there had been no vomiting or diarrhea. She had not been vaccinated for the past 4 years but was on regular flea preventative medication (nitenpyram as well as fipronil).

Physical Examination

Body weight: 4.1 kg.

General: Quiet, alert, and responsive, T = 100.5°F (38.1°C), HR = 170 beats/minute, RR = 28 breaths/minute, CRT <1 second, pale pink mucous membranes.

Integument: A dull, slightly unkempt haircoat with mild scale was noted.

Eyes, ears, nose, and throat: Immature cataracts were present bilaterally, and all teeth were absent on examination of the oral cavity. No other clinically significant abnormalities were detected.

Musculoskeletal: BCS was 4/9, and there was mild generalized muscle atrophy. The cat was reluctant to ambulate, and appeared painful on manipulation of the elbows, stifles, and coxofemoral joints bilaterally. Crepitus was detected on manipulation of the tarsus.

Cardiovascular and respiratory systems: A grade II/VI left parasternal heart murmur was auscultated. Pulses were strong and synchronous. No other abnormalities were detected.

Abdominal palpation: The abdomen was soft and nonpainful. Both kidneys were small (approximately 2 cm in diameter) and irregular. The urinary bladder was approximately 5 cm in diameter and soft. Severe erythema was noted around the vulva.

Lymph nodes: All were < 1 cm in diameter.

Continued

CASE EXAMPLE—cont'd

Laboratory Findings

Urinalysis: SpG 1.030; pH 6.0, 75 mg/dL protein, 1,000 mg/dL glucose, no ketones or bilirubin, 250 erythrocytes/μL hemoprotein, >100 WBC/HPF, >100 RBC/HPF, few transitional and squamous epithelial cells, many budding yeast organisms.

Microbiologic Testing

Aerobic bacterial urine culture: 10^5 *C. albicans*/mL were cultured.

Yeast antifungal drug susceptibility panel: Susceptible to 5-flucytosine (0.5 μg/mL), caspofungin (0.25 μg/mL), fluconazole (0.25 μg/mL), itraconazole (0.06 μg/mL), voriconazole (0.015 μg/mL). MICs for AMB and posaconazole were 0.5 μg/mL and 0.03 μg/mL, respectively (no interpretative criteria available).

Diagnosis

Susceptible *C. albicans* UTI.

Treatment

Lizzie was treated with fluconazole (50 mg, PO, q12h). At a recheck examination 10 days later, the owner reported ongoing pollakiuria and incontinence. A fungal urine culture again revealed 10^5 *C. albicans*/mL with a similar susceptibility profile. Addition of flucytosine was recommended (250 mg, PO, q8h) but was considered unaffordable to the owners. Treatment was continued for another month with little clinical improvement and persistence of infection. A blood glucose curve revealed 2-hourly blood glucose concentrations that were "high", 470, 368, 300, 383, and 423 mg/dL, respectively, so the insulin dose was increased to 4 U, q12h. Two weeks later, the owner described some improvement in the urinary incontinence and reduction in stranguria, but again 10^5 *C. albicans*/mL was cultured from the urine, and persistent urine scalding was noted around the perineum and on the pelvic limbs on physical examination. Body weight was 3.8 kg, and a blood glucose curve revealed 2-hourly blood glucose concentrations that were 457, 301, 209, 227, 300, and 296 mg/dL, respectively.

Topical treatment with clotrimazole was elected. Before the procedure was performed, a preanesthetic evaluation was done. A CBC showed a normocytic, normochromic, nonregenerative anemia (HCT 28.3%; reference range [RR]: 30%–50%), mature neutrophilia (15,206 cells/μL; RR; 2,000–9,000 cells/μL), lymphopenia (919 cells/μL; RR: 1,000–7,000 cells/μL), and monocytopenia (33 cells/μL; RR: 50–600 cells/μL). A serum biochemistry profile was unremarkable with the exceptions of a BUN concentration of 49 mg/dL (RR: 18–33 mg/dL) and a glucose concentration of 314 mg/dL (RR: 63–118 mg/dL). Urinalysis showed a specific gravity of 1.022; pH 6.0, 25 mg/dL protein, 1,000 mg/dL glucose, 0–2 WBC/HPF, 0–2 RBC/HPF, and moderate numbers of budding yeast organisms and fungal structures. Thoracic radiographs revealed mild cardiomegaly and a diffuse, static bronchial pattern consistent with the previous diagnosis of feline bronchial disease. Abdominal ultrasound findings included an enlarged and hyperechoic liver, mild diffuse thickening of the GI mucosa and submucosa, decreased renal corticomedullary distinction bilaterally with thickening of the renal cortices, a markedly thickened and irregular urinary bladder wall that contained hypoechoic, ill-defined nodules, and thick sediment within the urinary bladder lumen. Cystoscopy revealed a large amount of white, fluffy debris adherent to an edematous bladder wall as well as in the lumen (Fig. 85.3B). A 10F Foley catheter was placed over a 0.025-inch guidewire. The bladder was flushed and the majority of the debris removed. A total of 47 mL of 1% clotrimazole solution was infused into the bladder, and the solution was allowed to remain in place for 1 hour. The solution was removed, and Lizzie was allowed to recover from anesthesia. Treatment with fluconazole was continued, although the dose was lowered (25 mg, PO, q12h). At a recheck 2 weeks later, the owners reported that Lizzie was more active and was no longer pollakiuric, although she still urinated outside the litter box and intermittent vomiting had been noted. A CBC, biochemistry panel, and urinalysis revealed nonregenerative anemia (HCT 21.2%); lymphopenia (349 cells/μL); monocytopenia (70 cells/μL); increased activities of serum ALT (1028 U/L; RR: 27–101 U/L), AST (226 U/L; RR: 17–58 U/L), and ALP (223 U/L; RR: 14–17 U/L); hypercholesterolemia (324 U/L; RR: 89–258 U/L); and hyperbilirubinemia (0.7 mg/dL; RR: 0–0.2 mg/dL). Aerobic bacterial urine culture revealed more than 10^5 CFU/mL of hemolytic *E. coli*, and fungal culture of the urine was negative. The fluconazole was discontinued, after which the vomiting ceased and liver enzyme activities returned to reference ranges. Multiple bacterial UTIs were diagnosed over the following 6 months, but *Candida* was never again isolated from the urine.

Comments

In this cat, the *C. albicans* UTI may have occurred secondary to a combination of factors that likely included poorly controlled diabetes mellitus, CKD, neurologic disease, and repeated treatment with broad-spectrum antimicrobial drugs. Systemic antifungal drug treatment and improved control of diabetes mellitus were initially used as treatment strategies but failed, probably because of the large mats of fungus that were adherent to the bladder wall. Fortunately, a single topical clotrimazole treatment resulted in resolution of the yeast infection. The hepatopathy that developed was thought to be secondary to fluconazole toxicity since it resolved when the drug was discontinued.

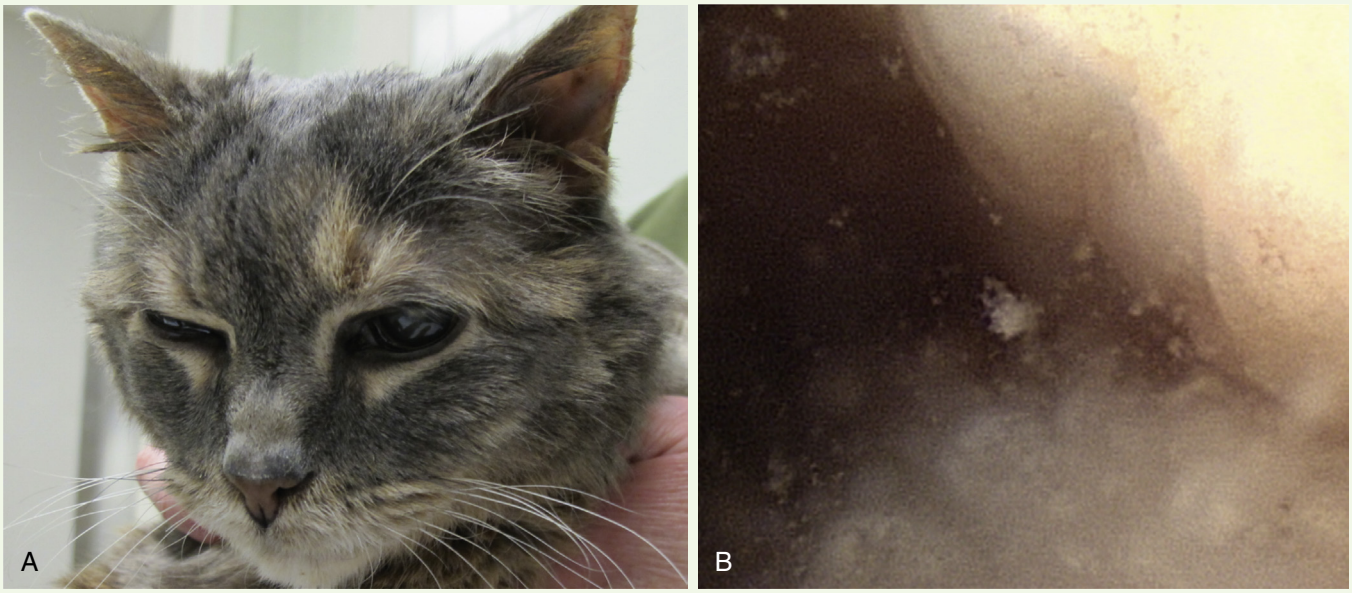

Fig. 85.3 (A) An 18-year-old female spayed domestic shorthair cat with a *Candida albicans* urinary tract infection, as well as diabetes mellitus, feline bronchial disease, a myelopathy, and generalized osteoarthritis. (B) Bladder lumen as viewed by cystoscopy. The urine contains large amounts of fluffy white debris that was loosely adherent to the bladder wall.

Aspergillosis and Penicilliosis

Vanessa R. Barrs, Jonathan D. Dear

KEY POINTS

- Cause: *Aspergillus* spp. and *Penicillium* spp., which are ascomycetes in the family Aspergillaceae, order Eurotiales.[1]
- First Described: Invasive aspergillosis was first described in 1815 in a jackdaw bird (Meyer).[2] Aspergillosis was first described in dogs in 1897 and in cats in 1982.[3]
- Affected Hosts: Dogs, cats, humans, and a variety of other animal species.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Inhalation of fungal spores (conidia) from the environment.
- Major Clinical Signs: Sinonasal aspergillosis and penicilliosis: nasal discharge, sneezing, epistaxis, depigmentation of the nares in dogs. Sino-orbital aspergillosis (cats): exophthalmos, third eyelid prolapse, and oral mass lesions or ulcers in the pterygopalatine fossa. Disseminated aspergillosis: inappetence, weight loss, spinal pain, lameness, pelvic limb paresis or paralysis, cough, vomiting, and tachypnea.
- Differential Diagnoses: Sinonasal aspergillosis: neoplasia, inflammatory rhinitis, oronasal fistulas, cryptococcosis, nasal mites (dogs), foreign bodies, and polyps (cats). Disseminated aspergillosis and penicilliosis: bacterial discospondylitis, bacterial pyelonephritis, and other systemic mold infections, especially paecilomycosis.
- Human Health Significance: Human *Aspergillus* infections are acquired from the environment. *Aspergillus fumigatus* is the most prevalent airborne fungal pathogen in developed countries. The global burden of aspergillosis is high; approximately 3 million people have chronic pulmonary aspergillosis and almost 5 million have allergic bronchopulmonary aspergillosis. Ten million immunocompromised patients per year are at risk of developing invasive aspergillosis, resulting in 200,000 new cases per annum, with a mortality rate of > 50%. Direct transmission from affected dogs and cats to humans does not occur.

Aspergillosis and penicilliosis are diseases caused by pathogenic fungi that belong to genus *Aspergillus* and *Penicillium,* respectively. These fungi are ubiquitous, saprophytic, hyaline molds that sporulate abundantly; their spores (conidia) can be found in soil, water, air, and decaying vegetation. Conidia become airborne after environmental disturbance and strong air currents. Their small size keeps them airborne both indoors and outdoors.[4] It is estimated that an individual person inhales several hundred *Aspergillus* conidia each day.[5] *Aspergillus* species, and very rarely *Penicillium* species, cause a variety of noninvasive and invasive forms of disease in dogs and cats that include keratomycosis, fungal otitis externa, fungal rhinosinusitis (FRS), bronchopulmonary aspergillosis, and disseminated invasive aspergillosis (DIA). *Aspergillus* species known to cause disease in dogs and cats are listed in Table 86.1.[6–23] The genus *Aspergillus* contains several hundred individual species and can be divided into six subgenera (*Aspergillus, Polypaecilum, Cremei, Fumigati, Nidulantes,* and *Circumdati*) comprising 27 sections and 75 series.[24] The subgenera most frequently implicated in canine and feline aspergillosis are *Fumigati, Circumdati,* and *Nidulantes*. Teleomorphs (sexual forms) have been identified for some *Aspergillus* and *Penicillium* species; the asexual state (anamorph) comprises hyphae with mitotic spores (conidia), while the teleomorph consists of fruiting bodies that contain meiotic spores (ascospores) (Fig. 86.1). Teleomorphs are likely to be present in the growth phase of these organisms, when growth has been long-term and the nutrients of the substrate favor sexual differentiation. Under the previous dual nomenclature system, the teleomorph of a fungus was assigned to a separate genus, which had taxonomic precedence over the anamorph name. Most species in section *Nidulantes* (one of nine sections in subgenus *Nidulantes*) have a sexual state and were named *Emericella*. Similarly, *Neosartorya* in section *Fumigati* (subgenus *Fumigati*) and *Eurotium* in section *Aspergilli* were teleomorph genus names of *Aspergillus* species with sexual states. In 2011, dual nomenclature was abandoned in favor of a "one-fungus, one-name" taxonomic rule in the International Code of Nomenclature for algae, fungi, and plants, under which teleomorph genus names have been transferred into *Aspergillus*; for example, *Neosartorya udagawae* is now *Aspergillus udagawae*.[25] This information is relevant for veterinarians and microbiologists since clinically relevant reports may have been published using either the anamorph or teleomorph name of the fungus.

Because accurate identification of *Aspergillus* and *Penicillium* species requires advanced molecular techniques, organisms can be misidentified based on their morphology in culture alone.

Because the etiology, epidemiology, clinical signs, diagnosis, and treatment of upper respiratory tract (URT) aspergillosis, DIA, and keratomycosis/otomycosis differ, they are considered separately in this chapter. The discussion is focused on aspergillosis because of the rarity of penicilliosis; however, clinical disease, diagnosis, and treatment are the same for penicilliosis.

UPPER RESPIRATORY TRACT ASPERGILLOSIS

ETIOLOGY AND EPIDEMIOLOGY

In dogs, sinonasal aspergillosis (SNA) is a subacute to chronic, noninvasive disease of the nasal cavity and sinuses. It is most often caused by *Aspergillus fumigatus*. Rarely, infection by other species, such as *Aspergillus niger* complex organisms (e.g., *Aspergillus tubingensis*) or *Aspergillus flavus* and the closely related fungus *Penicillium,* occurs

TABLE 86.1 *Aspergillus* Species Associated with Disease in Dogs and Cats[6–23]

Clinical Form	Host Species	*Aspergillus* Subgenus/Section/Series	*Aspergillus* Species[a]
Keratomycosis	Cats	*Fumigati/Fumigati/Fumigati*	*A. fumigatus*
		Circumdati/Flavi/Flavi	*A. flavus*
	Dogs		*Aspergillus* spp.[b]
Otomycosis	Cats	*Fumigati/Fumigati/Fumigati*	*A. fumigatus*
	Dogs	*Circumdati/Nigri/Nigri*	*A. niger*
			A. welwitschiae

[a]Some isolates have not been identified beyond the series level level (including some *A. flavus, A. fumigatus*, and *A. niger*).
[b]Reported isolates have not been identified beyond genus level.

(see Table 86.1). SNA occurs worldwide, with cases most commonly reported from the United States and Australia. Any breed of dog can be affected, but disease is most common in large, nonbrachycephalic breeds, especially golden/Labrador retrievers, German/Belgian shepherd dogs, rottweilers, malamutes, and rough/Border collies.[26–40] Smaller breeds most frequently affected include bull terriers, Staffordshire terriers, and miniature schnauzers. Dogs of any age can be affected (median age around 6 years).[26,32,35,41–45] Males appear to be at greater risk of infection than females; of 459 reported cases, 62% were male.[27–42,44–46] Systemic immunodeficiency or concurrent systemic disease is rare in dogs with SNA. Local sinonasal cavity disease including foreign bodies, neoplasia, and trauma is occasionally identified.

Two forms of FRS occur in cats—SNA and sino-orbital aspergillosis (SOA). Similar to dogs, SNA is generally a noninvasive mycosis, with plaques or mats of hyphae that adhere to, but do not penetrate, the mucosal epithelium. By contrast, SOA is a deeply invasive mycosis that extends beyond the nasal cavity and paranasal sinuses to involve adjacent tissues including the orbit. The first case of feline FRS described was in a cat with SOA in 1982, more than a century

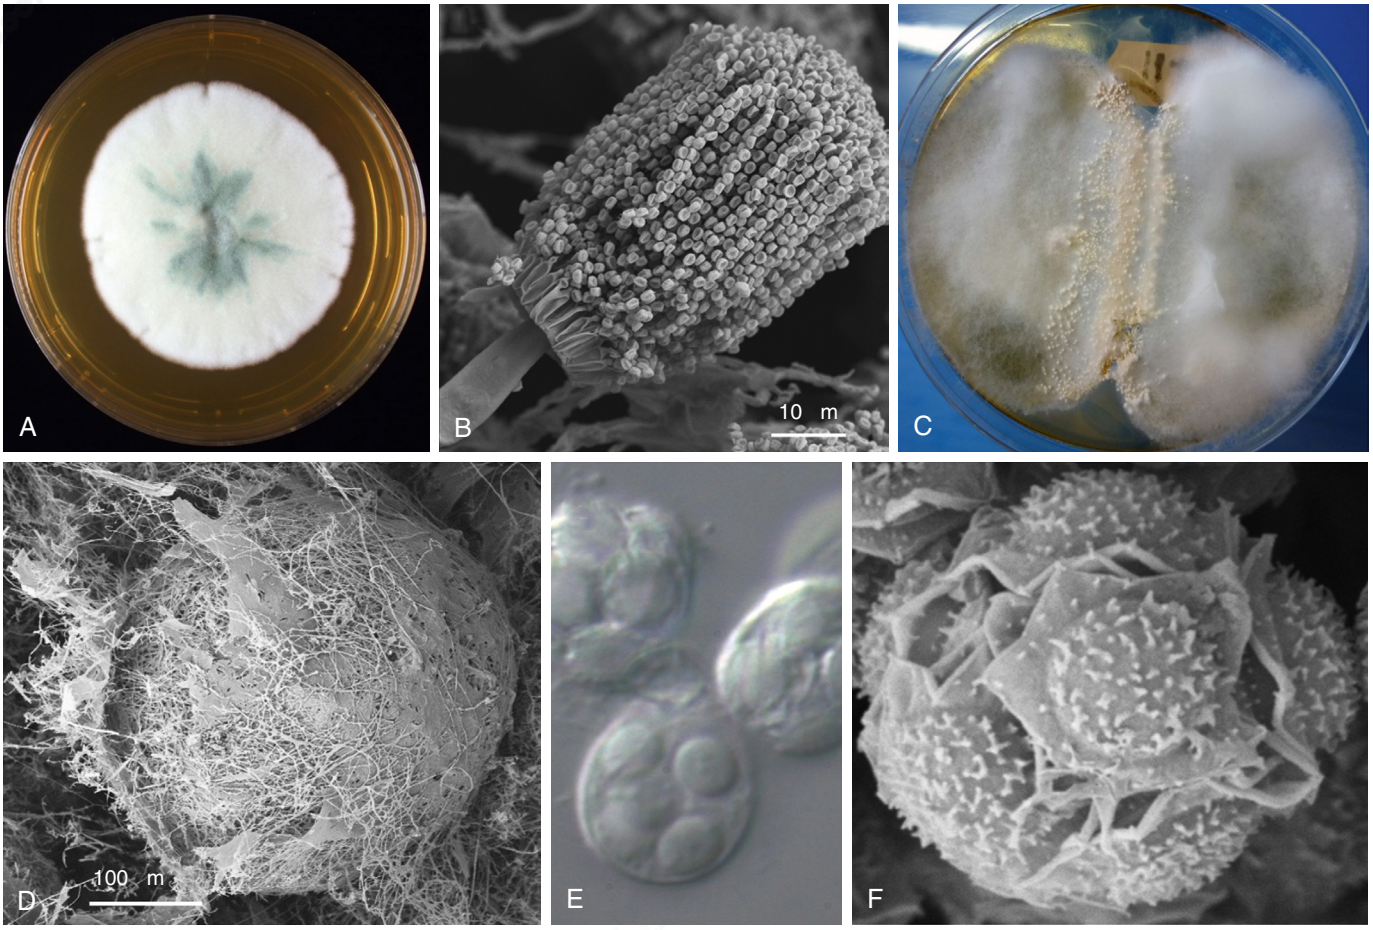

Fig. 86.1 Anamorph phase and teleomorph phase of *Aspergillus felis*. (A) Colony growth on malt extract agar comprising fungal hyphae *(white)* with green conidia centrally. (B) Scanning electron microscopic image of a conidiophore bearing chains of conidia. (C) At the intersection of growth of two colonies of *A. felis* of opposite mating type are multiple fruiting bodies or cleistothecia. (F) Scanning electron microscopic image of 8 ascospores inside an ascus.

after SNA was first described in dogs.[3] Since then over 70 cases of FRS have been reported in cats, mostly in the last decade.[3,6–9,11–13,47–62] Whether this increased reporting frequency is due to increased disease awareness or increased disease prevalence is not yet clear. Similar to canine SNA, the majority of cases in cats are from Australia or the United States, but cases from Japan, the United Kingdom, and mainland Europe reflect the global environmental presence of saprophytic *Aspergillus* species that cause these infections.

SNA in cats is most frequently caused by *A. fumigatus.* Other species within subgenus *Fumigati* such as *Aspergillus lentulus* and *Aspergillus thermomutatus* can also cause feline SNA (see Table 86.1). These closely related species are also called "cryptic" species because of their close morphologic resemblance to *A. fumigatus.* Accurate identification of cryptic species requires molecular techniques, and is important since antifungal resistance is common among these species. Species from other subgenera including *A. niger* and *A. flavus* can also cause feline SNA.

In early descriptions of SOA, causative organisms were not identified beyond the genus *Aspergillus.*[3,49] In several subsequent cases, *A. fumigatus* was identified, but identification was not definitive since it was morphological.[54] Where molecular methods have been used for definitive fungal identification (>25 cases), a novel species of *Aspergillus* discovered in affected cats, *Aspergillus felis*, was the most common cause of SOA, followed by *A. udagawae.* These species, in subgenus *Fumigati*, are cryptic species related to *A. fumigatus,* and even more closely related to *Aspergillus viridinutans*. There are currently 10 species in the *A. viridinutans* species complex, and of these, 3 have been detected in cats with SOA: *A. felis, A. udagawae,* and *Aspergillus wyomingensis.*[63]

Brachycephalic breeds of Persian and related lineage (Himalayans, exotic/British/Scottish shorthair cats, ragdolls) are predisposed to SNA and to SOA, but both conditions occur in any breed. Disease can occur in cats of any age (median, 5 years) and there is no sex predisposition. Most cats with URT aspergillosis test negative for FeLV or FIV infection. SNA and SOA occasionally occur in association with facial trauma, nasal neoplasia, and inhaled plant material, as has been reported in canine SNA.[64,65] Although cats with FRS are usually systemically immunocompetent, diabetes mellitus, a known risk factor for aspergillosis in humans, is likely also a risk factor for feline aspergillosis with upper or lower respiratory tract involvement.[11,51,57,66,67]

PATHOGENESIS

Sinonasal Aspergillosis

The pathogenesis of canine SNA is not fully understood despite investigations of innate and adaptive immune responses.[68–73] There are three lines of defense against fungal respiratory infection: (1) the respiratory mucosal epithelium traps and removes inhaled conidia via the mucociliary escalator and acts as an anatomic barrier to invasion; (2) fungal elements are phagocytosed by host cells (monocytes, macrophages, neutrophils, and respiratory epithelial cells) resulting in direct

pathogen killing; and (3) dendritic cells respond to phagocytosis by promoting differentiation of naïve T cells into effector T-helper (Th) cell subtypes.

After inhalation, *Aspergillus* conidia that are not trapped and removed by mucociliary defenses germinate, if temperature and humidity are favorable, to form plaques of fungal hyphae that are adherent to the sinonasal mucosa. *Aspergillus* conidia are coated with hydrophobin proteins that facilitate mucosal adherence and protect conidia from recognition of PAMPs by innate and adaptive immune cells.[74] SNA is usually noninvasive; therefore, fungal hyphae do not penetrate the mucosal epithelium.

Dendritic cells express pattern recognition receptors (PRRs) including C-type lectin receptors, TLRs, NOD-like receptors (NLRs), and galectin family proteins that recognize specific fungal epitopes and induce specific Th responses, which are an essential determinant of host susceptibility or resistance to invasive aspergillosis.[75] In the immune response of humans to *A. fumigatus*, Th1 cytokine responses are generally protective, while Th2 cytokine responses increase susceptibility to invasive disease. Th17 responses are regulatory, promoting Th1 responses and suppressing Th2 responses. Th17 responses are implicated in the immunopathogenesis of chronic fungal infections by failure to restrain inflammation after IL-17A-dependent neutrophil recruitment.[75] T-regulatory (Treg) cells restrain exuberant immune reactivity and limit tissue damage in many chronic infections, but can handicap the effect of protective immunity. In addition to infected cells, or cells exposed to fungal PAMPs, Treg cells are a principal source of IL-10.

Cytokine profiling of dogs with SNA demonstrated upregulation of mRNA for cytokines associated with a Th1 response compared with normal controls or dogs with lymphoplasmacytic rhinitis.[68,69,72] In addition, there was upregulation of IL-10, which may limit the extent of local tissue destruction,[76] but paradoxically could also impede clearance of infection. Compared with normal dogs, dogs with SNA were found to have significantly higher expression of all 10 TLRs except for TLR5, and of NLR2, but not NLR1 in the nasal mucosa.[73] A subsequent mutational analysis of TLRs 2, 4 and 9 was performed,[70] since single-nucleotide polymorphism (SNPs) in these specific TLRs have been associated with higher risk of fungal disease in humans.[77] However, no SNPs associated with canine SNA were detected.

The functional phenotype of peripheral blood mononuclear cells (PBMCs) from normal dogs and dogs with SNA after challenge with heat-inactivated *A. fumigatus* conidia has also been determined.[71] There was significantly greater expression of IL-17A mRNA in PBMCs from affected dogs compared with controls, suggesting a role for a Th17-driven uncontrolled inflammatory response that could counteract the host's efforts to clear fungal infection through Th1-directed immunity.

Although SNA in dogs is noninvasive, it results in nasal turbinate and paranasal bony lysis, which can be severe. This is attributed to the inflammatory response of the host.[78] In addition, *A. fumigatus* synthesizes proteases, phospholipases, and toxic secondary metabolites, which may contribute to tissue destruction.[79] Other fungal metabolites unique to section *Fumigati* have one or more virulence properties including cytotoxicity (e.g., fumiquinazolines, trypacidin), ability to induce ciliastasis (e.g., verruculogen, helvolic acid) or apoptosis; and inhibition of immune responses, neutrophil responses, phagocytosis, and/or angiogenesis (e.g., gliotoxin, fumagillin, pyripyropenes).[79]

Sino-Orbital Aspergillosis

In SOA there is direct extension of a sinonasal infection to involve paranasal structures, usually via lysis of the thin orbital bone.[8] Cats with SOA have granulomatous invasive mycotic rhinosinusitis with submucosal hyphal invasion.[3,6,55] Once infection reaches the orbit, multilobulated fungal granulomas form in which hyphae are confined centrally.

As orbital granulomas expand, they cause dorsolateral displacement of the globe and bulge ventrally into the caudal oral cavity. In advanced disease, local extension to involve the CNS can occur, resulting in granulomatous mycotic meningitis. Hematogenous dissemination to involve other organs was reported in one case.[80] A role for species-specific fungal virulence factors in the development of disease is suspected since different fungal species cause SNA and SOA. The *A. felis* type strain, isolated from a cat with SOA, had significantly higher virulence in *Galleria melonella* larvae than *A. fumigatus*.[81] Whether unique fungal metabolites are involved in pathogenicity is not known, for example, viriditoxin is produced by all members of the *A. viridinutans* complex but not by *A. fumigatus*.[79]

CLINICAL FEATURES

Clinical Signs

Clinical signs of SNA in dogs include sneezing, reverse sneezing, chronic serous to mucopurulent nasal discharge, depigmentation, crusting or ulceration of the nasal planum, muzzle pain and, less commonly, epistaxis (Fig. 86.2). Clinical signs are subtle early in disease. Nasal discharge is initially unilateral but can become bilateral as the disease progresses. Signs in advanced disease may include lethargy, inappetence, and weight loss. Nasal pain can manifest as pawing at the face, hiding, or withdrawal when approached. Destruction or obstruction of the nasolacrimal duct can lead to epiphora. Osteolysis of the cribriform plate is often subclinical, but occasionally leads to meningitis with neurologic signs such as obtundation or seizures. Clinical signs of SNA in cats are similar although nasal depigmentation and signs of nasal pain have not been reported.

Cats with SOA are usually examined because of signs associated with a retrobulbar fungal granuloma including unilateral exophthalmos, a prolapsed, inflamed third eyelid, and blepharospasm or conjunctival discharge (Fig. 86.3). Exposure keratitis is common and uveitis is sometimes present. Nasal signs may be subtle or absent; however, the history usually reveals sneezing or nasal discharge in the 6 months before examination. In advanced disease, vision loss can occur due to severe ulcerative keratitis or infiltration of the optic nerve and/or optic chiasm.[6,49,50,55] Exophthalmos may become bilateral and neurologic signs may develop including seizures, nystagmus, circling, facial muscle fasciculation, and hyperesthesia.[6,58,59] Inappetence and dysphagia can also occur.[59]

Physical Examination Findings

Physical examination findings in dogs with SNA include unilateral or bilateral serous or mucopurulent nasal discharge, epistaxis, pain on palpation of the face, mild mandibular lymphadenomegaly, depigmentation, crusting or ulceration of the nares, and occasionally epiphora (see Fig. 86.2). Nasal airflow is usually normal or increased because of turbinate lysis. Sometimes palpation of the nasal bones or hard palate can reveal defects in the underlying bone. Dogs with cribriform plate involvement and meningitis may be obtunded or dehydrated. Dogs with severe epistaxis can have melena on rectal examination secondary to swallowed blood. Most affected dogs are afebrile.

Physical examination findings in cats with SNA consist of serous or mucopurulent nasal discharge, sneezing, stertor, epistaxis, and, in some cases, mandibular lymphadenomegaly, fever, or a discharging sinus over the nasal bridge or frontal sinus.[6] Cats with SOA most commonly have unilateral exophthalmos with dorsolateral

deviation of the globe and prolapse of the third eyelid, which may also be inflamed. Corneal ulcers are usually central and are readily visualized with fluorescein stain (see Fig. 86.3). Other ocular signs variably present include miosis, an absent pupillary light response, an absent menace response, and signs of anterior or posterior uveitis. Resistance to retropulsion of the globe and normal intraocular pressure readings on tonometry enables differentiation of exophthalmos from buphthalmos.

Oral cavity involvement is first visible as a submucosal swelling in the pterygopalatine fossa adjacent to the last molar tooth, which may become ulcerated (Fig. 86.4). Ulceration of the hard palate occurs occasionally. Fungal invasion of maxillary subcutaneous tissues causes facial swelling, which may be subtle or severe and can ulcerate.[61] Fever and mandibular lymphadenomegaly are variably present. In most cases, there is no pain on opening of the mouth.

DIAGNOSIS

Early diagnosis of URT aspergillosis relies on a high degree of suspicion for the disease and availability of client financial resources because of a lack of uniformly available sensitive, noninvasive diagnostic tests for the disease. Serologic tests are performed early in investigation. Definitive diagnosis requires a combination of imaging, visualization of fungal plaques by rhinoscopy/sinuscopy (SNA), and identification of fungal elements on cytology or histopathology. Imaging should be performed before rhinoscopy to avoid the influence of iatrogenic hemorrhage on the results. Duplicate tissue or fungal plaques can be stored frozen, as well as submitted fresh for culture and in formalin for histopathology. If fungal cultures are negative, frozen tissues can be retrieved for molecular testing.

Laboratory Abnormalities

Dogs with SNA often have no abnormalities on CBC, serum chemistry profile, or urinalysis. Occasionally, mild nonregenerative anemia; mild neutrophilia, rarely with a left shift; mild eosinophilia; and/or mild hypoalbuminemia are present.[10] Cats with SOA may have a mild mature neutrophilia and sometimes mild to severe hyperglobulinemia.[6,49]

Diagnostic Imaging

Plain Radiography

Plain skull radiographs in dogs or cats with SNA may show unilateral or bilateral loss of turbinate detail, destruction of the nasal septum, and/or increased soft tissue opacity within the nasal cavity. The open-mouth view provides optimum evaluation of the turbinates (Fig. 86.5A). A "skyline" view of the nasal sinuses may show opacification of one or both sinuses and frontal bone hyperostosis (Fig. 86.5B).[33]

Advanced Imaging

Whenever possible, CT or MRI are preferred imaging modalities for the nasal cavity because of their increased sensitivity over plain radiography for evaluation of the nasal cavity, sinuses, and cribriform plate.[33] Bony changes are best appreciated on CT. Sinonasal cavity involvement can be unilateral or bilateral in dogs, and is usually bilateral and asymmetric in cats.[32,33] In some animals, lesions are limited to the frontal sinus.[8,45] Findings on CT or MRI in canine and feline SNA include moderate to severe "cavitated" nasal turbinate lysis and defects in the nasal septum; increased soft tissue opacity within the nasal cavity and/or sinuses due to mucosal inflammation, fluid accumulation, or fungal plaques; hyperostosis of the frontal

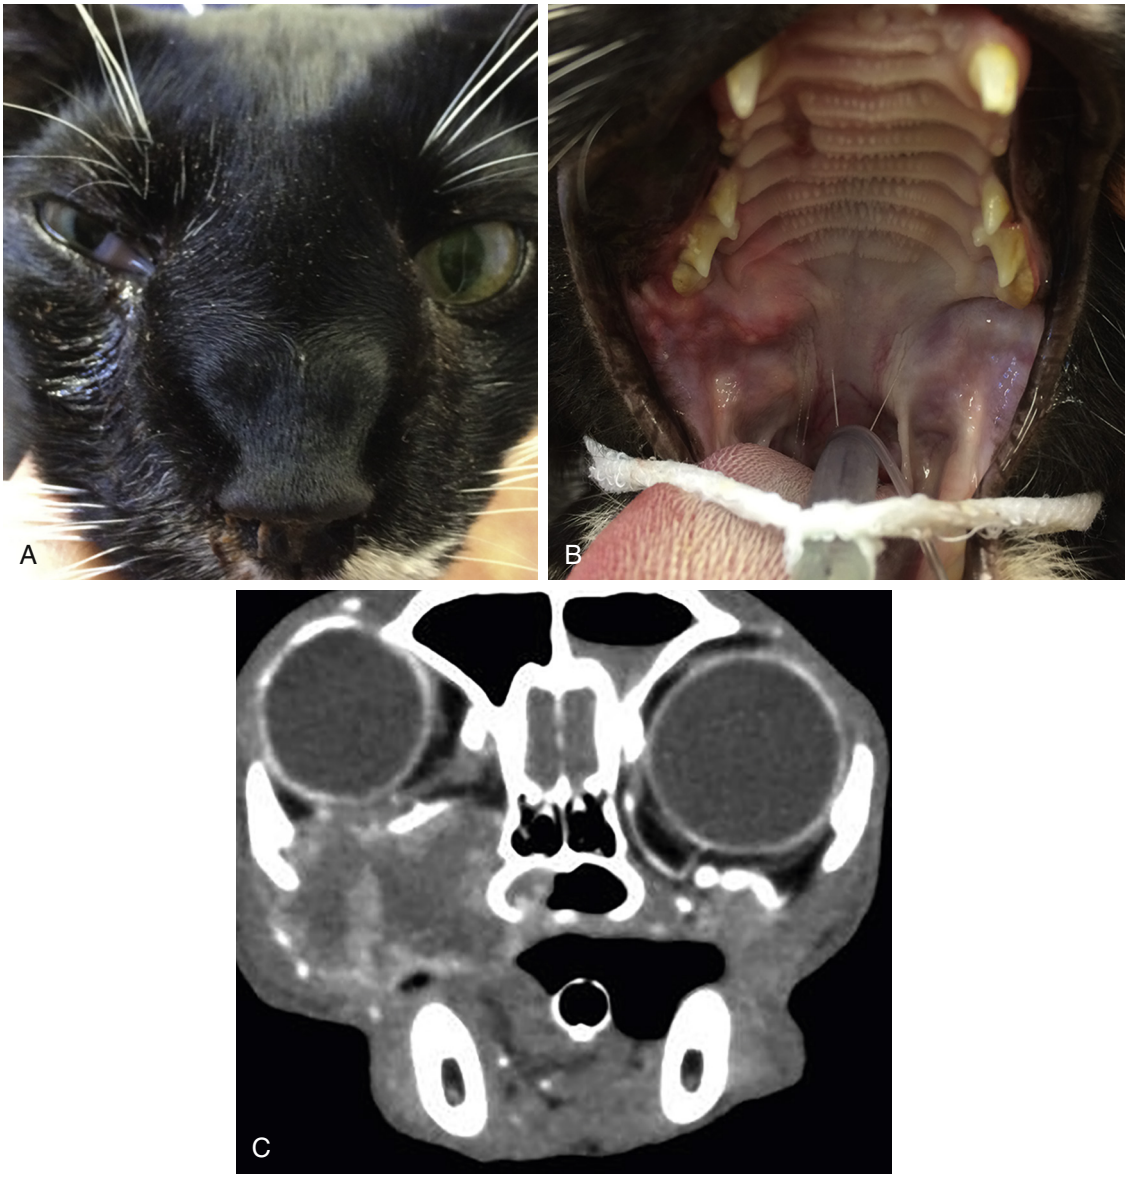

Fig. 86.4 A 3-year-old domestic shorthair cat with sino-orbital aspergillosis with unilateral right exophthalmos with prolapse of the third eyelid, blepharospasm, conjunctival discharge, and unilateral right nasal discharge (A); the orbital mass has extended into oral cavity in the right pterygopalatine fossa (B) and is visible on a post-contrast axial computed tomography scan in a soft tissue window as a heterogeneous mass with characteristic peripheral rim enhancement causing dorsolateral displacement of the globe and invasion into the oral cavity and subcutaneous maxillary tissues (C).

bones; and mandibular or retropharyngeal lymph node enlargement.[8,32,33,45] Nasal mucosal thickening is detected as a rim of soft tissue along the nasal bones, maxillary recess, and frontal bone. Osteolysis of the cribriform plate, orbital bone, frontal bones, and, rarely, the maxillary or palatine bones may be present (Fig. 86.5C). Meningeal enhancement is sometimes evident on contrast administration in dogs with cribriform plate destruction.[41] Fungal plaques and mucosal secretions fail to enhance with contrast and cannot be readily distinguished from each other. Deposits of calcium-containing fungal metabolites that aggregate to cause sinoliths are common in human maxillary sinus mycetomas, but have only been reported in one cat with SNA (rhinoliths),[50] one cat with SOA (sinolith),[8] and not in dogs.

Advanced imaging is recommended for all cases of suspected feline URT aspergillosis to differentiate SNA from SOA. In early disease, orbital involvement may not be apparent on clinical examination, and, if present, is an indication for systemic antifungal therapy as part of the management plan. CT findings in SOA include a retrobulbar mass in the rostral and ventromedial aspect of the orbit with indentation or dorsolateral displacement of the globe. In most cases, there is involvement of the ipsilateral paranasal maxillary soft tissues, and less commonly of the pterygopalatine fossa, either of which may cause a mass effect (see Fig. 86.4). There may also be a mass effect in the nasal cavity, nasopharynx, or paranasal sinuses. Orbital masses show heterogeneous contrast enhancement and often contain lobulated hypoattenuating foci with peripheral rim enhancement (see Fig. 86.4).[8,12,55,58,59] However, this

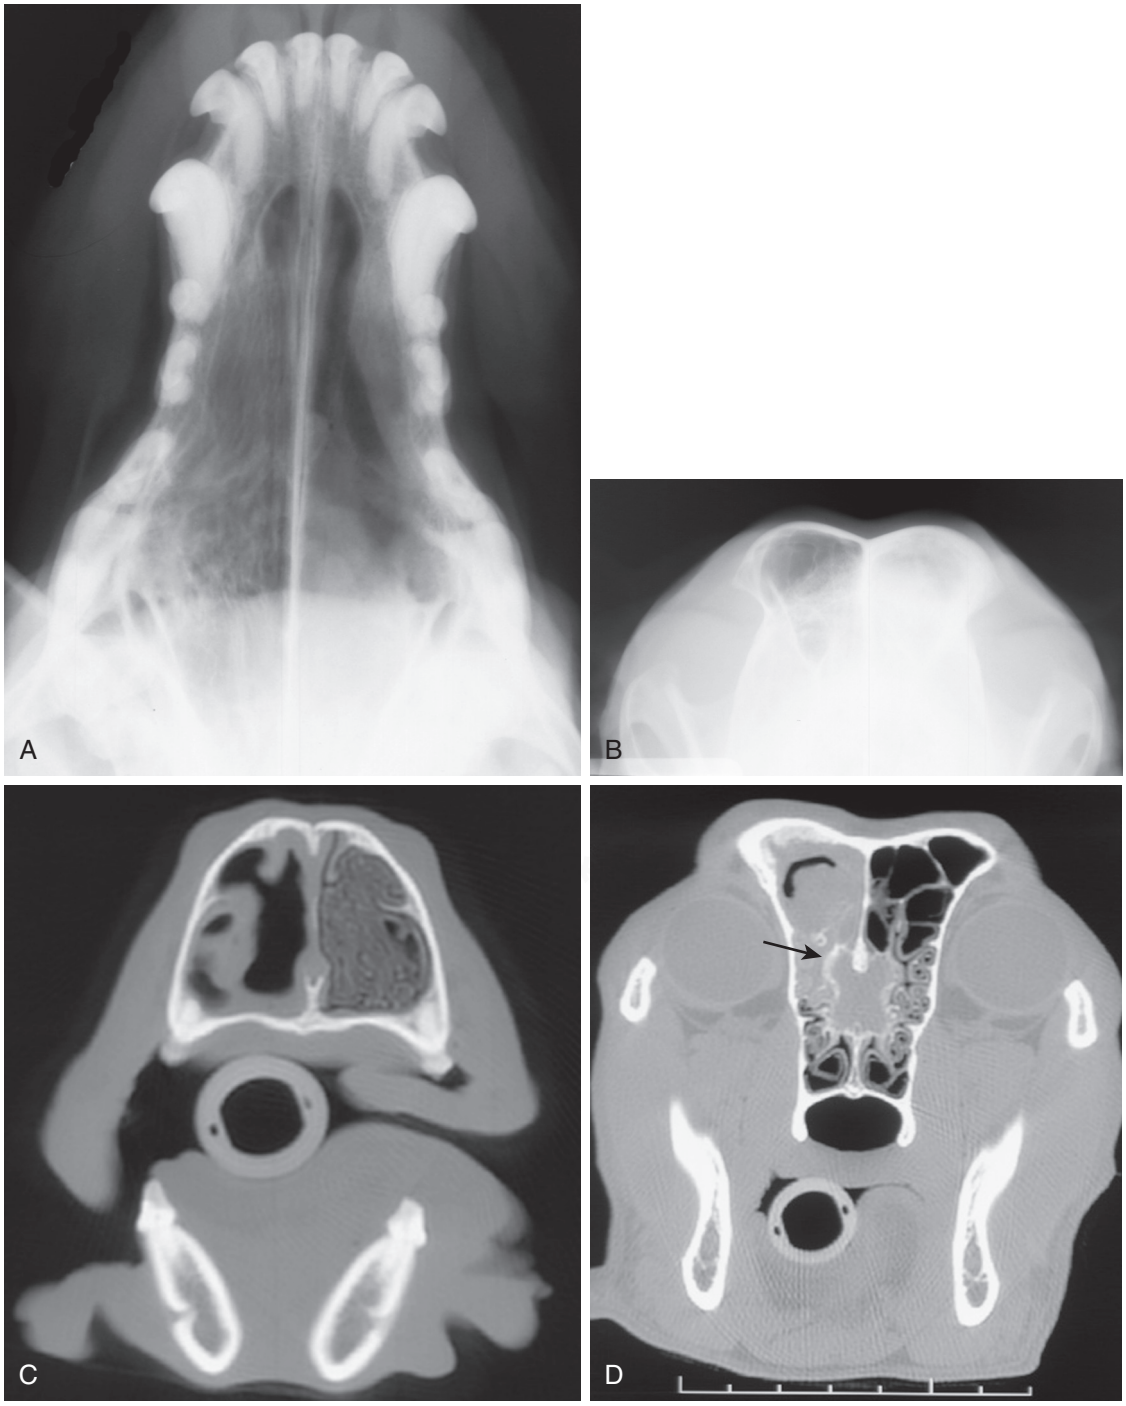

Fig. 86.5 Plain radiographs and computed tomography scan images of the nasal cavity of a 6-year-old female spayed golden retriever with sinonasal aspergillosis. (A) Open-mouth view. There is marked loss of detail in the left nasal cavity. (B) Skyline projection of the frontal sinuses. There is increased opacity in the left frontal sinus. (C) A transverse image through the nasal cavity shows marked turbinate loss on the left side. (D) Transverse image through the frontal sinuses and region of the cribriform plate. There is moderate fluid accumulation and irregular soft tissue structures in the left frontal sinus, and the frontal bone that overlies the sinus is thickened and irregular. Bony destruction at the level of the cribriform plate is present *(arrow)*.

pattern of enhancement is not specific for aspergillosis and can be seen with other mycoses (e.g., cryptococcosis) or neoplasia.[8] Sinonasal cavity involvement can almost always be detected in cats with SOA; changes are similar to SNA, but may be more subtle. With MRI, retrobulbar masses are T2-hyperintense. Invasion of temporal and masseter muscles by the mass may also be apparent on MRI (Fig. 86.6).[58]

Rhinoscopy and Sinuscopy

Visualization of fungal plaques by rhinoscopy and sinuscopy confirms the presence of mycotic rhinitis, and is a noninvasive, reliable method for obtaining fungal plaques and mucosal biopsies for cytology, histopathology, and fungal culture. Plaques are white, gray, yellow, black, greenish, or a mixture of these colors and are adhered to the nasal

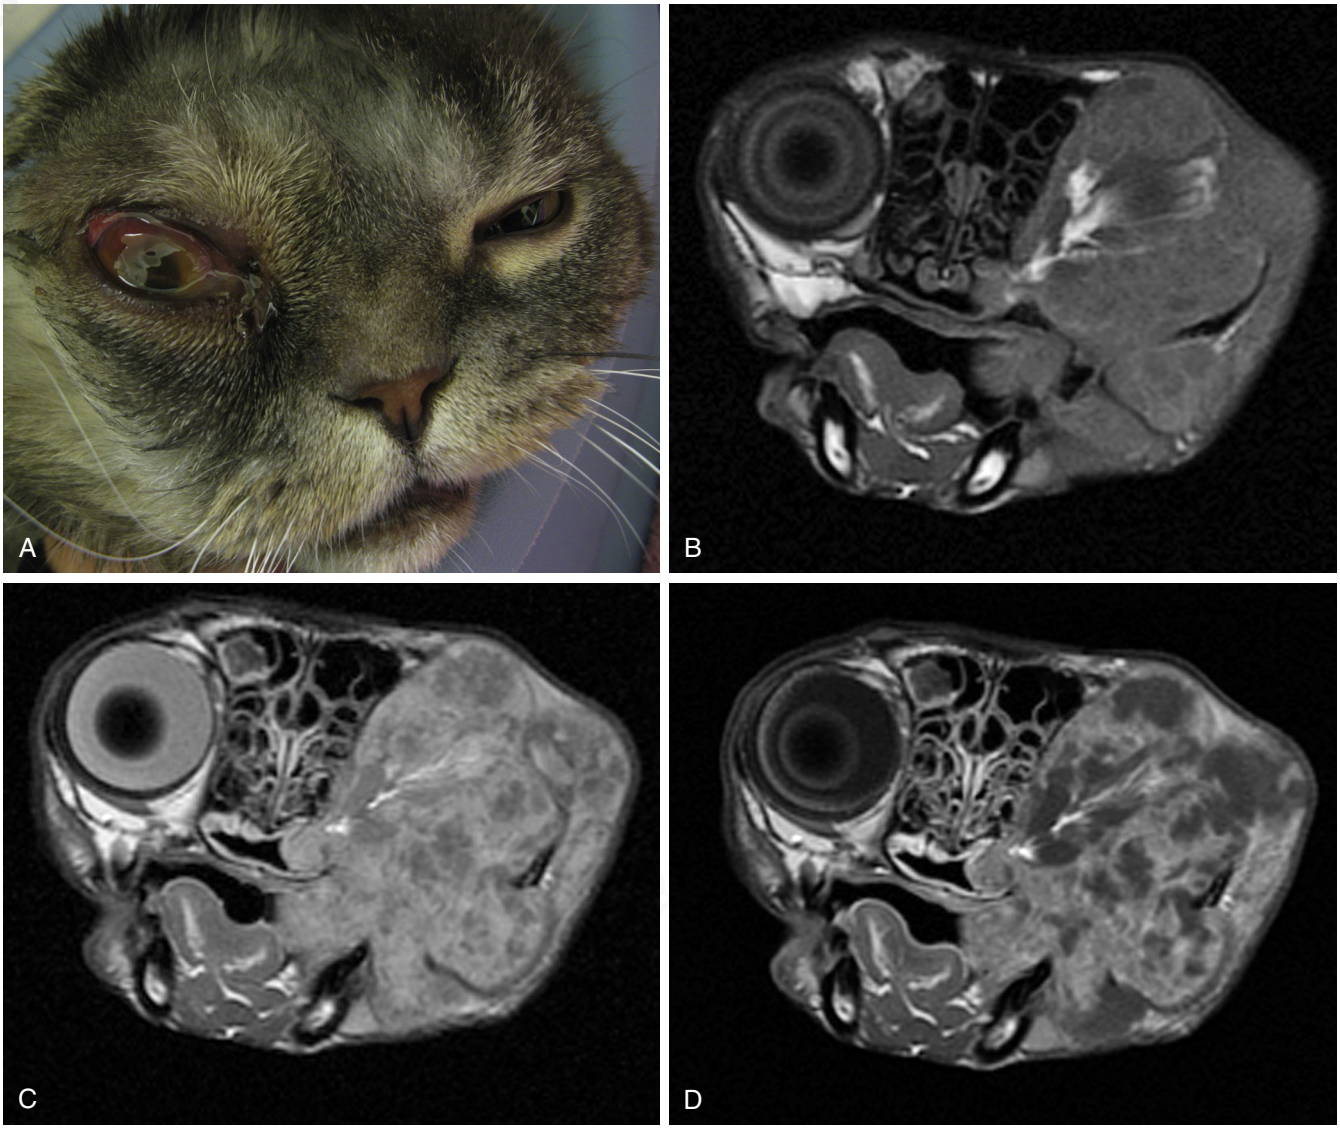

Fig. 86.6 (A) A 7-year-old male neutered Scottish fold cat with exophthalmos, conjunctivitis, and blindness of the right eye secondary to sino-orbital aspergillosis. A 1- to 2-cm mass was also identified in the pterygopalatine fossa on oral examination. (B–D) Magnetic resonance imaging of the head of the same cat. The right eye was displaced rostrally by a large retrobulbar mass that is (B) mildly, heterogeneously hyperintense on T1-weighted images, (C) hyperintense on T2-weighted images, and (D) enhanced with contrast. The mass extends medial to the ramus of the mandible and enters the nasopharynx as well as the oropharynx. A small T1-hyperintense structure is noted in the left frontal sinus.

mucosa or mucosa of the frontal sinus in cases of SNA. (Fig. 86.7). Cytologic examination is important to establish a diagnosis of SNA since there are other causes of mycotic rhinitis, and because mucopurulent exudates can occasionally be mistaken for fungal plaques.

In dogs, nasopharyngoscopy is performed with a flexible endoscope, after which a rigid telescope or flexible endoscope is used to examine the rostral portions of the nasal cavity. In some cases, extensive turbinate destruction allows a flexible endoscope to be passed directly into the frontal sinuses through the nasofrontal opening. If this is not possible, but CT or MRI findings suggest the possibility of frontal sinus lesions, trephination or surgical exploration of the frontal sinuses is necessary to visualize (and treat) this region. After trephination, a rigid endoscope can be used to examine the frontal sinus through the trephination site.

Nasopharyngoscopy using a flexible endoscope is useful in cats to identify choanal and nasopharyngeal fungal plaques or granulomas. In cats with SOA, although mycotic rhinitis is usually present, fungal plaques are not seen on rhinoscopy because of deep tissue invasion by fungal hyphae. The nasal cavity is examined using a rigid rhinoscope. Indications for sinus trephination are the same as for dogs.

Microbiologic Tests

Cytologic Examination

Cytologic examination of blind or rhinoscopy-directed mucosal swabs, brush specimens of the nasal cavity, or nasal biopsies from dogs or cats with SNA can reveal filamentous fungal hyphae and sometimes also conidia (Table 86.2). Hyphae stain well with Wright stain. They are septate and branch at 45-degree angles (see Fig. 4.3). Large numbers of degenerate neutrophils, ciliated epithelial cells, and/or bacteria are also usually present. In one study, the sensitivity of cytologic examination was 93% for endoscopic-guided cytology brush specimens, and 100% for squash preparations of biopsies of suspected mucosal fungal plaques, but it was only 20% or less for nasal discharge or smears made from blind swab specimens.[40]

TABLE 86.2 Diagnostic Assays Available for Aspergillosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of biopsies	Fungal hyphae (with or without conidia in tissues exposed to air)	False negatives can occur when specimen size is small or low numbers of fungi are present. Cytology of brush specimens optimizes sensitivity for dogs with SNA. Identification to species level requires culture and molecular testing.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids	*Aspergillus* species	Sensitivity for diagnosis of canine SNA is at least 75% when endoscopically guided nasal biopsies are cultured. Specificity is > 95%. Culture of a typical species (*A. terreus* or *A. deflectus*) from a dog with signs consistent with disseminated disease strongly suggests DIA. Molecular testing by PCR may be required to identify beyond the species complex level.
Antibody serology (AGID or ELISA)	Serum	Antibodies to *Aspergillus* species	Assays vary in sensitivity and specificity. In general, positive results support a diagnosis of canine SNA, but negative results do not rule out the disease. Insensitive for diagnosis of DIA.
Galactomannan antigen assay (ELISA)	Urine, serum	*Aspergillus* spp. galactomannan cell wall antigen	Insensitive for diagnosis of SNA, SOA, and probably bronchopulmonary disease. Very sensitive for diagnosis of DIA. Cross-reactivity with other fungal pathogens may occur (especially other molds). False positives also occur with Plasmalyte administration.
Real-time PCR assays	Whole blood	*Aspergillus* spp. DNA	Assays studied lack sensitivity or specificity for diagnosis of canine SNA. Usefulness for diagnosis of DIA requires further study.
Histopathology	Biopsy specimens from affected tissues	Fungal hyphae (with or without conidia in tissues exposed to air)	Sensitivity for diagnosis of canine SNA in rhinoscopically guided biopsies was 82%. Hyphae are usually visualized in biopsies from animals with DIA, but lesions may be difficult to access for biopsy. Special stains assist organism detection.

AGID, agar gel immunodiffusion; *DIA,* disseminated invasive aspergillosis; *ELISA,* enzyme-linked immunosorbent assay; *PCR,* polymerase chain reaction; *SNA,* sinonasal aspergillosis; *SOA,* sino-orbital aspergillosis.

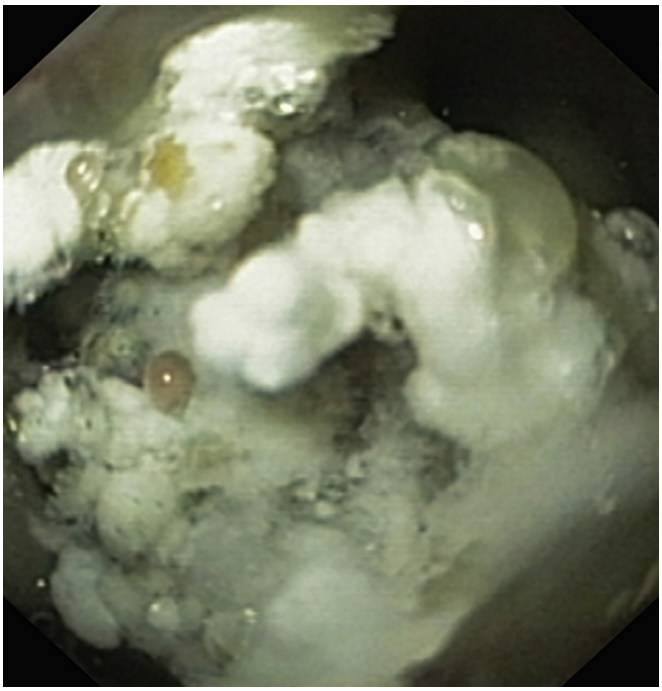

Fig. 86.7 Rhinoscopic view of white to gray fungal plaques in the nasal cavity of a 9-year-old male miniature schnauzer with sinonasal aspergillosis.

Fungal hyphae may be identified in cats with SOA on cytologic examination of fine-needle aspirates or squash preparations of nasopharyngeal or retrobulbar masses biopsied via the oral cavity or with ultrasound or CT guidance. However, because fungal hyphae are confined to central areas of granulomatous lesions, they may be missed.

Serologic Diagnosis

The sensitivity of serologic tests to detect the fungal cell wall antigen galactomannan (GM) or *Aspergillus*-specific antibodies in aspergillosis is heavily influenced by host immunocompetence (see Table 86.2). Antigen tests are affected by host ability to clear fungal antigen from the circulation, and antibody tests rely on an adequate humoral immune response. A commercial ELISA to detect GM in the serum (Platelia *Aspergillus* EIA, Bio-Rad) has a sensitivity of up to 90% in systemically immunocompromised patients, including neutropenic human patients with pulmonary aspergillosis and dogs with DIA.[82,83] However, in non-neutropenic patients with pulmonary aspergillosis, the assay sensitivity is < 30%.[82,84,85] Similarly, in dogs and cats with SNA, GM also performs poorly (23%–24% sensitivity).[43] In immunocompetent patients, GM is cleared by neutrophils, which possess mannose-binding receptors, or is complexed by antibody.[86,87] Also, lack of tissue invasion in noninvasive mycoses such as SNA may contribute to the lack of detectable circulating GM.

Assays to detect serum *Aspergillus*-specific antibodies include immunodiffusion (ID) assays that detect precipitins, such as AGID or counter immunoelectrophoresis (CIE) (see Fig. 2.7A), and ELISA assays. In general, ID assays have lower sensitivity and higher specificity than ELISAs for diagnosis of canine and feline URT aspergillosis. However, clinical performance data for some assays used in commercial veterinary diagnostic laboratories may not be available. The sensitivity of one ID assay (Meridian Bioscience, USA) for diagnosis was 57% to 77% for canine SNA[41–43] and 43% for feline URT aspergillosis.[9] The specificity for both assays was 98%–100%.The sensitivity and specificity of another ID assay (Immuno-Mycologics, OK, USA) for canine SNA was 31% and 97%, respectively.[88] The sensitivity and specificity of an ELISA assay that detects antibodies against a commercial *Aspergillus* antigen extract derived from *A. fumigatus, A. niger,*

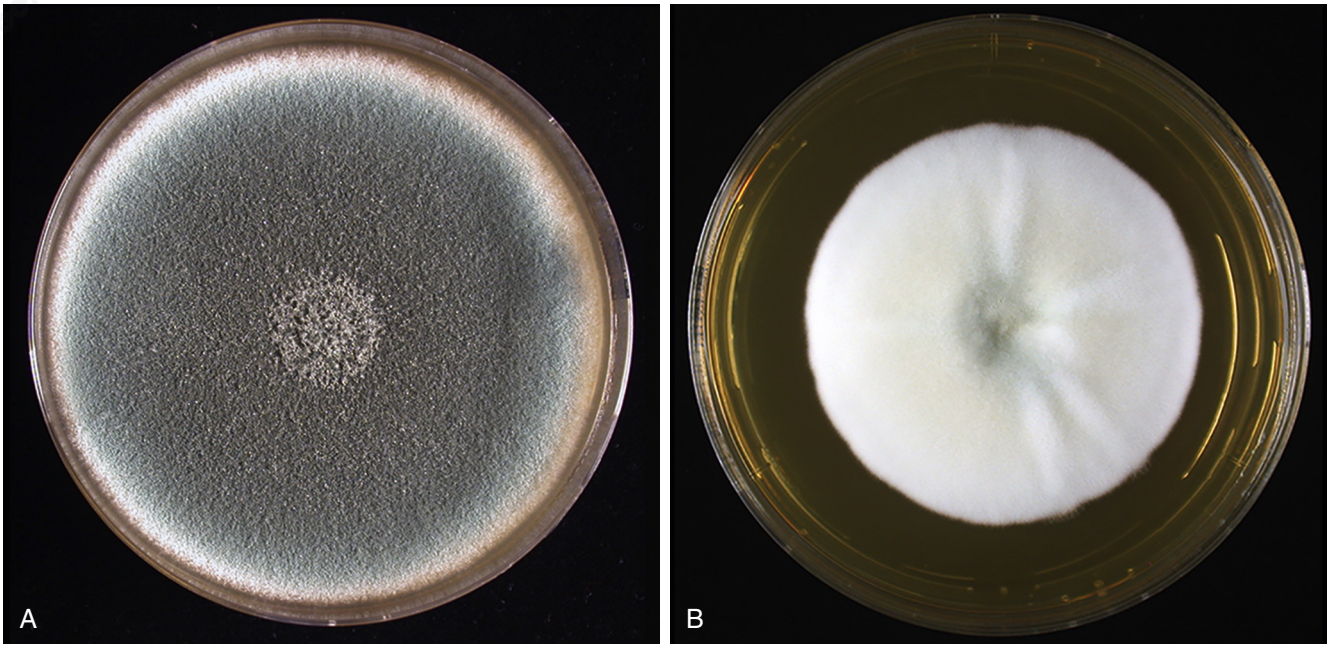

Fig. 86.8 Cultures of (A) *Aspergillus fumigatus* and (B) *Aspergillus felis* on malt-extract agar after 7 days of incubation at 27°C. Note the grey-green conidia of *A. fumigatus* which sporulates rapidly compared with *A. felis*.

and *A. flavus* was 88% and 97%, respectively, for canine SNA and 95% and 93%, respectively, for feline URT aspergillosis.[9,43] Thus, negative results with these antibody assays do not rule out SNA, but positive results strongly suggest the disease is present.

Fungal Culture

Aspergillus fumigatus can be readily grown on routine laboratory media. Colonies of mold generally appear within 96 hours, but occasionally longer incubation times are required.[44] In the absence of supportive rhinoscopic, cytologic, or histopathologic findings, positive cultures from the nasal cavity require cautious interpretation because *Aspergillus* may be found within the URT of healthy animals. Nevertheless, in two separate studies, no dogs with nonfungal nasal disorders had positive culture results for *Aspergillus*.[42,44] In one of these studies (which included 21 dogs with SNA and 37 dogs with nonfungal nasal disease), the sensitivity of fungal culture of endoscopic nasal tissue biopsies (including nasal mucosa and fungal plaques if visualized) for diagnosis of canine SNA was 81%.[42] In the other study, the sensitivity of fungal culture of nasal mucosal biopsies at 37°C was 75%, 88% for fungal plaques and < 19% for blindly collected nasal swab specimens (see Table 86.2).[44]

The fungal pathogens that cause feline URT aspergillosis can usually be isolated from tissue biopsies or fungal plaques on commercial culture media such as Sabouraud's dextrose agar or malt extract agar. Of 23 cases of feline SNA and SOA, 22 were culture-positive in one study.[6] One useful distinguishing feature of the cryptic species in *Aspergillus* subgenus *Fumigati* that cause URT aspergillosis in cats (e.g., *A. felis*) is their inability to grow at 50°C, in contrast to *A. fumigatus*, which does exhibit growth at 50°C. Fungal cultures from cats with URT aspergillosis can be subcultured and incubated at 50°C to determine whether a cryptic species is present. Fungal isolates that fail to grow at 50°C should be submitted for molecular testing for species identification. Cryptic species are also slower to sporulate than *A. fumigatus* and have white or cream-colored fungal colonies before sporulation in contrast to the rapidly sporulating grey-green colonies of *A. fumigatus* (Fig. 86.8).

Identification of *Aspergillus* species using macroscopic and microscopic morphologic features is inaccurate and many cryptic species within a complex cannot be reliably differentiated from each other. Morphologic features in combination with demonstration of fungal growth at 50°C is usually adequate to differentiate *A. fumigatus* from cryptic species.[21] Accurate identification of other species in *Aspergillus* subgenus *Fumigati* requires PCR and sequencing. Using DNA extracted directly from fungal cultures, longer gene targets can be amplified than from formalin-fixed paraffin-embedded tissues, and amplification of the ITS1-5.8S-ITS2 region of rDNA (751 bp) using primers ITS1 and ITS4 is standard. For some species, amplification of a secondary identification target such as calmodulin, β-tubulin, or the RNA polymerase II second largest subunit (*RPB2*) is required for definitive identification.[89]

MALDI-TOF MS is an alternative method for identification of *Aspergillus* species but has been limited by inadequate species and strain spectra representation in commercial libraries (see Chapter 3). For example, of 55 clinical *Aspergillus* isolates from Australia, 69% were correctly identified using the commercial database alone, but 93% were correctly identified when it was combined with an in-house database constructed from strains of *Aspergillus* circulating in Australia.[90]

Molecular Diagnosis Using Nucleic Acid–Based Testing

In veterinary medicine, the use of panfungal PCR assays for the diagnosis of mycotic disease is increasing. PCR can lack sensitivity for detection of fungi when compared with bacteria due to problems associated with fungal cell wall lysis in order to release DNA during the first step of DNA extraction. PCR assays targeting the ribosomal DNA (rDNA) gene cluster have the broadest application because this gene is multicopy (>50,000 copies per haploid fungal genome). It also contains regions that are highly conserved between fungal genera and that flank highly variable regions. Thus, universal primers can be designed based on the conserved regions, and the resulting sequences enable identification to at least genus or species complex level. The rDNA gene cluster comprises the small subunit rDNA (18*S*) gene, the 5.8*S* gene, and the large subunit (28*S*) gene. These regions are separated

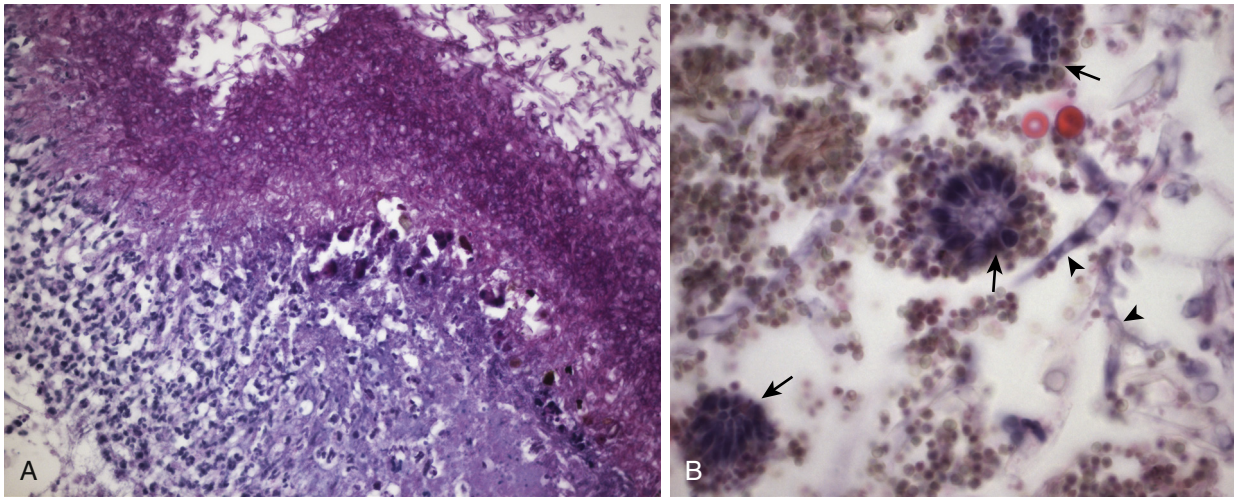

Fig. 86.9 Histopathology of a nasal biopsy from a 4-year-old intact male Border collie with sinonasal aspergillosis. (A) There is a profound neutrophilic inflammatory response beneath a thick mat of fungal hyphae, which stains magenta. Periodic acid-Schiff stain, 400× magnification. (B) *Aspergillus* hyphae *(arrowheads),* conidiophores *(small arrows),* and conidia *(spores)* can be seen on the surface of the lesion. Hematoxylin and eosin stain, 1000× oil magnification.

by the intergenic transcribed spacer (ITS) regions, ITS1 and ITS2, which are the most hypervariable regions. PCR assays that target the 361 bp ITS1 region (primers ITS1 and ITS2) or the 231 bp ITS2 region (primers ITS3 and ITS4) have been used to identify fungal pathogens in fresh, frozen, or formalin-fixed canine and feline tissues.[91,92] In two studies, the sensitivity of these PCR assays to correctly identify a fungal pathogen to genus or species level was approximately 65%.[91,92] Real-time PCR methods are increasingly used together with fungal antigen detection tests for the diagnosis of pulmonary aspergillosis in immunocompromised humans using blood (plasma or serum) or bronchoalveolar lavage fluid.[93] The use of real-time PCR assays to detect *Aspergillus* DNA in nasal biopsy specimens was evaluated for diagnosis of SNA in dogs, but assays evaluated had either unacceptably high rates of false-positive test results (PenAsp assay) or a low sensitivity (*Aspergillus* genus-specific PCR).[88] For both assays, dogs with SNA had higher DNA copy numbers than control dogs or dogs with lymphoplasmacytic rhinitis or neoplasia, but there was considerable overlap in copy numbers between dogs with SNA and those without SNA.

Pathologic Findings

The sensitivity of histologic examination of nasal mucosal biopsies for diagnosis of SNA was approximately 80% in two studies in which fungal plaques and adjacent mucosa were biopsied under endoscopic guidance (see Table 86.2).[41,42] Biopsy of the nasal mucosal tissue without the overlying fungal plaque can cause a false-negative result. Special fungal stains (e.g., PAS or GMS) increase the sensitivity of detection of fungal hyphae in histologic sections.

Histopathology of nasal biopsies from dogs and cats with SNA usually reveals mats of branching, septate fungal hyphae attached to nasal or sinus mucosa or within luminal exudates, in a background of lymphoplasmacytic and neutrophilic inflammation. Occasionally, the neutrophilic component predominates. Variable numbers of macrophages and eosinophils may also be present, as well as necrotic debris. Other findings include osteolysis, turbinate remodeling, and intralesional bacteria. Occasionally, intralesional plant material is detected. Conidiophores and conidia can be found because the fungus is exposed to air within the nasal cavity (Fig. 86.9).

In cats with SOA, retrobulbar fungal granulomas contain central areas of coagulative necrosis in which fungal hyphae are confined and surrounded by peripheral zones of inflammatory cells including neutrophils, eosinophils, macrophages, peripheral fibroblasts, lymphocytes, and plasma cells (Fig. 86.10A and B). Inflammatory lesions can also efface adjacent skeletal muscle and bone. The globe is resistant to fungal invasion, but may be affected by keratitis and anterior uveitis.[6,49,55,58] There may be invasion of adjacent structures including the nictitating membrane, eyelid, optic nerve, and optic chiasm.[6,49,54,55,59] Mycotic invasion of the sinus or nasal mucosa may also be evident (Fig. 86.10C).

TREATMENT AND PROGNOSIS

Successful treatment of SNA is challenging. Because of the large size of the nasal cavity and sinuses, clinical signs are often not apparent until disease is advanced. Delays in diagnosis can occur because of the costly and invasive nature of diagnosis and treatment and the need for specialized imaging techniques and endoscopic expertise. Owners of adult dogs that develop persistent nasal discharge (e.g., present for at least 1 week) should be encouraged to pursue advanced imaging and rhinoscopy as soon as possible so that the disease can be recognized and treated early, especially in regions such as California and Australia where there is a high disease incidence. Treatment with antibacterial drugs alone is discouraged because primary bacterial infection of the nasal cavity in adult dogs (in the absence of an underlying causes such as neoplasia or fungal infection) is extremely rare.

In general, treatment of canine and feline SNA requires thorough mechanical debridement of plaques with endoscopic biopsy forceps and copious irrigation until no visible fungus remains, which may necessitate extended anesthesia. In some cases, treatment is performed immediately after imaging and rhinoscopy, which further prolongs the period of anesthesia. If plaques within the frontal sinuses cannot be accessed by antegrade rhinoscopy through the nasofrontal opening, frontal sinus trephination and curettage or open surgical debridement of the frontal sinus may be required. Debridement of fungal plaques is followed by repeated lavage with 0.9% saline and suction, followed by topical antifungal drug therapy with clotrimazole or enilconazole. Additional systemic antifungal drug treatment could also be considered, but whether this improves the outcome over topical therapy alone is unknown.

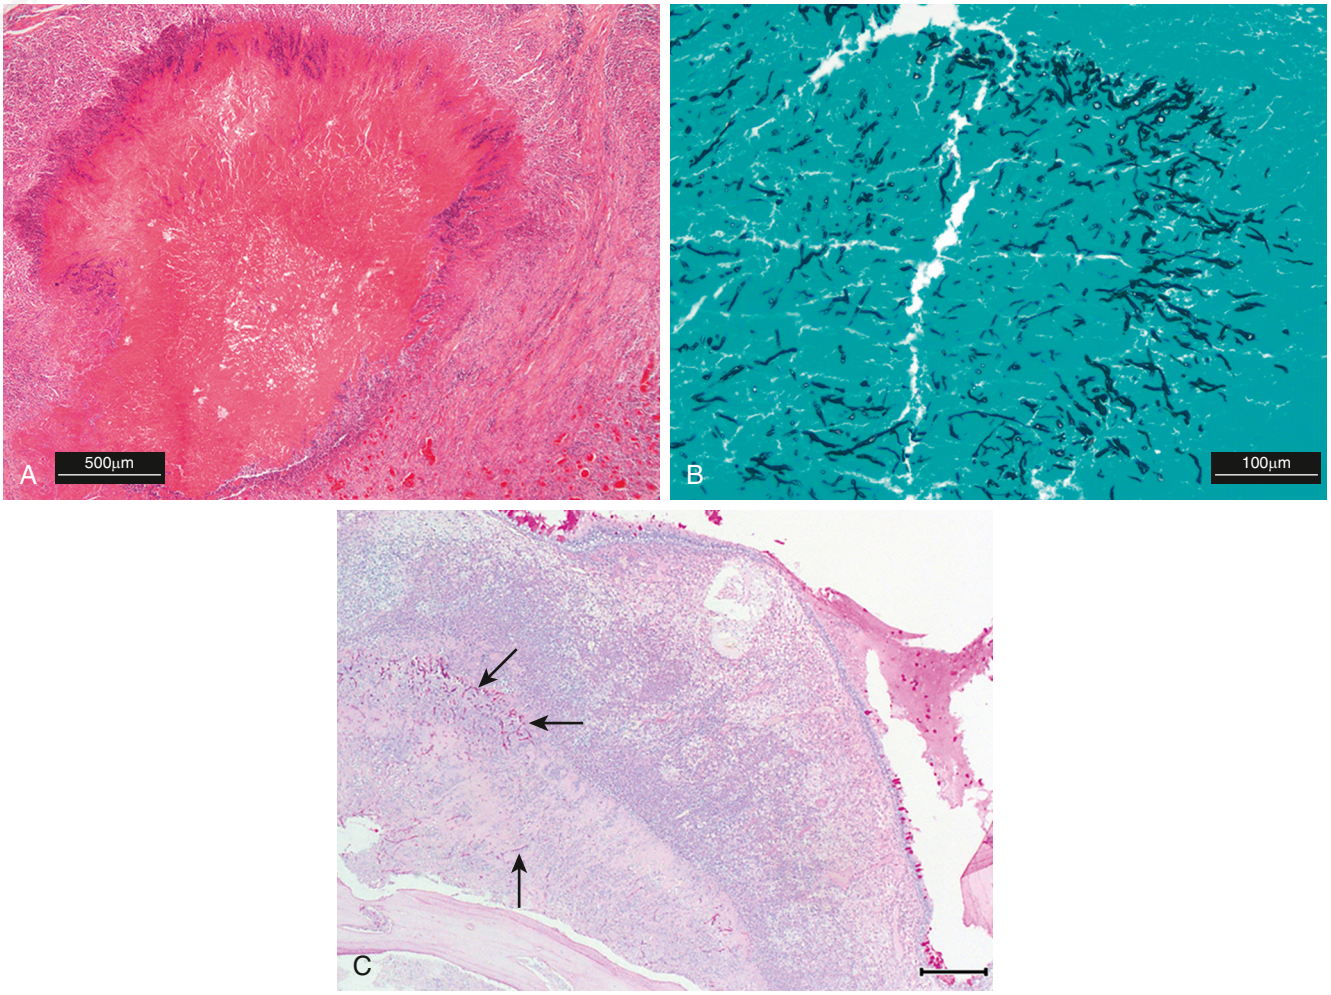

Fig. 86.10 Histopathology of (A and B) an orbital mass and (C) sinus mucosa from a 2-year-old domestic shorthair cat with sino-orbital aspergillosis, an invasive mycosis. (A) The orbital fungal granuloma contains central areas of coagulative necrosis in which fungal hyphae are confined and surrounded by peripheral zones of mixed inflammatory cells. (B) Septate, branching fungal hyphae are darkly stained with GMS stain. (C) Below the ciliated epithelium of the frontal sinus is an extensive inflammatory infiltrate and magenta-stained fungal hyphae *(arrows)*. Periodic acid-Schiff stain, scale bar 300 μm.

Canine Sinonasal Aspergillosis

A variety of noninvasive and invasive protocols for topical antifungal drug treatment of canine SNA after debridement of fungal plaques in the nasal cavity and frontal sinuses have been described, with varied rates of success. Currently, there is a lack of masked, randomized prospective clinical trials with consistent and long-term follow-up evaluation that indicate clear benefit of one treatment over another. Complete debridement of fungal plaques is associated with an improved first treatment success rate compared to partial debridement in dogs treated with topical antifungal azole infusions.[94] The protocol described here is used at the University of California Davis, Veterinary Medical Teaching Hospital (UCD VMTH). A similar protocol has been used successfully to treat SNA in cats.[57]

After thorough debridement of fungal plaques, a 24F Foley catheter is retroflexed over the soft palate and the balloon inflated until it can be palpated above the soft palate (Fig. 86.11). Placement of the catheter can be facilitated by insertion of a stiff guidewire into the catheter. Alternatively, a flexible catheter can be advanced from the rostrum through the nasal passage and into the oropharynx. The Foley catheter can then be sutured to this second catheter and be drawn into the nasopharynx by withdrawing the second catheter from the nasal folds. The tip of the catheter can then be bent into a U shape and hooked over the soft palate, after which the balloon is inflated. The nasopharynx is packed with moistened laparotomy pads, a gauze pad is placed over the incisive papilla, and the proximal end of the Foley catheter is clamped across the guidewire to prevent leakage of antifungal drug from the nasal cavity. The dog is then placed in dorsal recumbency with the skull positioned vertically (at 90 degrees to the tabletop), the eyes are lubricated and a protective wrap is placed around the muzzle to prevent spillage of medication into the eye. Clotrimazole (1%) or enilconazole (1% or 2%) solution is then administered into each nasal passage until full and a meniscus is visible. For large-breed dogs, 20 to 30 mL of solution is administered per side initially, and medication is dripped in to maintain filling of the nasal passage for 15 minutes.[94] The catheters and sponges are then removed with the dog's head tilted downward at an angle of 30 degrees, and the material is allowed to drain from the nasal cavity for 10 minutes. Debridement and a second treatment are then routinely performed 1 month later. Sometimes, a third treatment 1 month after that may be necessary. Clotrimazole can be irritating to tissues, and solutions with a propylene glycol vehicle can cause nasopharyngeal irritation and edema.[95,96] In general, however, clotrimazole solutions with a polyethylene glycol vehicle cause minimal adverse

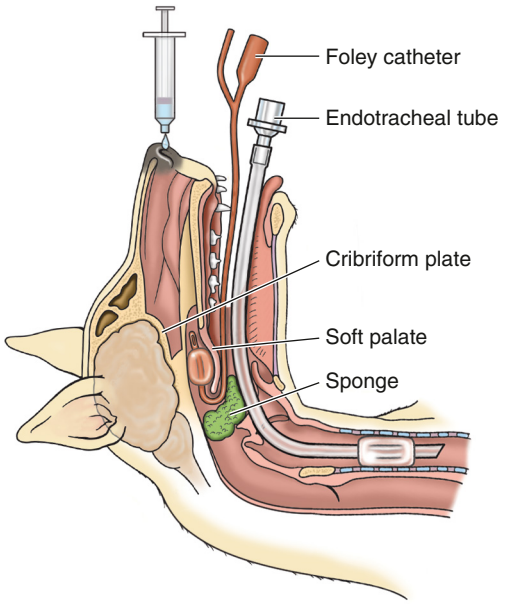

Fig. 86.11 Placement of catheter for topical treatment of canine sinonasal aspergillosis with clotrimazole or enilconazole.

effects. Enilconazole solutions may be less irritating, but there is no evidence that they are more effective than clotrimazole. They also tend to be less viscous, and may be more likely to be aspirated as a result.

One retrospective study compared two minimally invasive topical enilconazole infusion protocols after endoscopic plaque debridement.[94] One group of 24 dogs was treated with a 1-hour infusion of 2% enilconazole with rotation of the dog every 15 minutes by 90° to maximize sinonasal mucosal drug contact. After enilconazole drainage, 1% bifonazole cream was administered into the frontal sinuses. The second group of 24 dogs was treated with a simplified protocol using a 2% enilconazole infusion instilled for 15 minutes without rotation or addition of bifonazole cream. The simplified protocol was of much shorter duration (median 92 min compared to 201 min) and overall treatment success was 96% for both groups.[94]

Other studies describe administration of 1% clotrimazole cream into the nasal cavities and frontal sinuses after fungal plaque debridement with overall treatment success of 94% and 100%, respectively.[97,98] In one of these studies, sinus irrigation and topical application of clotrimazole was performed using a minimally invasive endoscopic approach to place a rigid urinary catheter over a guidewire into the frontal sinus.[98] This approach replaced the need for sinus trephination.

When cribriform plate lysis or lysis of the floor of a frontal sinus is present, topical treatment could potentially cause life-threatening neurologic signs or failure to recover from anesthesia. Chemical irritation from the topical azole drug could cause meningoencephalitis. Similarly, hyperosmolar carriers used in topical infusions (e.g., polyethylene glycol) could cause CNS injury.[99] Nevertheless, treatment has been performed without complication in some dogs with these defects.[41,98–100] Although their efficacy for treatment of SNA has been debated, oral azole antifungals with activity against molds (i.e., itraconazole, posaconazole, or voriconazole) have been used either as monotherapy for dogs with braincase lysis or in combination with terbinafine or topical antifungal drugs.[26,46,101,102] Debridement before commencing systemic antifungal drug treatment is strongly recommended, because effective drug concentrations are not likely to be obtained within fungal plaques. Antifungal susceptibility testing can also be considered for animals undergoing systemic therapy. Although there is no evidence of emerging azole resistance among *A. fumigatus* isolates from dogs and cats,[103] the prevalence of acquired azole resistance in environmental and human clinical isolates of *A. fumigatus* is increasing in many geographic regions.

The prognosis for canine SNA depends on the extent of disease at the time of diagnosis. Success rates vary from less than 30% to 100%, but methods to assess treatment success and follow-up times have not been consistent. Serial serologic testing by ID or ELISA is not useful to monitor treatment success since positive titers can persist for months to years beyond resolution of infection.[41] Response to treatment can only be assessed accurately by endoscopy. Even if infection is eliminated based on endoscopic reevaluation and biopsy, dogs with extensive turbinate loss are predisposed to recurrent bacterial infections of the nasal cavity, which result in persistent nasal discharge and sneezing. One study showed no difference in the prevalence of sneezing and nasal discharge between dogs that responded to initial treatment and dogs that failed to respond.[41] In studies where treatment protocols included debridement, a topical intranasal or intrasinusal azole (solution and/or cream), and endoscopic evaluation to confirm resolution of fungal plaques, 48% to 62.5% of dogs were clear of disease after one treatment, and 88% to 100% of dogs were clear of disease after at least one more treatment.[26,30,41,94,104] Relapse or re-infection occurs in 11–20% of treated dogs within 2 months to 2–3 years.[30,41,46,98] However, only two of these studies took into account relapse or reinfection, after the overall cure rate was reduced from 88% to 68% in one study[41] and from 100% to 89% in the other.[30] In another study, 11% (7/64) of dogs were diagnosed with relapse or reinfection 12 to 30 months after debridement and topical clotrimazole treatment, and all were successfully treated again.[46]

BOX 86.1 Therapeutic Approach for Feline Sinonasal Aspergillosis

1. Determine whether infection is invasive or noninvasive based on histopathology and computed tomography (CT) findings.
2. Submit positive fungal culture to a mycology reference laboratory to determine species.
3. Identify and assess the presence of lysis of the cribriform plate or floor of the frontal sinuses on CT examination.
4. Debride fungal plaques from nasal cavity and frontal sinuses using endoscopy, suction, and copious saline irrigation.
5. Instill a 1% solution of clotrimazole solution in polyethylene glycol intranasally (1-hour soak under general anesthesia with 15-minute rotations).
6. If infection is invasive, or if cryptic species are identified, give additional systemic antifungal therapy.

Feline Upper Respiratory Tract Aspergillosis

Evidence-based treatment protocols for feline SNA are not available due to a lack of prospective treatment trials. Successful treatment regimens reported in individual cases include oral azole therapy (itraconazole or posaconazole), oral azole therapy plus topical azole infusion (clotrimazole or enilconazole solution), or topical clotrimazole alone.[6,50,53,57,105] Similar to canine SNA, debridement of fungal plaques was an integral component of therapy for most successfully treated cases. A suggested strategy for treatment of feline SNA based on previous reports, treatment of canine SNA, and consideration of whether infection is invasive or noninvasive is outlined in Box 86.1. Overall, the prognosis for feline SNA appears similar to canine SNA, but a comparatively small number of cases has been evaluated.

Cats with SOA require treatment with systemic antifungal drugs. The results of antifungal susceptibility testing may be of value. One case that failed sequential treatment with itraconazole then amphotericin B (AMB) was cured with oral posaconazole.[54] The fungal isolate from that cat had high MICs for AMB and itraconazole and a low MIC for posaconazole. In one study, 12 cats with SOA were treated with an oral azole (itraconazole or posaconazole) alone or in combination with AMB and/or terbinafine, and 5 cats also had aggressive orbital debridement with enucleation. Treatment was successful in only one cat that did not have surgery.[6] Relapse of infection occurred 19 months after treatment was stopped but resolved after treatment with caspofungin and posaconazole. Results of antifungal susceptibility testing show that pathogenic species belonging to the *A. viridinutans* complex, including *A. felis, A. udagawae* and *A. wyomingensis* frequently have high MICs for itraconazole. A common method of antifungal susceptibility testing used in commercial laboratories, the Sensititre YeastOne method (Trek Diagnostic Systems Ltd., East Grinstead, UK) provides unreliable results for itraconazole compared with a reference broth microdilution method (EUCAST), but performs well for other antifungal drugs including azoles, AMB, and echinocandins, providing final results are reported at 72 hours of incubation, and not at 48 hours of incubation.[23] Overall the MICs of posaconazole and the echinocandins are usually low for these species, are higher for voriconazole, and variable for AMB. Thus, itraconazole is not recommended as a first-line therapy when these species are identified in cats with SOA. The combination of posaconazole and terbinafine is suggested as first-line therapy for cases of SOA and was effective in curing two cats with SOA caused by cryptic *Aspergillus* species.[106] In a previous study, isolates of *A. felis* were demonstrated to have low MICs for terbinafine.[7]

Posaconazole is well tolerated after oral and IV administration in cats, and hepatotoxicity is less common than with itraconazole.[6,23,107] Voriconazole administration has been associated with severe adverse effects in cats including paraplegia, blindness, anorexia, and cardiac arrhythmias (see Chapter 11).[6,58,60] In cats, voriconazole has a long oral half-life (>43 hours) and nonlinear pharmacokinetics are suspected to be the cause of toxicosis at higher drug doses due to saturation of metabolizing enzymes and decreased drug clearance.[108] The pharmacokinetics of caspofungin have been determined in cats; minimum effective concentrations appropriate for therapy can be reached using a loading dose of 1 mg/kg IV and subsequent daily doses of 0.75 mg/kg IV.[109] Overall, the prognosis for complete remission of SOA is guarded to poor.

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is commonplace for human patients being treated for protracted periods with newer-generation antifungal azole drugs with low and/or highly variable oral bioavailability including posaconazole, voriconazole and isavuconazole.[110] TDM involves collection of a plasma sample from a patient immediately prior to the next dose of the drug. The most common and reliable method used for TDM is high-performance liquid gas chromatography (HPLC) combined with mass spectrometry.[111] TDM can be used in veterinary medicine using the same assays used for human patients since these assays are not species specific (see also Chapter 11).

PUBLIC HEALTH ASPECTS

There are no reports of transmission of SNA from affected dogs or cats to humans. Whether the handling of affected dogs by immunosuppressed humans poses a risk to their health is unknown, but such individuals should probably minimize close contact with affected animals. If contact is necessary, they should be encouraged to discuss the problem with their medical practitioner. At the least, gloves should be worn and proper hand washing practiced.

DISSEMINATED INVASIVE ASPERGILLOSIS AND PENICILLIOSIS

ETIOLOGY AND EPIDEMIOLOGY

DIA, formerly known as systemic aspergillosis, may involve the respiratory tract (bronchopulmonary aspergillosis) or may be a disseminated disease of multiple organ systems. The portal of entry of *Aspergillus* is thought to be via the respiratory tract with subsequent hematogenous spread, though rare cases of infection restricted to the lungs have been recorded.[112,113] As with other bloodborne pathogens, common sites of embolic dissemination of fungal organisms are the intervertebral discs, kidneys, brain, and eyes; nonetheless, other organs, muscles, and long bones may be affected.

Localized bronchopulmonary aspergillosis is rare in dogs and cats, and often follows underlying local or systemic immunodeficiency.[14,66,112,114] German shepherds appear to be predisposed to a form of bronchopulmonary aspergillosis characterized by the development of cavitary lung lesions.[14,115–117] These cases usually involve infection by *A. fumigatus* or cryptic species in subgenus *Fumigati*, whereas DIA in dogs is most often caused by *Aspergillus terreus* in subgenus *Circumdati*, or *Aspergillus deflectus* in subgenus *Nidulantes*. These findings contrast with SNA and SOA in dogs and cats (see previous section on Upper Respiratory Tract Aspergillosis) in which *A. fumigatus* and *A. felis* are most common. Other *Aspergillus* species have also been isolated from dogs with disseminated disease (see Table 86.1) In addition, fungal species from other families in order Eurotiales, including Trichocomaceae (including *Talaromyces* species and *Rasamsonia* species) and Thermoascaceae (*Paecilomyces* species) have been found to cause some cases of disseminated mold infections in dogs.[118–120].

In dogs, DIA may occur as a result of an uncharacterized genetic immunodeficiency, because female German shepherds are strongly predisposed to the disease, and immunosuppressive drug treatment is rarely present in the history of affected dogs.[15] Cases of DIA have been documented worldwide and the disease is likely ubiquitous, albeit underdiagnosed.[15,121–134] Two thirds of affected dogs seen at the UCD VMTH were German shepherds, and German shepherds were 43-fold more likely to develop the disease than other dog breeds.[15] Rhodesian ridgebacks also appear to be predisposed. Females are three times as likely to develop disseminated aspergillosis as males, and the median age of affected dogs is 4 years (range, 2 to 9 years). Concurrent or sequential infections with other opportunistic pathogens have been described in some dogs as in people.[135–137]

DIA in humans is usually secondary to immunodeficiency or immunosuppression, although invasive *Aspergillus* infections have been described in apparently immunocompetent individuals.[138] The most common underlying predisposing factors are leukemia (and subsequent hematopoietic stem cell transplant), neutrophil or macrophage dysfunction, neutropenia, acquired immunodeficiencies, and prior chronic antibacterial therapy.[139–141] The protective immune response to *Aspergillus* has been well characterized in murine models of infection and includes a variety of innate mechanisms (e.g., expression of TLR2 by pulmonary dendritic cells) in addition to Th1-regulated adaptive immunity characterized by the production of cytokines such as IL-18, IL-12, TNF-α, and IFN-γ.[142] Additionally, the protective immune response to *Aspergillus* in dogs is known to involve the activity of the Th17 subset of Th cells.[143] Individuals that have dominant Th2 immunity develop

TABLE 86.3 Historical Signs in 30 Dogs with Disseminated Invasive Aspergillosis

Signs	Percent of Dogs

progressive disease, and glucocorticoid therapy is known to stimulate Th2-driven immune responses.[142,144,145] Hematopoietic stem cell transplant recipients have significantly greater risk of *Aspergillus* infection when donor stem cells carry the S4 TLR4 haplotype.[140]

Disseminated and bronchopulmonary aspergillosis are rare in cats.[66,80,146,147] Reported cases have occurred mostly in young cats, though one study documented infection in middle-age to older cats. No breed predispositions have been identified. Affected cats often have recognizable underlying immunosuppressive conditions such as diabetes mellitus, cancer chemotherapy, or severe viral infections (feline panleukopenia, FIP, or FeLV).[148] Aspergillosis has not been reported in cats with FIV infection, although such cats may have other opportunistic mycoses.[148]

CLINICAL FEATURES

Clinical Signs and Pathogenesis

Pulmonary aspergillosis or DIA is thought to develop after inhalation of *Aspergillus* conidia, which lodge in the alveoli and adhere to epithelial cells. In the absence of adequate local immune defenses, the conidia enlarge and germinate to form hyphae. Invasion of the bloodstream and dissemination to distant sites may occur because of systemic immunosuppression (either congenital or acquired). Fungal virulence factors are also likely to be important, although why *A. terreus* and *A. deflectus* are more likely than *A. fumigatus* to cause disseminated disease in dogs is unclear as DIA in humans is most frequently caused by subgenus *Fumigati* isolates.[149]

Anatomic sites of predilection in dogs with DIA are the vertebral endplates and discs, renal pelvis, spleen, long bones, and lymph nodes. However, any organ may be affected, including the liver, heart, cardiac valves, pancreas, eyes, lungs, brain, bone marrow, meninges, small intestine, skin, spinal cord, thyroid, adrenal glands, prostate, and trachea. Nasal cavity involvement is not generally a feature of the bronchopulmonary or disseminated forms, and dogs with DIA often lack evidence of pulmonary involvement. Disease involves multiple organ systems and develops over several months, but many dogs are terminally ill when first examined. The median reported duration of illness before admission in one study was 1 month (range, 2 days to 9 months).[15]

The most frequent clinical signs are lethargy, decreased appetite, pain, lameness, and neurologic signs secondary to discospondylitis (especially ataxia and paresis) (Table 86.3). A sudden onset of paraplegia may result from rupture of an infected intervertebral disc or vertebral subluxation from instability. Other signs include apparent blindness, ataxia, circling, head tilt, seizures, respiratory distress, and vomiting.[150] Cough, increased respiratory effort, and rarely hemoptysis may occur in dogs with bronchopulmonary aspergillosis.[14,117] Polyuria and polydipsia may develop as a consequence of renal insufficiency. Uveitis or endophthalmitis may be clinically apparent some months before generalized illness develops and thus may be an important clue to early diagnosis. Although uncommon, aspergillosis can also involve body cavities. Further systemic spread can occur from these sites. Pericarditis and associated effusion can result in signs of right-sided heart failure such as abdominal distention from a modified transudate peritoneal effusion.[151] It can also arise from rupture of a myocardial abscess, or from contiguous spread from the lung or hematogenous source. Fever, GI signs, abdominal distention, and anorexia are the most common findings with abdominal infections.

In the cat, clinical signs are generally referable to GI or pulmonary involvement, with nonspecific findings similar to those in dogs.

TABLE 86.4 Physical Examination Findings in 30 Dogs with Disseminated Invasive Aspergillosis

Finging	Percent of Dogs
Muscle wasting/thin body condition	40

Physical Examination Findings

Physical examination findings in dogs with DIA are listed in Table 86.4. On physical examination, dogs with DIA may have muscle wasting and/or a thin body condition. Fever (up to 104.2°F or 40.1°C) was described in one quarter of affected dogs.[15] Musculoskeletal abnormalities include spinal pain, lameness, and, rarely, inability to stand. Neurologic signs include vestibular abnormalities, ataxia, mental dullness, paraparesis, vision impairment, hemiparesis, circling, and seizures. Dogs with respiratory involvement may cough and have harsh lung sounds and/or increased respiratory effort. Peripheral lymphadenomegaly may be detected. Ocular abnormalities include chorioretinitis, hyphema, and panophthalmitis.[15] Rarely, arrhythmias are detected secondary to myocardial involvement, but myocardial involvement is often subclinical.

DIAGNOSIS

Clinical Laboratory Findings

Complete Blood Count

Most dogs with DIA have leukocytosis due to a neutrophilia (Table 86.5).[15] A left shift with toxic neutrophils, eosinophilia,

TABLE 86.5 Selected Hematologic and Serum Biochemistry Analysis Results in 30 Dogs with Disseminated Invasive Aspergillosis

Variable	Median (Range)	No. (%) With Low Values	No. (%) With High Values	Reference Range
Hematocrit (%)	42 (14–46)	8 (31)	0	40–55

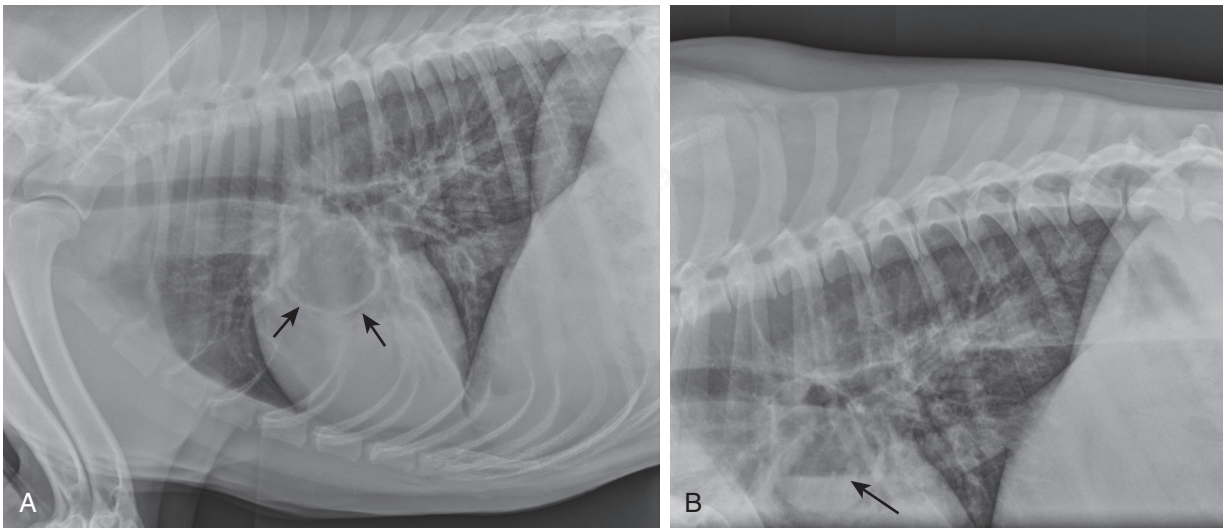

Fig. 86.12 Lateral thoracic radiograph of a 2-year-old male neutered German shepherd that had a 4-month history of cough and exercise intolerance. (A) A cavitary lesion *(arrows)* and alveolar infiltrates in the right middle lung lobe are present. (B) On a horizontal beam projection, a fluid line is present *(arrow)* within the dependent aspect of the lesion.

or monocytosis may also be present. Normocytic, normochromic nonregenerative anemia occurs in approximately one third of affected dogs and may be secondary to inflammatory or kidney disease.

Serum Biochemical Tests

Common abnormalities in the serum biochemical profiles of dogs with DIA include hyperglobulinemia, azotemia, hypercalcemia, and hypoalbuminemia (see Table 86.5).

Urinalysis

The urine specific gravity of azotemic dogs with DIA may be in the isosthenuric range because of renal insufficiency. Hematuria, proteinuria, and pyuria may also be detected. Fungal hyphae are rarely detected and were only identified in the urine sediment of 2 of 25 (8%) dogs with DIA in one study.[15]

Cerebrospinal Fluid Analysis

Analysis of the CSF in dogs with neurologic signs or spinal pain in affected dogs can be normal, or show an increased nucleated cell count and CSF protein concentration. The differential cell count reveals mixed or primarily mononuclear or neutrophilic pleocytosis.[150] Abnormalities of the CSF were identified in 8 of 10 dogs with DIA at the UCD VMTH.[135]

Diagnostic Imaging

Thoracic radiographs in dogs with bronchopulmonary aspergillosis may show a bronchial pattern or lung lobe consolidation.[112,127] Consolidation and cavitary lesions may be seen in the lungs of German shepherd dogs (Fig. 86.12).[115–117] Pulmonary cavitary lesions may be observed in dogs with chronic pulmonary localization.[115,116] Abnormalities in dogs with DIA include enlarged tracheobronchial and/or sternal lymph nodes, cranial mediastinal masses, pleural effusion, and/or pulmonary alveolar infiltrates.[15]

Fig. 86.13 Lateral radiograph of the left humerus of a 2-year-old male neutered German shepherd with disseminated aspergillosis. A primarily osteoproductive lesion is present in the mid-diaphysis.

Spinal radiographs reveal evidence of discospondylitis in approximately half of dogs with DIA, with a median of two sites affected (range, 1 to 9 sites).[15] Productive and destructive bony changes consistent with osteomyelitis may be present in other parts of the skeleton (Fig. 86.13). Most dogs have multiple affected sites, which include the vertebral bodies, sternebrae, ribs, scapula, humerus, and tibia.[15]

Sonographic Findings

Abdominal ultrasound abnormalities in dogs with DIA are most often in the kidneys, spleen, and abdominal lymph nodes.[15] Renal abnormalities include pyelectasia, a distorted and mottled architecture, decreased corticomedullary distinction, echogenic debris within the renal pelvis and proximal ureter, papillary blunting, and nodules or masses within the renal cortex (Fig. 86.14).[15] Occasionally, hydronephrosis is detected. Splenic abnormalities include hypoechoic nodules or masses, splenomegaly, changes consistent with infarction, or a mottled echotexture. Abdominal lymph nodes may be enlarged and/or hypoechoic. Other findings include diffuse hepatic or pancreatic hypoechogenicity, ascites, or evidence of venous thrombosis.

Advanced Imaging

MRI of the brain in dogs with *Aspergillus* infections that have disseminated to the CNS may reveal multifocal lesions that are hypointense to isointense and enhance with contrast on T1-weighted images. Three out of seven dogs with neurologic signs and confirmed *Aspergillus* infection had no identifiable MRI lesions in a recent case series.[150] Identified lesions are hyperintense or heterogenous on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images. Mild or severe meningeal enhancement may also be present.

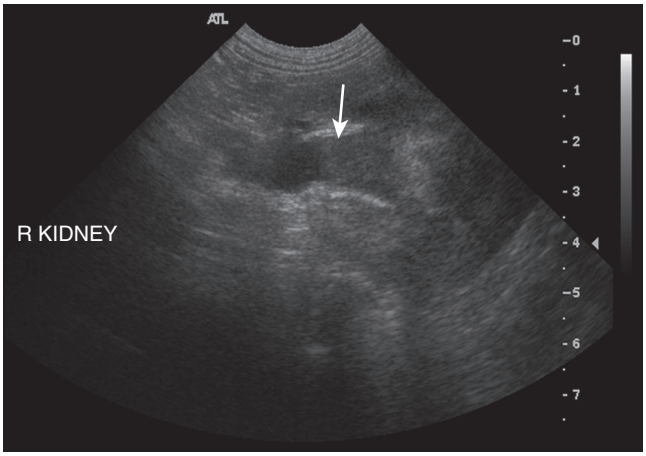

Fig. 86.14 Ultrasound image of the right kidney of a 6-year-old female spayed German shepherd dog with disseminated aspergillosis. There is dilation of the renal pelvis, which contains echogenic material *(arrow)*.

Cytologic Identification

Hyphae with morphology consistent with *Aspergillus* spp. may be present in aspirates of lymph nodes, kidney, lung tissue, or vertebral endplates or bone from dogs with systemic aspergillosis (see Fig. 4.3).[15] Cytologic examination of pleural effusion, airway lavage specimens, or urine may also reveal hyphae. False-negative results occur when organism numbers are low or specimen size is small. Accurate identification of the organism present requires fungal culture or molecular diagnosis (PCR) (see Table 86.2).

Microbiologic Testing

Aspergillus spp. are readily isolated on routine laboratory media. Isolation of *Aspergillus* spp. (especially *A. terreus* or *A. deflectus*) from normally sterile sites such as urine, blood, or aspirates of lymph node, bone, intervertebral disc, liver, or splenic tissue supports a diagnosis of DIA. Approximately 50% of dogs with DIA have positive urine cultures for *Aspergillus* spp., and around one third of dogs have positive blood or CSF cultures.[15] Isolation of *A. fumigatus* from airway washes should be interpreted more cautiously as it may represent contamination. Concurrent cytologic evidence of fungal hyphae is required for definitive diagnosis in this situation.

Once growth of mold occurs in culture, *Aspergillus* species can be identified to the subgenus and section level based on conidiophore morphology (Fig. 86.15). Accurate identification to the species level requires molecular techniques such as PCR, followed by sequencing, which can be performed by mycology reference laboratories (e.g., the Fungus Testing Laboratory at the University of Texas Health Science Center, San Antonio) (see Table 86.2). Such laboratories can also perform antifungal drug susceptibility testing. However, because clinical breakpoints have not been established for dogs or cats, the relevance of MICs for molds remains unclear.

Serologic Diagnosis

Assays that detect antibodies to *Aspergillus* species are insensitive for diagnosis of DIA.[15] This may reflect underlying host immunodeficiency (and hence inability to produce antibodies). Alternatively, antibodies in affected dogs may not cross-react with the antigens used in the test kits (see Table 86.2).

Antigen Detection

An *Aspergillus* GM antigen ELISA assay (Platelia, Bio-rad) has high sensitivity for diagnosis of disseminated aspergillosis in dogs when serum or urine specimens are tested.[83] In the author's hospital, all

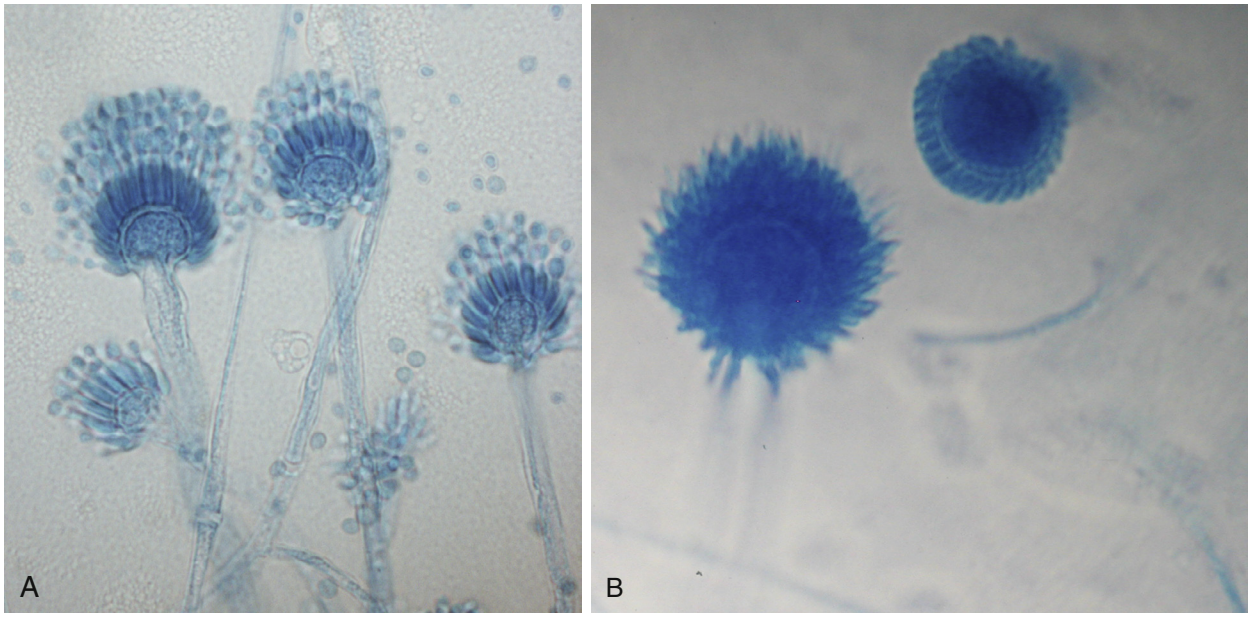

Fig. 86.15 (A) Morphology of *Aspergillus fumigatus*. (B) Morphology of *Aspergillus terreus,* which has an "upswept" appearance. The conidiophore is the specialized hyphal branch that bears the conidia (spores). The vesicle is the dilated top part of the conidiophore. Phialides are flask-shaped projections from the vesicle from which the conidia arise.

12 dogs with DIA had positive test results, with galactomannan indices (GMIs) that ranged from 6.4 to 12.2 (reference range, <0.5). Two dogs with localized pulmonary disease had serum GMIs of 0.14 and 0.77, which suggests that, as for SNA, the sensitivity of this assay for diagnosis of bronchopulmonary aspergillosis may be lower. High-level false-positive test results (GMIs > 1.5) appear to only occur in dogs with other fungal infections, especially those caused by *Penicillium, Rasamsonia* or *Paecilomyces*, and dogs treated with Plasmalyte IV fluid therapy. Plasmalyte contains sodium gluconate, which is produced by fermentation by *A. niger*; carry-over of small amounts of GM during production of the fermentation product is thought to occur.[152] Low-level false positives (0.5–1.5) can occur in dogs infected with other fungi (such as *Cryptococcus* spp.), some dogs with nonfungal disease such as neoplasia, some dogs treated with penicillin derivatives, and some dogs receiving oral probiotic nutraceuticals containing *Aspergillus*-derived ingredients.[153] A strong positive assay result in a dog with clinical abnormalities consistent with DIA and no history of Plasmalyte administration within the last 72 hours supports a diagnosis of a mold infection, but fungal culture or molecular identification is required to confirm that *Aspergillus* is the causative agent. A negative result in a dog with disseminated disease suggests that *Aspergillus* is not the cause, but it does not rule out the possibility of infection with another fungal species (see Table 86.2).

Molecular Diagnosis Using Nucleic Acid–Based Testing

Several real-time PCR assays have been developed and applied for the diagnosis of invasive aspergillosis in humans using blood or bronchoalveolar lavage fluid.[154–156] The sensitivity and specificity of these assays has varied, though they appear to be useful in monitoring response to therapy, becoming negative with successful treatment.[156,157] PCR assays have not been widely applied to diagnosis of DIA in dogs or cats. However, endpoint (conventional) PCR assays have been used for pathogen identification in cases where the organism cannot be cultured using fresh, frozen, or formalin-fixed tissue (see Table 86.2).[92]

Fig. 86.16 Sagittal section of one kidney from a 2-year old female spayed Belgian Malinois with a disseminated Aspergillus deflectus infection. There were multifocal 0.3 to 0.5 cm tan firm nodules in the cortex and medulla. (Image courtesy University of California-Davis Veterinary Anatomic Pathology Service.)

Pathologic Findings

Gross pathologic findings in dogs with DIA include enlarged and/or congested lymph nodes; multifocal, pale, tan to white masses or nodules within a variety of parenchymal organs including the kidneys, liver, pancreas, or the pleura (Fig. 86.16); evidence of discospondylitis and/or osteomyelitis; serosanguinous pleural effusion; and/or mottled

and congested lung lobes. Splenic infarction is also a common finding. The renal pelvis may be dilated and contain soft, granular material. Histopathology reveals granulomatous or pyogranulomatous inflammation with abundant intralesional fungal hyphae in a variety of tissues.[126,158] Infarcted areas secondary to thrombi containing fungal elements have been found in the spleen, kidneys, and liver. Some species, such as *A. terreus,* also produce accessory conidia (aleuriospores) in tissues, which may be free or extend from hyphae. Fibrinoid necrosis of blood vessels and associated hemorrhage may be present. Special stains such as GMS or PAS can delineate fungal hyphae in tissues. IHC and PCR on formalin-fixed tissues have also been used to identify *Aspergillus* (see Table 86.2).[92,126,128]

Diagnosis of DIA in cats is often made at necropsy, and findings may include pleural effusion, pulmonary granulomas, GI ulcers, or pseudomembranes, and involvement of urinary system or CNS.[66,159] The lesions are characterized by hemorrhage and necrosis, with variable numbers of inflammatory cells and fungal hyphae that may invade blood vessels, leading to thrombosis. Calcium oxalate crystals, a precipitate of oxalic acid produced by *Aspergillus* during the tricarboxylic acid cycle, have been identified in feline, human, and avian cases, though they are not reported often in dogs.[159,160]

TREATMENT AND PROGNOSIS

Many dogs with DIA have advanced disease at the time of evaluation, sometimes with respiratory distress, pathologic fractures, and vertebral subluxations resulting in cord compression. The prognosis for these dogs is poor. In one study, 57% of 30 dogs were euthanized within a week of examination (median, 3 days).[15] However, dogs that lack severe CNS signs, pain, or respiratory distress may enter remission for months and occasionally years when treated aggressively with antifungal drugs.[161,162] These dogs typically maintain high antigen titers or persistently positive urine cultures, and they ultimately relapse and die from the disease. Sometimes, euthanasia is performed earlier because of deteriorating quality of life or the unaffordable cost of treatment.

Since the disease was first documented in the 1970s, there have been progressive advances in the development of antifungal agents, and most of these human medications have been trialed in the treatment of small numbers of dogs with DIA. In many individual cases, a range of different drugs has been introduced sequentially as complications arose to specific agents. Overall, most agents are able to prolong the life of infected dogs only by months, with occasional individual animals surviving for up to 3 years.

The relative efficacy of different antifungal drug treatment regimens for DIA in dogs has not been studied prospectively. The most widely used treatments have been itraconazole, voriconazole, posaconazole, and/or AMB. Terbinafine has been used in addition to azole therapy with limited success in the authors' experience.[15] *Aspergillus* species are intrinsically resistant to fluconazole, so it should not be used.[163] Because azole-resistant strains of *Aspergillus* and other fungi are now recognized, a new generation of triazole drugs has now been developed for human medicine. Voriconazole, posaconazole, and isavuconazole all have activity against *Aspergillus* spp.[164,165] Although expensive, treatment with voriconazole or posaconazole can result in remissions of many months' duration in some dogs.[15,162,166] Posaconazole and isavuconazole in particular have shown promising activity in human patient and mouse models of invasive *A. terreus* infection.[167,168] Many dogs require treatment with multiple antifungal drugs to maintain remission, either in combination or in series. *A. terreus* strains from humans with invasive aspergillosis can become resistant to azoles during treatment and are also relatively resistant to AMB,[168,169] but clinical improvement can still occur after treatment of infected dogs with AMB (see Chapter 11).[15,170] The potential fungicidal and immunomodulatory effects of AMB are counterbalanced by its nephrotoxicity, which limits its use in patients with renal dysfunction. This problem has been addressed by the use of novel delivery systems that enhance uptake of the drug by reticuloendothelial cells at sites of inflammation and reduce accumulation in the kidneys. These formulations are: AMB-lipid complex (Abelcet, Liposome Co., Princeton, NJ); AMB-colloidal dispersion (Amphocil/Amphotec, Sequus Pharmaceuticals, Menlo Park, CA); and liposome-encapsulated AMB (AmBisome, Fujisawa Healthcare, Deerfield, IL, and Nexstar, San Dimas, CA).[171] AMB-lipid complex has been used to treat DIA in humans[172] and companion animals, but its use may be limited by its expense. An alternative IV lipid formulation has proven efficacious in the treatment of canine leishmaniosis but has not been evaluated for aspergillosis.[173]

Echinocandins selectively inhibit fungal β-glucan synthase (e.g., caspofungin). Caspofungin is efficacious in invasive aspergillosis of humans and is an attractive treatment due to its relatively low incidence of adverse events and drug interactions.[174,175] Expense and the need for IV administration has limited the use of echinocandins in dogs, but cost has decreased and is now more economical, though still incurs infusion-related costs.[176]

Dogs with localized bronchopulmonary aspergillosis have the best prognosis. These dogs are sometimes cured after treatment with itraconazole alone. Lung lobectomy may be required for successful treatment of German shepherds with cavitary lung lesions or dogs with pneumothorax resulting from their disease.[15,115,116,177]

Glucocorticoids should never be administered to dogs with aspergillosis, and their use has often inadvertently precipitated dissemination of the infection.

Feline DIA is so uncommon that treatment options have not been extensively reviewed. Rare cases of localized *Aspergillus* infection have recovered after complete surgical debridement of affected tissue. For example, fungal lobar pneumonia associated with pyothorax has been successfully managed by pulmonary lobectomy followed by systemic antifungal therapy.[66]

IMMUNITY AND VACCINATION

Immunity to disseminated aspergillosis is critically dependent on the function of neutrophils and dendritic cells, as well as effective T-cell function.[178] A vaccine to prevent the disease is not available. In an experimental system, mice vaccinated with *Aspergillus* antigens developed a protective Th1 immune response; however, vaccination for aspergillosis is unlikely to have a role in a clinical setting.[179] In experimental infections, a sonicate vaccine given before the administration of glucocorticoids protected mice against lethal pulmonary aspergillosis.[180]

PUBLIC HEALTH ASPECTS

In human patients, invasive aspergillosis primarily occurs in immunosuppressed humans with hematologic malignancy, or after solid organ or hematopoietic stem cell transplantation.[149] Infections are acquired from the environment. Transmission from affected dogs has not been described. Most cases (>70%) are caused by *A. fumigatus.* Infection with *A. terreus* is rare, and *A. deflectus* infection has not yet been described in humans.

Fig. 86.17 Severe ulcerative keratitis in a 12-year-old spayed female domestic shorthair cat caused by an *Aspergillus fumigatus* complex organism. The condition was successfully treated using topical voriconazole and a conjunctival island graft. (Courtesy the University of California, Davis, Veterinary Ophthalmology Service.)

OCULAR AND OTIC DISEASE CAUSED BY *ASPERGILLUS* SPECIES

Infection of the cornea,[16,181,182] lens,[183] and ear canal[17–19] by *Aspergillus* species occur rarely in dogs and cats (see Table 86.1, Fig. 86.17). Diagnosis of these conditions requires visualization of hyphae on cytologic examination or histopathology of biopsy specimens in addition to fungal culture to rule out the possibility of contamination or colonization. One cat with *A. flavus* keratomycosis had a history of FHV-1-associated conjunctivitis and keratitis[16] and was successfully treated with 1% topical voriconazole (q2h to q4h). Similarly, a dog with *Aspergillus* keratoconjunctivitis was successfully treated with a corneal graft and 1% topical voriconazole.[182] Cats with *Aspergillus* otomycosis often have a history of diabetes mellitus or allergic dermatitis.[17,135] Dogs with otomycosis may have a history of grass awn foreign body, underlying allergic dermatitis, or otitis externa that has been extensively treated with topical and oral antibiotics.[17,18]

CASE EXAMPLE

Signalment

"Zach," a 2-year-old male neutered German shepherd from Roseville in northern California.

History

Zach was evaluated at the University of California, Davis, Veterinary Oncology Service for possible bone cancer. Two months previously, the owners noted that the dog vocalized when he stood up from rest. He was taken to a local veterinary clinic where he was diagnosed with lumbosacral pain and treated with carprofen (1.5 mg/kg, PO, q12h). Two weeks later, right pelvic limb lameness developed. Pelvic radiographs showed evidence of moderate osteoarthrosis of the left coxofemoral joint. Carprofen treatment was continued. After an additional 2 weeks, lethargy, inappetence, increased thirst and urination, and left thoracic limb lameness developed, and the dog began vomiting once daily. Radiographs of the left thoracic limb revealed an osteoproductive lesion in the mid-diaphysis of the left humerus, which was interpreted as a primary or metastatic bone tumor (see Fig. 86.13). Zach was one of two dogs in the household, was normally fed a dry commercial dog food diet, and was up to date on vaccinations, which included those for distemper, adenovirus, parvovirus, rabies, *Borrelia*, and *Bordetella*.

Physical Examination

Body weight: 33.5 kg.

General: Quiet, alert, and responsive. T = 103.4°F (39.7°C), HR = 120 beats/minute, panting, CRT < 2 seconds, mucous membranes moist and pink.

Eyes, ears, nose, and throat: No clinically significant abnormalities were detected. Fundoscopic examination revealed multiple hyporeflective regions, consistent with chorioretinitis, in the right fundus.

Musculoskeletal: BCS was 4/9, and generalized muscle wasting was present. There was no evidence of lameness or bone pain on orthopedic examination.

Cardiovascular, respiratory, GI, genitourinary, and lymph nodes: No clinically significant abnormalities were present.

Laboratory Findings

CBC: HCT 32.8% (40%–55%), MCV 65.2 fL (65–75 fL), MCHC 35.7 g/dL (33–36 g/dL), WBC 18,530 cells/μL (6,000–13,000 cells/μL), neutrophils 13,768 cells/μL (3,000–10,500 cells/μL), lymphocytes 2,687 cells/μL (1,000–4,000 cells/μL), monocytes 1,334 cells/μL (150–1,200 cells/μL), eosinophils 741 cells/μL (0–1,500 cells/μL), platelets 262,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 152 mmol/L (145–154 mmol/L), potassium 3.8 mmol/L (4.1–5.3 mmol/L), chloride 113 mmol/L (105–116 mmol/L), bicarbonate 24 mmol/L (16–26 mmol/L), phosphorus 5.7 mg/dL (3.0–6.2 mg/dL), calcium 11.8 mg/dL (9.9–11.4 mg/dL), BUN 31 mg/dL (8–21 mg/dL), creatinine 1.9 mg/dL (0.5–1.6 mg/dL), glucose 107 mg/dL (60–104 mg/dL), total protein 6.8 g/dL (5.4–7.4 g/dL), albumin 2.8 g/dL (2.9–4.2 g/dL), globulin 4.0 g/dL (2.3–4.4 g/dL), ALT 15 U/L (19–67 U/L), AST 27 U/L (21–54 U/L), ALP 28 U/L (15–127 U/L), GGT 2 U/L (0–6 U/L), cholesterol 205 mg/dL (135–345 mg/dL), total bilirubin 0.1 mg/dL (0–0.4 mg/dL).

Urinalysis: SpG 1.010; pH 7.0, 1+ protein (SSA), no bilirubin, 3+ hemoprotein, no glucose, 10–15 WBC/HPF, 50–60 RBC/HPF, 0–2 transitional epithelial cells, a few amorphous crystals, and a few budding organisms were seen.

Imaging Findings

Thoracic radiographs: The cardiopulmonary structures were unremarkable.

Bone survey radiographs: Single lateral radiographs of the distal left antebrachium, distal right antebrachium, and distal left and right pelvic limbs were performed. An additional lateral radiograph of the left humerus was also obtained and compared with referral radiographs taken 1 month previously. This showed progression of a primarily osteoproductive lesion in the mid-diaphysis of the left humerus. An additional site of chronic active periosteal reaction was noted along the distal caudal aspect of the left femur. Patchy increases in medullary density were identified in the distal diaphysis of both humeri.

CASE EXAMPLE—cont'd

Abdominal ultrasound: Hypoechoic mottling of the splenic hilus was identified. There was bilateral renal pyelectasia with echogenic material within the renal pelves bilaterally. There was marked blunting of the renal pelves bilaterally with mild hydroureter.

Microbiologic Findings

Cytologic examination of a fine-needle aspirate of lesion in the left humerus: Smears were moderately cellular with a dense, proteinaceous background and moderate amounts of cellular debris. Nucleated cells consisted of a population of numerous activated macrophages and variably degenerate neutrophils that were evenly distributed throughout the smear as well as in variably sized aggregates. Numerous multinucleated giant cells were noted. Throughout the specimen were moderate numbers of small, round, yeast organisms as well as numerous fungal hyphae, which were found intracellularly and extracellularly. The fungal hyphae were negative staining, branching, and septate, often with bulging ends.

Fungal culture and susceptibility (left humerus fine-needle aspirate, sent to University of Texas for molecular identification): Moderate numbers of *A. terreus*. MICs for AMB, itraconazole, and voriconazole were 2, 0.125, and 0.25 μg/mL, respectively.

Aerobic urine bacterial culture: Six colonies of *A. terreus*.

Aspergillus antibody serology (gel immunodiffusion): Negative.

Diagnosis

Disseminated invasive *A. terreus* infection.

Treatment

The dog was treated with IV fluids (lactated Ringer's solution with 20 mEq/L KCl at 75 mL/hour), lipid-complexed AMB (1 mg/kg IV on a Monday-Wednesday-Friday basis for 4 weeks), and itraconazole (5 mg/kg, PO, q12h). Over the course of AMB treatment, the dog's inappetence, lethargy, and lameness resolved and his serum creatinine and BUN concentrations remained stable with values of 2.1 mg/dL and 49 mg/dL, respectively, by the end of treatment. At a recheck 2 months after treatment was initiated, fungal culture of the urine revealed a single colony of *A. terreus*, and the creatinine was 1.7 mg/dL. After an additional month, bone survey radiographs showed significant remodeling of the left humeral and left femoral lesions. A serum biochemistry panel showed mildly increased creatinine concentration (1.8 mg/dL) and a serum ALT activity of 364 U/L; the increased serum ALT activity was thought to be secondary to itraconazole administration. Ultrasound of the abdomen showed mild renal pelvis dilatation, but the echogenic material within it had disappeared. Fungal culture of the urine was negative. Four months after treatment was initiated, intermittent vocalization and right pelvic limb lameness developed. Pain was detected only on lumbosacral palpation. Radiographs of this region revealed focal osteolysis of the ventral caudal aspect of the sixth lumbar vertebra. Clinical improvement did not occur after treatment with carprofen and tramadol.

Two weeks later, the dog developed respiratory distress and was seen by the Emergency and Critical Care Service. Mild dehydration, pyrexia (105.8°F or 41.0°C), gagging, and ptyalism were detected on physical examination. Thoracic radiographs were unremarkable, but a soft tissue density was seen in the pharyngeal region on cervical radiographs. Blood cultures were negative. The dog was sedated, and on oral examination, multiple large soft tissue masses were observed within the pharynx and around the rim of the epiglottis. Aspiration of the masses revealed suppurative inflammation and possible occasional fungal hyphae. Bronchoscopy was performed, and numerous yellow plaque-like lesions were visualized on the tracheal mucosa. Cytologic examination of biopsies of these lesions revealed fungal hyphae. The owner elected euthanasia. Necropsy findings included severe, locally extensive mural granulomas of the tracheal mucosa with intralesional fungal hyphae and suppurative and eosinophilic pharyngitis with necrosis and edema. There was evidence of healed pyelonephritis and granulomatous nephritis with intralesional fungal hyphae. Granulomatous osteomyelitis with intralesional hyphae was present in the left femur and humerus. There were multiple granulomas in the pancreas and spleen.

Comments

Disseminated aspergillosis in this dog was initially confused with bone neoplasia. An *Aspergillus* antibody titer was negative, which illustrates the lack of sensitivity of this assay for diagnosis of disseminated disease. GM antigen testing was not performed, but bone lesions were readily accessible for aspiration and culture. The small, round yeast organisms visualized together with the hyphae were likely accessory conidia, which can be found in *A. terreus* infections. Treatment with lipid-complexed AMB and itraconazole was initially associated with clinical remission, but infection was not eliminated. Based on necropsy examination, the cause of the suppurative pharyngeal masses that impaired respiration was not clear. Fungal cultures of the masses were negative.

Miscellaneous Fungal Diseases

Amy M. Grooters

KEY POINTS

Phaeohyphomycosis

- Causes: *Alternaria*, *Aureobasidium*, *Bipolaris*, *Cladophialophora*, *Cladosporium*, *Curvularia*, *Exophiala*, *Fonsecaea*, *Lecytophora*, *Microsphaeropsis*, *Moniliella*, *Mycoleptodiscus, Phialophora*, *Rhinocladiella*, *Scolecobasidium*, *Scytalidium*, and *Ulocladium*, among others.
- Affected Hosts: A variety of animal hosts that include cats, dogs, horses, and humans.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Cutaneous inoculation of organisms from the environment.
- Major Clinical Signs: Localized cutaneous nodules that may appear pigmented, often on the nose or digits; occasionally meningoencephalitis, with associated neurologic signs.
- Differential Diagnosis: Neoplasia, cryptococcosis, blastomycosis, sporotrichosis, hyalohyphomycosis, mycobacterial infections, actinomycosis, nocardiosis.
- Human Health Significance: Direct transmission from animals to humans has not been described; humans develop infections from environmental sources.

Hyalohyphomycosis

- Causes: *Acremonium*, *Chrysosporium*, *Fusarium*, *Rasamsonia* (formerly *Geosmithia*), *Lomentospora*, *Oxyporus*, *Paecilomyces*, *Purpureocillium*, *Scedosporium* (*Pseudallescheria*), *Sagenomella*, *Talaromyces*, *Geomyces*, *Schizophyllum*, *Scopulariopsis*, *Lecythophora*, and *Westerdykella*, among others.
- Affected Hosts: A variety of animal hosts that include dogs, cats, and humans.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Inhalation or cutaneous inoculation of organisms in the environment.
- Major Clinical Signs: Keratitis; lymphadenopathy; discospondylitis; osteomyelitis; pneumonia; cutaneous lesions; disseminated disease with involvement of kidneys, liver, spleen, bone marrow, heart, endocrine tissues, and/or CNS.
- Differential Diagnosis: Neoplasia, aspergillosis, penicilliosis, phaeohyphomycosis, sporotrichosis, cryptococcosis, blastomycosis, candidiasis, endemic mycoses, nocardiosis, actinomycosis, mycobacteriosis.
- Human Health Significance: Direct transmission from animals to humans has not been described; humans develop infections from environmental sources.

INTRODUCTION

In contrast to the well-recognized fungal pathogens that cause endemic mycoses (such as *Blastomyces, Histoplasma,* and *Cryptococcus*), miscellaneous fungal pathogens comprise large groups of fungi with unfamiliar names that traditionally have caused disease only sporadically. Although some of these fungi occasionally cause disease in immunocompetent patients, many cause infection only when normal host resistance mechanisms are compromised. Over the past 35 years, these opportunists have become increasingly important in human patients because immunocompromise associated with chemotherapy, organ transplantation, and HIV infection has become more prevalent. Similarly, over the past 15 years, the incidence of opportunistic fungal infections in dogs has increased substantially in association with the use of multiagent immunosuppressive therapy (especially with cyclosporine), with a 2017 study showing an incidence of 6.5% in dogs being treated for immune-mediated disease.[1] Thus, veterinarians are increasingly likely to encounter patients infected by an opportunistic fungal pathogen with which they are unfamiliar. Diagnosis of disseminated infections with these organisms in young, adult, purebred or inbred dogs with no evidence of underlying immunocompromising conditions may suggest the possibility of genetic immune defects. German shepherd dogs and anecdotally, Hungarian Vizslas appear to be at increased risk of disseminated aspergillosis (see Chapter 86), and some of the mold pathogens listed in this chapter have been reported as causes of disseminated disease in these breeds or their crosses.[2–6]

Unlike the common endemic fungal pathogens (for which a definitive diagnosis can often be made simply by visualizing the unique morphologic features of the organism in cytologic or histologic specimens), opportunistic fungi can only be identified to genus and species level by culture or molecular methods. However, they can be assigned to categories based on their morphologic features in tissue, such as pigmentation, hyphal diameter, and frequency of septation. These categories include *phaeohyphomycosis* (pigmented hyphal or yeast forms); *hyalohyphomycosis* (nonpigmented hyphal forms); *eumycotic mycetoma* (fibrosing granuloma with black or white tissue grains consisting of aggregates of pigmented or nonpigmented fungi, respectively); and *entomophthoromycosis* and *mucormycosis*, which together were previously termed zygomycosis (wide, infrequently septate, nonpigmented hyphae associated with pyogranulomatous and eosinophilic inflammation). Because of the similarities to pythiosis and lagenidiosis, entomophthoromycosis and mucormycosis are discussed in Chapter 88. Although identification of a specific organism after culture is ideal, classification of opportunistic mycoses based on the categories listed above is often sufficient to allow the clinician to make a reasonable prediction about clinical course and prognosis and to make appropriate treatment recommendations. This approach is perhaps most limiting for immunocompetent dogs with hyalohyphomycosis because

some of the causative fungal agents (such as *Scedosporium boydii* [*Pseudallescheria boydii*] and *Paecilomyces variotii*) are inherently resistant to amphotericin B (AMB) and itraconazole, making genus- and species-level identification and sometimes antifungal susceptibility testing important.

When culture is performed, fresh tissue rather than swabs should be submitted to a laboratory with expertise in fungal culture. This author prefers to use a laboratory (Box 87.1) in which molecular identification of cultured isolates can routinely be performed when morphologic features alone are insufficient for definitive identification.

BOX 87.1 Diagnostic Laboratories with Expertise in Fungal Diagnostic Testing

Clinical Bacteriology and Mycology Laboratory, University of Tennessee College of Veterinary Medicine	https://vetmed.tennessee.edu/vmc/dls/bacteriology/
University of Florida Veterinary Diagnostic Labs, Molecular Fungal ID Lab	https://cdpm.vetmed.ufl.edu/services/diagnostic-labs/molecular-fungal-id-laboratory/
Fungus Testing Laboratory, University of Texas Health Science Center, San Antonio	https://lsom.uthscsa.edu/pathology/reference-labs/fungus-testing-laboratory/

An alternative to culture that has become more routinely available in recent years is extraction, amplification, and sequencing of fungal DNA from paraffin-embedded tissues, which is appealing because it does not require a second biopsy. Reported sensitivities for these assays have ranged from 54% to 94%.[7–10] Although a number of commercial laboratories now offer molecular diagnostics based on panfungal amplification and sequencing, use of a laboratory that interprets results in the context of histologic findings, and for which assay sensitivity and specificity have been described is preferred. Since many opportunistic fungi are common contaminants and can normally be found on skin, nasal mucosa, and other nonsterile sites, identification of a potential opportunistic fungal pathogen from a skin specimen, nasal swab, or exudate should not be considered evidence of fungal infection unless there is supportive histologic or cytologic evidence of tissue invasion by a morphologically compatible organism.

PHAEOHYPHOMYCOSIS

ETIOLOGY AND EPIDEMIOLOGY

The term "phaeohyphomycosis" refers to cutaneous, subcutaneous, cerebral, or disseminated infections caused by pigmented (also known as dematiaceous) hyphal or yeast forms that contain melanin in their cell walls.[10] Infection usually results from cutaneous

TABLE 87.1 Causative Agents and Histologic/Cytologic Characteristics Associated with Miscellaneous Fungal and Pseudofungal Pathogens

Disease	Causative Agents	Histologic and Cytologic Characteristics
Phaeohyphomycosis	*Alternaria, Aureobasidium, Bipolaris, Cladophialophora, Cladosporium, Curvularia, Exophiala, Fonsecaea, Lecytophora, Microsphaeropsis, Moniliella, Mycoleptodiscus, Phialophora, Rhinocladiella* (formerly *Ramichloridium*), *Scolecobasidium, Scytalidium, Ulocladium,* others	Pyogranulomatous inflammation associated with pigmented, irregularly septate hyphae or yeast-like cells that may be solitary or may cluster in small groups or chains. A beaded chain or toruloid appearance is supportive of a diagnosis of phaeohyphomycosis.
Hyalohyphomycosis	*Acremonium, Chrysosporium, Fusarium, Rasamsonia* (formerly *Geosmithia*), *Oxyporus, Paecilomyces, Purpureocillium, Scedosporium, Sagenomella, Geomyces, Schizophyllum, Scopulariopsis, Lecythophora, Westerdykella,* others	Pyogranulomatous inflammation associated with hyphal elements that have nonpigmented (transparent, hyaline) walls; *Aspergillus caninus (previously Phialosimplex caninus), Talaromyces spp., and Trichosporon asahii* may cause yeast-like forms in tissue
Mycetoma (black-grain)	*Curvularia, Cladophialophora, Madurella*	Pyogranulomatous inflammation associated with aggregates of pigmented fungal organisms (which appear grossly as pigmented tissue grains)
Mycetoma (white-grain)	*Scedosporium apiospermum, Acremonium*	Pyogranulomatous inflammation associated with aggregates of nonpigmented fungal organisms (which appear grossly as nonpigmented tissue grains)
Pythiosis	*Pythium insidiosum*	Pyogranulomatous and eosinophilic inflammation associated with broad (2–7 μm), infrequently septate hyphae (see Chapter 88)
Lagenidiosis	*Lagenidium giganteum* forma *caninum*	Pyogranulomatous and eosinophilic inflammation associated with broad (4–25 μm), infrequently septate hyphae (see Chapter 88)
Paralagenidiosis	*Paralagenidium karlingii*	Pyogranulomatous and eosinophilic inflammation associated with broad (2–11 μm), infrequently septate hyphae (see Chapter 88)
Entomophthoromycosis and mucormycosis (together previously termed zygomycosis)	Entomophthoromycosis: *Conidiobolus, Basidiobolus ranarum* Mucormycosis: *Rhizomucor, Mucor,* and *Cokeromyces*	Pyogranulomatous and eosinophilic inflammation associated with broad (5–20 μm), infrequently septate hyphae with thick prominent eosinophilic sleeve (see Chapter 88)
Aspergillosis	*Aspergillus terreus, A. deflectus, A. flavipes, A. fumigatus* species complex, others	Suppurative to granulomatous inflammation associated with multiple, nonpigmented, 2- to 6-μm, septate hyphae with parallel walls and 45-degree angle branching (see Chapter 86)
Candidiasis	*Candida albicans,* other *Candida* species	Suppurative inflammation with numerous 2- to 6-μm oval yeasts, pseudohyphae (chains of oval yeast cells), and true hyphae (see Chapter 85)

Fig. 87.1 Left distal thoracic limb of an 8-year-old male neutered Burmese cat with digital phaeohyphomycosis. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

Fig. 87.2 Popliteal lymphadenopathy and abscessation caused by *Curvularia* spp. infection in a 1-year-old female Yorkshire terrier with cutaneous phaeohyphomycosis. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

inoculation of organisms from the environment. For animals and humans with cerebral or disseminated infections, the route of infection is not always apparent. Fungal genera that have been identified as agents of phaeohyphomycosis in veterinary patients include *Alternaria, Aureobasidium, Bipolaris, Cladophialophora, Curvularia, Exophiala, Fonsecaea, Lecytophora, Microsphaeropsis, Moniliella, Mycoleptodiscus, Phialophora, Rhinocladiella* (formerly *Ramichloridium*),[11] *Scolecobasidium*, *Scytalidium*, and *Ulocladium,* among others (Table 87.1). In human patients, infections with some of these organisms occur more commonly in certain geographic locations where soil conditions may optimize their survival; for example, *Rhinocladiella mackenziei* and *Exophiala dermatitidis* infections predominate in the Middle East/India and East Asia, respectively.[12–14] In fact, infections with *R. mackenziei* account for the majority of fungal infections of the brain in the Middle East, and genomic analysis of this fungus suggests that the organism may be adapted to oil-polluted desert soil.[14]

CLINICAL FEATURES

The most common clinical manifestations of phaeohyphomycosis in immunocompetent small animal patients are lesions associated with the digits, pinnae, nasal planum, or nasal cavity in cats (Fig. 87.1).[15–24] Affected animals typically have cutaneous nodules or a visible nasal mass that may appear grossly pigmented, and thus may be confused with melanomas. Lesions tend to be locally invasive and may extend to involve regional lymph nodes (Fig. 87.2). Less commonly, granulomatous meningoencephalitis caused by pigmented fungi (especially *Cladophialophora* spp.) has been described in dogs and cats.[25–29] Systemic dissemination, as reported in two dogs with mycotic meningoencephalitis and nephritis, and in a cat with multiorgan involvement, is rare in the absence of immunosuppression and carries a poor prognosis.[28,30,31]

In immunocompromised patients, the most common presentation for phaeohyphomycosis is focal or multifocal cutaneous lesions in dogs treated with multiagent immunosuppressive therapy, especially which includes cyclosporine.[32–36] Dissemination to multiple cutaneous sites, lymph nodes, or even other organ systems seems to occur more often in immunocompromised than in immunocompetent patients.[37–39]

DIAGNOSIS

Laboratory and Imaging Abnormalities

Results of a CBC, biochemistry panel, and urinalysis in animals with cutaneous phaeohyphomycosis are typically unremarkable. Animals with disseminated disease can have abnormalities associated with underlying immunosuppressive illness or drug treatment. Imaging with CT or MRI in animals with CNS involvement may reveal focal or multifocal contrast-enhancing lesions that may be associated with hydrocephalus (Fig. 87.3).

Cytologic and Histologic Findings

On histologic or cytologic examination, dematiaceous fungi appear as dark-walled, irregularly septate hyphae of variable diameter, sometimes with bulbous ends, or as yeast-like cells, solitary or in small groups or chains (Fig. 87.4). Pigment may not always be apparent on cytologic examination (Fig. 87.5), or it may have a blue-green tint on Wright-Giemsa–stained specimens. On histologic examination, the presence of melanin in the walls of lightly pigmented hyphae can often be confirmed by the examination of unstained sections, by lowering the microscope condenser during examination, or by using a Fontana-Masson stain for melanin.

Isolation and Identification

Organisms that cause phaeohyphomycosis are readily isolated on routine fungal culture of infected tissue biopsies as well as from fine-needle aspirate specimens from infected lymph nodes. Further identification is based on colony and conidial morphology (see also Fig. 4.9B) and PCR and sequencing of ribosomal RNA genes. Identification of molds using MALDI-TOF MS has been challenging owing to the complex extraction protocols needed, but with refinement of protocols and libraries, this method shows great promise for reliable and rapid identification (see Chapter 4).[40] Because pigmented fungi are common laboratory contaminants and can sometimes be isolated from nonsterile sites on healthy animals (such as skin), positive cultures from potentially contaminated sites should only be considered significant if accompanied by cytologic or histologic evidence of fungal infection with a morphologically compatible organism.

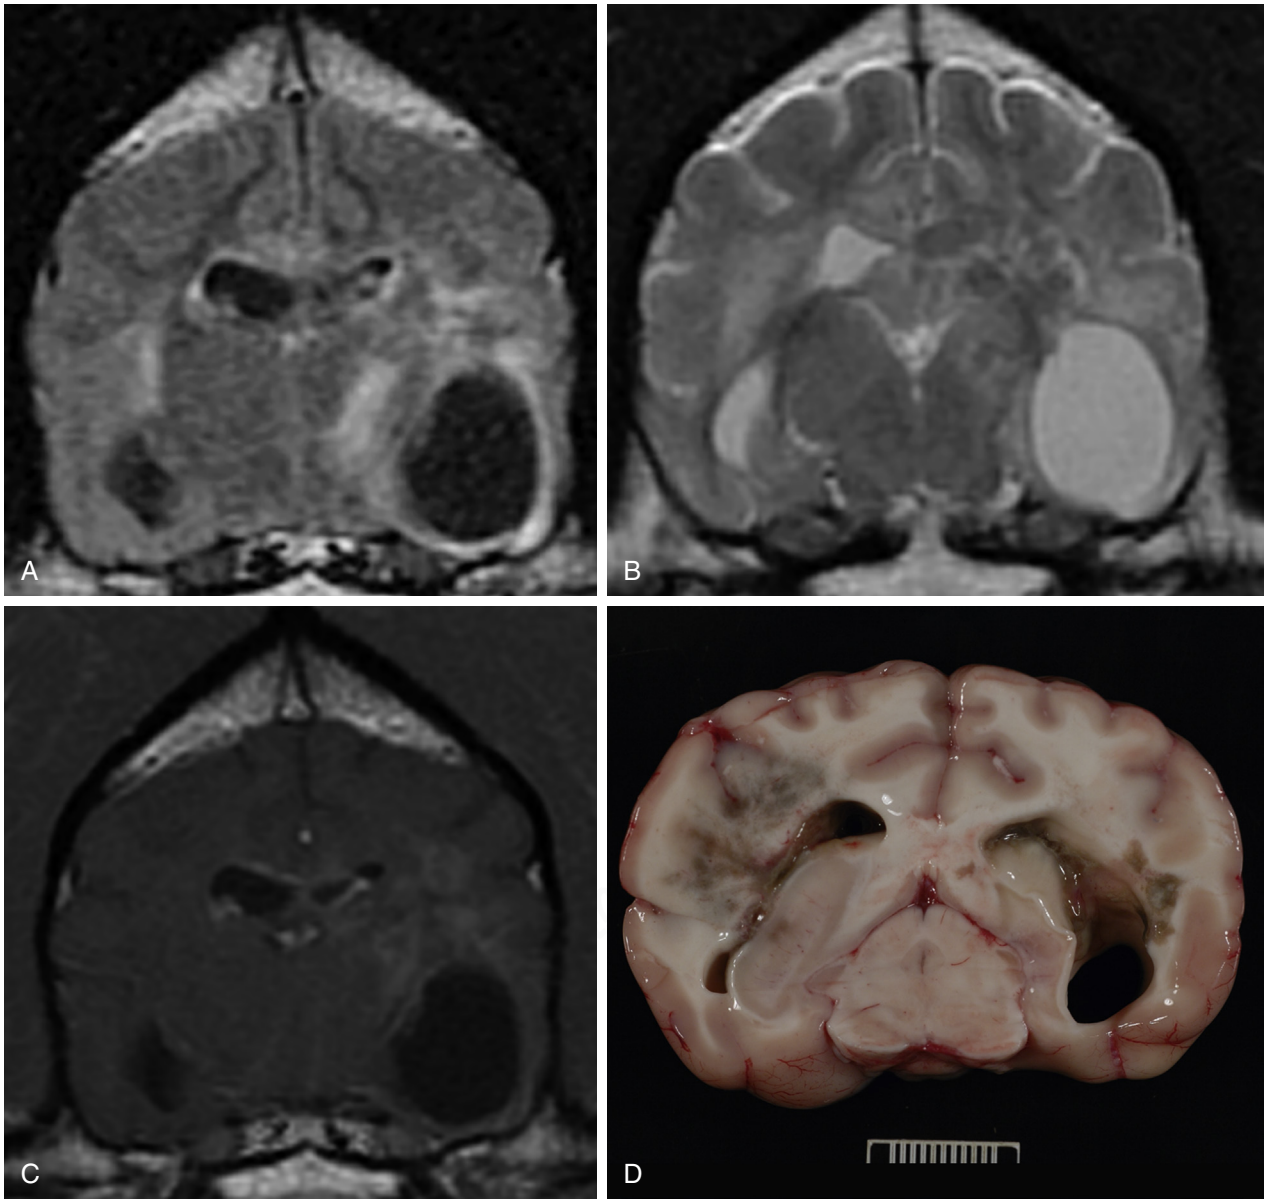

Fig. 87.3 Axial T1 postcontrast, T2, and FLAIR magnetic resonance images (A, B, and C, respectively) of the brain of a 6-year-old male neutered Border collie mix that was evaluated for neurologic signs including seizures and progressive obtundation. In the images shown, there is bilateral but asymmetric ventricular dilation that is severe on the right and mild to moderate on the left (asymmetric hydrocephalus). Multifocal regions of contrast enhancement are also present (A). Some of these regions appeared nodular; others had a ring-like appearance. There is also marked contrast enhancement of the ventricular ependymal lining. The regions of contrast enhancement correlate with regions of T2 and FLAIR hyperintensity (B and C) and were isointense on precontrast T1-weighted sequences (not shown). Meningoencephalitis caused by *Cladophialophora bantiana* and secondary hydrocephalus was diagnosed on brain biopsy and at necropsy (D). Olive-green pigmented masses can be seen on both the left and right sides of the brain. Interestingly, the dog also had cutaneous protothecosis. (Courtesy University of California, Davis, Veterinary Neurology and Anatomic Pathology Services.)

TREATMENT AND PROGNOSIS

Pigmented fungi are often poorly responsive to medical therapy, in part because melanin is a virulence factor. Aggressive surgical resection is the treatment of choice for solitary cutaneous phaeohyphomycosis lesions. The surgeon should attempt to obtain wide margins at the time of the initial surgery, submit the excised tissue for histopathology, and request that the margins be evaluated for evidence of incomplete resection. Digit amputation is usually indicated for lesions of the distal phalanx. If a full digit or more is involved, limb amputation should be considered. Medical therapy with itraconazole, posaconazole, or voriconazole (dogs only) is recommended for 3 to 6 months after surgery, because recurrence of disease at the surgical site is common.

Limited data are available regarding *in vitro* susceptibilities for isolates of pigmented fungi. Itraconazole, voriconazole, posaconazole, and AMB have the most consistent activity against pigmented fungi, whereas reported activities of fluconazole and ketoconazole have been poor.[41] For nonresectable lesions, treatment with itraconazole (10 mg/kg/day) often results in partial or complete resolution of cutaneous lesions, but recurrence is very common, so prolonged courses (9 to 12

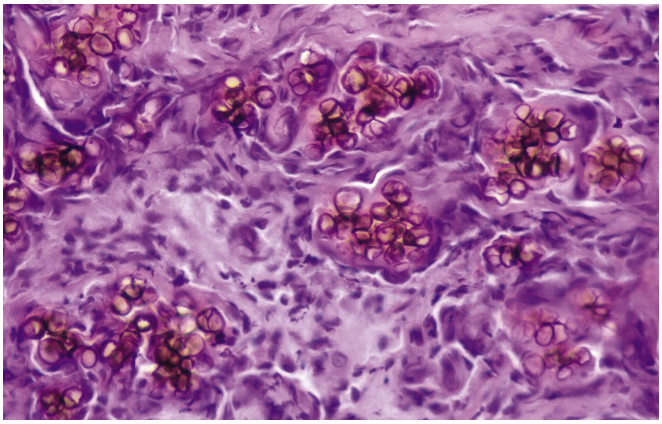

Fig. 87.4 Histopathology showing small groups of pigmented, yeast-like fungal organisms in tissue from a nasal mass in a cat with phaeohyphomycosis; hematoxylin and eosin stain. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, LA.)

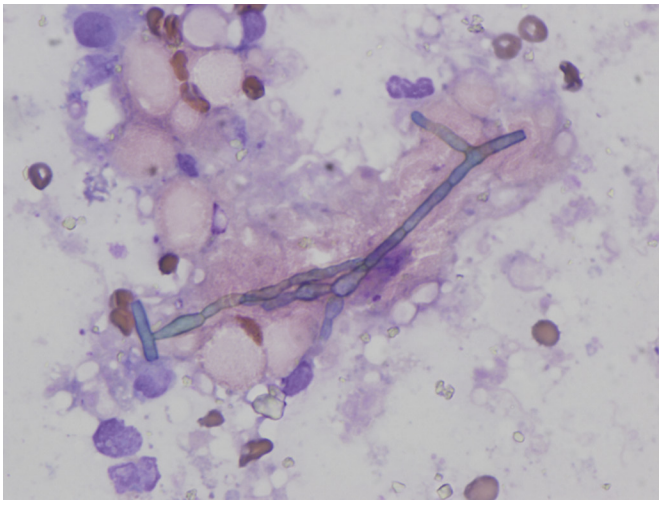

Fig. 87.5 Impression smear from the brain of the dog in Fig. 87.3. Septate, branching hyphae are present, but pigmentation is not clearly apparent. Wright stain, 1000× magnification. (Courtesy University of California, Davis, Veterinary Pathology Service.)

months) should be recommended. Posaconazole and voriconazole may be more effective than itraconazole for the treatment of phaeohyphomycosis. Posaconazole is typically easier to administer in cats because of its availability as a well-tolerated oral suspension. Voriconazole reaches high concentrations in the CNS, making it the drug of choice for treating intracranial phaeohyphomycosis. Long-term voriconazole therapy (7 to 10 mg/kg/day for 10 to 12 months) was used successfully to treat intracranial phaeohyphomycosis in one dog[26] and mycotic peritonitis caused by *Exophiala* in another.[37] Voriconazole has not been routinely used in cats because of associated neurotoxicity,[42] although the use of a lower dose in conjunction with therapeutic drug monitoring has recently been evaluated (see Chapter 11).[43]

In patients receiving immunosuppressive medications, cutaneous phaeohyphomycosis often responds more readily to medical therapy than does comparable disease that develops in an immunocompetent patient, but only if cyclosporine can be discontinued and other immunosuppressive medications can be rapidly tapered.[36] This author most often treats cutaneous phaeohyphomycosis that occurs in dogs receiving immunosuppressive therapy with itraconazole (10 mg/kg/day) for at least 6 months. If lesions are focal or otherwise amenable to wide surgical excision, a combination of medical and surgical therapy may be effective.[36] In one cat with a refractory *Cladophialophora* spp. infection that involved the dorsal aspect of the nose, rhinotomy with debulking together with topical malachite green and long-term oral itraconazole treatment was successful.[15] Although the author has observed two dogs in which lesions caused by cutaneous phaeohyphomycosis resolved without antifungal therapy after immunosuppressive drugs were discontinued, dissemination of disease despite therapy has also been observed. Therefore, the recommendation should be to discontinue immunosuppressive drugs as quickly as possible and also treat medically with itraconazole, posaconazole, or voriconazole (in dogs) for at least 2 months beyond lesion resolution.

PUBLIC HEALTH ASPECTS

Phaeohyphomycosis in humans clinically resembles that in dogs and cats and may include localized cutaneous lesions in immunocompetent hosts; life-threatening CNS infections in immunocompromised or apparently immunocompetent hosts; and, rarely, disseminated phaeohyphomycosis, primarily in immunocompromised hosts. The species most often associated with CNS infections are *Cladophialophora bantiana, Exophiala* (*Wangiella*) *dermatitidis,* and to a lesser extent, *Verruconis gallopava, R. mackenziei*, and *Fonsecaea monophora*.[12,44] A deficiency in CARD9, which leads to macrophage and microglial dysfunction, has been recognized in association with invasive *E. dermatitidis* in some human patients.[13] Infections caused by pigmented fungi are acquired from the environment. Although there is no evidence of transmission between mammalian hosts, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed. Precautions should also be taken to prevent needle-stick injuries if phaeohyphomycosis is suspected.

HYALOHYPHOMYCOSIS

ETIOLOGY AND EPIDEMIOLOGY

The term "hyalohyphomycosis" refers to infections caused by fungi that are nonpigmented (hyaline or transparent) in tissue. Genera that have been described as agents of hyalohyphomycosis in dogs and cats include *Acremonium, Chrysosporium, Fusarium, Rasamsonia* (formerly *Geosmithia*), *Lomentospora, Oxyporus, Paecilomyces, Purpureocillium, Scedosporium, Talaromyces, Sagenomella, Geomyces, Schizophyllum, Scopulariopsis, Lecythophora,* and *Westerdykella,* among others (see Table 87.1). By convention, infections caused by *Aspergillus* and *Penicillium* species are not included in the term "hyalohyphomycosis," because aspergillosis and penicilliosis can usually be identified as such based on their clinicopathologic features in association with morphologic features that are fairly distinct (narrow, straight-walled septate hyphae that branch at acute angles, occasionally with conidia and conidiophores when lesions are in the nasal cavity).[45] Examples include sinonasal aspergillosis caused by *Aspergillus fumigatus*, and disseminated aspergillosis caused by *Aspergillus terreus* and *Aspergillus deflectus*. Other types of aspergillosis may be indistinguishable from hyalohyphomycosis without culture, and therefore may be grouped into the category of hyalohyphomycosis when culture or sequencing has not been performed. Examples include *Aspergillus caninus* (formerly *Phialosimplex caninus*), which produces scant irregular hyphae and numerous round to ovoid fungal structures in tissue, and *Aspergillus alabamensis*, both of which have been described to cause infection in dogs on immunosuppressive drug therapy.[46,47] As discussed in Chapter 4, fungal nomenclature can be confusing because of assignment of anamorph (asexual stage) and telomorph (sexual stage) names, and despite the move to the use of only one name, the use of older names still occurs in the published literature, and this, combined with changes in taxonomy related to analysis of sequence

Fig. 87.6 *Scedosporium prolificans* infection in a domestic shorthair cat. There are multiple draining skin lesions and soft tissue swelling. (Courtesy Spencer Jang, University of California, Davis.)

data perpetuates confusion. For example, *Scedosporium apiospermum* was first isolated as a cause of white-grain mycetoma in humans in 1909, and was considered as the anamorph form of *S. boydii* (formerly *P. boydii*). Subsequently, analysis of molecular and phenotypic data indicated that *S. boydii* and *S. apiospermum* were two distinct species.[48,49] They are now grouped with three other *Scedosporium* species into the *S. apiospermum* species complex (sometimes also referred to as the *S. apiospermum/P. boydii* species complex)[50]; only *Scedosporium aurantiacum, S. boydii,* and *S. apiospermum* cause human disease. Similarly, *Rasamsonia argillacea*, formerly known as *Geosmithia argillacea*, is a complex that comprises four different species: *R. argillacea*, *Rasamsonia piperina, Rasamsonia eburnean,* and *Rasamsonia aegroticola*, all of which have been isolated from diseased humans.[51,52]

CLINICAL FEATURES

In general, hyalohyphomycosis occurs more often in dogs than in cats, with young adult, large-breed dogs most commonly affected. Clinical signs in immunocompetent animals are similar to those associated with systemic aspergillosis and include poor body condition, fever, lameness, and lymphadenomegaly, as well as CNS and ocular signs.[4] Although local disease confined to the skin (Fig. 87.6), nasal mucosa, or cornea can occur,[53–56] lymphadenopathy, osteomyelitis, discospondylitis, pneumonia, and chorioretinitis are more common manifestations.[57–59] Erosive polyarthritis and granulomatous lymphadenitis have been described in association with *Talaromyces* spp. infections in dogs (*Talaromyces georgiensis* and *Talaromyces helicus*).[6,60] Disseminated disease may also involve kidney, bone marrow, liver, spleen, heart, bladder, pancreas, thyroid, adrenal, and CNS, sometimes with associated fungemia.[6,61–63]

When hyalohyphomycosis develops in dogs receiving immunosuppressive medications, the clinical course may differ from that typically seen in immunocompetent dogs in two ways. First, the disease may be confined to the skin without evidence of systemic dissemination.[64] Second, like phaeohyphomycosis, hyalohyphomycosis that develops in animals on immunosuppressive therapy may respond more readily to medical therapy than disease that occurs in immunocompetent patients, but only if cyclosporine can be discontinued and other immunosuppressive drugs can be tapered. Still, the prognosis for these patients should be considered guarded because of the potential for dissemination.[61,65]

DIAGNOSIS

Cytologic and Histologic Findings

Cytologically and histologically, fungi that cause hyalohyphomycosis are nonpigmented, frequently septate hyphae that typically branch at acute angles. They are often pleomorphic and may contain areas of globose swelling, especially at the end of the hyphae or between septations (Fig. 87.7 and see Fig. 4.8).[45] *Aspergillus caninus* (previously *Phialosimplex caninus*), *Talaromyces* spp., and *Trichosporon asahii* may cause yeast-like forms in tissue. Most of these organisms do not have other distinct morphologic characteristics, precluding further identification. Special stains such as PAS and Gomori's methenamine silver may be used to visualize organisms more readily.

Isolation and Identification

The fungi that cause hyalohyphomycosis are readily isolated by routine fungal culture methods from infected tissues as well as from fine-needle aspirate specimens from infected lymph nodes, bones, or abdominal organs. Because these fungi are common laboratory contaminants and can sometimes be isolated from the skin or hair of healthy animals, positive cultures from nonsterile sites should be considered significant only if accompanied by cytologic or histologic evidence of fungal infection with a morphologically compatible organism. Species identification is based on conidial morphology (Fig. 87.8) and may require PCR and sequencing of ribosomal RNA genes. As for phaeohyphomycosis, identification using MALDI-TOF MS may be useful in the future with refinement of methods and libraries. Genus and species identification may assist in selection of antifungal drug treatments, because some species are predictably less susceptible to conventional antifungal drugs (see Treatment and Prognosis).

Antigen Testing

Serology for detection of fungal galactomannan antigen is routinely included in the diagnostic evaluation of human patients suspected to have invasive aspergillosis or hyalohyphomycosis, but has only been evaluated in a limited number of veterinary patients.[66–69] In an investigation of galactomannan assay results in dogs with systemic

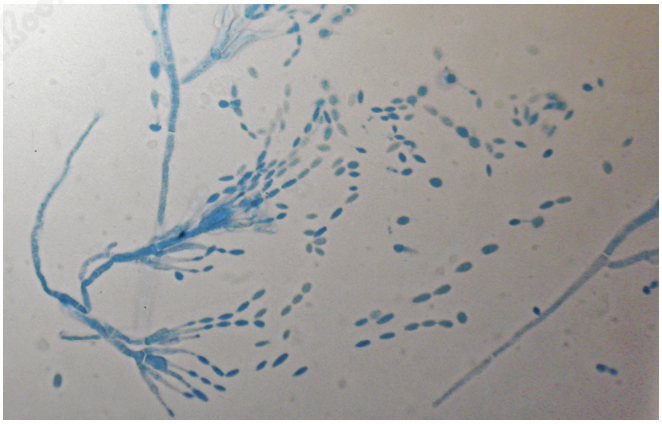

Fig. 87.8 Cytologic appearance of *Paecilomyces variotii* growing in culture in the laboratory. Lactophenol cotton blue, 1000× magnification. (Courtesy Spencer Jang, University of California, Davis.)

aspergillosis as well as those with other types of systemic fungal disease, the assay was found to be positive in two dogs with typical hyalohyphomycosis and negative in one dog that developed hyalohyphomycosis involving only skin and regional lymph nodes after immunosuppressive drug therapy.[67] In addition, positive galactomannan results have been observed in human patients with endemic mycoses (e.g., blastomycosis and coccidioidomycosis) as well as those receiving beta-lactam antibiotics.[70,71] Based on very limited information in dogs, it appears that a positive galactomannan assay may increase the index of suspicion for either hyalohyphomycosis or aspergillosis in animals with supportive clinical signs, but specificity for this purpose has not yet been adequately studied. False-negative results may also occur, especially in dogs without widespread disease.

TREATMENT AND PROGNOSIS

Treatment of hyalohyphomycosis has traditionally been challenging because many animals have disseminated disease. Drugs used most often to treat hyalohyphomycosis in small animals include AMB, itraconazole, voriconazole, posaconazole, and caspofungin. In human patients, *Scedosporium* spp., *Fusarium* spp., *P. variotii*, and *Purpureocillium lilacinum* (formerly *Paecilomyces lilacinus)* typically have highly resistant *in vitro* susceptibility patterns and are more difficult to treat successfully.[72] Specifically, *S. boydii* (previously *P. boydii*) is routinely resistant to AMB and has variable susceptibility to the triazoles, *P. lilacinum* is typically resistant to AMB, *P. variotii* is often resistant to voriconazole, and *Scopulariopsis* isolates are resistant to triazoles with variable susceptibility to AMB.[72–74] Voriconazole is considered the initial treatment of choice for several of these inherently resistant fungi, with posaconazole either as salvage therapy or as first-line therapy when *P. variotii* infection is identified.[72,73] The novel drug olorofim has recently shown considerable promise for treatment of refractory mold infections in humans based on *in vitro* susceptibility data, but the safety and efficacy of this drug in animals requires investigation.[75] The role of antifungal susceptibility testing for the treatment of hyalohyphomycosis is unclear, as clinical breakpoints have not been established for human or veterinary patients, and correlation between susceptibility results and clinical outcomes has not been demonstrated. However, one recent retrospective study of human isolates suggested that a lower MIC for the first drug used for treatment was associated with a better outcome, especially if that drug was AMB.[76] Susceptibility testing is often of limited value for veterinary cases because it requires culture, is expensive, requires submission of an isolate to an experienced reference laboratory (see Box 87.1), and many clients cannot afford the newer triazoles or echinocandins that the results may indicate are more likely to be effective. However, when an isolate is available and client finances do not limit choice of therapy, susceptibility testing may provide important information about which antifungals have a high MIC and thus are unlikely to result in a positive outcome, especially if used as a first-line therapy.

In animals with disseminated hyalohyphomycosis in which the specific pathogen is unknown, ideal therapy would typically combine a course of lipid-complexed AMB with a triazole, the latter of which is then continued indefinitely. Alternatively, when financial limitations preclude administration of AMB, patients who do not require hospitalization may be treated with a triazole alone. The efficacy of voriconazole and posaconazole is generally better than itraconazole for the treatment of hyalohyphomycosis, but the cost is significantly greater.[72] Posaconazole has been used successfully to resolve or reduce clinical signs in dogs with systemic aspergillosis, although relapse is common.[77] Similar results may be achieved in some dogs with hyalohyphomycosis. Although fluconazole is the least expensive of these medications, its efficacy for infections caused by molds is generally inferior to the newer triazoles, so its use is not recommended for the treatment of hyalohyphomycosis. The addition of terbinafine to azole antifungals has been recommended for the treatment of many opportunistic mycoses, but has not been well studied in dogs. Caspofungin may be used for the treatment of *Scedosporium* spp. infections in human patients, but no data regarding its use for treating hyalohyphomycosis in animals are available.[72] Although treatment of disseminated hyalohyphomycosis with antifungal drugs can prolong survival, clinical signs often recur even if signs initially resolve. Therefore, disseminated hyalohyphomycosis generally carries a guarded to poor prognosis.

Cutaneous hyalohyphomycosis that develops in an animal receiving immunosuppressive drug therapy may respond well to oral triazole therapy (assuming cyclosporine can be discontinued and other immunosuppressive drugs tapered)[78] or may rapidly disseminate. Therefore, fungal skin lesions that develop in immunocompromised patients should be treated aggressively, an attempt should be made to identify occult extracutaneous lesions, and a guarded prognosis should be offered. This author most often uses itraconazole (10 mg/kg/day) administered orally for at least 6 months. Other options include voriconazole, posaconazole, or AMB, the latter usually reserved for cases in which extracutaneous lesions are detected. Surgical removal of a focal lesion is rarely indicated and should only be considered if the lesion is confined to the skin and a thorough diagnostic evaluation has failed to find evidence of other organ involvement.

PUBLIC HEALTH ASPECTS

Hyalohyphomycosis in humans is acquired as a result of infection by fungi in the environment. Keratitis and nailbed infections (onychomycosis) can occur in immunocompetent humans. Invasive infections occur in immunocompromised patients such as transplant recipients, patients with AIDS, and leukemic or neutropenic patients. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed. Precautions should especially be taken to prevent needle-stick injuries if hyalohyphomycosis is suspected.

EUMYCOTIC MYCETOMA

The term "mycetoma" refers to localized mycotic or actinomycotic infections of the skin, subcutaneous tissue, muscle, or bone that are characterized by the presence of colonies or aggregates of organisms

that form "grains" in tissue. Actinomycotic mycetomas are caused by bacteria such as *Actinomyces* spp. or *Nocardia* spp. (see Chapters 59 and 60), dermatophytic mycetomas are caused by dermatophytes (see Chapter 78), and eumycotic mycetomas are caused by nondermatophyte fungi. Lesions result from traumatic implantation of soil organisms into tissue. The grains or granules of eumycotic mycetomas are pigmented (for black-grain mycetoma, caused by dematiaceous fungi) or hyaline (for white-grain mycetoma, caused by nonpigmented fungi), depending on the type of fungal pathogen involved (see Table 87.1).

Black-grain mycetomas are most often caused by *Madurella mycetomatis*, *Curvularia*, or *C. bantiana* and are typically associated with chronic nonhealing wounds and cutaneous nodules on the extremities.[79–82] Lesions often develop weeks to months after a traumatic incident in the same area. Draining tracts are often present, and black grains may be observed in the exudate. White-grain mycetomas, usually caused by *S. apiospermum* or *Acremonium* spp., most often occur as body-wall and/or intra-abdominal granulomas that develop subsequent to wound or incision contamination or postoperative dehiscence.[83–87] Interestingly, the lesions associated with white-grain mycetoma may not be evident until months or even a year or more after the surgical or traumatic event. Affected dogs may be evaluated for a draining mass on the body wall or clinical signs of peritonitis.

The treatment of choice for eumycotic mycetoma is aggressive surgical excision of infected tissues, including amputation if clinically indicated. Unfortunately, lesion location may preclude complete resection. Response to medical therapy is generally poor as the causative agents of eumycotic mycetoma are inherently resistant to most antifungals, but administration of itraconazole, voriconazole, or posaconazole may be considered as adjunctive therapy following surgical excision when wide margins cannot be achieved. Because the lesions are slowly growing, debulking the lesions followed by long-term triazole therapy may improve quality of life for a significant period of time.[86] Dissemination of eumycotic mycetoma beyond local tissues is rare, but disease within the abdomen or other local tissues may be extensive.

CASE EXAMPLE

Signalment

"CJ," a 1-year-old male intact boxer dog from central Louisiana.

History

CJ was initially evaluated for acute ataxia and abnormal limb placement. Based on results of CSF analysis as well as MRI of the brain and spinal cord, inflammatory CNS disease was diagnosed, and treatment with prednisone (1 mg/kg, PO, q12h) was initiated. Despite a good initial response, neurologic signs recurred 2 weeks later, at which time cytosine arabinoside (50 mg/m^2, SC, q12h, for four doses, repeated every 3 weeks) and azathioprine (1.6 mg/kg, PO, q48h) were added to the treatment protocol. Neurologic signs again improved, but 7 weeks later, the dog was evaluated for ulcerative lesions on the distal extremities that had been present for 1 week and lethargy that had been present for 3 days.

Physical Examination

Body weight: 29 kg.

General: Alert and responsive, but painful on ambulation because of ulcerative lesions on all four feet. Vital parameters were within normal limits. Peripheral lymph nodes were palpably normal.

Dermatologic examination: Pitting edema and multifocal ulcerative lesions were present on all four distal extremities, with sloughing of multiple footpads (Fig. 87.9A and B). Some of the pad lesions were proliferative and extended into the interdigital area (Fig. 87.9C). Multiple light brown–colored areas could be visualized within the fibrinonecrotic material that covered the area of the left metacarpal pad (see Fig. 87.9B). In addition, a 1-cm ulcerated lesion was present on the left pinna, a crusted lesion was present on the tip of the tail, and a small subcutaneous mass was present in the right saphenous area. Larger (3 cm) ulcerated lesions partially covered with eschar were present on the medial aspect of the right tarsus and the dorsal aspect of the left antebrachium. Major differential diagnoses considered were opportunistic fungal infection and drug eruption.

Cytology and Histology Findings

Cytologic evaluation of the left pinnal lesion, subcutaneous right saphenous mass, and right popliteal lymph node revealed septic neutrophilic to pyogranulomatous inflammation with septate, branching, 3- to 7-μm fungal hyphae, both extracellularly and within neutrophils. Pigmentation of hyphae was not observed.

Histologic evaluation of punch biopsies obtained from cutaneous lesions on the left front foot, right hind foot, and right forelimb revealed severe pyogranulomatous dermatitis with intralesional septate, pigmented hyphae.

Diagnosis

Disseminated cutaneous phaeohyphomycosis extending to regional lymphadenitis.

Treatment and Outcome

Pentoxifylline (30 mg/kg, PO, q24h) was administered because of suspected vasculitis associated with the cutaneous lesions. Antifungal therapy with itraconazole (10 mg/kg, PO, q24h) was initiated, but lesion progression was observed over the next several days, so lipid-complexed AMB treatment (2 mg/kg diluted in 5% dextrose, IV, over several hours three times weekly) was initiated. Unfortunately, 2 days later lesions had progressed rapidly with appearance of new draining tracts and abscess

CASE EXAMPLE—cont'd

Fig 87.9–cont'd

formation. Because of the poor prognosis and pain associated with the lesions, the dog was euthanized.

Comments

As was noted here, pigmentation of hyphae may not always be visible on cytologic examination of lesions caused by phaeohyphomycosis, in part because hyphae and the cells that phagocytize them often take up enough color with the Wright-Giemsa stain to mask the pigmentation. Therefore, in this case, evaluation of histologic samples was important for differentiating phaeohyphomycosis from hyalohyphomycosis. Culture would have been ideal for definitive identification of the opportunistic fungal organism that caused the infection in this dog, but was not performed.

Pythiosis, Lagenidiosis, Paralagenidiosis, Entomophthoromycosis, and Mucormycosis

Amy M. Grooters

KEY POINTS

Pythiosis

- First Described: In 1884, India, in horses.[1]
- Cause: *Pythium insidiosum* (kingdom Stramenopila, class Oomycota), related to algae and *Prototheca* spp.
- Affected Hosts: Dogs and horses; less commonly cats, sheep, cattle, exotic species, and humans.
- Geographic Distribution: Tropical, subtropical, and some temperate regions worldwide, especially the Gulf Coast region of the United States.
- Mode of Transmission: Likely penetration of damaged skin or mucosa by motile zoospores, often after exposure to standing freshwater sources.
- Major Clinical Signs: Ulcerative, nodular, and mass-like cutaneous lesions with draining tracts (cutaneous form); weight loss, anorexia, vomiting, diarrhea, hematochezia (GI form).
- Differential Diagnosis: For suspected GI pythiosis, differential diagnoses include neoplasia, entomophthoromycosis, histoplasmosis, eosinophilic gastroenteritis, or chronic intestinal foreign bodies; for suspected cutaneous pythiosis, they include lagenidiosis, paralagenidiosis, entomophthoromycosis, phaeohyphomycosis, mycobacterial infections, actinomycosis, or furunculosis.
- Human Health Significance: *Pythium insidiosum* is a rare cause of disease in human patients; infection is not transmitted directly from affected animals to humans.

Lagenidiosis and Paralagenidiosis

- First Described: *Lagenidium giganteum* forma *caninum*: 2003, Louisiana, USA, in dogs.[2] *Lagenidium deciduum*: 2016, Louisiana, USA, in cats.[3] *Paralagenidium karlingii*: 2004, Louisiana, USA, in dogs; and Illinois, USA, in a human patient.[4]
- Geographic Distribution: Southeastern United States, Australia.
- Mode of Transmission: Likely penetration of damaged skin or mucosa by motile zoospores.
- Major Clinical Signs: *Lagenidium giganteum* forma *caninum*: Ulcerative, nodular, and mass-like cutaneous lesions with draining tracts; pelvic limb edema; local, thoracic, or abdominal lymphadenopathy; rupture of infected great vessels in the abdomen may result in hemoabdomen. *Paralagenidium karlingii* (dogs) and *L. deciduum* (cats): Nodular or ulcerative dermatopathy that may extend locally but rarely invades beyond cutaneous and subcutaneous tissues.
- Differential Diagnosis: Neoplasia, pythiosis, entomophthoromycosis, mucormycosis, mycobacterial infections, actinomycosis, snake bite.
- Human Health Significance: Infection is acquired from the environment; it is not transmitted from affected animals to humans.

Entomophthoromycosis and Mucormycosis (Together Previously Termed Zygomycosis)

- First Described: Reports of these infections in humans date back to the 1800s.
- Causes: *Basidiobolus* and *Conidiobolus* spp. (kingdom Fungi, order Entomophthorales); *Rhizopus, Absidia, Mucor* spp., and others (kingdom Fungi, order Mucorales).
- Affected Hosts: Dogs, cats, humans, horses, sheep, and other mammalian species.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Inhalation, ingestion, or cutaneous exposure to organisms in soil and decaying organic matter.
- Major Clinical Signs: Entomophthoromycosis (also known as entomophthoramycosis) is associated with chronic, slowly progressive subcutaneous, GI, respiratory, retrobulbar, or nasal infections in immunocompetent animals; mucormycosis is associated with systemic (respiratory or GI) or cutaneous-subcutaneous infections in immunocompromised animals.
- Differential Diagnosis: Neoplasia, pythiosis, lagenidiosis, other deep mycoses, mycobacterial infections, actinomycosis.
- Human Health Significance: Disease in humans results from exposure to organisms in the environment, and direct transmission between animals has not been reported.

INTRODUCTION

Pythiosis, lagenidiosis, paralagenidiosis, entomophthoromycosis (also known as entomophthoramycosis), and mucormycosis are often grouped together because of similarities in their clinical presentations and histologic characteristics; all cause pyogranulomatous and eosinophilic inflammation associated with large, infrequently septate hyphae with nonparallel walls. Despite their clinicopathologic similarities, however, the pathogens that cause these infections are taxonomically diverse. *Pythium insidiosum, Lagenidium giganteum* forma *caninum, Lagenidium deciduum,* and *Paralagenidium karlingii* are water molds in the class Oomycetes. As such, they are more closely related to red algae and *Prototheca* spp. than to true fungi.[5] Important traits that distinguish oomycetes from fungi

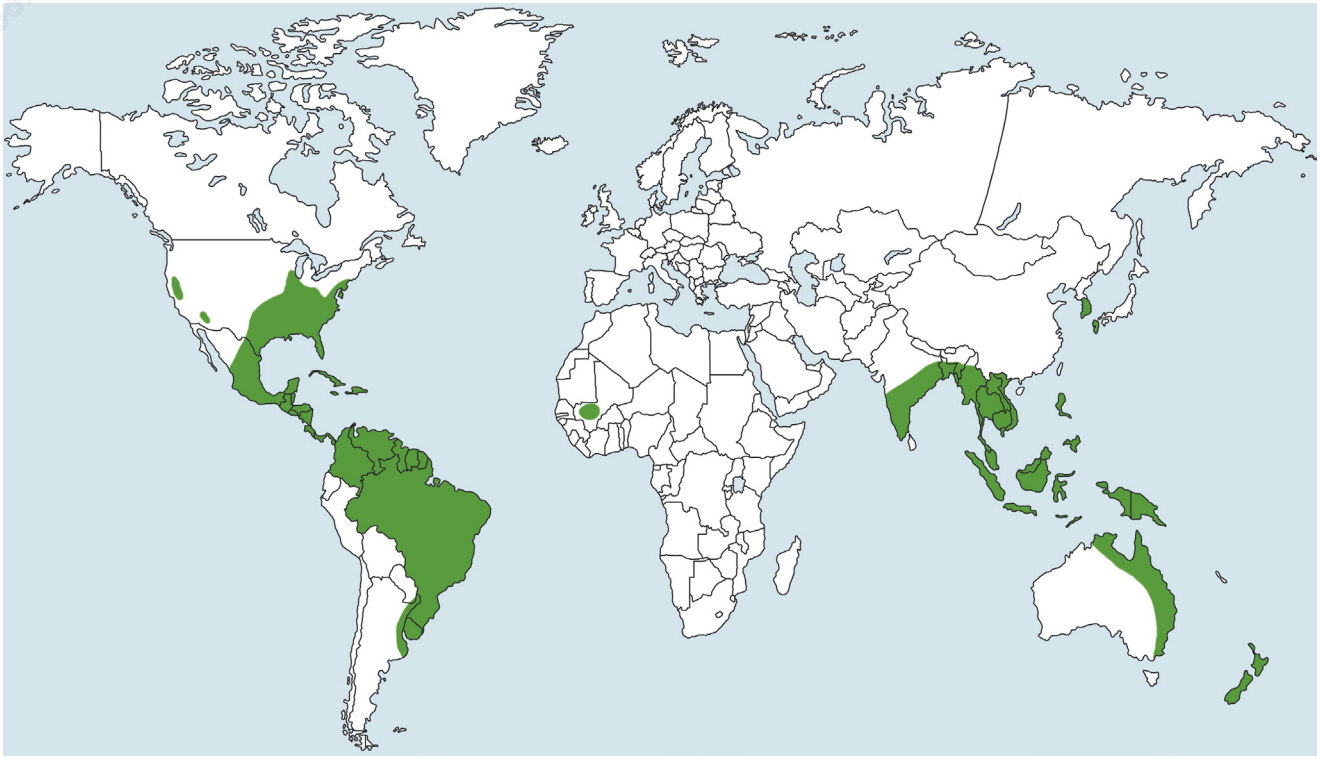

Fig. 88.1 Worldwide geographic distribution of pythiosis.

include the production of motile, flagellate zoospores that act as infective elements in wet environments, and the fact that the oomycete cell membrane generally lacks ergosterol.[6] In addition, there are clinically relevant differences in prognosis, recommended treatment, and epidemiology that make it important to distinguish among pythiosis, lagenidiosis, paralagenidiosis, entomophthoromycosis, and mucormycosis. Although *P. insidiosum* has been recognized as a pathogen in dogs and horses for more than 30 years, *Lagenidium* and *Paralagenidium* species have only been recognized as mammalian pathogens since 1999. In comparison to infections caused by the oomycetes, infections caused by fungi in the Entomophthorales and Mucorales in dogs and cats are rare. These organisms used to be referred to as zygomycetes, but molecular studies have led taxonomists to recommend abolishment of the class Zygomycota, instead placing the Entomophthorales within the phylum Zoopagomycota, and the Mucorales within the phylum Mucormycota.[7,8]

PYTHIOSIS

ETIOLOGY AND EPIDEMIOLOGY

Pythium insidiosum is an aquatic oomycete that causes severe, progressive GI or cutaneous disease that is often fatal. The infective form of *P. insidiosum* is thought to be the motile flagellate zoospore, which is an asexual reproductive structure produced in wet environments in association with plant material.[9] Zoospores of *P. insidiosum* are attracted to damaged tissue, and likely cause infection by encystation on and invasion of damaged skin or GI mucosa.[10] In support of this mechanism of infection, clinical reports have long suggested an association between pythiosis and frequent exposure to warm freshwater habitats. However, some infections occur in dogs with no history of access to lakes or ponds.

Globally, pythiosis occurs in tropical and subtropical climates, including Southeast Asia, eastern coastal Australia, and South America (Fig. 88.1). In the United States, the disease occurs most often in the Gulf Coast states, but it has also been recognized throughout the south; along the east coast as far north as Maryland and New Jersey; in the midwest including Missouri, Kansas, southern Illinois, and Indiana; and in the west in Arizona and California.[11,12]

Pythiosis is most common in young, large-breed dogs, especially Labrador retrievers and other outdoor working breeds. Infected dogs are typically evaluated by veterinarians in the fall, winter, and early spring.[13] Pythiosis is uncommon in cats compared with dogs, and specific breed and sex predilections have not been observed in the cases described to date. However, the development of cutaneous pythiosis in very young animals (less than 1 year of age) appears to occur more often in cats than in dogs. For both species, affected animals are typically immunocompetent.

CLINICAL FEATURES

The clinical signs associated with pythiosis are caused by GI or cutaneous lesions, or by extension of disease into regional lymph nodes or adjacent tissues. Generally, GI and cutaneous lesions do not occur together in the same animal. Rare cases of respiratory involvement with tracheobronchial lymphadenomegaly and disseminated pythiosis have been reported.[14,15]

Gastrointestinal Pythiosis

Gastrointestinal pythiosis in dogs is characterized by severe, segmental, transmural thickening of the stomach wall (Fig. 88.2), small intestine, colon, rectum, or, rarely, the esophagus.[13,16,17] It is not uncommon to find multiple segmental lesions in the same patient. The most commonly affected regions of the GI tract are the gastric outflow area, proximal duodenum, and ileocolic junction. Mesenteric lymphadenopathy is common but it is usually the result of reactive hyperplasia rather than infection. Extension of disease into the mesenteric root often causes severe mesenteric lymphadenomegaly,

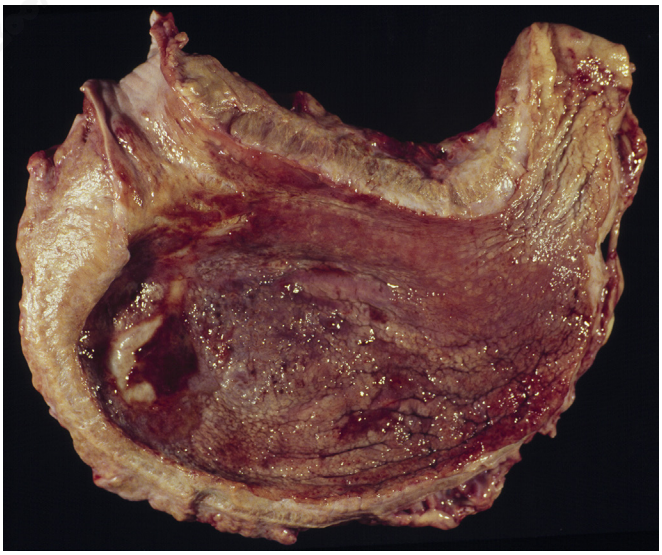

Fig. 88.2 Gastric pythiosis in a 1-year-old male neutered mixed-breed dog. Note extreme thickening of the gastric wall. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

with the lymph nodes embedded in a single large, firm mass that is palpable in the cranial to midabdomen. Invasion of mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen. Rarely, infection may extend into adjacent tissues such as the pancreas or the uterus. Gastrointestinal pythiosis is rare in cats but has been described in two young adult male cats from the southeastern United States with focal intestinal lesions that were amenable to surgical resection,[18] a 2-year-old cat from Missouri, USA, with a sublingual mass,[19] and a cat from northeastern Brazil with a jejunal wall mass.[20]

Dogs with GI pythiosis typically have a history of chronic progressive weight loss, vomiting, diarrhea, anorexia, and sometimes hematochezia, depending on the location of the lesions. Regurgitation may be present in dogs with esophageal involvement. Physical examination usually reveals a poor body condition and often a palpable abdominal mass. Signs of systemic illness such as lethargy or depression are absent unless intestinal obstruction, infarction, or perforation occurs.

Cutaneous Pythiosis

Cutaneous pythiosis in dogs occurs most often at the base of the tail, or on the extremities, ventral neck, or perineum,[15,21,22] and is characterized by nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts (Fig. 88.3). In contrast to GI pythiosis, regional lymphadenopathy associated with cutaneous pythiosis often reflects extension of infection rather than just reactive hyperplasia. Extension of cutaneous disease to tissues other than regional lymph nodes is rare, but pulmonary lesions caused by *P. insidiosum* have been observed rarely in dogs.[14]

In cats, lesions associated with cutaneous pythiosis include cervical, inguinal, or truncal subcutaneous masses; draining nodular lesions or ulcerated plaque-like lesions on the tailhead or extremities[20,22]; and periorbital and nasopharyngeal lesions.[23]

DIAGNOSIS

Laboratory Abnormalities

The most common laboratory abnormalities associated with pythiosis are eosinophilia, anemia, hyperglobulinemia, and hypoalbuminemia. Hypercalcemia has been described once.[24]

Fig. 88.3 Cutaneous pythiosis with paw involvement in a 6-month-old female Labrador retriever. Ulcerations, swelling, alopecia, and draining tracts are present. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

Imaging Findings

In dogs with GI pythiosis, common radiographic findings include poor abdominal detail and the presence of an abdominal mass. Evidence of small bowel obstruction may also be observed. In rare cases of esophageal pythiosis, thoracic radiographs reveal increased soft tissue opacity in the region of the esophagus and deviation of the trachea. A dog with respiratory involvement had radiographic and CT evidence of severe tracheobronchial lymphadenomegaly with tracheal and mainstem bronchial compression.[14] Abdominal ultrasonography is the tool of choice for imaging animals suspected to have GI pythiosis and usually reveals severe segmental thickening of the GI tract, loss of normal wall layering, and mesenteric lymphadenomegaly, although lymphadenomegaly is not observed in all dogs.[25] Evidence of invasion of the pancreas and extrahepatic bile duct obstruction was described in one dog.[25] In addition, Doppler ultrasonography may identify the presence of vascular pathology (such as an aneurysm) that can result from invasion of mesenteric vessels. Abdominal ultrasonography is a critical tool for determining the location and extent of disease in dogs with GI pythiosis to determine the likelihood that surgical resection could be performed successfully and to assess prognosis. In addition, ultrasonography facilitates the acquisition of fine-needle aspirate specimens from affected segments of the GI tract and enlarged lymph nodes. In animals with cutaneous pythiosis, CT may provide information about the extent of disease and may assist with surgical planning when lesions are not located on an extremity.[26]

Microbiologic Tests

Diagnostic assays currently available for pythiosis, lagenidiosis, paralagenidiosis, entomophthoromycosis, and mucormycosis, in dogs and cats are described in Table 88.1.

TABLE 88.1 Diagnostic Assays Currently Available for Pythiosis, Lagenidiosis, Paralagenidiosis, Entomophthoromycosis and Mucormycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Impression smears or aspirates of affected tissues	Negatively staining to rarely basophilic, broad, rarely septate fungal hyphae with tapered, rounded ends	Does not reliably differentiate among pythiosis, lagenidiosis, paralagenidiosis, entomophthoromycosis, and mucormycosis.
Culture	Biopsies of affected tissues	*Pythium insidiosum*, *Lagenidium* spp., *Paralagenidium* spp., *Conidiobolus* spp., *Basidiobolus* spp., and mucormycetes	Special tissue handling and expertise required for culture (see text). The use of swab specimens or aspirates may result in false negatives. Species identification requires the use of molecular techniques.
Antibody serology	Serum	Antibodies to *P. insidiosum*	Assays that detect anti-*Pythium* antibodies are sensitive and reasonably specific, although false-positive results can occur; titers fall with successful treatment. Assays that detect *Lagenidium* and *Paralagenidium* antibodies in dogs have poor specificity and should not be used.
Histopathology	Biopsies of affected tissues	Broad, rarely septate fungal hyphae with tapered, rounded ends	Does not reliably differentiate among pythiosis, lagenidiosis, paralagenidiosis, entomophthoromycosis, and mucormycosis. Use of special stains may facilitate detection.
PCR amplification and sequencing of rDNA	Biopsies of affected tissues	Oomycete, entomophthoramycete, or mucormycete DNA	Can be performed on cultured isolates (Box 88.1, *A*) or on formalin-fixed paraffin-embedded tissues (Box 88.1, *B*)

Cytologic Examination

Cytologically, pythiosis is characterized by pyogranulomatous and eosinophilic inflammation that can be visualized on impression smears made from firmly expressed exudate from draining tracts or fine-needle aspirates of subcutaneous lesions, thickened GI wall, or enlarged lymph nodes. Hyphae are observed occasionally in cytologic specimens, and their morphologic appearance (negatively staining to rarely basophilic, broad, pauciseptate hyphae with tapered, rounded ends) in conjunction with a typical inflammatory response can provide a tentative diagnosis of oomycosis, entomophthoromycosis, or mucormycosis.[24] Although a hyphal diameter > 7 μm makes a diagnosis of lagenidiosis or entomophthoromycosis more likely than pythiosis or paralagenidiosis, cytomorphologic features alone cannot provide a definitive diagnosis.

Isolation and Identification

Isolation of *P. insidiosum* from infected tissues is not difficult but does require specific specimen handling and culture techniques. For best results, unrefrigerated tissue specimens should be wrapped in a saline-moistened gauze sponge and shipped at ambient temperature to arrive within 24 hours at a laboratory that has experience with culture of pathogenic oomycetes (Box 88.1, *A*). Small pieces of fresh, nonmacerated tissue are placed directly on the surface of vegetable extract agar supplemented with streptomycin and ampicillin (or an alternative selective medium) and incubated at 37°C.[27] Mycelial growth is typically observed within 12 to 24 hours. Isolation of *P. insidiosum* from swabs of exudate collected from draining skin lesions is generally unsuccessful. Because generation of the sexual reproductive structures that are necessary for definitive morphologic classification of pathogenic oomycetes rarely occurs in the laboratory, identification of *P. insidiosum* isolates is based on species-specific PCR amplification[28] or rRNA gene sequencing. Although production of zoospores is an important supporting feature for the identification of pathogenic oomycetes, it is not specific for *P. insidiosum*. MALDI-TOF MS has also shown promise for identification of *P. insidiosum*.[29,30]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Species-specific PCR assays have been used to identify *P. insidiosum* DNA in fresh, frozen, or paraffin-embedded tissues from humans and animals, as well as DNA extracted directly from cultured isolates.[28,30–32] A sensitive isothermal PCR (LAMP) assay has also been developed; unlike PCR assays, this does not require a thermocycler and so is suited to low-resource settings.[33] In addition, amplification and sequencing of fungal and oomycete DNA from paraffin-embedded tissues using panfungal primers has recently become routinely available. Reported sensitivities for these panfungal assays have ranged from 54% to 94%.[34–36] Although a number of commercial laboratories now offer panfungal DNA amplification and sequencing, this author prefers to use a laboratory that interprets results in the context of histologic findings, and for which assay sensitivity and specificity have been described (Box 88.1, *B*).

BOX 88.1 Laboratories with Expertise in Diagnosis of Pythiosis, Lagenidiosis, Paralagenidiosis, Entomophthoromycosis, and Mucormycosis

A. Clinical Bacteriology and Mycology Laboratory, University of Tennessee College of Veterinary Medicine: https://vetmed.tennessee.edu/vmc/dls/bacteriology/

C. Department of Pathobiology, College of Veterinary Medicine, Auburn University: https://www.vetmed.auburn.edu/academic-departments/dept-of-pathobiology/diagnostic-services/

Serologic Testing

ELISA detection of anti–*P. insidiosum* antibodies in dogs has been reported to be sensitive and specific for the diagnosis of pythiosis, and also allows response to therapy to be monitored.[37] Following complete surgical resection of infected tissues, a dramatic decrease in antibody levels is typically detected within 2 to 3 months. Although ELISA serology has been adapted for detection of anti–*P. insidiosum* antibodies in domestic and exotic cats, case numbers are too small to generate strong estimates of sensitivity and specificity. An ELISA-based serologic assay for anti–*P. insidiosum* antibodies is available at the time

of writing through Auburn University (Box 88.1, *C*). Unfortunately, sensitivity and specificity for this assay have not been reported. A strongly false-positive result using the Auburn assay was reported in a dog with GI basidiobolomycosis,[38] and this author is aware of another false-positive result in a dog with hyalohyphomycosis. Therefore, the specificity of antibody serology for the diagnosis of pythiosis may be poorer than was previously thought, and positive results should always be interpreted in light of clinicopathologic findings.

Sensitive and specific ELISA or immunochromatographic assays that use the bacterial protein A/G as a conjugate have been reported.[39,40] This conjugate binds anti-*Pythium* antibodies from a variety of animal and human host species, which provides the potential for increased availability of serodiagnostic assays for dogs and cats, especially in parts of the world where more traditional assays are not available. Further clinical validation of these assays in dogs and cats with pythiosis is required, because of the low number of specimens from dogs and cats included in these studies.

Pathologic Findings

Histologically, pythiosis is characterized by eosinophilic pyogranulomatous inflammation, with multiple foci of necrosis that are surrounded and infiltrated by neutrophils, eosinophils, and macrophages. In addition, discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and fewer neutrophils and eosinophils are often observed. Organisms are typically found within areas of necrosis or at the center of granulomas. Vasculitis is occasionally present. In GI pythiosis, inflammation centers on the submucosal and muscular layers rather than the mucosa and lamina propria. Therefore, the diagnosis of pythiosis may be missed if endoscopic biopsies that fail to reach deeper tissues are submitted. Similarly, disease in animals with cutaneous pythiosis is typically found in the deep dermis and subcutis, necessitating deep wedge biopsies rather than punch biopsies for optimal evaluation. *Pythium insidiosum* hyphae are not routinely visualized on H&E–stained sections but may be identified as clear spaces surrounded by a narrow band of eosinophilic material. Hyphae are readily visualized in sections stained with Gomori's methenamine silver (GMS), but usually do not stain well with PAS. They are wide (mean, 4 µm; range, 2–7 µm), have nonparallel walls, are infrequently septate, and occasionally branch at right angles.[13,15]

TREATMENT AND PROGNOSIS

When lesion location allows resection with 5-cm margins, aggressive surgical resection of all infected tissues with wide margins is the treatment of choice for pythiosis. In animals with cutaneous lesions that are confined to a single distal extremity, amputation should be recommended unless there is evidence of regional lymph node infection. In patients with segmental GI pythiosis confined to the jejunum, ileocolic junction, or proximal colon, discrete lesions should be resected with 5-cm margins. Because mesenteric lymph nodes are usually reactive rather than infected, the presence of nonresectable mesenteric lymphadenopathy should not dissuade the surgeon from pursuing resection of a segmental bowel lesion, but enlarged lymph nodes should always be biopsied for prognostic information. In contrast to GI pythiosis, enlarged regional lymph nodes encountered in dogs with cutaneous pythiosis are often infected rather than reactive; therefore, they should be evaluated cytologically or histologically before amputation or other aggressive resection is attempted. In the author's experience, surgery is curative in a majority of animals with a distal limb lesion treated with amputation, or with a midjejunal lesion assessed as completely resected with 5-cm margins.

Historically, because of routinely poor responses of *P. insidiosum* to traditional antifungal drugs, very aggressive surgery such as a partial gastrectomy,[24] Billroth II procedure,[41] or massive resection of cutaneous lesions combined with reconstructive techniques[26] have been recommended for treatment of lesions in which optimal margins could not be obtained. Although these resections can sometimes result in a successful outcome, more often they are associated with lesion recurrence and/or significant postoperative morbidity. Surprisingly good outcomes have been observed using prednisone-containing medical protocols in dogs with GI pythiosis. These observations have led to recommendations that dogs with GI lesions that cannot be completely resected undergo medical therapy, rather than aggressive surgery that may not achieve 5-cm margins. In contrast, long-term positive responses to prednisone-containing medical protocols have not been observed in dogs with cutaneous pythiosis, so aggressive surgical resection remains the recommended therapy when skin margins of 5 cm and deep margins of two fascial planes may be achievable.[26] Local postoperative recurrence of disease is common in these patients, and can occur either at the site of resection or in regional lymph nodes. For this reason, postoperative therapy with itraconazole (10 mg/kg, PO, q24h) and terbinafine (5 to 10 mg/kg, PO, q24h) is often recommended for 2–6 months. To monitor for recurrence, ELISA serology can be performed at the time of surgery and 2 to 3 months later. In animals that have had a complete surgical resection and subsequently show no recurrence of disease, serum antibody levels usually drop 50% or more within 3 months. If this occurs, medical therapy can be discontinued. Unfortunately, if resection is incomplete, lesions often progress despite postoperative medical therapy, and clinical signs recur within weeks to months.

Medical therapy for nonresectable pythiosis has traditionally been unrewarding, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the oomycete cell membrane. Despite this fact, clinical and serologic cures have occurred in some patients treated with a combination of itraconazole (10 mg/kg, PO, q24h) and terbinafine (5 to 10 mg/kg, PO, q24h).[42] The addition of anti-inflammatory doses of prednisone to antifungal therapy significantly increases the likelihood of complete resolution of disease in dogs with nonresectable GI pythiosis.[12] As a result, this combination has become the treatment of choice in the author's practice for GI pythiosis when optimal margins may not be achievable. In addition, the author has observed complete resolution of GI pythiosis in a small number of dogs treated with prednisone alone. Current treatment recommendations for dogs with nonresectable GI pythiosis are: itraconazole (10 mg/kg, PO, q24h, usually FDA-approved generic capsules), terbinafine (5 to 10 mg/kg, PO, q24h), and prednisone (1 mg/kg, PO, q12h for 5–7 days, then q24h for 1 month). After the first 5 weeks of therapy, recheck ultrasonography is performed. At that time, lesions are typically either dramatically improved (in which case most patients go on to completely resolve their lesions) or unchanged (in which case lesions are very unlikely to improve). In patients that have improved, prednisone is continued at 1 mg/kg, q24h, for 1 additional month, and then slowly tapered if the patient is doing well clinically. Antifungals are usually administered for a total of at least 6 months. Although this protocol is not recommended for animals with lesions that are clearly resectable, it has substantially improved the prognosis for dogs with nonresectable GI pythiosis in the author's practice. Unfortunately, although the addition of prednisone to antifungal therapy for nonresectable cutaneous pythiosis may considerably improve lesions in the short term, the author has not observed complete long-term resolution of lesions in dogs with cutaneous pythiosis using medical therapy.

Mefenoxam, an agricultural fungicide used to treat oomycete pathogens that affect crops and ornamentals, has been used together with itraconazole and terbinafine to treat dogs with nonresectable or incompletely resected pythiosis.[42,43] However, there have been no evaluations of the efficacy of mefenoxam when used alone. Anecdotally, this author has found it to be ineffective in a very small number of dogs with pythiosis when used as sole therapy. Additional studies of the pharmacokinetics and safety of mefenoxam in dogs are required, as achievable tissue concentrations following oral administration are unknown. Therefore, at this time, its routine use cannot be recommended. An immunotherapy product derived from antigens of *P. insidiosum* has been used successfully to treat pythiosis in horses and humans.[44,45] Unfortunately, although controlled trials have not been completed, the efficacy of this product in dogs appears to be poor, and clinical improvement has not been observed in any of the author's patients.

PUBLIC HEALTH ASPECTS

Human infections caused by *P. insidiosum* are rare. Infections are acquired from the environment and have resulted in keratitis, periorbital cellulitis, and arteritis of the lower extremities. Most cases have been reported from Thailand, and almost all patients have thalassemia. Extremely rare reports of the disease exist from humans in North, South, and Central America, Australia, New Zealand, and other parts of Asia, many of whom are apparently healthy. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed.

LAGENIDIOSIS AND PARALAGENIDIOSIS

ETIOLOGY AND EPIDEMIOLOGY

Most species in the genus *Lagenidium* are pathogens of insects, crustaceans, algae, and nematodes. The most well-studied species, *L. giganteum* f. *giganteum*, is a mosquito larval pathogen that was previously used as a biologic pesticide for control of mosquito populations. In the late 1990s, two novel oomycete pathogens that appeared to be members of the genus *Lagenidium* were recognized in dogs as causes of cutaneous lesions that resemble those associated with pythiosis. More recently, multigene phylogenetic analyses have allowed formal names to be published for these pathogens.[3] The first pathogen, which causes severe and often fatal progressive cutaneous disease, lymphadenopathy, pulmonary nodules, and great vessel invasion,[2] has been formally described as *L. giganteum* f. *caninum* because of its close phylogenetic relationship with *L. giganteum* f. *giganteum*. The second pathogen causes more slowly progressive disease that is limited to skin and subcutaneous tissues.[4] Although it shares many antigenic and morphologic similarities with *L. giganteum* f. *caninum* and other *Lagenidium* species, phylogenetic analyses support placement of this second novel pathogen in the new genus *Paralagenidium*.[3] Within *Paralagenidium*, phylogenetic analyses show two clades, one of which has the species name *Paralagenidium karlingii*.[3] Insufficient numbers of isolates from the second clade (AG-2015a) were available at the time of analysis to determine whether it falls within *P. karlingii* or represents a separate species within *Paralagenidium*.[3] The author has noted that dogs infected with isolates from *Paralagenidium* clade AG-2015a may have a more chronic clinical course than dogs infected with *P. karlingii*, with some dogs having very slowly progressive lesions for many years. In addition, the hyphae may exhibit some unique cytomorphologic features.[46] In addition to *L. giganteum* f. *caninum* and the *Paralagenidium* pathogens, a previously uncharacterized oomycete was isolated from chronic, ulcerative cutaneous lesions in two cats from Louisiana. Multigene phylogenetic analyses indicate that this pathogen is identical to *L. deciduum,* a novel oomycete isolated from nematodes in Taiwan.[3]

The epidemiologic features of lagenidiosis and paralagenidiosis are similar in many respects to those associated with cutaneous pythiosis. Sporulation and infectivity is thought to be similar to that associated with *P. insidiosum*, causing infection through production of motile aquatic zoospores that adhere to and encyst in damaged tissues. Affected animals are typically young to middle-aged dogs that live in the southeastern United States. Although most affected dogs have lived in Florida or Louisiana, cases in Texas, Tennessee, Alabama, Georgia, South Carolina, Maryland, Virginia, Indiana, and Illinois, as well as Australia have been identified. A number of infected dogs have had frequent exposure to lakes or ponds. None have had historic evidence of immunocompromise or were treated with immunosuppressive therapy before development of the infection.

CLINICAL FEATURES

Dogs with *L. giganteum* f. *caninum* infection are typically evaluated for progressive, multifocal or focal, cutaneous or subcutaneous lesions that involve the extremities, mammary region, perineum, or trunk.[2] These lesions may appear as firm dermal or subcutaneous nodules, or as ulcerated, thickened, edematous areas of deep cellulitis with regions of necrosis and numerous draining tracts (Fig. 88.4). As with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to medical therapy. In contrast to cutaneous pythiosis, dogs with lagenidiosis typically have regional lymphadenopathy and may also have occult lesions in the thorax or abdomen involving the great vessels, sublumbar and/or inguinal lymph nodes, lung, pulmonary hilus, or cranial mediastinum. Animals with great vessel or sublumbar lymph node involvement usually have cutaneous or subcutaneous lesions on the pelvic limbs and often develop pelvic limb edema. Sudden death caused by great vessel rupture and associated hemoabdomen may occur in these animals. A dog from Florida was described that had extension of a mass lesion that involved the right masseter muscle into the brain, with associated forebrain neurologic signs.[47]

Fig. 88.4 Tailhead mass caused by lagenidiosis in a 9-year-old female spayed mixed-breed dog. Note the extensive tissue necrosis. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

In dogs with paralagenidiosis, lesions are characterized by solitary or multifocal dermal nodules or nodular thickening (sometimes without alopecia) or an ulcerative, crusting dermatopathy that may become extensive but rarely invades beyond cutaneous and subcutaneous tissues. Distant lesions in the thorax and abdomen have not been identified, and the clinical course appears to be chronic and slowly progressive. The author observed one dog with paralagenidiosis caused by a clade AG-2015a isolate that had slowly extending, waxing and waning lesions for 8 years. In the one cat with *L. deciduum* infection for which detailed clinical information is available, there was a chronic, pruritic lesion over the caudodorsum that was characterized by miliary dermatitis, alopecia, and crusting that progressed to papules coalescing into erythematous to whitish plaques (personal communication, Drs. Laura Sickafoose and Sandra Merchant, Louisiana State University).

DIAGNOSIS

Because of their clinical, epidemiologic, and histologic similarities to pythiosis, lagenidiosis and paralagenidiosis are often misdiagnosed as pythiosis during routine histologic evaluation. Although there are subtle differences in hyphal size, morphology, and distribution among these infections, histologic lesions associated with lagenidiosis and paralagenidiosis are still often labeled as "suspected pythiosis" or "suspected zygomycosis" during routine evaluation. For this reason, clinicians should always attempt to confirm a suspected histologic diagnosis with culture or molecular diagnostic assays.

Laboratory Abnormalities

Laboratory abnormalities are often absent in dogs with lagenidiosis and paralagenidiosis; when present, they most often include hyperglobulinemia and eosinophilia. Hypercalcemia was associated with *L. giganteum* f. *caninum* infection in one dog with cutaneous lesions on all four limbs and severe lymphadenitis associated with popliteal, inguinal, and superficial cervical lymph nodes.[48]

Imaging Findings

Radiographic imaging of the thorax and sonographic imaging of the abdomen are essential parts of the diagnostic evaluation in dogs suspected to have *L. giganteum* f. *caninum* infection because of the potential for occult lesions in the thorax or abdomen. These may include solitary pulmonary nodules; sublumbar, inguinal, and medial iliac lymphadenopathy; thickening and invasion of the wall of the aorta or caudal vena cava (sometimes with associated aneurysm); and retroperitoneal or epaxial masses. MRI findings in the dog with right masseter muscle infection that extended into the brain included marked patchy hyperintense soft tissue lesions adjacent to the mandible (T1W, T2W, and FLAIR) that exhibited marked heterogeneous contrast enhancement, marked right-sided meningeal enhancement; T2W and FLAIR hyperintense, T1W hypointense, contrast-enhancing regions in the right piriform and temporal lobes; and a mass effect causing deviation of the falx cerebri and right lateral ventricle compression.[47]

Microbiologic Tests

Cytologic Examination

Cytologic examination of lymph node aspirates or impression smears made from draining lesions in dogs with lagenidiosis and paralagenidiosis reveal pyogranulomatous to eosinophilic inflammation with or without negatively staining to rarely basophilic, broad, poorly septate hyphae. Cytologic examination of impression smears from one dog infected with a clade AG-2015a *Paralagenidium* isolate showed hyphae that contained numerous colorless oval internal structures.[46]

Isolation and Identification

The diagnosis of lagenidiosis and paralagenidiosis can only be made by PCR amplification and rRNA gene sequencing performed on DNA extracted from either cultured isolates or infected tissue. Isolation techniques for *Lagenidium* and *Paralagenidium* species are similar to those described for *P. insidiosum*, but with peptone-yeast-glucose (PYG) agar. If PYG agar is not available, blood agar is a reasonable second choice. For best results, small pieces of fresh, nonmacerated tissue are placed directly on the surface of the agar and incubated at 37°C. Growth is typically observed within 24 to 48 hours. Because production of the sexual reproductive structures necessary for morphologic classification has not yet been possible, definitive identification of *Lagenidium* and *Paralagenidium* species is currently based on rRNA gene sequencing. Therefore, this author utilizes a laboratory that is experienced with both culture and amplification/sequencing of pathogenic oomycetes (see Box 88.1, *A*).

Serologic Testing

An ELISA for quantitation of anti–*L. giganteum* f. *caninum* antibodies has been described as a sensitive but nonspecific serologic test for the identification of *L. giganteum* f. *caninum*–infected, and to a lesser degree, *P. karlingii*–infected dogs.[49] Because of extensive cross-reactivity with anti–*P. insidiosum* and anti-*Paralagenidium* antibodies, positive ELISA results are often observed in dogs with pythiosis or paralagenidiosis in addition to those with lagenidiosis. In addition, some dogs with nonfungal dermatopathies have had false-positive results. Because of these limitations, serology should not be used as a basis for the diagnosis of lagenidiosis or paralagenidiosis.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Amplification and sequencing of ribosomal DNA is currently the only diagnostic tool that allows differentiation among *L. giganteum* f. *caninum, P. karlingii*, clade AG-2015a *Paralagenidium* isolates, and *L. deciduum* (although it should be noted that *L. deciduum* infection has only been documented in cats). Molecular methods can be applied to DNA extracted from cultured isolates or from infected tissues.[31] Recently, amplification and sequencing of oomycete DNA from paraffin-embedded tissues using panfungal primers has become routinely available (see Box 88.1, *B*), which allows a diagnosis to still be made when culture was either not performed or was unsuccessful.

Pathologic Findings

Histologically, lagenidiosis and paralagenidiosis share many characteristics with pythiosis, entomophthoromycosis, and mucormycosis. All of these diseases are characterized by pyogranulomatous and eosinophilic inflammation associated with broad, irregularly branching, infrequently septate hyphae with nonparallel walls. Multinucleated giant cells and plasma cells are commonly present. In contrast to *P. insidiosum*, *L. giganteum* f. *caninum* and *Paralagenidium* spp. hyphae are often visible on H&E–stained sections. On GMS-stained sections, numerous broad, thick-walled, irregularly septate hyphae are easily recognized (Fig. 88.5), sometimes with visible round internal structures or a scant to thin eosinophilic sleeve noted around the hyphae. *Lagenidium giganteum* f. *caninum* hyphae typically demonstrate a great deal of variability in size, but in general are larger than *P. insidiosum* and *Paralagenidium* spp. hyphae (diameter range, 7–25 µm; mean, 12 µm).[2] In some sections, hyphae appear as round or bulbous structures, and right-angle branching is occasionally observed. *Paralagenidium* spp. hyphae are closer in diameter to *P. insidiosum*, with a mean diameter of 7.5 µm (range, 3–11 µm).[4,46]

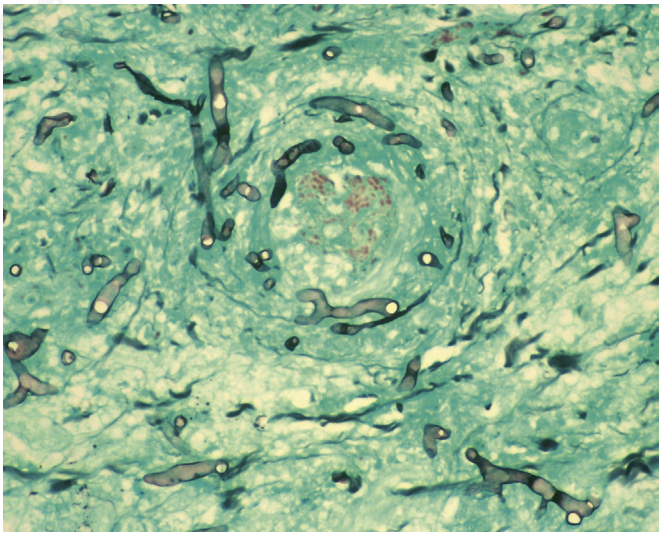

Fig. 88.5 Broad, thick-walled, infrequently septate hyphae associated with granulomatous vasculitis in a lymph node from a dog infected with *Lagenidium giganteum* forma *caninum*. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

TREATMENT AND PROGNOSIS

As with pythiosis, aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis and paralagenidiosis when disease is confined to a resectable cutaneous lesion. For *L. giganteum* f. *caninum* infection, because occult systemic lesions are common, radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen should be performed to determine the extent of disease prior to attempting surgical resection of cutaneous lesions. Unfortunately, the vast majority of dogs with lagenidiosis have nonresectable disease in the thorax, abdomen, or regional lymph nodes by the time the initial diagnosis is made. Because response to medical therapy is uniformly poor, the disease is routinely fatal.

In contrast, for dogs infected with paralagenidiosis, surgery that achieves 3- to 5-cm margins is often curative. As with pythiosis and lagenidiosis, medical therapy is usually ineffective in resolving lesions.[46] However, it may slow progression of the disease to a point that improves quality of life. The author is aware of one dog with recurrent multifocal cutaneous lesions due to paralagenidiosis in which treatment with a combination of itraconazole (10 mg/kg, PO, q24h) and terbinafine (5 to 10 mg/kg, PO, q24h) along with repeated aggressive surgical resection was curative. One dog with cutaneous *P. karlingii* infection of the perianal region was treated successfully with a combination of mefenoxam (8 mg/kg, PO, q24h; see Pythiosis), minocycline (10 mg/kg, PO, q12h), prednisone (0.5 mg/kg, q24h, tapered over 4 weeks), and hyperbaric oxygen therapy, followed by aggressive surgical resection.[50] The one cat with *L. deciduum* infection for which clinical information is available was poorly responsive to treatment in the short-term, but was not available for long-term follow-up, so no information about long-term response or prognosis is available.

PUBLIC HEALTH ASPECTS

Infections caused by *Lagenidium* and *Paralagenidium* species are acquired from the environment. Although there is no evidence to suggest that transmission between mammalian hosts is possible, routine precautions (such as wearing gloves when handling infected tissues or exudate) should be followed.

ENTOMOPHTHOROMYCOSIS AND MUCORMYCOSIS (PREVIOUSLY TOGETHER REFERRED TO AS ZYGOMYCOSIS)

ETIOLOGY AND EPIDEMIOLOGY

The term "zygomycosis" has been used to refer to disease caused by pathogenic fungi of the genera *Basidiobolus* and *Conidiobolus* (order Entomophthorales) and the genera *Rhizopus, Absidia, Mucor, Saksenaea, Cokeromyces*, and others (order Mucorales). These two orders were previously grouped in the phylum Zygomycota. Subsequent molecular studies led to reclassification of these fungi, placing the Entomophthorales within the phylum Zoopagomycota, and the Mucorales within the phylum Mucormycota. Therefore, although the term "zygomycosis" may continue to be used colloquially by pathologists and clinicians for some time, it is taxonomically obsolete, and should be replaced by the more specific and current terms "entomophthoromycosis" (also known as "entomophthoramycosis") and "mucormycosis."

In human patients, the Entomophthorales typically cause chronic localized infections in subcutaneous tissue or nasal submucosa of immunocompetent patients that reside in tropical or subtropical locations,[51] whereas the Mucorales tend to cause acute, rapidly progressive disease in debilitated or immunocompromised individuals or in immunocompetent individuals following trauma.[52] In veterinary patients, entomophthoromycosis is more common than mucormycosis, and is typically associated with infections caused by *Basidiobolus* and *Conidiobolus* spp., which are saprophytes commonly found in soil and decaying plant matter. Cutaneous infection with *Basidiobolus* or *Conidiobolus* spp. likely occurs by percutaneous inoculation of spores via minor trauma or insect bites. Infection may also result from inhalation or ingestion of spores. Culture-confirmed infections caused by pathogens in the order Mucorales have been described in only a small number of dogs and cats with a range of clinical presentations and underlying clinical conditions, making general characterizations of etiology difficult.

CLINICAL FEATURES

Entomophthoromycosis

In dogs, humans, horses, sheep, and other mammalian species, conidiobolomycosis occurs most often as a nasopharyngeal infection with or without local dissemination into tissues of the face, retropharyngeal region, and retrobulbar space. Manifestations of infection in dogs may include nasal or facial swelling or deformity, nasal discharge, ulceration of the nasal planum or hard palate, exophthalmos, chemosis, ocular discharge, and sometimes skin lesions near the eye (Fig. 88.6). In animals with retrobulbar disease that extends into the brain, neurologic signs may occur. *Conidiobolus* infection has been described in a single dog as a cause of multifocal nodular draining subcutaneous lesions and regional lymphadenopathy[53] and as a cause of pneumonia in a dog that was receiving chemotherapy.[54] Basidiobolomycosis is a rare cause of ulcerative skin lesions in dogs and has also been reported as a cause of respiratory disease in a dog.[55] It has also been reported to cause segmental GI disease with clinical features similar to those associated with GI pythiosis. *Basidiobolus ranarum* was described as a cause of a colonic mass in a shiba dog from Japan[56] and of colorectal disease in a French bulldog from central Louisiana.[38] *Basidiobolus microsporus* was identified in the feces of a boxer dog from Texas with colonic disease caused by *P. insidiosum*, but the clinical significance of the presence of *B. microsporus* was unclear.[57] Disseminated *Basidiobolus* infection involving the GI tract and other abdominal organs has been described in two dogs.[13,58]

Fig. 88.6 (A) Nasopharyngeal *Conidiobolus* spp. infection in a 4-year-old male neutered German shepherd dog. (B) Note the severe swelling of the nose and muzzle and ulceration of the nasal planum. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

Mucormycosis

In dogs and cats, culture-confirmed cases of mucormycosis are sparse and have been limited to single case reports. *Rhizomucor* was identified as the cause of duodenal perforation in a 7-month-old Persian cat,[59] and *Cokeromyces recurvatus* was isolated from abdominal fluid in a 16-year-old cat following jejunal perforation secondary to intestinal lymphoma.[60] *Rhizomucor pusillus* infection was associated with cerebral disease in a cat from France.[61] A subcutaneous mass caused by a *Mucor* species on the dorsum of the nose of a 14-year-old cat was treated successfully with posaconazole.[62] In dogs, infection by *Saksenaea vasiformis* was described in association with ulcerative cellulitis on the distal thoracic limb of a dog, and *C. recurvatus* was associated with the colonic mucosa in a dog with protein-losing enteropathy.[63]

DIAGNOSIS

Because of their histologic similarities, entomophthoromycosis and mucormycosis are often confused with pythiosis (which is much more common) when tissue biopsies are evaluated. Unfortunately, there are no serologic or immunohistochemical techniques that are routinely available for the differentiation of these infections, making identification of infected animals reliant on fungal culture of fresh tissues or ribosomal DNA amplification and sequencing from infected tissues.

Laboratory and Imaging Abnormalities

Laboratory abnormalities are not well described in animals with entomophthoromycosis or mucormycosis and would be expected to vary with the wide range of potential clinical presentations. Diagnostic imaging in the form of computed tomography often provides important information about the location and extent of disease in animals with nasopharyngeal and retrobulbar lesions caused by *Conidiobolus* spp. In addition, ocular ultrasonography may help to characterize the extent of disease in dogs with retrobulbar lesions.

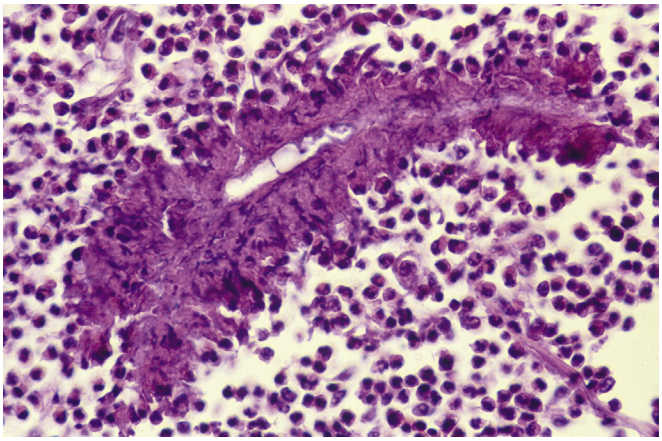

Fig. 88.7 *Conidiobolus* spp. hyphae in a tissue biopsy from an ulcerated palate lesion in a 3-year-old female boxer. Note the large amount of amorphous eosinophilic material (sleeve) surrounding the hyphal segment; hematoxylin and eosin stain. (Courtesy Amy M. Grooters, Louisiana State University, Baton Rouge, LA.)

Cytologic and Histologic Findings

The cytologic and histologic features of entomophthoromycosis and mucormycosis are similar to those associated with pythiosis and lagenidiosis. On GMS-stained sections, hyphae are broad, thin-walled, and occasionally septate. The histologic hallmark of entomophthoromycosis is the presence of a wide (2.5–25 μm) eosinophilic sleeve that surrounds the hyphae and makes them easily located on H&E-stained sections (Fig. 88.7). This finding may help to differentiate entomophthoromycosis from pythiosis and lagenidiosis, in which eosinophilic sleeves tend to be thin or absent. The hyphal diameter is also significantly larger for *Basidiobolus* spp. (mean 9 μm; range, 5–20 μm) and *Conidiobolus* spp. (mean 8 μm; range, 5–13 μm) than for *P. insidiosum*

(mean, 4 μm; range, 2–7 μm).[64] Histologic features of mucormycosis vary because of the more numerous genera in this group. *Cokeromyces recurvatus* is a dimorphic fungus that may appear in cytologic or histologic specimens as unique, very large (30–90 μm), spherical, thick-walled yeasts that are often confused with *Coccidioides* spp. spherules.[60,63,65]

TREATMENT AND PROGNOSIS

Recommendations for the treatment of entomophthoromycosis and mucormycosis are not straightforward because attempted therapy has only been described in a few patients with culture-confirmed diagnoses. Although anecdotal information as well as a small number of cases in the literature suggest that cutaneous entomophthoromycosis may be less aggressive than cutaneous pythiosis or lagenidiosis, progression of lesions and sometimes even dissemination despite treatment have also been observed in *Conidiobolus* or *Basidiobolus*-infected dogs. The author's current recommendation for dogs with nasopharyngeal conidiobolomycosis is treatment with itraconazole (10 mg/kg, PO, q24h) for 12–18 months. Recurrence is common after medication is discontinued, so a prolonged course is usually prescribed. Newer oral azoles such as posaconazole would also be reasonable choices and may have better efficacy but may be more expensive. Cutaneous entomophthoromycosis in small animal patients should be treated with aggressive surgical resection of infected tissues whenever possible, followed by itraconazole therapy for at least 3 months, especially if 3- to 5-cm margins cannot be achieved. If resection is not possible, treatment with itraconazole, voriconazole, or posaconazole for 6 to 18 months should be recommended. In dogs with GI basidiobolomycosis, guidelines based on the human medical literature would suggest that resectable lesions should be treated with a combination of surgical resection with wide margins followed by itraconazole therapy for 6 months. For nonresectable lesions, a combination of anti-inflammatory doses of prednisone (as recommended for GI pythiosis) combined with long-term itraconazole, voriconazole, or posaconazole therapy is recommended by the author. The recently described dog with colorectal basidiobolomycosis initially responded to treatment with itraconazole, terbinafine, and prednisone, with nearly complete resolution of clinical signs and sonographic lesions.[38] However, therapy was discontinued after only 15 weeks and the dog died with metastatic neoplasia 3 weeks later. Despite the lack of gross lesions at necropsy, fungal organisms were identified on histopathologic examination of rectal tissues, emphasizing the importance of long-term antifungal therapy in these patients. For mucormycosis, lipid-complexed amphotericin B or posaconazole are generally recommended for treatment of human patients.[52,66] In veterinary patients, this author would consider posaconazole the treatment of choice, although data supporting this choice is largely based on information from human patients.

PUBLIC HEALTH ASPECTS

Entomophthoromycosis and mucormycosis are rare in human patients. Infections are acquired from the environment. There is no evidence to suggest that transmission between mammalian hosts occurs, provided normal precautions are followed.

CASE EXAMPLE

Signalment

"Jasper," an 18-month-old intact male Labrador retriever from central Louisiana.

History

Jasper was evaluated for a 1-month history of frequent vomiting and persistent diarrhea and a 2-week history of intermittent anorexia. In addition, the owner reported that the dog had lost approximately 6 kg. The diarrhea was watery and yellowish-brown and was produced in large quantity; hematochezia had not been noted. A fecal flotation and heartworm antigen test performed by the referring veterinarian 1 week before the dog was evaluated at the author's institution had been negative. Treatment with metronidazole (17 mg/kg, PO, q12h) and a change to an easily digestible prescription diet had failed to improve the vomiting and diarrhea. The patient was a field trial dog used for duck and dove hunting in central Louisiana. He frequently worked in rice fields and occasionally in bodies of fresh water and was generally housed in an outdoor kennel.

Physical Examination

Body weight: 30 kg.

General: Bright, alert, and responsive. Body temperature = 102.7°F (39.2°C), HR = 110 beats/minute, RR = 20 breaths/minute, mucous membranes pink, CRT ~ 2 seconds.

Eyes, ears, nose, and throat: No significant abnormalities were noted.

Musculoskeletal: The dog was underweight with a BCS of 3/9.

Cardiovascular and respiratory: Strong femoral pulses. No murmurs or arrhythmias were auscultated. Respiratory rate and effort were normal.

GI and genitourinary: The patient showed signs of discomfort during abdominal palpation; a large, firm, tubular mass was palpated in the midabdomen. Mild prostatomegaly was detected on rectal examination.

Lymph nodes: All palpable peripheral lymph nodes were normal in size and shape.

Laboratory Findings

CBC: HCT 33.7% (37%–55%), MCV 61.7 fL (62–77 fL), MCHC 20.8 g/dL (32–37 g/dL), WBC 10,600 cells/μL (8,000–14,500 cells/μL), neutrophils 6,200 cells/μL (3,000–11,500 cells/μL), lymphocytes 1,700 cells/μL (1,000–4,800 cells/μL), monocytes 1,100 cells/μL (100–1,400 cells/μL), platelets 254,000/μL (220,000–600,000 platelets/μL).

Serum chemistry profile: Sodium 142 mmol/L (140–153 mmol/L), potassium 4.4 mmol/L (3.8–5.5 mmol/L), chloride 110 mmol/L (107–115 mmol/L), bicarbonate 20 mmol/L (17–27 mmol/L), phosphorus 4.6 mg/dL (3.4–6.3 mg/dL), calcium 9.1 mg/dL (9.4–11.4 mg/dL), BUN 11 mg/dL (8–22 mg/dL), creatinine 0.7 mg/dL (0.5–1.7 mg/dL), glucose 96 mg/dL (80–115 mg/dL), total protein 5.7 g/dL (5.8–7.5 g/dL), albumin 2.0 g/dL (2.6–4.2 g/dL), globulin 3.7 g/dL (2.5–4.0 g/dL), ALT 34 U/L (0–60 U/L), AST 22 U/L (0–50 U/L), ALP 13 U/L (0–100 U/L), creatine kinase 134 U/L (0–200 U/L), cholesterol 158 mg/dL (150–240 mg/dL), total bilirubin 0.2 mg/dL (0–0.4 mg/dL).

Urinalysis: SpG 1.041, pH 7.5, 3+ protein, 3+ bilirubin, negative hemoglobin, negative glucose, negative ketones, 0–5 WBC/HPF, 0 RBC/HPF, many lipid droplets.

Imaging Findings

Plain abdominal radiographs: There was a generalized loss of serosal detail in the abdomen. Gas was present in the GI tract, but there was no evidence of abnormal intestinal tract dilation.

Abdominal ultrasound: A severely thickened segment of small bowel could be visualized extending from the cranial to the caudal abdomen. The wall of this bowel segment measured 1.1 cm in thickness and lacked normal layering (Fig. 88.8A). Mesenteric lymph nodes were enlarged and heterogeneous (Fig. 88.8B). There was a small amount of free abdominal fluid.

Cytologic Findings

Cytologic evaluation of ultrasound-guided mesenteric lymph node aspirates revealed reactive lymphoid hyperplasia. Examination of ultrasound-guided aspirates of

CASE EXAMPLE—cont'd

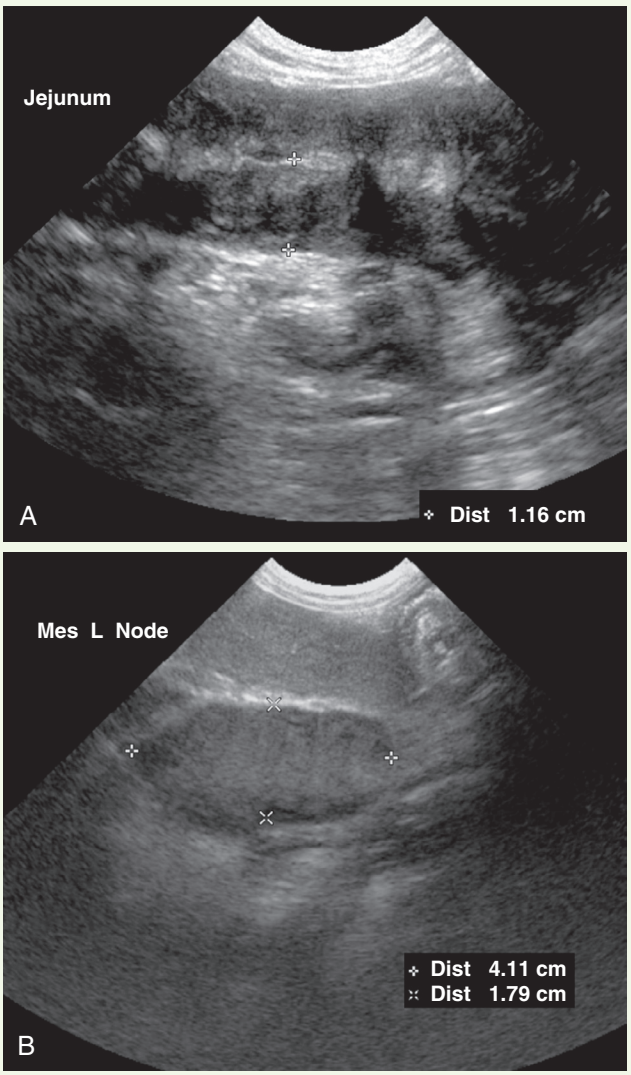

Fig. 88.8 Sonographic images of the abdomen of the dog described in the case example. Note the severe thickening and loss of layering in the wall of the jejunum (A) and the enlarged, heterogeneous appearance of the mesenteric lymph node (B).

the thickened segment of bowel showed that the cellularity was too low for cytologic evaluation.

Serologic Findings

ELISA serology for anti–*P. insidiosum* antibodies: Positive at 69%. Results of this assay are expressed as percent positivity in comparison with a strong positive control sample, with values > 40% positivity having been shown to be highly specific for pythiosis in dogs. Values in healthy dogs range from 3% to 15%.[37]

Diagnosis

Jejunal pythiosis.

Treatment

Abdominal exploratory examination revealed a 50-cm segment of the midjejunum that was severely thickened and firm. This segment was resected with 5-cm margins. After an uneventful postoperative recovery, the dog's vomiting, diarrhea, and anorexia resolved quickly. He was treated with itraconazole (10 mg/kg, PO, q24h) and terbinafine (8.3 mg/kg, PO, q24h) for 2 months in an effort to decrease the chance of recurrence of disease at the site of resection. Liver enzyme activities and serum bilirubin concentration were monitored during this time and remained within reference intervals.

Histopathologic Findings

Both the resected segment of jejunum as well as jejunal and ileocolic lymph nodes were submitted for histologic examination. Results revealed severe transmural eosinophilic pyogranulomatous enteritis and lymphoid hyperplasia. In the jejunal lesion, wide (3–8 μm), poorly septate hyphae with nonparallel walls were visualized on GMS-stained sections. No organisms were observed in the lymph node sections.

Follow-Up

At reevaluation 2 months after resection of the jejunal lesion, the dog remained free of clinical signs and had gained 3 kg body weight. Reevaluation of anti–*P. insidiosum* antibody serology at that time yielded a percent positivity of 20%. Because the rapid decrease in antibody levels from 69% to 20% was strongly suggestive of a surgical cure of GI pythiosis, oral antifungal medications were discontinued. Reevaluation of anti–*P. insidiosum* antibody serology 2 years later yielded results within the range observed in healthy dogs (6%).

Comments

Although most dogs with GI pythiosis have nonresectable lesions, those with midjejunal lesions can often be surgically cured. Preoperative abdominal ultrasound is essential since it helps to determine whether or not a GI lesion might be surgically resectable. Postoperative medical therapy was probably not necessary in the case described here since the postoperative clinical course and follow-up serology results strongly supported a surgical cure. In the author's experience, most dogs with a midjejunal lesion are surgically cured when the surgeon is confident that greater than 5-cm margins of healthy tissue were obtained with the resection and lymph node histology shows hyperplasia rather than infection. In such cases, medical treatment with itraconazole and terbinafine can be offered as optional but likely unnecessary therapy for 2 months until follow-up serology is performed.

Pneumocystosis

Remo Lobetti, Jane E. Sykes

KEY POINTS

- First Described: *Pneumocystis* was first discovered in Brazil in 1909 (Chagas), when it was initially mistaken for a trypanosome. It was first reported in dogs in the 1950s.
- Causes: *Pneumocystis* spp. (an Ascomycete).
- Affected Hosts: Dogs, humans, pigs, horses, goats, nonhuman primates.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Opportunistic invasion of immunosuppressed hosts after aerosol transmission.
- Major Clinical Signs: Weight loss, respiratory distress, exercise intolerance, variable cough.
- Differential Diagnoses: Bacterial pneumonia, mycobacterial infections, other fungal causes of pneumonia, diffuse pulmonary neoplasia, parasitic lung disease.
- Human Health Significance: Severely immunocompromised humans are at risk for pneumocystosis, but only *Pneumocystis jirovecii* infects humans. Whether humans can become colonized with *Pneumocystis* strains that can infect dogs is not known.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Pneumocystis carinii, the etiologic agent of pneumocystosis, occurs worldwide and infects virtually all mammalian species, including humans. *Pneumocystis* is a saprophyte of low virulence that exists in temperate and tropical climates at altitudes up to 5,000 feet. Its primary habitat is the mammalian lung where it causes opportunistic pneumonia. Clinical pneumonia has been reported to occur spontaneously in dogs, pigs, horses, goats, primates, and humans. Subclinical or latent infections are common in rats, mice, guinea pigs, rabbits, cats, sheep, and various wild animals. Most reports of clinical *Pneumocystis* pneumonia are linked with documented or suspected immunodeficiency syndromes in the host. In humans with AIDS within the United States, it has been the most important opportunistic infection, occurring in 60% of patients over the course of disease.[1] With the availability of effective antiretroviral drugs but increased use of potent immunosuppressive drugs, *Pneumocystis* infections are now emerging as a serious problem in non-HIV-infected humans that are being treated with immunosuppressive or cytotoxic drugs.

Previously, *Pneumocystis* was classified as a unicellular protozoan (phylum Sarcomastigophora). However, ultrastructurally the reproductive behavior of *Pneumocystis* is similar to the ascospore formation of yeast cells, and its organelles and staining properties by light microscopy resemble those of pathogenic fungi. Phylogenetic classification based on 16S-like rRNA sequences indicates that *Pneumocystis* is most closely related to the fungi of the class Ascomycetes, especially *Saccharomyces cerevisiae*, and so it has been reclassified as a fungus, "albeit an odd one." Most recently, *Pneumocystis* has been assigned to the subphylum Taphrinomycotina within the division Ascomycota.[2] Biologically, however, *Pneumocystis* exhibits behavior that resembles a protozoan, because it is susceptible to drugs used to treat sporozoan infections but resistant to most antifungal drugs. Its cell wall contains cholesterol rather than ergosterol, which is the target of azole antifungals. The morphology of the organisms and the histopathology of the lesions produced by both human and animal isolates throughout the world are similar. Although controversial, five species of *Pneumocystis* have been described, which appear to be highly host-specific: *P. carinii* and *Pneumocystis wakefieldiae* that infect rats; *Pneumocystis murina* that infects mice; *Pneumocystis oryctolagi* that infects rabbits; and *Pneumocystis jirovecii* (pronounced "yee row vet zee") that infects humans.[1,3–5] The name *P. carinii* f. sp. *canis* was proposed for the organism that infects dogs.[6,7] Historically, *P. carinii* was thought to cause *Pneumocystis* pneumonia in humans, so *Pneumocystis* pneumonia has long been referred to as "PCP". Despite the name change to *P. jirovecii* in the 1970s, the term PCP has been retained because of familiarity. Biologic differences among isolates from different hosts are suggested by the relative difficulty of experimental cross–host species transmission. For purposes of this chapter, the organism that appears to be adapted to dogs will be referred to as *Pneumocytis canis*, which was also used in a large study that examined genomic relationships among different Pneumocystis species.[8]

Pneumocystis spp. appear to be maintained in nature by transmission from infected to susceptible animals within a species. The primary mode of spread is thought to be airborne droplet transmission among hosts, with neonates becoming colonized at birth.[9] Sporadic cases may represent an activation of latent infection by stress, crowding, and immunosuppressive therapy during hospitalization of latent carriers. Clinical disease has also been experimentally activated after glucocorticoid therapy and cytotoxic chemotherapy. A higher prevalence of infection has been reported in dogs with CDV infection compared with a corresponding control population,[10,11] and recently, a case was reported in a mix-breed dog (Maltese terrier-Papillon) that was treated with toceranib phosphate.[6] Genetic analysis of isolates in humans indicates that most infections are not previously acquired but rather result from an infected source that is likely of the same host species within a given geographic region.[12]

Most affected dogs have been miniature dachshunds younger than 1 year and adult Cavalier King Charles spaniels.[11,13–15] Cases also have occasionally been reported in other dogs, including a Pomeranian, Yorkshire terrier, a shih tzu, and a whippet.[16–18] The miniature dachshund, Cavalier King Charles spaniel, and Pomeranian had an underlying primary immune deficiency.[17,19,20] The shih tzu dog was found to have an X-linked CD40 ligand deficiency, a defect that impairs T cell costimulation and leads to a combined T cell and B cell immunodeficiency. It is possible that this mutation may have been present in other dogs with pneumocystosis, because genetic characterization

at this level was not done.[18] Although the organism has been found in the lungs of cats, clinical disease has not been reported and thus in general, *Pneumocystis* infections of cats appear to be latent or subclinical. Cats that were experimentally infected with *P. carinii* isolated from mice developed a cough, tachypnea, and pneumonia if they were immunosuppressed with concurrent glucocorticoid administration.[21] In contrast, subclinical infections occurred in cats that did not receive immunosuppressive therapy.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Pneumocystis is inhaled from the environment and then can colonize the lower respiratory tract of clinically healthy mammals; however, they rarely multiply to large numbers in the lungs of clinically healthy hosts. Transmission of infection to neonates occurs almost ubiquitously during the birth process, with clearance and transient colonization over the course of a lifetime.[2] In conditions in which impaired host resistance (especially with reduced CD4 T-cell counts) or preexisting pulmonary disease is present, rapid proliferation of organisms can occur, either as a result of new infection or reactivation of "latent" infections.[1,2,22] The entire life cycle of *Pneumocystis* is completed within the alveolar spaces where organisms adhere in clusters to the lining cells (Fig. 89.1). In this location, two main forms, the haploid trophozoite (1–4 μm in diameter) and cyst (8 μm), are found. Trophozoites undergo sexual reproduction and pass through three stages (early, intermediate, and late sporocysts) to form a thick-walled mature cyst. The wall of these cysts is composed of the major surface glycoprotein (MSG), β-1,3 glucan, and β-1,6 glucan. The cyst contains eight ascospores, which form because of multiple nuclear division. The cyst ruptures, and the spores transform into trophozoites, which may replicate asexually to form more trophozoites, or sexually to form more cyst forms. The trophozoite form predominates in the lungs during infection, whereas cysts are responsible for propagation. The wall of the trophozoite contains MSG but not β-glucans.[2] Because β-glucans are essential for activating the dendritic cell and subsequent CD4+ T-cell immune response, the trophozoite form may be able to evade cellular recognition to a greater extent than the ascus form. Cells involved in the immune response to *Pneumocystis* are shown in Fig. 89.2. Existing studies in mice suggest that M2 macrophages are proinflammatory, and important in clearance of infection, whereas M1 macrophages exhibit defective clearance.[2]

The overgrowth and clustering of *Pneumocystis* within alveolar spaces leads to blockage of capillaries and decreased gaseous exchange. Intraalveolar organisms are often accompanied by thickening of alveolar septa, but they seldom invade the pulmonary interstitium and are rarely phagocytosed by alveolar macrophages. With an adequate immune response, the body usually eliminates the infection, but the removal of large numbers of organisms and cellular debris may take up to 8 weeks. Both the presence of the organisms and the minimal inflammatory response they provoke contribute to the pulmonary alveolar damage.

Although *Pneumocystis* infections are usually confined to the lungs, organisms have been reported in extra-pulmonary sites in humans and an infection in one dog. In humans, extra-pulmonary pneumocystosis is extremely rare and occurs primarily when accompanied by overwhelming pulmonary infection, profound underlying immunodeficiency, and long-term use of aerosolized pentamidine for prophylaxis against *P. jirovecii* pneumonia in individuals infected with HIV.[21] Sites of extra-pulmonary infection include the lymph nodes, spleen, liver, bone marrow, GI tract, eyes, thyroid gland, adrenal glands, kidneys, heart, pancreas, and external auditory canal.

The typical clinical history is that of gradual weight loss and respiratory difficulty that progresses over 1 to 4 weeks. Weight loss, which occurs despite a good appetite in most dogs, may be associated with diarrhea and occasional vomiting. Cough is not always reported, but reduced exercise tolerance is uniform. Infected animals often show a minimal or temporary response to antibiotic and glucocorticoid therapy.

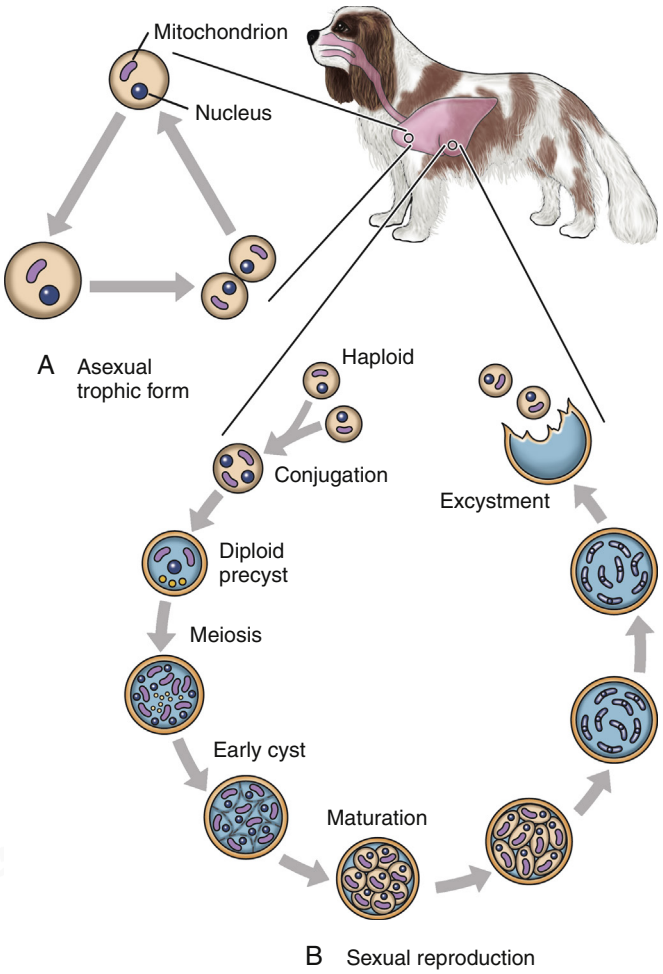

Fig. 89.1 Life cycle of *Pneumocystis* species. Trophozoites adhere to alveolar epithelial cells in the lungs and undergo both asexual (A) and sexual (B) reproduction. Sexual reproduction is initiated by conjugation, which results in formation of a zygote. Meiosis occurs followed by mitosis, which leads to the formation of eight ascospores within a mature cyst. The cyst ruptures, releasing spores that become trophozoites.

Physical Examination Findings

Abnormalities on physical examination include dyspnea, tachypnea, increased breath sounds on thoracic auscultation, and variable cyanosis.[11] Animals are often in poor condition and cachectic, and can show dermatologic changes, as a result of superficial bacterial pyoderma and/or demodicosis (Fig. 89.3). Affected dogs remain relatively alert and fever is uncommon.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

Hematologic abnormalities are usually nonspecific, with neutrophilic leukocytosis being the most consistent finding.[11] Less frequently, eosinophilia and monocytosis are found. Lymphocyte numbers can be elevated, normal, or low. Polycythemia may occur secondarily to arterial hypoxemia from impaired gaseous exchange. Thrombocytosis is

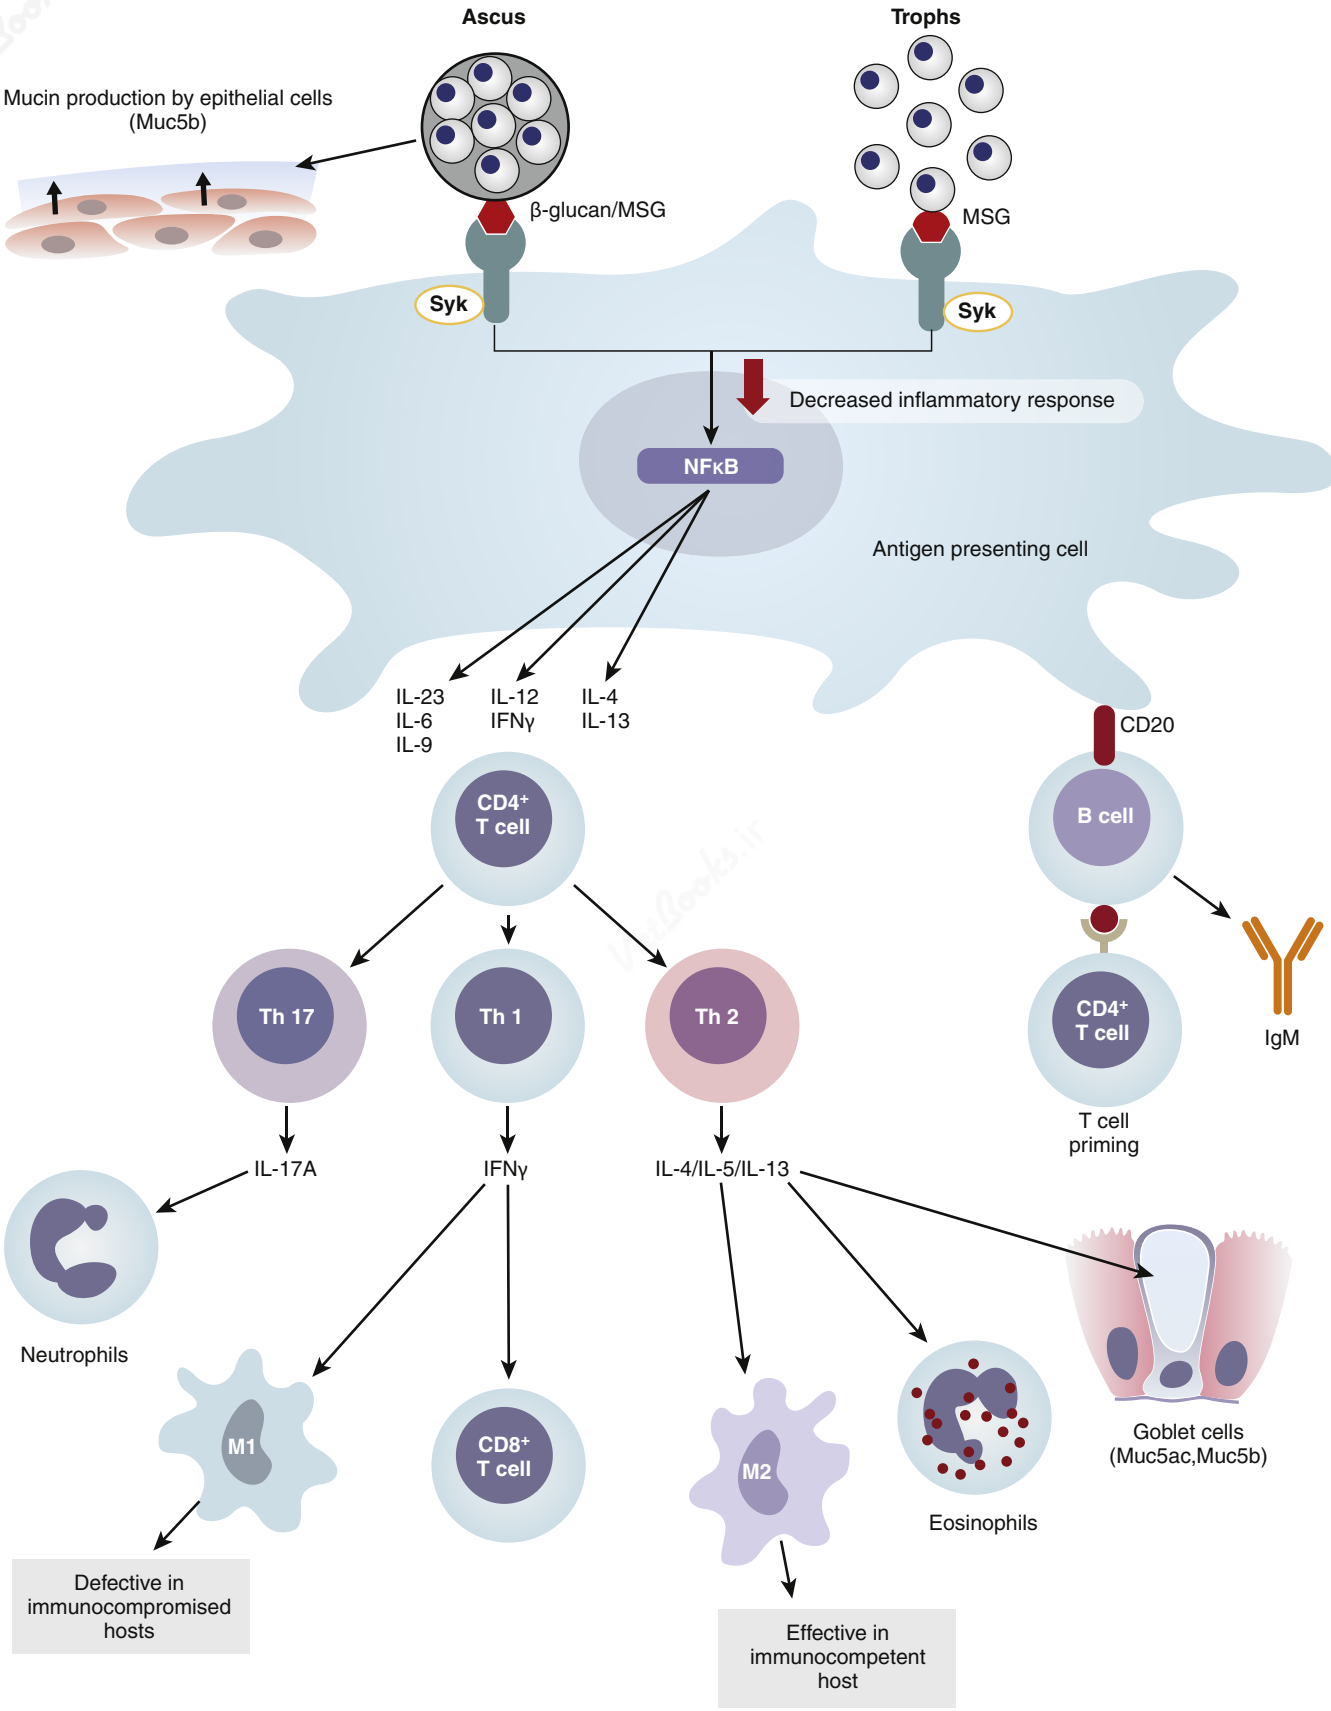

Fig. 89.2 Pathways involved in the immune response to *Pneumocystis* spp. *MSG,* major surface glycoprotein; *M1,* M1 type macrophage; *M2,* M2 type macrophage. (Modified from Walzer PD, Smulian AG. *Pneumocystis* species. In: Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases*. 7th ed. Philadelphia: Elsevier; 2010:3377–3390.)

Fig. 89.3 A 1-year-old dachshund with pneumocystosis. Note the thin body condition and alopecia secondary to generalized demodectic mange.

often present in miniature dachshunds. Artifactual thrombocytopenia and megathrombocytosis can occur in Cavalier King Charles spaniels, which is unrelated to the suspected immunodeficiency.

Serum Chemistry Profile

Biochemical alterations are usually nonspecific. Total serum proteins are usually within reference limits with a low to borderline-low globulin level, which correlates with low γ-globulin levels on serum protein electrophoresis.[11] Arterial hypoxemia, hypocapnia, and increased arterial blood pH indicate an uncompensated respiratory alkalosis. The pO_2 is often lower than would be expected from the clinical signs and thoracic radiographic findings.

Diagnostic Imaging

Findings on thoracic radiography are typically diffuse, bilaterally symmetric, granular or miliary-interstitial to alveolar changes (Fig. 89.4).[23] Solitary lesions, unilateral involvement, cavitary lesions, spontaneous pneumothorax, pneumomediastinum, and lobar infiltrates have also been described.[11,16,18] Additional findings in the dog may be tracheal elevation, right-sided heart enlargement, and pulmonary arterial enlargement secondary to pulmonary hypertension. CT findings in dogs with pneumocystosis reflect diffuse or multifocal pulmonary interstitial infiltrates ("ground glass appearance") and focal regions of increased opacity (Fig. 89.5).[6,18,24] Other reported CT findings are parenchymal bands, bronchiolar dilation, pleural thickening, and tracheobronchial lymphadenopathy.

Microbiologic Tests

Cytologic Diagnosis

The diagnosis of pneumocystosis requires direct demonstration of *Pneumocystis* in biopsy specimens, respiratory fluids, or occasional extrapulmonary sites (Table 89.1). Transtracheal, endotracheal, or bronchoalveolar washings; lung aspirates; and oropharyngeal secretions may contain organisms. Transtracheal washings have been effective for identification of organisms in dogs; however, cytologic examination of wash specimens can

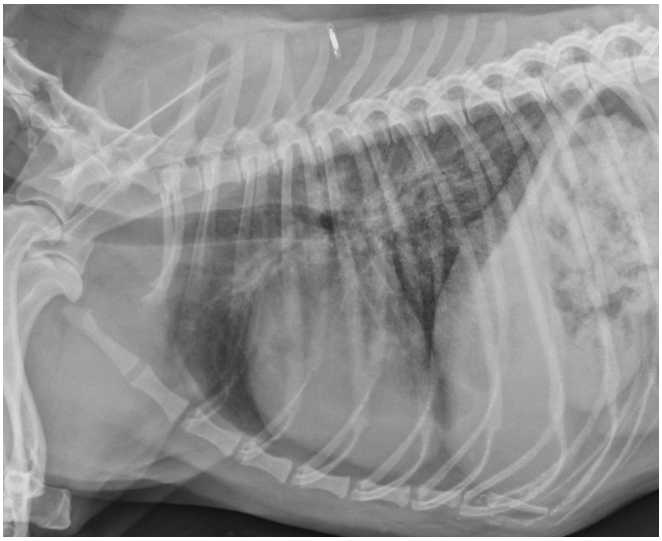

Fig. 89.4 Lateral thoracic radiographs from a 1-year-old male neutered Cavalier King Charles spaniel with pneumocystosis. A diffuse marked interstitial pattern is present. Mild right-sided cardiomegaly was also identified.

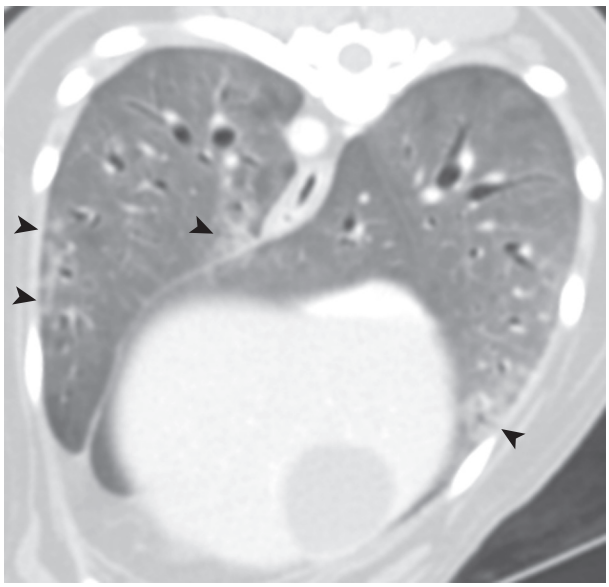

Fig. 89.5 Thoracic computed tomography scan from a 4-year-old female spayed Cavalier King Charles spaniel with pneumocystosis that was evaluated for lethargy, inappetence, and respiratory distress. There is a diffuse interstitial pattern and focal peripheral alveolar infiltrates *(arrowheads).*

lack sensitivity.[25] Direct FA assays have been effective in increasing sensitivity for detection of organisms in sputum and respiratory lavage specimens from humans, and have been used as a gold standard.[26] None of the cytologic techniques are as reliable or as definitive as is histopathology examination of lung biopsy specimens for documenting active pneumocystosis. Lung biopsy is, however, more invasive, has potential complications of hemorrhage or pneumothorax, and associated with additional costs and hospitalization. *Pneumocystis* organisms are difficult to detect in respiratory secretions or washings, especially trophozoites, and success in finding them usually depends on the experience of the examiner and the collection and processing of specimens. Polychrome stains, such as Wright's, Giemsa, and methylene blue, will demonstrate nuclei of trophozoites and intracystic sporozoites in cytologic specimens, but the walls

TABLE 89.1 Diagnostic Assays Available for Pneumocystosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Lung aspirates; transtracheal, endotracheal, or broncho-alveolar lavage specimens	*Pneumocystis* trophozoites and cysts	False negatives can occur when specimen size is small or low numbers of organisms are present. Identification to the genus level requires immunostaining or PCR assay.
PCR assays	Lung aspirates; transtracheal, endotracheal, or broncho-alveolar lavage specimens	*Pneumocystis* spp. DNA	The sensitivity and specificity of assays may vary depending on assay design. Assays designed to detect *Pneumocystis jirovecii* may not detect organisms that infect dogs. In the absence of cytologic evidence of *Pneumocystis* infection, the significance of a positive PCR result must be interpreted in light of clinical findings, because of the potential for subclinical colonization.
Histopathology	Lung biopsy or necropsy specimens	*Pneumocystis* trophozoites and cysts	Large numbers of organisms are usually found filling alveolar spaces. Cyst forms are best demonstrated with silver stains or periodic acid–Schiff. The identity of the organisms can be confirmed with immunohistochemistry or PCR assay.

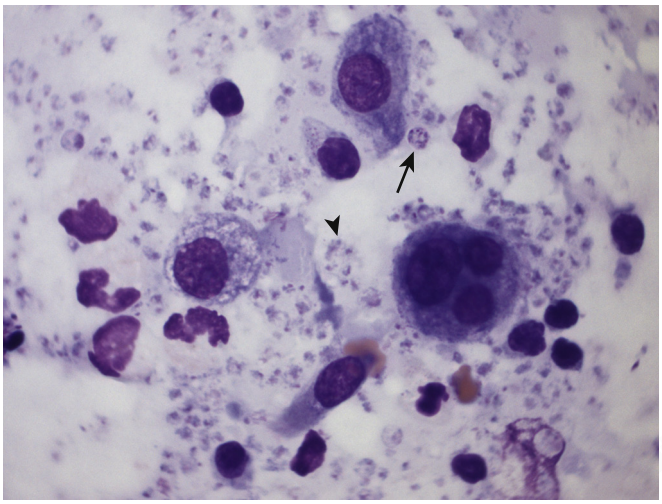

Fig. 89.6 Impression smear of lung tissue from a 1-year-old male neutered Cavalier King Charles spaniel with pneumocystosis. Large foamy and activated macrophages are present, as well as fewer neutrophils and lymphocytes. Abundant trophozoites are present and range in size from 1 to 2 μm *(arrowhead)*. Organisms can also be seen within a cyst *(arrow)*. Wright's stain.

of cysts and trophozoites will not be apparent (Fig. 89.6). Diff-Quik stain may be useful to rapidly identify organisms.[11,27]

Serologic Diagnosis

Serologic assays are available for detection of human infections with *P. jirovecii*; however, their diagnostic value is uncertain as many immunodeficient humans who develop pneumocystosis fail to produce antibody titers, and healthy individuals frequently have high titers. Increased antibody titers to *Pneumocystis* persist for long periods, offering a valuable index of infection in epidemiologic studies. However, they are of limited use for an immediate diagnosis.[28] Circulating *Pneumocystis* antigen has been detected in human serum by counter-immunoelectrophoresis and ELISA methods. However, antigenemia also is found in up to 15% of clinically normal humans who have been tested. Immunoperoxidase techniques have also been used to identify *Pneumocystis* spp. in impression smears and in formalin-fixed, paraffin-embedded lung sections.[11,29]

Culture

Pneumocystis spp. cannot be cultured in the laboratory from clinical specimens.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays have been effective in the detection of *Pneumocystis* spp. in bronchoalveolar lavage specimens from humans[30] and in clinical specimens from dogs.[7,25] Assays designed to detect *P. jirovecii* typically do not detect *P. canis*, and so specific assays have been developed for diagnosis of pneumocystosis in dogs.[25] The sensitivity of PCR on bronchoalveolar lavage fluids from infected humans has been greater than that of conventional staining, but has the potential to detect both colonization as well as clinical infection, so results must be interpreted in light of clinical findings.[25,30,31] In human patients, use of quantitation in real-time PCR has shown potential for differentiation between colonization and pneumonia.[32] The same appears to be true in dogs.[25] DNA typing of *Pneumocystis* isolates using multilocus sequence typing has been used for epidemiologic studies of isolates from humans and dogs.[25,33]

Immunologic Findings

The majority of the immunologic studies in dogs have been performed in the miniature dachshund,[19] and a Pomeranian.[17] Lymphocyte stimulation assay results using phytohemagglutinin and pokeweed mitogen show severe immunosuppression, especially when compared with controls, even though a normal lymphocyte count can be present. Low globulin levels, immunoglobulin deficiencies, and decreased lymphocyte function have been reported in the Cavalier King Charles spaniel.[20,34] The absence of immunoglobulins in the presence of pathologic changes is a significant finding, as affected dogs have chronic persistent infections, which should result in an immunoglobulin response. Immunoglobulin deficiencies are still present after *P. canis* and skin infections have resolved, which suggests that the deficiency is a primary defect. From the lymphocyte transformation studies and the immunoglobulin fraction quantification, it would appear as though there are both T- and B-cell abnormalities in affected dogs. Serum complement activity measured in affected miniature dachshunds has been normal. CD3 and CD79a lymphocyte staining of lymph nodes and spleen shows marked absence of B cells with the presence of T cells.

The immunologic abnormalities in the miniature dachshund and Pomeranian are similar to what has been described in humans affected with common variable immunodeficiency syndrome, also known as acquired or adult-onset hypogammaglobulinemia. It is a primary immunodeficiency disease characterized by little or no antibody production by the B cells, normal or decreased numbers of B cells, and abnormal T-cell function.[35] In the shih tzu with CD40L deficiency, serum IgG and IgA concentrations were at the low end of the reference range, and the serum IgM concentration was in the middle of the reference range.[18] In humans, CD40L mutations are associated

with hyper-IgM syndrome, where IgM concentrations are normal or increased, and IgG and IgA concentrations are low.

Pathologic Findings

Gross Pathological Findings

Pathologic findings in pneumocystosis are primarily confined to the lungs, although dissemination to regional lymph nodes, spleen, liver, bone marrow, and other organs has been reported. On gross examination, lungs are firm, consolidated, and pale brown or gray. The pulmonary and mediastinal lymph nodes are often enlarged. Despite the apparent lack of pleural inflammation, small amounts of fluid may be found in the pleural cavity. Cardiac enlargement, when present, has been right sided in all cases.

Histopathologic Findings

On histologic examination, alveolar spaces are filled with cohesive aggregates of amorphous, foamy, eosinophilic material that has a honeycomb-like pattern (Fig. 89.7). A few macrophages and detached alveolar lining cells also may be present, but polymorphonuclear leukocytes are generally absent. Special stains are needed to identify cyst forms (Fig. 89.8). Little or no phagocytosis of intact *Pneumocystis* organisms is present. However, nonviable organisms, such as those seen after treatment, are often phagocytosed, and macrophages may contain GMS-positive granular material that represents the residuum of cyst wall degradation. In some instances, alveolar septa are markedly thickened by dense accumulations of plasma cells, lymphocytes, and macrophages. The septa may be widened by fibrosis in chronic infections, especially after treatment. With GMS stain, cyst forms appear as black, spherical, ovoid, or crescent-shaped structures that range from 4 to 7 μm in diameter and have dot-like, argyrophilic, focal, cyst wall thickenings. Trophozoites in tissue sections and smears do not stain well with GMS or PAS and are best demonstrated with Giemsa or Gram stain. On ultrastructural examination, intact alveoli are filled with compact aggregates of trophozoite and cyst forms. Trophozoites commonly line alveoli. When compared with GMS, Gram stain and Giemsa have lower sensitivity, but molecular diagnosis has the highest sensitivity.

Appropriate histologic staining is essential to ensure detection of *Pneumocystis* spp. organisms. Various modifications of methenamine silver staining can be employed to stain the cyst walls brownish-black, but trophozoites will not be detected. The cysts of *Pneumocystis* spp. can be confused with small yeast-form fungi in GMS-stained tissue sections.

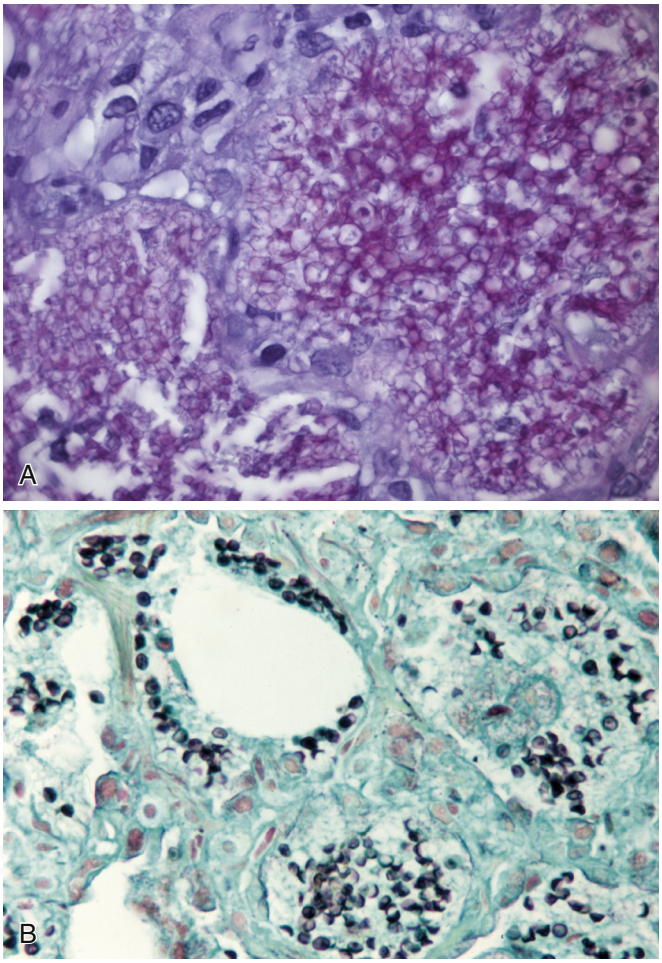

Fig. 89.7 Histopathology of the lung of an 18-month-old male neutered Cavalier King Charles spaniel with pneumocystosis. Foamy, honeycomb-like material fills the alveoli. (A) Periodic acid–Schiff stain. (B) Gomori's methenamine silver stain.

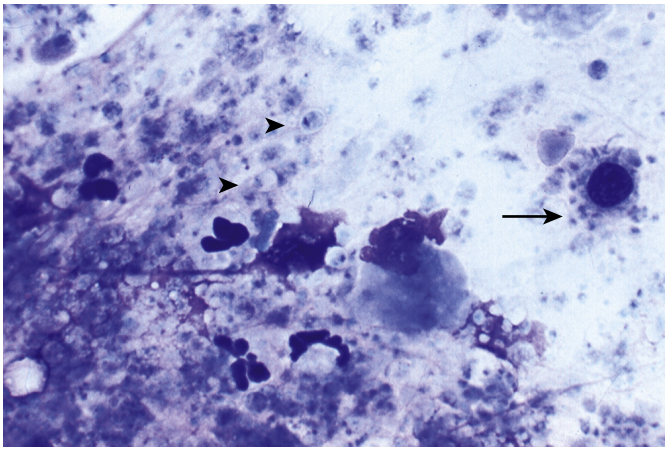

Fig. 89.8 Transtracheal aspirate cytology from a miniature dachshund showing *Pneumocystis* spp. organisms. Both free *(arrowheads)* and phagocytosed *(arrow)* organisms are evident (Diff-Quik stain, ×1000).

TREATMENT AND PROGNOSIS

Specific antimicrobial chemotherapy is most beneficial in cases in which the disease is suspected or diagnosed during its early stages (usually because of the affected dog breed). The two major chemotherapeutic agents that have successfully been used to treat pneumocystosis are TMS and pentamidine isethionate. Pentamidine isethionate is an aromatic diamidine that has been provided to reduce fatalities from the disease in humans.

TMS is more effective and less toxic than pentamidine for the treatment and prevention of PCP in immunodeficient humans. Most dogs in the literature have been treated with TMS,[11,18,23,36] and four were dachshunds that subsequently recovered.[23] The shih tzu with CD40L deficiency also recovered following treatment with TMS. A TMS dose of 15 mg/kg, every 8 hours, or 30 mg/kg, every 12 hours, for 3 weeks was used in these dogs; the longest reported follow-up in these studies was for 4 months, but the shi tzu was followed for 2 years. Folic acid supplementation should be given if adverse effects such as leukopenia and anemia are observed or if long-term therapy is required. In human infections, genotypic resistance to sulfonamides has been noted among some strains of *P. jirovecii*.[37]

Atovaquone is licensed for the treatment of humans with pneumocystosis;[38] it is not as effective against *Pneumocystis* as is pentamidine or TMS, but has lower toxicity. In humans, pentamidine and atovaquone have also been administered by aerosol and are well-tolerated alternatives for PCP prophylaxis.[39]

Combination therapy using clindamycin and primaquine also has been effective, but neither drug is effective alone. Further investigation on the effect of these treatments in naturally occurring disease is needed. Dapsone and trimethoprim or pyrimethamine, in combination, has been effective in experimental animals and clinical trials in immunosuppressed humans with pneumocystosis.[40,41] In experimentally infected animals, *P. carinii* is resistant to azole antifungal drugs and amphotericin B (because it lacks ergosterol in its cell wall).[42]

Supportive care is essential for any dog with *Pneumocystis* pneumonia because of disturbed alveolar gaseous exchange. Supplemental oxygen therapy may be needed, and ventilatory assistance may also be required. Immunosuppressive agents should be discontinued if possible. Antimicrobial chemotherapy of pulmonary pneumocystosis results in a decline in arterial oxygen related to the inflammatory reaction to dying organisms. Administration of anti-inflammatory doses of glucocorticoids has been shown to improve pulmonary function and survival in humans.[43–45] Medical management for pulmonary hypertension (e.g., sildenafil) may be required.

PUBLIC HEALTH ASPECTS

Pneumocystis organisms are ubiquitous in the environment. Humans and animals are exposed to the same environmental sources of *Pneumocystis*. Molecular and epidemiologic evidence suggests that spread may occur between humans because of localized outbreaks. Clinically affected humans and animals have the greatest concentrations of organisms in their airway secretions, and host immunocompetence is the most critical factor in determining whether illness develops. However, evidence suggests that the species of *Pneumocystis* that infects dogs is distinct from *P. jirovecii*, and so the risk of human infection with canine *Pneumocystis* strains may be negligible.[25]

CASE EXAMPLE

Signalment

"Tessa," a 1-year-old intact female miniature dachshund from the Johannesburg area, South Africa (see Fig. 89.3).

History

Tessa was evaluated for a history of tachypnea and weight loss that had been present over a 2-month period. The clinical signs had been nonresponsive to various treatments that had included multiple antibiotics, bronchodilators, mucolytics, multivitamins, and glucocorticoids. Additional history was that, since the age of 2 months, Tessa had had recurrent infections including otitis externa, hemorrhagic enteritis, tonsillitis, folliculitis, and pyogranulomatous dermatitis. These conditions had responded each time to supportive treatments.

Physical Examination

Body weight: 4.5 kg.

General: Quiet, alert, and responsive. Ambulatory on all four limbs. Rectal temperature = 101.8°F (38.8°C), HR = 138 beats/minute, RR = 129 breaths/minute, mucous membranes pink, CRT = 1 second.

Integument: Poor coat with focal alopecia on the head and back. No evidence of ectoparasites.

Eyes, ears, nose, and throat: No significant abnormalities noted. No evidence of ocular or nasal discharge.

Musculoskeletal: BCS 3/9 with symmetrical muscle wasting.

Cardiovascular: Strong femoral pulses. No murmurs or arrhythmias auscultated.

Respiratory: Increased respiratory rate with increased abdominal effort, tracheal palpation elicited a dry cough.

Abdomen: Normal abdominal palpation.

Rectal examination: No abnormalities detected. Normal feces in the rectum.

Lymph nodes: Normal mandibular, superficial cervical, and popliteal lymph nodes.

Laboratory Findings

CBC: HCT 54% (40%–55%), MCV 68 fL (65–75 fL), MCHC 35.7 g/dL (33–36 g/dL), WBC 34,600 cells/μL (6,000–15,000 cells/μL), neutrophils 23,200 cells/μL (3,000–11,000 cells/μL), band neutrophils 700 cells/μL (0–300 cells/μL), lymphocytes 5,500 cells/μL (1,000–4,800 cells/μL), monocytes 4,800 cells/μL (100–2,000 cells/μL), basophils 350 cells/μL (100 cells/μL), platelets 730,000 platelets/μL (200,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 147 mmol/L (145–154 mmol/L), potassium 4.6 mmol/L (3.6–5.3 mmol/L), phosphorus 4.8 mg/dL (3.0–6.2 mg/dL), calcium 10.9 mg/dL (9.7–11.5 mg/dL), BUN 17 mg/dL (5–21 mg/dL), creatinine 0.5 mg/dL (0.3–1.2 mg/dL), glucose 132 mg/dL (64–123 mg/dL), total protein 5.1 g/dL (5.3–7.5 g/dL), albumin 3.5 g/dL (2.3–3.5 g/dL), globulin 1.6 g/dL (2–3.7 g/dL), α-globulins 0.8 (0.8–1.6 g/dL), β-globulins 0.6 (0.7–1.3 g/dL), γ-globulins 0.3 (0.4–1.1 g/dL), ALT 65 U/L (10–60 U/L), ALP 210 U/L (100–250 U/L), cholesterol 196 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.045; pH 6.0, negative for protein, bilirubin, blood, and glucose. Inactive sediment.

Imaging Findings

On thoracic radiographs, the cardiovascular structures appeared within normal limits. A diffuse interstitial pulmonary pattern was present, similar to that shown in Fig. 89.4.

Cytology Findings

Transtracheal wash cytology demonstrated reactive alveolar macrophages with phagocytic vacuolization, large numbers of neutrophils, and many free and phagocytosed *Pneumocystis* organisms (see Fig. 89.8).

Aerobic Bacterial Culture

Culture of the transtracheal wash fluid yielded no growth after 48 hours' incubation.

Fecal Examination

Fecal flotation: Negative for parasites.

Diagnosis

Pneumocystis spp. pneumonia.

Treatment

Treatment instituted was a potentiated sulfonamide at 15 mg/kg, PO, q8h for 3 weeks, which resulted in a complete recovery.

Comments

This dog was diagnosed with *Pneumocystis* pneumonia as a result of a primary immune deficiency disease, most likely common variable immunodeficiency syndrome. The latter would also account for the chronic skin infections and gastroenteritis. CD3 and CD79a cell staining of a peripheral lymph node biopsy showed a marked absence of B cells with the presence of T cells.

Protothecosis and Chlorellosis

Jane E. Sykes

KEY POINTS

- First Described: *Prototheca* spp. was first isolated from tree slime in the 1880s. Naturally occurring protothecosis was not described until 1952, in cattle (mastitis). Canine disease was reported in 1969, 5 years after the first description of human protothecosis.[1]
- Cause: *Prototheca* spp. (belonging to the lower algae, *Chlorphyceae*).
- Affected Hosts: Dogs, cats, cattle, humans, other domestic and wild animal species.
- Geographic Distribution: Worldwide except Antarctica, but especially in warm, humid climates and where there is organic matter with a high water content.
- Mode of Transmission: Cutaneous inoculation of organisms into tissues, or possibly systemic invasion in the face of immunosuppression by organisms that have been ingested or colonize the intestinal tract.
- Major Clinical Signs: Cutaneous nodules or masses or systemic illness with weight loss, blindness due to ocular involvement, polyuria and polydipsia, hematochezia, vomiting, lameness, neurologic signs.
- Differential Diagnoses: Chlorellosis (a rare algal disease), a variety of fungal diseases (e.g., histoplasmosis, cryptococcosis, sporotrichosis), intestinal pythiosis, neoplasia (especially round cell neoplasia), toxoplasmosis, neosporosis, granulomatous colitis of boxer dogs, inflammatory bowel disease.
- Human Health Significance: Human infections occur as a result of exposure to organisms in the environment, and are often associated with underlying immune compromise.

PROTOTHECOSIS

ETIOLOGY AND EPIDEMIOLOGY

Protothecosis is an uncommon cutaneous or systemic disease caused by *Prototheca* species, which are unicellular algae. *Prototheca* spp. lack chlorophyll, and as a result they are dependent on a saprophytic lifestyle. Although ubiquitous in nature, they are especially prevalent in warm, humid climates (e.g., southern and southeastern USA, northeastern Australia, southern continental Europe, Japan) in aqueous environments where decaying organic matter is present. They have been isolated from tree slime, sewage, fresh and saltwater sources, fish tanks, soil, animal excrement, and foodstuffs. Routine water chlorination may not inactivate the organisms.[2] *Prototheca* spp. can also colonize the skin, GI, and respiratory tracts of humans.[3]

The algae are round to oval, 5 to 30 μm in diameter, have a thick cell wall, and reproduce asexually by endosporulation (internal division), which results in a sporangium that contains up to multiple sporangiospores. Rupture of the sporangium releases sporangia into tissues, and the cycle continues (Fig. 90.1). Although the classification of *Prototheca* species is still in flux, 15 species have recently been proposed based on analysis of partial *cytb* gene sequences (Table 90.1).[4] *Prototheca bovis*, *Prototheca wickerhamii*, *Prototheca cutis,* and *Prototheca miyajii* have been associated with human disease; over 200 human cases have been described in the literature and most human infections are characterized by localized cutaneous lesions. Disease in dogs has been associated with infections by *P. wickerhamii*, *Prototheca zopfii*, *Prototheca ciferrii*, and *P. bovis*,[4,5] although the *P. zopfii* cases may have been *P. bovis*. *Prototheca zopfii* genotypes 1 and 2 have been reclassified as *P. ciferrii* and *P. bovis*, respectively.

Prototheca ciferrii is weakly pathogenic and has been isolated from a minority of cases of protothecal mastitis in dairy cows.[6,7] In contrast, *P. bovis* is the most virulent species; it causes the vast majority of bovine mastitis cases worldwide and almost all disseminated cases of protothecosis in dogs.[6] *Protheca wickerhamii* has to date been isolated from all except one cat, some dogs, and almost all human patients, and is often associated with cutaneous disease (see Table 90.1).[5,8] Disseminated disease caused by *P. wickerhamii* infection in dogs may follow a less aggressive clinical course than that caused by *P. bovis*.[9]

Protothecosis is an uncommon and sporadic disease of dogs, with approximately 70 cases reported in the literature, and it is rarely reported in cats (less than 10 cases reported worldwide). In dogs, protothecosis is usually a serious disseminated disease but occasionally localized cutaneous disease occurs. Most affected dogs do not have a history of immunosuppressive drug therapy or illness. Boxer dogs and collies may be predisposed,[9,10] possibly secondary to an underlying genetic immunodeficiency, although a variety of other small and large breed dogs also can be affected.[5] Occasionally it occurs in dogs in conjunction with infection by other opportunistic pathogens such as *Neospora*,[11] which supports the likelihood that underlying immune deficiency is present. One report from Germany described disseminated disease in a Rhodesian ridgeback,[12] a breed predisposed to disseminated aspergillosis[13] and possibly neosporosis. One dog seen at the author's hospital was euthanized 4 years after renal transplantation and cyclosporine treatment because of disseminated protothecosis, and another dog with a lymphocutaneous *P. wickerhamii* infection had a history of treatment with chemotherapy for lymphoma.[11] The median age of affected dogs in one series of 17 dogs was 4 years (range, 18 months to 11 years), and approximately 70% of the affected dogs were female.[9]

In cats, protothecosis is manifested as single or multiple nodular skin lesions; disseminated disease has not been reported. As noted, almost all cats are infected with *P. wickerhamii*; there is one report of

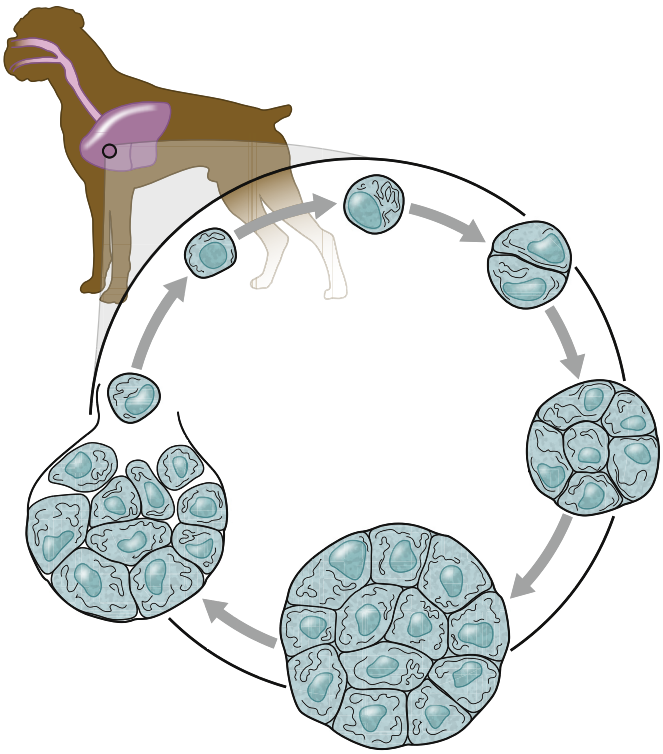

Fig. 90.1 Life cycle of *Prototheca*. The organism multiplies asexually by endosporulation, which results in a sporangium containing multiple sporangiospores. The sporangium ruptures, releasing spores into tissues, and the life cycle continues. (Redrawn from Klintworth GK, Fetter BF, Nielsen HS. Protothecosis, an algal infection: report of a case in man. *J Med Microbiol*. 1968;1:211–216.)

TABLE 90.1 Major Species of *Prototheca* and Their Clinical Relevance

Species	Host Species Infected	Clinical Manifestations
P. ciferrii (previously *P. zopfii* genotype 1)	Cattle, dogs	Mastitis (low pathogenicity), dogs (uncommon, disseminated infections or disseminated cutaneous infections)
P. bovis (previously *P. zopfii* genotype 2)	Dogs, humans, cattle, horses	Mastitis (cattle), disseminated infections (dogs)
P. wickerhamii	Dogs, cats, goats	Cutaneous and mucocutaneous disease
P. blaschkeae	Cattle, humans	Mastitis (cattle), cutaneous disease (humans)
P. cutis	Humans	Cutaneous disease
P. miyajii	Humans	Disseminated disease
P. zopfii[a]	Humans, dogs, cattle	Mastitis (cattle), cutaneous disease (humans), disseminated disease (dogs)
P. stagnora, P. ulmea, P. tumulicola, P. cerasi, P. cookei, P. pringsheimii, P. xanthoriae, P. paracutis	Nonpathogenic	NA

[a]Currently may refer to previously reported infections where genotyping was not performed, given that genotypes 1 and 2 were classified as *P. ciferrii* and *P. bovis*, respectively.
NA, not applicable.

a cat infected with *P. zopfii* genotype 2 (*P. bovis*), which had nodular lesions on the bridge of the nose and within the right nostril.[14] Affected cats are typically FIV and FeLV negative, otherwise in good health and have ranged in age from 3 to 16 years.[15-20] There is one report of an FIV-infected cat from Australia that developed multiple skin lesions; two of the lesions were associated with *P. wickerhamii* infection and the remaining were Bowenoid in situ carcinomas that contained *Felis catus* papillomavirus 2 sequences.[21]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The pathogenesis of protothecosis is not fully understood. Infection may occur secondary to cutaneous inoculation of organisms, which may be followed by development of localized cutaneous lesions or dissemination through lymphatic or hematogenous spread. It is also possible that systemic invasion occurs through organisms that are

ingested or colonize the GI tract. *Prototheca* spp. were not detected using PCR in feces or rectal scrapings of 200 dogs from Italy, including stray dogs that roamed on dairy cattle farms (including farms where *Prototheca* mastitis had been diagnosed), and so it was suggested that invasion by commensals was an unlikely mode of infection.[5] An incubation period of 10 days to several weeks has been suggested for human protothecosis based on recollection of penetrating injuries before onset of disease.[2]

In dogs, *Prototheca* typically disseminates to a variety of tissues, but especially the colon, eyes, brain and meninges, kidneys, and long bones. This results in clinical signs of inappetence and weight loss; acute or chronic large bowel diarrhea (often accompanied by hematochezia and tenesmus); blindness; neurologic signs such as obtundation, seizures, or ataxia; polyuria and polydipsia; and sometimes lameness due to osteomyelitis.[9,20,22-24] Discospondylitis was reported in one dog with disseminated infection.[25] Deafness is often reported in association with disseminated protothecosis, and may occur as a result of CNS or inner ear involvement.[20,24,26] Ocular lesions include granulomatous chorioretinitis, uveitis, and panophthalmitis. Other affected organs include the liver, skeletal muscle, thyroid gland, lymph nodes, spleen, pancreas, stomach, small intestine, omentum, myocardium, aorta, spinal cord, and/or lungs.[24,26-28] Involvement of these organs may lead to other signs such as vomiting, small bowel diarrhea, and/or melena. Sudden death has also been reported, possibly secondary to myocardial involvement.[9,29,30] Cutaneous lesions in dogs with *P. wickerhamii* infection may be a manifestation of systemic infection rather than local inoculation; one dog with ulcerated lesions of the nares also had evidence of infection in multiple peripheral lymph nodes.[31]

Physical Examination Findings

Cutaneous lesions in dogs are alopecic, nodular, and may ulcerate. They often involve the footpads or distal limbs and associated draining lymph nodes, but involvement of other sites such as the trunk and planum nasale can also occur (Fig. 90.2A).[31] In cats, single or multiple firm and sometimes ulcerated cutaneous nodules may be present. Lesions may be located on the head, footpads, and distal limbs and tail base[15-17,21] and can resemble those caused by *Cryptococcus* or *Sporothrix* spp. (Fig. 90.2B).

Dogs with disseminated disease may be obtunded, dehydrated, and can have a thin body condition. Some dogs are febrile, but rectal temperature may also be normal. Ocular involvement may be manifested by blindness or evidence of conjunctivitis, hyphema, uveitis, cataract formation, panophthalmitis, or granulomatous chorioretinitis, often with retinal detachment.[32] Arrhythmias with pulse deficits may be present in dogs with protothecal myocarditis.[11] Neurologic signs that may be detected on physical or neurologic examination include obtundation, blindness, deafness, ataxia, deficits of conscious proprioception, circling, head tilt, nystagmus, strabismus, and abnormalities of cranial nerve function such as absent or decreased facial sensation, palpebral, menace, or gag reflexes.[9,22,33-36] Dried fecal material or blood may be present around the anus and rectal examination may reveal hematochezia, increased fecal mucus, or melena.

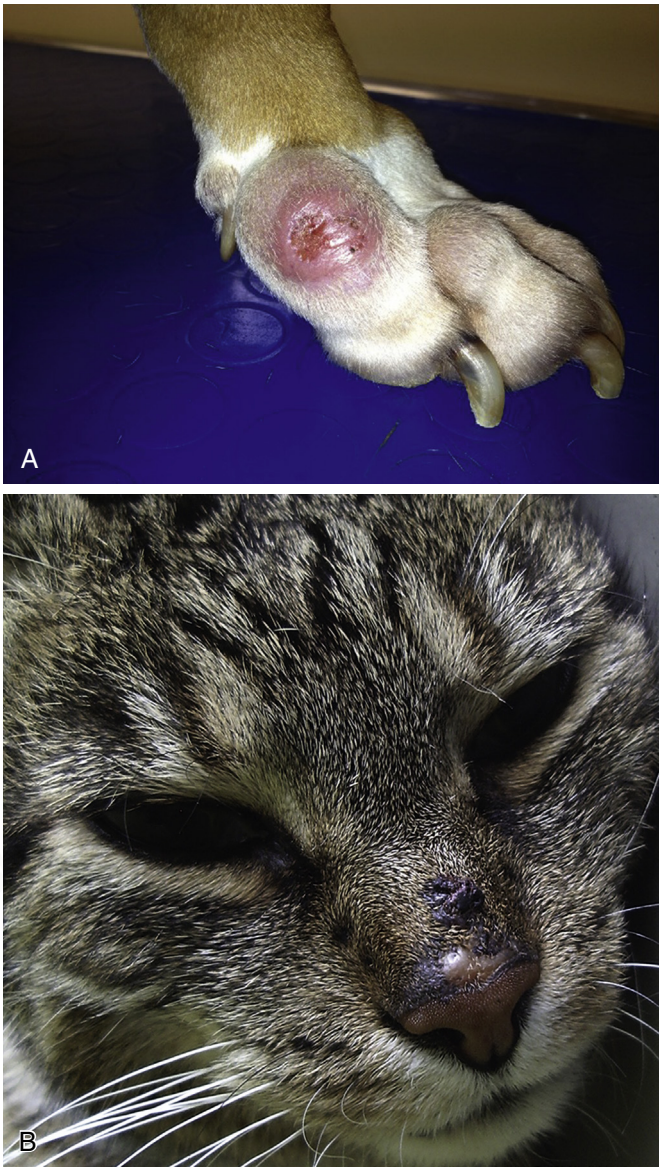

Fig. 90.2 Cutaneous manifestations of protothecosis. (A) *Prototheca wickerhamii* infection in a 6-year-old female boxer dog showing an ulcerated nodular lesion on the distal limb. The dog's footpads were also affected. (B) Nodular crusted lesions on the bridge of a 14-year-old female spayed domestic shorthair cat associated with a *Prototheca bovis* (previously *Prototheca zopfii* genotype 2) infection. DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

The CBC in dogs with disseminated protothecosis is often normal. Occasionally it may show nonregenerative anemia and/or leukocytosis due to neutrophilia and sometimes monocytosis.[23,24,27] Mild bandemia and/or eosinophilia may be present in some dogs. The serum biochemistry panel may also be normal or reveal a mild hypoalbuminemia and hyperglobulinemia due to a polyclonal gammopathy. Mild to moderate azotemia may be evident in dogs with renal involvement.[23,27] More severe hypoalbuminemia and hypocholesterolemia may occur with diffuse small intestinal involvement.[9]

Urinalysis

The urinalysis may be unremarkable or show isosthenuria due to renal involvement. Other findings that may be present in dogs with urinary

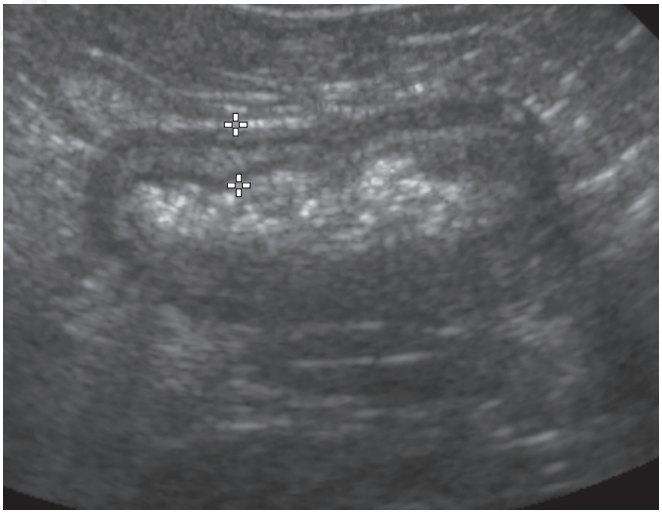

Fig. 90.3 Thickening and irregularity of the submucosal layer of the descending colon in a 2-year-old English springer spaniel with disseminated protothecosis. (Image courtesy University of California-Davis VMTH Diagnostic Imaging Service.)

tract involvement include hematuria, pyuria, proteinuria, and the presence of *Prototheca* organisms in the sediment.[23] Urinalysis and urine culture should be performed in all dogs suspected to have protothecosis, because more than half of affected dogs shed algae into the urine.

CSF Cytology

CSF analysis in dogs with CNS protothecosis may be normal or reveal markedly increased total nucleated cell count (sometimes > 1,000 cells/μL) and increased CSF protein concentration (often > 500 mg/dL).[27,33,34] Eosinophilic pleocytosis has been described in some dogs,[33,36] but eosinophils are not always present.[34] *Prototheca* algae may also be found in the CSF.[33,34]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with disseminated protothecosis are usually unremarkable.[23,27,28,30] Radiographs of affected long bones may reveal periosteal proliferative and/or osteolytic lesions due to osteomyelitis.[9] Bony lysis of lumbar vertebral endplates was described in one dog with *Prototheca* discospondylitis, with infection in this location confirmed at necropsy.[25]

Sonographic Findings

Findings described on abdominal ultrasound examination in dogs with disseminated protothecosis include hyperechogenicity of the renal cortices,[23] a thickened colonic wall with loss of normal bowel wall layering,[9] and abdominal lymphadenomegaly (Fig. 90.3). Some dogs have no abdominal sonographic abnormalities despite the presence of disseminated disease with colonic and renal involvement.[11]

Other Imaging

Colonoscopy in dogs with signs of large bowel diarrhea may reveal a hyperemic, friable, thickened, irregular, and ulcerated mucosa.[9] MRI of the brain of one dog with CNS involvement revealed mild to moderate ventriculomegaly, mild protrusion of the cerebellar vermis through the foramen magnum, syringomyelia, meningeal contrast enhancement, and a focus of increased signal intensity in the brain on T2-weighted and FLAIR sequences.[34] As it enlarged, the focus developed contrast enhancement and caused deformation of a lateral ventricle.

Microbiologic Tests

Cytologic Examination

Prototheca organisms may be seen using cytologic examination of rectal scrapings; fine-needle aspirates of lymph nodes, bone, or skin lesions; CSF, vitreal, or aqueous humor; and urine sediment. The organisms are spheroid, ovoid, bean-shaped, or elliptical and range in size from 1.5 to 30 μm in diameter (*P. bovis*) or up to 10 μm in diameter (*P. wickerhamii*).[31] They have a thick, hyaline cell wall that does not take up stain, and a basophilic, granular cytoplasm. Several daughter cells (usually < 10) may be seen inside the cell (Fig. 90.4). In the case of *P. wickerhamii* the endospores are arranged symmetrically like a daisy or soccer ball, whereas the endospores of *P. bovis* are distributed randomly.[2] The algae may be mistaken for fungi such as *Blastomyces, Coccidioides*, or *Cryptococcus*. Because large numbers of organisms are typically present, the sensitivity of cytological examination for diagnosis of algal infection is high. However, failure to find organisms does not rule out protothecosis.

Culture

Prototheca species can be readily cultured in the microbiology laboratory on standard media (such as blood agar and Sabouraud dextrose agar), and yeast-like colonies are usually visible within 7 days. Suitable specimens for culture include aspirates or biopsies of affected tissue and body fluids such as urine, CSF, and vitreous or aqueous humor. *Prototheca* was also cultured from the blood of a dog with disseminated disease.[30] Biochemical testing of isolates excludes other possible causes such as the green alga *Chlorella*, a very rare cause of disseminated disease in dogs that can closely resemble *Prototheca* in its microscopic appearance.[2,37] Differentiation of *Prototheca* species requires PCR and ribosomal RNA gene sequencing. MALDI-TOF MS has also been used for rapid identification of the species and genotype level.[6,12,38]

Antifungal susceptibility testing has been performed for *Prototheca* but has not been standardized, and the clinical relevance of the results is not clear.[2]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays have been developed for detection and differentiation of *Prototheca* species,[39] but these are not available on a commercial basis for diagnosis of protothecosis in animals (Table 90.2).

PATHOLOGIC FINDINGS

Gross pathologic findings in dogs with disseminated infections include enlarged lymph nodes and gray, tan, or white nodular lesions or streaks in affected organs.[20,24,27,36] The colonic wall may be thickened and contain bloody fluid. Malacic foci may be present in the brain or the brain may appear normal grossly, even when meningoencephalitis is present.[11,35] Histopathologic examination of affected tissues typically reveals large numbers of sporulating and nonsporulating algal organisms (see Cytological Examination) accompanied by a mixed inflammatory response and foci of necrosis (Fig. 90.5). In some tissues the inflammatory response may be minimal to absent.[24,27] Organisms may be seen free and within macrophages. The cell wall stains well with Gomori's methenamine silver and PAS stain, but in contrast to *Chlorella*, cytoplasmic granules of *Prototheca* are PAS-negative. Cutaneous lesions in cats have been associated with a granulomatous inflammatory response with multinucleated giant cells and in some cases, necrosis and neutrophilic inflammation.[16,18] Because one cat had multiple skin lesions, some of which were Bowenoid in situ carcinomas and others associated with *Prototheca* spp. infection,[21] biopsy of multiple lesions is recommended.

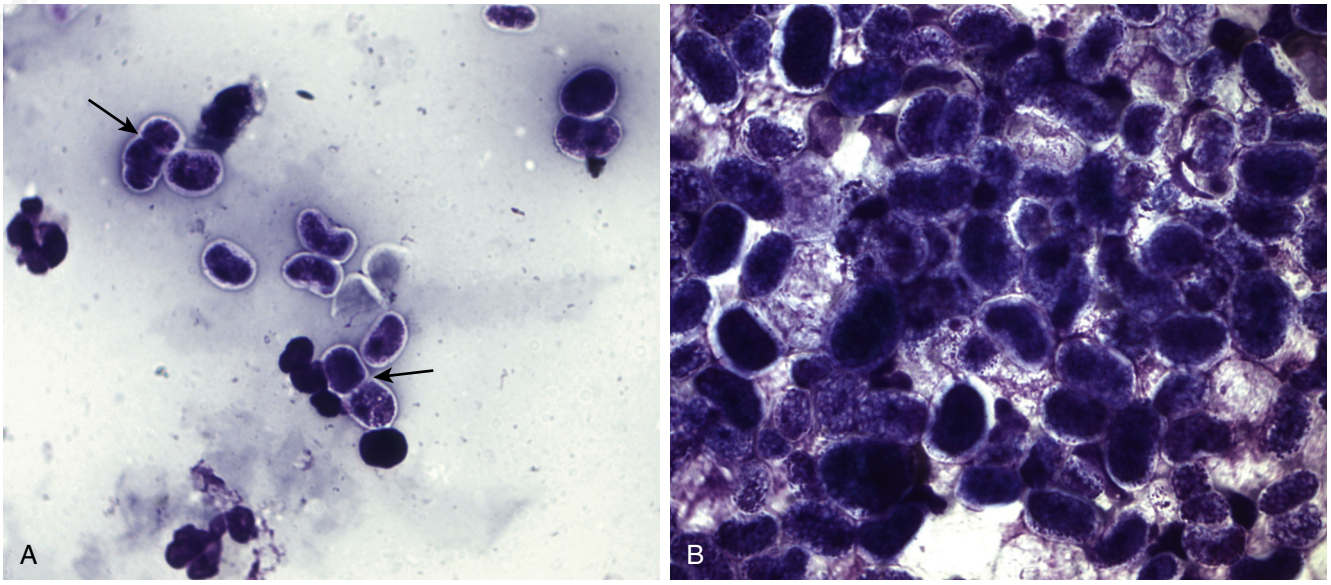

Fig. 90.4 (A) Cytology of a subretinal aspirate from an 8-year-old intact male mixed-breed dog with panophthalmitis due to *Prototheca* spp. infection. Moderate numbers of oval to bean-shaped organisms are present in a proteinaceous background that contained variably degenerate and ruptured neutrophils. The organisms have a thin clear capsule with deep purple cytoplasmic granulation. Sometimes endosporulation was evident *(arrows)*. Wright stain, 1000× oil magnification. (B) Cytology of a bone aspirate from a 2-year-old female mixed-breed dog that developed acute vision loss. Physical examination revealed bilateral retinal detachment and a nonpainful swelling of the right distal medial humerus. Abundant numbers of *Prototheca* algae are present. (Courtesy Dr. Emily Pieczarka.)

TABLE 90.2 Diagnostic Assays Available for Protothecosis

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, urine sediment, vitreous or aqueous humor, CSF	*Prototheca* algae	Usually large numbers of organisms are present, so sensitivity is high, but false negatives can occur (such as when urine sediment or fine-needle aspirates are examined). Organisms may be confused with other fungi or *Chlorella* species, so confirmation of the diagnosis requires culture.
Culture	Urine, blood, CSF, vitreous or aqueous humor, aspirates or biopsies of affected tissues	*Prototheca* species	*Prototheca* spp. grow rapidly (usually within 3 days) on routine media such as blood agar and Sabouraud dextrose agar. Species identification can be verified using nucleic acid–based methods and MALDI-TOF MS.
Histopathology	Skin or colonic biopsies, enucleated eyes, tissues collected at necropsy	*Prototheca* algae	Usually large numbers of organisms are present, so sensitivity is high. Organisms are highlighted with PAS or silver stains. Organisms may be confused with other fungi or *Chlorella* species, so confirmation of protothecosis requires culture. Grossly, tissues affected by *Chlorella* are green, and *Chlorella* infections in dogs are extremely rare.

TREATMENT AND PROGNOSIS

Where possible, surgical excision may be curative for localized cutaneous protothecosis.[16] However, even when lesions are solitary, cutaneous lesions may be a manifestation of disseminated disease, so medical therapy should also be used. Medical treatment of protothecosis is challenging. In human patients, treatment is generally with amphotericin B, which in some cases has resulted in complete cure. Addition of a tetracycline has also been associated with positive outcomes.[2,40] Azole antifungal drugs have also been tried but outcomes with azole antifungals alone are often poor, although clinical responses occur in some dogs with itraconazole alone.[11] In one human patient, a combination of amikacin and tetracycline led to cure.[41] Treatment of dogs with disseminated infections with amphotericin B has led to remission in some cases, but relapse occurs when the drug is discontinued, or dogs may fail to respond to treatment and ultimately die or be euthanized as a result of the disease.[9,30] One dog with protothecal meningoencephalitis appeared to improve clinically after treatment with systemic itraconazole and intrathecal amphotericin B (0.5 g q48h for five treatments), but was euthanized 4 weeks later due to progressive disease.[34]

Other treatments that may be required for protothecosis include IV fluid therapy, antiemetics, topical prednisolone acetate ophthalmic drops for uveitis, and ocular enucleation to control pain and/or remove

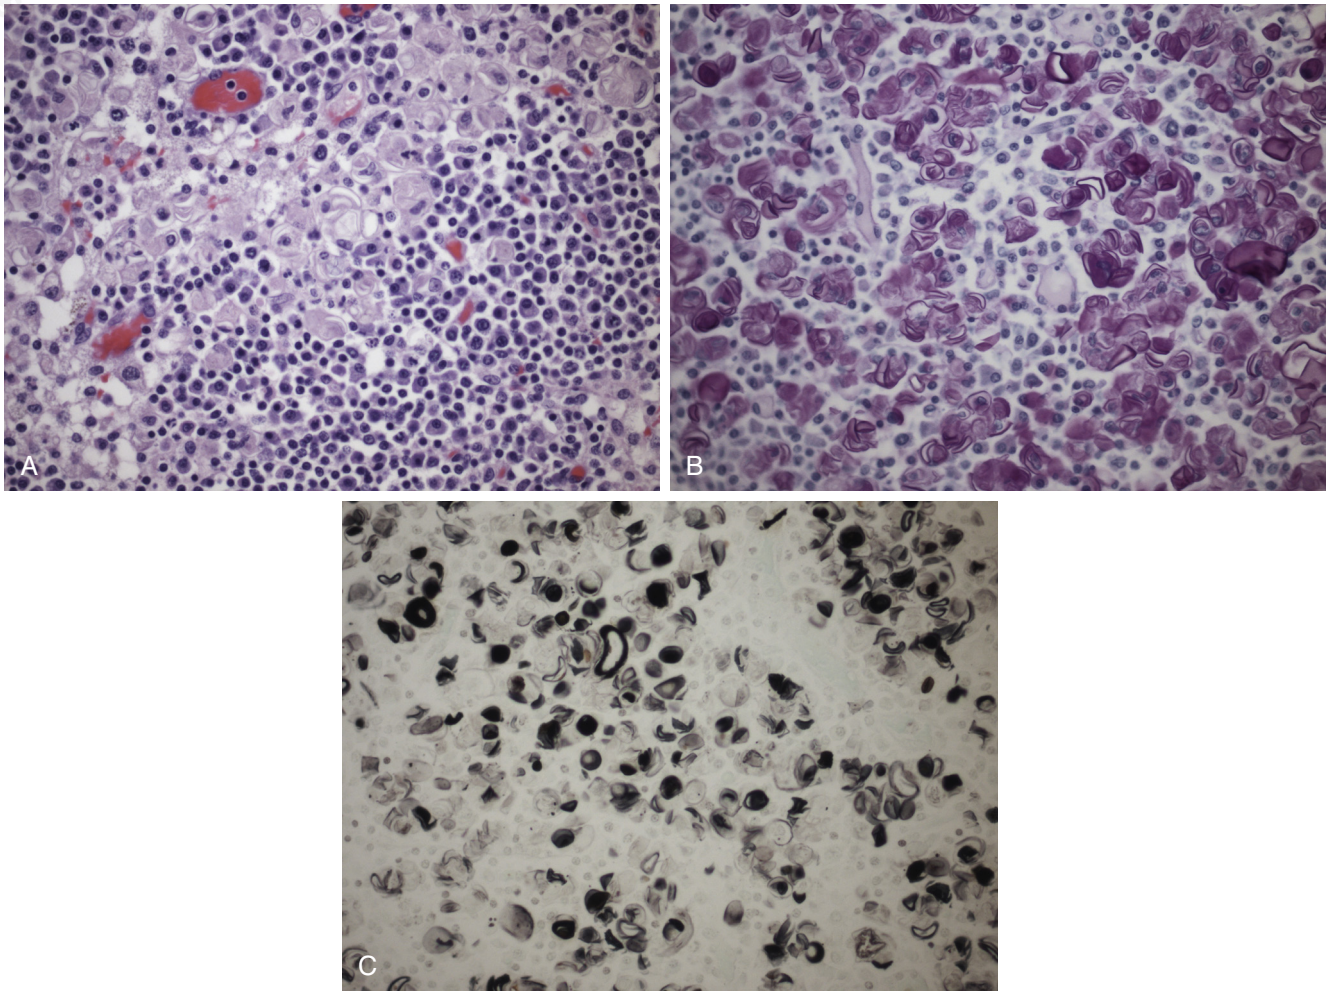

Fig. 90.5 Histopathology of the renal lymph node of a 6-year-old spayed female shih tzu with protothecosis that was being treated with cyclosporine after renal transplantation. Numerous *Prototheca* organisms are present. The organisms range in diameter from 5 to 15 μm and have several morphologic forms. Sporulating forms are up to 15 μm in diameter and contain two to four wedge-shaped endospores (daughter cells). Many of the organisms present as clear, refractile, oval to polyhedral bodies composed of a thick wall and devoid of cytoplasm and nuclei. (A) Hematoxylin and eosin stain. (B) PAS stain. (C) Gomori's methenamine silver.

a focus of infection that fails to respond to chemotherapy (see Case Example). Other treatments such as metronidazole, sulfasalazine, or dietary manipulation may help to control signs of protothecal colitis.

PUBLIC HEALTH APSECTS

Protothecosis is an uncommon disease of humans and most often caused by *P. wickerhamii*. Infection is acquired from environmental sources, and direct transmission from other animals or humans does not appear to be important. Mortality is low (< 5%) and two-thirds of infections are chronic infections that are localized to the skin.[2] Joint infections and tendonitis have been described after surgical or accidental wounds; some have been traced back to cleaning an aquarium.[42] Disseminated infections and a syndrome called olecranon bursitis (which follows elbow trauma) account for the remaining third of cases. Underlying local or systemic immune defects can be identified in many patients, and topical, local, or systemic glucocorticoid treatment is the most frequently identified risk factor. Other immunosuppressive disorders that may predispose humans to protothecosis include diabetes mellitus and malignancy. Severe disseminated disease has been described in bone marrow and kidney transplant recipients,[43,44] those with longstanding indwelling catheters or endotracheal tubes, and rarely in AIDS patients.[42,45] However, some severe infections have been reported in immunocompetent patients.[40]

CHLORELLOSIS

Chlorella spp. (order Chlorellales, family Chlorellaceae) are green (chlorophyll-containing) algae with an apparently identical ecologic niche and asexual reproductive cycle similar to *Prototheca* spp. The chlorophyll is contained within a single, large chloroplast. The precise relationship between these two genera is unclear, but similarities in morphology, life cycle, and environmental distribution suggest that *Prototheca* spp. may be achlorophyllous mutants of *Chlorella* spp. At necropsy, grossly affected tissues are bright green.[46] However, because chlorophyll is dissolved during tissue processing, formalin-fixed *Chlorella* spp. and *Prototheca* spp. are both colorless.[47] Therefore, *Prototheca* and *Chlorella* cannot be differentiated in H&E-stained tissues using standard light microscopy. Alternatively, when viewed under polarized light, large, irregular,

birefringent starch granules are present within the cytoplasm of all *Chlorella* spp. endospores, whereas in *Prototheca* spp. these granules, if present, are smaller, less distinct, and present in only a minority of cells. These starch granules stain uniformly with PAS or Gomori's methenamine silver stains. Examination of ultrastructural features via transmission electron microscopy is likely the most reliable method for differentiating *Chlorella* spp. from *Prototheca* spp., because the large cytoplasmic chloroplast in the former organism is clearly visible.[46,47]

Disseminated chlorellosis has only been reported in one dog in 2009.[37] In that dog, which was from Michigan, USA, a granulomatous lingual mass with intralesional algal organisms was initially diagnosed as localized protothecosis. Over the course of 6 months of evaluation, the dog developed an extradural lumbar mass that resulted in caudal lower motor neuron signs, weight loss, and cough despite fluconazole treatment. Disseminated algal infection was confirmed on necropsy, including an exudative greenish mass infiltrating the epaxial musculature and contiguous with the adjacent lumbar extradural and intradural surfaces. Light and electron microscopy confirmed chlorellosis using the criteria described previously.

No information exists as to whether treatment options for chlorellosis differ from those previously discussed for protothecosis. A single case of *Chlorella* spp. infection was reported in 1983 in a 30-year-old woman from Nebraska, USA.[48] In that patient, localized cutaneous infection of the foot developed after exposure of a surgical wound to river water while canoeing. The infection was successfully managed with debridement and open-wound management until granulation occurred.

CASE EXAMPLE

Signalment

"Merlot," a 3-year-old female spayed Siberian husky dog from San Francisco, CA.

History

Merlot was evaluated at the University of California, Davis VMTH for a 1-month history of hemorrhagic diarrhea, decreased appetite, and weight loss. Initially the diarrhea contained fresh blood and mucus but more recently had contained only blood. The diarrhea occurred frequently and in small quantities, but hematochezia was not observed. The owner reported that Merlot had lost approximately 5 kg over the last month, and had increased thirst and urination. There had been no history of vomiting and Merlot's activity level was normal. Her diet consisted of a commercial dry dog food.

At a local veterinary clinic, multiple fecal flotations had been negative, and Merlot had been treated with metronidazole, aminopentamide, bismuth subsalicylate, enrofloxacin, loperamide, tetracycline, metoclopramide, and a highly digestible diet without clinical response. A barium series had been recently performed and findings were consistent with gastroenteritis.

Merlot moved to San Francisco from Massachusetts 4 months before the clinical signs began. On the way over the owner stopped in Texas, where Merlot became lost in a field for 30 minutes. The owner reported that Merlot was taken to a dog park in San Francisco several times a week. No other previous history of illness existed.

Physical Examination

Body weight: 18.2 kg

General: Bright, alert, responsive, and hydrated. T = 102.3°F (39.1°C), pulse = 80 beats/min, panting, mucous membranes pink, capillary refill time 1 s.

Eyes, ears, nose, and throat: Dried barium present on the lips. No other clinically significant findings. Fundoscopic examination revealed a region of retinal separation in the left ocular fundus that was adjacent to, dorsomedial to, and approximately the size of the optic disc. The lesion appeared to contain yellowish fluid.

Integument: Full haircoat.

Musculoskeletal: Thin but well-muscled.

Cardiorespiratory: No clinically significant findings.

Gastrointestinal/genitourinary: No masses palpated in the abdomen. Vocalized and appeared painful on caudal abdominal palpation. Frank blood was present on the glove after rectal examination.

Peripheral lymph nodes: No clinically significant findings.

Laboratory Findings

CBC: HCT 48.6% (40–55%), MCV 70.9 fL (65–75 fL), MCHC 34.6 g/dL (33–36 g/dL), WBC 12,100 cells/μL (6,000–13,000 cells/μL), neutrophils 9,438 cells/μL (3,000–10,500 cells/μL), lymphocytes 2,057 cells/μL (1,000–4,000 cells/μL), monocytes 363 cells/μL (150–1,200 cells/μL), eosinophils 242 cells/μL (0–1,500 cells/μL), platelets 259,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: sodium 150 mmol/L (145–154 mmol/L), potassium 4.3 mmol/L (3.6–5.3 mmol/L), chloride 114 mmol/L (108–118 mmol/L), bicarbonate 28 mmol/L (16–26 mmol/L), phosphorus 4.2 mg/dL (3.0–6.2 mg/dL), calcium 9.8 mg/dL (9.7–11.5 mg/dl), BUN 21 mg/dL (5–21 mg/dL), creatinine 1.2 mg/dL (0.3–1.2 mg/dL), glucose 99 mg/dL (64–123 mg/dL), total protein 6.4 g/dL (5.4–7.6 g/dL), albumin 2.9 g/dL (3.0–4.4 g/dL), globulin 3.5 g/dL (1.8–3.9 g/dL), ALT 61 U/L (19–67 U/L), AST 42 U/L (19–42 U/L), ALP 126 U/L (21–170 U/L), cholesterol 145 mg/dL (135–361 mg/dL), total bilirubin 0 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.005; pH 6.0; no protein (SSA), bilirubin, hemoprotein, or glucose; 0–1 WBC/HPF, rare RBC/HPF, rare transitional epithelial cells; no crystals, casts, or bacteria. Moderate numbers of encapsulated organisms were present that measured 10 × 17 μm.

Imaging Findings

Abdominal ultrasound examination: No abnormalities were identified.

Microbiologic Testing

Centrifugal zinc sulfate fecal flotation: Negative, but yeast-like bodies observed.

Giardia and *Cryptosporidium* fluorescent antibody testing (fecal specimen): Negative

Cytologic examination of rectal scrapings: Moderate numbers of neutrophils, small numbers of gram-positive coccobacilli, and small numbers of what appeared to be algal organisms were present.

Aerobic bacterial urine culture: Small numbers of *Prototheca* spp.

Algal susceptibility testing: MICs for amphotericin B, fluconazole, and itraconazole were 0.5 μg/mL, > 64 μg/mL, and 1 μg/mL, respectively.

Histopathology (rectal biopsy obtained by proctoscopy): Erosive and hemorrhagic colitis, eosinophilic and lymphoplasmacytic, moderate, with marked expansion of the lamina propria by intralesional spherical organisms (protothecal colitis) (see Fig. 90.5).

Aerobic bacterial and fungal culture of a rectal biopsy: Small numbers of mixed enteric species and *Prototheca* spp.

Diagnosis

Disseminated *Prototheca* spp. infection with ocular and colonic involvement.

Treatment

Merlot was initially treated with lipid-complexed amphotericin B (3 mg/kg IV) on a Monday, Wednesday, and Friday basis for five doses, after which increased serum creatinine concentration was noted (1.7 mg/dL). She was also treated with oxytetracycline (21 mg/kg PO q8h) during this time. She was discharged

CASE EXAMPLE—cont'd

after 11 days with instructions to administer itraconazole (5 mg/kg PO q12h) and lufenuron (5 mg/kg PO q24h). At a recheck examination 2 weeks later, the owners reported Merlot's appetite had improved slightly and that she was having normal bowel movements once to twice a day. Each bowel movement was followed by a small amount of diarrhea at the end of defecation, with bloody mucoid material occasionally present. Since her previous visit, a foxtail had been removed from her right pelvic limb and she had been sprayed in the face by a skunk. Physical examination revealed a body weight of 19.2 kg, but aqueous flare and multifocal retinal separations were present in both eyes. Urinalysis was unremarkable and rectal scrapings showed no evidence of algal organisms. A biochemistry panel showed normalization of the creatinine and mildly increased activity of ALT, likely secondary to itraconazole administration. Topical prednisolone acetate ophthalmic drops and two additional lipid-complexed amphotericin B treatments were administered, but bilateral retinal detachment, blindness, then bilateral hyphema, and apparent ocular pain developed despite this treatment. Bilateral enucleation was performed. Histopathology of the enucleated globes showed bilateral granulomatous uveitis and retinitis with intralesional *Prototheca* organisms (see Fig. 90.5B). In the left eye, posterior synechiae, intraocular hemorrhage, and cataract formation were identified.

At a recheck examination 3 months after enucleation, Merlot was eating well and had no signs of large bowel diarrhea. Her body weight was stable and physical examination, a CBC, a biochemistry panel, and cytological examination of a rectal scraping were unremarkable. Itraconazole treatment was continued at a lower dose (5 mg/kg PO daily) and the lufenuron was discontinued. Two months later, and shortly after a new puppy was introduced, Merlot developed vomiting and diarrhea with small amounts of hematochezia, and her body weight dropped to 17.5 kg. A serum biochemistry panel showed mild hypoalbuminemia (2.6 g/dL). Cytologic examination of a rectal scraping again revealed *Prototheca* organisms, and a fecal flotation was negative. Merlot was treated with fenbendazole and the dose of itraconazole was increased to 7.5 mg/kg PO daily, after which diarrhea resolved. Four months later (14 months after initial diagnosis), the dog remained in remission but was subsequently lost to follow-up.

Comments

Diagnosis of protothecosis in this dog was straightforward and initially based on routine urine sediment examination and culture. Colonic involvement was confirmed using proctoscopy and biopsy. The most likely place that *Prototheca* infection was acquired was in Texas, but it is possible that infection was acquired elsewhere. Partial clinical remission was observed after treatment with lipid-complexed amphotericin B and itraconazole, but enucleation was required to control pain. Remission was prolonged (> 1 year) even though only seven amphotericin B treatments were administered in the first 2 months after diagnosis. Lufenuron is a chitin synthetase inhibitor. Chitin is present in the cell wall of some algae (including *Chlorella*), but whether *Prototheca* possess chitin in their cell wall is not clear.

Rhinosporidiosis

Jane E. Sykes

KEY POINTS

- First Described: In the 1890s, in Argentina (Malbran and then Seeber).[1]
- Cause: *Rhinosporidium seeberi* (kingdom Protista, class Mesomycetozoea).
- Affected Hosts: Dogs, humans, horses, rarely cats, and other domestic animals.
- Geographic Distribution: Worldwide but especially in warm, wet environments such as the southeastern and southcentral United States.
- Mode of Transmission: Unclear, possibly exposure to contaminated water sources in association with trauma.
- Major Clinical Signs: Sneezing, epistaxis, mass protruding from nares.
- Differential Diagnoses: Nasal neoplasia, cryptococcosis, sinonasal aspergillosis, nasal mites, foreign bodies.
- Human Health Significance: Human infections by *R. seeberi* are likely acquired from the environment, and direct transmission from affected animals to humans has not been described.

ETIOLOGY AND EPIDEMIOLOGY

Rhinosporidiosis is caused by *Rhinosporidium seeberi*, which causes slow-growing tumor-like masses in the nasal cavity. Although once thought to be a fungus, molecular methods have identified this organism as an aquatic protistan parasite (class Mesomycetozoea) that is taxonomically located where animals and fungi diverge and is closely related to pathogens of fish.[2,3] The organism is difficult or impossible to culture. Rhinosporidiosis has been most widely reported in humans and dogs, but cats, horses, and other mammalian and avian species may also be affected. There is some evidence that host-specific strains of *R. seeberi* exist.[4]

Rhinosporidiosis is most prevalent in humans from southern India, Sri Lanka, and Argentina but also occurs in North America, Africa, Europe, and Asia. In dogs and cats, rhinosporidiosis has been reported from many regions of the United States, Ontario in Canada,[5] Argentina,[6] northern Brazil,[7] Paraguay,[2] Italy in continental Europe,[8] and the United Kingdom.[9] Within North America, the disease has most often been reported in dogs and cats from the southcentral and southeastern states (Fig. 91.1). The overwhelming majority of affected dogs have been young adult to middle-aged (with a range of 1 to 13 years of age), otherwise healthy, large-breed hunting dogs such as Labrador and golden retrievers, Doberman pinschers, Siberian huskies, German shepherds, and Rhodesian ridgebacks. However, small-breed dogs can also be affected.[9] No clear sex predisposition has been identified, but of cases reported in the literature, males have outnumbered females. Affected cats have been outdoor cats. One affected cat had concurrent nasal adenocarcinoma,[10] but other cats have had no reported comorbidities.

While the mode of transmission of *R. seeberi* is not precisely understood, disease often occurs in association with contact with aquatic or marshy environments. It is thought that spores are released into the environment, where they come into contact with susceptible human and animal hosts.[3] Spores may be introduced into tissues after trauma to the mucous membranes, where they form sporangia that produce new spores. Because disease in humans also occurs in arid regions, airborne spore transmission has also been suggested.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In dogs and cats, infection by *R. seeberi* leads to formation of pedunculate or sessile masses within the nasal cavity, usually in the rostral third.[8] The polyps can range in size from a few millimeters to several centimeters. Clinical signs consist of subacute (weeks) to chronic (> 1 year) sneezing with or without epistaxis, snuffling, and sometimes a serous to serosanguinous unilateral nasal discharge. Sneezing may be frequent and severe and associated with excitement or increased activity. In some dogs, a polypoid pink mass protrudes from the nasal cavity. The masses are often stippled with white-yellowish granules less than 1 mm in diameter, which represent mature sporangia.[8]

DIAGNOSIS

Most animals with rhinosporidiosis have no significant hematologic or biochemical abnormalities on blood work. Plain radiography is insensitive for detection of nasal masses caused by *R. seeberi*.[8] CT reveals soft tissue masses in the rostral third of the nasal cavity that can enhance with contrast (Fig. 91.2). In some cases, evidence of turbinate loss is present. The masses can be visualized directly using rostral rhinoscopy and are pink to gray and may be covered with miliary white to yellow foci (Fig. 91.3).

Definitive diagnosis requires cytology or histopathology of the masses, which reveal large numbers of organisms. Cytologic examination of smears from nasal swabs, cytology brush specimens, or impression smears made from biopsies of the polyps reveals suppurative to pyogranulomatous inflammation with dysplastic epithelial cells and numerous immature to mature *R. seeberi* endospores, which occur singly or in clusters.[11] Sometimes sporangia that contain hundreds of endospores are visualized. Mature endospores stain intensely, are round to oval and 10 to 15 μm in diameter, and have a thick cell wall (Fig. 91.4). Immature endospores are 2 to 4 μm in diameter, contain a paracentral, light pink-purple structure that may represent nuclear material, and 1 to 2 smaller, spherical, dark purple structures.[11]

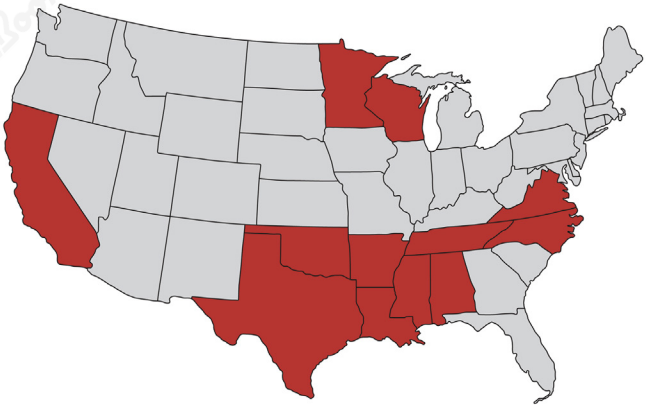

Fig. 91.1 States within the United States in which rhinosporidiosis has been reported in dogs and cats.

Fig. 91.2 Computed tomography scan of the nasal cavity of a 16-month-old female Labrador retriever with rhinosporidiosis. A soft tissue mass that enhanced with contrast is present in the rostral nasal cavity *(arrow)*.

Histopathology reveals the presence of abundant sporangia in various stages of development and a mild to severe pyogranulomatous inflammatory response (Fig. 91.5). Lymphocytes, plasma cells, and in some cases, multinucleate giant cells and evidence of turbinate remodeling with activated osteoclasts and osteoblasts may be present. Juvenile sporangia are small (< 100 µm in diameter) and have a single nucleus that is surrounded by fibrillar material. Mature sporangia are up to 500 µm in diameter and may be seen releasing endospores at the polyp surface through a pore in the sporangial wall. Although the organisms stain well with special stains such as PAS, Gomori's methenamine silver, and Meyer's mucicarmine, these stains are usually not required for diagnosis.[8]

TREATMENT AND PROGNOSIS

The treatment of choice for dogs and cats is surgical removal of polyps, which generally requires rhinotomy. Because the polyps are often rostrally located, excisions can often be extended caudally from the nares. Many dogs have no recurrence of clinical signs thereafter, but some

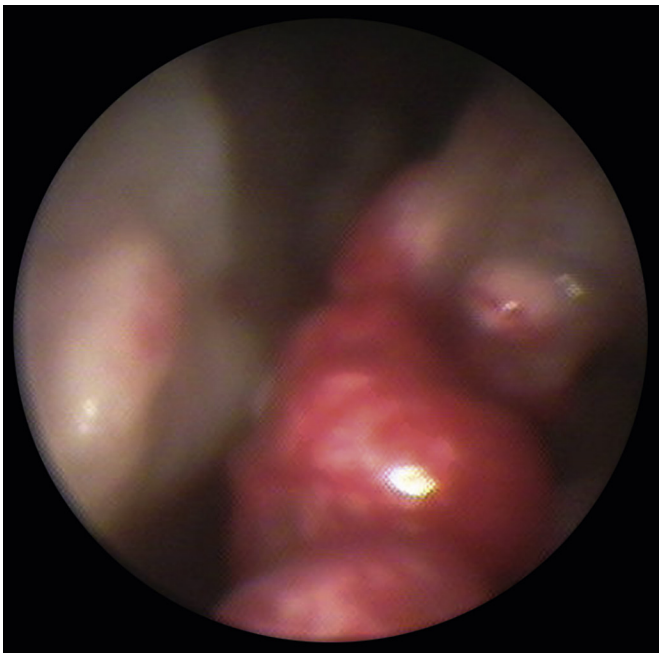

Fig. 91.3 Rhinoscopic image of a polypoid mass caused by *Rhinosporidium seeberi* in the nasal cavity of a 10-year-old intact female yellow Labrador retriever.

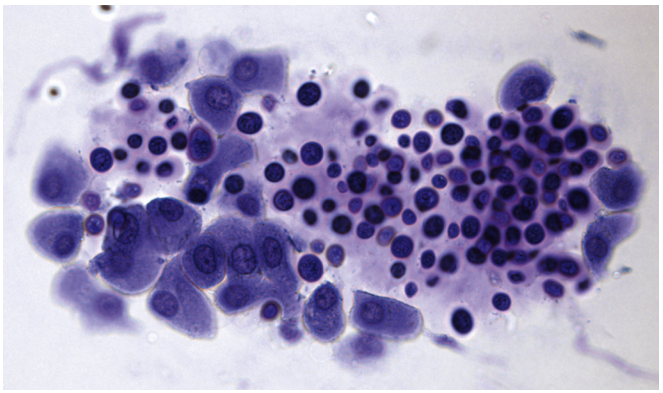

Fig. 91.4 Impression smear of a biopsy taken from the nasal cavity of a 6-year-old female spayed Labrador retriever with rhinosporidiosis. A large cluster of endospores is present together with several epithelial cells.

dogs experience disease recurrence within months of surgery.[6,12,13] The median time to recurrence in 4 dogs from Mississippi treated surgically was 749 days (range, 180-916 days).[14] Treatment of these dogs can be frustrating and costly. Povidone iodine is active *in vitro* against *R. seeberi* and could be applied in the form of gauze packs topically after surgery in an attempt to minimize the chance of recurrence (see Case Example).[15] Further study is required to determine if this changes outcome. In some dogs, apparent transient or long-term responses to treatment with ketoconazole[9,16] or dapsone (1.1 mg/kg, PO, q8–12h) have been described. Responses to dapsone have also been described in human patients. Dapsone could be used to treat dogs with refractory disease, but because both dapsone and ketoconazole have the potential to cause significant adverse effects, careful monitoring is required. Dapsone is a sulfur drug (diaminophenyl sulfone) that has been reported to cause leukopenia or thrombocytopenia in dogs.[17] Treatment of cats with dapsone is not recommended due to a high prevalence of adverse effects in this species, specifically neurotoxicosis and anemia.

(B) High-power image (1000× oil magnification) that shows a juvenile sporangium adjacent to a mature sporangium, which contains endospores *(right)*. Hematoxylin and eosin stain.

PUBLIC HEALTH ASPECTS

In humans, rhinosporidiosis usually involves the nasal cavity or nasopharynx, but involvement of the conjunctiva, genitalia or the skin, and rarely disseminated cutaneous disease, can occur.[2,18] Involvement of calvarial bones was described in one person who also had evidence of dissemination affecting the right lower limb.[19] Disease is most often reported in males with a male-to-female ratio of 3:1, and affected individuals are most often 15 to 40 years of age. Infection is likely acquired from the environment, and transmission from animals to humans has not been described. It is possible that strains of *R. seeberi* that infect humans may differ from those that infect dogs.

CASE EXAMPLE

Signalment

"Sarah," a 16-month-old intact female Labrador retriever from the central valley of northern California.

History

Sarah was evaluated by her local veterinary clinic for a 1-month history of sneezing, which occurred throughout the day and was more frequent and severe during periods of excitement. The owners had not noted any nasal discharge and were concerned about the possibility of a foreign body. A limited rhinoscopic examination with an otoscope cone at the local veterinary clinic revealed a large, fleshy, irregular mass in the dorsal meatus near the nares. A biopsy of the mass was consistent with a diagnosis of rhinosporidiosis, and Sarah was referred to the University of California, Davis Veterinary Internal Medicine service, for further evaluation and treatment.

Sarah was obtained from a breeder in Oregon as a puppy and since then has been used as a duck hunting dog in California. During the hunting season, she wades and swims in both stagnant and fresh water sources. The owners also have ponds in their backyard. She was otherwise healthy and was fed a dry commercial dog food diet.

Physical Examination

Body weight: 32.2 kg.

General: Excited, alert, responsive, and hydrated. T = 101.6°F (38.7°C), HR = 140 beats/minute, panting, CRT < 2 seconds, mucous membranes were moist and pink.

Eyes, ears, nose, and throat: Face was symmetrical with no pain on palpation, normal ocular retropulsion. No evidence of nasal discharge. Absent nasal airflow on the right side. Minimal dental calculus present. No other clinically significant findings.

Musculoskeletal: BCS 4/9. Adequate musculature, normal gait.

Cardiovascular: No murmurs or arrhythmias were auscultated. Pulses strong and symmetrical.

Respiratory: No significant abnormalities were detected.

Abdominal palpation and genitourinary examination: No significant abnormalities were detected.

Lymph nodes: All were < 1–1.5 cm in diameter and soft.

Laboratory Findings

Pre-anesthetic laboratory assessment: PCV 44%, total solids 6.6 g/dL. Serum urea nitrogen estimated at 15–26 mg/dL with a reagent strip.

Imaging Findings

CT of the head: A round, 0.9 × 1.7 × 2.3-cm, soft tissue mass was present in the rostral, dorsal right nasal cavity extending from the level of the incisors to the root of the right maxillary canine tooth. The mass was moderately, heterogeneously contrast enhancing. The superficial soft tissues overlying the mass were thickened and contrast enhancing. The remainder of the nasal cavities and sinuses appeared within normal limits. The mandibular and medial retropharyngeal lymph nodes appeared within normal limits.

Diagnosis

Nasal rhinosporidiosis.

Treatment

A rhinotomy was performed using an anterolateral approach, and a single 1.5 × 0.5-cm pedunculated mass was identified attached to the mucosal layer of the nasal septum. The mass was resected with sharp dissection and diathermy. A povidone

Continued

CASE EXAMPLE—cont'd

iodine-soaked gauze pad was placed on the site of resection for 7 minutes, and the nasal vestibule was packed with an iodine-soaked gauze pad for 1 hour after surgical closure. Histopathology confirmed the diagnosis of nasal rhinosporidiosis. The dog was discharged with instructions to administer tramadol (3 mg/kg, PO, q12h) for pain relief and dapsone (0.8 mg/kg, PO, q8h, for 2 weeks, then 0.8 mg/kg, PO, q12h, for 3 months). At a recheck 2 weeks later, the sneezing had reduced in frequency but vomiting was reported every 2 days approximately 2 hours after the morning dose of dapsone. A CBC and biochemistry panel were unremarkable. The frequency of dapsone administration was reduced to twice daily. Subsequently, Sarah did well with no recurrence of disease or adverse effects of medication.

Comments

In this dog, topical povidone iodine and dapsone were used after rhinotomy in an attempt to prevent recurrence, because the owners indicated that they would not have sufficient funds to repeat rhinotomy. The owners were warned about the possibility of re-infection if Sarah continued her hunting activities.

VetBooks.ir

Microsporidiosis (Encephalitozoonosis)

Karen F. Snowden, Jane E. Sykes

KEY POINTS

- First Described: In 1922, the first reports described histologic lesions and organisms in the brains of rabbits.[1] A series of clinical papers authored by Levaditi, Nicolau, and Schoen describing lesions in rabbits followed in 1923, and the organism was named by that group in 1924.[2] Canine infections were first described as an encephalitis-nephritis syndrome in 1952 by Plowright.[3] *Encephalitozoon cuniculi* was first isolated from dogs in 1978 by Shadduck et al.[4]
- Cause: *Encephalitozoon cuniculi*, phylum Microsporidia, family Unikaryonidae. Microsporidia are eukaryotic, intracellular organisms related to fungi that are found in a wide range of invertebrate and vertebrate hosts including a limited number of species found in mammals.
- Affected Hosts: *Encephalitozoon cuniculi* infects a wide range of mammalian hosts including domestic rabbits, mice, rats, hamsters, guinea pigs, dogs, nonhuman primates, humans, and a number of wild rodent species; additional host species are described in miscellaneous reports.
- Geographic Distribution: *Encephalitozoon cuniculi* infections in rabbits, rodents, dogs, and other hosts are geographically widespread with reports from the United States, Europe, South America, Africa, and Asia.
- Primary Route of Transmission: *Encephalitozoon cuniculi* has a direct life cycle with the major route of transmission through the ingestion of infective environmentally resistant spores. Transplacental transmission has also been documented in rabbits, dogs, and blue foxes.
- Major Clinical Signs: Encephalitis-nephritis syndrome. Young animals demonstrate inappetence and depression with progressive neurologic signs such as incoordination and ataxia, circling, and central blindness leading to death. Chronic progressive renal disease and end-stage renal failure have also been documented in young adult animals.
- Differential Diagnoses: Clinical disease in dogs is most frequently confused with neurologic signs associated with CDV infections as well as rabies or systemic toxoplasmosis.
- Human Health Significance: Systemic, sometimes fatal, *E. cuniculi* infections have been reported in a small number of immunocompromised humans. Direct transmission of the pathogen from animals to humans has not been clearly documented, but it is likely that indirect transmission of the organisms may be related to animal shedding of infective spores into the environment with subsequent human exposure.

ETIOLOGY AND EPIDEMIOLOGY

Members of the phylum Microsporidia are eukaryotic obligate intracellular pathogens that occasionally cause infection and disease in mammalian hosts. Historically these organisms were taxonomically classified as protozoa, but molecular analysis has reclassified Microsporidia as more closely related to the fungi.[5–7] More than 1,200 species of microsporidia, grouped into approximately 100 genera, infect insects and members of all classes of vertebrates.[8,9]

Microsporidia have a unique mechanism for host cell invasion. They contain a distinctive coiled polar filament or tubule structure that acts as an extrusion apparatus (Figs. 92.1 and 92.2).[8,9] This polar filament is used to propel the sporoplasm (spore contents containing the microsporidian nucleus) into the host cell. The spore has a tri-layered coat which consists of an outer glycoprotein layer, a middle layer that contains chitin, and an internal plasma membrane; together these confer resistance to destruction by environmental factors. Spore infectivity is minimally affected by freezing and thawing, and spores survive at pH levels from 4 to 9. The infectivity of spores stored in neutral buffer at 4°C and 20°C persisted for more than 24 days.[9,10] However, spores can be inactivated by various disinfectants including 0.5%–30% hydrogen peroxide, 5% ammonium hydroxide, peroxyacetic acid, or didecyl dimethyl ammonium chloride with adequate contact time.[11,12] Similarly, spores were rapidly inactivated with 10% sodium hypochlorite (bleach) or 70% ethyl alcohol.[11,13]

Natural infections with microsporidia have been described in a wide range of mammalian hosts including domestic and wild rabbits, domestic and wild rodents, dogs, foxes, cats, nonhuman primates, and humans, with sporadic reports in other domestic animals and a variety of wildlife.[8,14,15] Several different microsporidial species infect humans, causing diarrhea, encephalitis, keratoconjunctivitis, respiratory, or disseminated disease primarily in immunocompromised hosts (Fig. 92.3). The most important is *Enterocytozoon bieneusi*, followed by *Encephalitozoon intestinalis*; others include *Encephalitozoon cuniculi* and *Encephalitozoon hellem*. From a veterinary perspective, the most important microsporidian pathogen is *E. cuniculi*, the primary focus of this chapter.

Infections with *E. cuniculi* have been described in rabbits, rodents, and dogs with occasional reports in cats, nonhuman primates, and a wide range of domestic and wild mammals.[8,14,15] Three genotypes (strains) of *E. cuniculi* have been identified.[16] Differences in these isolates have been confirmed by protein electrophoresis, Western blotting, and small-subunit rRNA (SSU rRNA) gene sequence analysis. Genotype I has been identified in rabbits and humans.[17] Genotype II has been identified in mice, rats, and blue foxes.[15,16] The only strain identified in dogs to date is genotype III, which has also been found in nonhuman primate and human infections.[18–21]

Infection of most mammalian hosts with *E. cuniculi* occurs following ingestion of spores shed in the urine or feces of infected hosts, which subsequently contaminate the environment (Fig. 92.4).[8,9,15] Transplacental

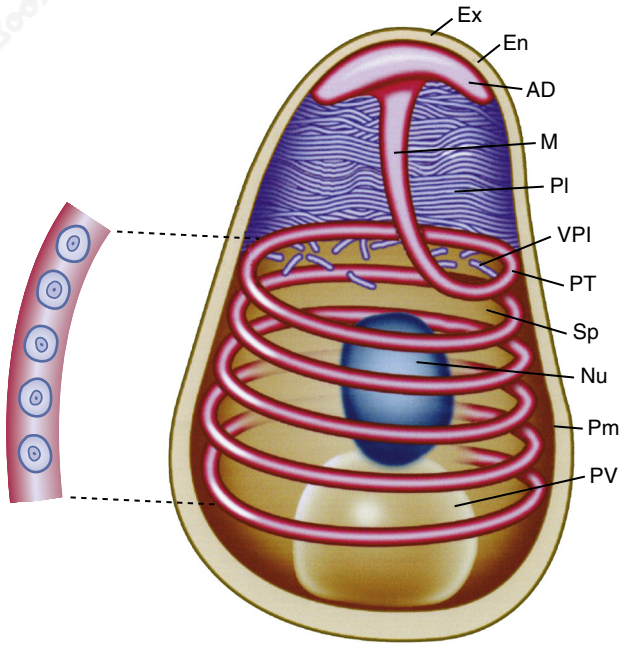

Fig. 92.1 Schematic diagram illustrating the structure of a microsporidian spore. The extrusion apparatus consists of the polar tube *(PT)*, vesiculotubular polaroplast *(VPI)*, lamellar polaroplast *(PI)*, anchoring disc *(AD)*, and manubrium *(M)*. The inset shows a cross-section of the polar tube coils. The endospore *(En)* is an inner, thicker, electron-lucent region. The exospore *(Ex)* is an outer electron-dense region. The plasma membrane *(Pm)* separates the spore coat from the sporoplasm *(Sp)* which contains ribosomes in a coiled helical array. The posterior vacuole *(PV)* is a membrane-bound structure below the nucleus *(Nu)*. (Modified from Wittner M, Weiss LM, eds. *The Microsporidia and Microsporidiosis*. Washington, DC: American Society of Microbiology Press ©1999 American Society for Microbiology. Used with permission. No further reproduction or distribution is permitted without the prior written permission of American Society for Microbiology.)

transmission has been reported in rabbits and dogs.[22,23] Inhalation of spores is included in the literature as a route of transmission, but there is little evidence to confirm or refute that possibility for dogs.

Neurologic disease attributed to *E. cuniculi* was first described in rabbits in the early 1920s.[1,2] Histologically confirmed reports of microsporidial infections in dogs were published in the 1950s and 1960s that described an encephalitis-nephritis syndrome in puppies caused by *E. cuniculi*.[3,24] The scientific name *Nosema cuniculi* was also used in some scientific reports in the 1960s and 1970s.[24] The organism was first isolated from dogs in 1978.[4]

Microsporidial diseases are not well recognized in dogs. The prevalence of antibodies to *Encephalitozoon cuniculi* in domestic dogs has ranged from 0% in specimens submitted to diagnostic laboratories in Norway[25] to 70% in a South African dog kennel.[25] Other surveys report seroprevalence rates of 14.3% in Brazil,[26] 18% in South Africa,[25] 18.5% in Colombia,[26] 20.5% in the United Kingdom,[27] 21.8% in Japan,[28] 40% in Egypt,[29] and 29.8%, 37.8%, and 48.5% in three studies from Slovakia.[30–32] The wide range in seroprevalence can partly be explained by the use of different immunodiagnostic test methods (ELISA, IFA, direct agglutination) and evaluation of dogs from various sources (strays, kennels, veterinary clinics, or unknown) and from different geographic locations. These data suggest that exposure of dogs to microsporidia is frequent, and that subclinical infections are probably common but are unrecognized or undetected.

Microsporidial spores were detected microscopically in fecal specimens from 6 of 20 dogs in an urban animal shelter in the United States.[33] In a study from Egypt, spores were microscopically detected in trichrome-stained smears in 36 of 108 (33.3%) dog fecal specimens.[34] Using a fecal PCR test, 18 of 100 dog fecal specimens collected at a veterinary clinic in Iran were positive.[35] One of the difficulties in interpreting data from fecal microscopy is that the microsporidial species is not determined, and so the possibility that the dog ingested spores from environmental sources without being infected cannot be ruled out. Similarly, detection of microsporidial DNA in fecal specimens does not clearly confirm infection, but could result in ingestion of spores from food sources or environmental contamination, since microsporidia in general are ubiquitous.

Experimental infections have shown that cats may become infected with *E. cuniculi*; however, natural infections of cats are rare and epidemiologic information is minimal.[36] In a survey of 232 cats in Virginia, 15 animals were seropositive by IFA, and the prevalence of IgG antibodies to *E. cuniculi* was not significantly different between cats with or without CKD.[37] In a Swiss study, one of 45 cats were seropositive, and no microsporidial spores were detected in 45 cat fecal specimens.[38]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Once internalized, infectious spores invade host cells by propelling the sporoplasm through the everted polar filament by a process called "germination." The sporoplasm of *E. cuniculi* develops within a host cell–derived membrane-bound parasitophorous vacuole. The organisms undergo asexual replication and then sporogony to develop the spore coat and organelles, which are needed for infectivity and environmental resistance. Host cells eventually rupture and release organisms that infect new cells. Alternatively, environmentally resistant spores form, which are shed in the urine or feces. Typical organs of localized infection in dogs and cats include the kidney, liver, and brain.[15,36,39]

The development of clinical signs has been most commonly reported in domestic rabbits and dogs, with sporadic reports in other species.[15] Clinically significant *E. cuniculi* infections generally occur in neonatal and young puppies and are acquired by transplacental transmission or ingestion of spores shed from the mother.[18,23] Older dogs may become infected with microsporidia by ingestion of spores from contaminated urine or feces. Experimental canine infections have been documented after transmission by oral or intraperitoneal inoculation, or transplacentally from infected bitches.[39,40] Kittens have been infected experimentally by intracerebral, intraperitoneal, or oral inoculation.[36]

Dogs

The clinical presentation of *E. cuniculi* infection in dogs ranges from subclinical to fatal. Based on seroprevalence studies, exposure to the pathogen and subclinical infections are probably common, but undocumented. The most common clinical manifestation of encephalitozoonosis is an encephalitis-nephritis syndrome, which occurs in puppies from 4 to 10 weeks of age.[3,18,23,24,41–43] A single pup, several pups, or an entire litter may show signs of inappetence, stunted growth, and unthriftiness. As infection progresses, animals show neurologic abnormalities such as mental obtundation, loss of awareness of surroundings, incoordination progressing to pelvic limb ataxia, seizures, and blindness. Clinical disease is most frequently confused with neurologic signs associated with CDV infections as well as rabies, neosporosis, or

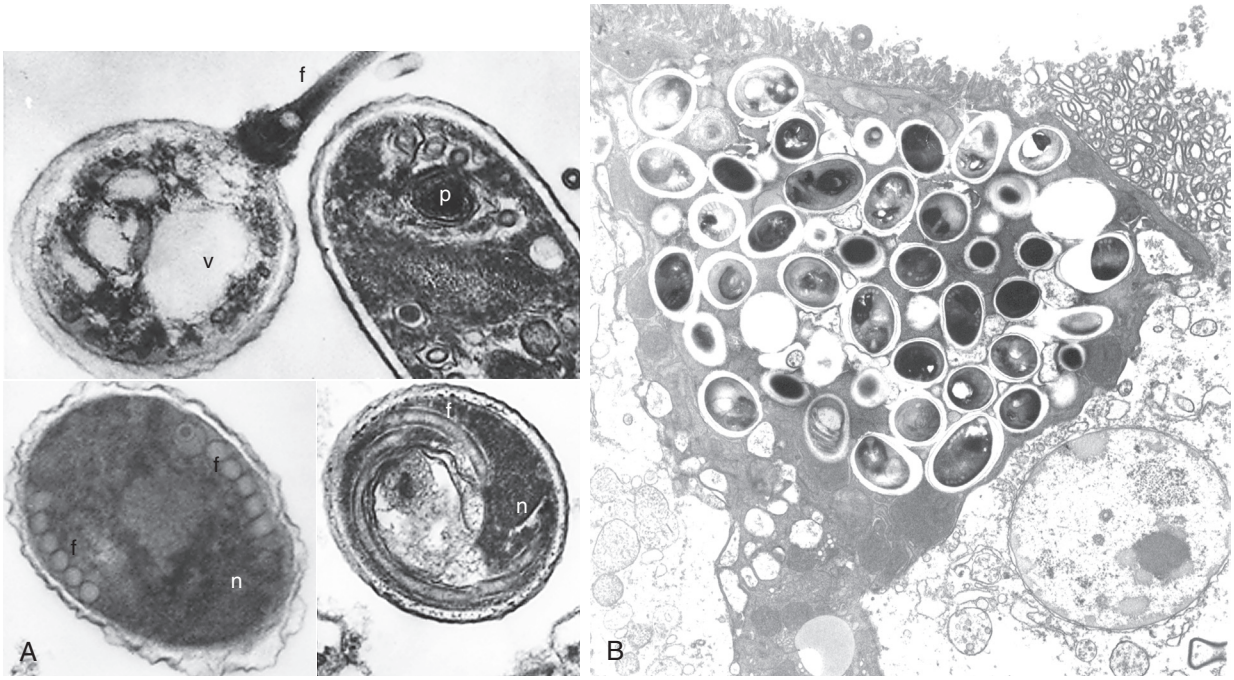

Fig. 92.2 (A) Electron microscopy of a mature *Encephalitozoon cuniculi* spore. Anterior polaroplast (*p*), loops of the polar filament (*f*) in longitudinal and cross-section views, nucleus (*n*), posterior vacuole (*v*), and electron-lucent spore wall are shown. (B) Transmission electron micrograph showing a cluster of *Encephalitozoon hellem* spores within an enterocyte of a hummingbird. (B, Courtesy Karen F. Snowden DVM, PhD, DACVM.)

Fig. 92.3 Ocular slit lamp examination of a human patient with punctate keratoconjunctivitis caused by *Encephalitozoon hellem.* (From Weiss LM. Microsporidiosis. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases.* Philadelphia: Elsevier Saunders; 2015:3031–3046.)

toxoplasmosis. Most puppies succumb to the infection over the course of a few days. Bitches that produce infected litters consistently exhibit subclinical infection.[18,23]

In addition to neurologic disease, chronic bilateral nephritis that culminates in renal failure has occasionally been reported in puppies and young adult dogs.[18,41,43] Bilaterally, the kidneys may be palpably enlarged or may be fibrotic and shrunken in size, and the dogs are usually emaciated.

Ocular lesions have also been described in dogs in one report from Europe.[44] Chronic anterior uveitis and focal cataracts were reported in three cases, and all three dogs had high titers against *E. cuniculi* with microsporidia identified microscopically or by PCR testing. The case descriptions are similar to ocular lesions that are more widely recognized in rabbits.[45–47] Ocular encephalitozoonosis has also been described in blue foxes raised for fur production in Scandinavia[48] and in cats (see below).

Cats

Naturally occurring feline encephalitozoonosis is not well described in veterinary literature. Neurologic disease was described in three Siamese cat littermates from South Africa.[49] Infected kittens exhibited lethargy, muscle twitching, and spasms. In another report, a young kitten with cerebellar hypoplasia was euthanized, and necropsy revealed generalized encephalitozoonosis. The intralesional presence of *E. cuniculi* was confirmed using molecular methods.[50]

Several additional reports describe ocular lesions in cats. In one report from the late 1970s, conjunctivitis, uveitis, and corneal opacities in a cat were attributed to *E. cuniculi*,[51] but in a later review, the morphologic features of the organisms in histologic sections were challenged, and a new scientific name was suggested.[8] More recently, uveitis and cataracts associated with *E. cuniculi* infection were described in 11 cats (19 eyes).[52] All cats were seropositive for *E. cuniculi*, and *E. cuniculi* was identified histologically or using molecular assays in surgically removed lenses. *Encephalitozoon cuniculi* was also detected by PCR in enucleated ocular material from a cat with chronic anterior uveitis and cataracts.[53] These lesions were similar to those described in rabbits infected with *E. cuniculi*.[45–47]

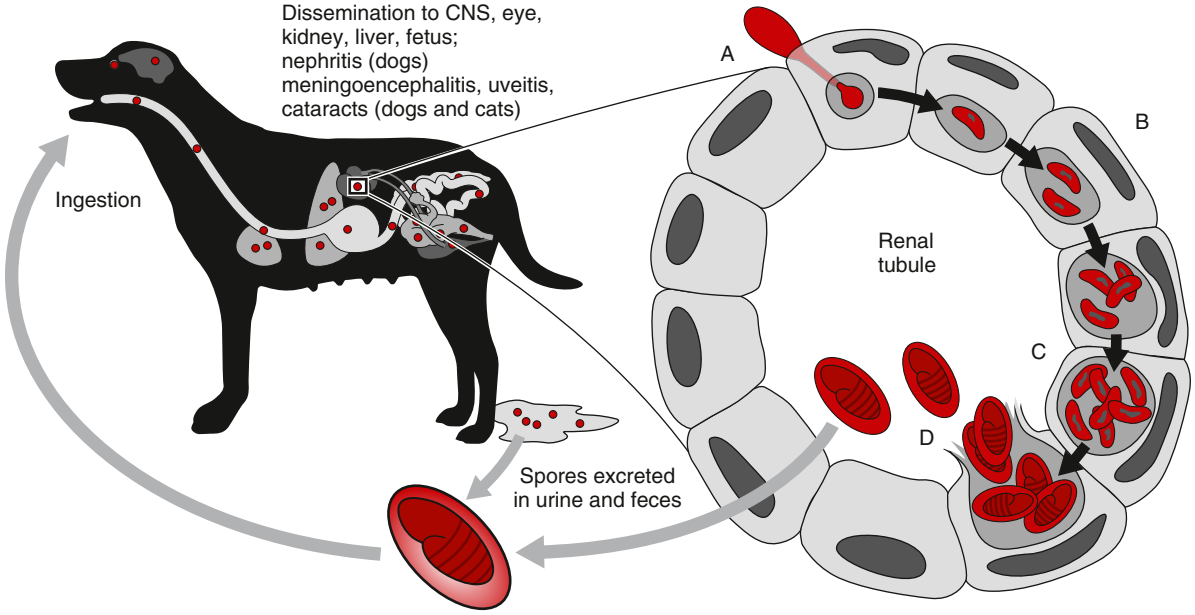

Fig. 92.4 Intracellular life cycle of *Encephalitozoon cuniculi* in the renal tubular epithelium. Diagram is based on light and electron microscopic examination of the organism. Spores are ingested and penetrate the gut wall, entering the systemic circulation. Spores can spread to many organs, such as the kidney shown here. *(A)* The mature spore uses a polar filament to propel its sporoplasm into the host cell. *(B)* Proliferative forms of pathogen (schizonts) replicate within a vacuole. Binary fission occurs during contact with membrane of intracellular vacuole. As maturation progresses, spores collect in the center of vacuole. (C) "Parasitophorous" vacuole containing spores and proliferative forms. These stages are visible under light microscope. (D) The vacuole ruptures, releases its spores into the renal tubular lumen, and the organism is excreted in urine.

Experimentally, infection was readily established in cats, but severe clinical disease was not noted.[36] Meningoencephalitis and nephritis of varying severity were noted on histopathology at necropsy, similar to lesions reported in dogs and other hosts. However, infection with *E. cuniculi* has not been associated with naturally occurring CKD in cats.[54]

DIAGNOSIS

Diagnosis of *E. cuniculi* infections can be challenging due to a lack of readily available commercial diagnostic testing options. Both microscopic and serologic methods have been used antemortem to facilitate the diagnosis of microsporidial infections in dogs. Frequently, a definitive diagnosis is made at necropsy based on histopathologic lesions and observation of intracellular parasites in multiple organs. Mature spores of *E. cuniculi* are small and oval, measuring approximately 1.5 µm wide and 2.5 µm long. Therefore, the small size and poor staining qualities of *Encephalitozoon* organisms make them difficult to visualize with routine microscopic and histologic techniques.

Laboratory Abnormalities

In one report documenting a litter of naturally infected puppies, no abnormalities were reported on CBCs, blood urea nitrogen tests, or urinalyses.[4] In other reports, anemia has been documented, with variable findings on the leukogram.[39,41] Increased serum urea nitrogen or creatinine concentrations have been reported in clinically ill puppies and subclinically infected bitches in association with impaired renal function.[23,41,55,56]

In experimentally infected animals, a normochromic, normocytic anemia is a consistent finding and may be secondary to kidney injury and impaired erythropoietin production.[39,40] Serum biochemical findings have been variable, and include increased activities of serum ALT and ALP along with variably increased serum urea nitrogen and creatinine concentrations, and sometimes increased serum total protein concentrations.[39,40,57]

Microbiologic Tests

Cytologic Diagnosis

Cytologic examination of body fluids, tissue specimens, or feces is important when making a clinical diagnosis in animals with disseminated infections. A variety of staining techniques for the detection of spores in body fluids have been developed for diagnostic use in human medical laboratories.[58,59] These methods work equally well when applied to animal feces, urine sediment, or sputum, but are not readily available in commercial veterinary diagnostic laboratories. Fee-for-service testing using these methods may be locally available through human hospital services. Spores shed into the urine from infected renal tubular epithelial cells are readily identifiable in urine sediment with Gram or Ziehl-Neelsen staining.[58,59] Spores may also be found in aqueous humor and phacoemulsified lens material from cats with uveitis and cataracts.[52] Stained spores are gram positive, whereas proliferative stages are gram negative. Microsporidia in stool specimens are sometimes more difficult to distinguish from other gram-positive bacteria than in urine sediment or other body secretions.[60]

Microsporidia stain with modified trichrome stain (e.g., StainQuick Microsporidia Kit, Scientific Device Laboratory, Des Plaines, IL, USA)

and appear bright pink with a diagonal pink band and a clear posterior vacuole; bacteria stain with the counterstain (Fig. 92.5A).[61–64] Yeasts also stain bright pink but lack a posterior vacuole, they are usually larger and more round than the oval microsporidia, and they show budding characteristics.

Chitin-staining fluorochromes (e.g., calcofluor white) are useful for detecting microsporidia but require a microscope equipped with UV lighting and appropriate barrier filters.[61,62,65,66] Organisms stain as white to turquoise oval halos when viewed with UV microscopy (Fig. 92.5B). These staining methods do not distinguish species of microsporidia.

Indirect fluorescence assays using monoclonal antibodies or hyperimmune polyclonal antisera can specifically identify microsporidia spores to the genus or species level (Fig. 92.5C). However, this method is generally used in research settings or in epidemiologic surveys and is not readily available as a diagnostic test for use in clinical settings since reagents are not commercially available.[55,67]

Electron Microscopy

Transmission electron microscopy (TEM) has been considered a gold standard for the specific diagnosis of microsporidiosis in the medical field and in selected veterinary cases.[56,68–70] Microsporidial spores contain the distinctive coiled polar tubule organelle that distinguishes microsporidia from all other organisms (see Figs. 92.1 and 92.2A).[7] The number and organization of the polar tubule coils are important morphologic characteristics that aid in identifying the organisms to a genus or species level. However, TEM is relatively insensitive, costly, and time consuming and requires technical expertise.

Serologic Diagnosis

Immunocompetent hosts produce antibodies to *E. cuniculi*, which can be detected using IFA, ELISA, and direct agglutination.[27,36,57,71] However, serologic tests for dogs or cats are not readily available on a commercial basis. Also some concerns exist about the sensitivity of these serologic tests in immunologically immature puppies or in clinically normal exposed hosts where infection is not confirmed.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Increasingly, microsporidia are diagnosed in body secretions, feces, or tissues from human patients using molecular methods.[72–75] Some of these methods have been utilized for diagnosis of encephalitozoonosis in animals.[18,68,69] Both endpoint (conventional) PCR and real-time PCR assays have been described in the literature but are not currently available on a commercial basis. Molecular assays may soon replace TEM as the method of choice for confirmation of microsporidiosis because of increased sensitivity, availability, and the ability to identify organisms to a species level.

Pathologic Findings

Gross Pathologic Findings

Descriptions of gross lesions are mostly based on necropsy evaluation of puppies with the encephalitis-nephritis syndrome.[18,23,41] Typically, puppies are in poor or emaciated condition with bilaterally enlarged, pale kidneys, sometimes with pale radiating streaks in the renal cortex. Brain congestion or swollen, edematous gyri, or hemorrhagic foci in meninges are sometimes observed. In older dogs, the kidneys are often shrunken with irregular cortical surfaces, and may contain mild petechiae or severe cortical cysts and infarcts (Fig. 92.6). Additional abnormalities sometimes reported include lymphadenopathy, splenomegaly, pinpoint white lesions in the hepatic parenchyma, patchy consolidation and edema of the lungs, fibrinous pericarditis, regional enteritis, and gastric mucosal petechiation. Gross lesions of encephalitozoonosis in experimentally infected dogs include hepatomegaly, petechiae on multiple organs, renomegaly, hemorrhagic cystitis, and splenomegaly.[39]

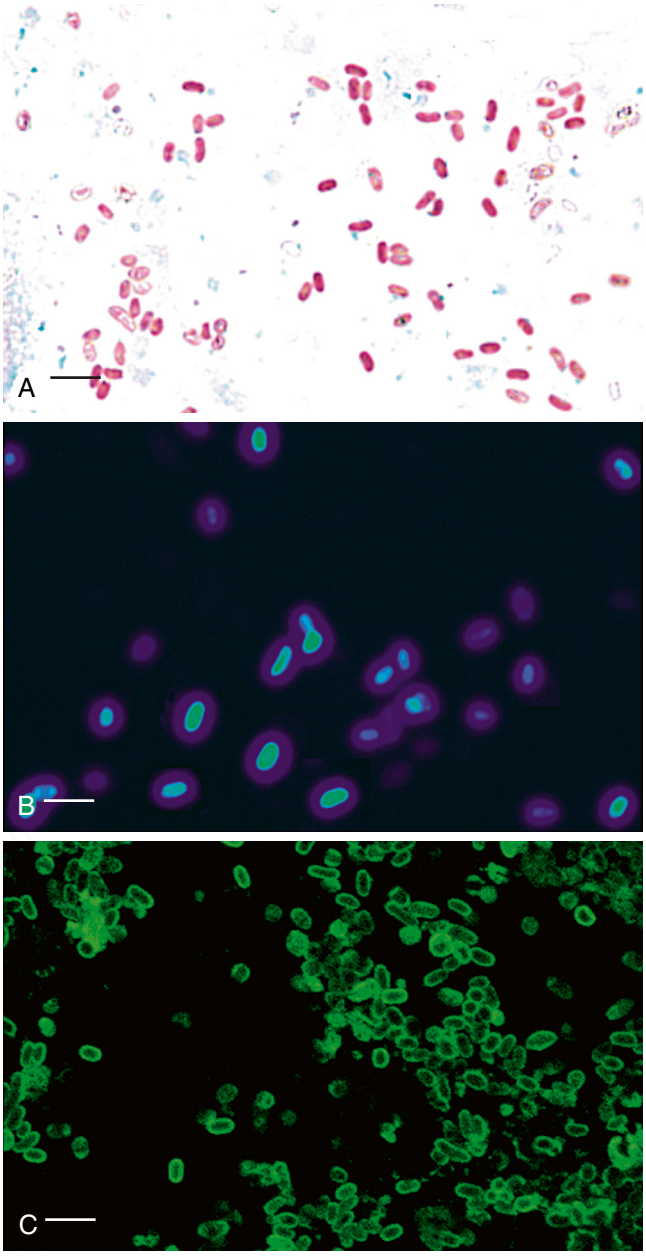

Fig. 92.5 Diagnostic assays for detection of *Encephalitozoon cuniculi* in urine and feces. (A) *E. cuniculi* spores stained with trichrome and viewed by brightfield microscopy. Of the three techniques, this provides the best demonstration of size and polar vacuole (bar = 5 μm). (B) *Encephalitozoon cuniculi* spores stained with calcofluor white. White organisms with blue halo viewed with ultraviolet microscopy. (C) *Encephalitozoon cuniculi* spores stained with rabbit polyclonal antiserum, secondary antibody linked to Alexa 468 fluorochrome, and visualized with fluorescence confocal microscopy.

Histopathology

Histologically, dogs with encephalitozoonosis consistently have nonsuppurative meningoencephalitis (Fig. 92.7).[18,42,70] Fibrinoid necrosis of small- and medium-size arteries of the brain can result in vasculitis, thrombosis, encephalomalacia, and infarction. The kidneys of dogs and cats exhibit multifocal nonsuppurative interstitial nephritis.[76] Parasitophorous vacuoles with organisms are present in the renal tubular epithelia. Nonsuppurative vasculitis around small- and medium-sized arteries is often visualized in other tissues such as the heart or liver. Other nonspecific lesions include pulmonary edema, nonsuppurative interstitial pneumonia and enteritis, reticuloendothelial hyperplasia of the spleen, and hyperplasia of the bone marrow. Experimentally infected animals have had brain and kidney lesions similar to those described in natural infections.[39]

Fig. 92.6 Kidney with pale, firm cortex that has irregular-subcapsular surface and numerous projecting cysts filled with clear fluid.

Reported findings in cats with uveitis, cataracts, or both have included lymphoplasmacytic inflammation of the ciliary body and iris, and perivascular lymphoplasmacytic infiltrates within the retina.[52] Lenses have had evidence of liquefaction of lens fibers, deposition of calcium salts, epithelial hyperplasia, and fibrous metaplasia; organisms have been visible in liquefied lens fibers primarily adjacent to the anterior lens capsule, but in some cases, the posterior lens capsule as well. Rupture of the lens capsule was identified in one of 11 cats (19 eyes) with *E. cuniculi*–associated ocular disease.[52]

It should be noted that intracellular organisms are easily overlooked using microscopy with H&E staining, especially when few organisms are present. Tissue Gram stains such as Brown and Brenn stain can aid in visualization of gram-positive *E. cuniculi* organisms in histologic sections of host tissues.[18]

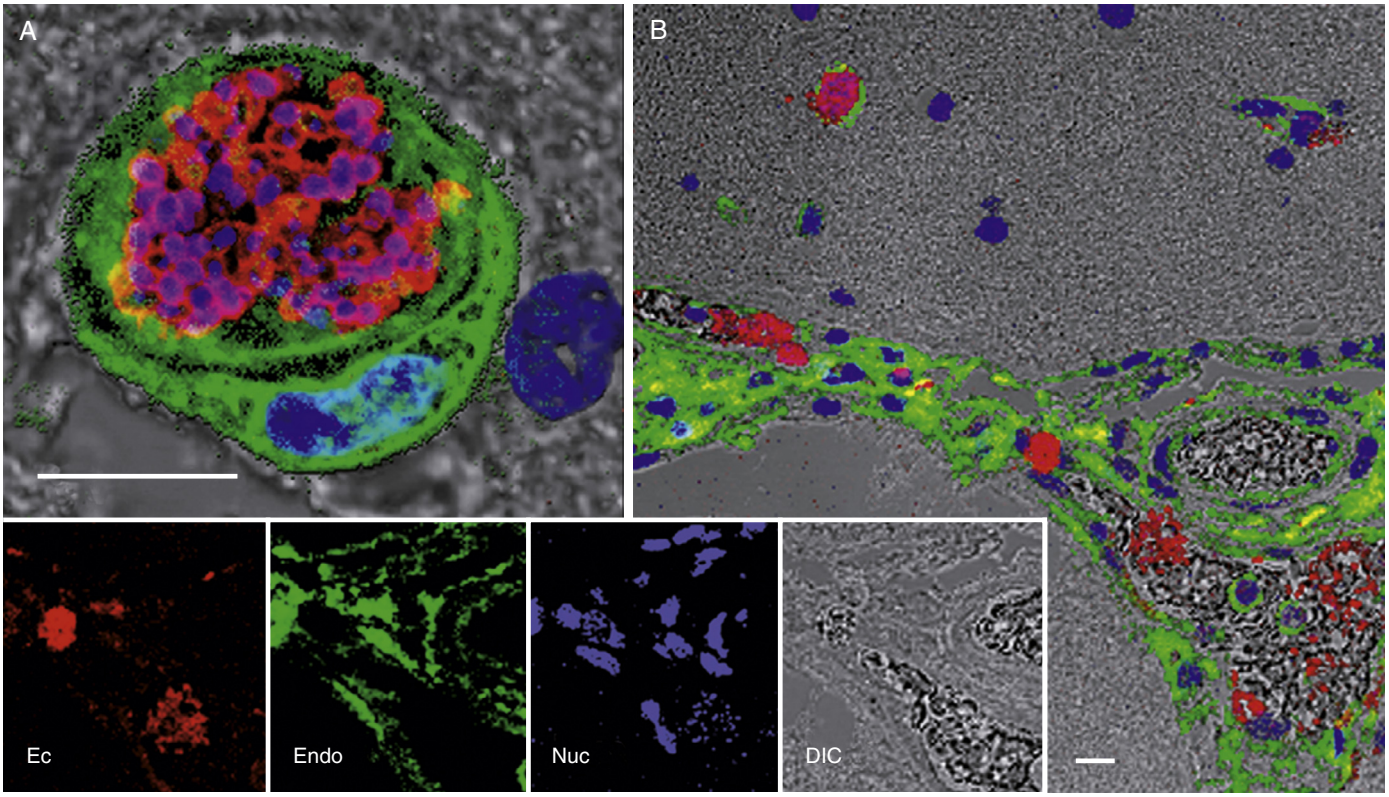

Fig. 92.7 (A) Parasitophorous vacuole packed with *Encephalitozoon cuniculi* (*red*) in endothelial cell (*green*) of nearly occluded cerebral capillary from fetal dog with transplacental infection. (B) Lower-power confocal image demonstrates *E. cuniculi* in and near cerebral vasculature. *Encephalitozoon cuniculi (Ec)* is stained with rabbit antiserum and secondary antibody linked to Alexa 468; endothelium (*Endo*) is marked with isolectin B4 and Alexa 568. Small numbers of inflammatory cell and resident nuclei (*Nuc*) are blue (TO-PRO-3 dye). Background (gray) is differential interference phase contrast (*DIC*). Bar = 5 μm.

TREATMENT AND PROGNOSIS

Although no treatment is currently recommended for either canine or feline encephalitozoonosis, some clinical and experimental therapies have been evaluated in humans, rabbits, and mice. The benzimidazoles have activity against *Encephalitozoon* spp. Albendazole has been used to successfully treat *Encephalitozoon* infections in humans and in domestic rabbits.[7,46,77–79] The related drug, fenbendazole, has been used with variable success in rabbits,[46,80,81] and was used successfully to treat a dog with nephritis caused by *E. cuniculi* genotype I.[82]

A second antimicrobial compound isolated from fungi, fumagillin, and its synthetic analogue, TNP-470, has been used to treat ocular disease caused by microsporidia.[79,83] Fumagillin is toxic for mammals, but its therapeutic use has been reported in selected human cases.[7,84,85] Fumagillin is not commercially available as a pharmaceutical product, but can be compounded from a product available for use with honeybees (Fumadil B, available from bee suppliers).

A number of additional antibiotic and antiprotozoal compounds have been explored for efficacy against microsporidia with variable or minimal success such as atovaquone, clindamycin, furazolidone, nikkomycin-Z, and nitazoxanide.[7,79] Clearly, better therapeutic products are still needed for microsporidiosis treatment in humans and animals.

PREVENTION

Since *Encephalitozoon* is primarily transmitted through the ingestion or possible inhalation of environmentally resistant spores that are shed in urine or feces, proper cleaning and disinfection of the environment is an often overlooked starting point at infection prevention. Maintaining sanitary conditions is also important when handling suspected cases of encephalitozoonosis.

PUBLIC HEALTH ASPECTS

Encephalitozoon cuniculi is generally considered an animal pathogen, but systemic, sometimes fatal, infections have been reported in humans.[86,87] The zoonotic potential of *E. cuniculi* remains unclear and needs to be explored. No direct evidence proves that dogs infect humans with microsporidia, or that humans infect dogs. One report suggested transmission of *E. cuniculi* to a dog groomer with AIDS.[87] Another report described a 10-year-old girl who underwent seroconversion to *E. cuniculi* after close contact with an infected puppy.[23] Relatively few isolates of *E. cuniculi* from a variety of host species are available for comparison, so the host predilection of the *E. cuniculi* strains is still unclear.

OTHER MICROSPORIDIAN SPECIES

Several additional microsporidian species have been identified in humans, dogs, and cats, suggesting zoonotic potential (Table 92.1). These organisms have not been associated with disease in dogs and cats. *Encephalitozoon intestinalis* is primarily recognized as a diarrhea-associated enteric pathogen in humans but has been sporadically reported in dogs in epidemiologic surveys.[88,89] In a small study of animal samples from Mexico, *E. intestinalis* spores were detected by PCR and IFA in one dog fecal specimen.[88] In Turkey, 12.4% of 282 fecal specimens from dogs tested positive for *E. intestinalis* using PCR, and 2.4% were positive for *E. cuniculi*.[90] Using light microscopy and a PCR assay, *E. intestinalis* was detected in feces of a pet cat and its owner, who was an AIDS patient with chronic diarrhea.[91] No clinical disease caused by *E. intestinalis* has been reported in dogs or cats. The potential for dogs or cats to serve as a reservoir host or to be a source of human exposure is unknown. It is also possible that these rare pet infections with *E. intestinalis* are examples of zooanthroponosis, where the parasite is transmitted from humans to animals.

Similarly, *E. bieneusi*, a common intestinal opportunistic parasite in human AIDS patients, has been identified in stool specimens from cats, dogs, and other domestic animals.[7,79,92–96] In a survey of stray and pet dogs and cats in China, *E. bieneusi* was detected by PCR in fecal specimens from 15.5% of 348 dogs and 11.7% of 96 pet cats.[97] In contrast, in Thailand, *E. bieneusi* was not detected by nested PCR in fecal specimens from 206 dogs, but was identified in 31.3% of 80 cat fecal specimens.[98] In a Japanese study that examined 104 animal fecal specimens by PCR, *E. bieneusi* was detected in two dogs and a cat.[92] *Enterocytozoon bieneusi* was also detected using PCR in 15% of 120 dog fecal specimens and 17% of 46 cat fecal specimens from Colombia,[99,100] and 4.9% of 82 dog fecal specimens and 9.1% of 44 cat fecal specimens from Poland.[96]

A number of genotypes of *E. bieneusi* have been described. Some strains have been found only in humans, others have only been described in domestic animals, and other genotypes have been documented in both human and animal hosts.[93–95,97] The zoonotic potential of these infections needs additional investigation.

TABLE 92.1 Major Genera of Microsporidia That Cause Disease in Humans

Microsporidia	Human Condition
Anncaliia spp.	Keratitis, myositis, cutaneous infections, disseminated infections
Enterocytozoon bieneusi	Diarrhea, cholangitis, rhinitis, bronchitis
Encephalitozoon cuniculi	Peritonitis, hepatitis, rhinosinusitis, seizures, nephritis, disseminated infection
Encephalitozoon hellem	Conjunctivitis, keratoconjunctivitis, rhinosinusitis, pneumonia, nephritis, cystitis, diarrhea, disseminated infection
Encephalitozoon intestinalis	Diarrhea, cholecystitis, cholangitis, nephritis, pneumonia, disseminated infection
Pleistophora spp.	Myositis
Trachipleistophora spp.	Myositis, keratoconjunctivitis, rhinosinusitis, encephalitis, disseminated infection
Tubulinosema spp.	Myositis, disseminated infection
Nosema ocularum	Keratoconjunctivitis
Vittaforma corneae	Keratoconjunctivitis, disseminated infection

CASE EXAMPLES

CASE 1

Signalment

"Zara," an approximately 15-year-old female spayed domestic shorthair cat from northern California, United States.

History

Zara was referred to a small animal internal medicine specialty service with a 1- to 2-week history of diarrhea and weight loss. A thin body condition was noted on physical examination. The only finding on blood work was mild hypoalbuminemia (2.4 g/dL). Abdominal ultrasound examination revealed mild diffuse small bowel wall thickening, with loss of normal wall layering and mild mesenteric lymphadenopathy. Serum cobalamin concentration was low. Histopathology on full-thickness biopsies of the stomach, duodenum, and jejunum, as well as a mesenteric lymph node, revealed a well-differentiated intestinal lymphoma that involved the duodenum and jejunum. The lymph node was reactive with no evidence of neoplasia. Zara was treated with prednisolone (5 mg, PO, q12h), chlorambucil (2 mg, PO, q48h), and cobalamin (250 μg, SC, weekly for 6 weeks, then once monthly). The diarrhea resolved, but inappetence continued and Zara failed to gain weight.

After 5 weeks, the owner then took Zara to a second specialty clinic. Zara had lost 0.5 kg (11% of body weight). A comprehensive profile was unremarkable, and abdominal ultrasound revealed resolved bowel wall thickening. The new internist altered the chlorambucil/prednisone dose regimen (chlorambucil: 2 mg, PO, q24h for 4 days once every 2 weeks; prednisolone: 5 mg, PO, q24h) in case the weight loss and persistent inappetence were adverse reactions to the medications. Four months later, the owner reported that Zara was eating well, with no diarrhea or vomiting, and she had gained 0.3 kg.

Three months later, Zara was seen again by the second internist for a sudden onset of vision loss and decreased appetite.

Current Medications

Prednisolone (5 mg, PO, q24h), chlorambucil (2 mg, PO, q24h for 4 days once every 2 weeks), and cobalamin (250 μg, SC, once monthly).

Other Medical History

Zara had been adopted as a stray 3 years previously and was housed exclusively indoors with several other indoor-only cats.

Physical Examination

Mild weight loss (0.3 kg) and bilateral mature cataracts were noted on physical examination. There were no other clinically significant findings.

Laboratory Findings

CBC and serum chemistry profile: The results of a CBC and serum chemistry profile were unremarkable.

Serologic testing: FeLV antigen and FIV antibody (SNAP FIV/FeLV Combo Test, IDEXX Laboratories): Negative.

FCoV IFA serology: Negative for antibodies.

Toxoplasma gondii ELISA serology: Negative for antibodies.

Imaging Findings

An abdominal ultrasound examination was unremarkable. There were no abnormalities of the bowel wall and lymph nodes.

Zara was referred to a veterinary ophthalmologist for cataract surgery. A PCR assay for *E. cuniculi* DNA on phacoemulsified lens material was positive. Serologic testing for IgG to *E. cuniculi* was positive at 1:64.

Diagnosis

Bilateral mature cataracts secondary to *E. cuniculi* infection.

Treatment

At the time of referral to the veterinary ophthalmologist, the prednisone dose was increased (5 mg, PO, q12h) and the chlorambucil was discontinued. When the results of the PCR assay for *E. cuniculi* were available, Zara was also treated with fenbendazole (20 mg/kg, PO, q24h for 3 weeks). Prednisolone and chlorambucil were discontinued. Two months later, she had regained 0.3 kg, and was feeling very well. However, because of recurrence of inappetence and weight loss, 16 months after diagnosis of encephalitozoonosis, biopsies of the stomach and intestines were repeated using gastroendoscopy and again revealed small cell lymphoma. Prednisolone and cyclophosphamide treatment was commenced. However, 18 months after the cataract surgery, she was evaluated by the emergency service at the second specialty practice for sudden-onset neurologic signs that included obtundation, circling, and pacing with pelvic limb paresis. The owner declined further work-up by the neurology service, and Zara was euthanized. A necropsy was not performed.

Comments

This cat was diagnosed with ocular encephalitozoonosis based on the rapid development of cataracts in the absence of diabetes mellitus, together with a positive PCR result for *E. cuniculi* on phacoemulsified lens material and a positive antibody test for *E. cuniculi*. The cause of the neurologic signs was unknown; given her advanced age, neoplasia is a likely differential diagnosis, but encephalitozoonosis also remains a possibility.

Acknowledgment

This case was courtesy of Dr. Marcia Smith, DVM DipACVIM, Loomis Basin Veterinary Clinic.

CASE 2

Signalment

"Pixie," a 24-day-old female Boston terrier puppy from Houston, Texas, United States.

History

Pixie was presented at her local veterinary clinic with a 2-day history of decreased activity and failure to nurse adequately. The puppy was one of a litter of two pups from a 3-year-old multiparous bitch, and the other puppy behaved normally according to the owner. Pixie came from a small breeding kennel with three Boston terrier females aged 2, 3, and 4 years old, and one 6-year-old male. The 2-year old bitch whelped 4 weeks ago, and all three pups from that litter died at 14 to 21 days old. No investigation of those neonatal deaths was requested by the kennel owner since it was the first litter for this recently purchased bitch.

Clinical Findings

On physical examination, Pixie was moribund with a body temperature of 96.8°F (36.0°C) and HR of 64 beats/minute. The owner declined further diagnostic testing, and since the prognosis was grave, the puppy was humanely euthanized. The body was submitted to the state veterinary medical diagnostic laboratory for necropsy. The pathologist made a presumptive diagnosis of disseminated microsporidiosis with histopathologic findings compatible with *E. cuniculi* infection.

Additional Diagnostic Testing

Serum was submitted from all four adult dogs to a research laboratory for IFA testing. The 2-year-old bitch had a high titer to *E. cuniculi* of 1:128, the 3-year-old dam of the puppy had a titer of 1:32, and the other two dogs from the kennel had no significant titer. These data suggest that the recently purchased 2-year-old bitch was infected with *E. cuniculi* that resulted in the death of her litter. It is likely that the 3-year-old periparturient bitch became infected through environmental contamination and passed that infection on to Pixie. The infection status of Pixie's littermate was unknown, but scientific reports have documented canine litters where some puppies were infected while littermates were not.

SECTION 4

Protozoal Diseases

Jane E. Sykes

Protozoa are unicellular eukaryotes that may be free-living or parasitic. Parasitic protozoa are the cause of important zoonotic diseases of dogs and cats worldwide, such as toxoplasmosis, leishmaniosis, giardiasis, and cryptosporidiosis. They also cause regional vector-borne systemic diseases such as babesiosis, hepatozoonosis, trypanosomiasis, rangeliosis, and cytauxzoonosis that can be associated with a high degree of morbidity and mortality in companion animals. With advancement in molecular techniques, there has been the recognition of new species and strains of many pathogens that cause these diseases in animals, as well as improved understanding of their epidemiology. For example, we now know that there are at least 15 different *Babesia* species that infect dogs and cats worldwide, we have seen expansion of the geographic range of *Cytauxzoon felis* infections, and we have a deeper understanding of the zoonotic potential of different *Giardia* and *Cryptosporidium* strains. However, even in this era of molecular pathogenesis studies, our knowledge of the basic life cycles and transmission dynamics of some protozoal pathogens of dogs and cats remains incomplete (such as for *Rangelia vitalii* and certain *Sarcocystis* species), and new drugs are needed in order to treat them effectively. Undoubtedly, more studies in the near future will shed light on these diseases with improved opportunity for intervention strategies to promote the health of not only dogs and cats but also other animal species that may be infected with these organisms.

Toxoplasmosis

Michael R. Lappin, Jitender P. Dubey

KEY POINTS

- First Described: The organism that was ultimately named *Toxoplasma gondii* was first described in France in 1908 (Nicolle and Manceaux).[1]
- Cause: *Toxoplasma gondii,* a coccidian protozoan parasite (phylum Apicomplexa).
- Affected Host Species: Cats are the definitive host and are the only species known to complete the sexual phase of *T. gondii* culminating in the passage of oocysts in feces. Cats and most other vertebrates can serve as intermediate hosts; invertebrates can serve as transport hosts by mechanical carriage of *T. gondii* oocysts.
- Geographic Distribution: *Toxoplasma gondii* has a worldwide distribution except in the absence of cats.
- Major Clinical Signs: Fever, ocular inflammation, ataxia, seizures, muscle pain, and respiratory distress are the most common clinical signs in cats; dogs have similar signs but develop illness less frequently than cats.
- Differential Diagnoses: In the dog, *Neospora caninum* induces the most similar clinical signs; many other chronic intracellular bacterial infections and fungal infections in dogs and cats need to be considered as differential diagnoses for many of the clinical and laboratory abnormities induced by *T. gondii.*
- Human Health Significance: There is significant risk to the fetus after transplacental infection and to any immunocompromised person; whether significant effects on human behavioral abnormalities are induced by infection is still debated.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Toxoplasma gondii is a coccidian that is one of the most prevalent parasites infecting warm-blooded vertebrates around the world.[2-5] Only cats complete the sexual phase in the GI tract (also known as the enteroepithelial cycle) and pass environmentally resistant oocysts in feces (Fig. 93.1). Sporozoites develop within oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity (Fig. 93.2). This process is known as sporulation. After a new potential host ingests sporulated oocysts, sporozoites are released that can penetrate the intestinal tracts of cats or intermediate hosts and disseminate in blood or lymph as tachyzoites (rapidly dividing) during active infection. *Toxoplasma gondii* tachyzoites can penetrate most mammalian cells and they replicate asexually within infected cells until the cell is destroyed. If an appropriate immune response occurs, replication of tachyzoites is attenuated and slowly dividing bradyzoites develop that persist within cysts in extraintestinal tissues. These tissue cysts form readily in the CNS, muscles, and visceral organs. Live bradyzoites may persist in tissue cysts for the life of the host. Ingestion of *T. gondii* bradyzoites in uncooked, infected tissues of prey species or species used for food in people is a common way to induce infection in cats, dogs, and people. Commercial raw meat diets for companion animals occasionally contain *T. gondii*.[6] Cats that ingest bradyzoites excrete more *T. gondii* oocysts than cats that ingest sporulated oocysts.[7]

It is likely that most *T. gondii*–infected cats and dogs harbor tissue cysts for life. Thus, the presence of serum antibodies is likely to indicate current infection. *Toxoplasma gondii* seroprevalence rates vary by the lifestyle of the cat or dog. In general, increased seroprevalence correlates with increased age as a result of increased risk of exposure over time. It also correlates with outdoor exposure, since animals with access to the outdoors are most likely to contact infected intermediate hosts. A meta-analysis of global feline *T. gondii* seroprevalence studies was published in 2020; the pooled global seroprevalence was estimated to be 35% (Fig. 93.3A).[8] In a study of clinically ill cats in the United States, *T. gondii* antibodies were detected in 31.6% of the 12,628 cats tested.[9] The seroprevalence was lowest in regions with low humidity (Fig. 93.3B). In another study of feral cats in Florida, *T. gondii* antibodies were detected in 12.1% of the cats.[10] Although *T. gondii* infection is common among cats, the oocyst excretion period is generally less than 21 days if the infection was initiated by ingestion of tissue cysts containing bradyzoites. Thus, detection of *T. gondii* oocysts in feline feces is uncommon. For example, in two studies in the United States, *T. gondii* oocysts were detected in feces of fewer than 1% of cats.[11,12] Cats allowed outdoors were shown to be 2.77 times more likely than indoor cats to be parasitized and *T. gondii* oocysts can be detected in the soil.[12-14] While the largest number of *T. gondii* oocysts excreted are after the first exposure to tissue cysts, repeat excretion can occur.[15]

Dogs do not produce *T. gondii* oocysts, but they can mechanically transmit oocysts after they ingest feline feces.[16] The tissue phases of *T. gondii* infection occur in dogs and may be associated with clinical disease. Approximately 20% of dogs in the United States are seropositive for *T. gondii* antibodies.[17] Before 1988, many dogs diagnosed with toxoplasmosis based on histologic evaluation were in fact infected with *Neospora caninum* (see Chapter 94).

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of *T. gondii* (sporozoite, tachyzoites, bradyzoites) or it can occur by transplacental transmission. Cats can also be infected through the transmammary route.[18] In dogs, evidence for venereal transmission also exists, and repeated transplacental infection has been documented.[19,20]

Most cats are not purposely coprophagic, so most are infected when they ingest *T. gondii* bradyzoites in tissue cysts during carnivorous

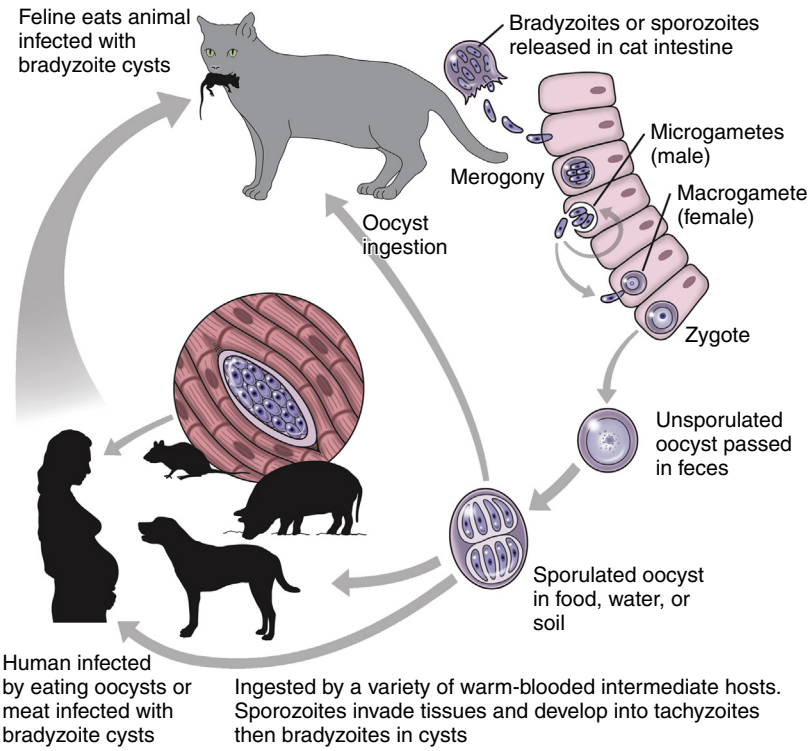

Fig. 93.1 Life cycle of *Toxoplasma gondii*. Cats are most often infected when they ingest tissue cysts in prey. The bradyzoites transform into merozoites and undergo repeated cycles of schizogony in the cat's intestinal tract. The merozoites then transform into microgametes (male) and macrogametes (female). When a microgamete penetrates a macrogamete, a zygote forms. The zygote is excreted as an unsporulated oocyst in the feces, which is not infectious. Sporulation occurs after 1 to 5 days. The extraintestinal cycle occurs in cats or other intermediate hosts after they ingest sporulated oocysts or tissue cysts. Sporozoites penetrate intestinal cells and transform into tachyzoites, which rapidly multiply in nucleated cells throughout the body in the face of immunosuppression. This can result in severe disease in the developing fetus. Ultimately, organisms are contained by the immune system within bradyzoite cysts in muscle, brain, and visceral organs (latent infection).

feeding. After ingestion, the bradyzoites transform into merozoites, which replicate in the epithelial cells of the intestinal tract, then transform into microgametes and macrogametes. When a microgamete penetrates a macrogamete, a zygote forms. The zygote then transforms into an unsporulated oocyst, which is excreted in feces for 3 to 21 days. After sporulation (formation of sporozoites within the oocyst), oocysts can survive in the environment for months to years and are resistant to most disinfectants. The *T. gondii* oocyst excretion prepatent period is stage dependent (ingestion of bradyzoites has a shorter prepatent period than ingestion of sporozoites) but is not dose dependent.[7] In addition, transmission of *T. gondii* is most efficient when cats consume tissue cysts (carnivorism) and when intermediate hosts consume oocysts (fecal-oral transmission). Infection of rodents with *T. gondii* leads to clinical signs of altered behavior, so the rodent becomes less fearful of cats.[21] This may increase the likelihood that the definitive host (cat) will become infected and potentiate the sexual phase of the organism. People and cats develop antibodies against sporozoites confirming infection after ingestion of sporulated oocysts.[22-24]

Whether clinical toxoplasmosis develops is dependent on both host and parasite effects. Some strains of *T. gondii* may be more pathogenic than others, and some genotypes may have specific tissue affinities, such as a tendency to cause ocular disease in cats or people.[25-30] If a poor immune response is mounted after primary infection, overwhelming tachyzoite replication that results in tissue necrosis is the major cause of disease.[2-5] This mechanism is also likely in cats or dogs with chronic (latent) toxoplasmosis that then become immune suppressed. One example is activation of *T. gondii* infection in cats or dogs after administration of immunosuppressive drugs such as cyclosporine.[31-34] Other immunosuppressive conditions such as FIV infection can also result in activation of toxoplasmosis.[35] The mechanisms for chronic clinical toxoplasmosis have not been fully determined. *Toxoplasma gondii* antigens and antigen-containing immune complexes have been documented in the serum of affected cats and so could play a role in some syndromes like uveitis.[36,37] However, persistent infection was not associated with chronic kidney disease in cats of one study.[38]

The large majority of cats infected with *T. gondii* never develop detectable clinical abnormalities. In general, the enteroepithelial cycle in the cat rarely leads to clinical signs. Only 10% to 20% of experimentally inoculated cats develop self-limiting, small bowel diarrhea for 1 to 2 weeks following primary oral inoculation with *T. gondii* tissue cysts; this is presumed to be from the enteroepithelial replication of the organism. *Toxoplasma gondii* enteroepithelial stages were found in intestinal tissues from two cats with inflammatory bowel disease that had positive response to administration of anti-*Toxoplasma* drugs.[39] Eosinophilic fibrosing gastritis was described in one *T. gondii*–infected cat.[40]

Fatal extraintestinal toxoplasmosis in cats can develop from overwhelming intracellular replication of tachyzoites following primary infection; hepatic, pulmonary, CNS, and pancreatic tissues are commonly involved.[2-5,41-43] Kittens infected by the transplacental or transmammary routes develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease. Common clinical signs in cats with disseminated toxoplasmosis

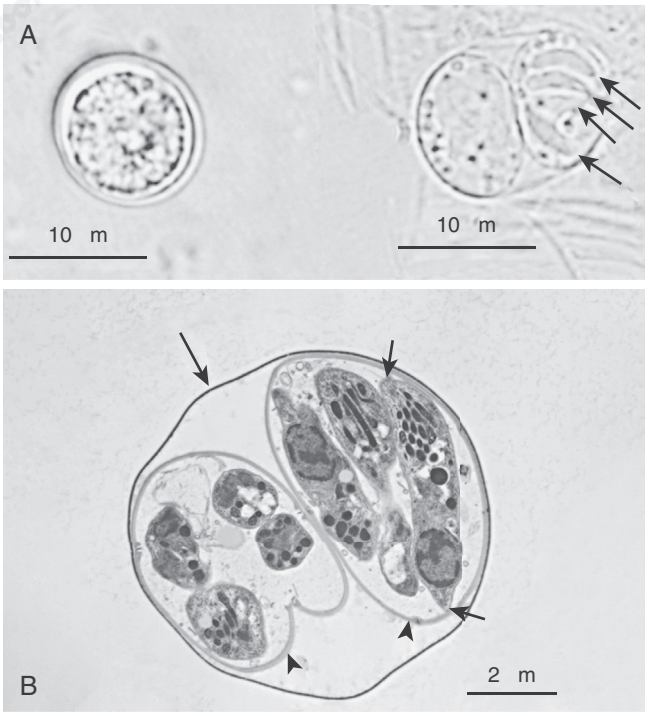

Fig. 93.2 (A) Unsporulated oocyst of *Toxoplasma gondii. (left)*. Sporulated oocyst with two sporocysts *(right)*. Four sporozoites *(arrows)* are visible within one of the sporocysts. (B) Transmission electron micrograph of a sporulated oocyst. Note the thin oocyst wall *(large arrow)*, two sporocysts (*arrowheads*, one of which is cut longitudinally), and sporozoites (short arrows, anterior and posterior end of one sporozoite). (A, From Dubey JP, Miller NL, Frenkel JK. The *Toxoplasma gondii* oocyst from cat feces. *J Exp Med*. 1970;132:636-662. B, From Dubey JP, Lindsay DS, Speer CA. Structure of *Toxoplasma gondii* tachyzoites, bradyzoites and sporozoites, and biology and development of tissue cysts. *Clin Microbiol Rev*. 1998;11:267-299.)

include lethargy, anorexia, and respiratory distress.[44] Disseminated toxoplasmosis has been documented in cats concurrently infected with FeLV, FIV, or FIP virus, as well as following cyclosporine administration for allergic dermatitis, immune-mediated disorders, or after renal transplantation.[31,32,45]

Chronic toxoplasmosis occurs in some cats and should be on the differential diagnosis list for cats with uveitis, chorioretinitis (Fig. 93.4), cutaneous lesions, fever, muscle hyperesthesia, myocarditis with arrhythmias, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, respiratory distress, pyogranulomatous cystitis, or pancreatitis.[2-5,46-59] Toxoplasmosis appears to be a common infectious cause of uveitis in cats; anterior uveitis or posterior uveitis can occur, and the manifestations can be either unilateral or bilateral.[2,60,61] Kittens infected transplacentally or through the transmammary route commonly develop ocular disease.[25]

In dogs, respiratory, GI, or neuromuscular infection with associated signs of fever, vomiting, diarrhea, respiratory distress, ataxia, seizures, and icterus occurs most commonly with generalized toxoplasmosis.[2,62-68] Generalized toxoplasmosis is most common in immunosuppressed dogs, such as those with CDV infection or those that have been treated with cyclosporine to prevent renal transplant rejection. Neurologic signs depend on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis present with weakness, stiff gait, or muscle atrophy. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. One study associated *T. gondii* antibodies with polyradiculoneuritis in dogs.[68] Some dogs with suspected neuromuscular toxoplasmosis probably have neosporosis. While *T. gondii* has been associated with retinitis, anterior uveitis, iridocyclitis, nodular conjunctivitis, and optic neuritis in some dogs with toxoplasmosis, these manifestations are less common than in cats.[2,69] One study of 51 dogs with uveitis and 84 dogs without uveitis failed to show an association with *T. gondii* antibodies in serum and the presence of uveitis.[70] *Toxoplasma gondii* was detected in 78.6% of 41 stillborn puppies in one study.[71] Myocardial infarction with ventricular arrhythmias occurs in some infected dogs and cutaneous disease manifested as pustules, pruritus, subcutaneous nodules, and/or alopecia can occur.[34,72]

DIAGNOSIS

Diagnosis of toxoplasmosis requires interpretation of specific microbiologic tests (Table 93.1) in light of the presence of consistent clinical abnormalities. No clinical abnormalities are specific for the disease.[2-5]

Laboratory Abnormalities

Complete Blood Count

Toxoplasma gondii should be on the differential diagnosis list for cats or dogs with appropriate clinical findings and nonregenerative anemia, neutrophilic leukocytosis or neutropenia, lymphocytosis or lymphopenia, monocytosis, and/or eosinophilia.

Serum Chemistry Profile

Depending on the organ system involved, cats with clinical toxoplasmosis may have increases in serum protein and bilirubin concentrations, as well as increased activities of creatine kinase, ALT, ALP, and lipase.[2-5] Findings are similar for dogs; dogs with chronic toxoplasmosis may develop hyperglobulinemia that is generally polyclonal.[73]

Urinalysis

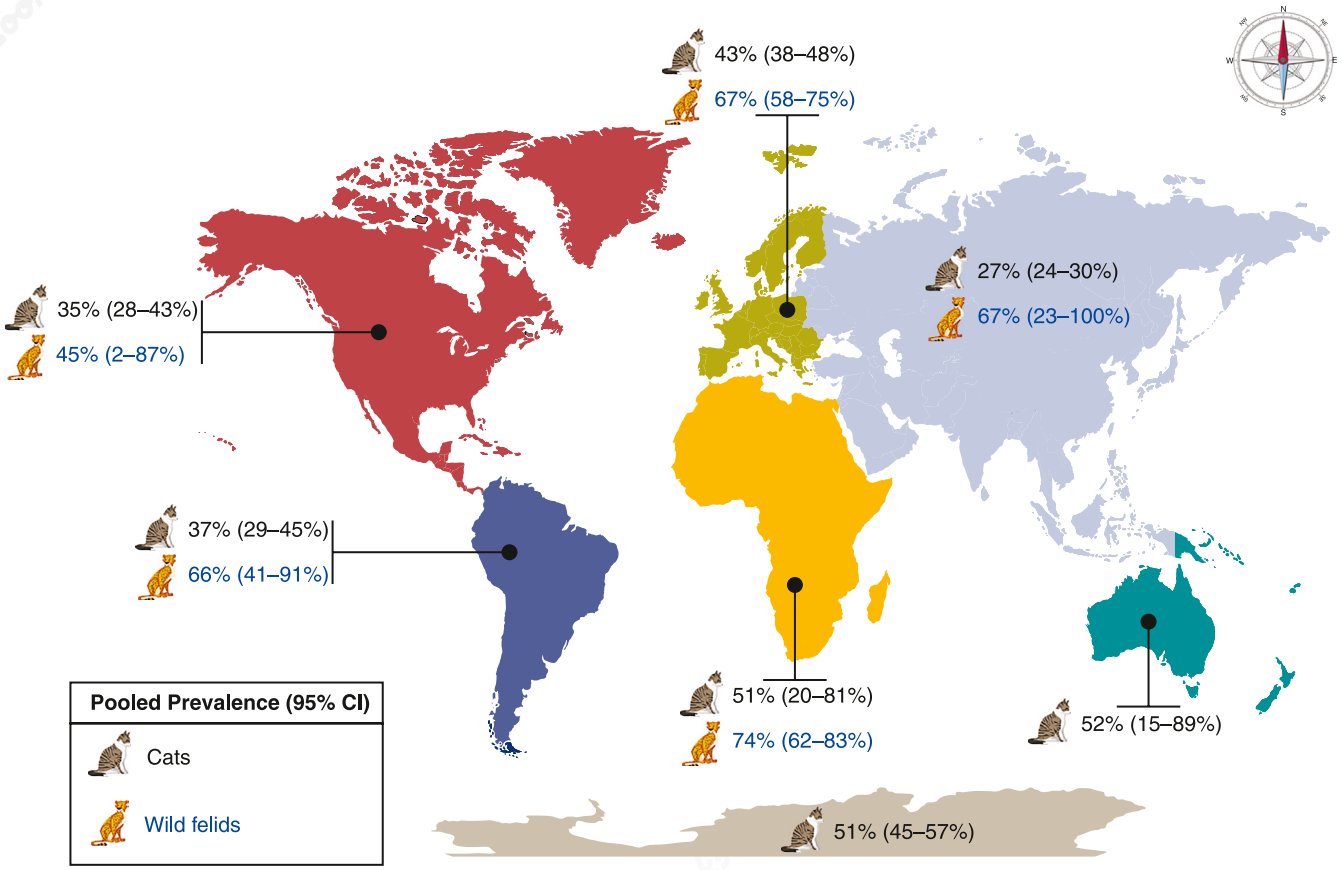
Proteinuria and bilirubinuria have been detected in some dogs or cats with clinical toxoplasmosis.

Cerebrospinal Fluid Analysis

CSF protein concentrations and cell counts are often higher than normal, with the predominant white blood cells in CSF being small mononuclear cells. However, increased neutrophils also are commonly found in cats with acute CNS toxoplasmosis. Increased CSF protein concentrations and mixed inflammatory cell infiltrates occur in dogs with CNS toxoplasmosis.

Diagnostic Imaging

Plain Radiography



Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns (Fig. 93.5); pleural effusion has rarely been documented.

Sonographic Findings

Ultrasound findings consistent with pancreatitis or diffuse hepatitis could be noted in dogs or cats with involvement of these tissues due to *T. gondii* infection. Intra-abdominal lymphadenomegaly may be noted in dogs or cats with polysystemic disease.

Advanced Imaging

MRI findings in dogs and cats with toxoplasmosis may be unremarkable, or focal or mass lesions may be identified in the brain and/or spinal cord. On MRI, lesions are often isointense on T1-weighted imaging and hyperintense on T2-weighted imaging, and they may enhance peripherally or uniformly with contrast (Fig. 93.6).[74-76]

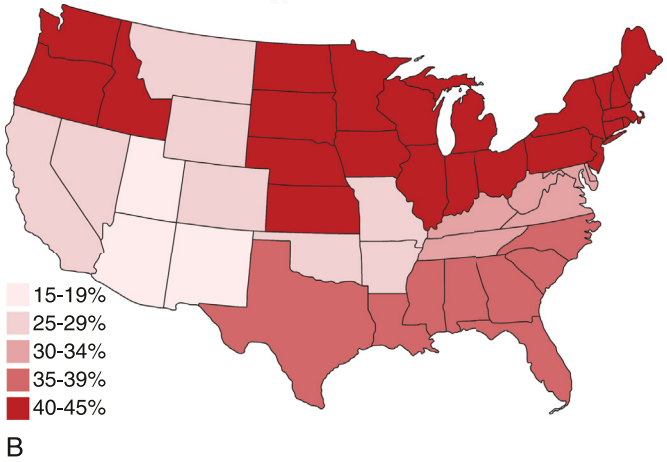


Fig. 93.3 (A) Global *Toxoplasma gondii* seroprevalence in domestic cats and wild felids from different continents. Data are reported as mean (range). (B) Continental United States regional seroprevalence of *T. gondii* antibodies in clinically ill cats. Results were based on the presence of *T. gondii*-specific IgG or IgM in serum. Information was available from 3,640 serum specimens. (A, Modified from Montazeri M, Galeh TM, Moosazadeh M, et al. The global serologic prevalence of *Toxoplasma gondii* in felids during five decades (1967-2017): a systematic review and meta-analysis. *Parasites Vectors*. 2020;13:82. B, From Vollaire MR, Radecki SV, Lappin MR. Seroprevalence of *Toxoplasma gondii* antibodies in clinically ill cats in the United States. *Am J Vet Res*. 2005;66:874-877.)

Microbiologic Tests

Cytologic Diagnosis

Using cytologic examination, *T. gondii* bradyzoites or tachyzoites can be detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF (Fig. 93.7).[47,51,52,54] A definitive antemortem diagnosis of toxoplasmosis can be made if the organism is identified; however, this is uncommon, particularly in association with sublethal disease. In the dog, *N. caninum* tachyzoites cannot be distinguished from those of *T. gondii* on cytologic examination, and so further diagnostics are needed to make a definitive

Fig. 93.4 *Toxoplasma gondii*–associated chorioretinitis in an experimentally inoculated cat.

diagnosis; results of PCR assays are used frequently to differentiate these pathogens.[2-5]

Fecal Flotation

Toxoplasma gondii oocysts measure 10 × 12 µm. When identified in feces of cats with diarrhea, this suggests infection by *T. gondii*.[2-4,77] However, *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts. If oocysts of this size are detected in feces of dogs, *N. caninum* infection is most likely if clinical disease is present.[2] However, *T. gondii* oocysts can be present if the dog has ingested infected feline feces. As discussed, PCR assays are available commercially to differentiate DNA of *T. gondii* and *N. caninum*. Alternately, serum antibody responses can be followed sequentially to attempt to determine the infecting genus. Overall, detection of oocysts in cats has a poor negative predictive value for clinical toxoplasmosis, because the signs that develop from disseminated infections occur after oocyst excretion has been completed.

Serologic Diagnosis

Cats. Detection of *T. gondii* antibodies in serum is used most frequently for the diagnosis of clinical toxoplasmosis in cats. A multitude of different techniques have been evaluated, including ELISA, IFA, Western blot immunoassay, and a variety of agglutination tests.[78-88] ELISA, IFA, and Western blot immunoassays have been adapted to detect IgM, IgG, and IgA antibody responses by using heavy-chain–specific secondary antibodies.[78,84,85] *Toxoplasma gondii*–specific serum IgA antibody responses are similar to IgG antibody responses, and this antibody class is usually measured only in research studies. Several commercial laboratories in the United States offer *T. gondii* IgM and IgG testing by ELISA.[89] The following are common findings concerning *T. gondii* IgM and IgG antibody test results in cats.

Toxoplasma gondii IgM antibody titers

- Using ELISA, approximately 80% of healthy, experimentally infected cats have detectable *T. gondii*–specific IgM in serum within 2 to 4 weeks after inoculation with *T. gondii*; these titers generally are negative within 16 weeks after infection.[78,79]
- As occurs in some healthy women, persistent IgM titers (>16 weeks) have been documented commonly in cats co-infected with FIV and in cats with ocular toxoplasmosis.[60,86] Because of these findings and the fact that some cats never have a detectable IgM response, IgM titers cannot accurately be used to predict when a cat is excreting oocysts. If a clinician is concerned that an individual cat is excreting *T. gondii* oocysts, fecal flotation or a fecal PCR assay should be performed.
- In one study of cats with clinical toxoplasmosis, *T. gondii* IgM titers were detected in the serum of 93% of the cats, whereas *T. gondii* IgG titers were detected in only 60% of the cats. Thus, IgM antibodies have a higher etiologic predictive value than IgG for clinical feline toxoplasmosis.[78,86]
- Some cats with chronic *T. gondii* infections that are initially IgM positive, but then become IgM negative, again became IgM positive after repeat inoculation with *T. gondii* in the face of FIV- or glucocorticoid-induced immunosuppression.[78,88] However, clinical signs of toxoplasmosis do not develop in these cats. Thus, presence of IgM antibodies in feline serum does not always mean that clinical toxoplasmosis is present.

Toxoplasma gondii IgG titers

- *Toxoplasma gondii*–specific IgG can be detected by ELISA in serum in the majority of healthy experimentally inoculated cats within 3 to 4 weeks after infection.[78,79]
- By the time IgG antibodies are detected, the oocyst excretion period has usually been completed. Thus, IgG-seropositive cats are of minimal public health risk.
- *Toxoplasma gondii* agglutinating antibody titers can be detected for at least 6 years after infection in experimentally inoculated cats. Because the organism probably persists in tissues for life, IgG antibodies probably do as well.[83]
- Single, high IgG titers do not necessarily suggest recent or active *T. gondii* infection; healthy cats can have titers that exceed 1:10,000 as long as 6 years after experimental induction of toxoplasmosis.[83]
- Some cats with low *T. gondii* antibody titers can become seronegative based on the cutoff value used in an individual assay even though *T. gondii* is still within tissues. Based on an approximately 10% interassay variation in the ELISA technique, some cats with low positive IgG titers (1:64) can be positive for IgG antibodies on one analysis and negative on a subsequent analysis or vice versa.
- An increasing *T. gondii* IgG titer documents recent or active infection, but in experimentally infected cats, the time span from the first detectable positive IgG titer to the maximal IgG titer is approximately 2 to 3 weeks. Thus, some cats with clinical toxoplasmosis will have reached their maximal IgG titer by the time they are evaluated serologically.
- Rising *T. gondii* IgG antibody titers occur in healthy infected cats as well as cats with clinical toxoplasmosis and so, when assessed alone, do not prove clinical toxoplasmosis.
- In humans and cats that reactivate chronic *T. gondii* infection after immune suppression, IgG titers only rarely increase.

Dogs. In dogs, assays that detect IgM and IgG titers are available in some commercial laboratories.[89] There have been very few research studies that assess canine serologic responses to *T. gondii* in different situations. However, most of the findings documented in cats appear to be true in dogs, based on the author's clinical experience.

For the reasons just discussed, antibody test results alone cannot be used to make a diagnosis of feline or canine toxoplasmosis. However,

TABLE 93.1 Microbiologic Assays for Diagnosis of *Toxoplasma gondii* Infection

Assay	Specimen Type	Assay Target	Comments
Fecal flotation	Feces	*T. gondii* oocysts	The negative predictive value of this assay is poor for clinical toxoplasmosis, since most cats cease excretion by the time illness occurs.
Fecal PCR assay	Feces	*T. gondii* DNA	As for fecal flotation.
Cytologic examination	Effusions, skin lesions, tissue aspirates	*T. gondii* tachyzoites and occasionally bradyzoites	Confirms current infection and is generally associated with disease. Organisms cannot be readily distinguished from *Neospora caninum*.
Histopathology	Multiple tissues	*T. gondii* tachyzoites and bradyzoites	If the organisms are detected in the presence of inflammation and necrosis, clinical toxoplasmosis is likely. Can be difficult to differentiate *T. gondii* from tissue protozoans such as *N. caninum* in dogs. Immunohistochemistry can be used to differentiate the two agents.
PCR assay	Effusions, blood, multiple tissues	*T. gondii* DNA	*T. gondii* DNA can be amplified from the blood of normal dogs and cats and so PCR on blood has a low positive predictive value. Amplification of specific DNA confirms infection, and if appropriate clinical signs and inflammation are present, positive results document clinical toxoplasmosis.
Serology for *T. gondii* IgM	Serum	*T. gondii* IgM antibodies	Most consistent with recent infection but can be induced during reinfection and by other immune drugs such as glucocorticoids. Positive results do not correlate with active disease.[a]
T. gondii IgG	Serum	*T. gondii* IgG antibodies	Most consistent with infection of > 10 days duration. Positive results do not correlate with active disease.[a]
Agglutination assays	Serum	*T. gondii* antibodies	Hypothetically detects all antibody classes but can be falsely negative in animals that only possess anti-*Toxoplasma* IgM antibody. Positive results do not correlate with active disease.[a]

[a]Results of serum antibody assays are combined with clinical findings to aid in making a diagnosis of clinical toxoplasmosis.

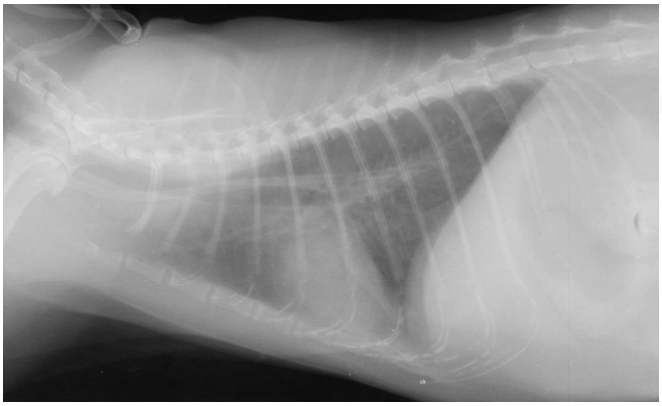

Fig. 93.5 Thoracic radiographs of a 7-year-old female spayed domestic shorthair cat with pulmonic toxoplasmosis that developed 1 month after renal transplantation. There is a diffuse interstitial pattern. The cat subsequently developed respiratory arrest, and tachyzoites were seen in fluid that was suctioned from the endotracheal tube used for resuscitation. Necropsy revealed severe, diffuse, necrotizing pneumonia with intralesional tachyzoites. Histiocytic, lymphoplasmacytic, and necrotizing lesions with intralesional tachyzoites were also seen in the renal allograft, ureter, bladder, liver, pancreas, peritoneum, muscularis mucosa of the stomach, and myocardium. Tachyzoites were not seen in the brain, but there was perivascular inflammation that suggested the possibility of infection. Immunohistochemistry confirmed that the tachyzoites were *T. gondii*.

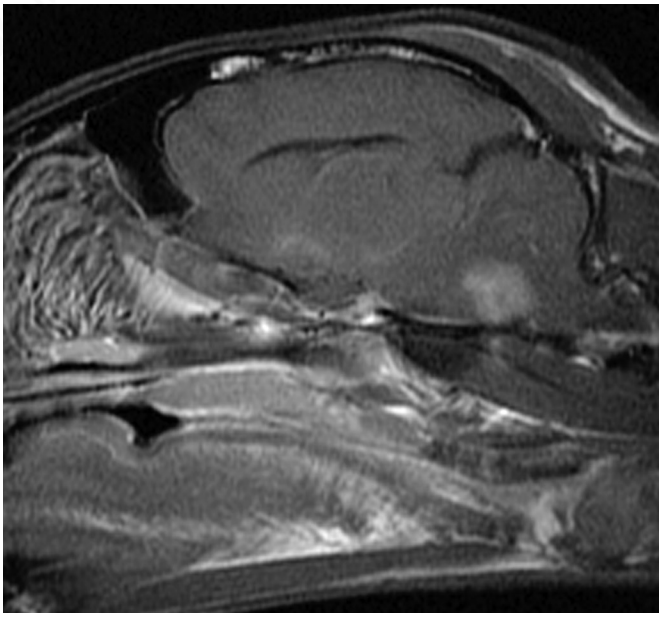

Fig. 93.6 T1-weighted postcontrast sagittal magnetic resonance image from an 11-year-old female spayed domestic longhair that was evaluated for a 5-day history of inappetence, ataxia, abnormal vocalization, and circling. The cat was FIV and FeLV negative and had no other immunosuppressive conditions. A contrast-enhancing lesion is present in the right brainstem. CSF analysis revealed a mixed monocytic (primarily lymphocytic) pleocytosis with a total nuclear cell count of 36 cells/μL and a total protein concentration of 78 mg/dL. Meningoencephalitis secondary to *T. gondii* infection was confirmed at necropsy.

the following combination can be used to make a presumptive antemortem diagnosis:

- Demonstration of antibodies in serum that suggest exposure to *T. gondii*.
- Demonstration of an IgM titer higher than 1:64, or a fourfold or greater rise in IgG titer, which suggests recent or active infection.
- Clinical signs of disease consistent with toxoplasmosis.
- Exclusion of other common causes of the clinical syndrome.
- Positive response to appropriate treatment.

Because *T. gondii* infection cannot be eliminated from tissues, most cats and dogs will be antibody positive for life, so there is little reason to repeat serum antibody titers after the clinical disease has resolved or to

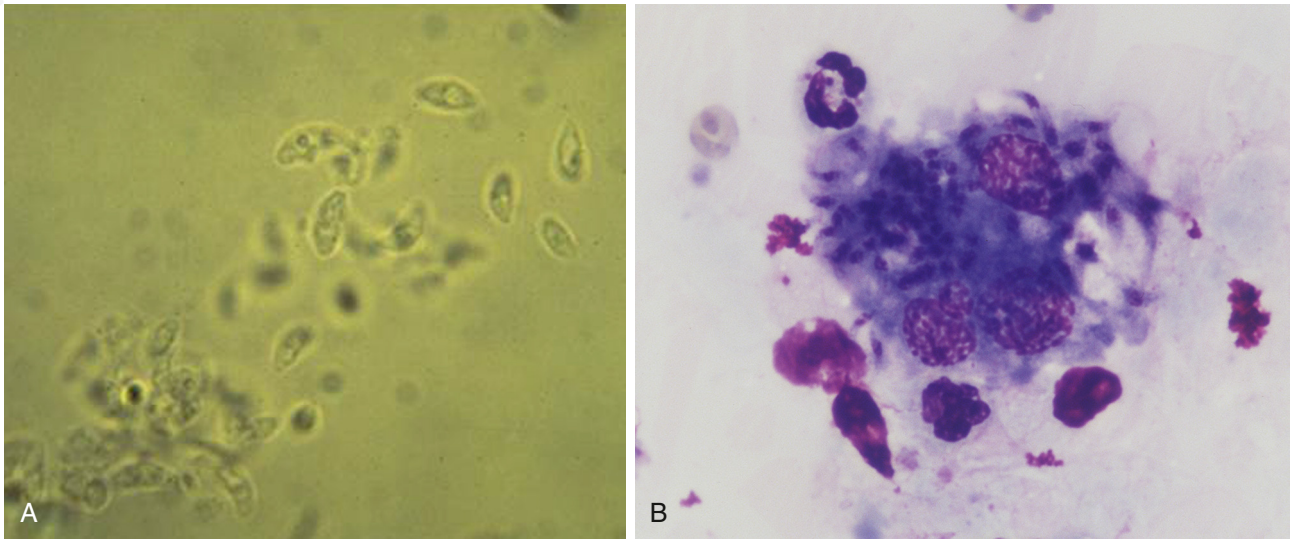

Fig. 93.7 (A) Tachyzoites of *Toxoplasma gondii* from the peritoneal cavity of a cat with fulminant toxoplasmosis. Unstained specimen. (B) Cluster of tachyzoites in a tracheobronchial lavage specimen from a 12-year-old male neutered cat that developed respiratory distress 3 weeks after renal transplantation. Wright stain, 1000× oil magnification.

administer drugs with *T. gondii* activity to cats or dogs without clinical signs of toxoplasmosis.

Other Serologic Assays. Assays that measure *T. gondii* antigens or immune complexes have been evaluated in some cats. However, as for antibody tests, antigen or immune complexes can be detected in cats with or without clinical illness. These assays are not offered commercially.[35,36,78]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Recently, PCR assays have been used to document *T. gondii* DNA in feces and can be used to differentiate among *T. gondii* strains as well as to distinguish *T. gondii* from other organisms.[77] *Toxoplasma gondii* DNA can be amplified from the blood of healthy cats and dogs, and so positive PCR assay results do not correlate with clinical disease.[90,91] Thus, PCR assays are used most frequently with cytologic examination or histopathology to document that the organisms seen were *T. gondii*, or to detect *T. gondii* in aqueous humor or CSF in conjunction with serology.[61,63-65,91] The genotype of *T. gondii* can also be determined, and additional studies are needed to more closely correlate genotypes to clinical disease-inducing potential or manifestations in dogs and cats.[27-29]

The combination of detection of *T. gondii*–specific antibody in serum, blood, aqueous humor, or CSF and amplification of *T. gondii* DNA using NAATs the most accurate way to diagnose ocular or CNS toxoplasmosis. While *T. gondii*–specific IgA, IgG, and DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats, *T. gondii*–specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and so may be the best indicator of clinical disease. Whether this is true for dogs has not been assessed to date.

Pathologic Findings

Gross Pathologic Findings

Infection with *T. gondii* generally induces pyogranulomatous reactions and necrosis. The pyogranulomas may be visualized grossly depending on the organ involved. Effusions that are characteristic of modified transudates or exudates may be found at necropsy.

Histopathologic Findings

Histopathology in animals with toxoplasmosis usually reveals pyogranulomatous inflammation with necrosis. *Toxoplasma gondii* tachyzoites or tissue cysts are commonly detected (Fig. 93.8A and B). However, if necrosis is severe, the organism may be obscured. In these cases, DNA can often be amplified from the tissues or the agent can be visualized after immunohistochemical staining (Fig. 93.8C). Because *T. gondii* and *N. caninum* induce similar syndromes in dogs, performance of PCR assays for both organisms in dogs is indicated in order to differentiate between them.

TREATMENT AND PROGNOSIS

Cats or dogs with suspected clinical toxoplasmosis should be administered supportive care as needed. Clindamycin hydrochloride or a trimethoprim-sulfonamide combination has been prescribed most frequently for the specific treatment of clinical toxoplasmosis (Table 93.2).[2-5,87] One of the drugs should be prescribed for 1 week, since most clinical signs of toxoplasmosis will begin to resolve within that time period. If a positive response is recognized, treatment should be continued for a total of 4 weeks if possible. If there is a poor response to therapy after the first 7 days, an alternative drug should be considered. Recurrence of clinical signs may be more common in cats or dogs treated for less than 4 weeks.[92]

Azithromycin has been used successfully in a limited number of cats, but the optimal duration of therapy is unknown. Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicity in cats. Pyrimethamine has been administered successfully with other drugs for the treatment of neosporosis in dogs and so may be effective for treatment of clinical toxoplasmosis in this species. Ponazuril has been used experimentally in *T. gondii*–infected rodents and should be studied for the treatment of feline toxoplasmosis.[93,94] Currently, an optimal treatment regimen for the use of this drug for this purpose in cats is unknown. However, ponazuril (20 mg/kg PO q24h for 28 days) was apparently successful in the treatment of a dog with suppurative keratitis and necrotizing conjunctivitis due to *T. gondii* infection.[69] Addition of fluconazole to pyrimethamine and trimethoprim was also effective in rodent models of toxoplasmosis and requires further study.[95] Cats or dogs with suspected *Toxoplasma* uveitis should be treated with anti-*Toxoplasma* drugs in combination with topical or systemic glucocorticoids to avoid secondary lens

luxations and glaucoma. Enucleation may be required if lens luxations and glaucoma develop from persistent uveitis.

The prognosis is poor for cats or dogs with hepatic, CNS, or pulmonary disease caused by tachyzoite replication, particularly in those that are immunocompromised by anti-inflammatory drugs or retrovirus co-infection. If they survive, cats or dogs with CNS involvement may not experience complete resolution of neurologic signs after treatment.

IMMUNITY AND VACCINATION

There is no evidence to suggest that any drug can eliminate *T. gondii* infection in dogs or cats. Thus, recurrence of disease is always possible, and infected dogs and cats often remain seropositive. Systemic reactivation of *T. gondii* infection after administration of immunosuppressive drugs can occur in both dogs and cats as discussed in the clinical features section. In cats, if repeat oocyst excretion occurs, the number of oocysts excreted is smaller than after the primary inoculation and excretion is of short duration.[18] However, it has been difficult to induce repeat oocyst excretion in chronically infected cats with clinical doses of cyclosporine.[33]

Several types of vaccines have been studied to block oocyst excretion in cats, but there is no vaccine for prevention of clinical toxoplasmosis in dogs or cats.[96]

PREVENTION

To avoid exposure to *T. gondii,* cats and dogs should not be allowed to hunt or be fed undercooked meats.[2,6,13,97,98] Care should be taken to control transport hosts such as cockroaches that have been shown to carry *T. gondii* oocysts. Cleaning cat litterboxes daily may lessen the risk of sporulated oocyst transmission between cats and between cats and their owners. Pallas cats are known to be very susceptible to *T. gondii*–associated illness. In a recent study, use of clindamycin prophylactically was shown to lessen neonatal mortality rates.[99]

PUBLIC HEALTH ASPECTS

Primary *T. gondii* infection in immunocompetent humans results in self-limiting fever, malaise, and lymphadenopathy that may not be recognized or is misdiagnosed. Primary infection of mothers by *T. gondii* during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations (Fig. 93.9). As T-helper cell counts decline, approximately 10% of people with AIDS develop toxoplasmic encephalitis from reactivation of bradyzoites in tissue cysts.[100-104] Results of studies attempting to associate *T. gondii* infection with behavioral or mental abnormalities in people have variable results.[105,106] Since it is difficult or impossible to eliminate *T. gondii* from the tissues of people, avoiding exposure is optimal.[101,107-109]

People most commonly acquire toxoplasmosis by ingestion of sporulated oocysts or tissue cysts, or transplacentally (Fig. 93.10). To prevent toxoplasmosis, humans should avoid consumption of undercooked meats or ingestion of sporulated oocysts. In a study of 6,282 meat samples from 698 retail meat stores, using a feline bioassay, *T. gondii* was detected in none of the beef or chicken specimens tested and only a small number of pork specimens.[97] However, *T. gondii* has been detected in the tissues of free-ranging chickens.[98]

Although exposure to cats is epidemiologically associated with acquiring toxoplasmosis in some studies, touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons:[2-5,100,107]

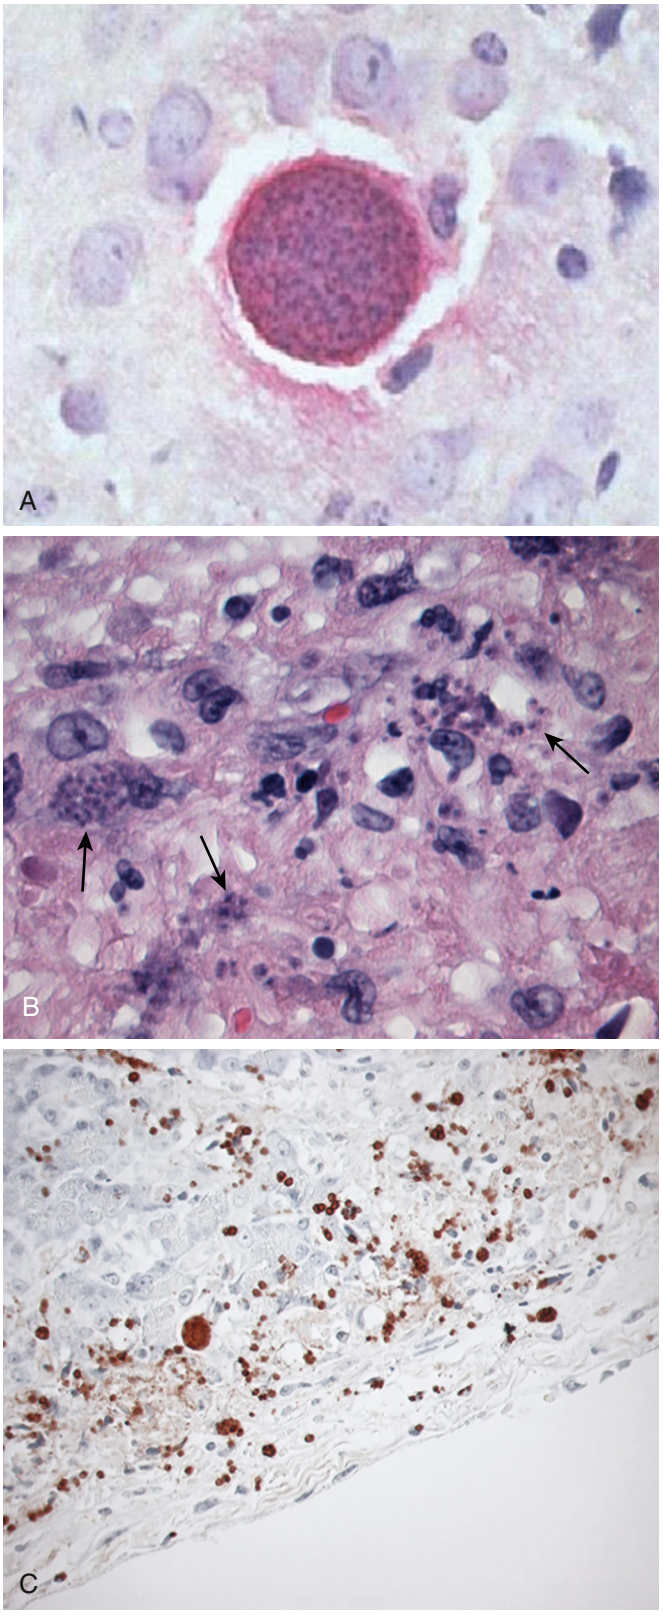

Fig. 93.8 Histopathologic findings in *Toxoplasma gondii* infections. (A) A tissue cyst filled with *T. gondii* bradyzoites in the brain tissues of an experimentally infected mouse. (B) Pancreas of the cat in Figure 93.4. There is pyogranulomatous inflammation with intralesional tachyzoites *(arrows)*; hematoxylin and eosin stain. (C) Immunohistochemistry clearly demonstrates the presence of *T. gondii* tachyzoites in the pancreas (brown staining).

TABLE 93.2 Antimicrobial Drugs That May Be Used to Treat Clinical Toxoplasmosis in Dogs and Cats

Drug	Dose	Route	Interval	Duration
Azithromycin	10 mg/kg	PO	q24h	4 weeks
Clindamycin	10–12 mg/kg	PO	q12h	4 weeks
Ponazuril	20 mg/kg	PO	q24h	4 weeks
Trimethoprim-sulfa	15 mg/kg	PO	q12h	4 weeks

If a positive response to treatment is achieved by week 4 but the animal is still improving slowly, continue treatment for 1 week past clinical resolution or when maximal response is recognized.

- Cats generally only excrete oocysts for days to several weeks after primary inoculation.
- Repeat oocyst excretion is rare and when it occurs, it is generally associated with smaller numbers of oocysts being excreted than after primary infection, even in cats receiving glucocorticoids or cyclosporine, or in those infected with FIV or FeLV.
- Cats are very fastidious and usually do not allow feces to remain on their skin for time periods long enough to lead to oocyst sporulation; the organism was not isolated from the hair of cats that had been excreting millions of oocysts 7 days previously.

However, because some cats will repeat oocyst excretion when exposed a second time, cat feces should always be handled carefully.[15] If a fecal specimen from a cat contains oocysts that measure 10 × 12 µm, it should be assumed that the organism present is *T. gondii*. The feces should be collected and removed daily until the oocyst excretion period is complete; administration of clindamycin (20 mg/kg PO daily) may shorten the oocyst excretion period if started after infection is documented.[2]

Because humans are not commonly infected with *T. gondii* through contact with individual cats, testing healthy cats for evidence of *T. gondii* infection is not recommended.[101,107] Fecal examination is an adequate procedure to determine when cats are actively excreting oocysts but cannot indicate when a cat has excreted oocysts in the past. There is no serologic assay that accurately indicates this, and most cats that are excreting oocysts are seronegative. Most seropositive cats have completed the oocyst excretion period and are unlikely to repeat excretion of large numbers of oocysts; most seronegative cats would excrete the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their physicians for testing.

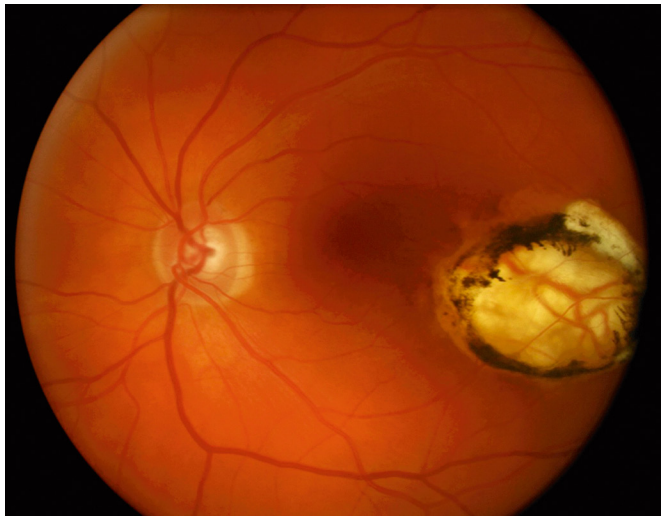

Fig. 93.9 Healed chorioretinitis in a 60-year-old woman who had recovered from congenital toxoplasmosis. The infection resulted in a permanent visual deficit. (Courtesy Mrs. Susan Sykes.)

Dogs do not complete the enteroepithelial phase of *T. gondii* but can mechanically transmit oocysts after ingesting feline feces.[16]

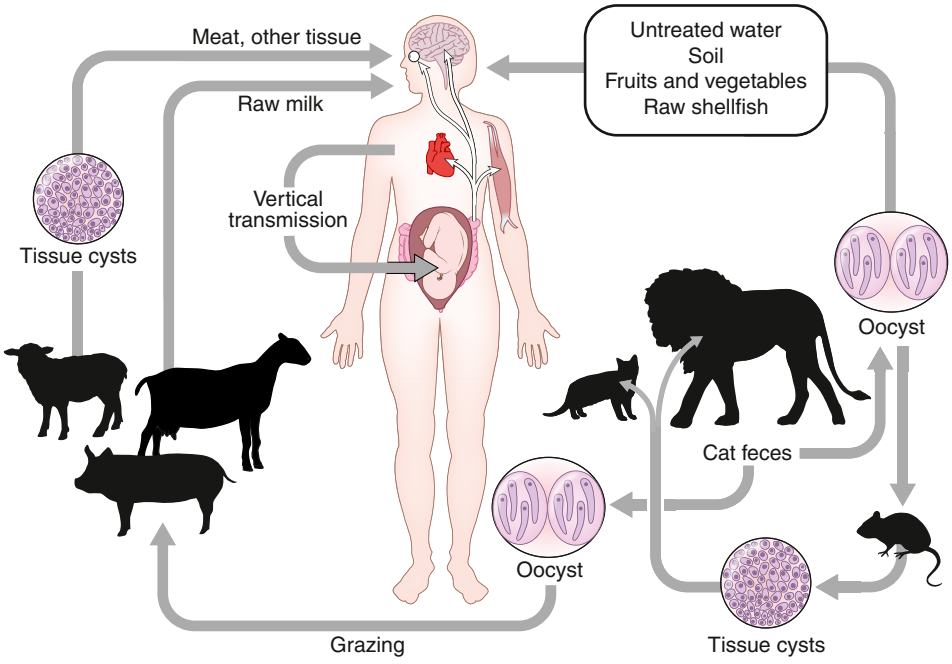

Fig. 93.10 Routes of zoonotic transmission of *Toxoplasma gondii*. (From Montoya JG, Boothroyd JD, Kovacs JA. *Toxoplasma gondii*. In Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:pp. 3355-3387.)

CASE EXAMPLE

Signalment
"Fluffy," a 3-year-old male neutered Siamese mix from Evans in northern Colorado.

History
Fluffy was referred after being treated for anterior uveitis and recurrent fever at another clinic. The clinical signs had been noted for approximately 1 month. Fluffy was entirely indoors in a suburban environment, but adopted from a humane society at around 6 months of age. His last vaccines (rabies, FHV1, FCV, and panleukopenia virus) were administered 6 months before the uveitis was first noted. He was fed a commercial processed food. There were no other animals at the house. He was treated with selamectin monthly but had not received his dose this month because of the fever. The fever seemed intermittent, and when normal, Fluffy had normal appetite and attitude. The uveitis persisted in spite of treatment with amoxicillin-clavulanic acid administered daily for 10 days and topical 1% prednisolone acetate applied three times daily.

Physical Examination
Body weight: 4.2 kg

General: Quiet, alert, and responsive. Ambulatory on all four limbs. T = 104.3°F (40.2°C), HR = 180 beats/min, RR = 30 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A dull haircoat was present. There was no evidence of ectoparasites.

Eyes: Bilateral anterior uveitis was present; fundoscopic examination was difficult due to aqueous flare.

Musculoskeletal: Body condition score was 4/9; possible discomfort was detected on muscle palpation.

Gastrointestinal: The cranial abdomen was tense with abdominal splinting noted on palpation.

All other systems: No significant abnormalities were noted.

Laboratory Findings
Complete blood count: All values were within reference ranges.

Serum biochemistry profile: All values were within reference ranges except for the activity of serum AST (190 U/L; reference range, 19–42 U/L) and the activity of serum CK (2000 U/L; reference range, 50–125 U/L).

Urinalysis: No significant abnormalities; SpG = 1.041.

Imaging Findings
Thoracic and abdominal radiographs and abdominal ultrasound were offered but declined by the owner.

Microbiologic Testing
Serologic testing: FeLV antigen negative; FIV antibody negative; serum *Bartonella* IgG negative; *Bartonella* PCR assay negative on whole blood; *T. gondii* serum IgM 1:256; *T. gondii* serum IgG 1:1024.

Diagnosis
Suspected chronic, and possibly recurrent, toxoplasmosis.

Treatment
Clindamycin (12 mg/kg PO q12h) was administered for 28 days; fever resolved on day 3 of treatment. Prednisolone acetate was continued every 6 hours topically bilaterally for the first 14 days and was discontinued after anterior uveitis resolved. Subsequently, chorioretinal scars were noted on fundoscopic examination.

Comments
The findings were suggestive of chronic recurrent toxoplasmosis, which does not respond to treatment with β-lactam antibiotics. Myositis or pancreatitis may have contributed to some of the clinical and laboratory findings. These tissues commonly contain tissue cysts with *T. gondii* bradyzoites that can repeatedly replicate as tachyzoites, which in turn results in acute disease. *Toxoplasma gondii* IgM can be detected in some cats with recurrent disease. Fluffy may have been infected with *T. gondii* when he was a stray and had an exacerbation or alternatively may have been infected more recently in the home environment by ingestion of a transport host (cockroach, etc.) or intermediate host (rodent).

Neosporosis

Jane E. Sykes, Michael R. Lappin, Jitender P. Dubey

KEY POINTS

- First Described: In 1984, in boxer dogs in Norway (Bjerkas et al.).[1]
- Cause: *Neospora caninum,* a coccidial protozoan parasite (phylum Apicomplexa).
- Affected Hosts: Dogs are the definitive hosts, and canids are the only species known to complete the sexual phase of *N. caninum* replication with passage of oocysts in the feces. Clinical illness primarily occurs in dogs and cattle. Livestock and many other species of animals, including dogs, act as intermediate hosts.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Dogs can be infected transplacentally. Postnatally, dogs may be infected after they ingest infected tissues of intermediate hosts, bovine fetal membranes, or sporulated oocysts in the environment.
- Major Clinical Signs: Stillbirth, abortion, ascending paralysis, muscle atrophy, neurologic (especially cerebellar) signs, nodular dermatitis, respiratory distress.
- Differential Diagnoses: Toxoplasmosis, sarcocystosis, hepatozoonosis, deep mycoses, protothecosis, rabies, CDV infection, West Nile virus infection, canine monocytic ehrlichiosis, migrating ascarid infections, neuronal storage diseases, granulomatous meningoencephalitis, immune-mediated neuromuscular disease, primary or metastatic neoplasia.
- Human Health Significance: *Neospora caninum* antibodies have been detected in some humans, but the parasite has not been detected in human tissues; therefore, zoonotic health consequences are still unclear.

ETIOLOGY AND EPIDEMIOLOGY

Neospora caninum is an obligately intracellular protozoan pathogen that closely resembles *Toxoplasma gondii*; before its description in 1984, it was misidentified as *T. gondii*.[2–4] Domestic dogs and wild canids (coyotes, dingoes, and wolves) act as definitive hosts of *N. caninum* and shed oocysts after ingestion of *N. caninum* tissue cysts (extraintestinal cycle) (Fig. 94.1).[5–7] Although antibodies against *N. caninum* have been detected in naturally exposed cats and cats have developed clinical neosporosis after experimental infection, neither the parasite nor clinical neosporosis has been detected in naturally exposed cats.[8–10] Clinical neosporosis results from systemic replication of *N. caninum* tachyzoites (which divide by a process known as endodyogeny) and has been described in dogs and certain domestic and wild herbivores such as cattle, sheep, goats, deer and other cervids, and marsupials. A related parasite, *Neospora hughesi,* sporadically causes myeloencephalitis in horses.[11] This organism has an unknown definitive host.[12]

Neospora caninum is one of the most important causes of infertility, abortion, and neonatal mortality in cattle worldwide. Sheep and goats can also develop reproductive and neonatal disease, but the economic importance of *N. caninum* in sheep and goats is less clear when compared with cattle.[13] Herbivores likely become infected when they ingest sporulated oocysts excreted in feces of canids or through transplacental transmission. Oocysts sporulate and become infective 24 to 72 hours after they are excreted in feces of canids and can survive in the environment for prolonged periods. After oocysts are ingested, sporozoites are released in the intestinal tract and penetrate intestinal epithelial cells. Organisms can then disseminate to a variety of tissues, where they transform into bradyzoites and become encysted (tissue cysts). In dogs, transplacental infection can occur when bitches acquire infection during pregnancy or when there is reactivation of infection in dams infected before pregnancy. Transplacental infections can occur in subsequent pregnancies from the same dam or repeated up to three generations, so that multiple litters of puppies can be affected. In one study, *N. caninum* DNA was amplified from the tissues of 52.4% of 41 stillborn puppies from five seropositive bitches.[14] Infection of immunologically naïve cattle late in pregnancy is most likely to lead to transplacental spread with abortion (also known as *exogenous* transplacental transmission).[15] However, transplacental transmission as a result of reactivation of latent infection during pregnancy (*endogenous* transplacental transmission) can also occur.[16] The pregnant cow typically shows no other overt clinical signs of infection.

Aside from transplacental transmission, dogs can become infected and excrete oocysts when they ingest bovine placental material as well as other bovine tissues, such as the muscle, liver, brain, and heart muscle.[5] This horizontal transmission is important and is thought to maintain infection in the dog population.[17] Antibodies or DNA of *N. caninum* has been found in birds, small rodents, and lagomorphs, but whether predation of these species leads to oocyst excretion by dogs is not clear.[13] Because birds can ingest *N. caninum* sporulated oocysts while feeding on the ground, a number of studies have evaluated the role of birds in this parasitism.[18] In one experimental study, chickens were resistant to *N. caninum* infection.[19] In another study, the evidence suggested that ingestion of infected chicken eggs by dogs may lead to oocyst excretion.[20] In dogs, carnivorism is considered the main route of postnatal transmission; dogs fed sporulated oocysts did not develop a patent infection.[21]

When dogs do excrete *N. caninum* oocysts, excretion begins 5 to 13 days after ingestion of infected tissues; oocysts can be excreted for several days but seroconversion does not always occur. Rarely, protracted oocyst excretion for several months has been described.[22] Generally, puppies excrete more oocysts than adult dogs,[23] and the number of oocysts shed decreases with repeated exposures to infected tissues.

In dogs, seroprevalence increases with age (because of an increased likelihood of exposure through horizontal transmission over time) and

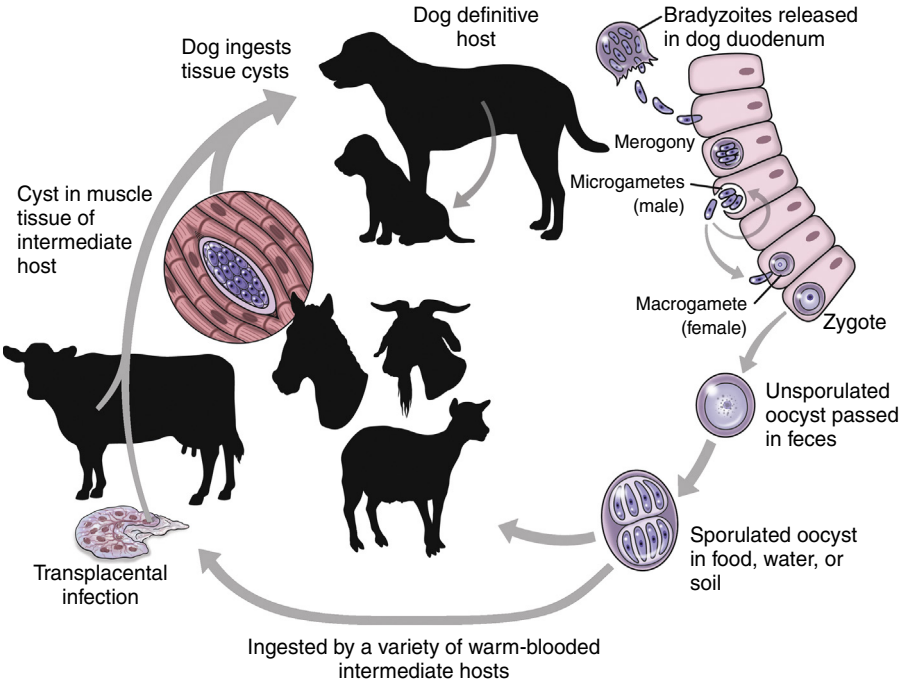

Fig. 94.1 Life cycle of *Neospora caninum*. Dogs become infected when they ingest tissue cysts in bovine placental material and other bovine tissues. Bradyzoites are released in the intestine and transform into merozoites, where they undergo merogony. A zygote forms and is shed in the feces as an unsporulated oocyst. In addition, organisms can penetrate the dog's intestinal tract and form tissue cysts. Reactivation of these cysts in pregnancy can result in repeated transplacental transmission to the fetus. Herbivores are infected when they ingest sporulated oocysts. Infection of cattle can lead to transplacental spread of tachyzoites and abortion.

is higher in free-roaming dogs than in pet dogs. Dogs that reside on cattle farms or dogs in rural areas are also more likely to be seropositive than dogs that reside in urban areas.[24–27] Introduction of infected dogs to a farm can lead to outbreaks of abortion in cattle on the farm,[28] and the more dogs present on a farm, the greater the chance that cattle will be exposed. In one study from Australia, the prevalence in dogs increased over a 20-year period.[29] Although mixed-breed dogs are more likely to be seropositive than purebred dogs, purebred dogs often develop clinical neosporosis,[30] possibly because of genetic defects in CMI. Commonly affected breeds in the literature and/or in the practices of the authors include boxers, Rhodesian ridgebacks, bull mastiffs, greyhounds, basset hounds, Labrador retrievers, Rottweilers, and West Highland white terriers.[13]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Although exposure to *N. caninum* is common, clinical disease (neosporosis) is uncommon in dogs. The development of neosporosis, the signs that develop, and their rate of progression may depend on the virulence of the infecting *N. caninum* strain and the age and immunocompetence of the host.[2,4,13,30,31] Many affected dogs are infected transplacentally, after which clinical signs usually become apparent from 4 weeks to 6 months of age. Up to 50% of puppies in a litter can be infected, but not all puppies develop signs simultaneously, and sometimes only one puppy in the litter develops clinical illness.[32] Stillbirths and neonatal deaths may also be reported.[30] Reactivation of subclinical infection can occur in older dogs after treatment with immunosuppressive drugs or chemotherapy.[33–35] Co-infection with *Ehrlichia canis* and *Hepatozoon canis* was recognized in one adult dog from Israel with meningoencephalitis.[36] In this dog, *E. canis* morulae and *N. caninum* tachyzoites were identified within CSF eosinophils (which is atypical for *E. canis*) and CSF monocytes, respectively; *H. canis* DNA was only detected in peripheral blood. Seven years before the onset of CNS signs, *E. canis* morulae and *H. canis* gamonts had been detected in peripheral blood. The dog had been treated with doxycycline and imidocarb dipropionate at that time, with normalization of CBC and disappearance of organisms. However, it is possible that persistent infection with *E. canis* contributed to immunosuppression and reactivation of neosporosis. Horizontal acquisition of *N. caninum* infection by adult dogs may occur through consumption of raw meat; one dog that developed neosporosis had a history of being fed raw elk meat.[34]

Transplacental infection of puppies usually leads to myositis and polyradiculoneuritis that initially involves the lumbosacral spinal nerve roots. This is manifested as ascending paralysis, muscle atrophy, and fibrous muscle contracture with arthrogryposis (joint contracture), hyperextension of the pelvic limbs, and loss of patellar reflexes.[30] Early signs of disease include exercise intolerance, ataxia, a high-stepping gait, splaying of the pelvic limbs, a "bunny hopping" gait, urinary incontinence, and/or muscle pain.[30,37–39] Clinical signs progress in some dogs to lethargy, tetraplegia, inability to fully open the mouth, dysphagia, and respiratory difficulty. Involvement of esophageal muscle may lead to megaesophagus.[40,41] Mandibular paralysis, vomiting, and lethargy were described as the only clinical signs in one affected dog.[41] Although ocular lesions are not a major clinical feature of neosporosis, focal chorioretinitis has been reported in some puppies.[42] Less often, young dogs develop signs of hepatitis; pneumonia; meningoencephalomyelitis; or myocarditis with arrhythmias, acute onset of respiratory distress, or sudden death.[39,40,43,44] Puppies with neuromuscular signs may have subclinical infection of other organ systems.[40]

In contrast to puppies, adult dogs typically develop polymyositis and/or meningoencephalomyelitis, with a variety of neurologic

TABLE 94.1 Diagnostic Assays Available for Neosporosis in Dogs

Assay	Specimen Type	Target	Performance
Fecal flotation	Feces	*Neospora caninum* oocysts	Dogs with clinical neosporosis typically are negative for oocysts in feces when tested, so this has a very low sensitivity and is not used routinely for diagnosis. Oocysts cannot be readily distinguished from those of *Hammondia heydorni* or *Toxoplasma gondii*.
Fecal PCR assay	Feces	*N. caninum* DNA	As for fecal flotation but additional data are needed.
Cytologic examination	CSF, aspirates of skin lesions, rarely specimens from the respiratory tract	*N. caninum* tachyzoites	Insensitive except in the case of skin lesions. Confirms active infection and is generally associated with disease. Organisms cannot be readily distinguished from *T. gondii*.
Serology (IFA or ELISA)	Serum or CSF	Antibodies to *N. caninum*	Assays can vary in performance between laboratories. A fourfold increase in titer is associated with recent infection. Dogs with chronic neosporosis may not show a rise in titer, but titers > 1:800 in conjunction with consistent clinical signs suggest neosporosis.
Histopathology	Muscle biopsies, multiple tissues collected at necropsy	*N. caninum* bradyzoites and tachyzoites	If organisms are detected in the presence of inflammation and necrosis, clinical neosporosis is likely. May be difficult to differentiate between *N. caninum* and *T. gondii*. Immunohistochemistry or PCR assay can aid in the differentiation of the two species.
PCR assay	CSF, bronchoalveolar lavage fluid, lymph node, liver, or lung aspirates, tissue biopsies (e.g., muscle, lung, liver, lymph node), or other tissues (CNS or ocular) collected at necropsy	*N. caninum* DNA	Assay performance may vary between laboratories. Because positive PCR results can occur in healthy dogs, they must be interpreted in light of clinical signs and detection of characteristic granulomatous infection in the specimens tested.

CNS, central nervous system; *CSF,* cerebrospinal fluid; *ELISA,* enzyme-linked immunosorbent assay; *IFA,* immunofluorescent antibody; *PCR,* polymerase chain reaction.

signs.[31,40,45] Although lesions can occur throughout the CNS,[40] *N. caninum* has a predilection for the cerebellum.[46] Some dogs can develop cerebellar atrophy. Disseminated infections that involve the myocardium, liver, lungs, skin, GI tract, pancreas, and/or eyes can also occur in adult dogs but are less common than encephalitis. Unusual cases are occasionally reported in the literature, including a dog with bacterial peritonitis and identification of *N. caninum* tachyzoites in peritoneal fluid.[47] In some cases, signs of localized neosporosis can occur before a disseminated infection is recognized. Examples include a 12-year-old schipperke dog with a 2-month history of severe colitis[48,49] and a 7-year-old boxer with an 8-day history of widespread ulcerated cutaneous nodules and lethargy. In both cases, treatment with systemic glucocorticoids was administered shortly before clinical deterioration in association with widespread disseminated infection.

Physical Examination Findings

Physical examination findings in puppies with polyradiculoneuritis-myositis vary from mild ataxia and muscle atrophy to tetraparesis with rigid extension of one or both pelvic limbs and arthrogryposis. Reduced patellar and sometimes other segmental reflexes (including the perianal reflex) are often present.[30,37,50,51] Severely affected dogs may be lethargic and exhibit respiratory difficulty, and it may only be possible to open the mouth a few centimeters. Fever is rare.[30]

Adult dogs with *N. caninum* meningoencephalitis may be obtunded and exhibit signs that include ataxia, circling, head tilt, nystagmus, hypermetria, head tremors, delayed placing reactions, abnormal cranial nerve function, anisocoria, depressed segmental reflexes, tetraparesis, cervical hyperesthesia, and seizures.

Dogs with myocardial involvement may develop acute onset of respiratory difficulty and cyanosis.[30] Cutaneous involvement is manifested as dermatitis with single or multifocal firm nodules, crusting, and/or ulceration, which can appear at additional sites over time and may or may not be accompanied by other systemic signs of infection.[33,52–55] Rarely, dogs with pulmonary involvement are evaluated for cough or respiratory difficulty.[56]

DIAGNOSIS

Neosporosis should be suspected in young dogs (<1 year of age) that develop ascending paralysis and muscle atrophy. It should also be suspected in dogs that develop neurologic (and especially cerebellar) signs or nodular dermatitis, especially in predisposed breeds or dogs treated with immunosuppressive drugs. Diagnosis most often relies on serology or detection of protozoal organisms in body fluids, aspirates, or tissues using light microscopy and/or PCR assays (Table 94.1). Often, antemortem diagnosis is based only on serologic testing because organisms are not easily found.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemistry Panel, and Urinalysis

As for toxoplasmosis, there are no specific hematologic or biochemical abnormalities that suggest neosporosis. The CBC is often normal, but occasionally mild nonregenerative anemia, mild eosinophilia, or monocytosis is evident.[30] The serum biochemistry panel reveals increased CK and AST activity in dogs with myositis.[35,37,39,57] In a study from the UK of dogs with meningoencephalitis, increased activity of CK and AST could be used to raise suspicion for a diagnosis of neosporosis as opposed to noninfectious causes of meningoencephalitis.[58] Occasionally, increased activity of serum ALT (due to hepatitis or severe myositis) or hyperglobulinemia is evident.[35,57] The urinalysis is generally unremarkable.

Cerebrospinal Fluid Analysis

The CSF of dogs with *N. caninum* meningoencephalitis may be normal or show mild to markedly increased total nuclear cell count (sometimes > 1,000 cells/μL) and mild to markedly increased CSF protein concentration.[31,45] Usually, a mononuclear pleocytosis is present, but

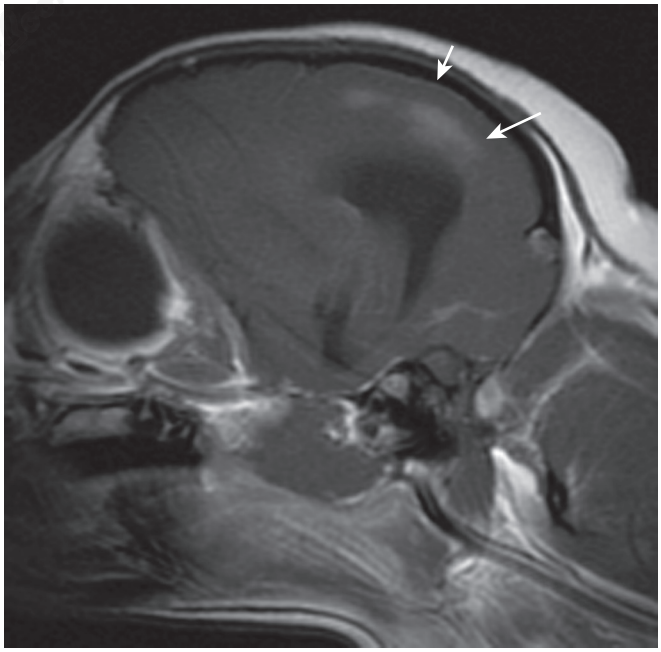

Fig. 94.2 Sagittal T1-weighted postcontrast MRI image from a 4-year-old female spayed Chihuahua with suspected *Neospora caninum* meningoencephalitis. Multiple poorly defined regions of contrast enhancement were identified in the cerebral cortices *(large arrow),* and mild meningeal enhancement was evident *(small arrow).* Cerebrospinal fluid (CSF) analysis revealed a mononuclear pleocytosis, and *Neospora* DNA was detected in the CSF using polymerase chain reaction.

occasionally the response is mixed or primarily composed of neutrophils or eosinophils.[31,37,45,50] *Neospora caninum* tachyzoites are occasionally seen cytologically in CSF.[34,45]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with neosporosis are usually unremarkable but may show a diffuse interstitial pattern in dogs with pneumonia, or evidence of megaesophagus in dogs with neuromuscular signs.[30]

Sonographic Findings

Abnormalities are rarely detected on abdominal ultrasound examination of dogs with neosporosis.

Advanced Imaging

MRI of adult dogs with cerebellar signs associated with *N. caninum* infection may show moderate to marked bilateral cerebellar atrophy.[31] Meningeal contrast enhancement may be present.[31,45] Single or multifocal T2-weighted and FLAIR hyperintensities that enhance with contrast on T1-weighted images may be present within the cerebellum or other parts of the brain (Fig. 94.2). Mild to moderate heterogeneous T2-weighted and FLAIR hyperintensities can also be seen in the masseter and temporalis muscles, which may appear atrophied.

Electrodiagnostic Testing

Electromyography in dogs with neosporosis may reveal spontaneous fibrillation potentials, positive sharp waves, and repetitive discharges.[37,39] In some dogs, nerve conduction studies have revealed reduced conduction velocities and compound muscle action potentials.[37]

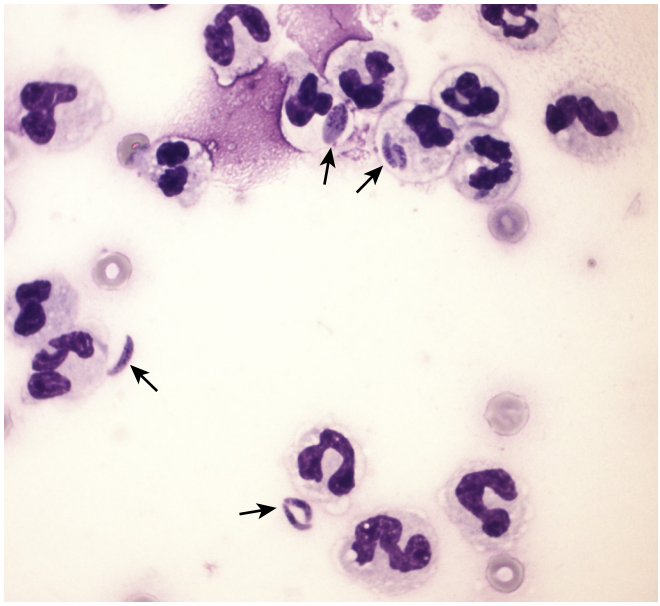

Fig. 94.3 Cytology of abdominal fluid sediment in a 7-year-old male neutered Rhodesian ridgeback showing intracellular and extracellular *Neospora caninum* tachyzoites *(arrows).* Nucleated cells are predominantly nondegenerate to mildly degenerate neutrophils.

Microbiologic Tests

Cytologic Examination

The tachyzoites of *N. caninum* may be visualized within aspirates of skin lesions (which often contain many organisms) and rarely in CSF or other body fluids. They are approximately 6 × 1 μm and oval to crescent shaped.[34,45,47,50] They may be seen singly, in pairs, or in larger groups, extracellularly and intracellularly, and are often associated with a pyogranulomatous inflammatory response (Fig. 94.3). *Neospora caninum* tachyzoites cannot be distinguished from those of *T. gondii* on cytologic examination. Because some cross-reactivity between *N. caninum* and *T. gondii* can occur with immunocytochemistry depending on the antibodies used, the use of PCR assays is recommended to definitively identify organisms as *N. caninum.* For unknown reasons, such cross-reactivity may be most likely to occur in dermal neosporosis.[17]

Fecal Flotation

Microscopic examination of feces after use of centrifugal techniques with sugar or zinc sulfate solutions can be used to detect the oocysts of *N. caninum*. However, clinically affected dogs do not typically shed oocysts. When oocysts are seen, they are indistinguishable from those of *Hammondia heydorni* or *T. gondii.* While dogs do not complete the life cycle of *T. gondii*, the oocysts of *T. gondii* can be detected in feces transiently if a dog ingests positive cat feces.

Serologic Diagnosis

Serologic assays are available commercially that detect antibody to *N. caninum* in serum and/or in CSF. Titers are often higher in serum than in the CSF of affected dogs. Indirect IFA assays are widely used, but ELISA assays have also been developed and may be used to detect IgM and IgG antibodies. Seroconversion usually occurs within 2 to 3 weeks of infection, and a rising serum titer can be identified in acutely infected dogs.[39] This rise may not occur in chronically infected dogs, so in this case a single high titer in a dog with consistent clinical signs is suggestive of the diagnosis. The magnitude of titer should not be relied on for clinical diagnosis

because congenitally infected sick puppies usually have low antibody titers.[13] Whether use of antibiotics during the acute phase of illness blunts antibody titer development is unknown. Some dogs with neosporosis have extremely high serum titers (e.g., in the tens of thousands), but others have only low antibody titers. The latter situation might reflect the presence of underlying immunodeficiency and inability to produce antibodies. Because interassay variation may cause results to differ between laboratories,[59] the same laboratory should always be used when paired titers are performed or when titers are monitored over time.

Some weak serologic cross-reactivity may occur between the antigens of *T. gondii* and *N. caninum*, so low titers to *T. gondii* may be present in dogs infected with *N. caninum*. Cross-reactivity appears to be less common when IFA assays are used.[59] Serologic cross-reactivity can also occur to *N. hughesi,* again at a slightly lower titer,[60] but the extent to which this organism infects dogs is not clear. Since many of the clinical manifestations of neosporosis and toxoplasmosis are similar, the authors recommend screening affected dogs for antibodies against both agents concurrently. If antibodies against both agents are present, the highest titer may indicate the infecting organism. However, it is also possible that dual infection could occur.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Both endpoint (conventional) and real-time PCR assays are available to aid in the diagnosis of neosporosis.[61–64] Suitable specimens for testing include CSF, bronchoalveolar lavage fluid, lymph node, liver or lung aspirates, tissue biopsies (e.g., muscle, lung, liver, lymph node), or other tissues (CNS or ocular) collected at necropsy. If pyogranulomatous inflammation is detected but organisms are not seen cytologically or histopathologically, the use of PCR assays that detect both *N. caninum* and *T. gondii* should be considered. The sensitivity and specificity of these assays have the potential to vary considerably between laboratories, and more information is required on how these assays perform for antemortem diagnosis of clinical neosporosis in dogs. Because *N. caninum* DNA can be amplified in tissues from healthy dogs, PCR results must always be interpreted considering the clinicopathologic findings and serologic test results. In one study, *N. caninum* DNA was amplified from the liver and/or spleen of one third of shelter dogs that had been euthanized, and PCR assay results did not always correlate with the results of serology.[61] PCR assays can be used to confirm that organisms seen in tissues or body fluids are truly *N. caninum* and not another protozoan parasite such as *Sarcocystis* or *T. gondii*.[63]

Pathologic Findings

Gross pathologic findings may be absent in dogs with neosporosis, or foci of discoloration may be present in the brain and spinal cord, and/or there may be evidence of meningitis (e.g., meningeal thickening or adherence of the meninges to the brain or cranial vault). White streaks within muscle may be found in affected puppies.[37] Histopathology in these puppies reveals polyradiculoneuritis with myelin loss and axonal degeneration, and there may be evidence of muscle fiber degeneration and fibrosis.

Examination of the brain and spinal cord of dogs with CNS involvement usually reveals multifocal nonsuppurative meningoencephalitis and/or myelitis with neuronal degeneration and necrosis, perivascular cuffing, and gliosis. Both gray and white matter can be affected, and the cerebellum may be primarily involved. A mixed inflammatory response with myonecrosis and sometimes dystrophic mineralization may be seen in affected skeletal or cardiac muscle. Tissue cysts or tachyzoites may be evident (Fig. 94.4). Tissue cysts are up to 100 µm in diameter and have a wall that is 4 µm in diameter, which is thicker than that for *T. gondii*. Skin biopsies from dogs with dermal neosporosis contain tachyzoites and pyogranulomatous inflammation. Occasionally (such as in acute, fulminant infections in immunosuppressed dogs), tachyzoites are found in other tissues, including the peripheral nerves, the eye, reproductive tissues, adrenal glands, lung, liver, kidney, spleen, and esophageal muscle.[40] If intralesional protozoa are identified or suspected, IHC and PCR assays can be used to distinguish *N. caninum* from other protozoal species.[63] Although serologic cross-reactivity between *N. caninum* and *T. gondii* is uncommon, it can occur with some antibodies, so IHC is best performed with a panel of antibodies to each protozoan parasite.

In healthy dogs or dogs that die of other diseases, rare tissue cysts in the absence of an inflammatory response may be found at necropsy in skeletal muscle and the CNS.

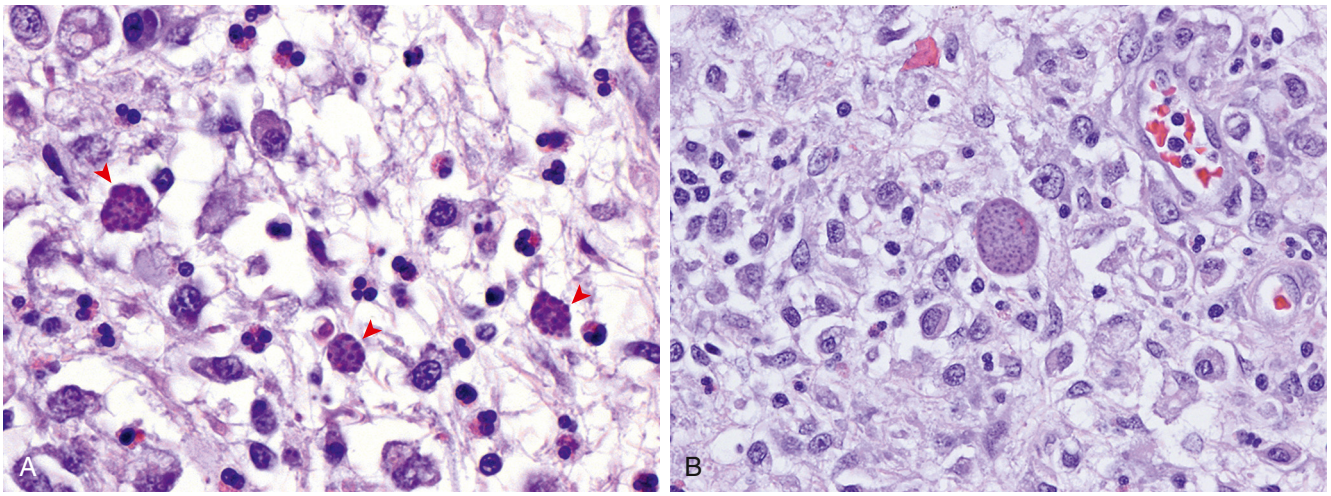

Fig. 94.4 Histopathology of the cerebellum from a 6-year-old intact male Rhodesian ridgeback with neosporosis. (A) Large areas of malacia were present admixed with a marked granulomatous inflammatory infiltrate and abundant protozoal cysts *(arrowheads).* (B) The protozoal cysts had a thick wall and stained positive with anti-*Neospora* antibodies (not shown). (Courtesy Dr. Robert Higgins, University of California, Davis Veterinary Anatomic Pathology Service.)

TREATMENT AND PROGNOSIS

Several antimicrobial drugs have been prescribed in an attempt to treat neosporosis in dogs (Table 94.2). Historically, clindamycin has frequently been used in many cases because of potential activity against *T. gondii*.[30,64,65] Treatment is usually only temporarily, partially, or completely ineffective, and long periods (>8 weeks) of treatment may be required.[2,4,30,31] Tissue cysts persist despite treatment with clindamycin.[64] Other treatments that have been successful (or partially successful) are trimethoprim-sulfadiazine-pyrimethamine, combinations of clindamycin and trimethoprim-sulfadiazine, or combinations of clindamycin and pyrimethamine. Clindamycin and sulfa-drugs have static effects against *N. caninum*. Ponazuril and toltrazuril have cidal effects and show promise based on studies in *N. caninum*–infected mice.[66] Ponazuril was used safely for weeks in the treatment of keratoconjunctivitis due to *T. gondii* in a dog after treatment with clindamycin failed.[67] Treatment should be continued so long as clinical improvement is occurring. The prognosis for puppies once muscle contracture has developed is poor. It has been suggested that once neosporosis has been diagnosed in a puppy, all dogs in a litter should be treated, because the later the treatment is initiated after the onset of clinical signs, the worse the prognosis. However, without data to confirm that recommendation, veterinarians should at least consider checking the serum *N. caninum* antibody titers of puppies whose littermates have succumbed to neosporosis, and treatment should be considered for those with positive titers. The use of immunosuppressive drugs should be avoided in seropositive puppies.

TABLE 94.2 Antimicrobials Used To Treat Neosporosis in Dogs

Drug[a]	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)
Clindamycin	10–12	PO	q8h	At least 4 weeks
Trimethoprim-sulfa	15	PO	q12h	At least 4 weeks
Pyrimethamine	1	PO	q24h	At least 4 weeks
Ponazuril[b]	20	PO	q24h	At least 4 weeks

[a]Combinations of drugs are commonly prescribed to severely affected puppies.
[b]Ponazuril or toltrazuril have cidal effects and may be best for central nervous system lesions.[66]

A low dose of glucocorticoids (e.g., prednisone, 0.5 mg/kg, PO, q12h) in addition to anti-protozoal drugs is often used to treat *N. caninum* meningoencephalomyelitis, but no prospective controlled trials have been performed to determine if this alters outcome. Since latent *N. caninum* infection has been activated by the use of immunosuppressive drugs, the concurrent administration of glucocorticoids could promote a negative outcome.[33–35] Physiotherapy may also be beneficial for young dogs with polyradiculoneuritis-myositis.

IMMUNITY AND VACCINATION

Immunity to *N. caninum* is dependent on CMI responses. No vaccines for canine neosporosis exist.

PREVENTION

Neosporosis on farms can be prevented by not allowing dogs to access bovine placental materials, dead calves, or raw or undercooked meat and by preventing dogs from defecating around livestock. Predation should also be discouraged. The use of a muzzle for dogs that work on farms has been suggested to prevent *Neospora* abortions in cattle.[17] It may be necessary to stop the breeding of bitches that have puppies that develop neosporosis, and the owners of puppies that are diagnosed with neosporosis should be advised to inform the breeder of the diagnosis. No drugs are known to prevent transplacental transmission. Where possible, avoidance of excessive pharmacologic immunosuppression (e.g., with glucocorticoids, cyclosporine, azathioprine, or other immunosuppressive drugs) may help to prevent the disease in adult dogs. However, the relative rarity of reactivated neosporosis in adult dogs does not justify routine serologic screening of dogs for infection before commencing immunosuppressive drug treatment.

PUBLIC HEALTH ASPECTS

Antibodies against *N. caninum* have been detected in the serum of some humans, including those with current HIV antibodies.[68,69] However, in one small study of women with repeated abortion, no link to *N. caninum* was found.[70] Most recently, none of the 600 human clinical samples that were from people with signs of toxoplasmosis but negative for *T. gondii* were positive for DNA of *N. caninum*.[71] Overall, the evidence to date suggests that *N. caninum* is not a significant zoonosis. However, it is still prudent for pregnant or immunosuppressed people to wear gloves or wash hands carefully while gardening or cleaning up canine feces and to avoid undercooked meats, particularly beef for this agent.

CASE EXAMPLE

Signalment

"Lenny," a 6-year-old intact male Rhodesian ridgeback from coastal northern California.

History

Lenny was evaluated on a referral basis for a 1-week history of an abnormal gait. The owner first noticed that Lenny was not paying attention during an obedience show. Over the next few days, Lenny was observed to stumble on stairs, and he also fell from a bed. For the 3 days before evaluation, the owner had noted that Lenny appeared uncoordinated and off balance. There had been no changes in his mentation and no evidence of inappetence, vomiting, diarrhea, or changes in thirst or urination. A soft, intermittent nonproductive cough had been noted since the onset of the other clinical signs. Bloodwork at a local veterinary clinic showed a normal CBC, increased activity of serum CK (2,922 U/L, reference range [RR]: 10–200 U/L), ALT (155 U/L, RR: 5–60 U/L), and AST (135 U/L, RR: 5–55 U/L). Serum thyroxine concentration was within the reference range. A urinalysis was unremarkable and aerobic bacterial urine culture was negative. Serology for antibodies to *Borrelia burgdorferi*, *Anaplasma* spp., *Ehrlichia* spp., and antigen of *Dirofilaria immitis* (SNAP 4Dx Plus test, IDEXX Laboratories) was negative. A *T. gondii* titer was pending. Lenny was treated with clindamycin (7.5 mg/kg, PO, q12h) and doxycycline (5 mg/kg, PO, q12h) with no signs of improvement.

Lenny had traveled extensively to Iowa, Colorado, and Kentucky but had no history of toxin exposure or trauma. He was fed a raw diet that consisted of turkey necks, chicken meat, lamb, and vegetables. He was up to date on routine vaccinations (distemper, adenovirus, parvovirus, and rabies) and on heartworm prophylaxis, but did not receive flea or tick prophylaxis and had been exposed to ticks in the past. He had been bred once and only one of three puppies survived. There was no other significant medical history.

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 40.2 kg.

General: Bright and alert, hydrated. T = 100.5°F (38.1°C), HR = 80 beats/minute, panting, mucous membranes pink and moist, CRT = 1 second.

Musculoskeletal: BCS was 4/9. Truncal ataxia was present with a wide-based stance (see Neurologic examination). There was no evidence of lameness or muscle atrophy.

All other systems: With the exception of the neurologic examination, no other clinically significant abnormalities were detected.

Neurologic examination: The dog was alert and responsive. Truncal ataxia was present with hypermetria that was most pronounced on the left side. Head tremors were also noted. A slight left-sided head tilt was present, together with a decreased to absent menace response on the left side. There was normal physiologic nystagmus and no evidence of spontaneous nystagmus. Delayed placing reactions were detected in all four limbs but were most pronounced on the right side. Spinal reflexes were within normal limits. Neuroanatomic location: cerebellar/vestibular disease.

Laboratory Findings

Muscle biochemistry panel: AST 85 U/L (21–54 U/L), CK 1,683 U/L (46–320 U/L).

Imaging Findings

Thoracic radiographs and abdominal ultrasound examination: No abnormalities were detected.

Magnetic resonance imaging (brain): On T2-weighted images, there was increased intensity of the vermis and left cerebellar hemisphere. The cerebellum appeared normal on T1-weighted images. Subtle regions of contrast enhancement were suspected in the left cerebellum on sagittal T1-weighted postcontrast images.

Other Testing

CSF analysis: Total nucleated cell count (TNCC) was 62 cells/μL (normal < 2 cells/μL); total protein was 75 mg/dL (normal < 25 mg/dL). There were 86% eosinophils, 8% small mononuclear cells, 5% large mononuclear cells, and 1% nondegenerate neutrophils. The large mononuclear cells were mostly of unremarkable morphology but occasionally had mildly increased cytoplasmic vacuolation. No infectious agents were seen.

Microbiologic Testing

Serologic testing (IFA): *Neospora caninum* serum antibody titer positive at 1:20,480; the CSF titer was 1:640.

Zinc sulfate fecal flotation: Negative for parasite ova.

Fecal Baermann examination: Negative for parasite larvae.

Treatment

Before the *Neospora* titers were available, a diagnosis of eosinophilic meningoencephalitis was made, and the dog was treated with prednisone (0.5 mg/kg, PO, q12h) but showed no clinical improvement over the subsequent 3 days. A second CSF specimen collected at that time had a cell count of 37 cells/μL and a total protein concentration of 59 mg/dL, with no change in the differential cell count. Lenny was discharged from the hospital, and once the *N. caninum* serology results became available (1 week later), treatment with trimethoprim-sulfamethoxazole (15 mg/kg, PO, q12h) and ponazuril (10 mg/kg, or 2.5 mL of 15% ponazuril paste, PO, q24h) was added. A baseline Schirmer tear test (performed to monitor for keratoconjunctivitis sicca secondary to sulfamethoxazole) was negative. At a recheck examination 3 weeks later, all neurologic signs were persistent but mildly improved. A CBC showed mild, nonregenerative anemia (34.9%) and mild bandemia (198 cells/μL). Serum CK activity was 88 U/L. CSF analysis showed a total protein concentration of 33 mg/dL and a TNCC of 2 cells/μL, with 0% eosinophils, 51% small mononuclear cells, and 49% mildly reactive large mononuclear cells. The serum and CSF antibody titers to *N. caninum* were both 1:5,120. A Schirmer tear test was normal. Two weeks later, the trimethoprim-sulfamethoxazole was discontinued. Neurologic signs persisted but continued to show mild but slow improvement over the next 3 weeks. The ponazuril was discontinued, but after an additional 3 weeks, the head tremors worsened slightly. Blood work was unchanged, CSF analysis (cisternal and lumbar) was within normal limits, and serum and CSF *N. caninum* antibody titers were 1:1,280 and 1:640, respectively. The prednisone was also discontinued. Two months later (4 months after initial diagnosis), severe ataxia and falling returned over a 2-week period. The owner declined reinstitution of antiprotozoal treatment and elected euthanasia. A complete necropsy revealed severe, locally extensive, necrotizing granulomatous encephalitis that was localized to the cerebellum. Abundant protozoal cysts were present within the cerebellar lesions, which were identified using immunohistochemical stains as *N. caninum*. Protozoa were not visualized in any other tissues.

Diagnosis

Granulomatous cerebellitis secondary to *N. caninum* infection.

Comments

Neosporosis in this dog resulted from cerebellar encephalitis, which illustrated the suggested predilection of *N. caninum* for the cerebellum. Development of encephalitis rather than polyradiculoneuritis-myositis is typical of neosporosis in adult dogs. It is possible this dog contracted neosporosis as a result of consumption of a raw food diet; tissue cysts have been identified in the CNS tissues of a lamb,[72] and chickens are possibly intermediate hosts based on seropositivity and positive PCR assay results on the brain tissue.[18–20] The inflammatory response in the CSF was profoundly eosinophilic, as previously reported in other dogs with neosporosis. Fecal flotation was negative for *N. caninum* oocysts, which is expected given the life cycle of the parasite and the short shedding period with low numbers of oocysts shed. The fecal examinations were performed to evaluate for the possibility of visceral larva migrans, given the CSF eosinophilia. Although treatment with trimethoprim-sulfamethoxazole and then ponazuril led to resolution of CSF abnormalities, clinical signs showed only mild improvement. Treatment of neosporosis with glucocorticoids remains controversial, but attempts to reduce the prednisone dose were associated with worsening of clinical signs. Ultimately, all treatment was discontinued because of minimal improvement in clinical signs but resolution of laboratory abnormalities. Relapse subsequently ensued, and the diagnosis was confirmed at necropsy.

Sarcocystosis

Jitender P. Dubey, Jane E. Sykes

KEY POINTS

- Cause: Protozoan parasites belonging to order Apicomplexa, family Sarcocystidae. There are more than 200 named species of *Sarcocystis.*[1] Disease in dogs and cats results from infection with *Sarcocystis neurona* or *S. neurona*-like organisms, *Sarcocystis felis*, *Sarcocystis canis*, and *Sarcocystis caninum.*
- First Described: The encysted stage of the parasite (sarcocyst: in Greek, sarkos = flesh, kystis = bladder) was first found in the muscle of a house mouse in 1843,[2] but its life cycle remained unknown until 1970. Natural sarcocyst infection was reported in dogs in 1966[3] and in cats in 1986.[4]
- Affected Hosts: Most warm-blooded animals, humans, and some cold-blooded animals.
- Intermediate and Definitive Hosts: These vary with each *Sarcocystis* species.
- Geographic Distribution: Worldwide. Some species may be confined to geographic locations defined by the distribution of definitive or intermediate hosts. For example, *S. neurona* is confined to the Americas, dependent on the geographic location of its definitive host, the opossum (*Didelphis* spp.).
- Route of Transmission: Definitive hosts become infected by ingestion of muscles of an infected intermediate host. Intermediate hosts are infected by ingestion of food or water that has been contaminated with sporocysts.
- Major Clinical Signs: These depend on the *Sarcocystis* species and the specific intermediate hosts infected, but include fever, lethargy, neurologic signs (*S. neurona*), muscle pain, weakness (myositis due to sarcocysts), and icterus as a result of hepatitis (*S. canis*, *S. caninum*).
- Differential Diagnosis: Toxoplasmosis, neosporosis, hepatozoonosis, rabies, CDV infection, infectious canine hepatitis, West Nile virus infection, canine monocytic ehrlichiosis, RMSF, deep mycoses, migrating ascarid infections, neuronal storage diseases, granulomatous or eosinophilic meningoencephalitis, immune-mediated neuromuscular diseases, primary or metastatic neoplasia.
- Human Health Significance: Humans can be definitive and intermediate hosts for certain species of *Sarcocystis.* However, *Sarcocystis* species of dogs and cats do not infect humans.

ETIOLOGY AND EPIDEMIOLOGY

Sarcocystis spp. are obligatory intracellular protozoal pathogens that resemble *Toxoplasma* and *Neospora*. The epidemiology of *Sarcocystis* spp. is dependent on the various hosts involved in the organism's complex life cycle, which includes an asexual phase that culminates in the form of schizonts then sarcocysts in tissues of intermediate hosts, and a sexual cycle with formation of oocysts containing sporocysts in the small intestine of a definitive host (Fig. 95.1). Although infections occur worldwide, the distribution of the intermediate host involved affects the geographic distribution of some *Sarcocystis* spp.

Dogs and cats are definitive hosts for more than 40 species of *Sarcocystis*.[1] The life cycles of these *Sarcocystis* species are largely unknown. When dogs and cats act as definitive hosts, infection appears to be subclinical. In contrast, when dogs and cats act as intermediate hosts, infections can be clinical or subclinical. Sarcocysts have been found in the skeletal muscles or myocardium of dogs and cats worldwide, including dogs from India[3] and Kenya,[5] cats from Chile, and dogs and cats from the United States.[6] These animals typically died or were euthanized for other conditions, such as neoplasia, and sarcocysts were detected as an incidental finding.

Clinical infections can involve the CNS, muscles, liver, and less often the skin and respiratory tract, depending on the *Sarcocystis* species involved. Disease is rare, but has been described in dogs and cats as a result of infection with *Sarcocystis canis*, *Sarcocystis neurona*-like organisms, and *Sarcocystis caninum* (Table 95.1). Lower numbers of sarcocysts of another species, *Sarcocystis svanai*, were detected in the muscles of a dog from Colorado that had severe myositis and larger numbers of *S. caninum* sarcocysts, as well as in a dog from Finland with necrotizing myositis and *S. caninum* co-infection.[7] Dogs and cats with severe *Sarcocystis* infections frequently have underlying immunosuppression, due to young age,[8,9] concurrent CDV infection,[9,10] or immunosuppressive drug treatment.[11] Affected adult dogs often reside in rural areas and many have had a history of ingestion of wildlife feces, carrion, or prey.

Sarcocystis neurona is the principal parasite associated with equine protozoal encephalomyelitis. The Virginia opossum (*Didelphis virginiana*) is its definitive host in North America (see Fig. 95.1). The opossum's range includes the eastern half of the United States, the Pacific Coast states, and Mexico, with lesser population numbers in the northern states. Several other animal species, including dogs, cats, rodents, primates, marine mammals, birds, and horses, act as intermediate or aberrant hosts. Animals that ingest oocysts from opossums and serve as intermediate hosts are the nine-banded armadillo (*Dasypus novemcinctus*), striped skunk (*Mephitis mephitis*), raccoon (*Procyon lotor*), sea otter (*Enhydra lutris*), and domestic cats.[12–16] These animals develop muscle sarcocysts and are capable of infecting new opossums that ingest their carrion. Sarcocysts have been identified in the skeletal and cardiac muscles of free-ranging wild felids.[17,18] Horses are incidental or aberrant dead-end hosts because they develop encephalomyelitis with lesions only within the CNS; muscle sarcocysts have not been confirmed. Fatal encephalomyelitis with an organism that resembles *S. neurona* has also been described in Canadian lynx (*Lynx*

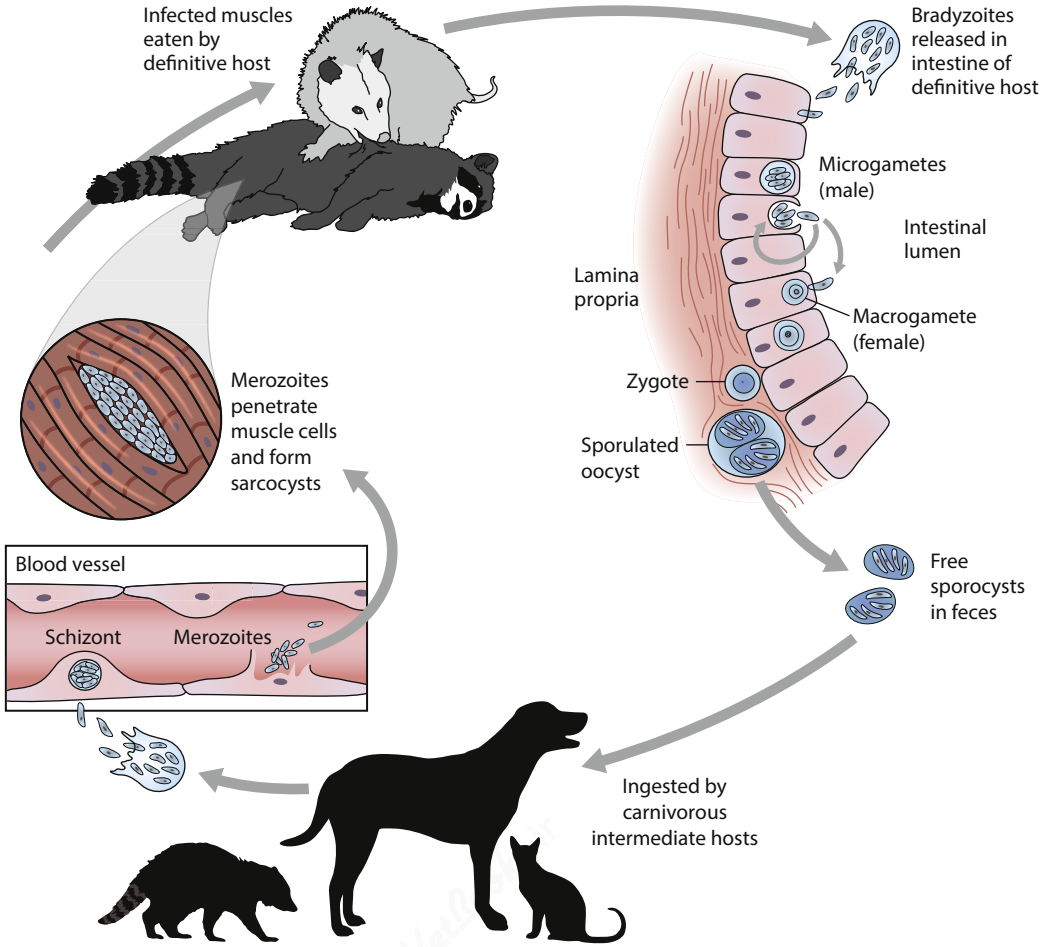

Fig. 95.1 Life cycle of *Sarcocystis*. After ingestion of infected muscles of intermediate host containing the *sarcocyst* stage, bradyzoites enclosed in the sarcocyst are released in the gut lumen and penetrate enterocytes, and transform into male and female gamonts. After fertilization, *oocysts* are formed in the lamina propria of small intestine. Oocysts sporulate *in situ* and sporulated oocysts contain two *sporocysts*, each with four sporozoites. Sporulated oocysts, but more often, sporocysts are excreted in feces. Because oocysts are trapped in the lamina propria, they are released at irregular intervals, even several months after initial infection. The intermediate host becomes infected by ingesting food or water contaminated with sporocysts. The replicative cycle in intermediate hosts varies depending on the *Sarcocystis* species involved. In general, sporozoites released from sporocysts penetrate the intestine and form *schizonts*, often in endothelial cells. After one or more replicative cycles, the organisms encyst in the muscle as sarcocysts, where they wait to be ingested by a carnivore.

TABLE 95.1 *Sarcocystis* Species that Cause Disease in Dogs and Cats and Associated Clinical Syndromes

Sarcocystis Species	Affected Host Species	Clinical Manifestations
Sarcocystis canis	Dogs	Hepatitis, meningoencephalomyelitis, pneumonia, dermatitis
Sarcocystis neurona or *S. neurona-like*	Dogs, cats	Meningoencephalomyelitis, chorioretinitis, myositis
Sarcocystis caninum/ *Sarcocystis svanai*	Dogs	Hepatitis, myositis

canadensis), raccoons, striped skunks, American mink (*Mustela vison*), Pacific harbor seals (*Phoca vitulina*), and nonhuman primates such as the rhesus monkey (*Macaca mulatta*) and lemurs (*Eulemur macaco*, *Lemur catta*). An atypical disseminated infection was described in a white-nosed coati (*Nasua narica molaris*) that had been housed for over 10 years at the Philadelphia Zoo, United States.[19] Experimentally and naturally, domestic cats have been shown to be intermediate hosts of *S. neurona*, although results have varied with individual isolates.[20] Cats experimentally fed sporocysts shed by opossums develop schizonts in their tissues and sarcocysts in their muscles, and infected cats develop high antibody titers (e.g., 1:4,000).[21,22] Opossums excrete *S. neurona* sporocysts after they are fed tissues from cats that contain sarcocysts.[14,21] There are rare reports of severe *S. neurona* or *S. neurona*-like infections in dogs and cats from the eastern, central, and southern United States, usually with CNS signs associated with the schizont stage.[23–28] Serum antibodies to *S. neurona* were detected in 13% of 310 farm cats from Ohio,[29] 9% of 232 cats from Virginia,[30] 5% of 209 cats from Pennsylvania,[30] and 5% of 196 domestic cats from Michigan whose sera were submitted for *Toxoplasma gondii* antibody testing.[31]

Sarcocystis canis has been associated with hepatic, pulmonary, cutaneous, and/or CNS infections in puppies less than 10 months of age.[8–10] Reported cases have been from Maryland, Kansas, and Colorado (United States), and one dog from Costa Rica. *Sarcocystis canis* has also been

reported as a cause of hepatitis in a California sea lion and a Steller sea lion from Alaska, a striped dolphin from Spain, a Hawaiian monk seal, polar bears, a chinchilla, a horse, and a black bear.[32] Genetic characterization of the organism has been based on DNA extracted from the liver of wildlife species with hepatitis.[32] The definitive host of *S. canis* is unknown.

Sarcocystis caninum has been identified as a cause of systemic illness and myositis/necrotizing myopathy in domestic dogs from Canada, Finland, and the United States.[7,11,33,34] *Sarcocystis caninum* sarcocysts also were identified in the muscle tissue from 2 of 37 dogs on sale for dog meat consumption at a market in southwestern China.[35] The life cycle of this organism is also unknown.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After ingestion of infected muscles of intermediate host containing the sarcocyst stage, bradyzoites enclosed in the sarcocyst are released in the gut lumen and penetrate enterocytes, and transform into male and female gamonts. After fertilization, oocysts are formed in the lamina propria of small intestine. Oocysts sporulate *in situ* and sporulated oocysts contain two sporocysts, each with four sporozoites. Sporulated oocysts, but more often, sporocysts are excreted in feces. Because oocysts are trapped in the lamina propria, they are released at irregular intervals even several months after initial infection. The intermediate host becomes infected by ingesting food or water contaminated with sporocysts. The replicative cycle in intermediate hosts varies depending on the *Sarcocystis* species involved. In general, sporozoites released from sporocysts penetrate the intestine and form schizonts, often in endothelial cells. After one or more replicative cycles, the organisms encyst in the muscle as sarcocysts, where they wait to be ingested by a carnivore.

Sarcocystis canis

Sarcocystis canis can cause hepatitis, meningoencephalitis, and pneumonia in dogs, with most reports involving puppies.[8–10] Clinical signs have been complicated by comorbidities such as CDV and *Blastomyces* spp. infection, but include fever, lethargy, vomiting, diarrhea, cough, abdominal effusion, dehydration, obtundation, ataxia, abnormal placing reactions, circling, nystagmus, and seizures.[8–10] The life cycle of *S. canis* is unknown. Organisms that are morphologically similar to *S. canis* have also been found in noncanid carnivores and marine mammals,[36–38] although application of molecular methods is needed to confirm these are truly *S. canis*. In these intermediate hosts, only schizonts are present, and they are primarily confined to the liver. Recently, molecular methods were used to identify infection with an *S. canis*-like organism as well as *Sarcocystis arctosi* in a grizzly bear with fatal hepatic sarcocystosis.[39]

Sarcocystis neurona

Most dogs and cats with *S. neurona* infections have had neurologic signs secondary to meningoencephalomyelitis.[25–27,40] One dog with pelvic limb paresis was treated with glucocorticoids, and after temporary remission of signs, the dog developed progressive tetraparesis with recumbency and hyperesthesia.[27] On retrospective examination, dogs with neurologic sarcocystosis originally attributed to *S. canis* were found to be infected with *S. neurona*, and organisms were found in extraneural tissues of some dogs.[40] One dog had chorioretinitis in addition to meningoencephalitis.[26] *Sarcocystis neurona* infection was also described in a dog with myositis and muscle atrophy.[41] Sarcocysts were found in many skeletal muscles. PCR testing confirmed *S. neurona* in the muscle tissue, although the dog had received immunosuppressive therapy for its clinical illness, and whether the cysts were a cause of the disease or effect of therapy was uncertain.

Sarcocystis neurona–associated meningoencephalomyelitis was described in a 13-week-old Burmese kitten from California with progressive lethargy, vocalization, and hemiparesis.[28] Another 12-week-old kitten from Illinois developed progressive neurologic signs with ataxia 3 days after castration.[23] A third report described a 5-month-old domestic shorthair from Indiana with fever, dull mentation, spinal pain, muscle fasciculations, ataxia, postural reaction deficits, hyperesthesia, and anisocoria.[24] An *S. neurona*-like organism was detected in the brain tissue using molecular analysis.

Sarcocystis caninum

Dogs infected with *S. caninum* have had a biphasic illness characterized by variable fever, lethargy, anorexia, ptyalism, diarrhea, dehydration, icterus, thrombocytopenia, hyperbilirubinemia, and increased serum liver enzyme activities, followed by development of generalized muscle stiffness, muscle atrophy and weakness, muscle pain, delayed placing reactions, decreased segmental reflexes, and increased CK activity.[11] The latter phase resembles a systemic immune-mediated neuromuscular disease. The dog from Finland that was co-infected with *S. caninum* and *S. svanai* had signs of nonambulatory tetraparesis, and decreased to absent placing reactions, but no evidence of muscle pain.[7]

DIAGNOSIS

A diagnosis of sarcocystosis should be considered in young (<1 year) or immunosuppressed dogs and cats with systemic signs of illness, especially involving the liver, CNS, or muscle. Diagnosis most often relies on detection of protozoal organisms in tissues using light microscopy and/or PCR assays. Diagnosis of intestinal infections is dependent on microscopic examination following centrifugal zinc sulfate fecal flotation.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemistry Panel, and Urinalysis

There are no specific hematologic or biochemical abnormalities that suggest sarcocystosis. When laboratory findings have been reported, the CBC has been normal or there has been evidence of mild nonregenerative anemia, neutrophilia with a left shift and toxic change, monocytosis or monocytopenia, lymphopenia, or mild to moderate eosinophilia (up to 6,300 cells/μL).[7,8,11,25,33,34] Some affected dogs and cats have had thrombocytopenia. On the serum chemistry panel, abnormalities have included hypoalbuminemia, moderate to severe elevations in the activity of serum ALT (655–3,436 U/L), mild to moderate elevations in the activity of serum ALP (312–2,203 U/L), mild to moderate hyperbilirubinemia, and/or increased CK activity (623–13,206 U/L).[8,11,33,34] One dog with *S. caninum*/*S. svanai* myopathy had only increased activity of serum AST (459 U/L) and CK (5,018 U/L).[7] The urinalysis may be normal or show bilirubinuria.

Cerebrospinal Fluid Analysis

Findings on CSF analysis in dogs and cats with sarcocystosis have been reported rarely. One dog with neuromuscular disease due to *S. caninum* had a mild increase in CSF protein concentration (62 mg/dL).[11] A dog with encephalomyelitis secondary to infection with *T. gondii* and *S. neurona* had lymphocytic pleocytosis (70 cells/μL) and a moderate increase in CSF protein concentration (260 mg/dL).[25] A dog seen at the author's institution with *Sarcocystis* meningoencephalitis was initially diagnosed with eosinophilic meningoencephalitis because the CSF had a total nucleated cell count of 117 cells/uL with 23% eosinophils, 34%

small mononuclear cells, 40% large mononuclear cells, and 3% neutrophils, with 54 mg/dL protein.[42] In contrast, a cat with *S. neurona* encephalomyelitis had neutrophilic pleocytosis with both intracellular and extracellular merozoites.[24] Intracellular merozoites were also described in the CSF of a dog infected with *S. neurona*.[26]

Diagnostic Imaging

Reports of diagnostic imaging findings in dogs and cats with clinical sarcocystosis have been limited. Findings on thoracic radiography in two dogs were normal.[8,11] Hepatomegaly has been described on abdominal radiography and ultrasound examination in dogs with hepatitis.[8,34] Abdominal lymphadenomegaly and mild peritoneal effusion also have been described on abdominal ultrasound examination.[8,34] MRI of the thoracolumbar spine of a dog that was co-infected with *S. neurona* and *T. gondii* revealed focal spinal cord enlargement at T4 to T6 and L2 to L4, with asymmetric intramedullary parenchymal T2 hyperintensity with associated contrast enhancement in these regions.[25] A dog with suspected *S. canis* meningoencephalitis at the author's institution had multifocal T2- and FLAIR-hyperintense, contrast-enhancing regions throughout the cerebrum, thalamus, midbrain, and brainstem with meningeal enhancement (Fig. 95.2). Evidence of mandibular lymph node reactivity was also present.

Electrodiagnostic Testing

Electrodiagnostic findings were described in one dog from the United States with *S. caninum* myositis[11] and the dog from Finland with *S. caninum/S. svanai* myopathy.[7] Electromyography (EMG) in the first case showed spontaneous activity with increased insertional activity and fibrillation potentials in a generalized distribution. There was marked decrease in motor nerve conduction velocity, and compound motor unit amplitudes were decreased with dispersion. In the dog from Finland, EMG evaluation revealed no changes in insertional activity and no spontaneous activity. Motor nerve conduction velocity was normal and compound motor unit amplitudes showed temporal dispersion with no decrement following repetitive nerve stimulation.[7]

Microbiologic Tests (Table 95.2)

Cytologic Examination

Cytological diagnosis of *Sarcocystis* infections has been reported in a cat and a dog with *S. neurona* encephalomyelitis. *Sarcocystis* merozoites were observed intracellularly and extracellularly in the CSF, and measure 2–4 μm × 4–6 μm (Fig. 95.3).[24,26]

Fecal Flotation

Fecal flotation with sugar or zinc sulfate solutions can be used to detect the sporocysts of *Sarcocystis* in feces. However, clinically affected dogs do not typically excrete oocysts. *Sarcocystis* is excreted in feces fully sporulated, often as free sporocysts when examined (Fig. 95.4). It is not possible to differentiate the species based on sporocyst size or appearance using light microscopy. Free sporocysts are small and not very dense, so they lie at a different plane of focus than other parasites.

Serology

Serologic assays for diagnosis of *Sarcocystis* infections in dogs and cats are not available commercially. Diagnosis of *S. neurona* infection in horses has involved immunoblot testing for specific antibodies to *S. neurona* in CSF, but this is not commercially available for dogs and cats due to the need for feline- and canine-specific antibody conjugates. Infected dogs and cats most often have negative antibody titers to *Toxoplasma* and *Neospora*. Nevertheless, positive antibody titers have been described,[11,33] possibly as a result of previous exposure to these pathogens.

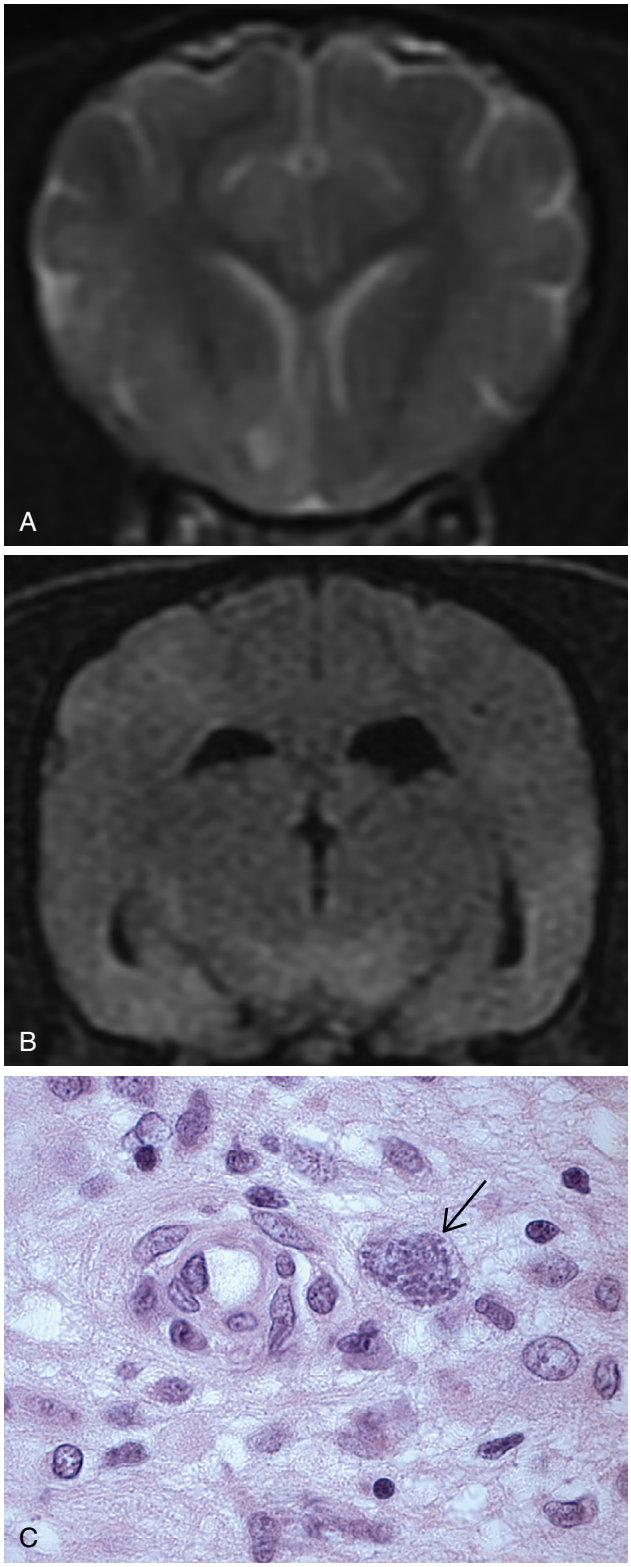

Fig. 95.2 (A, B) Magnetic resonance images of an 8-month-old dog (papillon mix) with *Sarcocystis* meningoencephalomyelitis. The dog had acute onset of vomiting and diarrhea followed by seizures, head-pressing, vocalization, and pacing. Multifocal T2 (A) and FLAIR (B) hyperintense, contrast-enhancing regions were apparent throughout the cerebrum, thalamus, midbrain, and brainstem with meningeal enhancement. At necropsy, abundant intralesional *Sarcocystis* spp. cysts were found throughout the brain parenchyma (C, *arrow*). (Courtesy University of California, Davis Diagnostic Imaging, Neurology/Neurosurgery, and Anatomic Pathology Services.)

TABLE 95.2 Diagnostic Assays Available for Sarcocystosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Fecal flotation	Feces	*Sarcocystis* sporocysts	Dogs with clinical sarcocystosis typically do not excrete oocysts, so this is not used for diagnosis.
Cytologic examination	CSF, tissue aspirates	*Sarcocystis* merozoites	Insensitive. Confirms active infection. Organisms resemble *Toxoplasma gondii* or *Neospora* tachyzoites.
Histopathology	Muscle biopsies, multiple tissues collected at necropsy	*Sarcocystis* sarcocysts, schizonts, merozoites	If organisms are detected in the presence of inflammation and necrosis, clinical sarcocystosis is likely. Immunohistochemistry can aid in the differentiation of *Sarcocystis* from *Toxoplasma* and *Neospora*.
PCR assay	Muscle biopsies, body fluids (especially CSF), tissues collected at necropsy	*Sarcocystis* DNA	Assay performance may vary between laboratories. Because positive PCR results can occur in healthy animals, they must be interpreted in light of clinical signs and other findings in the specimens tested. May not readily distinguish between *Sarcocystis* species.

CSF, cerebrospinal fluid; *PCR,* polymerase chain reaction.

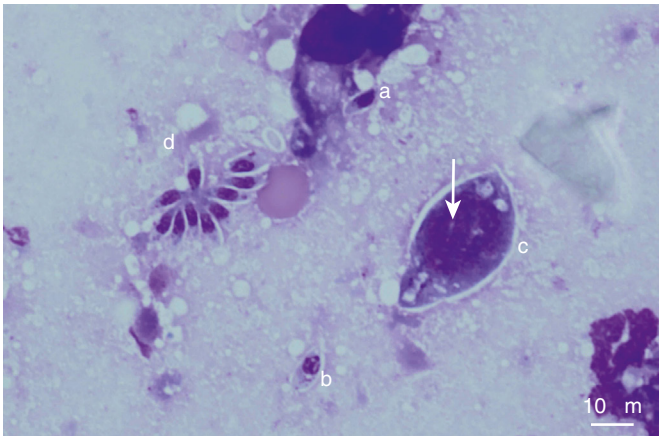

Fig. 95.3 *Sarcocystis* spp. merozoites and schizonts in varying stages of development; depicted are a merozoite *(a)*, a merozoite transitioning to a schizont *(b)*, an immature schizont with a large undivided nucleus *(arrow) (c)*, and a mature schizont with merozoites attached to a residual body *(d)*. Note erythrocyte for size comparison.

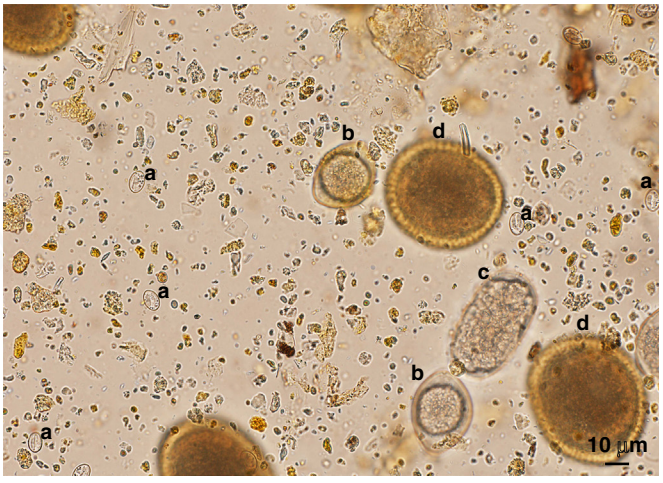

Fig. 95.4 Fecal flotation showing several *Sarcocystis* sporulated sporocysts *(a)*, *Cystoisospora felis* oocysts *(b)*, *Ancylostoma* egg *(c)*, and *Toxocara* egg *(d)*. Note that *Sarcocystis* is excreted sporulated, whereas *C. felis* is excreted unsporulated.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays are commercially available for detection of *S. neurona* in horses and could be used on the CSF or aspirates of affected tissues from dogs and cats suspected to have *S. neurona* infections, although the clinical sensitivity of these assays in dogs and cats is unknown. Broad-spectrum *Sarcocystis* PCR assays that amplify 18S and ITS-1 gene sequences have been used on a research basis for diagnosis.[11,24,27,34,40,41] Sequence analysis of PCR products has limited ability to distinguish among *Sarcocystis* species, and typically species identification is based on sequence analysis of the ITS-1 gene combined with phenotypic characteristics of the organisms using light and transmission electron microscopy (e.g., sarcocyst ultrastructure, lack of rhoptries in *S. canis*). As is the case for *Neospora* and *Toxoplasma*, PCR results must always be interpreted in light of clinicopathologic findings, because *Sarcocystis* DNA can be detected in tissues from healthy dogs and cats.

Pathologic Findings

Gross lesions at necropsy may be absent, or findings such as hepatomegaly, muscle atrophy, or spinal cord swelling and discoloration may be present.[8] Histopathologic abnormalities in dogs and cats with clinical *Sarcocystis* infections of the CNS have typically included granulomatous or pyogranulomatous necrotizing meningoencephalomyelitis with intralesional merozoites and schizonts of varying stages of development (see Fig. 95.3).[26–28,40] Schizonts and merozoites have been reported within neurons and other neuropil cells. The schizonts range in size from 3 to 25 µm × 5–20 µm and contain up to 40 merozoites. The merozoites measure 1–2 × 2–5 µm and form rosettes that may surround a residual body. Perivascular cuffing with mixed mononuclear inflammatory cells (lymphocytes, plasma cells, and histiocytes) and gliosis is commonly reported in the gray and white matter. Lesions have been in the cerebral cortex, caudate nucleus, cerebellum, brainstem, and spinal cord.[23,27,28] One dog with *S. neurona* infection had chorioretinitis in addition to meningoencephalitis, with retinal necrosis and detachment, and merozoites and schizonts in all layers of the retina.[26] There was also significant involvement of skeletal muscle of the tongue. Dogs with *Sarcocystis* hepatitis have had often widespread hepatic necrosis and hepatic vasculitis with infiltrates of eosinophils, neutrophils, lymphocytes, and plasma cells.[8,10,40] In one dog, many hepatocytes were reported to contain merozoites, sometimes forming rosettes.[8] Pulmonary *Sarcocystis* infections in dogs have been characterized by necrotizing bronchiolitis and schizonts within endothelial cells, epithelial cells, or macrophages, with concurrent evidence of co-infections with organisms such as CDV.[9] The presence of multinucleated giant cells has

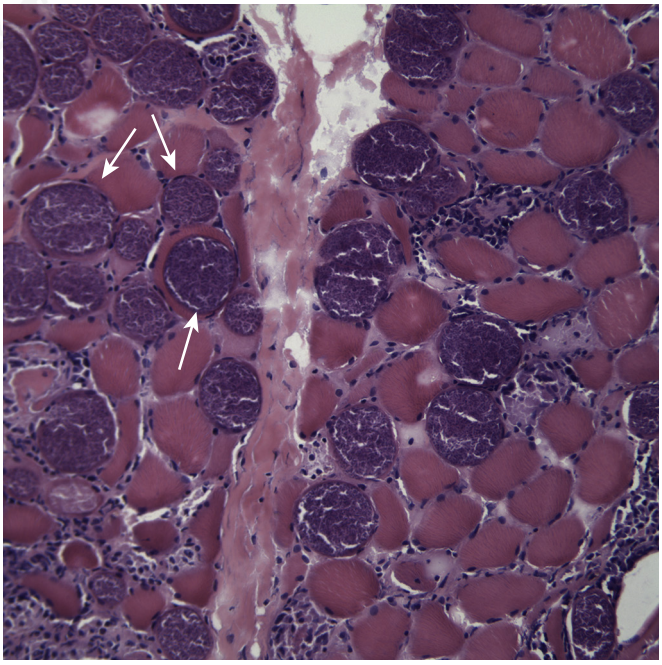

Fig. 95.5 Hematoxylin and eosin–stained cryosection of a biopsy from the deep digital flexor muscle of an 11-year-old male neutered golden retriever with myositis showing numerous myofibers containing large and encapsulated parasite cysts that were confirmed to be *Sarcocystis* spp. (200× magnification). (Reprinted from Sykes JE, Dubey JP, Lindsay LL, et al. Severe myositis associated with *Sarcocystis* spp. infection in 2 dogs. *J Vet Intern Med.* 2011;25:1277–1283.)

been reported in a variety of tissues from multiple dogs and cats with *Sarcocystis* infections.[25,26,33,40] Dogs with *S. caninum* myositis have necrotizing myositis with mixed mononuclear cell to pyogranulomatous inflammation and intracellular sarcocysts, which measure up to 1200 µm long and 25 to 75 µm wide (Fig. 95.5).[7,11] The sarcocysts have a thin wall and contain metrocytes peripherally and differentiating bradyzoites centrally. The single dog with myositis thought to be secondary to *S. neurona* infection had necrotizing, pyogranulomatous myositis with intralesional cysts that were smaller (40–100 µm × 15–40 µm) than those described for *S. caninum*. The cysts contained many circularly arranged metrocytes.[41]

IHC can be used to increase sensitivity for detection of parasitic stages and can help distinguish between *Sarcocystis* infection and infection with *Toxoplasma* and *Neospora*. Tissues from affected dogs and cats have not reacted to *Toxoplasma* and *Neospora* antisera, but had positive reactions to *Sarcocystis cruzi* or *S. neurona* antisera.[9,10,23,27,28,33,41] However, *S. canis* does not appear to react with *S. neurona* antisera.[8]

TREATMENT AND PROGNOSIS

Intestinal Infections

Sarcocystis species do not cause clinically relevant intestinal tract lesions in dogs and cats, so treatment of intestinal infections is not necessary.

Extraintestinal Infections

There are few reports of antiprotozoal treatment of dogs and cats with clinical *Sarcocystis* infections because most affected dogs and cats have been diagnosed with sarcocystosis at necropsy. Clinical signs worsened after glucocorticoid therapy in some animals, suggesting that immunosuppression may allow for proliferation of the parasite.

TABLE 95.3 Antimicrobials Used To Treat Sarcocystosis in Dogs and Cats

Drug	Dose (mg/kg)	Route	Interval (hours)	Duration (days)
Clindamycin	10–12	PO	q8h	At least 4 weeks
Trimethoprim-sulfa	15	PO	q12h	At least 4 weeks
Pyrimethamine	1	PO	q24h	At least 4 weeks
Ponazuril	20	PO	q24h	Not determined

Effective treatment of horses has involved the use of ponazuril. Other anticoccidial drugs such as clindamycin, tetracyclines, or antifolate inhibitors might also be considered, especially if parenteral therapy is considered (Table 95.3). A cat with encephalomyelitis thought to be caused by *S. neurona* was treated with ponazuril followed by a combination of clindamycin, pyrimethamine, and trimethoprim sulfonamide, and recovered with the only residual neurologic abnormality being delayed placing reaction in the right thoracic limb.[24] Treatment of a dog infected with *S. caninum* with decoquinate led to resolution of signs of myositis,[11] and two others appeared to respond clinically to treatment with clindamycin.[33,34]

IMMUNITY AND VACCINATION

Immunity to *Sarcocystis* is cell-mediated. No vaccines exist for prevention of disease in dogs and cats.

PREVENTION

Sarcocystis infections can be prevented by cooking all meat fed to animals, prevention of hunting behavior, keeping cats indoors, or feeding only commercially processed diets. Prevention of roaming and coprophagy may reduce the chance that dogs act as intermediate hosts.

PUBLIC HEALTH ASPECTS

Humans can be definitive and intermediate hosts for certain species of *Sarcocystis*. However, *Sarcocystis* species of dogs and cats do not infect humans. The primary public health significance of sarcocystosis is that it can resemble rabies, and a number of dogs and cats with *Sarcocystis* infections were euthanized because of a suspicion for rabies virus infection. The potential for zoonotic transmission in China through consumption of infected dog meat was raised in one study where sarcocysts of *S. caninum* were found in 2 of 37 dogs on sale for dog meat consumption at a market in southwestern China.[35]

Leishmaniosis

Gad Baneth, Christine Petersen, Laia Solano-Gallego, Jane E. Sykes

KEY POINTS

- First Described: The cause of visceral leishmaniasis was first described in India in 1903 (separately by William Leishman and Charles Donovan).[1]
- Causes: Canine and feline leishmaniosis is caused by *Leishmania infantum* (synonymous with *Leishmania chagasi*) (class Kinetoplasta, family Trypanosomatidae). Other species such as *Leishmania braziliensis* cause localized cutaneous lesions in South America (American tegumentary leishmaniosis).
- Affected Hosts: Dogs and less commonly cats; also humans, rodents, wild canids, horses, and marsupial species.
- Geographic Distribution: Primarily southern Europe and the Middle East, Asia, northern Africa, Central and South America; also some parts of the United States. Travel-related disease may occur in nonendemic regions worldwide.
- Mode of Transmission: *Phlebotomus* and *Lutzomyia* spp. sand flies. Transmission through blood transfusion as well as vertical transmission can occur.
- Major Clinical Signs: Weight loss, inappetence, scaling and/or ulcerative non-pruritic cutaneous lesions, onychogryphosis, keratoconjunctivitis, uveitis, lymphadenomegaly, hepatosplenomegaly, pallor, lameness, signs of renal failure.
- Differential Diagnoses: Differential diagnoses in dogs with systemic disease include canine monocytic ehrlichiosis, babesiosis, histoplasmosis, brucellosis, hemic neoplasia, other metastatic neoplasms, and primary autoimmune diseases such as systemic lupus erythematosus. Differential diagnoses for cutaneous lesions in dogs include demodectic mange, pyoderma, *Malassezia* dermatitis, cutaneous vasculitis, and pemphigus foliaceus. Differential diagnoses for cutaneous lesions in cats include cutaneous neoplasia, cutaneous vasculitis, herpesviral dermatitis, and dermatophytosis. The primary differential for American tegumentary leishmaniosis is sporotrichosis.
- Human Health Significance: Human infections are primarily transmitted by sand flies, and are caused by a large number of different *Leishmania* species. Dogs are considered the major reservoir for *L. infantum* infections. Precautions should be taken when handling potentially infected tissue and blood specimens.

INTRODUCTION

The leishmaniases are a group of infectious diseases that affect humans and domestic and wild animals worldwide and are caused by members of the genus *Leishmania*. Leishmaniosis is the preferred term for the disease in animals.[2] The infection is transmitted by sand flies of the genus *Phlebotomus* in the Old World (Europe, Asia, and Africa), and *Lutzomyia* in the New World (South, Central, and North America). Reservoir hosts vary within different geographic areas and can include domestic or wild animals. Leishmaniosis caused by *Leishmania infantum* (synonymous with *Leishmania chagasi*)[3] is a frequent cause of clinical illness in dogs in some regions but is less common in cats.[4] Dogs are the major reservoir for canine and human *L. infantum* infection in an area that stretches from Portugal to China and across South, Central, and parts of North America (Fig. 96.1). As reservoir hosts, dogs can infect feeding sand flies and remain subclinical carriers for extended periods. Canine leishmaniosis is sometimes found in nonendemic countries because of international tourists and immigrants who bring infected pets or because of dog importation. Leishmaniosis due to *L. infantum* has been reported among soldiers returning from Afghanistan.[5,6] Similarly, pet dogs belonging to military personnel and other individuals from *Leishmania*-endemic regions are transported back to the United States. Subclinical dogs can remain healthy for months to years after being introduced or reintroduced to the United States.

This chapter presents a global overview of leishmaniosis, followed by two recognized geographic forms of emerging disease in animals in the New World. The last section is devoted to leishmaniosis in cats.

OVERVIEW OF LEISHMANIOSIS WORLDWIDE

Leishmaniosis is caused by diphasic protozoans of the genus *Leishmania* in the class Kinetoplasta and family Trypanosomatidae. The genus *Leishmania* is divided into the subgenera *Leishmania* and *Viannia* based on differences in the location of parasite development within the sand fly. Organisms of the *Viannia* subgenus (e.g., *Leishmania braziliensis*) replicate in the sand fly hindgut (see Canine American Tegumentary Leishmaniosis, later), in contrast to the midgut replication characteristic of other *Leishmania* species. Several different species are recognized within the *Leishmania* and *Viannia* subgenera, and classification is primarily based on DNA sequence comparisons, electrophoresis migration patterns of isoenzymes (zymodemes), and reactivity to monoclonal antibodies and to membrane-shed antigens.

Phlebotomine sand flies of the genus *Phlebotomus* in the Old World (Europe, Asia, and Africa) and *Lutzomyia* in the New World (the Americas) are the natural vectors of leishmaniosis. Sand flies are small insects with a body length that seldom exceed 3 mm.[7] The biting activity of sand flies is crepuscular (at twilight) and nocturnal. In the Mediterranean and Asia, sand flies are primarily active in the warm months, from spring to late fall. In Latin America, some sand fly species are active throughout the year. Sand flies do not move long distances, and studies have shown that they are seldom dispersed more than 1 km away from their breeding sites. Many species of sand fly exist, but only some of them act as *Leishmania* vectors. Different vector species may be found in distinct geographic regions and ecologic niches. Some sand fly species exclusively transmit only one *Leishmania*

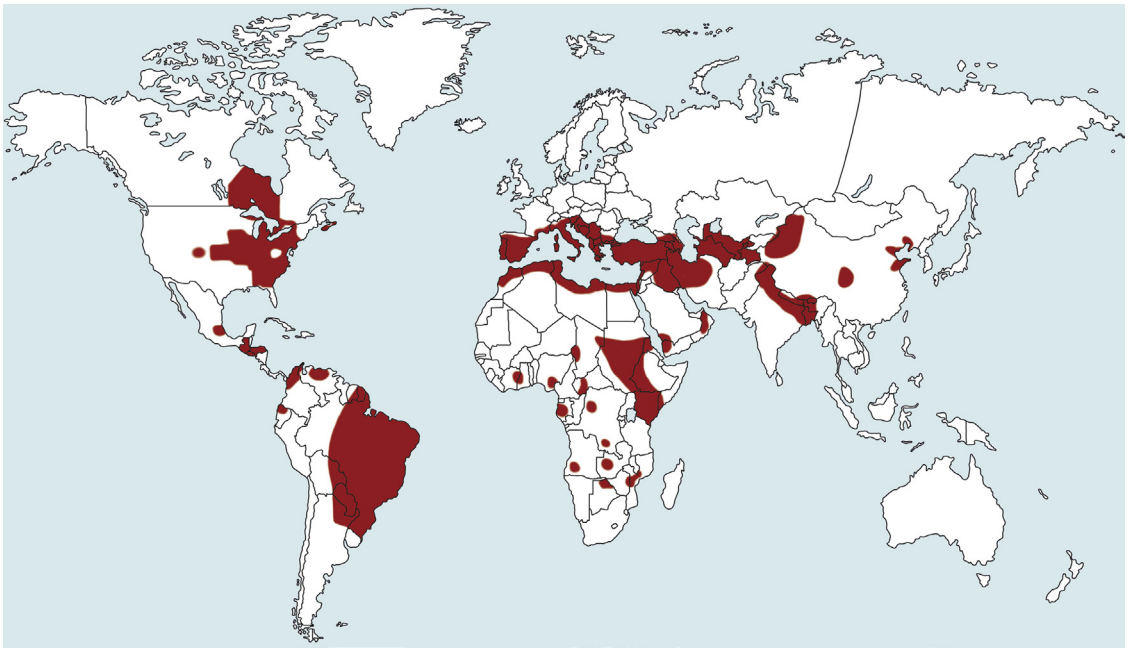

Fig. 96.1 The global distribution of visceral leishmaniosis in humans and dogs.

species, whereas others are vectors for multiple species. The capacity of different sand fly species to act as vectors appears to be related to the ability of promastigotes to specifically bind to ligands in the sand fly gut. When they do not bind to the sand fly gut, the parasites that initially replicated in the gut lumen are excreted with the sand fly feces and presumably do not reach the critical mass needed to infect a host during a second blood meal.[8]

In vertebrate hosts, *Leishmania* is found in macrophages in its nonflagellate form, the amastigote (Fig. 96.2). Amastigotes are ovoid or round, 2.5 to 5 μm long and 1.5 to 2 μm wide. In addition to a basophilic-staining nucleus, a rod-shaped, darker-staining kinetoplast is visible with Wright or Giemsa stain (Fig. 96.3). Amastigotes multiply by binary fission, and then subsequently rupture out of the macrophage to infect new cells. Sand flies can ingest amastigotes when they become engorged with blood from an infected host. In the sand fly gut, amastigotes are released from host cells; transform into the extracellular, flagellated procyclic promastigote (Fig. 96.4); and replicate. In an appropriate vector, there is sufficient replication and regulated molecular changes in the parasite's cell surface and the parasite detaches from the midgut epithelium. This results in anterior migration of infectious metacyclic promastigotes into the foregut and mouthparts of the vector. Promastigotes are injected with saliva into the skin of a vertebrate host when the female sand fly feeds again. After inoculation into the host, the promastigotes lose their flagella and transform back into amastigotes (see Fig. 96.2).

About 30 different *Leishmania* species are found in various parts of the Old World and New World. Of these, about 20 cause a wide spectrum of clinical illnesses in humans.[9] Most *Leishmania* spp. that infect humans are zoonotic, and only a few are strictly anthroponotic (i.e., transmitted directly from human to human via sand flies). Human leishmaniasis is endemic in 88 countries—66 countries in the Old World and 22 in the New World—and affects the world's poorest populations living mainly in rural and suburban areas.[10] Approximately 12 million humans are infected with leishmaniasis, and some 350 million humans are at risk of acquiring the disease, with a yearly incidence of 1 to 1.5 million new cases of cutaneous

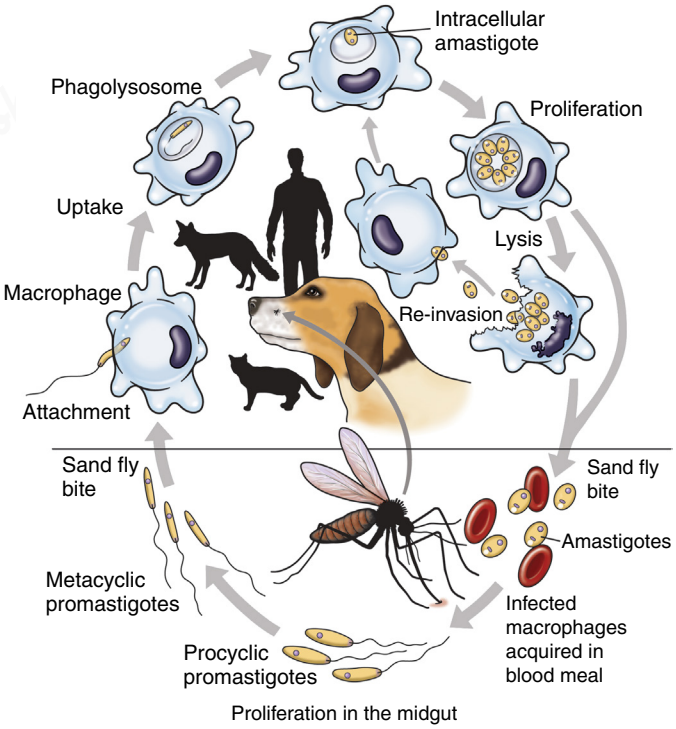

Fig. 96.2 The life cycle of *Leishmania infantum*. Dogs, cats, and humans become infected when they are bitten by a sand fly. Promastigotes are inoculated into the dermis and penetrate macrophages. Within the macrophage, they transform into amastigotes and replicate within a phagolysosome. The macrophage ruptures and new macrophages are infected. If the host fails to control the infection in the skin, amastigotes disseminate via regional lymphatics and the blood to infect the entire reticuloendothelial system. Amastigotes that are ingested by a female sand fly during feeding convert back into promastigotes, and replication of promastigotes within the sand fly completes the life cycle.

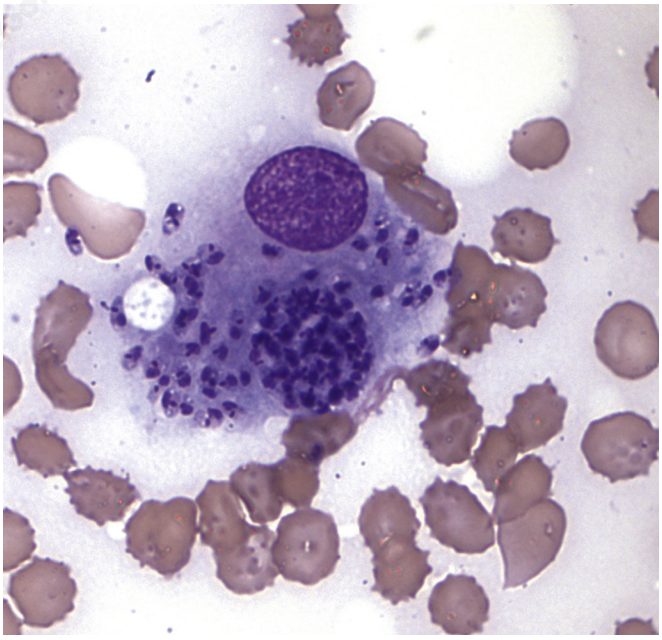

Fig. 96.3 Bone marrow aspirate cytology findings in a dog with leishmaniosis due to *L. infantum*. Numerous *Leishmania* amastigotes can be seen within the cytoplasm of a histiocyte as well as extracellularly. disease and 500,000 new cases of the potentially fatal visceral form.[11,12] Disease caused by the various *Leishmania* spp. in humans is divided into three forms according to clinical features: cutaneous leishmaniasis (CL), mucocutaneous leishmaniasis, and visceral leishmaniasis (VL). Some species cause more than one form. Anthroponotic VL caused by *Leishmania donovani* is responsible for a large part of the fatalities due to the visceral disease in humans and is present in East Africa, Bangladesh, India, and Nepal.[10] Humans are the reservoir hosts for *L. donovani*, and animals do not appear to play a significant role in the anthroponotic epidemiology of infection,[13] although dog ownership has been associated with human leishmaniasis in Ethiopia.[14] The main reservoir hosts for *Leishmania* spp. causing CL and mucocutaneous leishmaniasis in humans are rodents and other wild animal species.[15]

CANINE LEISHMANIOSIS

EPIDEMIOLOGY

Domestic dogs are the main reservoirs for human leishmaniasis caused by *L. infantum* in the Mediterranean basin, Middle East, and South America. The low genetic variability of *L. infantum,* as compared with other species of *Leishmania*, is consistent with its more contemporary importation to the New World; it is thought to have been introduced by infected dogs from Europe that arrived with early settlers to the Americas.[16] Other species of *Leishmania* that infect dogs in different geographic regions include *L. donovani*, *Leishmania tropica, Leishmania major, L. braziliensis, Leishmania mexicana, Leishmania peruviana, Leishmania panamensis*,[17] and *Leishmania amazonensis.*[18]

Seroprevalence studies from Spain, France, Italy, and Portugal estimate that 2.5 million dogs in these countries are infected with *L. infantum*, and infection is spreading north in Europe, reaching the foothills of the Alps,[19] Pyrenees,[20] and northwestern Spain.[21] The number of infected dogs in South America is in the millions, with high infection rates in some areas of Brazil and Venezuela.[22] In regions with a high infection rate among dogs, the incidence of clinical VL in the general human population has generally been low. In contrast, the rates of human exposure to *Leishmania* (as determined by the prevalence of specific antibodies or positive leishmanin skin test results) can be high.[22–25] This suggests that either subclinical infection or protective immunity exists in humans. Clinically healthy human blood donors from southern France[26] and the Balearic Islands[27,28] also have a high rate of infection.[29]

Canine leishmaniosis caused by *L. infantum* is an important cause of zoonotic disease in many endemic countries and areas, including Spain, Portugal, southern France, Italy, Malta, Greece, Turkey, Israel, Egypt, Tunisia, Algeria, Morocco, Iraq, Iran, the former Asian republics of the Soviet Union, Pakistan, China, Brazil, Argentina, Uruguay, Paraguay, and Venezuela.[30–34] Leishmaniosis may also be transmitted in southern Germany.[35] Sporadic cases of canine leishmaniosis occur as a result of importation or transport of infected dogs to countries where sand fly transmission of *Leishmania* does not occur, such as the Netherlands, the United Kingdom,[36] and Sweden.[37] Because many dogs in endemic areas harbor subclinical infections, infection rates are often estimated not only by the presence of clinical signs compatible with the disease but also by serologic test results, demonstration of specific CMI responses against *Leishmania*, and the presence of parasite DNA in tissues as determined using PCR assays. Canine infection rates approach 70% to 90%, as shown by PCR and serology in highly endemic foci, such as the Balearic Islands of Spain,[38] the Marseille area in France,[39] throughout Greece,[40] and the Naples area in Italy.[41] This is a much higher prevalence of infection than that associated with disease or determined by serology alone. It is thought that most or all dogs in these areas are infected at some point during their lives.[38,41] A low proportion of dogs succumb to the infection and develop disease, whereas the majority of dogs are resistant and harbor the pathogen subclinically.[17,42] In other areas, infection is not as highly prevalent, possibly because of less favorable environmental conditions for transmission and vectors.[22,43] The age distribution of clinical disease has two peaks, one in young dogs (2 to 4 years old) and another in older dogs (more than 7 years old)[44] Several dog breeds, including boxers, cocker spaniels, Rottweilers and German shepherds, are apparently more susceptible to disease.[44–46] Other breeds that arose and evolved in endemic areas, such as the Ibizan hound from the Balearic Islands, only develop

mild forms of disease such as papular dermatitis and possess protective cellular immunity.[47,48]

In Europe and South America, sensitive xenodiagnostic studies, involving feeding of vector sand flies on dogs, have demonstrated that dogs with or without clinical illness and with serum antibody titers to *Leishmania* are a source of infection for a high proportion of feeding sand flies.[49] The percentage of infected sand flies increased with the presence and severity of clinical signs, high anti-*Leishmania* antibody levels, and decrease in $CD4^+$ T-cell counts.[50–53] These findings corroborate that clinical disease and high anti-*Leishmania* antibody levels are positively correlated with high parasite burdens.[54,55] Risk of sand fly-borne transmission is reduced as parasite loads decline after treatment.[56–58]

Although *L. infantum* is transmitted most frequently through the bites of sand flies, other modes of transmission are possible. *In utero* transmission has been documented in clinical reports[59] and under experimental[60] and natural conditions as well as in humans.[61,62] Venereal transmission of leishmaniosis from infected males to healthy bitches can occur.[63] Transmission by hematophagous arthropods other than sand flies has been investigated but not proven to have epidemiologic significance. *Rhipicephalus sanguineus* ticks acquire *Leishmania* organisms in their gut after feeding on infected dogs[64]; however, the tick's competence as a vector has not been confirmed.[65] Fleas have been proposed as alternative vectors of *Leishmania* transmission, but proof of transmission is still lacking.[66,67] Transmission by blood transfusion has been reported[68,69] and is of special concern in areas where blood donors are subclinical carriers of infection.[70,71] Direct dog-to-dog transmission has been suspected in areas where sand fly vectors are apparently absent.[72] Modalities of transmission other than by sand flies require further investigation to define their relative importance in the natural history and epidemiology of leishmaniosis.[42]

Infection of dogs occurs mostly in periurban or rural areas; however, canine and human infections have been reported in urban areas and pose a threat to the well-being of dogs, cats, and humans.[73,74] The potential importance of reservoir hosts other than domestic dogs in the epidemiology of *L. infantum* infection is less well known.[49] *Leishmania infantum* infection has been reported in many domestic animals from the Old and New Worlds.[49] A high prevalence of infection based on positive serum antibody titers and PCR results has been reported in domestic cats in some areas of Europe[75] and Brazil.[76] Clinical disease occurs in cats.[77–80] Infections have also been reported infrequently in horses in Europe,[81,82] and South America[83] and cellular immunity tests in horses have shown that exposure is more frequent than clinical disease.[84,85] Serologic responses of pigs to *L. infantum* have been described in Brazil.[86] Infection has been reported in a wide range of wild carnivores and rodents in the Old World, including a seal.[49,87] In the New World, infection has been detected in crab-eating foxes (*Cerdocyon thous*) and in a range of other carnivores and rodents, including bats.[49] A high prevalence of infection exists in populations of foxes in Europe and South America.[49,87] Clinical disease has been reported in wild canids.[88,89] The majority of reports in other domestic or wild mammals describe subclinical infections.

Transmission of *Leishmania* to feeding sand flies has been confirmed from humans, black rats, domestic cats, hares,[90] crab-eating foxes, and opossums. These hosts, therefore, have the potential to act as primary or secondary reservoirs.[49,87] However, infected crab-eating foxes in Brazil exhibited low rates of transmission to the sand fly *Lutzomyia longipalpis.* Similar results were found in humans, who were not considered to be important as reservoirs of leishmaniosis in Brazil.[49,91]

Although leishmaniosis is infrequently reported in humans and domestic animals in North America, the disease has become established in dogs, predominantly hunting hounds. No autochthonous (local, non-travel-related) human cases have been reported in association with these dogs. The first report of autochthonous leishmaniosis in dogs in the United States was in a hunting hound in 1980.[92] An outbreak in 1999 among foxhounds in a New York kennel revealed a puzzling epizootiologic situation suggesting endemic transmission.[93,94] Organisms isolated from infected dogs were typed biochemically as *L. infantum* zymodeme MON-1, the most common zymodeme found in the Mediterranean region, suggesting an origin from Europe and not South America. Subsequent to the New York kennel investigation, the CDC screened sera from 13,000 foxhounds from across North America. Positive animals were found in 28 states and 2 Canadian provinces.[72] Positive serum antibody reactivity to *L. infantum* was identified in foxhounds from 69 kennels. Organisms isolated from 45 hounds across multiple states and provinces were again identified as *L. infantum* MON-1 (Fig. 96.5).[72] Leishmaniosis became enzootic in North American hunting hounds via vertical transmission.[95,96] North American dogs with leishmaniosis have the same clinical abnormalities as dogs from endemic areas.[97] Leishmaniosis can also be diagnosed in North America in any dog breed originating from endemic areas following importation and breeding of one or more infected dogs. Breeds include Corsicas, Neapolitan Mastiffs, Spinones, Cane Corso, and potentially other breeds.[98]

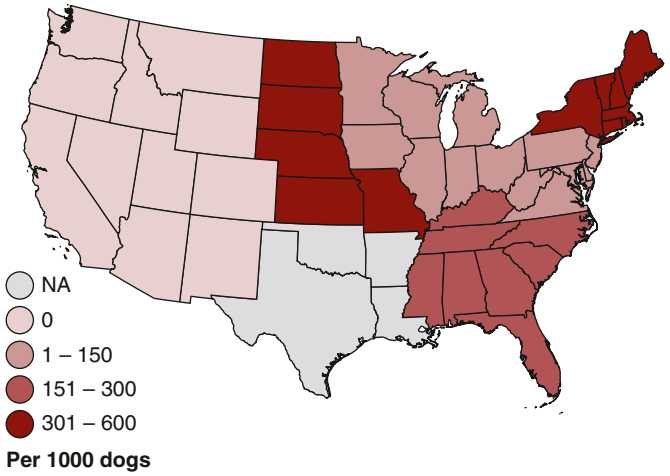

Fig. 96.5 Geographic distribution of leishmaniosis in dog kennels in North America in 2015 as determined using real-time PCR. *NA*, no specimens from these states were tested. (From Toepp AJ, Schaut RG, Scott BD, et al. *Leishmania* incidence and prevalence in U.S. hunting hounds maintained via vertical transmission. *Vet Parasitol Reg Stud Reports*. 2017;10:75–81.)

Transplacental transmission can affect almost all pups born to a subclinically infected dam, and can lead to a full spectrum of clinical outcomes over multiple years.[99] Vertical transmission of *Leishmania* spp. occurs globally in both endemic and nonendemic countries, and in humans as well as dogs, hamsters, and other rodents.[62] Blood-to-blood contact due to fighting,[100] or other direct contact could also potentially lead to transmission, but factors for direct transmission in the environment are poorly understood. Because the most common Mediterranean *L. infantum* strain (MON-1) has been identified in North America, the possibility of a suitable North American vector has been a concern for the persistence and potential spread of infection. The most prevalent sand fly in United States, found in 21 states as of 2012, is *Lutzomyia shannoni*.[101] *Lutzomyia shannoni* develops heavy parasite burdens when experimentally fed on dogs infected with *L. infantum*[102]; however, the vector competence of *Lu. shannoni* for the natural transmission of the parasite to dogs has not been established. *Lutzomyia longipalpis* is found as far north as Mexico, and *Lu. longipalpis* was able to transmit *L. infantum* from infected North American foxhounds to hamsters.[103] Because the presence and the role of sand flies as the primary vector of leishmaniosis have not been determined in North America, biologic transmission by other insects has also

been investigated and rejected.[104] Evidence for transvaginal transfer of infection during parturition or spread through milk is lacking.[105] Some researchers have suggested the possibility of venereal transmission[59,76,106]; however, further investigation is needed. Leishmaniosis has been reported in Canada[72]; however, the Canadian food inspection agency lists it as one of the "non-reportable list B" diseases.

Other *Leishmania* Species

Leishmania tropica occurs in the Old World and is a rare cause of infection in dogs. *Leishmania tropica* is an important agent of CL in humans in some parts of the Middle East and Africa. It also caused VL in American soldiers returning from the Persian Gulf after the 1991 Operation Desert Storm[107] and has been described in patients from India.[108] It has been sporadically found in dogs with cutaneous lesions from Tunisia, Morocco, and Israel,[109,110] and was described in a dog from Morocco with visceral involvement and no dermal abnormalities,[111] as well as a dog from Iran.[112] *Leishmania major* infection has been associated with cutaneous disease in dogs in the Middle East.[113,114]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Infection of the vertebrate host starts when *Leishmania* promastigotes are injected along with sand fly saliva into the vertebrate host's dermis. These promastigotes are phagocytized by localized immune phagocytes including dermal macrophages and Langerhans cells. Surviving intracellular parasites shift to the aflagellar amastigote phase and multiply within parasitophorous vacuoles that have the characteristics of phagolysosomes. Upon phagocyte rupture, freed amastigotes penetrate additional host cells and disseminate primarily via lymphatic circulation from the local bite site to the draining lymph node and further to hemolymphatic organs including the spleen, bone marrow, liver, and remote dermal areas. This establishes systemic infection.

Not every dog naturally or experimentally infected with *Leishmania* develops disease.[115] The ability to mount a productive, robust, proinflammatory immune response at the time of infection and thereafter appears to be the most important factor in determining whether dogs develop generalized infection or remain healthy and whether infection will progress from a subclinical to a clinical state.[105] Infection initially is subclinical but can progress into clinical disease unless parasite replication is controlled. Dogs that are able to control infection, restricting parasite burden and remaining subclinical for long periods or life, are considered *clinically resistant.* Infected animals predisposed to disease either genetically, or due to secondary factors including comorbid infection(s), poor nutrition or other immunosuppressive disease or treatments, are considered *susceptible.* These same factors, if they occur later in life, can also lead to loss of immune control and progression of disease.[17] This occurs in human patients with HIV and *Leishmania* co-infection, as well as cats infected with FeLV or FIV.[4,116]

The innate, or pattern-based early immune response is the first line of defense encountered by *Leishmania* parasites when entering a host. One of many mechanisms by which *Leishmania* parasites evade innate immune defenses involves the ability of promastigotes to survive within macrophage phagolysosomes by producing surface glycolipids such as lipophosphoglycans that may inhibit phagosome maturation.[117]

A protective immune response to all *Leishmania* species, as an intracellular pathogen, is dependent upon a Th1 response including IL-12 production by dendritic cells and macrophages, efficient antigen presentation, and subsequent IFN-γ production from T cells.[118,119] Innate immune system–based clearance of *Leishmania* requires intracellular killing via production of oxygen radicals within the phagolysosomes of infected cells. Critical innate responses are mediated through detection of parasite surface molecules, or PAMPs, detected by pattern recognition receptors, including TLRs, NOD-like receptors, and others. TLRs appear to play an important role.[120] Generally speaking, TLR2 upregulation appears to be associated with disease, while TLR4 downregulation appears to be associated with disease progression in dogs.[121,122] There is limited information regarding the role of other TLRs such as TLR3 and TLR9, which recognize nucleic acids in canine leishmaniosis.[120,123] Surface PAMPs are key components in many current *Leishmania* vaccines as antigens, adjuvants, or both. This response is enhanced by IFN-γ stimulation of phagocytes by NK cells early after *Leishmania* infection and by IFN-γ from CD4+ T cells at later stages of infection,[124] also indicated by IL-17 expression by infected dogs.[123] Therefore, the initial understanding of a dichotomous immune response (Th1/Th2) has been expanded to include additional types of T-cell immunity including Th17, T-regulatory responses, and others.[125] Although protective immunity for leishmaniosis is still described as Th1, this response is likely to also contain elements of a Th17 response and be dampened by a regulatory response, leading to a mixed overall cytokine profile. Shorter-term robust Th1 responses are believed to control *Leishmania* infection, but alone in chronic settings or when combined with hyperinflammatory Th17 responses, inflammation is harmful and is likely to drive T cells to shift to IL-10–based regulatory immune responses.[125,126] Regulatory immunity leads to T-cell exhaustion, predominance of regulatory B-cell responses, hyperproduction of immunoglobulins, expansion of parasite burden, and clinical disease.[125,127] A strong DTH response with the leishmanin intradermal skin test indicative of a CMI response to *Leishmania* infection is found in resistant dogs that have been exposed to the parasite, and is absent in severely ill dogs.[47] While elements of cytokine production that provide protective immunity against *Leishmania* spp. are thought to be understood (high IFN-γ, low IL-10, and low IL-4),[126] development of protective immunity through vaccination has been more challenging.[119] Vaccination as immunotherapy for canine leishmaniosis has had conflicting results.[125,128] These studies demonstrated successful stimulation of a balanced Th1 response from canine cells following exposure to a TLR agonist, but inclusion of a TLR4 agonist within a subunit vaccine formulation was not successful in halting disease progression.[129,130] Perhaps more importantly, healthy yet infected dogs progressing to clinical leishmaniosis already have T-cell exhaustion,[127] which can interfere with the response to vaccines or immunotherapeutics.[125] When exposed to vaccine antigens and mitogen, CD4+ T cells from dogs with clinical leishmaniosis had significantly reduced proliferation and IFN-γ production when compared with those from healthy dogs. At its heart, leishmaniosis is an opportunistic infection which manifests clinically when there is immune compromise. Therefore, consideration of an animal's immune status before starting any immunomodulatory therapy, including vaccination, is important.

Susceptibility and resistance to canine leishmaniosis appear to have a genetic basis. Studies on polymorphisms of the *Slc11c1* (*Solute carrier family 11 member a1*) canine gene (formerly *NRAMP1*), which encodes an iron transporter protein involved in the control of intraphagosomal replication of parasites and macrophage activation, implied that susceptible dogs have polymorphism and mutations in this gene.[131–133] Similar mutations have also been described in humans.[134] A DLA class II DLA-DRB1 genotype, which is a dog MHC II allele, was linked to the risk of susceptibility to leishmaniosis in an endemic area in Brazil.[135] A similar HLA DQ/DR allele was identified to lead to human susceptibility to leishmaniasis in a multicentric study of patients in both India and Brazil.[136] Genome-wide analysis has demonstrated that multiple loci are responsible for the progression of *Leishmania* infection to clinical disease. Genetic biomarkers of susceptibility to infection and disease in canines is extensively reviewed elsewhere.[137]

Canine leishmaniosis is a chronic disease, and clinical signs may develop 3 months to 7 years or more after infection. T-cell regions in

the lymphoid organs become depleted, and antibody-producing B-cell regions proliferate. The proliferation of B cells, plasma cells, histiocytes, and macrophages results in generalized lymphadenomegaly, splenomegaly, and hyperglobulinemia. As with other chronic persistent intracellular infections, the immunoglobulin response is usually excessive, not necessarily targeted at parasite antigens, not protective, and often detrimental. Autoantibodies in dogs with clinical leishmaniosis[138,139] are thought to be associated with the development of pathologic phenomena such as ITP.[140,141] Serum anti-histone antibodies have been associated with glomerulonephritis, and antigen-antibody depositions were frequent in dogs with leishmaniosis.[142,143] Impaired T-cell regulation with exuberant regulatory B-cell activity leads to large amounts of circulating immune complexes (CICs).[144] Deposition of CICs in the walls of blood vessels may cause vasculitis, polyarthritis, uveitis, and glomerulonephritis, the latter being the main cause of death. Immune complexes that activate the complement cascade also induce vasculitis and renal damage.[142] This important pathologic mechanism is responsible for tissue necrosis and accounts for dermal, visceral, and ocular lesions. Systemic vasculitis may lead to visceral and cutaneous necrosis and rarely nervous system involvement.[145–147] CICs may also include cryoglobulins. These may precipitate in the blood vessels of the extremities when exposed to cold and cause ischemic necrosis.

Canine leishmaniosis is most often associated with various skin lesions, which can be generalized rather than local because *L. infantum* disseminates systemically.[148] In addition, microscopic lesions and intralesional amastigotes are detected in normal-appearing skin from sick dogs as well as in clinically apparent dermal lesions.[149] Extracellular matrix assessment in the skin of sick dogs demonstrated a decrease in collagen type I and an increase in collagen type III fibers proportional to the severity of the skin lesion and tissue destruction.[150] Dermatologic abnormalities may occur in the apparent absence of other signs, but any animal with dermal manifestations is likely to have visceral involvement, because dissemination occurs before generalized skin lesions develop. Cutaneous lesions are present in 56% to 90% of dogs with clinical leishmaniosis.[151–153] Several dermatologic entities have been described, which are rarely associated with pruritus:[152,154,155] (1) desquamative dermatitis with alopecia, which can be generalized or localized to the face, ears, and limbs (Fig. 96.6A); (2) ulcerative dermatitis over bony prominences, and in mucocutaneous junctions, paws, and the ear pinnae (Fig. 96.6B); (3) focal or multifocal nodular dermatitis; (4) mucocutaneous proliferative dermatitis (Fig. 96.7); (5) papular dermatitis (Fig. 96.8); (6) abnormally long or brittle nails (onychogryphosis); (7) pustular dermatitis; (8) nasal and digital hyperkeratosis; and (9) multifocal alopecia.

Dogs with leishmaniosis may show hemorrhagic diatheses, manifested primarily as epistaxis, and less commonly as hematuria and hemorrhagic diarrhea. Epistaxis appears to be the result of multiple abnormalities of primary and secondary hemostasis, such as thrombocytopathy, hyperglobulinemia-induced serum hyperviscosity, and lymphoplasmacytic or granulomatous rhinitis with or without nasal mucosal ulceration.[156–158] Anemia usually develops as a sequela to inflammatory disease or CKD, but may be aggravated by blood loss.

Lymphadenomegaly of multiple superficial lymph nodes frequently develops[159] with lymph nodes enlarging to two to six times their normal size, occasionally mimicking lymphoma. Splenomegaly is also common.

Approximately 16% to 80.5% of dogs have ocular lesions, including conjunctivitis, blepharitis, keratoconjunctivitis, and anterior or posterior uveitis, glaucoma, panuveitis, and panophthalmitis (Fig. 96.9).[151,153,160–162] In keratoconjunctivitis sicca, inflammatory infiltrates located around the lacrimal ducts cause secretory retention and a decrease in tear production.[163] Less frequently, nictitating membrane or iris granulomas may be identified. In the majority of cases, ocular signs are bilateral, while unilateral ocular lesions are associated with an early diagnosis of the disease.

Weight loss and muscle atrophy are the most common signs of visceral involvement (Fig. 96.10). Some dogs lose weight despite a ravenous appetite. Muscle weakness is associated with mononuclear myositis, neutrophilic vasculitis, and IgG immune complexes in muscle tissues in conjunction with serum anti-myofiber antibodies.[164,165] Progressive CKD may be accompanied by anorexia, obtundation, polyuria, polydipsia, and vomiting. Transient diarrhea may occur. Kidney disease may be the only abnormality apparent; dogs with CKD in endemic areas should be tested for *Leishmania* infection.

In cases of overt disease, decreased physical activity is obvious and related to somnolence, decreased endurance, and locomotion disturbances. Locomotion disturbances may be caused by neuralgia, erosive and nonerosive polyarthritis, polymyositis, footpad clefts, interdigital

Fig. 96.6 Alopecic cutaneous lesions in dogs with leishmaniosis. (A) Periocular alopecia and crusting in an 8-year-old male neutered husky mix with leishmaniosis. The dog was evaluated in northern California and had a history of travel to Spain. Lesions were also present on the muzzle and the pinnae. (B) Typical exfoliative facial dermatitis with alopecia of the tips of the pinnae. (B, Courtesy Dr. Gad Baneth, Koret University, Israel.)

ulcers, osteoarticular and osteolytic lesions, or proliferative periostitis.[166,167] Both CNS and peripheral nervous system can be affected.

Small and large intestinal disease such as colitis and duodenitis can occur.[168] The clinical picture may be complicated by conditions such as demodicosis, pyoderma, and pneumonia. Co-infections with other endemic infections such as *Anaplasma, Ehrlichia, Babesia, Bartonella, Dirofilaria, Hepatozoon*, *Rickettsia*, and *Trypanosoma* can exacerbate clinical signs and/or clinicopathologic abnormalities.[169] Case-control studies have associated clinical leishmaniosis with co-infections with *Ehrlichia canis*[170,171] and other pathogens such as *Rickettsia* and *Anaplasma* spp.[169] Co-infections may induce progression from subclinical to clinical leishmaniosis in dogs.[172] Other less common manifestations may include pericardial tamponade,[173] masticatory myositis,[165] pancreatitis,[174] meningitis,[175] and pemphigus.[176] Thrombosis can

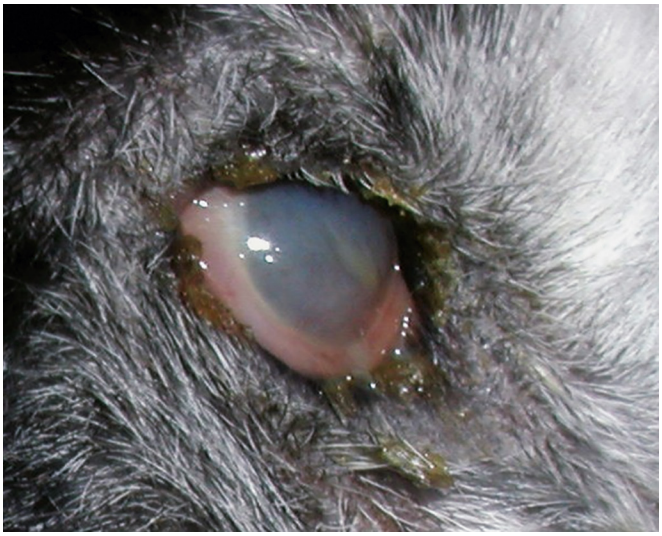

Fig. 96.9 Conjunctivitis and uveitis in a dog with leishmaniosis.

Fig. 96.10 Dog with advanced leishmaniosis. Cachexia, muscle atrophy, and generalized scaling are present.

occur secondary to nephrotic syndrome.[177,178] Signs secondary to DIC may occur.[179] Cardiac and pulmonary alterations associated with leishmaniosis have been sporadically described in dogs.[180–183]

Physical Examination Findings

Canine leishmaniosis may be subclinical, a self-limiting disease, or the classical non–self-limiting and severe illness.[17] Canine leishmaniosis due to *L. infantum* is often classified as visceral disease in compliance with the classification of the disease caused by this pathogen in humans; however, dogs usually have both visceral and cutaneous involvement. Canine leishmaniosis is essentially a chronic systemic disease that may involve any organ, tissue, and biological fluid and is manifested by a plethora of clinical signs and physical examination findings.[17] The main historic and physical examination findings in typical cases are skin lesions, local or generalized lymphadenomegaly, thin body condition, exercise intolerance, inappetence, lethargy, splenomegaly, polyuria and polydipsia, ocular lesions, epistaxis, onychogryphosis, lameness, vomiting, and diarrhea (Table 96.1).[17,42,151,152] Rectal temperature may fluctuate but is usually normal. In some cases, ocular abnormalities are the only signs.[161] For this reason, it is important to perform a thorough ophthalmologic examination in dogs with suspected leishmaniosis. Epistaxis and cough are other clinical signs that may be present in isolation or with other clinical signs (Fig. 96.11).[157,158]

TABLE 96.1 Clinical Findings in Dogs with Leishmaniosis[151–153,161]

Findings	Percentage of Dogs
Clinical and Historic Findings	
Decreased endurance	67.5
Weight loss	64
Somnolence	60
Increased fluid intake	40
Anorexia	32.5
Diarrhea	30
Vomiting	26
Polyphagia	15
Epistaxis	6–15
Melena	12.5
Sneezing	10
Coughing	6
Fainting	6
Physical Examination Abnormalities	
Lymphadenomegaly	62–90
Skin involvement	81–89
Cachexia	10–48
Abnormal locomotion	37.5
Hyperthermia	4–36
Ocular disease	16–81
Palpable spleen	10–53
Abnormal nails	20–31
Rhinitis	10
Pneumonia	2.5
Icterus	2.5

DIAGNOSIS

The diagnosis of canine leishmaniosis is complex due to its variable clinical manifestations and laboratory findings. Vaccination efforts to prevent leishmaniosis have increased the complexity of diagnosis, as serologic tests may not distinguish between naturally infected and vaccinated dogs. Prevaccination screening tests are not sufficiently sensitive to detect subclinically infected dogs, resulting in the potential for vaccination of infected animals, which then remain infectious to sand flies.[184] Diagnosis is usually performed to confirm disease in a dog with signs compatible with leishmaniosis as well as to monitor response to treatment. However, detection of infection may also be pursued for clinically healthy dogs in endemic regions such as blood donors, breeding dogs, candidates for vaccination, dogs suspected to have progression of disease, dogs travelling from endemic to nonendemic countries, and to evaluate immune responses to vaccination.[17,184,185] The diagnostic procedures used, and the approach to interpretation of test results, will vary accordingly.[17]

Accurate diagnosis requires an integrated approach consisting of clinicopathologic tests and specific diagnostic assays.[17] Specific assays include microscopic demonstration of parasites in cytologic preparations or histopathologic specimens, serology, culture, or nucleic acid detection.

Laboratory Abnormalities

A summary of clinicopathologic findings in dogs with leishmaniosis from three large case series[151–153] is shown in Table 96.2.

Fig. 96.11 Epistaxis in a St. Bernard with leishmaniosis and no dermal lesions.

TABLE 96.2 Clinicopathologic Abnormalities in Dogs with Leishmaniosis[151–153]

Abnormality	Percentage of Dogs
Hyperproteinemia	63.3–72.8
Hyperglobulinemia (gamma and/or beta)	76–100
Hypoalbuminemia	68–94
Decreased albumin/globulin ratio	76
Azotemia	16–45
Increased serum ALP activity	16–51
Increased serum ALT activity	16–61
Proteinuria	71.5–85
Anemia	60–73.4
Leukocytosis	24
Leukopenia	22
Thrombocytopenia	29.3–50
Detectable antinuclear antibodies	31–53
Positive Coombs' test	21–84

ALP, alkaline phosphatase; *ALT*, alanine aminotransferase

Complete Blood Count

Mild to moderate nonregenerative anemia and lymphopenia are frequently found on the CBC. Mild leukocytosis, leukopenia, and pancytopenia are inconsistent findings.[158,186] Serum hyperviscosity, thrombocytopathy,[158] secondary ITP,[141] impaired secondary hemostasis, and fibrinolysis[156] may also be detected. Parasites are rarely detected in peripheral blood smears.

Serum Chemistry Profile

The most consistent serum biochemistry findings are serum hyperproteinemia with hyperglobulinemia and hypoalbuminemia, which results in a decreased albumin/globulin ratio. Serum globulin concentration ranges from mild to severe (up to 8 g/dL). Leishmaniosis should be suspected in dogs from endemic regions that have polyclonal beta and gamma hyperglobulinemia with no apparent cause. Dogs with leishmaniosis may have increases in the concentration of serum acute-phase proteins such as CRP and ferritin and decreases in negative acute phase proteins such as albumin and paraoxonase 1 (PON1).[187,188] Mild increases of liver enzyme activities are frequent; however, grossly elevated liver enzyme activities, severe azotemia, or both are found in only a minority of dogs.[186] However, glomerulonephritis eventually

TABLE 96.3 Diagnostic Assays Available for Leishmaniosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of lymph nodes, spleen, impression smears of skin lesions, bone marrow aspirates, rarely blood smears or buffy coat preparations	*Leishmania* amastigotes within mononuclear phagocytes	In the absence of experience, organisms may be confused with fungi such as *Histoplasma* or *Sporothrix*. Organisms may be few in number and in some cases are absent.
Antibody serology (IFA, immunochromatographic, or ELISA)	Serum	Antibodies to *Leishmania* spp. antigens	Most infected dogs with clinical disease test positive (sensitivity > 90%), but positive test results occur in healthy animals, so results must be interpreted in light of clinical signs. Sensitivity may be lower in cats. False positives can occur in dogs exposed to *Trypanosoma* spp. (IFA) and dogs vaccinated with the *Leishmania* vaccine.
Nucleic acid–based detection assays	Conjunctival swabs, aspirates of affected tissues, lymphoid organs, bone marrow, whole blood, skin biopsies	*L. infantum* DNA	May be useful in dogs with suggestive lesions in which organisms cannot be found cytologically. Sensitivity and specificity depends on assay design. Quantitative PCR may be useful for evaluation of treatment efficacy.
Histopathology	Biopsy specimens from affected tissues (e.g., skin lesions)	*Leishmania* amastigotes	Use of immunohistochemistry is needed to increase sensitivity and be used to confirm the presence of *Leishmania* spp. in tissues
Leishmania culture	Aspirates or biopsies of affected tissues	*Leishmania* spp.	Sensitive and specific but requires special techniques and expertise that are not widely available

develops with progressive pathologic renal dysfunction. Azotemia has been reported in 16% to 38% of dogs. Renal biomarkers, such as the serum symmetric dimethylarginine (SDMA), may also be useful to assess the extent of renal damage.[189,190] Test results for antinuclear antibodies can be positive, especially if co-infections are present.[139]

Urinalysis

Dogs with leishmaniosis may have proteinuria or isosthenuria secondary to glomerular and tubulointerstitial renal function impairment, respectively. Cylindruria may be detected in some dogs. The urinary protein/creatinine ratio and enzymuria have been proposed as tests to assess the extent of renal damage.[191–193]

Examination of Other Body Fluids

Lymphocytic and neutrophilic inflammation is observed with *Leishmania* amastigotes in the synovial fluid in dogs with both erosive and nonerosive polyarthritis.[166] Dogs with neurologic signs have most commonly a lymphocytic pleocytosis.[194] A reduction in semen quality of dogs with leishmaniosis has been reported with poor progressive motility and large score of total sperm defects and detached normal heads. Semen quality is partially reverted after long-term treatment.[195]

Bone Marrow Examination

Bone marrow cytologic alterations described in canine leishmaniosis include erythrophagocytosis, erythroid hypoplasia and dysplasia, eosinophilic hypoplasia, granulocytic hyperplasia, and increased numbers of lymphocytes and plasma cells.[196,197] Amastigotes may also be visible.

Diagnostic Imaging

Abdominal radiography or ultrasonography in dogs with leishmaniosis may reveal abdominal lymphadenomegaly, splenomegaly, and hepatomegaly. Radiographic lesions of long bones in dogs with bone involvement consist of soft periosteal proliferation, increased or decreased intramedullary opacity, and/or cortical and medullary destruction.[153,166] Lesions tend to be bilateral and symmetric. Joint radiographs in dogs with signs of arthritis may reveal erosive changes, or arthritis may be nonerosive.

Microbiologic Tests (Table 96.3)

Organism Identification by Microscopy and Culture

Diagnosis can be based on cytologic or histologic identification of amastigotes, either in macrophages or free in routinely stained smears. Organisms are often found in lymph nodes, splenic aspirates, skin touch impressions, bone marrow, or other tissues and body fluids.[193] The specificity of these methods is virtually 100%, but depending on the time spent searching for parasites, the maximum sensitivity is around 80% in dogs with clinical signs of the disease and lower in subclinically infected seropositive dogs. Cytologic studies may reveal few or no demonstrable parasites in dogs with overt clinical signs of disease.

Serologic Diagnosis

Various serologic methods have been used to detect serum anti-*Leishmania* antibodies. These include IFA testing, ELISA, immunochromatography with rapid POC devices, direct agglutination assays, and Western blotting. In general, most of these methods have good sensitivities and specificities for the diagnosis of clinical leishmaniosis. However, sensitivity and specificity greatly depend on the antigens employed. Whole-parasite extracts are sensitive for the detection of subclinical or clinical infections but provide a somewhat lower specificity.[198] On the other hand, assays that include recombinant protein antigens are very specific but may lack sensitivity for the detection of clinically healthy infected dogs, depending on the antigen employed.[199] The recombinant proteins reported to be highly sensitive for detection of infection in dogs are K39, K26, KMP11, SMT,[200,201] cysteine proteinase,[202] A2,[203] and the chimeric protein Q.[204] Another study demonstrated the high sensitivity and specificity of a ribosomal protein extract.[205]

Negative test results may reflect delayed seroconversion in some animals, which may take several months to occur. However, many dogs with clinical signs seroconvert after a long incubation period. Importantly, in endemic areas, positive serologic test results do not imply that disease is

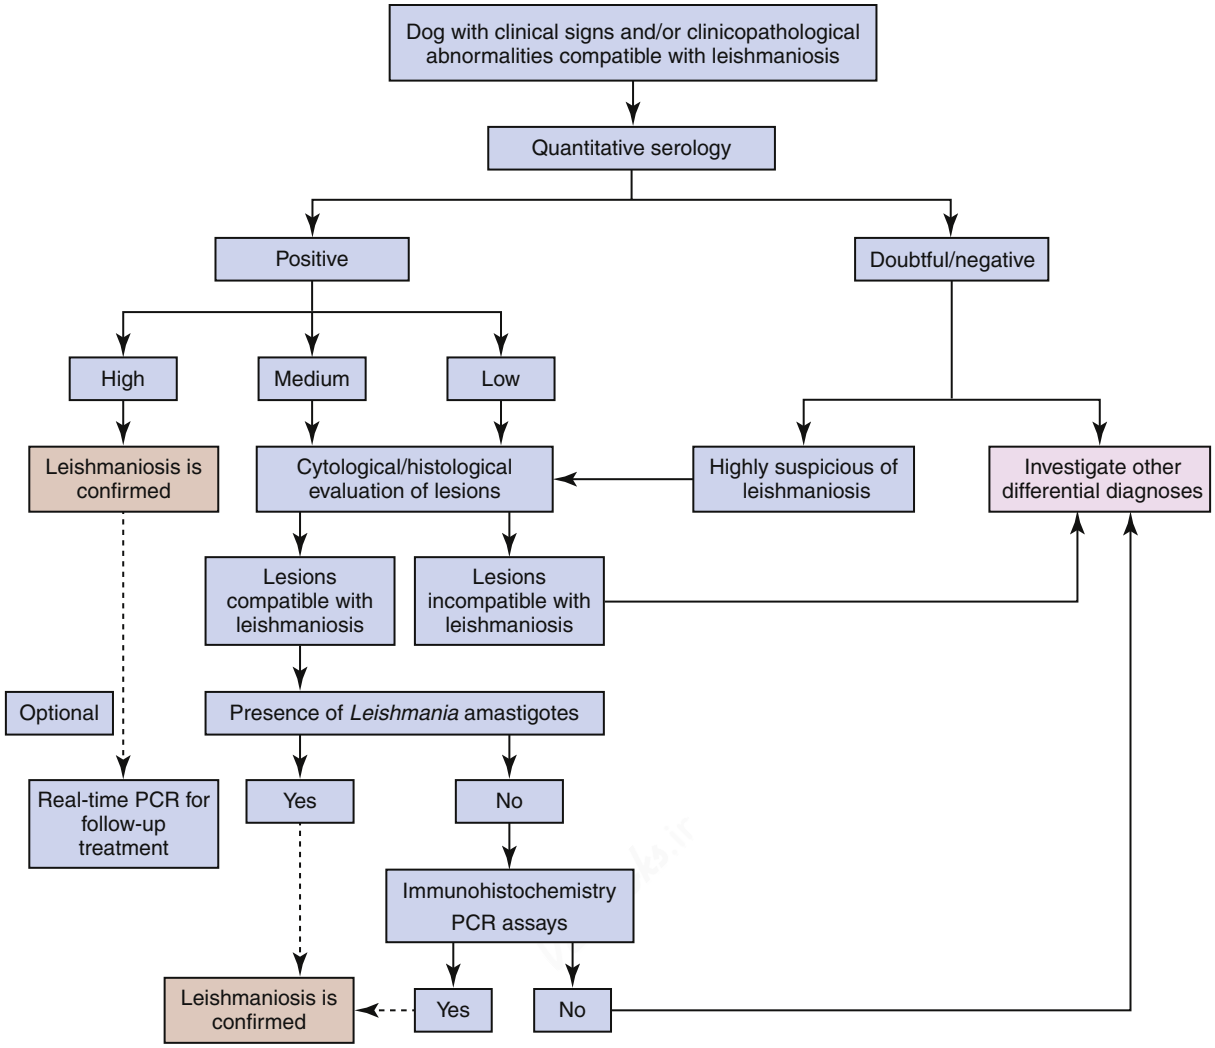

Fig. 96.12 Approach to diagnosis of leishmaniosis in dogs with compatible clinical signs and/or clinicopathologic abnormalities and no history of recent vaccination against leishmaniosis.

due to *Leishmania* spp. infection, because subclinical infections are widespread. Thus, for diagnosis of disease (leishmaniosis), results must be interpreted in conjunction with clinical findings and the results of cytologic and histopathologic evaluation of affected tissues. A diagnostic algorithm summarizing the use of antibody titers for leishmaniosis is shown in Fig. 96.12. High antibody levels are associated with high tissue parasite loads and disease.[54,55] Anti-*Leishmania* antibodies are rarely undetectable in infected dogs with clinical signs of leishmaniosis. Therefore, a high positive antibody titer strongly supports the diagnosis and is conclusive of leishmaniosis in dogs with compatible clinical signs or clinicopathologic abnormalities.[17] In cases with low antibody titers and compatible clinical signs, the use of additional detection methods is recommended to exclude or confirm the disease because a low positive titer result may be detected in dogs that are subclinical carriers (see Fig. 96.12).[17]

Serologic tests also may detect antibodies that form secondary to vaccination. This may not allow "differentiation between infected and vaccinated animals" (DIVA). Serologic cross-reactivity with other pathogens is possible with some tests, especially those based on whole-parasite antigen. Cross-reactions are less likely to occur when using recombinant peptides or extracts[199,202] or ribosomal protein extracts.[205] Cross-reactivity has been reported with other species of *Leishmania*[198,199] and *Trypanosoma*.[206] Cross-reactivity is less likely to occur to *Babesia canis* and *E. canis* antigens.[207]

Molecular Diagnosis Using Nucleic Acid–Dased Testing

PCR demonstration of *Leishmania* DNA in tissues of infected animals is sensitive. It is routinely used for diagnostic purposes, research studies, and screening for canine blood donors.[208,209] The small subunit rRNA gene, the internal transcribed spacer of the ribosomal operon, and high-copy sequences of kinetoplast DNA (kDNA) have been used as targets. The kDNA assays are considered the most sensitive due to the high copy number of this target[210] and, therefore, are the most commonly employed diagnostic assays. In contrast, rRNA assays are frequently used for speciation but are less sensitive. PCR can be performed on DNA extracted from tissues, blood, body fluids, or even histopathologic specimens.[211,212] PCR on bone marrow, lymph node, spleen, or skin is most sensitive and specific for the diagnosis of leishmaniosis.[213,214] PCR on whole blood, buffy coat, and urine is less sensitive than the aforementioned tissues.[214,215] Conjunctival swab specimens can be collected noninvasively and PCR on these specimens is accurate for diagnosis of seropositive dogs with clinical leishmaniosis.[216–218] The clinical performance of molecular assays

on other noninvasively collected specimens such as oral swabs,[219] hair,[220,221] and cerumen[222] is under investigation. PCR on cytologic stained samples from the bone marrow[223] and cutaneous lesions[224] is sensitive and specific for the diagnosis of *Leishmania* infection in dogs. Isothermal assays that have the potential to be used as sensitive and specific POC tests have also been developed and require further clinical validation.[225]

Culture

The diagnosis may also be established by the culture of parasites from tissues in Novy-MacNeal-Nicolle medium or Schneider's *Drosophila* medium, but this can take weeks and is typically only performed in the research setting.

Pathologic Findings

Severely affected animals are usually cachectic and suffer from muscle atrophy. The skin and hemolymphatic organs are primarily affected. Generalized lymphadenomegaly and splenomegaly are usually present. Hepatomegaly may be present, but it is less common. Small, light-colored focal nodular granulomas may develop in various organs, including the skin and the kidneys. Mucosal ulcerations in the nasal cavity, stomach, intestine, and colon are occasionally observed. Petechiae and ecchymoses on mucosal and serosal membranes are present in some cases. Osteolytic or proliferative periosteal lesions may be found in various parts of the skeleton.[166]

Most affected tissues exhibit an inflammatory reaction associated with macrophages in the presence or apparent absence of amastigotes. Amastigote numbers may vary from very few organisms within macrophages to large numbers in rarer events. Lymphoplasmacytic inflammation is also common. Classical histopathologic lesions have been described mainly in organs with abundant mononuclear-phagocytic system cells such as the spleen, lymph nodes, bone marrow, liver, GI tract,[226] and skin. Similar inflammatory patterns may be observed in other tissues such as the eyes[160] and nasal cavity.[158] Reactive lymphoid hyperplasia is found in lymphoid organs including the lymph nodes and spleen in association with monocytic hyperplasia in the spleen and bone marrow[227–229] and variable numbers of amastigotes.

The most common cutaneous findings are periadnexal nodular to diffuse pyogranulomatous or granulomatous dermatitis, together with orthokeratotic to parakeratotic hyperkeratosis, acanthosis, crusting, and ulceration. Other histopathologic patterns, such as subcorneal pustular dermatitis, lichenoid dermatitis, vasculitis, and panniculitis, have also been described.[17,149,154,167]

Renal lesions include glomerulonephritis, tubulointerstitial nephritis, and rarely amyloidosis.[230,231,232] Membranoproliferative glomerulonephritis is more frequently associated with CKD. Mesangioproliferative lesions and minimal-change glomerulonephritis have been detected in kidney tissue from infected dogs without clinicopathologic evidence of renal disease.[233]

In the liver, mild changes have been observed with the presence of individual or clustered macrophages, mostly within the sinusoids.[234] Moderate changes, the most common finding, are characterized by mononuclear infiltration in the portal space and hepatic parenchyma.[234,235] Hepatic granulomas and collagenogenesis (intralobular fibrosis) have been reported.[235,236] More severe hepatic pathology is characterized by marked lymphoplasmacytic portal hepatitis with occasional infiltration to the parenchyma and portal fibrosis.[234]

Histopathologic changes in the eyes are observed, in order of frequency, in the conjunctiva and limbus, ciliary body, iris, cornea, sclera and iridocorneal angle, choroid, and optic nerve sheath, with different inflammatory patterns and variable numbers of amastigotes.[160]

Pathologic changes in muscle are characterized by scattered to diffuse mononuclear myositis, myonecrosis, and endomysial fibrosis.[164]

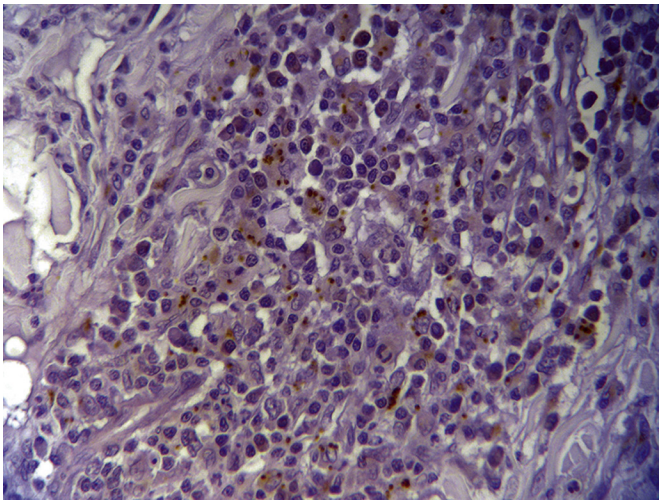

Fig. 96.13 Diffuse histiocytic dermal infiltrate with *Leishmania* amastigotes within the cytoplasm of macrophages from a dog with leishmaniosis; organisms revealed by immunohistochemical staining. *Leishmania* amastigotes are brown (×400). (Courtesy Univet, Barcelona, Spain.)

In the CNS, inflammatory cell infiltration including lymphocytes, macrophages, plasma cells, and some neutrophils was reported in the choroid plexi, subventricular zone, and leptomeninges as well as around parenchymal blood vessels in dogs with high anti-*Leishmania* antibody titers and clinical leishmaniosis with or without neurologic signs.[237] Cerebral blood vessel walls presented positive labeling against anti-*Leishmania* antibody in a histopathologic study, suggesting the deposition of circulating parasite antigens in the CNS.[237]

No gross lesions are normally detected in the external or internal genital organs of canine males and bitches.[106,238] However, a high frequency of microscopic inflammatory lesions and presence of amastigotes have been observed mainly in the epididymis, glans penis, prepuce, and testis.[106] In contrast, the only change in bitches was a mild to moderate vulvar dermatitis with no changes in other genital organs.[238]

Identification of amastigotes in formalin-fixed, paraffin-embedded sections of canine skin or visceral tissues may be facilitated by immunohistochemical methods such as immunoperoxidase staining (Fig. 96.13).[239,240]

TREATMENT AND PROGNOSIS

Canine leishmaniosis is more resistant to therapy than human leishmaniosis, and only rarely are all *Leishmania* organisms eliminated with available drugs.[241,242] Relapses necessitating retreatment are the rule rather than the exception, although dogs frequently become cured of the clinical disease. For a summary of the main drug dosages and adverse effects, see Table 96.4.[243] Follow-up and monitoring of clinical and laboratory parameters of treated dogs and healthy infected dogs are essential for adequate management.[17,184] A summary of the approach to monitoring sick and clinically healthy dogs is shown in Table 96.5.

For decades, pentavalent antimonials have been the primary drug for treatment of canine and human leishmaniosis. These selectively inhibit the protozoal enzymes required for glycolytic and fatty acid oxidation. Meglumine antimoniate (see Chapter 12) is the main antimonial used for treatment of dogs. It is administered at 75 to 100 mg/kg/day SC for 4 to 8 weeks and may cause cutaneous cellulitis or abscesses at the injection site and be potentially nephrotoxic.[56,57,243–246] The selection for *L. infantum* strains that are resistant to pentavalent antimonials has been reported in France, Spain, and Italy and is a veterinary and public health concern.[247–249]

TABLE 96.4 Antimicrobial Therapy for Canine Leishmaniosis

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Weeks)	Adverse Effects
Meglumine antimoniate[a]	75–100	SC	24	4–8	Local pain, pancreatitis, panniculitis, potential nephrotoxicity
Allopurinol	10	PO	12	At least 6–12 months. Some dogs need life-long treatment.	Xanthinuria, urolithiasis, renal mineralization
Miltefosine[b]	2	PO	24	4	Anorexia, vomiting, diarrhea

[a]Some studies suggest combined therapy with a 4- to 8-week course of meglumine antimoniate in combination with allopurinol. This is followed by allopurinol for at least 6–12 months and is currently considered the most effective treatment of *L. infantum* infections.
[b]Can be combined with allopurinol as an alternative to the meglumine antimoniate. In such cases, treatment with allopurinol is continued for at least 6–12 months after miltefosine discontinuation.

TABLE 96.5 Treatment Monitoring for Dogs Infected with *Leishmania infantum*[184]

Parameters	Frequency for Sick Treated Dogs	Frequency for Clinically Healthy Infected Dogs
History and physical examination; CBC, biochemical profile ± serum electrophoresis	After the first month of treatment and then every 3–4 months during the first year.	Every 3–6 months
Complete urinalysis ± UPCR and abdominal ultrasound	Every 6–12 months in dogs fully recovered clinically with treatment	
Quantitative serology[a]	Not before 6 months after initial treatment and every 3–6 months	
Real-time PCR (optional)	At the same time as serology	

[a]Some dogs have a significant decrease in antibody levels (i.e., more than three two-fold dilutions difference between samples) associated with clinical improvement within 6–12 months of therapy. A marked increase in antibody levels (i.e., more than three two-fold dilutions difference between samples) should be interpreted as a marker of relapse, especially in dogs following the discontinuation of treatment.
CBC, complete blood count; *UPCR,* urine protein to creatinine ratio.

Allopurinol is an indispensable part of the treatment of canine leishmaniosis, frequently used in combination with other drugs. It is a hypoxanthine compound that is metabolized by *Leishmania* spp. to produce an analogue of inosine. The analogue is incorporated into leishmanial RNA, causing faulty protein translation and inhibition of parasite multiplication. It is administered orally, has few adverse effects, and is readily available, even in the United States and countries where meglumine antimoniate is not marketed.[250,251] A dose of 10 mg/kg, q12h, PO often results in remarkable clinical improvement within 4 weeks and reduction of parasites to undetectable numbers. However, relapses may occur once therapy has been discontinued or while still on treatment due to selection for allopurinol resistance.[252] Even after conscientious administration of the drug for 6 months, complete recovery is rare,[253] and deterioration of kidney function may continue during allopurinol therapy despite resolution of dermal lesions and general improvement in the clinical condition. Use of allopurinol causes hyperxanthinuria, which may occasionally produce urolithiasis. Combined treatment with meglumine antimoniate and allopurinol is considered as the most effective therapy and constitutes the most frequently used protocol against the disease.[17,185] The combination is administered for 4 to 8 weeks, followed by continuation with allopurinol alone usually for at least 12 months.[254]

Miltefosine (see Chapter 12) is an alkylphospholipid with a direct toxic effect on *Leishmania* parasites that is effective for the treatment of human VL and has been introduced for use in veterinary medicine.[255,256] It is administered to dogs at 2 mg/kg/day PO for 4 weeks and is an alternative to meglumine antimoniate when combined with long-term allopurinol therapy.[243,257,258] In North America, miltefosine can be purchased from Profounda Pharmaceuticals (Orlando, FL, USA).

Additional drugs that are not recommended as first-line therapy for canine leishmaniosis because of the adverse effects associated with treatment include pentamidine, amphotericin B (AMB), and aminosidine.[259,260] Other drugs that have been evaluated for antileishmanial efficacy in dogs include ketoconazole, metronidazole and spiramycin, and marbofloxacin.[185] In a trial comparing the efficacy of conventional treatment with meglumine antimoniate and allopurinol against use of metronidazole and spiramycin, treated dogs showed some clinical improvement without a parasitologic cure, similar to control dogs.[261]

Additional treatment with immune system modulators for the prevention of disease progression is reviewed elsewhere[262] and includes dietary supplementation of nucleotides and active hexose as an adjunctive therapy.[263,264]

If dogs are seriously ill, and especially if they are in severe renal failure, it may be necessary to restore fluid and acid-base balances before antileishmanial drugs are administered. The prognosis of leishmaniosis depends on the severity of injury to the dog's systems at the time of diagnosis and the dog's individual response and rate of deterioration. In dogs that have not reached a progressive state of renal failure, treatment frequently significantly improves dermal and visceral signs of the disease. Immune responses were monitored in dogs before and after treatment and have indicated that in some cases, parasite-specific CMI that is absent before therapy is regained after drug administration but may deteriorate again during a clinical relapse.[260,265]

TABLE 96.6 Clinical Staging of Canine Leishmaniosis[184]

Clinical Stages (Antibody Levels[a])	Clinical Signs	Laboratory Abnormalities	Treatment and Prognosis
Stage I: mild disease (negative to low positive)	Mild localized peripheral lymphadenomegaly or papular dermatitis	Usually none Renal profile results within reference limits[b]	No treatment or treatment with a single drug or two combined drugs (allopurinol, meglumine antimoniate, or miltefosine)[c] Prognosis: good
Stage II: moderate disease (low to high positive)	Stage I signs *plus* diffuse or symmetric cutaneous lesions such as exfoliative dermatitis, onychogryphosis, ulcerations (planum nasale, footpads, bony prominences, mucocutaneous junctions), anorexia, weight loss, fever, and epistaxis, among others	Mild nonregenerative anemia, hypergammaglobulinemia, hypoalbuminemia Substage: a) No abnormalities in renal profile: no proteinuria b) Creatinine < 1.4 mg/dL; UPCR = 0.5–1	Allopurinol + meglumine antimoniate or miltefosine Prognosis: good to guarded
Stage III: severe disease (medium to high positive)	Stage I or II signs *plus* immune-complex lesions such as vasculitis, arthritis, uveitis, and glomerulonephritis.	Signs of stage II *and* CKD IRIS stage I with UPCR > 1 or stage II (creatinine 1.4–2 mg/dL)	Treatment: allopurinol + meglumine antimoniate or miltefosine Follow IRIS guidelines for CKD Prognosis: guarded to poor
Stage IV: very severe disease (medium to high positive)	Signs up through stage III *plus* pulmonary thromboembolism, or nephrotic syndrome and end-stage renal disease	Stage II signs *plus* CKD IRIS stage III (creatinine 2–5 mg/dL) and stage IV (creatinine > 5 mg/dL)[d] Nephrotic syndrome: marked proteinuria UPCR > 5	Specific treatment should be instituted based on individual case considerations. Follow IRIS guidelines for CKD Prognosis: poor

[a]Dogs with negative to medium-positive antibody levels should be confirmed as infected with other diagnostic techniques such as cytology, histology (preferably with immunohistochemistry), or PCR. High antibody titers in a sick dog, which was not previously vaccinated, with compatible signs and/or laboratory abnormalities are conclusive of a diagnosis of leishmaniosis and are defined as a three- to four-fold increase above the reference cutoff level in a well-established laboratory.
[b]Reference interval: creatinine < 1.4 mg/dL; UPCR < 0.5.
[c]Dogs in stage I (mild disease) are likely to require less prolonged treatment with one or two combined drugs (allopurinol, domperidone, meglumine antimoniate, or miltefosine) or alternatively monitoring with no treatment. There is limited information on dogs in this stage and, therefore, treatment options remain to be defined.
[d]IRIS (2022) http://www.iris-kidney.com/guidelines/index.html Accessed 4/9/2022.
CKD, chronic kidney disease; *IRIS*, International Renal Interest Society; *UPCR*, urine protein to creatinine ratio.

Staging

A clinical staging system for canine leishmaniosis divides the disease into four clinical stages from mild to very severe disease based on clinical signs, clinical laboratory abnormalities, and level of serum anti-*Leishmania* antibodies.[184] This system is helpful for decisions on the therapy most suitable for each patient and for consideration of a prognosis (Table 96.6). The clinical stage may change if the clinical health of the dog deteriorates or improves.

PREVENTION

Efforts to control leishmaniosis in the canine populations in some endemic countries are controversial and generally have not been considered to be successful.[50,266–269] Culling sick and seropositive dogs is obviously unacceptable to the owners, but it is also ineffective in controlling spread of the disease because subclinically infected dogs, and possibly wild canids are additional sources of parasite transmission. Furthermore, available methods for testing do not identify all infected dogs, and a population of young susceptible puppies can replace the culled animals.[43,268] Spraying for sand fly vectors and eradicating their presumptive breeding places has limited effectiveness in preventing spread of the disease. No prophylactic drug has yet been shown to be effective against infection, and medical treatment of infected dogs with antileishmanial drugs is ineffective in eliminating the parasite.

Sand fly bites can be reduced by keeping dogs indoors during the sand fly season from dusk to dawn, avoiding microhabitats favorable to sand flies in the location where the dog spends time, and using environmental insecticides and topical insecticides.[270] Topical insecticides for protecting dogs against sand fly bites include solutions, spot-on tubes, sprays, and collars. A spot-on containing imidacloprid and permethrin is recommended for dogs every 3 to 4 weeks for repelling sand flies.[271–273] Deltamethrin-impregnated collars (see Chapter 13) can protect dogs for about 8 months from more than 90% of bites from *Phlebotomus perniciosus*, the primary vector of *L. infantum* in France, Italy, and Spain; and *Lu. longipalpis*, a major South American vector.[274–276] A controlled study on the effect of using collars on dogs in a focus of VL in Iran indicated that the seroconversion rate after 1 year in dogs and children was significantly lower in intervention villages than in control villages.[277] Topical insecticide protection is valuable for dogs in endemic regions during transmission seasons and for dogs traveling to these areas. Use of collars or spot-on formulations on client-owned infected dogs treated medically and living in infected areas is warranted.

Commercial vaccines to protect dogs against canine leishmaniosis are available and widely used in Brazil and Europe. Vaccination decreases the occurrence of clinical disease, however, may not be as successful in preventing infection.[184,243,278] Domperidone is a dopamine D2 receptor agonist reported to act by the stimulation of prolactin secretion which acts as a pro-inflammatory cytokine. It is also used as a prophylactic

treatment in dogs in some European countries.[279] An integrated control approach that combines vaccination with the application of topical insecticides could reduce the burden of infection in dog populations in endemic countries.[243] There is no licensed vaccine against leishmaniosis for veterinary use in the United States. Euthanasia has been promoted to prevent leishmaniosis from becoming established in North America in settings where large numbers of dogs are infected in kennel situations.

PUBLIC HEALTH CONSIDERATIONS

VL is a serious human disease that may be fatal if untreated. Malnutrition predisposes to progression of infection.[10,280,281] Traditionally, VL primarily affected young children and infants, but now it is also often a complication in adults infected with HIV or those receiving cytostatic or immunosuppressive drugs.[116,282]

Transmission of *L. infantum* from dogs to humans via sand flies is the primary route of infection. Several studies have investigated the association between canine and human leishmaniosis in the same region.[185] Increased prevalence of infection in the dog population is associated with increased incidence of human leishmaniosis.[283] Poor socioeconomic conditions are risk factors for the association between canine and human infections,[282] and dog density and infected dog ownership are risk factors for infantile human leishmaniosis.[32,284,285] The link between dog and human infections probably differs from one region and lifestyle to another and could depend on multiple factors including human nutrition, time spent outdoors, the density of dogs, and the behavior of sand fly vectors. In southern Europe, where human disease is often sporadic and the ratio between clinically affected humans and infected dogs is low, ownership of dogs is usually not perceived as being associated with an increased risk to humans. Despite this, studies from Europe have established linkage between human and canine infection at the population level.[284] Effective control of canine leishmaniosis could lead to a decrease in human leishmaniosis in endemic regions. Control measures of canine leishmaniosis include vaccines, topical insecticides, and environmental control of sand flies.[286]

Transmission by direct contact between dogs and humans is speculated to be rare, if it occurs at all. Transmission of *L. infantum* through blood products has been reported in dogs that received blood transfusions from infected canine donors and in humans.[69] Studies in Spain have documented transmission among IV drug users as a result of shared needle use.[287] Therefore, direct contact with contaminated hypodermic needles or with open wounds or exudates from dogs with leishmaniosis should be avoided.

Direct blood-to-blood transmission would likely pose a far smaller risk to humans than transmission by insects such as sand flies. However, as sand flies are able to transmit *L. infantum* from infected to susceptible dogs in North America, zoonotic vector transmission might be possible.[103,288]

Infected pets may remain disease carriers despite treatment. In areas where sand fly vectors are found, this poses a concern to owners, veterinarians, and local public health and environmental agencies. Before deciding on the fate of an infected pet, owners should be consulted and educated about the disease, its zoonotic nature, the prognosis for their dog, what should be expected from therapy, and safety precautions that should be taken. A clear, official policy based on relevant research and a calculated estimation of the risk to the community is desirable.

CANINE AMERICAN TEGUMENTARY LEISHMANIOSIS

American cutaneous (tegumentary) leishmaniosis (ATL) is caused by multiple *Leishmania* species that belong to the subgenus *Viannia*.

Fig. 96.14 Pinnal ulceration in a dog infected with *Leishmania braziliensis* from the northeast of Brazil.

These include *L. braziliensis*, *L. mexicana* and *L. peruviana*. The condition affects dogs and humans in Latin America; infection in dogs has been reported from Brazil, Argentina, Bolivia, Peru, Ecuador, Colombia, Venezuela, and Panama. *Leishmania braziliensis* is the most widespread *Leishmania* species causing ATL in South America.[289–291] Outbreaks of ATL have been associated with jungle deforestation.[292]

The clinical signs of disease in dogs include single, double, or less commonly multiple chronic ulcerative lesions on the ears, scrotum, muzzle, face, or other areas of the skin, mucocutaneous erosive lesions in the mouth and nasal mucosa, and lymphadenomegaly (Fig. 96.14).[293–297] Anemia, hypoalbuminemia, and hyperglobulinemia are common clinicopathologic findings.[296] Sporotrichosis is an important differential diagnosis (see Chapter 84).[296] Diagnosis can be confirmed by microscopic detection of parasites, by serologic tests, or nucleic acid–based assays (see Table 96.3). On histopathology, a granulomatous inflammatory infiltrate is observed in the dermis, frequently without detectable parasites or in the presence of low numbers of amastigotes; however, a high percentage of dermal lesions are positive for parasites by culture.[298] It is more difficult to detect the organism in samples from hemolymphatic tissues or normal skin.[295,298] Co-infection with *L. braziliensis* and *L. infantum* has been reported in regions where both infections are endemic and poses a diagnostic challenge.[299,300] Sick dogs with ATL commonly have low levels of anti-*Leishmania* antibodies as compared to dogs with clinical visceral disease due to *L. infantum*. To add to the diagnostic challenges, several species of *Trypanosoma* are endemic in South America,[301] which can be associated with serologic cross-reactivity.[295] Reliable species-specific diagnostic assays that employ quantitative and/or recombinant antigen serologic tests,[302,303] discriminatory nucleic acid–based assays,[304] or culture are required for accurate diagnosis. The majority of infected dogs respond to systemic antimonial therapy, but they remain infected after therapy and commonly have clinical relapses.[136] Intralesional antimonial therapy has been reported to be beneficial in providing clinical improvement and limiting disease relapse.[305] Limited information is available about treatment of ATL and, therefore, the most adequate therapeutic protocol remains unclear. Numerous wildlife species including opossums and rodents can be infected with agents of ATL. Although dogs can be infected, their role as a reservoir host for human ATL is controversial.[291,306,307]

FELINE LEISHMANIOSIS

Laia Solano-Gallego and Gad Baneth

ETIOLOGY AND EPIDEMIOLOGY

Leishmania infection in a domestic cat was first described in 1912 in Algeria from the bone marrow of a 4-month-old kitten living in the

same house where a dog and a child were affected by leishmaniosis.[308] Since then, clinical disease and subclinical infections have been reported sporadically in the following regions and countries where canine leishmaniosis is endemic: southern Europe, North Africa, the Middle East, and Central and South America. Clinical leishmaniosis in domestic cats has been reported to involve *L. infantum* in Europe, the Middle East, and Brazil,[80,309,310] *L. mexicana* in Texas[311] and Venezuela, and *L. braziliensis*[312] and *L. amazonensis*[313] in Brazil.

Serologic and PCR surveys of cat populations in canine leishmaniosis–endemic regions in southern Europe[75,221,314,315] and the Middle East[175] indicate that feline infection is more widespread than clinical disease. Epidemiologic studies have described seroprevalence rates ranging from 0.9% to 28%.[75,314,316,317] PCR studies on blood samples have shown rates of infection from 0.43% to 30%.[75,314,315,318,319] The true role of the cat as a reservoir of *L. infantum* infection remains unclear. Transmission of *L. infantum* to sand flies (*P. perniciosus*) from a chronically infected cat under experimental conditions has been reported.[320]

Fig. 96.15 Cutaneous ulcer in cat with leishmaniosis. (Courtesy Prof. Maria Grazia Pennisi, University of Messina, Messina, Italy.)

CLINICAL FINDINGS

The most frequently described lesions in feline leishmaniosis caused by *L. infantum* are ulcerous crusting and nodular dermatitis, alopecia, and scaling predominantly affecting the face and ears (Fig. 96.15).[77–80] Visceral forms of disease with spleen, liver, bone marrow, lymph node, uvea, and kidney involvement have been less commonly described and are thought to be associated with immunosuppression caused by FeLV and FIV infections or other concomitant diseases.[4,77,309,321–323] One cat had visceral involvement that included hepatosplenomegaly, icterus, lymphoplasmocytic gastroenteritis with abundant *Leishmania* parasites, and membranous glomerulonephritis.[77] A second cat from which *L. infantum* MON-1 zymodeme was cultured had disseminated crusty cutaneous lesions and amastigotes in the bone marrow.[309] Another cat with disseminated disease had uveitis as a predominant finding.[321] A case of pancytopenia in a cat has been reported with amastigotes in blood smears, bone marrow, spleen, and lymph nodes.[324] As with dogs, hyperproteineimia with hypergammaglobulinemia is a common finding in feline leishmaniosis.[78,79,321,325] The serum antibody titers to *Leishmania* antigen ranged from low to high levels.[77,80,309] Diagnosis was made in the majority of cases by serologic, cytologic, histologic, or PCR methods.

Reports of feline leishmaniosis in the New World have primarily described cutaneous infections with species that cause CL in humans. Nodules on the pinnae of a cat from southern Texas caused by *L. mexicana* were described in one report.[326] Thirty months after surgical removal of the affected pinna, the cat developed more diffuse lesions on the muzzle and the nasal mucosa. No visceral involvement was found on necropsy.[311] Similar lesions were described in eight cats from Texas involving the ear pinnae, or less commonly the muzzle and periorbital skin.[327] Solitary or multiple ulcerative nodular lesions due to *L. mexicana* infection, located on the nose, ears, tail, and lower limbs were diagnosed in cats from Venezuela.[328,329] Infection with a *Leishmania* (*Viannia*) species in a cat from Brazil was detected in a proliferative interdigital lesion.[330] *Leishmania braziliensis* was also isolated from cutaneous lesions from two cats in Brazil.[312,313] Experimentally, cats were susceptible to a generally self-limiting infection with a human isolate of this organism.[331] PCR has been used to confirm the presence of *Leishmania* DNA in spleen and lymph nodes of affected cats in Brazil.[332]

CASE EXAMPLE

Signalment

"Fausto," an 8-year-old male neutered husky mix from northern California, United States.

History

Fausto was referred to the University of California, Davis VMTH, for evaluation of suspected autoimmune disease. The dog had a 6-month history of progressive skin lesions that began as crusting and ulceration around the elbow and stifle joints. This was followed by development of similar lesions above both eyes, and on the dog's ears and dorsal muzzle. Three months after the skin lesions appeared, Fausto became stiff, lethargic, and was reluctant to walk. He also appeared to be lame. At that time, Fausto was taken to another veterinary clinic where an injection of triamcinolone acetonide (Vetalog®) was administered, and he was prescribed NSAID (carprofen) and trimethoprim-sulfamethoxazole. There was no improvement in the clinical signs with this treatment. The day before he was brought to the VMTH, the owner had taken Fausto to a local emergency clinic because he was reluctant to move. Blood work and arthrocentesis (left and right tarsal joints) were performed. The blood work showed a mild normocytic, normochromic nonregenerative anemia (HCT 31%); mild hypoalbuminemia (2.4 g/dL); and moderate hyperglobulinemia (7.7 g/dL). Cytologic examination of the synovial fluid analysis revealed large numbers of nondegenerate neutrophils, which was considered consistent with immune-mediated polyarthritis. Cephalexin and carprofen were prescribed and the dog was referred for further evaluation.

The owner had not noticed any coughing, sneezing, vomiting, diarrhea, or changes in thirst or urination. Fausto was fed 3 cups of a commercial dry chicken and rice-based dog food once a day, and his appetite remained good. He was fully vaccinated for rabies, CDV, CAdV, and CPV. The dog did not receive heartworm prophylaxis medication but was treated with fipronil once a month for flea control. There was one other healthy dog in the household. The owner and his dogs had moved to California from Barcelona, Spain, a few weeks around the time that the skin lesions appeared. In Spain, Fausto had worn a collar to prevent insect bites.

Continued

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 34.4 kg.

General: Quiet, alert, and responsive, but reluctant to ambulate. T = 102.7°F (39.3°C), HR = 132 beats/minute, panting but eupneic, mucous membranes moist and pink.

Integument: Multiple focal regions of crusting, erythema, hyperpigmentation, thickening, and sometimes ulceration were present over the elbows and stifles, prepuce, ventral aspect of the mandible, above both eyes, and on both pinnae. Moderate pruritus was present.

Eyes, ears, nose, and throat: Apart from the skin lesions, only moderate periodontal disease was present. A fundoscopic examination showed no significant abnormalities.

Musculoskeletal: BCS 5/9. The dog was able to walk but had a shifting lameness. Pain was detected on extension of the joints but there was no palpable effusion present.

Cardiovascular: No murmurs or arrhythmias were auscultated. Femoral pulses were strong and synchronous.

Respiratory: No significant abnormalities detected.

Abdominal palpation: Splenomegaly was present.

Lymph nodes: Superficial cervical and popliteal lymph nodes were all enlarged (approximately 3 cm in diameter).

Laboratory Findings

CBC: HCT 32.4% (40%–55%), MCV 62.7 fL (65–75 fL), MCHC 35.2 g/dL (33–36 g/dL), reticulocyte count 54,500 cells/μL, WBC 9,300 cells/μL (6,000–13,000 cells/μL), neutrophils 7,533 cells/μL (3,000–10,500 cells/μL), lymphocytes 930 cells/μL (1,000–4,000 cells/μL), monocytes 651 cells/μL (150–1,200 cells/μL), eosinophils 186 cells/μL (0–1,500 cells/μL), platelets 338,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 140 mmol/L (145–154 mmol/L), potassium 4.4 mmol/L (4.1–5.3 mmol/L), chloride 107 mmol/L (105–116 mmol/L), bicarbonate 15 mmol/L (16–26 mmol/L), phosphorus 3.8 mg/dL (3.0–6.2 mg/dL), calcium 10.4 mg/dL (9.9–11.4 mg/dl), BUN 16 mg/dL (8–31 mg/dL), creatinine 0.9 mg/dL (0.3–1.2 mg/dL), glucose 109 mg/dL (70–118 mg/dL), total protein 10.7 g/dL (5.4–7.4 g/dL), albumin 2.1 g/dL (2.9–4.2 g/dL), globulin 8.6 g/dL (2.3–4.4 g/dL), ALT 12 U/L (19–67 U/L), AST 39 U/L (21–54 U/L), ALP 43 U/L (15–127 U/L), GGT 3 U/L (0–6 U/L), cholesterol 191 mg/dL (135–345 mg/dL), total bilirubin 0.1 mg/dL (0–0.4 mg/dL).

Serum protein electrophoresis: There was a marked increase in gamma-globulin with mild hypoalbuminemia. The gammopathy was polyclonal.

Urinalysis (cystocentesis): SpG 1.037; pH 7.0, 4+ protein (SSA), 1+ bilirubin, 1+ hemoprotein, no glucose or ketones, rare WBC/HPF, 1–3 RBC/HPF, rare hyaline casts, few lipid droplets.

Urine protein to creatinine ratio: 2.99 (normal, < 0.5).

Microbiologic Testing

IFA serology for antibodies for *Ehrlichia* spp., *Anaplasma* spp., *Rickettsia* spp., *Bartonella clarridgeiae*, *Bartonella vinsonii* subsp. *berkhoffii*, and *Bartonella henselae*: Negative.

Western immunoblot for antibodies to *Borrelia burgdorferi*: Negative.

Knott's and ELISA antigen test for *Dirofilaria immitis* infection: Negative.

Aerobic bacterial, anaerobic bacterial, and *Mycoplasma* culture of synovial fluid: Negative.

Aspiration cytology (right and left superficial cervical and popliteal lymph nodes): A heterogeneous population of lymphocytes was present, which consisted primarily of small mature lymphocytes and slightly increased numbers of intermediate-sized lymphocytes and lymphoblasts. Large numbers of plasma cells were noted, and a few macrophages were scattered throughout the specimen. Rare nondegenerate neutrophils and eosinophils were seen.

Bone marrow aspiration cytology: Many unit particles were present in a monolayer background of hemic cells and lipid vacuoles. Unit particles were normocellular and a small amount of storage iron was noted. Normal numbers of megakaryocytes were noted. The myeloid to erythroid ratio was mildly increased and both series were synchronous and complete. Increased numbers of plasma cells were noted throughout the sample with few small lymphocytes noted. Macrophages occasionally contained intracytoplasmic organisms consistent with *Leishmania* spp. amastigotes. Interpretation: mild erythroid hypoplasia, *Leishmania* spp., and mild plasma cell hyperplasia.

Skin biopsy (performed while the dog was sedated for bone marrow aspiration): There was a thick band of inflammatory cells that extended from the superficial to the mid-dermis. The inflammatory infiltrate comprised dense sheets of large foamy macrophages admixed with smaller numbers of lymphocytes and plasma cells and few neutrophils. Many of the large macrophages contained multiple, round to oval, intracytoplasmic basophilic organisms that were 1 to 2 μm in diameter. The epidermis was hyperplastic and hyperkeratotic and was covered by exudate admixed with keratin, degenerate neutrophils, and cellular debris.

Diagnosis

Canine leishmaniosis.

Treatment and Outcome

Fausto was initially treated with a combination of allopurinol (10 mg/kg, PO, q8h), ketoconazole (9 mg/kg, PO, q12h), cephalexin (30 mg/kg, PO, q12h for 4 weeks, for secondary bacterial pyoderma) and carprofen (4.4 mg/kg, PO, q24h). At a recheck examination 2 weeks later, the dog's owner reported that 1 or 2 days after treatment was started, Fausto became intensely pruritic. Fausto's appetite also decreased and he developed increased thirst and urination, but the lameness resolved. Physical examination showed severe crusting and ulceration of the face, with an associated foul odor. This extended from the dorsal nasal planum to the temporal and supra-ocular regions, as well as the inner aspect and tips of the pinnae, and had an associated foul odor. The lesions on the limbs were static or slightly improved from the last visit. A CBC was unchanged and a serum chemistry profile showed more severe hyperglobulinemia (9.3 g/dL) and hypoalbuminemia (1.9 g/dL). A drug reaction was suspected and the cephalexin was replaced with clavulanic acid-amoxicillin. Over the next month, the skin lesions improved (see Fig. 96.6A). The owner subsequently obtained meglumine antimoniate from Spain and treatment was changed to allopurinol (10 mg/kg, PO, q12h) and meglumine antimoniate (88 mg/kg, SC, q24h for 1 month). However, 6 days after treatment with meglumine commenced, the dog developed prolapsed third eyelids and was unable to catch treats when they were thrown to him. Physical examination showed healing skin lesions with evidence of hair regrowth, prolapsed third eyelids, risus sardonicus, and erect ears. A presumptive diagnosis of localized tetanus was made. A serum chemistry panel showed an albumin of 2.5 g/dL and a globulin of 6.4 g/dL, and the urine protein to creatinine ratio was 0.2. Fausto was treated with metronidazole (10 mg/kg, PO, q8h for 14 days) and tetanus antitoxin (20,000 U in 250 mL saline over 1 hour, IV, once). Clinical signs of tetanus had almost resolved 11 days later when the owner was contacted by telephone. The dog was subsequently lost to follow-up.

Comments

This case is an interesting example of travel-related canine leishmaniosis that was ultimately complicated by what appeared to be a cutaneous drug reaction to cephalexin and then localized tetanus. The diagnosis of leishmaniosis was suspected based on the clinical signs together with the travel history from southern Europe. The bone marrow aspirate and skin biopsies were obtained simultaneously for the sole purpose of cytologic diagnosis of leishmaniosis; impression smears of the skin lesions failed to yield organisms and the lymph node aspirates were also negative. The owner returned to Spain with his dog in order to obtain the meglumine antimoniate, which could not be obtained in the United States. The development of tetanus possibly may have followed use of contaminated needles by the owner for subcutaneous injection of the meglumine.

(Case example provided by Jane Sykes, University of California-Davis Veterinary Medical Teaching Hospital)

TREATMENT AND PROGNOSIS

Published information on the treatment of feline leishmaniosis is limited and controlled data on efficacy and safety is lacking. Allopurinol is the most frequently used drug, and meglumine antimoniate has also been used alone or in combination with allopurinol.[4,325] Successful treatment of cats with clinical improvement was achieved in the majority of cases with 5 to 10 mg/kg allopurinol, given twice daily.[78,79,321] Cats with disseminated forms of infection require longer allopurinol treatment of at least 6 months in comparison to the shorter course reported beneficial for cats with only cutaneous lesi ons.[78,79,321]

Prevention of feline leishmaniosis is available by using topical insecticides with activity against sand flies which are specifically licensed for cats including collars.[333] Caution must be exercised, as canine products, especially those with pyrethroids, are frequently toxic to felines. Commercial vaccines against leishmaniosis are currently not available for cats.

Babesiosis

Adam J. Birkenheuer

KEY POINTS

- First Described: Early descriptions of intraerythrocytic parasites in dogs with signs of babesiosis were made in Africa in 1893.[1] The first documented case of canine babesiosis in the United States was in 1934.[2]
- Cause: *Babesia canis, Babesia rossi, Babesia vogeli, Babesia gibsoni, Babesia conradae, Babesia vulpes, Babesia negevi* sp. nov. (dogs); *Babesia felis, B. canis, B. gibsoni, Babesia cati, Babesia lengau* (cats); several other unnamed *Babesia* species (dogs and cats) (phylum Apicomplexa).
- Affected Hosts: Domestic dogs and cats.
- Geographic Distribution: Worldwide, but different *Babesia* species vary in their geographic distribution.
- Mode of Transmission: A variety of tick vector species; fighting or biting interactions; vertical (perinatal) transmission; blood transfusion.
- Major Clinical Signs: Lethargy, pallor, splenomegaly. Many infected dogs show no overt clinical signs. Dogs with severe babesiosis (*B. rossi*) may show neurologic signs, anuria, tachypnea, and poor perfusion parameters.
- Differential Diagnoses: IMHA and/or ITP, other causes of hemolysis such as oxidative toxins or microangiopathic hemolysis (e.g., with splenic hemangiosarcoma). Other causes of protein-losing nephropathy (borreliosis, immune-mediated, amyloidosis, etc.). Canine monocytic ehrlichiosis, RMSF, bacterial endocarditis, and hemoplasmosis should also be considered.
- Human Health Significance: *Babesia* species that infect dogs and cats are not known to infect humans.

ETIOLOGY AND EPIDEMIOLOGY

Babesia spp. are intraerythrocytic protozoan parasites of the phylum Apicomplexa. Babesiosis is the disease caused by infection with organisms from the genus *Babesia.* Babesiosis is classically characterized by hemolytic anemia, thrombocytopenia, fever, and splenomegaly and can be a severe, life-threatening illness. *Babesia* infections can also be subclinical. Altogether, more than 100 species of *Babesia* have been described, and with the advent of molecular techniques such as PCR assays, new species and genotypes are identified each year. Historically, species have been named and identified based on the vertebrate host and the size of the parasite (large or small *Babesia* species). Large *Babesia* spp. are 3 to 7 µm in length, whereas small *Babesia* spp. are 1 to 3 µm in length. However, molecular phylogenetic analyses are critical for accurate identification and classification of *Babesia* spp. In most parts of the world, tick vectors are the most important means of transmission of *Babesia* species. For some *Babesia* species, such as *Babesia gibsoni* in North America and Europe, direct transmission between dogs, through fighting (and exchange of blood), or vertical (transplacental) transmission, is believed to be the most common route of transmission when competent tick vectors are absent.[3–5]

When ticks are involved in transmission, sporozoites are released from the tick salivary glands as the tick feeds and they enter the bloodstream of the vertebrate host (Fig. 97.1). They then attach to, and are endocytosed by, erythrocytes. Within the erythrocytes, they undergo asexual reproduction (merogony), and the daughter cells infect new erythrocytes. A naïve tick then ingests infected erythrocytes. It is unclear whether transformation from merozoite to gametocyte begins in the vertebrate host or in the tick. In the tick midgut, the sexual phase of reproduction occurs when the gametocytes fuse to form a zygote. The zygote invades epithelial cells of the tick gut. The resultant forms, known as ookinetes, leave the epithelial cell and invade either the salivary gland or the ovary, where they participate in transstadial or transovarial transmission, respectively. Prior to transmission, another asexual form of reproduction occurs in the salivary gland, sporogony.

Canine Babesiosis

Canine babesiosis is a disease of worldwide importance. Initially, two species of *Babesia* were recognized in dogs (*Babesia canis* and *B. gibsoni*); however, now at least nine genetically distinct canine piroplasms have been described.[6] Periodically, infections with piroplasmid species from other hosts have been documented using molecular assays.[7,8] Formal changes in eukaryotic nomenclature, including *Babesia* sp., should be proposed through the International Commission on Zoological Nomenclature (ICZN: http://www.iczn.org/). Unfortunately, there have not been formal proposals through the ICZN for the majority of *Babesia* spp. which has led to confusion when navigating the primary literature where many species are referred to using different nomenclature.

Babesia species that infect dogs vary in their geographic distribution; however, due to movement of infected animals, movement of tick vectors, and increased recognition due to improved diagnostic techniques, geographic range of many *Babesia* spp. is expanding. As new organisms are recognized, it has become more important for the clinician to understand the differences in diagnosis, prognosis, and treatment for infection with each organism.

Large *Babesia* Species

Large *Babesia* species are recognized throughout the world. The first description of a large canine *Babesia* species was by Piana in 1895 and is generally accepted to describe *B. canis*.[9] Likewise, *Babesia rossi* was first described in 1910 and 1912 by Nutall, and *Babesia vogeli* was described by Reichenow in 1935 and 1937.[10–13] In 1989, Uilenberg proposed that these organisms were all subspecies of a single species and proposed the names *B. canis canis*, *B. canis rossi*, and *B. canis vogeli*.[14] Since none

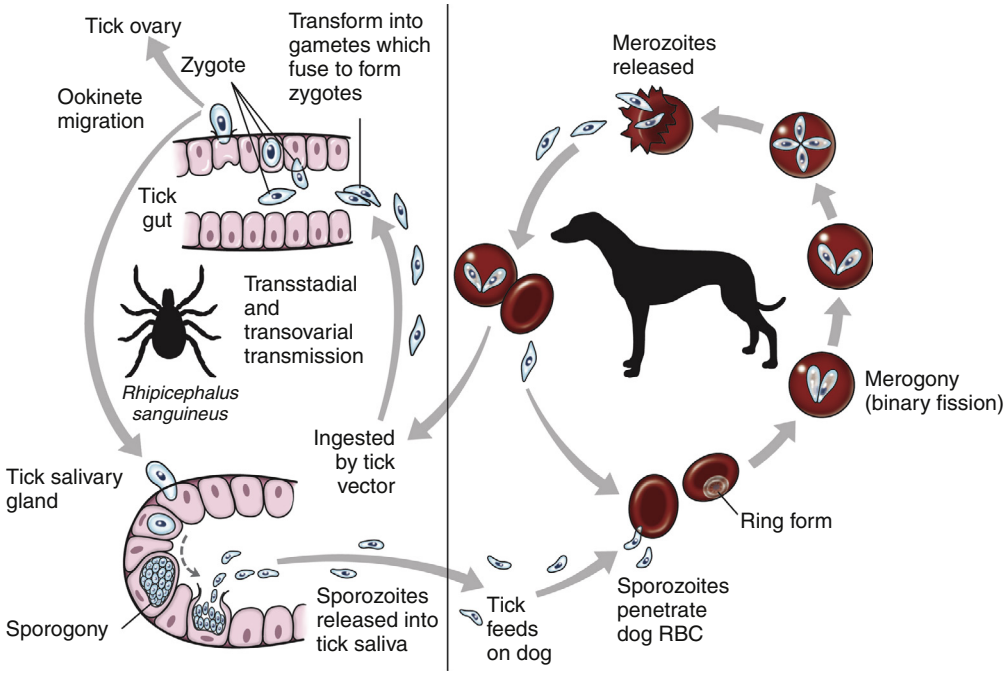

Fig. 97.1 Life cycle of *Babesia canis*.

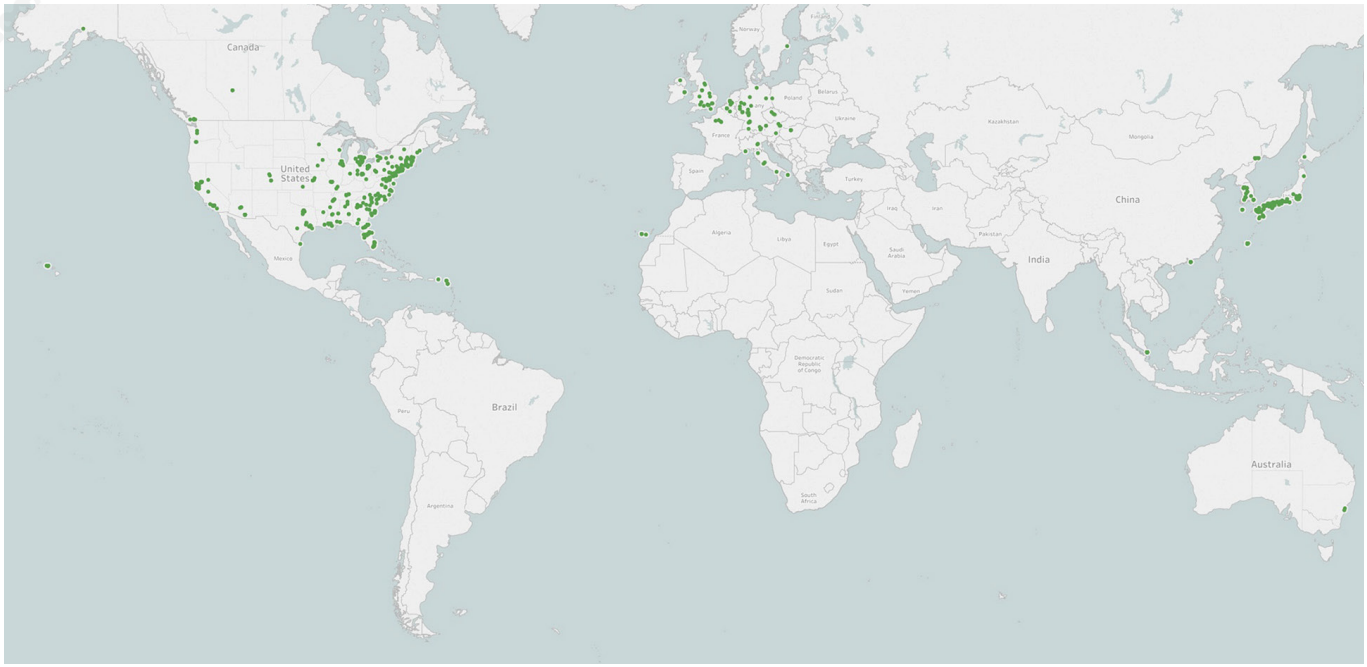
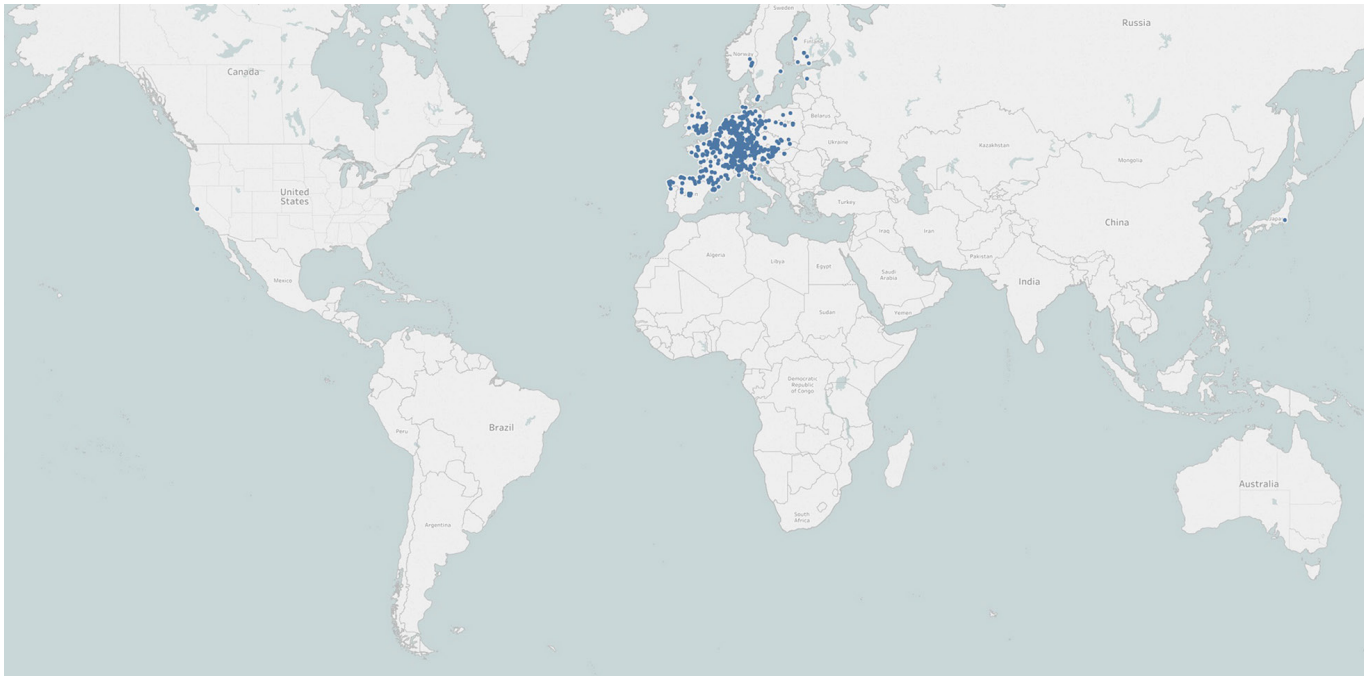


of these descriptions or proposals have met the standards of the ICZN, the original proposed nomenclature is now used: *B. canis*, *B. rossi*, and *B. vogeli*. Genetically unique large canine *Babesia* spp. that have been more recently described will be referred to as: *Babesia* sp. (followed by author and year of original description).

Babesia vogeli is the most common large *Babesia* species in the United States and transmitted by the brown dog tick *(Rhipicephalus sanguineus)*.[15] Infection is most commonly diagnosed in warm, humid regions of the world, and while transmission may be seasonal in some regions, disease manifestation can occur throughout the year. *Babesia vogeli* can be found in Africa, Asia, Australia, Europe, and the Americas (Fig. 97.2A).[15] The reported seroprevalence of *B. vogeli* in dogs has ranged from 3.8% to 59%.[16] The prevalence of seroreactivity is higher in adult dogs than in dogs younger than 1 year.[17] Greyhounds appear to have a higher rate of exposure and infection than other breeds. There is no definitive evidence that greyhounds are more susceptible to *B. vogeli* infection than other breeds, and it is this author's opinion that the higher rates of infection are secondary to increased risks such as exposure to infected ticks and direct dog-to-dog transmission (perinatal/transplacental and bites). In an antibody serosurvey of dogs in Florida, 46% of 393 greyhounds were seroreactive.[16] The prevalence of seroreactive dogs within these kennels ranged from 17% to 100%; the lower prevalence was noted in kennels with more intensive tick control. None of 50 non-greyhound, individually housed adult pet dogs within the same geographic area were seroreactive, which implicated environment and breed susceptibility as possible risk factors in endemic areas.[16] Transplacental transmission of *B. vogeli* infections is strongly suspected but has not yet been definitively documented.[18]



Babesia canis is the most commonly detected *Babesia* sp. in Europe, but is occasionally detected in dogs that have been imported from or traveled to Europe (Fig. 97.2B). *Babesia canis* is transmitted by the ornate cow tick, *Dermacentor reticulatus*.[15,19] The incidence of infection is highest in the fall and spring. Higher prevalence rates are most commonly found in rural or suburban areas that are adjacent to prairies or woodlands that provide suitable habitat for *D. reticulatus*.[20] *Babesia canis* infection has been commonly diagnosed in France. However, infections are being reported more frequently from other European countries such as Croatia, Poland, Germany, and the United Kingdom, likely due in part to changes in the distribution of *D. reticulatus*.[21,22] Outbreaks of disease due to *B. canis* infection in Polish sled dogs share many similarities with those due to *B. vogeli* infection in North American greyhounds.[23]

Babesia rossi is transmitted by the yellow dog tick, *Haemaphysalis elliptica* (syn. *Haemaphysalis leachi*).[24] Black-backed jackals are natural hosts for *B. rossi*.[25] Reports of autochthonous *B. rossi* infection have been limited to Africa, with the vast majority of reports coming from South Africa, where more than 10% of the dogs evaluated in some veterinary hospitals may be affected.[26,27] A 2021 study of vector-borne pathogens in 209 owned or stray dogs in Malawi identified *B. rossi* as the most prevalent vector-borne pathogen, infecting 23% of dogs as determined using PCR.[28] The incidence of infection is highest during the summer months. Breed predispositions for infection have not been well studied, but the traditional fighting breeds (American pit bull terriers [APBT], Staffordshire bull terriers, and bull terriers) are more likely to die when they are diagnosed with severe babesiosis.[29] Recent surveys have suggested a decline in the number of cases of babesiosis treated in South African hospitals since 2011 with a sharp decline in 2015. This decline coincides with the introduction of isoxazoline use in South Africa and has been postulated as a possible cause for some of the decline.[30]

Unnamed Large Babesia Species. At least two genetically unique large *Babesia* spp. that have not been formally named have been described in dogs. One is a large *Babesia* sp. (Birkenheuer, 2004) that has been isolated from dogs in North America.[31] The majority of these dogs had been splenectomized or were undergoing chemotherapy for cancer. Infected dogs have been identified throughout the southeastern and south central United States.[31–33] Another large *Babesia* sp. (Holm, 2006) was reported in a dog from the United Kingdom that never traveled outside of that country.[34] The dog died as a result of infection. There have not been any further reports of this infection in dogs or other vertebrate species. The natural vertebrate host(s) for either species has yet to be identified.

Continued

Babesia gibsoni

Infections with *B. gibsoni* occur throughout the world, and the insidious nature of this infection has allowed the inadvertent transport of infected dogs from Asia to other regions. *Babesia gibsoni* can be found in Africa, Asia, Australia, North and South America, and Europe (Fig. 97.2C); in a 2020 study, globally it accounted for almost 50% of positive *Babesia* PCR test results in specimens submitted to IDEXX Laboratories; this was followed by *B. canis* (35%) and *B. vogeli* (15%).[15,35] Antarctica is the only continent from which *B. gibsoni* infections have not yet been reported. *Babesia gibsoni* is the most commonly recognized *Babesia* sp. in the United States and Asia. Depending on the availability of suitable vectors, two distinct

C

Fig. 97.2, cont'd (C) *Babesia gibsoni*. (From Birkenheuer AJ, Buch J, Beall MJ, et al. Global distribution of canine *Babesia* species identified by a commercial diagnostic laboratory. *Vet Parasitol Reg Stud Reports*. 2020;22:100471.)

epidemiologic scenarios exist for *B. gibsoni*: tick transmission or direct transmission between dogs.[36,37] *Babesia gibsoni* is transmitted primarily by the tick vectors *Haemaphysalis* spp., and possibly by *Rh. sanguineus*.[38–47] In its original endemic area of Asia, the geographic range of *B. gibsoni* correlates with that of *Haemaphysalis bispinosa,* and tick infestation is a risk factor for infection in nonfighting breeds. In the United States where competent tick vectors are not widely distributed, *B. gibsoni* infections are believed to have originated from dogs engaged in fighting activities and most infected dogs have been APBT.[37,48,49] In one diagnostic laboratory, "pit bull" type dogs represented approximately 75% of the *B. gibsoni* infections between 2012 and 2017.[50] In the United States, many dogs with *B. gibsoni* infections that are not APBT have had fighting contact or blood transfusions from APBT. An increased prevalence of infection has also been noted in fighting breeds in areas such as Japan, where *Haemaphysalis* spp. are endemic. In fighting breeds, transmission has been associated with a fight or bite by an infected dog or having been born to an infected bitch. Perinatal transmission is documented to occur.[3–5]

Babesia conradae

Babesia conradae (previously referred to as "the California isolate" and the "western piroplasm", which has been historically misidentified as *B. gibsoni*) was originally detected in dogs from southern California, and more recently has been reported in dogs from southcentral USA (Oklahoma).[51–53] Tick vectors have not been identified. Transmission studies that attempted to prove vector competence for *Rh. sanguineus* and *Dermacentor variabilis* were unsuccessful or inconclusive.[54] The author has identified *Rh. sanguineus* as well as soft-bodied ticks, *Ornithodoros coriaceus*, on *B. conradae*–infected dogs.[55] A high prevalence (>50%) of *B. conradae* infection has been noted in greyhound mixed-breed dogs used to hunt coyotes in California, and infected greyhounds in the southcentral United States have also been used for coyote hunting.[53,56] Among the Californian dogs, a history of coyote fights was a risk factor for infection. *Babesia conradae* DNA has been detected in spleens from coyotes in California,[57], so fighting may be one mode of transmission for this *Babesia* species. Because greyhounds are used and exchanged for coyote-hunting across the continental United States, additional cases are likely to be recognized in other states.[57]

Babesia vulpes

Babesia vulpes (also referred to as *Babesia annae*, *Babesia microti*–like or *Theileria annae*) has been identified in dogs in Europe, Russia, and the United States.[58–60] The majority of cases described have been dogs that lived in, or traveled to, northwestern Spain.[61–65] More recently, infected domestic dogs in the United States have been identified.[66–68] Similar to *B. gibsoni* infections, a majority of these dogs have been APBT. In the United States, there has been a high rate of co-infection of these dogs with *B. gibsoni*. A high percentage of European and North American foxes are infected with a genetically identical parasite and they are believed to be the natural reservoir host.[69–72] A 2019 study found a high prevalence of *B. vulpes* infections in domestic dogs.[73] A tick vector has not been definitively identified, but in Spain an association between *Ixodes hexagonus* infestation and *B. microti*–like infection has been observed.[74] *Ixodes hexagonus* is not endemic in North America, so it is not likely to be the universal vector.

Babesia negevi sp. nov.

Babesia negevi sp. nov. is a novel intermediate-sized piroplasm that was detected in five dogs with signs of babesiosis from Israel and described in 2020.[75] The organism is named after the Negev desert in southern Israel, where the first infected dog was found.

Feline Babesiosis

Feline babesiosis has not been studied as extensively as canine babesiosis, but as with canine babesiosis, there has been increased recognition of the number of species that can infect cats in recent years.[76] Several small *Babesia* species have been identified in cats, which include *Babesia felis* sensu stricto, *Babesia cati, Babesia leo,* and a novel small *Babesia* species.[77–79] *Babesia felis* is a highly pathogenic *Babesia* species that infects domestic cats in southern Africa and the Sudan.[77] Infection of domestic cats has primarily been identified along the coast of South Africa.[80,81] Affected cats are usually younger than 3 years, and there is no recognized breed or sex predilection. *Babesia cati* is less pathogenic and found primarily in India. *Babesia leo* has been detected in lions (*Panthera leo*) in Kruger National Park, as well as a single domestic cat in a molecular survey.[82] A small piroplasm was visualized in blood smears from feral cats in Rio de Janeiro, Brazil, but no molecular data were available to confirm the identity of these organisms.[83] *Babesia gibsoni* was detected in 4% of 115 apparently healthy cats in the Caribbean; *B. vogeli* was detected in 13% of cats, and mixed infections with *B. vogeli* and *B. gibsoni* were detected in 3% of cats.[84]

Large *Babesia* species also appear to infect cats. *Babesia lengau*, originally described in cheetahs, was detected in two domestic cats from South Africa with cerebral and hemolytic disease.[85] DNA sequences, most similar to those of *B. vogeli* and *B. vulpes*, have been amplified from the blood of three cats with retroviral infections from Spain and Portugal, but no organisms were visualized.[86–90] *Babesia canis presentii* was identified in two cats in Israel.[89] Possible other novel *Babesia* species have been proposed that infect cats, such as *Babesia panickeri* sp. nov. (described in a 3-month-old cat from India with severe anemia and thrombocytopenia)[91] and *Babesia hongkongensis* (described in cats from Asia).[79] Another *B. canis*–like parasite has been identified in a naturally infected cat from Poland.[92] Feline babesiosis has not been well documented in the United States.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Canine Babesiosis

The pathogenicity of *Babesia* organisms is determined primarily by the species and strain involved. Host factors, such as the age of the host and the immunologic response generated against the parasite or vector tick, are also important. Although most often subclinically infected, dogs infected with "avirulent" species such as *B. vogeli* may have severe clinical disease. Similarly, dogs infected with "virulent" species such as *B. rossi* may be subclinically infected without overt clinical or laboratory findings. However, features that should raise clinical suspicion for babesiosis include fever, thrombocytopenia, hemolytic anemia, and splenomegaly. Dogs often have nonspecific signs such as lethargy, anorexia, and weakness (Box 97.1). Occasionally, owners note jaundice, mucosal pallor, or discoloration of the urine caused by bilirubinuria or hemoglobinuria. Azotemia and proteinuria have been identified with increased frequency in dogs with *Babesia* infections.[61,93–96] Dogs infected with *B. vogeli* may have fever of unknown origin only without overt hematologic abnormalities.[97] Co-infections with other tick- or bloodborne pathogens may also influence the clinical signs of disease.

Parasite antigens are incorporated on the erythrocyte surface and induce host-opsonizing antibodies, which in turn leads to removal of infected erythrocytes by the mononuclear phagocyte system. Soluble parasite antigens can also adhere to the surface of noninfected erythrocytes and platelets. This may lead to their opsonization by antibodies, with or without complement, and account for hemolytic anemia and thrombocytopenia that is often not correlated with the level of parasitemia. Parasitemia and anemia are more severe in splenectomized dogs, and splenectomy may precipitate disease in dogs with chronic subclinical infections. Mechanisms other than immune-mediated destruction that contribute to erythrocyte damage include increased erythrocyte osmotic fragility, direct injury of erythrocytes by *Babesia* parasites, accumulation of cyclic nucleotides, and oxidative injury.[98–102] Lipid peroxidation increases erythrocyte rigidity and slows the passage of erythrocytes through capillary beds. Soluble parasite proteases activate the kallikrein system and induce fibrinogen-like protein formation. These proteins make erythrocytes more "sticky," and they sludge in capillary beds, which contributes to anemia and many of the other potential clinical signs. The most severe sludging occurs in the CNS and muscles.

Thrombocytopenia may result from immune-mediated destruction of platelets or consumption coagulopathy. Despite severely decreased platelet counts, bleeding is rarely observed in dogs infected with most *Babesia* strains, and other abnormal coagulation test results are uncommon (with the exceptions of *B. conradae* and also *B. rossi* infections). Dogs with *B. conradae* infection have experienced life-threatening hemorrhage, the pathogenesis of which requires further study.[57]

Other possible complications include membranoproliferative glomerulonephritis, which may have an immune-mediated pathogenesis.[93,94,103] Renal failure occurs in up to 40% of dogs infected with *B. vulpes*, and the presence of renal failure has been associated with increased mortality.[61,63,65,104,105] Nonregenerative anemia, azotemia, and proteinuria with high UPCRs were found in these dogs. Renal disease and proteinuria have been identified in dogs with *B. gibsoni* infections.[93,94]

BOX 97.1 Clinical Findings in Dogs with Babesiosis

Common signs
- Anorexia
- Lethargy
- Weakness
- Pyrexia
- Weight loss

Uncommon/atypical signs (primarily *B. rossi*)
- Ascites
- Edema
- Constipation
- Diarrhea
- Ulcerative stomatitis
- Hemorrhage
- Congested mucous membranes
- Polycythemia
- Ocular and nasal discharge
- Respiratory distress
- Masticatory myositis
- Temporomandibular joint pain
- Spinal pain
- Central nervous system signs (seizures, ataxia, paresis)

Hyperacute signs (primarily *B. rossi*)
- Hypothermia
- Shock
- Coma
- Disseminated intravascular coagulation
- Metabolic acidosis
- Death

Acute signs
- Hemolytic anemia
- Icterus
- Splenomegaly
- Lymphadenopathy
- Vomiting

Chronic signs
- Intermittent pyrexia
- Partial anorexia
- Loss of body condition
- Lymphadenomegaly
- Splenomegaly
- No signs

Severe Babesiosis. Virulent *B. canis* and especially *B. rossi* strains may induce a profound systemic inflammatory response, which can result in a severe sepsis-like syndrome with multiple organ dysfunction (see Chapter 123). The majority of dogs infected with *B. rossi* have uncomplicated babesiosis and can be treated as outpatients. However, up to 31% of the dogs examined at a university clinic required hospitalization, and 10% of hospitalized dogs did not survive.[29] Severe clinical illness in dogs infected with *B. rossi* results from hypotension, AKI, neurologic complications, DIC, hepatopathy, and ARDS. Tissue hypoxia results from anemia, shock, vascular stasis, excessive endogenous production of carbon monoxide, parasitic damage to hemoglobin, and decreased ability of hemoglobin to off-load oxygen.[99,106] Lactic acid generation from tissue hypoxia can result in severe metabolic acidosis.[107]

"Red biliary syndrome" is a paradoxical phenomenon of severe intravascular hemolysis (manifested as hemoglobinemia and hemoglobinuria) in combination with hemoconcentration (high reference range or elevated hematocrit).[106] The hemoconcentration is thought to occur when plasma shifts from the vascular to the extravascular compartment as a result of increased capillary permeability, with a resultant decrease in blood volume. Hemoconcentration has been associated with cerebral babesiosis, DIC, AKI, and ARDS.

Neurologic complications result from sludging of parasitized erythrocytes in CNS capillary beds, with congestion and macroscopic and microscopic hemorrhages. Severe hypoglycemia can also result in neurologic signs. Other complications of severe babesiosis include pancreatitis, rhabdomyolysis, ocular involvement, upper respiratory signs, cardiac arrhythmias, necrosis of the extremities, and fluid accumulation. Pulmonary, CNS, and renal complications are associated with a higher rate of mortality. Persistent lactate concentrations above 40 mg/dL are a poor prognostic indicator for survival.[108] In a study of 240 babesiosis cases from central Europe, serum creatinine concentrations above 5 mg/dL and albumin concentrations less than 2.2 g/dL were negative prognostic indicators. When AKI was present, 34% of dogs died, and 40% of dogs with pancreatitis died.[109]

Feline Babesiosis

Cats with babesiosis from southern Africa generally show lethargy, anorexia, weakness, an unkempt haircoat, and/or diarrhea.[81] Fever and icterus are less common. Anemia can be severe and is the underlying reason for the clinical signs. The disease is chronic, and signs may not be apparent until a later stage of illness. Cats usually adapt to the anemia and may have only mild clinical signs until they are stressed by handling. Complications of hemolytic anemia include hepatopathy, pulmonary edema, renal failure, CNS signs, and concurrent infections.

Physical Examination Findings

Physical examination abnormalities in most dogs with babesiosis consist of mucosal pallor, lethargy, splenomegaly, and bounding pulses. Fever is not consistently identified because it often waxes and wanes. Tachycardia and tachypnea may be present in severely anemic dogs. Mucosal hemorrhages and/or epistaxis may be present in dogs with *B. conradae* infections (Fig. 97.3), and excessive bleeding from venipuncture sites may be noted.

Dogs with severe babesiosis may show CNS signs such as incoordination, pelvic limb paresis, muscle tremors, nystagmus, anisocoria, intermittent loss of consciousness, seizures, stupor, coma, aggression, or vocalization.[106] Dogs with red biliary syndrome may have congested mucous membranes or icterus. Other clinical abnormalities in dogs with severe babesiosis include tachypnea, increased lung sounds, and cardiac arrhythmias.

Fig. 97.3 Greyhound infected with *Babesia conradae*. Mucosal hemorrhages are apparent. These resolved after treatment with atovaquone and azithromycin. (Courtesy Dr. Jane E. Sykes, University of California, Davis.)

Affected cats may be lethargic, pale, tachycardic, and tachypneic, and in some cases, icteric.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

In dogs with babesiosis, the primary hematologic abnormalities are anemia and thrombocytopenia. Thrombocytopenia is the most common abnormality and is often present, even when anemia is absent. A mild, normocytic, normochromic anemia is generally noted in the first few days after infection, which becomes macrocytic, hypochromic, and regenerative as the disease progresses. Uncommonly with *B. rossi* infections, a relative polycythemia may be noted.[106] Leukocyte abnormalities are inconsistently observed but may include leukocytosis (with or without a left shift), leukopenia, neutrophilia, neutropenia, lymphocytosis, and/or eosinophilia.[56,110,111] Leukopenia or a low-normal leukocyte count due to relative neutropenia has been frequently observed in dogs from Europe with *B. canis* infections and dogs from the United States with *B. conradae* infections.[56,111] Autoagglutination, positive direct antiglobulin (Coombs') tests, and spherocytosis may also be present.[112] Some infected dogs have no hematologic abnormalities.

In cats, anemia associated with *B. felis* infection is typically macrocytic, hypochromic, and regenerative.[113] Thrombocytopenia is an inconsistent finding.

Serum Chemistry Profile

There are no pathognomonic biochemical findings in dogs with babesiosis, and serum biochemical profiles may have no abnormal findings. Common findings in North American dogs include hyperglobulinemia (which may be present in the absence of other laboratory abnormalities), mildly increased liver enzyme activities, and, less commonly, hyperbilirubinemia. A study of dual infections with *B. canis* and *Ehrlichia canis* showed that the prevalence of hyperglobulinemia was higher in dogs with dual infections than in dogs with a single infection

TABLE 97.1 Diagnostic Assays Available for Babesiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Babesia* spp.	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation.
Cytology	Whole blood, buffy-coat smears (the area just below the buffy coat), tissue aspirates	*Babesia* spp.	Rapid and specific (i.e., when merozoites are identified by experienced cytologists, the sample is likely to be infected with *Babesia* spp.; however, *Babesia* spp. cannot be accurately differentiated based on morphology alone). Less sensitive than PCR.
Immunofluorescent antibody serology	Serum	Antibodies to *Babesia* spp.	Acute and convalescent serology may be required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease and positive results may reflect previous exposure rather than active infection. Cross-reactivity can occur between *Babesia* spp. Some dogs do not develop detectable antibody titers despite chronic infection.
PCR	Whole blood, splenic aspirates	*Babesia spp.* DNA	Confirms active infection. Sensitivity and specificity varies depending on assay design and specimen type. Both false-positive and false-negative results are possible; PCR results must be interpreted in light of the clinical signs. Serial sampling (i.e., two or more tests on specimens obtained 2–4 weeks apart) will increase sensitivity, especially in chronically infected animals.

caused by either organism.[114] Hyperbilirubinemia is a more consistent finding during acute disease caused by *B. canis* and *B. rossi* but not by *B. gibsoni* or *B. conradae*.[56,110] Dogs with severe *B. rossi* infections may have hemoglobinemia, moderately increased liver enzyme activities, increased BUN and serum creatinine concentrations, hypoalbuminemia, hypoglycemia, and metabolic acidosis. Some dogs develop kidney injury with or without proteinuria and hypoalbuminemia.[61,94]

Cats infected with *B. felis* typically have elevated serum ALT activity and total bilirubin concentrations. Serum protein values are usually within reference limits, but hyperglobulinemia can occur. Renal parameters are unaffected.[113]

Urinalysis

Urinalysis abnormalities in dogs with babesiosis are variable but include bilirubinuria, hemoglobinuria, proteinuria, and, in rare cases, granular casts. Some dogs have pigmenturia consisting most commonly of bilirubin, and occasionally hemoglobin. Dogs with secondary glomerular nephritis have proteinuria and may have isosthenuria.

Coagulation Testing

The most consistent hemostatic abnormality in complicated and uncomplicated babesiosis is thrombocytopenia. DIC has been reported, but it is extremely rare. Dogs with *B. conradae* infection appear to have altered platelet function tests.[57]

Microbiologic Testing

There are three basic methods available for specific diagnosis of *Babesia* infections: microscopic identification, serologic testing, and nucleic acid–based testing (Table 97.1). The true clinical sensitivity and specificity of most of the available tests is unknown, but all modalities can have either false-positive or false-negative results. Therefore, there is no "perfect" test for *Babesia* infection, and in many cases, multiple diagnostic tests are indicated.

Cytologic Diagnosis

Light microscopic examination is highly specific for the identification of *Babesia* organisms, but because of its limit of detection (0.001% parasitemia), it has relatively poor sensitivity and is not suitable as a sole screening test. Several species/genotypes are virtually indistinguishable by light microscopy, making accurate identification to the species level impossible. However, when cytologic detection is used in combination with the history, signalment, physical examination, clinicopathologic data, and geographic location, the clinician may be able to predict the most likely species present.

Babesia canis, B. vogeli and *B. rossi* are large, pyriform organisms and usually exist singly or in pairs (Fig. 97.4A). Smaller single intracellular organisms are likely to be *B. gibsoni*, *B. conradae* or *B. vulpes* (Fig. 97.4B and C). However, when the parasites are rapidly replicating, the classic intraerythrocytic forms may not predominate and some more atypical irregular, amoeboid parasite forms with a wide range of sizes can be detected. During these phases of infection, some small *Babesia* spp. exhibit large forms and some large *Babesia* spp. exhibit small forms. In chronic infection, the level of parasitemia is often low, especially in dogs infected with large *Babesia* sp., and thorough examination of thin blood smears is necessary. Evaluation of stained slides requires experience and a significant time commitment on the part of the laboratory technician. For large *Babesia* spp. infections, blood collected from the peripheral capillary beds of the ear tip or nailbed may yield higher numbers of parasitized cells.[115] Rarely, phagocytized organisms and erythrocyte fragments are seen in neutrophils. Methods that concentrate and stain buffy-coat specimens may improve the sensitivity of parasite detection.[116,117]

Serologic Diagnosis

Because *Babesia* parasites are difficult to detect, especially in chronic carriers, immunodiagnostics may be used to screen for exposure. IFA assays are used most commonly to detect antibodies to *Babesia* species. Laboratory methods differ, and each laboratory should be consulted for cutoff antibody titers. As a general guideline, titers ≥ 1:64 on a single specimen are supportive of exposure. Serologic assays for *B. rossi, B. conradae,* and *B. vulpes* are not widely available at the time of writing.

Titers to multiple *Babesia* species must be measured if antibody testing is performed in geographic areas where more than one species of *Babesia* exists. Serologic cross-reactivity among *Babesia* spp. makes parasite identification by PCR necessary to definitively identify a given species. When titers against multiple species are performed, the highest titer is not always the infecting species. There are also many documented instances in which parasites or parasite DNA have been detected but anti-*Babesia* antibodies could not be detected. Very young dogs or dogs tested early in the disease course may have negative antibody test results, so convalescent serology is required in some cases. Antibodies were not detected in 36% of dogs with *B. canis* parasitemia in one study.[17] ELISAs that target several

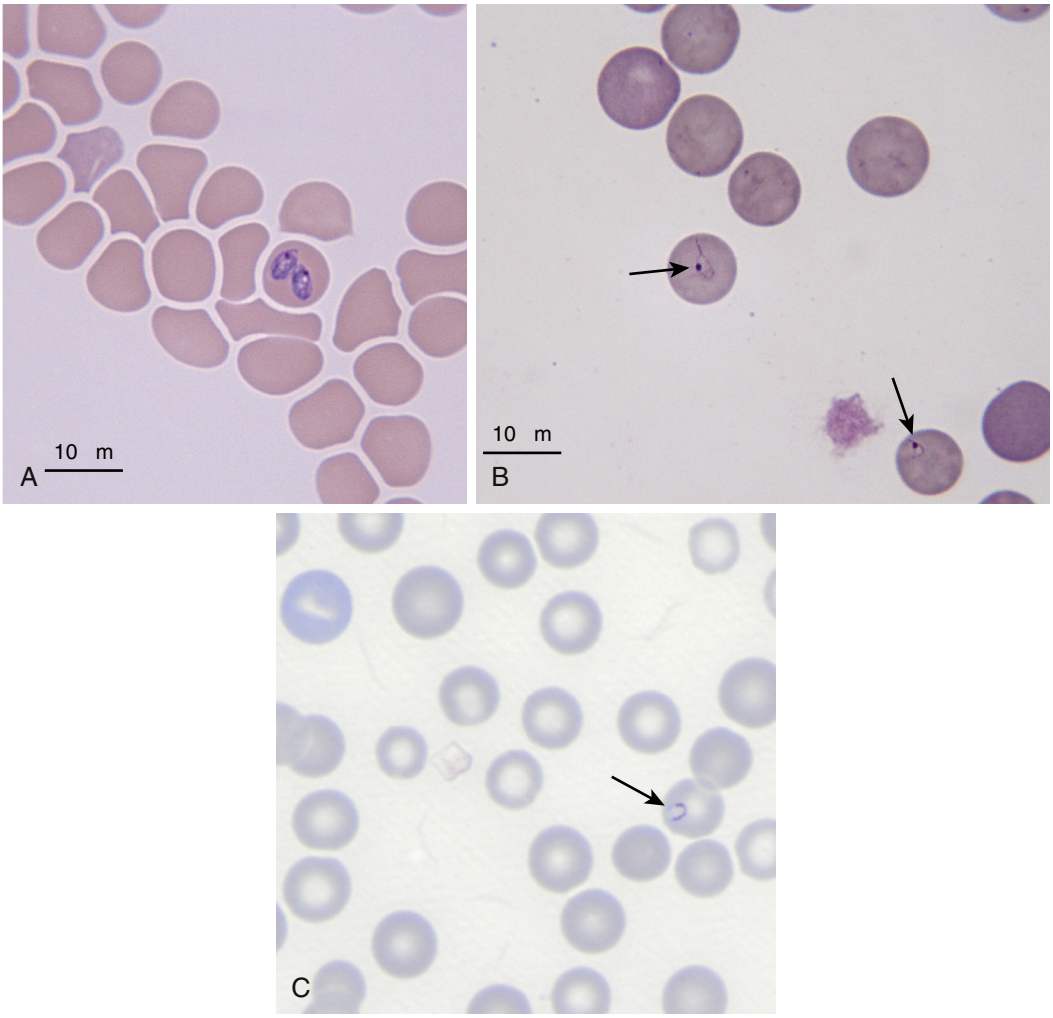

Fig. 97.4 Blood smears from dogs with babesiosis. (A) Large unnamed *Babesia* piroplasm originally identified in dogs in North Carolina. A pair of large, piriform-shape merozoites are present within an erythrocyte. (B) Individual merozoites of *Babesia gibsoni* in erythrocytes *(arrows).* (C) *Babesia conradae* merozoite within an erythrocyte *(arrow).* Polychromasia and anisocytosis are also present. Wright stain, 1000×.

different antigens have been developed for use in antibody or antigen detection tests and offer promise for serodiagnosis of canine babesiosis in the future. However, there are currently no commercially available ELISA assays for the detection of anti-*Babesia* antibodies in the United States.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Nucleic acid amplification tests (NAATs) such as PCR assays are the most specific means of detecting infection with *Babesia* and are essential for accurate species identification. Some assays have a lower limit of detection that is more than 1300-fold more sensitive than the level (0.001% parasitized erythrocytes) of light microscopy.[118] A 2018 study found PCR to be five times more sensitive than microscopy for the identification of infection.[119] Many different NAATs have been published for the identification and differentiation of *Babesia* infections, and several commercial diagnostic laboratories offer real-time PCR assays for detection of *Babesia* infection. Species identification can then be accomplished by DNA sequencing or by the use of species-specific assays. NAATs that are designed to detect multiple *Babesia* spp. (i.e., a broad-range *Babesia* PCR) are recommended for initial screening. A well-designed species-specific assay will only detect one species; the potential downside is that a negative test may lead clinicians to falsely conclude that the patient is not infected with *Babesia* because the wrong species was targeted for testing. In addition, broad-range PCR assays have been helpful for identification of novel *Babesia* species.

Pathologic Findings

The most striking pathologic findings occur in dogs that die from severe babesiosis (usually associated with *B. rossi*). These include staining of tissues with hemoglobin or bilirubin, hepatosplenomegaly, lymphadenomegaly, and kidneys that are a dark-reddish color. Edema and hemorrhage, which may indicate vascular injury and poor tissue oxygenation in severely affected dogs, are often most severe in the lungs. Nonparasitized cells often line the endothelial surface with parasitized cells sludged in the lumen. Pathologic changes in the brain of these dogs include congestion, macroscopic and microscopic hemorrhages, sequestration of parasitized erythrocytes in capillary beds, and pavementing of parasitized cells against the endothelium. Cardiac histologic changes include hemorrhage, necrosis, inflammatory infiltrates, and fibrosis. Microthrombi

TABLE 97.2 Selected Antibabesial Compounds Used in Dogs and Cats

Generic Name[a]	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)	ORGANISM: *Babesia canis, Babesia vogeli, Babesia conradae,* large *Babesia* spp.	ORGANISM: *Babesia gibsoni*	ORGANISM: *Babesia conradae*	ORGANISM: *Babesia felis*

[a]For specific information on each drug, see Chapter 12.
[b]For combination therapy, a dose of 3.5 mg/kg diminazene has been followed by a dose of 6.0 mg/kg imidocarb.
[c]Not available in the United States, except by compassionate use. For large *Babesia spp.*, this dose is sufficient; for *B. gibsoni*, repeat dose in 24 hours. Total dosages of 7 mg/kg or higher are associated with an increased risk of neural and parasympathomimetic toxicity.
[d]These two drugs should be used in combination. Atovaquone must be given with a fatty meal to facilitate absorption. The suspension causes minimal gastrointestinal adverse effects.
[e]Anecdotal evidence for activity against *B. vogeli*. Not effective in clearing the infection. Not recommended as sole therapy because of the potential to develop resistance. Further documentation needed to establish efficacy of this combination (see text).
[f]Note that 1 mg/kg is a lethal dose.
+++, very good; ++, good; +, fair to poor; —, not effective; *?*, unknown.

of many tissues may be evident in animals exhibiting signs of DIC. Impression smears of the spleen may substantiate the diagnosis of babesiosis at necropsy. Nonspecific findings in dogs with all forms of babesiosis include erythroid hyperplasia in the bone marrow, extramedullary hematopoiesis of the liver and spleen, mononuclear phagocyte system hyperplasia, and centrilobular necrosis of the liver. Vasculitis has been observed in *B. conradae* infections and is associated with hepatitis and lymphadenitis with multifocal deposits of IgM in inflamed arteries and renal glomeruli.[103] In chronic canine babesiosis and feline babesiosis, the only gross finding may be splenomegaly.

TREATMENT AND PROGNOSIS

Antiprotozoal Treatment

Dogs

Dogs generally show clinical improvement within 24 to 72 hours of treatment with antibabesial drugs, but some animals take as long as 7 days to respond (Table 97.2).

Imidocarb dipropionate can eliminate *B. canis*, *B. vogeli*, and *B. rossi* infections, but has shown variable efficacy for eliminating infections with large *Babesia* sp.[33] Imidocarb also eliminates infection with *B. canis* in ticks that engorge on treated animals for up to 4 weeks after treatment, and prevents infection for up to 6 weeks after a single injection.[120] A single dose of 7.5 mg/kg or a single dose of 6 mg/kg given the day after a dose of diminazene (3.5 mg/kg) also clears infection.[121] In areas where reinfection is likely, some practitioners use a lower dose, 2 mg/kg, SC, once. This approach is an attempt to induce a state of premunition. Premunition is the immunity of existing infection in which chronic subclinically affected carriers may be resistant to reinfection or at least have reduced morbidity with new infections. In contrast, animals that have been cleared of infection are more susceptible to reinfection with recurrent clinical disease. The risk of this approach is that clinical babesiosis may relapse in some chronic carriers. Therefore, this approach is not recommended for the treatment of canine babesiosis in many parts of the United States, where vector transmission and risk for reinfection are thought to be low. Imidocarb does not clear *B. gibsoni* infections, but reduces morbidity and mortality. Therefore, this is a reasonable alternative treatment for *B. gibsoni* infection if the owner cannot immediately afford more effective treatments. The same may be true for *B. conradae* infections. Pretreatment with atropine (0.025 mg/kg, SC, 30 minutes before injection) reduces the adverse effects of imidocarb (see Chapter 12).

Other related aromatic diamidines include diminazene aceturate, phenamidine isethionate, and pentamidine isethionate (see Chapter 12). Although these are not available for treatment of dogs in the United States, the first two of these drugs have been used in many other countries and are highly active against large *Babesia* sp. They do not clear *B. gibsoni* infections, but can reduce morbidity and mortality.

Atovaquone and azithromycin combination therapy is recommended for the treatment of *B. gibsoni* and *B. conradae* infections (see Table 97.2).[55,122,123] Anecdotally this author has seen clinical remissions in dogs infected with *B. vogeli* or the large *Babesia* sp. (Birkenheuer, 2004). Atovaquone and azithromycin are given for 10 days. Atovaquone must be administered with a high-fat meal to maximize drug absorption. There are also two commercially available formulations of atovaquone: a single-drug liquid suspension that is very well tolerated, and a combination tablet product (atovaquone and proguanil hydrochloride). Although the combination product is less expensive, it causes severe vomiting in some patients. Because drug absorption is critical and selection for resistance to atovaquone can occur, this author recommends *only* use of the single-drug suspension. The treatment appeared to sterilize *B. gibsoni* infections or reduce the parasitemia below detectable limits

in approximately 80% of dogs in a randomized double-blind placebo-controlled trial.[122] However, in another study, this combination only eliminated *B. gibsoni* infection (or reduced parasitemia below detectable limits of PCR assay), in two of seven dogs.[124] It also did not clear experimental infection with two Australian isolates of *B. gibsoni*.[125] When atovaquone is used alone to treat *B. gibsoni* infection, recrudescence of infection develops more than 30 days after treatment.[125] Drug resistance has been identified *in vitro*, so atovaquone should always be used in combination with other drugs. Mutations in the genes that encode the putative molecular target of atovaquone have been identified in *B. gibsoni* isolates from dogs that failed to clear infection after atovaquone treatment.[50,124,126,127]

In this author's experience, dogs that fail to clear *B. gibsoni* infections after initial treatment with atovaquone and azithromycin are infected with organisms with mutations in the cytochrome B gene and will not clear their infection after a follow-up treatment with the same drugs, although clinical disease may resolve. Dogs that have been splenectomized before treatment do not always appear to clear infections with treatment.[128] Likewise, immunosuppressive therapy may reduce the ability of antibabesial treatment to clear dogs of *B. gibsoni* infection. The recommended follow-up after treatment with atovaquone and azithromycin is a minimum of two PCR tests approximately 60 and 90 days after completing treatment. Earlier testing can result in false-negative or false-positive results due to decreased circulating parasitemia or detection of dead or replication-deficient organisms.[123] A trial comparing imidocarb, atovaquone and azithromycin, and buparvaquone and azithromycin was performed in dogs with *B. vulpes* infections. None of these treatments consistently cleared the infections. The combination therapies were superior to imidocarb for reducing clinical signs and parasitemias. Atovaquone and azithromycin reduced infections below the limit of detection of the PCR test in the highest proportion of cases (approximately 50%).[129]

An alternative treatment strategy can be used to treat *B. gibsoni* infections that fail to respond to atovaquone and azithromycin.[130] This regimen involves a combination of clindamycin, metronidazole, and doxycycline for a minimum of 3 months (see Table 97.2). In an uncontrolled study, three of four experimentally infected dogs had negative PCR assay results after treatment, whereas one dog remained persistently infected and experienced clinical relapses during treatment.[130] Clearance of the infection as determined by PCR was not detected until 30 and 72 days after completing a 90-day treatment course in two dogs. The PCR test result became negative in the third dog 12 days into treatment. Three of the dogs were initially treated with three doses of diminazene aceturate. In two other studies, naturally infected dogs that had clinical relapse after or during atovaquone and azithromycin treatment had clinical recoveries after treatment with the clindamycin, metronidazole, and doxycycline combination.[124,131] The small number of cases reported and the high degree of variability in the PCR results after treatment make the efficacy of this combination uncertain. However, as with the atovaquone-azithromycin combination, PCR testing 60 and 90 days after completing therapy is recommended.

Aggressive supportive care and monotherapy with clindamycin (25 mg/kg, PO, q12h for 7 to 21 days) has been recommended if specific antibabesial drugs are not available.[132] At this dosage, clinical abnormalities resolve even if organism clearance does not occur. This author *does not* routinely recommend this practice for *B. gibsoni*–infected dogs due to concerns about the selection for macrolide resistance that could potentially interfere with subsequent atovaquone and azithromycin treatment.

Doxycycline has some activity against *Babesia* spp., but there are no controlled studies evaluating efficacy. It is this author's experience that many dogs with babesiosis have a mild reduction in morbidity with doxycycline monotherapy. This frequently leads clinicians to suspect a rickettsial or bacterial infection. Doxycycline (5 mg/kg, PO, q12h) therapy can be instituted while awaiting specific antiprotozoal drugs.

Other treatments that have been used to treat *B. canis* infections are quinuronium sulfate and 1% trypan blue solution. Trypan blue does not clear infections and results in bluish discoloration of tissues and plasma. Tafenoquine, an 8-aminoquinoline, is an anti-malarial drug and has also been shown to have activity against *Babesia gibsoni* infections in experimentally-infected dogs through oxidative damage to parasites.[133]

Cats

Treatment of feline babesiosis has not been as critically evaluated, but most antibabesial drugs appear ineffective. Primaquine phosphate, an antimalarial compound, administered orally or as an intramuscular injection, is currently the drug of choice (see Table 97.2). However, the effective dose, 0.5 mg/kg, is very close to the lethal dose (1 mg/kg). In experimental studies, rifampin and trimethoprim-sulfadiazine were not as effective as primaquine.[134]

Supportive Care

Other supportive care measures that may be required to treat animals with babesiosis are packed red blood cell transfusions and IV crystalloid fluid therapy. The administration of the plasma component of whole blood is unnecessary in the majority of dogs with babesiosis and can place the patient at risk of volume overload and transfusion reaction or the transmission of other infectious agents. If rehydration is required, crystalloid replacement solutions are preferable. Whether glucocorticoids are indicated to counteract the immune-mediated complications of babesiosis is controversial. This author does not recommend the use of glucocorticoids to treat dogs infected with *B. gibsoni* or *B. vogeli*. In one study, 21% of 134 dogs with *B. rossi* infection had hemolytic anemias that did not respond to antibabesial therapy alone.[106] This seems less common with *B. vogeli* or *B. gibsoni* infections because these often respond completely to antibabesial treatment alone. In most dogs that require glucocorticoids, the glucocorticoid dosage can be tapered and discontinued within a 2- to 3-week period. Continued glucocorticoid therapy may predispose the animals to other infections and has the potential to induce babesial relapse.

IMMUNITY AND VACCINATION

The duration of protective immunity against *Babesia* spp. infection is limited. Antibody titers may gradually decline between 3 and 5 months after infection.[120] Recovered dogs are protected against homologous infection within 5 to 8 months after infection.[120] Cross-protection between strains does not occur, and seropositivity does not guarantee protection against heterologous challenge.

A vaccine produced from cell culture–derived exoantigens of *B. canis* is available in Europe.[135] An efficacy of 70% to 100% has been reported, with the disease occasionally seen in the vaccinates generally being mild. Other field studies have been less impressive. Vaccination does not prevent infection but appears to block initiation of many

of the pathologic processes involved in disease pathogenesis.[136,137] Vaccines may limit parasitemia and reduce development of anemia and splenomegaly. A bivalent vaccine derived from soluble parasite antigens from *B. canis* and *B. rossi* (Nobivac Piro, MSD Animal Health South Africa) reduces clinical signs after challenge with both species.[138] Differences in strain antigenicity limit the usefulness of the commercial vaccine in other areas. *Babesia canis* vaccines do not cross-protect against other *Babesia* species.

PREVENTION

Treatment of babesiosis is expensive and may be ineffective, so prevention is of paramount importance. Preventive measures alone may be sufficient to control *B. vogeli* outbreaks in kennels in the southeastern United States. The primary means of prevention is tick control (see Chapters 13 and 109). Early tick identification and removal is important because it likely takes a minimum of 2 to 3 days of feeding for transmission of the parasite to occur. Dogs should be tested, treated if necessary, and quarantined before being introduced into a colony. Several tick-control products (isoxazoline class, fipronil/permethrin, and imidacloprid/flumethrin) have reduced the experimental and natural transmission of *B. canis* and *B. rossi* infections.[139–149] Similar studies have not yet been performed/published for other canine *Babesia* spp. Prevention of aggressive interactions with other dogs (especially fighting breeds such as APBT) may also prevent infection. All prospective canine blood donors should be tested for babesiosis with serology and PCR assays, and animals positive by either or both methods should not be used for blood donation.

Splenectomy of at-risk breeds or exposed/infected dogs should be avoided if possible. If a nonemergent splenectomy must be performed, treatment should be considered before the procedure. Ideally treatment would be completed 60 days prior to the procedure.

PUBLIC HEALTH ASPECTS

Canine and feline *Babesia* spp. do not appear to pose a zoonotic risk to immunocompetent humans. Their risks to immunocompromised individuals are unknown, but as with many infectious diseases, people who are undergoing chemotherapy, are immunocompromised, or have been splenectomized should exercise special caution when handling blood samples from dogs. Babesiosis is a rare tick-borne zoonosis of people in Europe and in the United States, and isolated uncharacterized *Babesia* infections have been reported in Africa and Mexico.[150,151] The majority of infections are mild or asymptomatic; however, some result in severe illness and death. Splenectomized people or those older than 55 years are especially at risk.[151] No *Babesia* species has been identified that is host specific for people. Sylvan cycles with wild animal reservoirs occur in nature. People serve as accidental hosts for *Babesia* of animals when they are bitten by infected ticks. Transmission through blood transfusion has also been described. *Babesia microti* is the primary parasite that infects people in the northeast and upper Midwest of the United States. The vector tick is *Ixodes scapularis*, which can co-transmit *Anaplasma phagocytophilum* and *Borrelia burgdorferi*. The hemolytic disease with flu-like symptoms is usually mild and self-limiting or easily treated with atovaquone and azithromycin. Both asymptomatic infections and clinical babesiosis with severe anemia have been reported in people in California and Washington and is caused by the more recently described parasite *Babesia duncani*.[151]

Babesia divergens causes a severe form of human babesiosis in Europe, which usually occurs in people who have had a splenectomy and is often fatal. Babesiosis was also identified in splenectomized people from Italy and Austria with a new strain (EU1) that was more closely related to *Babesia odocoilei*.[152] Identical isolates of *Babesia* have been found in *Ixodes ricinus* ticks from Slovenia, suggesting a more widespread distribution of this organism in Europe.

CASE EXAMPLE

Signalment

"Dora," a 4-year-old female spayed American Staffordshire terrier from North Carolina.

History

Dora was evaluated for a 3- to 4-day history of anorexia and lethargy. Before referral, an ELISA that detects heartworm antigen and antibodies to *E. canis* or *B. burgdorferi* antigens was performed and the results were negative. The dog had mild anemia (HCT 28.4%) and moderate thrombocytopenia (59,000 platelets/μL) on an automated hematology analyzer. Amoxicillin-clavulanic acid, doxycycline, and famotidine were prescribed. The patient began showing signs of increased energy and appetite as well as an increase in the HCT (38%) and platelet count (147,000 platelets/μL) after 4 weeks of treatment. However, because the values did not return to within reference range, the case was referred.

Physical Examination

Body weight: 24.2 kg.

General: Bright, alert, responsive, hydrated. T = 101.6°C (38.7°F), HR = 100 beats/minute, RR = 24 breaths/minute, mucous membranes pink, CRT < 2 seconds. Physical examination was otherwise unremarkable.

Selected Laboratory Findings

	Pretreatment	Posttreatment	Reference Range
PCV (%)	41	52	39–58
Platelet count (×10^3/μL)	80	361	190–468
TP (g/dL)	6.3	6.5	5.2–7.3
Albumin (g/dL)	2.7	3.8	3–3.9
Globulin (g/dL)	3.5	2.7	1.7–3.8
Albumin/globulin ratio	0.78	1.38	0.9–1.8
Visualization of *Babesia* on microscopic examination of blood smear	Negative	Negative	
Babesia canis IFA	1:256	ND	
Ehrlichia canis IFA	<1:16	ND	
Bartonella vinsonii IFA	<1:16	ND	
Bartonella henselae IFA	<1:16	ND	
Rickettsia rickettsii IFA	1:64	ND	
SNAP 4Dx ELISA	Negative for all agents	ND	
Babesia spp. PCR	Positive (*B. gibsoni*)	Negative	

Continued

CASE EXAMPLE—cont'd

Diagnosis

Babesia gibsoni infection.

Treatment

Atovaquone and azithromycin.

Comments

Dogs with babesiosis often have a positive clinical response to doxycycline, which leads clinicians to suspect rickettsial infection. Although fever is considered a classic sign of babesiosis, most dogs are afebrile during initial examination, and waxing and waning fever is often documented with serial rectal temperatures. Thrombocytopenia is often a more prominent hematologic finding than anemia and may be the only finding in some cases. Babesiosis may be associated with changes in both albumin and globulin concentrations. Hypoalbuminemia can be secondary to proteinuria (not documented in this case). Globulins are often increased, although they may not be above the high end of the reference range. Organisms are frequently not observed on routine examination of stained blood smears, and PCR assays are required to document infection. Panels that detect antibodies to tick-borne pathogens typically either do not include *Babesia* spp. at all or only detect antibodies against *B. canis*. Serologic cross-reactivity among species can occur, leading to inappropriate diagnosis and treatment recommendations. The positive titer to *Rickettsia* spp. was interesting, but in this geographic location, approximately 20% to 25% of healthy dogs are seropositive to *Rickettsia* spp., so its significance was unclear. Although acute-phase serology for *B. gibsoni* was not done, a convalescent titer to *B. gibsoni* at a follow up examination was 1:64.

Cytauxzoonosis

Leah A. Cohn, Adam J. Birkenheuer

KEY POINTS

- First Described: Cytauxzoonosis was first recognized in domestic cats from Missouri during the mid-1970s.[1]
- Cause: *Cytauxzoon felis* is a hematoprotozoal pathogen of domestic and wild felids.
- Affected Hosts: Only felids are infected with *C. felis.* Domestic cats often develop a severe disease but occasionally only a mild, brief or unapparent illness. The bobcat reservoir host is believed to typically demonstrate mild illness but can die as a result of infection. Other felids (e.g., cougars, tigers, and lions) can also become infected.
- Arthropod Vectors: *Amblyomma americanum* (lone star tick) is the primary vector for pathogen transmission, although *Dermacentor variabilis* (American dog ticks) may also be competent vectors.
- Geographic Distribution: In the United States, cytauxzoonosis is identified in the midwest, south-central, south-eastern, and the mid-Atlantic states; the geographic range has expanded with the expanded range of *A. americanum* ticks. Cytauxzoonosis is also reported in South America (especially Brazil). Other species of *Cytauxzoon* cause infection in felidae in Eurasia.
- Route of Transmission: *Cytauxzoon felis* is transmitted by the feeding of vector ticks.
- Major Clinical Signs: Cytauxzoonosis is a rapidly progressive febrile illness characterized by anorexia, lethargy or depressed mentation, elevation of the third eyelid, vocalization, increased respiratory effort, icterus, pallor, lymphadenomegaly, splenomegaly or hepatomegaly, and sometimes seizures.
- Differential Diagnosis: Tularemia is an important differential for outdoor cats. Depending on clinical signs present, other differentials include hemotropic mycoplasmosis, cholangiohepatitis, histoplasmosis, sepsis, primary IMHA, oxidative toxicities, toxoplasmosis, and FIP.
- Human Health Significance: None.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Feline cytauxzoonosis, an emerging infectious disease with an expanding geographic distribution, is caused by the vector-borne hematoprotozoan parasite *Cytauxzoon felis*. A member of the order Piroplasmida, the organism is part of the family Theileriidae. Like other Theileriidae, *C. felis* exists in two distinct nonerythrocytic (schizont) and erythrocytic (piroplasm) forms within the mammalian host.

Although *C. felis* is the species most relevant to the health of domestic cats in the United States, it is only one of several species of the genus *Cytauxzoon*.[2] Outside the United States, cytauxzoonosis has been described in cats in South America (especially Brazil).[3–5] Other species of *Cytauxzoon* cause infection in felidae in Europe and Asia.[6–11] A morphologically indistinguishable intraerythrocytic parasite, *Cytauxzoon manul*, has been identified in Pallas's cats (*Otocolobus manul*) imported from Mongolia.[12] Sequence analysis of the 18S rRNA gene confirms that the organism is related to, but distinct from, *C. felis*.[9] When injected into domestic cats, *C. manul* produced erythroparasitemia, but no disease, and was unable to prevent virulent disease when those cats were subsequently infected with *C. felis*.[13] Similar but distinct pathogens have been detected in both wild and domestic cats in Eurasia (e.g., Spain, Portugal, Italy, France, Germany, Switzerland, Russia, Iran, and China) (Fig. 98.1).[7,8,10,11,14–21] *Cytauxzoon europaeus* is the proposed name for a species identified in domestic cats and wild felis in Europe, with rare novel species detected in European wildcats (*Felis sylvestris sylvestris*) from Romania (*Cytauxzoon otrantorum and Cytauxzoon banethi*).[11,21] *Cytauxzoon* parasites identified in domestic cats in South America may or may not be genetically identical to the *C. felis* found in the United States.[22–25] Infection with *C. felis* or very closely related protozoa occurs in a wide variety of non-domesticated felid species, including both wild and captive (i.e., non-native) large cats.[26–33] In the United States, the presumed reservoir host for *C. felis* is the bobcat (*Lynx rufus rufus*). In bobcats, infection is believed to commonly result in brief illness followed by persistent subclinical erythroparasitemia, but unknown numbers of wild cats may die of infection in endemic areas.[32,34–37] Experimental transmission studies to many nonfelid species, including immunodeficient mice, have failed.[38]

Cytauxzoonosis can occur in cats of any age and either sex, with no identified breed predilections. Immune suppression is not necessary for cats to become infected, and there is no evidence that infection is more likely in retrovirus-infected cats than in noninfected cats. Outdoor cats are more likely to become infected because of increased exposure to tick vectors. Infections occur during the warm months with a peak incidence during the spring, and a second smaller peak in the early autumn.[39] In retrospective studies, infection has rarely been identified from November through March.[37,39,40]

For many years after its original description in Missouri during the mid-1970s,[1] feline cytauxzoonosis was recognized only in the south-central United States. With expansion of the range of the primary vector tick, *Amblyomma americanum,*[41] the geographic range has expanded subsequently, with infections now reported in cats throughout the south-central, south-eastern, and mid-Atlantic regions.[42–47] Although not yet demonstrated in domestic cats, *C. felis* infection has been demonstrated in bobcats living as far north as Pennsylvania[48] and North Dakota.[45] Although it is possible that infections outside the south-central United States were simply missed in years past, the relative ease of recognition of the parasite on examination of blood smears or by finding organisms in tissues following necropsy makes

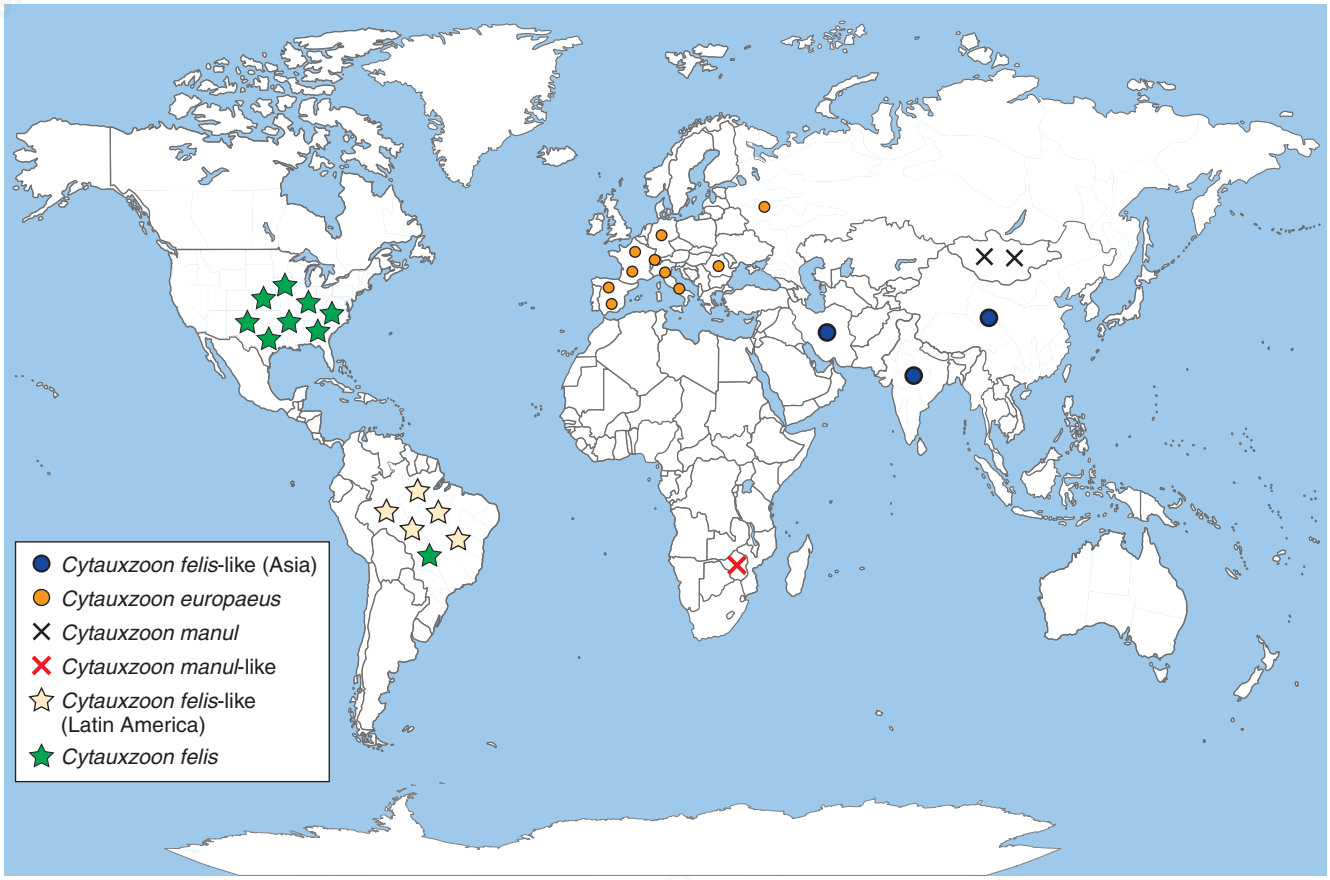

Fig. 98.1 Map of global reports of *Cytauxzoon felis* and related organisms in domestic and wild felids. Species with proposed names *Cytauxzoon banethi* and *Cytauxzoon otrantoreum* have been identified in European wildcats from Romania (see text, not marked).

this possibility seem unlikely. Instead, the parasite likely now occurs throughout a wider geographic region. The geographic range of reported *C. felis* infections in domestic cats in North America appears to overlap with the ranges inhabited by both bobcats and *Amblyomma americanum* (Fig. 98.2).[45] Ecological niche models using the distribution of tick vectors and the reservoir hosts predict a broader possible distribution of infection than models based on recognized cases in domestic cats.[37] Because the primary reservoir host for the pathogen in the United States is the bobcat, infected domestic cats are typically from rural or suburban rather than urban areas. Cats living close to wooded areas or less intensely managed land are more likely to become infected.[39] It is common for multiple cats in a neighborhood, or even a household, to become infected within a single season, likely reflecting the presence of infected carriers in the area.

There are few studies of incidence or prevalence in domestic cats. Prevalence studies focus on healthy carrier cats, but because infection is often rapidly fatal, prevalence (i.e., infections at any one time) cannot be used to estimate disease incidence (i.e., infections over a period of time). Interestingly, disease may be more virulent in some geographic regions than others, thus leading to a lower prevalence in those areas even if disease incidence is high.[49] In a study of 902 healthy cats, 18 of 60 blood samples (30%) from a single clinic in Arkansas were positive using PCR.[44,49] The clinic was in an area that was suspected to harbor a less virulent strain of the pathogen. The overall prevalence in that same study for cats tested in Arkansas (15.5%) and Missouri (12.9%) was higher than that in Oklahoma (3.4%).[44] Anecdotally, Oklahoma strains may be more virulent with few cats surviving infection despite aggressive treatment.[50] In another study

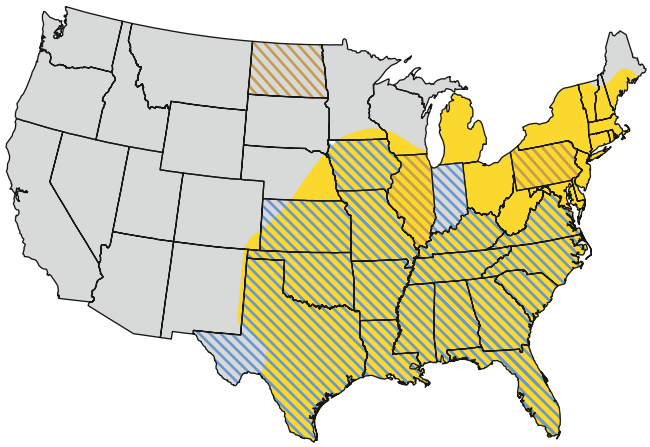

Fig. 98.2 Geographic distribution of *Cytauxzoon felis* infections in the United States. Shaded areas show confirmed cases in domestic cats (blue stripes) or bobcats only (black stripes; ND, IL and PA). The yellow region (with and without overlying stripes) represents the distribution of *Amblyomma americanum* ticks.

involving cats from northern Oklahoma, where disease is recognized only rarely, the prevalence of infection was less than 1%.[51] Few of the healthy cats that were part of TNR programs in North Carolina, Florida, and Tennessee were infected, with prevalence of 0 to 1.3%.[52] Among healthy cats considered at high risk due to outdoor exposure in endemic regions of Arkansas and Georgia, 27/89 (30.3%) of cats were PCR-positive.[53] The authors of this chapter are aware of several

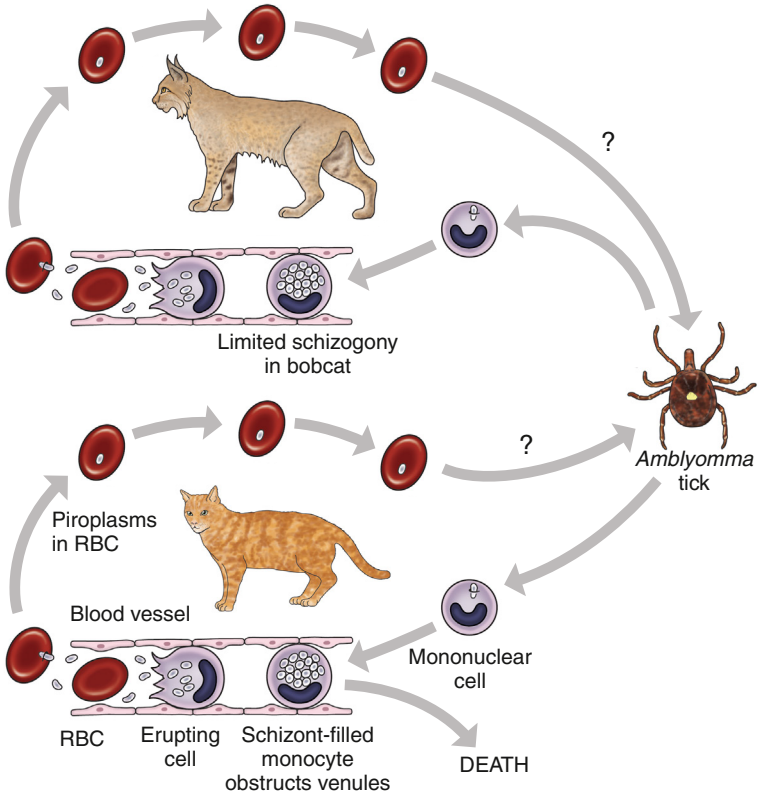

Fig. 98.3 Life cycle of *Cytauxzoon felis*. The parasite is maintained in bobcats *(top)* which are subclinically infected. The sexual cycle of the organism occurs in *Amblyomma americanum* hard ticks, which then transmit sporozoites to domestic cats. Sporozoites invade mononuclear cells, where they undergo schizogony. Schizont-filled monocytes obstruct capillaries and cause multiorgan failure and death. In cats that survive the schizogony phase, the organism infects erythrocytes and forms piroplasms. The importance of domestic cats as a reservoir for infection of ticks is uncertain. The schizogony phase in the bobcat is usually relatively mild and brief.

colonies of cats in Missouri and North Carolina with prevalence rates of up to 72%, nearly equivalent to rates seen in the bobcat reservoir in endemic areas. The prevalence of infection in cats from Brazil with a hematoprotozoan parasite morphologically indistinguishable from *C. felis* was similarly high, up to 48.5%.[24] The prevalence of infection in bobcats depends on geography; estimates range from 7% in Pennsylvania to 79% in Missouri.[45,48,54,55] In Florida, the prevalence of subclinical infection for transplanted Texas cougars was 39% and for Florida panthers was 35%.[56] There are fewer still estimates of disease incidence. Cytauxzoonosis accounted for approximately 1% of feline submissions to the Oklahoma Animal Disease Diagnostic Laboratory and 1.5% of feline admissions to the Oklahoma State University VMTH between 1995 and 2006 and between 1998 and 2006, respectively.[39] Personal communications with the authors of this chapter suggest that veterinarians in enzootic "hot spots" see as many as 5 cases of cytauxzoonosis a week during the peak season, with many more veterinarians in endemic areas reporting that they see 5–10 cases per summer.

Infection of domestic cats with *C. felis* in a natural setting requires a tick vector; ill and naïve cats can be co-housed without disease transmission.[57] Although perinatal transmission is important for other hematoprotozoal infections, there is little evidence that this is the case for *C. felis*.[58] Similarly, tick ingestion does not seem to be an important route of infection.[59] Experimentally, infection can be transmitted through inoculation of schizont-laden tissues or transfusion of blood collected during the acute illness.[34,57,60] Transfusion of blood from recovered cats, which contains only erythrocytes with piroplasms rather than mononuclear-associated schizonts, does transmit the piroplasm stage of infection but does not result in schizogony or clinical illness in the recipient.[34,61]

A variety of ticks feed on both domestic and wild felids, and *C. felis* has been recovered from *Dermacentor variabilis* and *A. americanum* ticks.[62] Although vector competence and transstadial transmission (nymphs to adults) have been demonstrated for both, *A. americanum* appears to be the primary natural vector.[41,61,63] Although neither *D. variabilis* nor *A. americanum* is found in Brazil, naturally occurring infection with *Cytauxzoon* spp. occur there.[3,5,23,25] Presumably, *Amblyomma cajennense* or another ixodid tick is the responsible vector.[64] There are no published studies investigating transovarial transmission in ticks.

When bobcats become infected with *C. felis*, there is limited schizogenous replication associated with a typically mild to moderate acute clinical illness, although fatal infection of bobcats has been described.[32,34,35] On recovery from illness, bobcats remain infected with piroplasms in their erythrocytes. Ticks become infected when they ingest piroplasms contained in erythrocytes of persistently infected carriers. These ticks then transmit sporozoites to the next felid host on which it feeds (Fig. 98.3). If the tick feeds on another bobcat, the sylvan cycle is repeated. If the tick feeds on a domestic cat, infection often results in massive schizogenous replication and profound illness.

For years, domestic cats were deemed terminal hosts because most died from cytauxzoonosis. Felids that recover from acute infection can apparently harbor piroplasms for months or even years without serious consequences.[24,49,52,53,65–68] Additionally, domestic cats that harbor

piroplasms without any history of clinical illness are occasionally identified.[25,44,49,52] In an experimental setting, domestic cats can transmit infection via the tick vector.[41,69,70] Although these studies demonstrate reservoir competence, more extensive studies are necessary to establish the actual reservoir capacity of domestic cats in a natural setting. The existence of domestic cat colonies with high prevalence rates of *C. felis* infections combined with extensive exposure to competent tick vectors suggests that both the reservoir and vector capacities are likely to be high in select populations.[44,53] If so, movement of domestic carrier cats (with their owners) might help account for the expansion in the endemic geographic region for this pathogen.[26,44]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Much of what we believe to occur in the life cycle of *C. felis* is inferred from what is known about related protozoan parasites. The sexual phase of reproduction occurs in the tick gut. Ookinetes leave the gut, enter the body cavity, and migrate to the salivary glands, where they replicate as infective sporozoites. After these sporozoites enter the host during tick feeding, they penetrate and develop, primarily within mononuclear phagocytes. They are visible first as indistinct vesicular structures within the cytoplasm of infected cells and later as large, distinct, nucleated schizonts that actively undergo division by schizogony and binary fission. Multiplication of schizonts within host cells is observed ultrastructurally to be true schizogony, without host cell division. Fission of the schizont within the mononuclear cells results in the formation of merozoites.[71] The phagocytes line the lumens of vessels within almost every organ and become huge and numerous, often occluding the vessel similar to a thrombus (Fig. 98.4). The host cell probably ruptures, releasing the merozoites into the blood or tissue fluid. Merozoites appear in macrophages 1 to 3 days before they are observed in erythrocytes. These organisms then invade uninfected erythrocytes and produce late-stage parasitemias that are detected on examination of blood smears (Fig. 98.5). Piroplasms (merozoites) reproduce through asexual binary fission only in erythrocytes.

The phase of asexual schizogenous reproduction, within the host's mononuclear phagocytic cells, is responsible for the pathologic processes resulting in clinical illness. It is unclear whether only sporozoites can enter macrophages and initiate schizogony or if early schizonts can spread from macrophage to macrophage. Regardless, infection results in massive numbers of schizont-distended mononuclear cells within the vascular lumen of the interstitium of most organs. This may be especially severe in the lungs, liver, spleen, and other lymphoid tissues.[57,72] DIC, presumably activated by vascular endothelial disruption, has been a complication based on laboratory findings in naturally infected cats.[73,74] Vascular obstruction, anoxia, and release of damaging substances secondary to cell death and rupture may all contribute to multiple organ failure. The presence of piroplasms is sometimes associated with hemolysis during the later stages of the acute illness, but piroplasms are not likely a major contributor to disease.

Less virulent strains of *C. felis* might result in a more limited schizogony with less associated pathology in domestic cats. The theoretical existence of less virulent strains is supported by a regional occurrence of survivors at a greater than expected rate.[49] Using noncoding regions of rRNA known as internal transcribed spacer (ITS) regions, variability in strains of *C. felis* from naturally infected cats in Georgia and Arkansas was demonstrated.[27] Despite initial findings suggesting an association between survivability and the particular strain of *C. felis,* a subsequent study found that ITS region-sequence type could not be used to discriminate between strain pathogenicity and disease survival.[53]

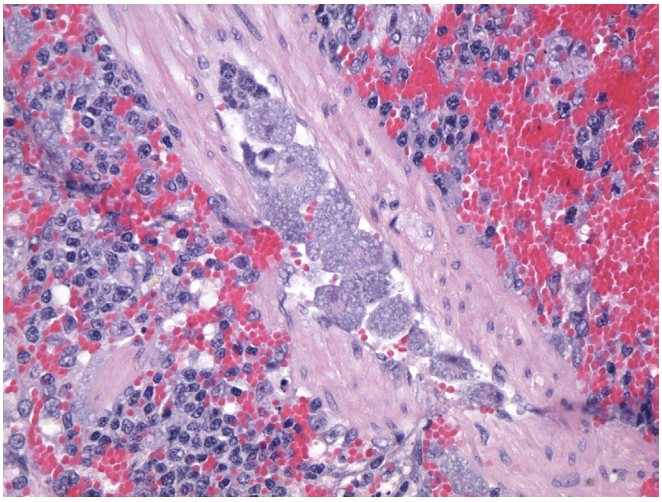

Fig. 98.4 Histologic image from the spleen of a cat that died of cytauxzoonosis demonstrates many readily recognizable schizont-laden mononuclear phagocytic cells occluding the vascular lumen (hematoxylin and eosin stain, ×100). Histologic disease diagnosis is generally straightforward. (Courtesy of Dr. Linda Berent.)

Although historic findings are nonspecific, an acute onset of anorexia, lethargy, and fever in cats given outdoor exposure within an endemic region (especially during spring, summer, or early autumn) should raise immediate suspicions for cytauxzoonosis. The onset of clinical disease occurs from 1 to 3 weeks after tick-transmitted infection.[41,61] Initial clinical signs are vague and typically include anorexia and lethargy. Within hours to days, illness becomes more severe and owners may notice increased vocalization, weakness, icterus, dark yellow urine color, respiratory distress, obtunded mentation, or even seizures.[42] Cats may become comatose shortly before death.

Physical Examination Findings

Physical examination findings are nonspecific. The most consistent alteration on physical examination is pyrexia (often marked: 39.4°C to 41.6°C [103°F to 107°F]), but hypothermia occurs in moribund animals. Higher rectal temperatures have not been associated with a poorer prognosis,[75] and in the author's experience, cats with a rapid drop in temperature after treatment is begun are less likely to survive. Mucous membranes may be icteric and/or pale. Evidence of dehydration and delayed CRT or mucosal pallor may be observed. Tachypnea and tachycardia are typical, with or without overt respiratory distress. Arrhythmia may also be identified.[76] Pleural effusion can lead to shallow breaths with inspiratory effort and paradoxical breathing. Lung sounds may be harsh due to interstitial pneumonia, or may be diminished ventrally due to effusion. Mild to moderate lymphadenomegaly, splenomegaly, and hepatomegaly are often detected. Sometimes, cats are hyperesthetic during muscle palpation and vocalize when handled. Cats may demonstrate ataxia, seizures, or become comatose shortly before death. Elevation of the third eyelid is common. The entire disease course is usually rapid, and many cats succumb within days.[42,77,78]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

A CBC with blood smear examination is the single most useful diagnostic test for cytauxzoonosis. Pancytopenia is often recognized in cats with cytauxzoonosis. A bone marrow crowded with schizont-laden

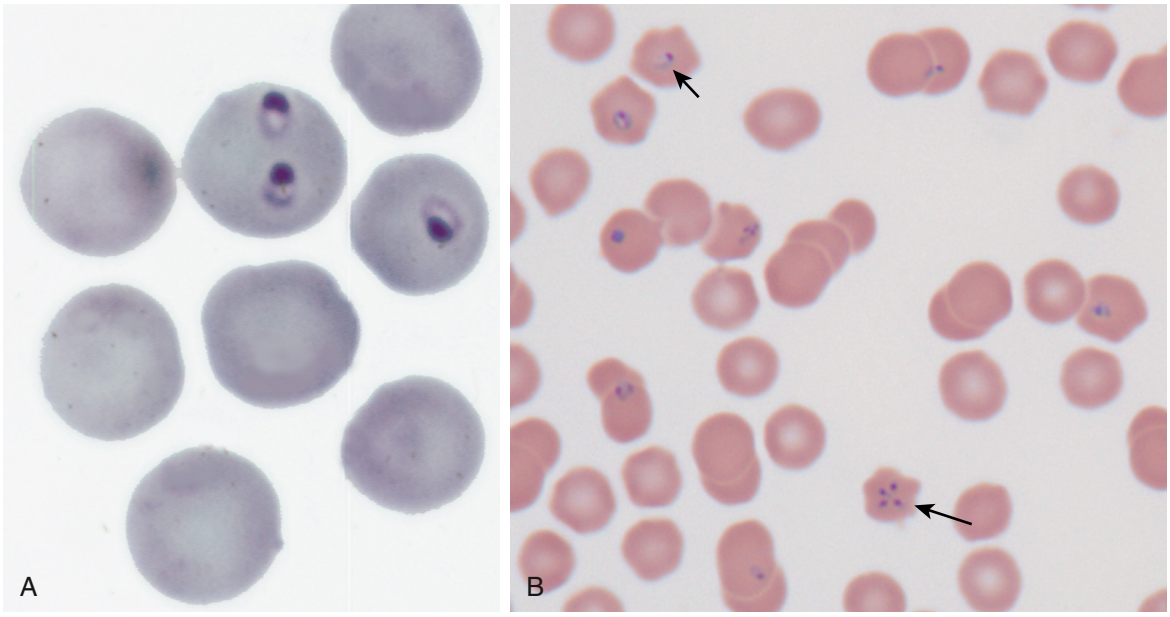

Fig. 98.5 Peripheral blood smears from cats with cytauxzoonosis that show erythrocytes infected with characteristic, signet ring-shaped *Cytauxzoon* piroplasms (Wright-Giemsa, ×1000). (A) The large, clearly evident nuclear area allows the organisms to be differentiated from hemotropic *Mycoplasma* organisms (Wright-Giemsa). (B) Multiple erythrocytes show signet ring-shaped piroplasms *(short arrow)*; a single erythrocyte contains a tetrad form *(long arrow)*. (Courtesy of Dr. Marlyn Whitney, University of Missouri—Veterinary Medical Diagnostic Laboratory.)

macrophages may lead to neutropenia, but neutrophilia resulting from an inflammatory response to infection may be identified alternatively. Leukopenia may be associated with a worsened prognosis.[75] Hemolytic anemia develops after the onset of signs and tends to be most severe as piroplasms become more numerous. Interestingly, severity of anemia has not been associated with a worse prognosis.[75] Because of the acute nature of the illness, anemia is usually normocytic, normochromic, and nonregenerative until disease recovery. Although anemia develops as piroplasms become apparent, these RBC parasites persist in low numbers for years in recovered cats without causing anemia.[42,49,66] Moderate to marked thrombocytopenia is believed to be related to consumptive processes, including the common complication of DIC. Coagulation times (e.g., activated partial prothrombin time, one-stage prothrombin time) are often prolonged as a component of DIC.[73,74,79]

Diagnosis of cytauxzoonosis can be accomplished by identification of erythroparasitemia or schizont-laden mononuclear cells on peripheral blood smears in cats with compatible history and physical examination findings. A thin, well-made blood smear can be stained with either Diff-Quik or Wright stain for identification of piroplasms. Blood smears should be scanned at low power (100×) on the outer edges as schizont-laden mononuclear cells can occasionally be seen at the feathered edge of peripheral blood smears (Fig. 98.6). Identification of even one such cell can confirm the diagnosis. Because these distended cells become lodged in the small blood vessels, they are more commonly identified on examination of tissue aspirates than peripheral blood smears. Aspirates from the spleen seem to be most useful for identification of these cells.[80] Next, the slide should be evaluated at high power (500–1000×) for piroplasms. The piroplasms of *C. felis* in erythrocytes are most often shaped as 1- to 1.5-μm signet rings, but "safety pin" and tetrad forms are also observed, or rarely chains of organisms resembling cocci (see Fig. 98.5B). Similar erythroparasites are identified in cats infected with *Babesia felis* and *C. manul*, but those pathogens have not been identified in the United States. *Mycoplasma haemofelis* might be mistaken for *C. felis* piroplasms (see Chapter 58). In addition to the

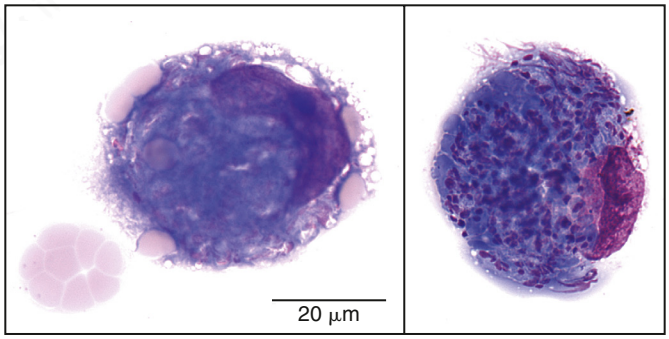

Fig. 98.6 Schizont-containing mononuclear cells on the feathered edge (cells shown from two different microscopic fields) of a Wright-Giemsa–stained peripheral blood smear from an acutely ill cat with cytauxzoonosis. (Courtesy of Dr. Marlyn Whitney, University of Missouri—Veterinary Medical Diagnostic Laboratory.)

smaller size of *M. haemofelis* (typically 0.3 to 0.8 μm), its epicellular location, frequent occurrence in pairs or short chains, and associated regenerative anemia help distinguish it from *C. felis*. Stain precipitate found overlying erythrocytes can easily be mistaken for piroplasms, but precipitate can usually be found unassociated with cells as well as overlying cells. Nuclear remnants known as Howell-Jolly bodies can likewise be mistaken for *C. felis* piroplasms.

Identification of *C. felis* piroplasms is not a sensitive method of disease diagnosis. The feathered edge of the stained blood smear must be carefully evaluated because erythroparasite burden is often low at the onset of infection. Even more importantly, piroplasms are not present in all infected cats, particularly early in the disease course. Piroplasms may be absent in up to 50% of cases at the time of initial illness, and in the author's experience there may be a several-day delay between initial clinical signs and the appearance of piroplasms on peripheral blood smear.[81]

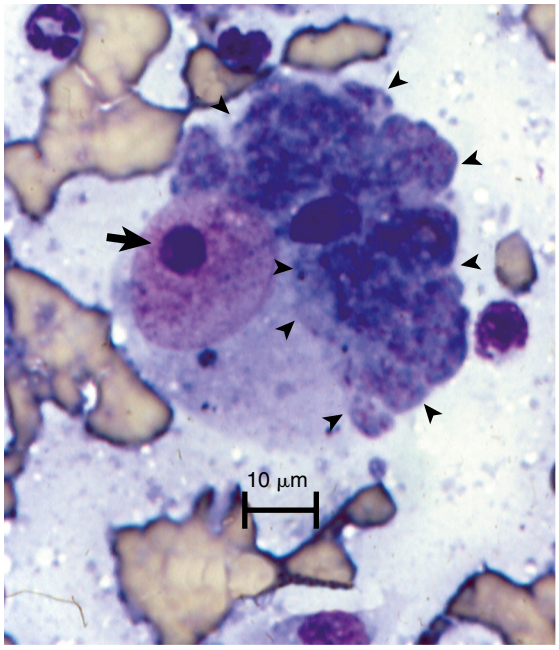

Fig. 98.7 Impression smear from a feline liver showing a macrophage that contains a developing *Cytauxzoon* schizont. The early schizont *(outlined by arrowheads)* appears as a lobulated basophilic area within the cytoplasm of the host cell. A large, prominent nucleolus is present in the host cell nucleus *(arrow)* (Wright-Giemsa, ×165).

Serum Chemistry Profile and Urinalysis

Aside from identification of protozoal pathogens on blood smear, there are no specific abnormalities on routine clinicopathologic testing. Hyperbilirubinemia is very common but rarely exceeds 5 mg/dL; more severe hyperbilirubinemia may be associated with a worsened prognosis.[75] Increased bilirubin occurs both as a result of intrahepatic infiltration of schizont-loaded macrophages as well as hemolysis.[75] Prerenal azotemia, hyperglycemia, and electrolyte and acid-base disturbances are documented in many infected cats. Other clinical chemistry changes are variable and less specific but include low serum concentrations of albumin, cholesterol, and potassium and high serum ALT activity.[42,75,77] Bilirubinuria is common, but hemoglobinuria is not observed because hemolysis is largely extravascular.[42]

Diagnostic Imaging

Imaging techniques do not contribute directly to the diagnosis of *C. felis* infection. Splenomegaly and hepatomegaly are commonly identified due to vascular occlusion by schizont-laden mononuclear cells. Pulmonary schizogeny can lead to interstitial pneumonia and edema; depending on severity, either an interstitial to alveolar lung pattern may be seen on thoracic radiographs.[5,82] Pleural effusion, and less often peritoneal effusion, are also identified in some cats.[42]

Microbiologic Tests

Cytologic Diagnosis

Fine-needle aspirates obtained antemortem or tissue imprints obtained at necropsy from parasitized tissues such as lymph node, spleen, or liver will often yield samples containing schizont-laden macrophages (Fig. 98.7).[80] Tissue biopsy is rarely employed for the diagnosis of cytauxzoonosis, but infection is easily confirmed at necropsy through microscopic identification of such schizont-laden cells.

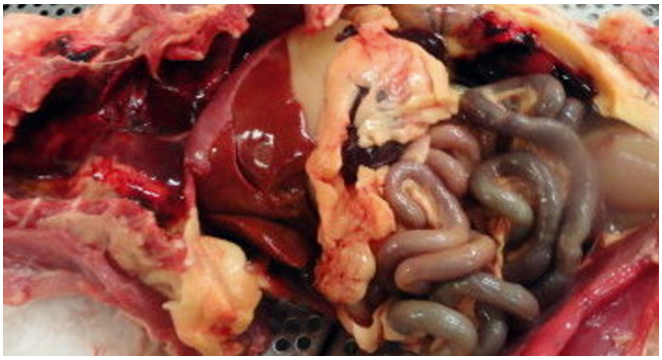

Fig. 98.8 Gross lesions in a cat naturally infected with *Cytauxzoon felis*. There is splenomegaly and an enlarged liver with rounded edges.

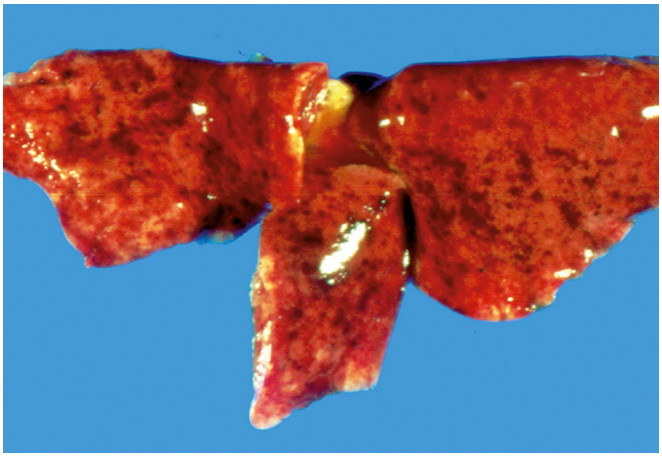

Fig. 98.9 Petechial and ecchymotic hemorrhages throughout the lungs of a cat that died from cytauxzoonosis. (Courtesy of Oklahoma State University Veterinary Pathobiology Teaching Set, Stillwater, OK.)

Molecular and Serologic Diagnosis

Diagnosis using PCR on blood is sensitive, with positive results possible many days prior to blood smear identification of pathogen.[83] Mitochondrial gene-based PCR testing was found to be even more sensitive than traditional 18S rRNA gene testing.[83] Even very early in disease, commercial PCR tests can be used to confirm the presence of *C. felis* DNA. Although test turnaround time is rapid, delays associated with sample submission are important considering the brief clinical course of illness. An important caveat to PCR testing is that PCR results may remain positive in recovered cats, meaning the test is specific for infection but not disease. Serologic testing for antibody to *C. felis* can be used in a research setting to document previous infection, but at the time of writing it is clinically impractical because infected cats may die before antibodies appear in circulation. To date, *C. felis* cannot be grown in culture.

Pathologic Findings

Experimental studies of *C. felis* infection have provided an extensive description of pathologic findings associated with acute illness.[72] Enlargement and mottling of the spleen and liver are common (Fig. 98.8), as is mild to moderate lymphadenomegaly. Interstitial pneumonia, pulmonary edema, and congestion with petechial hemorrhages on the lung surface are typical (Fig. 98.9). Petechial and ecchymotic hemorrhage may be detected in a variety of tissues. Venous distention can be appreciated grossly.

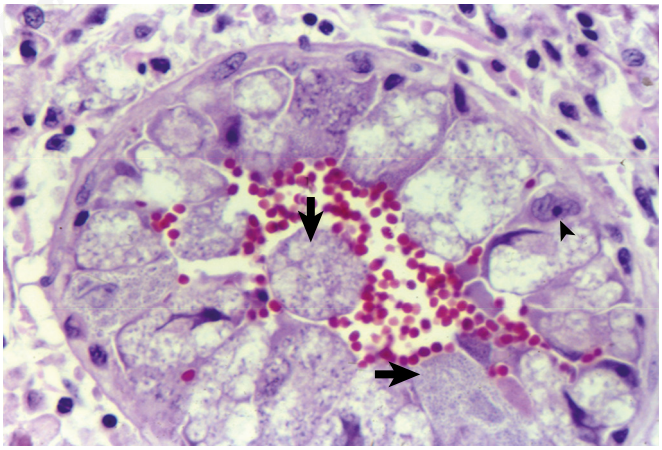

Fig. 98.10 Section of the lung from a cat with cytauxzoonosis. Schizont-containing macrophages completely line the endothelial surface and nearly occlude the lumen of a large vessel. The enlarged nucleoli of host cell nuclei are visible in some cells *(arrowhead).* Developing organisms can be seen as a faint granular appearance to the cytoplasm of some of the cells *(arrows)* (hematoxylin and eosin stain, ×66).

Histopathologic examination of tissues readily demonstrates the tissue stage of *C. felis* infection. Schizonts occur within the cytoplasm of mononuclear phagocytes in the tissues themselves, or attached to the endothelium or within the vasculature in essentially all organs (Fig. 98.10). Spleen, liver, lung, bone marrow, and lymph nodes are especially heavily parasitized. Partial or complete occlusion of blood vessels by infected mononuclear cells results in marked venous congestion of tissues. In a retrospective study of cats that died of cytauxzoonosis, all demonstrated vascular occlusion of the brain by schizont-laden macrophages with resultant edema, microgliosis, astrogliosis, microhemorrhage, and necrosis.[84] Similarly, a retrospective study of pulmonary lesions in cats that died with acute cytauxzoonosis found that vascular occlusion by parasitized macrophages was severe and consistent.[82] Other histopathologic findings in the lungs were more varied, but included interstitial pneumonia and hemorrhage. Spleen and lymph node should be used for tissue impression films, which should be stained with Wright or Giemsa stain. In situ hybridization or immunohistochemical methods can be used for specific identification of organisms within tissues.[85]

TREATMENT

Atovaquone and azithromycin combination therapy and supportive treatments are considered the standard of care for cats with cytauxzoonosis. Supportive care is indicated for ill cats although there are no studies demonstrating the utility of any specific supportive measure.[42] Crystalloid fluids are used to correct dehydration, preserve vascular volume, and maintain tissue perfusion but must be used with caution when pleural effusion or pulmonary edema are identified. Transfusion of whole blood or packed red blood cells is indicated for the treatment of anemia with associated tachypnea or tachycardia. Cytauxzoonosis is often accompanied by DIC,[73,79] so prophylactic heparinization administered to effect or by using a fixed heparin dose (Table 98.1) may prove useful in management of infected cats. Placement of nasogastric or esophageal feeding tubes can allow both nutritional support and ease in administration of oral medications (Fig. 98.11). Placement of feeding tubes early is important since most cats (even survivors) tend to develop more severe illness in the first 24 to 72 hours of hospitalization. Stressful events such as pilling or syringing medications can result in clinical decompensation and death. Although vomiting is not a common disease manifestation, maropitant may be used for cats with nausea. Because the pathogen can infect ocular vessels, identification and treatment of uveitis should be part of supportive care.[86] NSAIDs such as meloxicam have been used to provide analgesia and reduce fever. Some veterinarians treat ill cats with low-dose prednisolone. The potential benefit of NSAIDs or glucocorticoids has not been evaluated. While analgesia is important for humane reasons, in our experience, fever reduction does not correspond to improved survival. A variety of antimicrobial drugs (e.g., ampicillin, enrofloxacin, and doxycycline) have been used in infected cats alone or in combination.[77,79,87] Used alone, none of these drugs has demonstrated efficacy against protozoal agents such as *C. felis*. A combination of antimicrobials including doxycycline, metronidazole, and enrofloxacin[88] has been effective in treating dogs with *Babesia gibsoni* infection. In a small study of cats with experimentally induced cytauxzoonosis, a combination of doxycycline-metronidazole-pradofloxacin was not beneficial.[89]

TABLE 98.1 Treatment for Cytauxzoonosis

Drug[a]	Dose[b]	Route	Interval	Duration (Days)
Heparin (unfractionated)	100–200 U/kg	SC	8 hours	As needed[c]
Atropine	0.04 mg/kg	IV, IM, SC	24 hours	1[d]
Glycopyrrolate	0.005–0.01 mg/kg	IV, IM, SC	24 hours	1[d]
Imidocarb dipropionate	3.5–5.0 mg/kg	IM	14 days	14
Diminazene aceturate[e]	2 mg/kg	IM	7 days	7
Atovaquone[f]	15 mg/kg	PO	8 hours	10
and				
Azithromycin	10 mg/kg	PO	24 hours	10

[a]See Chapter 12 for specific information on each drug. Adjunctive isotonic fluid therapy is extremely important for this disease. See text.
[b]Dose per administration at specified interval.
[c]This dosage range is used until a cat's clinical signs have stabilized and hematologic abnormalities have improved. In lieu of this fixed dose, the therapeutic goal is prolongation of the baseline activated partial thromboplastin time by twofold. A variable dose would be administered at the 8-hour interval to achieve this effect.
[d]Given once, 15 minutes before injection of imidocarb or diminazene.
[e]Note that a higher dose than listed here (4 mg/kg q24h for 5 days) was not recommended due to lack of efficacy and adverse events in a 2014 study.[90]
[f]Thick, viscous liquid can be difficult to accurately dose; allow liquid to settle in syringe to confirm volume prior to administration.
IM, intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

Fig. 98.11 Nasoesophageal feeding tube in a cat with cytauxzoonosis. (Courtesy of Dr. Adam Birkenheuer.)

Treatment with a combination of atovaquone (15 mg/kg, PO, q8h) and azithromycin (10 mg/kg, PO, q24h) for 10 days was associated with a 60% survival rate in a randomized, prospective clinical trial; this was significantly different from the 26% survival rate with imidocarb dipropionate (Imizol, Merck Animal Health, Madison, NJ, USA).[75] Before publication of that study, imidocarb dipropionate was widely used for the treatment of cytauxzoonosis at a variety of different dose regimens (e.g., two doses at 2 mg/kg, IM, 7 days apart, two doses at 5 mg/kg, IM, 7 days apart, two doses of 5 mg/kg, 4 days apart) with little evidence of efficacy. There was also mention in a retrospective report on cats with *C. felis* infection that imidocarb lacked efficacy for treatment of experimentally induced cytauxzoonosis.[49] If used, pretreatment with atropine or glycopyrrolate may minimize the potential adverse cholinergic effects of imidocarb. Another aromatic diamidine, diminazene aceturate, has been used to treat cytauxzoonosis. In a retrospective study, five of six cats treated with diminazene plus aggressive supportive care survived.[79] Unfortunately, diminazene is not approved for use or available in the United States. Diminazene and imidocarb are also not effective in clearing piroplasms from healthy cats with chronic *C. felis* infection.[67,68,75,90] The antiprotozoal hydroxynaphthoquinolone agents, parvaquone and buparvaquone, are the treatment of choice for *Theileria* infection of African cattle. Despite the close relationship of *C. felis* to *Theileria* spp., these drugs were ineffective for treatment of cytauxzoonosis.[78] Although treatment with atovaquone and azithromycin is currently the standard of care, improved treatments are needed as this treatment is expensive, difficult to administer, and many cats die despite treatment. At the time of writing, the authors are conducting a prospective trial on the use of the antimalarial compounds artemether and lumefantrine (Coartem, Novartis, East Hanover, NJ, USA), for the treatment of cytauxzoonosis based on preliminary success in experimentally infected cats.

It is unclear whether treatment should be administered to healthy cats with persistent erythroparasitemia. In the few cats followed for months or years, clinical disease has not developed after recovery from initial infection. However, the possibility exists that these cats may experience hemolysis or some other immune-mediated sequelae from chronic infection at a future date. Of additional importance, it is possible that these carrier cats may serve to infect naïve ticks, which could then be a source of infection for other felids.[41,63,70] The combination of atovaquone and azithromycin was unable to uniformly cure infection, but many treated cats had negative PCR results after treatment.[67,75] Recommended dosages for these drugs are listed in Table 98.1.

PROGNOSIS

Although cytauxzoonosis was once described as a uniformly fatal infection, there are now many reports of surviving cats. In many cases, cats survived clinical cytauxzoonosis with aggressive supportive care that might or might not have included specific antiprotozoal therapy.[75,78,79,87] However, healthy carriers have also been identified with no known history of clinical illness, suggesting a limited schizogenous replication as is typical for the bobcat reservoir host.[27,44,49,51,52,66,90] Survivors might be explained by differences in the dose of inoculum or route of exposure, differences in the individual cat's immune response to pathogen, or pathogen strain variation. As mentioned previously, survival with or without antecedent clinical illness is often linked to certain geographic regions suggesting strain variation.[49]

Genetic differences in the pathogen have been identified that may account for response to treatment with atovaquone.[53,91] Atovaquone is presumed to work by disrupting electron transport in the parasite mitochondria via targeting protozoal cytochrome b (cytb). A recent pharmacogenomics study identified a *C. felis* cytb genotype associated with increased survival in cats treated with atovaquone and azithromycin but not in cats treated with imidiocarb.[91] Further, a quantitative real-time PCR assay that is coupled with high-resolution melt analysis of amplified DNA has been developed that detects the *C. felis* cytb genotype associated with improved survival.[92] Such testing could provide valuable prognostic information to help owners make difficult decisions regarding treatment of sick cats. A mutation in cytb has been detected in a cat that remained persistently parasitemic despite repeated treatments with atovaquone and azithromycin.[93]

IMMUNITY AND VACCINATION

Little is known about immunity to cytauxzoonosis. In addition to possible strain differences or varied dose inoculum, individual immune responses may also impact outcome. This is especially true in experimental settings where all cats are similarly exposed to the same *C. felis* strain, yet some develop only minimal illness. Cats that are experimentally inoculated with blood that contains piroplasms form antibodies, but these antibodies do not protect from illness after inoculation of schizonts.[34,36,78] On the other hand, experimental attempts to reinfect a small number of cats that have survived illness (and therefore survived the schizont stage of infection) do not result in recurrent illness, suggesting immunologic protection from disease.[77,79] Despite the failure to induce a second illness through experimental infection, a second illness due to reinfection 7 years after the first illness has been documented in at least one domestic cat.[94] Reinfection of bobcats in the wild with multiple strains of *C. felis*, as based on ITS1 and ITS2 genotypes, has been documented.[65]

There is no available vaccine for cytauxzoonosis. Although the growth of *C. felis* has not been sustained in culture, a report from 1978 describes a cat that was protected from infection after subcutaneous inoculation with a Vero culture that had been inoculated with splenic cells from a cat dying of cytauxzoonosis. It is unclear whether the Vero cells were truly infected or if they were co-cultured, resulting in an attenuated live or even killed vaccine.[95] Recently, genomic bioinformatic methods have been used to identify potential antigen vaccine candidates; however, initial attempts at vaccination did not result in protection from experimental infection.[96,97]

Few studies have been published that describe the immune response to *C. felis*. Clearly, infection of mononuclear cells will directly impact the immune response. A small study of naturally infected cats identified

increased expression of CD18, a key integrin for leukocyte adhesion to endothelium.[98] This same study found significantly increased serum TNF-α in cats that died of cytauxzoonosis when compared with healthy cats, but no statistically significant difference between survivors and non-survivors.[98] Lung tissues from cats that died of the disease stained positively for TNF-α, and many demonstrated increased staining (compared to uninfected cats) for IL-1β and IL-6.[99] Not surprisingly, these findings support the idea that cytauxzoonosis is an inflammatory disease, as is the case for other piroplasmoses.[100]

PREVENTION

For now, prevention is focused on prevention of tick bites. Indoor confinement of cats in endemic areas reduces the risk of tick bites. In a recent experimental controlled trial, ticks failed to attach and feed on cats wearing an imidacloprid 10%/flumethrin 4.5% impregnated collar and were protected from experimental tick-transmitted infection.[70] While this collar helps kill ticks on contact, other paraciticides approved for use in cats (i.e., fipronil, fluralaner) require tick feeding. The time required between tick attachment and transmission of *C. felis* can be less than 48 hours.[59] Rapid killing after tick feeding might be effective in prevention of pathogen transmission, as has been documented for topical selamectin plus sarolaner.[101] However, a number of cats reportedly treated with fipronil on a regular basis were nonetheless diagnosed with cytauxzoonosis.[75] Prophylactic chemotherapy is used to prevent malaria in humans in endemic regions. The role that prophylaxis may have in prevention of feline cytauxzoonosis remains to be determined. See Chapters 13 and 109 for more extensive information on tick control.

PUBLIC HEALTH ASPECTS

Infection with *C. felis* has only been recognized in felidae. Therefore, there are no recognized public health consequences of infection.

CASE EXAMPLE

Signalment and History

"Ginger," a 2-year-old female spayed domestic longhaired cat that lived near Springfield, Missouri, was evaluated for a 1-day history of anorexia and lethargy in April of the year. The cat was an indoor/outdoor cat with no known history of tick exposure. There were no other cats in the household.

Physical Examination

On examination, the cat's rectal temperature was 105.6°F (40.9°C), with HR of 200 beats/minute and RR of 28 breaths/minute. The spleen was prominent on abdominal palpation and the nictitans was elevated (Fig. 98.12), but examination was otherwise unremarkable.

Laboratory Findings

Blood was obtained for a CBC and retrovirus testing. The cat tested negative for FeLV antigen and FIV antibody. The cat had a mild, nonregenerative anemia (PCV 27%) and leukopenia (4,200 cells/μL, reference range 5,500–19,500 cells/μL).

Fig. 98.12 Cat with cytauxzoonosis. There is elevation and hyperemia of the nictitating membranes.

Although the platelet count was low, platelet clumps were present. Plasma in the spun hematocrit tube was icteric. No parasites were observed on microscopic slide review.

Because of a high degree of suspicion for cytauxzoonosis, a fine-needle aspirate was obtained from the spleen. Multiple markedly enlarged mononuclear cells containing numerous merozoites were observed.

Diagnosis

Cytauxzoonosis.

Treatment and Outcome

A nasoesophageal tube was placed to facilitate administration of atovaquone suspension (15 mg/kg, PO, q8h) and azithromycin (10 mg/kg, PO, q24h). A cephalic vein catheter was placed and IV crystalloid fluids administered at a maintenance rate. Heparin (200 units/kg, SC, q8h) and buprenorphine (0.01 mg/kg, SC, q8h) were administered.

The following day, the cat's PCV was 20% and icterus was evident on physical examination. Additionally, many piroplasms were visible on cytologic analysis of a smear of peripheral blood. A serum chemistry profile confirmed hyperbilirubinemia and a mild increase in the activity of serum ALT but was otherwise unremarkable.

By day 3, the PCV was 12%, and both RR and HR were increased. The cat was administered a single unit of whole blood, after which the PCV increased to 19%. Nutritional support was administered via the nasoesophageal tube, but otherwise treatment remained unchanged.

On day 5, the PCV dropped to 11%, which necessitated another whole blood transfusion. The cat remained tachypneic after transfusion. Thoracic radiographs revealed pleural effusion and a marked diffuse interstitial lung pattern. The cat was treated with supplemental oxygen, and 25 mL of a clear, yellow, modified transudate was removed using thoracocentesis.

By day 7, the cat no longer required supplemental oxygen to maintain respiratory function, and the anemia was regenerative. The cat was discharged from the hospital on day 8 with continued administration of atovaquone and azithromycin at home, but all other treatments were discontinued.

On recheck examination 1 week later, the cat was seemingly normal to the owners, and no abnormalities were detected on physical examination. The PCV was 29%, platelet and WBC counts had normalized, and a single piroplasm was observed on careful review of the entire feathered edge of the blood smear. The cat's owners were advised to keep the cat entirely indoors and to use an ectoparasiticide regularly to minimize any risk that the cat could serve as a reservoir for infection of ticks. The cat remained healthy 1 year later.

Hepatozoonosis

Nancy Vincent-Johnson, Gad Baneth, Kelly E. Allen

KEY POINTS

- Cause: Hepatozoonosis is an arthropod-borne infection caused by apicomplexan protozoa from the family Hepatozoidae in the suborder Adeleorina. Based on DNA analysis of the gene encoding for 18S rRNA and morphologic features, parasites in the genus *Hepatozoon* are most closely related to other apicomplexan parasites such as *Plasmodium* spp. and piroplasms. The genus was named *Hepatozoon* because merogonic development of the type strain *Hepatozoon muris* was observed in rat livers. However, the liver is not necessarily a major target tissue for other *Hepatozoon* spp. More than 300 *Hepatozoon* species have been described in amphibians, reptiles, birds, marsupials, and mammals Of these, more than 120 species infect snakes, and approximately 50 infect mammals. *Hepatozoon canis* and *Hepatozoon americanum* infect wild and domestic canids. *Hepatozoon* spp. infecting cats include *Hepatozoon felis*, *Hepatozoon silvestris*, and organisms closely related or identical to *H. canis* and *H. americanum.*
- First Described: *Hepatozoon canis* was first reported in dogs in 1905 in India, and has long been known to infect dogs in many regions of the world, including Asia, Africa, southern Europe, the Middle East, and more recently in North and South America and Australia. The first reports of *H. americanum* infection were from the Gulf Coast of Texas, United States, in 1978. In 1997, *H. americanum* was identified as a separate species, distinct from *H. canis.*[1,2] *Hepatozoon* sp. infection in cats was first reported in India in 1908, and infections in felids have since been documented in numerous countries.[3]
- Affected Hosts: *Hepatozoon canis*: domestic dogs, and some wild canids including foxes, jackals, African wild dogs, and coyotes. *Hepatozoon americanum*: domestic dogs, coyotes, and possibly other mammals. *Hepatozoon felis* and *H. silvestris*: domestic and wild felids; other *Hepatozoon* species infecting cats have also been reported, including *H. canis.*
- Geographic Distribution: *Hepatozoon canis* is found in canids in numerous countries in all inhabited continents. In the United States, *H. canis* has been reported in dogs from southeastern states including Alabama, Georgia, Louisiana, Mississippi, Oklahoma, New Jersey, and Virginia. *Hepatozoon americanum* infections occur primarily in the south-eastern and south-central United States. *Hepatozoon canis* and *H. americanum* co-infections in domestic dogs in North America have been reported in Alabama, Mississippi, and Louisiana. *Hepatozoon* sp. infections in domestic cats have been reported from many countries including Brazil, France, India, Israel, Nigeria, Portugal, Italy, Thailand, South Africa, Spain, and the United States.
- Route of Transmission: *Hepatozoon canis* is transmitted by ingestion of infected *Rhipicephalus sanguineus* ticks, and possibly other tick species (*Amblyomma ovale, Rhipicephalus turanicus, Rhipicephalus* (*Boophilus*) *microplus, Haemaphysalis longicornis*, and *Haemaphysalis flava*). Transplacental transmission *of H. canis* is also documented. *Hepatozoon americanum* is transmitted by ingestion of infected *Amblyomma maculatum*, and by ingestion of paratenic vertebrate hosts. The route of infection for *Hepatozoon* spp. infecting cats has not been elucidated, but may involve ingestion of infected arthropod and paratenic host tissues, and possibly transplacental transmission.
- Major Clinical Signs: *Hepatozoon canis* infections in dogs vary greatly in severity from inapparent to severe and life-threatening infection, although dogs are most often subclinically or mildly affected. A compromised immune status tends to lead to more severe disease. In patients with overt disease, clinical signs including fever, anemia, lethargy, and anorexia may be observed. *Hepatozoon americanum* causes American canine hepatozoonosis (ACH), which is associated with fever, lethargy, bilateral mucopurulent ocular discharge, pain and reluctance to move, altered gait, and muscle atrophy. The majority of cats reported with *Hepatozoon* sp. are subclinically infected.
- Differential Diagnoses: Anemia is the most common hematologic abnormality in dogs with *H. canis* infection. Therefore, other conditions causing anemia, including other vector-borne diseases, are differentials. For ACH, differential diagnoses include sterile or infectious meningitis, bacterial discospondylitis, Lyme borreliosis, canine monocytic or granulocytic ehrlichiosis, anaplasmosis, toxoplasmosis, sarcocystosis, bacteremia, and systemic immune-mediated diseases such as systemic lupus erythematosus. Cats infected with *Hepatozoon* spp. should be tested for immunosuppressive diseases including FIV and FeLV infection, and also for hemotropic mycoplasmosis.
- Human Health Significance: Canine and feline *Hepatozoon* species are not known to infect humans.

HEPATOZOON CANIS INFECTION

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Hepatozoon canis was first identified in India in 1905, and has long been known to infect dogs in many regions of the Old World, including Asia, Africa, southern and central Europe, and the Middle East.[4,5] More recently, it has been identified in the New World, both in North and South America and Australia.[1,6–10] The complete genome of *H. canis*, which provides information that may be used for diagnostic test development, has been published.[11]

The main definitive host of *H. canis* is the brown dog tick, *Rhipicephalus sanguineus*.[9] However, in Brazil, *Amblyomma ovale* has been suggested as a vector, and *Rhipicephalus turanicus* collected from

a naturally infected fox in southern Italy was also identified as a vector of *H. canis*.[13] *Rhipicephalus microplus* and *Haemaphysalis* spp. have been reported to harbor *H. canis* oocysts in Brazil and Japan, respectively, and are therefore considered suspected vectors.

The brown dog tick, which serves as the primary definitive host of *H. canis,* is found worldwide, and all three stages feed on dogs. Life stages of *H. canis* or morphologically indistinguishable *Hepatozoon* spp. have been reported in numerous carnivore species around the world, but the host range of *H. canis* in mammalian carnivores other than the domestic dog has not been clarified. *Hepatozoon canis* or *Hepatozoon* spp. that morphologically resemble *H. canis* have been reported in several wild canine species, from domestic and wild felids, and from other carnivores, including the wolf (*Canis lupus*), the red fox (*Vulpes vulpes*), crab-eating fox (*Cerdocyon thous*), black-backed jackal (*Canis mesomelas*), golden jackal (*Canis aureus*), African wild dog (*Lycaon pictus*), coyote (*Canis latrans*), raccoon (*Procyon lotor*), maned wolf (*Chrysocyon brachyurus*), hyena (*Crocuta crocuta*), palm civet (*Paradoxurus hermaphroditus*), white eared opposums (*Didelphis albiventris*), cheetah (*Acinonyx jubatus*), tiger (*Panthera tigris*), leopard (*Panthera pardus*), lion (*Panthera leo*), bobcat (*Lynx rufus*), Pallas's cat (*Felis manul*), ocelot (*Leopardus pardalis*), little spotted cat (*Leopardus tigrinus*), leopard cat, Iriomote wildcat (*Felis iriomotensis*), Tsushima leopard cat (*Felis bengalensis euptilura*), and flat-headed cat (*Prionailurus planiceps*).[5,14–19]

The geographic distribution of *H. canis* infections is tied closely to the distribution of *Rh. sanguineus*, the most widely distributed tick species in the world. This tick, which is now considered as a species complex and not just one species, is found in warm and temperate regions, but is adaptable to different environmental conditions. *Hepatozoon canis* is transmitted transstadially from the larva to the nymph stage, and also from the nymph to the adult stage in *Rh. sanguineus*.[20] Transovarial transmission through the tick's ovary and eggs could not be demonstrated under experimental conditions. *Rhipicephalus sanguineus* ticks can be infected experimentally through percutaneous injection of blood gamonts, allowing researchers to study the disease in ticks.[21] *Hepatozoon canis* infections are prevalent in regions with tropical, subtropical, and temperate climates. Infections have been reported in domestic dogs from all inhabited continents and numerous countries, including Greece, Italy, France, Spain, Portugal, Croatia, Albania, Romania, Poland, Ukraine, Czech Republic, Slovakia, and Bulgaria in Europe; Israel, Egypt, and Turkey in the Middle East; South Africa, Sudan, and Nigeria in Africa; India, Sri Lanka, Singapore, Malaysia, the Philippines, Thailand, and Japan in Asia; and Brazil, Argentina, and Venezuela in South America; Costa Rica and Mexico in Central America; and from Australia. *Hepatozoon canis* was also found in dogs from the Caribbean island of Grenada and the Cape Verde Islands. *Hepatozoon canis* is present in the south-eastern United States in some areas where *H. americanum* is enzootic, and co-infections with *H. americanum* and *H. canis* in dogs have been detected (Fig. 99.1).[6,7] *Hepatozoon canis* was also reported in ticks in Eastern Canada.[22] In addition, *H. canis* infections in Sweden[23] and in dogs imported into nonendemic areas have been reported in several countries, including Germany, The Netherlands, and the United Kingdom.[24]

Genetic variability exists among *H. canis* isolates.[25] Sequence identity in 18S rDNA fragments amplified from dogs ranges from 97% to 100%, whereas the diversity among dogs infected with *H. americanum* is higher, with identity that ranges from 92.7% to 99.6%.[6] Phylogenetic analyses of partial sequences of the 18S rDNA from *Hepatozoon* isolates from dogs in Japan and Brazil indicated that these isolates had a 99% identity with *H. canis* sequenced from Israel and were more distant to *H. americanum*.

Differences in the sensitivity and specificity of diagnostic techniques likely influence the observed prevalence rates among different regions. A study of 349 dogs from Turkey found that 10.6% had positive test results using blood smear evaluation for gamonts, 25.8% by PCR and 36.8% were seropositive by IFA testing. Circulating *H. canis* gamonts were detected by blood smear evaluation in 39% of dogs surveyed in rural areas of Rio de Janeiro, Brazil; 19.6% of dogs in nine

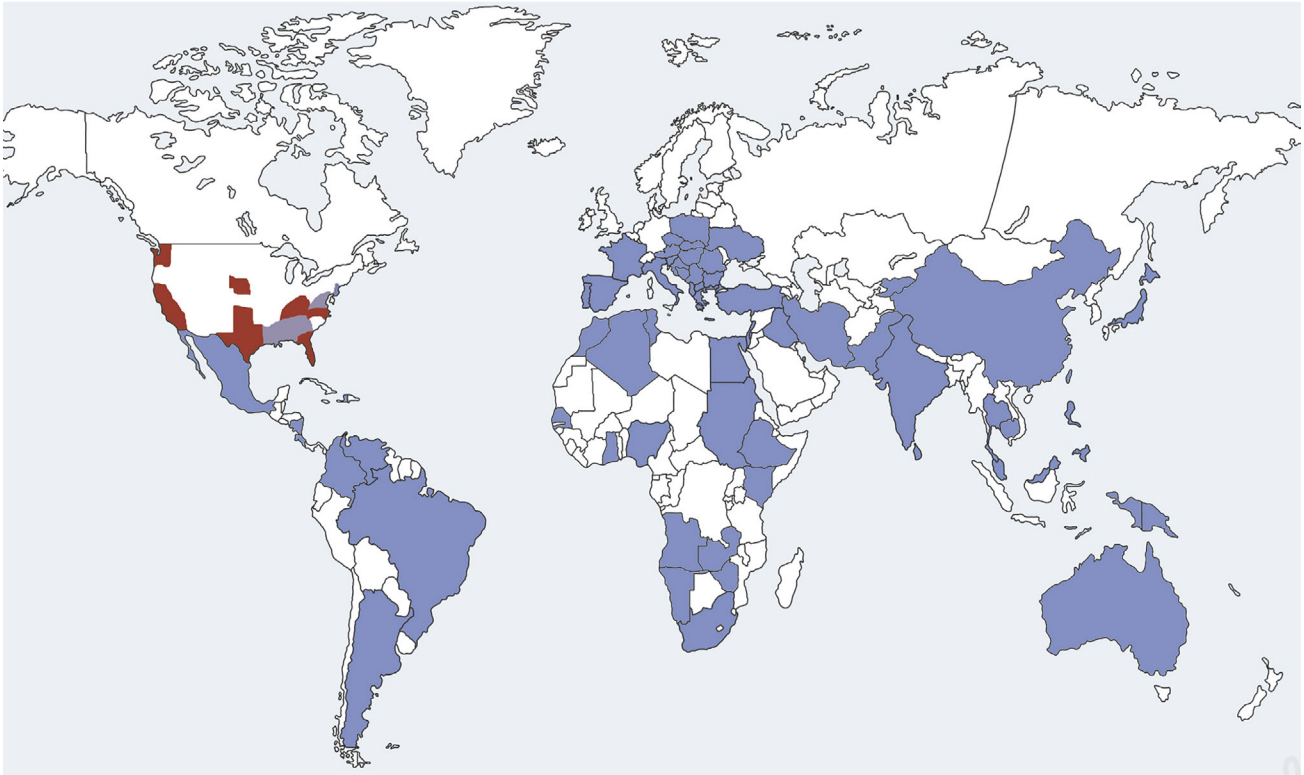

Fig. 99.1 Geographic distribution of reported *Hepatozoon canis (blue)* and *Hepatozoon americanum (red)* infections. Both species *(purple)* exist in the United States.

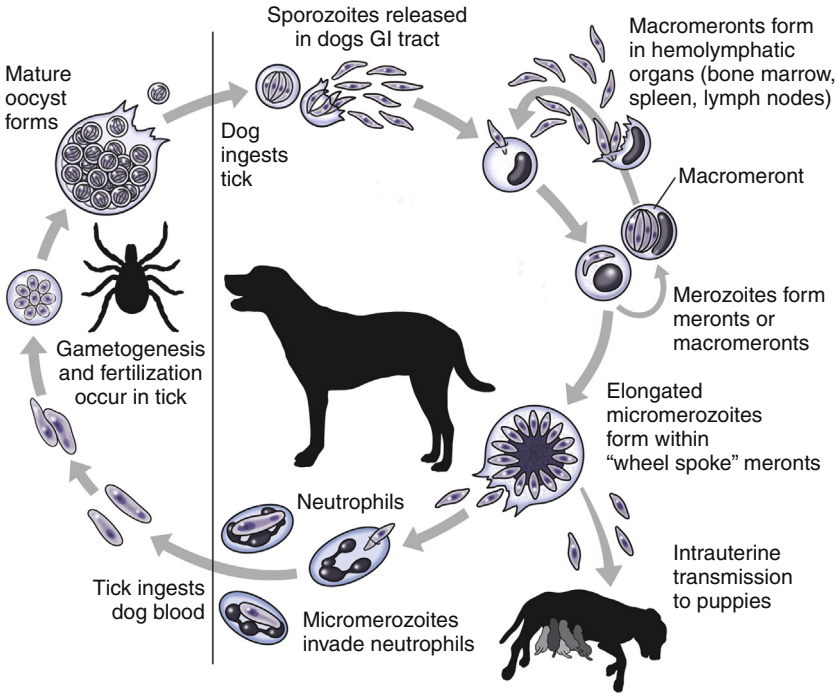

Fig. 99.2 Life cycle of *Hepatozoon canis*.

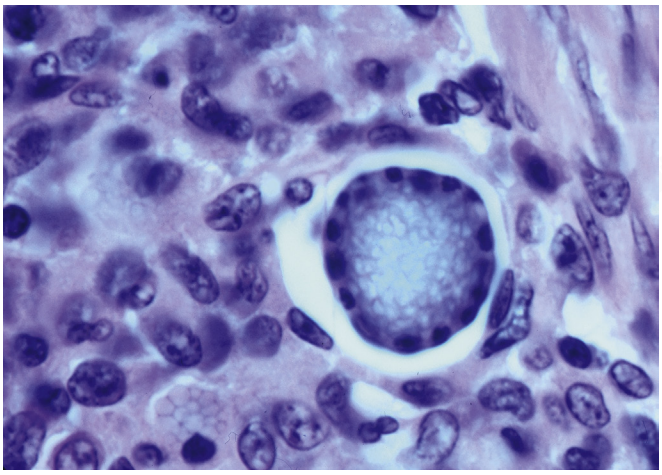

Fig. 99.3 *Hepatozoon canis* meront in splenic tissue of a dog from Israel demonstrating the typical "wheel-spoke" pattern. (Courtesy of Dr. Gad Baneth, Koret School of Veterinary Medicine, Israel.)

Japanese islands; 22% of dogs surveyed in Zaria, Nigeria; 12.5% of dogs in Mauritius; 2.3% of dogs in regions of India; 1.2% of dogs in Malaysia; and 1.0% of dogs in Turkey.

Molecular surveys using PCR to detect *H. canis* 18S rDNA revealed infection rates in dogs of 2% to 6% on the island of St. Kitts, West Indies; 2.5% to 42.9% in parts of Japan; 2.7% to 22.3% in Turkey; 3.1% in southern Portugal; 3.3% in Barcelona, Spain; 5.5% in Palestine; 8.9% in areas of northern Jordan; 10.1% in the Mahasarakham province of Thailand; 10.9% in northern Cambodia; 11.8% in Croatia; 11.9% in the Punjab region of Pakistan; 1.9% to 15% in areas of Hungary and Romania; 16.2% on the islands of Malta and Gozo; 17.5% in Luanda, Angola; 19.3% in Haiti; 20.3% to 41.4% in Nigeria; 26.0% in southern Hungary; 30.0% in Kumasi, Ghana; 30.0% in regions of India; 31.8% in central-western Colombia; 37.5% in Costa Rica; 42.3% in a village population in Sudan; 8.6% to 90.0% in various regions of Brazil; 45% in Venezuela; 51% in Rivas, Nicaragua; and 35.9% to 64% in the Cape Verde Islands.

Serologic studies using IFA revealed that 65.2% of dogs diagnosed with canine monocytic ehrlichiosis (CME) in Thessaloniki, Greece; 36.8% of dogs surveyed for *Hepatozoon* spp. infection around the Aegean coast of Turkey; 33% of the dogs surveyed in Israel; and 4.2% in the Yamaguchi region in Japan had been exposed to *H. canis*. The high seroprevalence rates suggest that most dogs infected with *H. canis* experience subclinical infection. Among dogs surveyed for *H. canis* antibodies in Israel, 3% of the 33% dogs with positive serum antibody titers had detectable blood gamonts, and only 1% had severe clinical signs.

Most dogs are thought to become infected with *H. canis* when they groom ticks from their haircoats or feeding on prey infested with parasitized ticks. An adult *Rh. sanguineus* tick might acquire *H. canis* as a larva or nymph feeding on a parasitemic dog, and then after molting, attach and feed on a new host, not necessarily a dog.[20] Ticks may also acquire infection during feeding at the adult stage as shown experimentally for *A. ovale* in Brazil. Both male and female adult *Rh. sanguineus* can harbor *Hepatozoon* oocysts and are potentially infective to dogs.

After tick ingestion, infected cells are carried by lymph or blood to the spleen, bone marrow, lymph nodes, and other organs such as the liver, kidney, and lungs where the organisms divide asexually through merogony (Fig. 99.2).[9] Two types of meronts form: (1) the "wheel-spoke" meront, which contains 20 to 30 micromerozoites around a central round structure (Fig. 99.3), and (2) a meront that contains up to four macromerozoites. Once released from the mature meront, micromerozoites invade neutrophils and monocytes and transform into gamonts, which can then be ingested by feeding ticks (Fig. 99.4). The larger macromerozoites are believed to be responsible for the production of secondary meronts in the target tissues, which continue the asexual cycle of merogony. Some confusion has been caused by synonymous use of terms relating to life-cycle stages of *H. canis*. Some studies describe schizonts and gametocytes, whereas other texts commonly use the terms meronts and gamonts (preferred by the authors) to describe the same structures. Another tissue stage found in dogs with *H. canis* but not *H. americanum* infections is a small monozoic

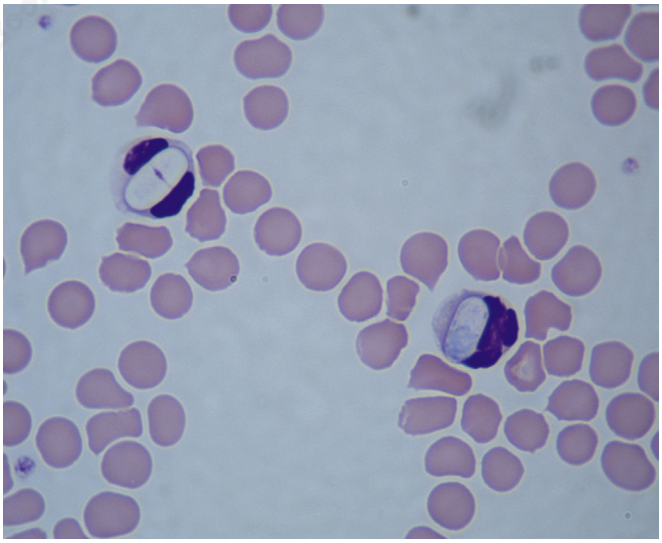

Fig. 99.4 Two *Hepatozoon canis* gamonts in neutrophils on a blood smear. The gamonts of *Hepatozoon americanum* are nearly identical in appearance to those of *H. canis,* although they are rarely seen. 1000× magnification. (Courtesy of Dr. Gad Baneth, Koret School of Veterinary Medicine, Israel.)

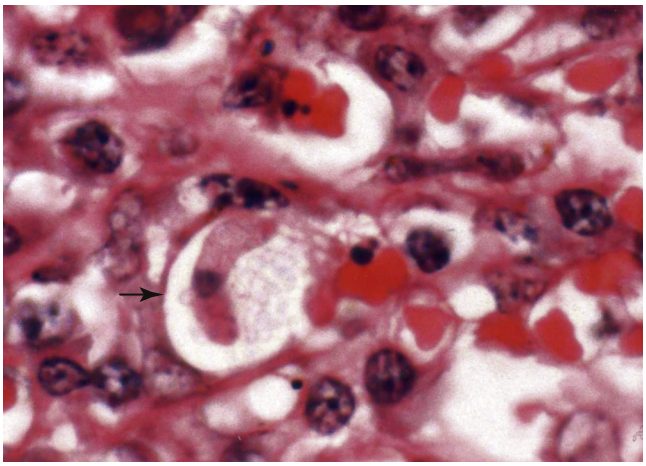

Fig. 99.5 A monozoic tissue cyst of *Hepatozoon canis (arrow)* in the splenic tissue of a naturally infected dog (hematoxylin and eosin stain, 500× magnification).

cyst (containing a single parasite) that resembles the cystozoite form in lizards and snakes affected by other *Hepatozoon* species in which transmission by predation has been shown (Fig. 99.5).[26] The predation route of transmission has not yet been proven to occur for *H. canis* and the role of these cysts in the life cycle of *H. canis* has not been clarified.

Ticks become infected when they ingest leukocytes that contain gamonts while feeding on a parasitemic dog. Morphologically indistinguishable male and female *H. canis* gamonts are released from the dog leukocytes within the tick gut, associate with one another, and differentiate in the process of gametogenesis to form distinct gametes. After fertilization, the zygote divides, and sporogony occurs with the formation of oocysts that are released into the tick's hemocoel. The oocysts are large, spherical forms consisting of a membrane that envelops hundreds of sporocysts in which the infective sporozoites are found. Sporozoites do not migrate to the feeding parts or salivary gland of the tick; therefore, the tick must be ingested to infect the dog.

The entire life cycle of *H. canis* (both tick and dog components) can be completed within 81 days. In an experimental transmission study, adult-stage *Rh. sanguineus* ticks were infective by ingestion to dogs 53 days after the ticks fed as nymphs on a naturally infected dog. Meronts were first detected in the experimentally infected dog's bone marrow 13 days postinoculation, and gamonts appeared in the blood in 28 days, thereby completing the life cycle.[9]

As for other apicomplexan parasites, such as *Toxoplasma gondii* and *Neospora caninum* (see Chapters 93 and 94), vertical transmission through the uterus from dam to its offspring has also been demonstrated for *H. canis*. Naturally infected pregnant dogs were allowed to give birth in a tick-free environment. Meronts were found in the spleen of a pup that died 16 days after birth, and blood gamonts were detectable as early as 21 days in other pups.[27]

Another likely mode of transmission that has not yet been demonstrated for *H. canis* infections is predation on another intermediate or transport host. Experimentally, infection could not be established through parenteral inoculation of tissues or blood from infected dogs but it could from inoculation of emulsified tick tissues. In an area of south-eastern Brazil with high *H. canis* prevalence, a survey study documented characteristic monozoic cysts of *Hepatozoon* spp. in many collected rodents, but molecular analysis revealed that the organism was distinct from *H. canis*. However, *H. americanum* may be transmitted by dog predation on wild rodents and rabbits harboring the tissue cyst stages of this parasite, and some other species of *Hepatozoon* that infect snakes, lizards, and frogs have also been shown to be transmitted through predation and ingestion of tissue cysts found in intermediate host tissues.[26]

No gender or breed predilection for disease caused by *H. canis* has been noted. Disease has been reported in all age groups, from pups younger than three months of age to geriatric dogs. In a case series of dogs from Greece, the female-to-male ratio was 1.2:1, and the mean age was 4.2 years. Dogs with disease caused by *H. canis* are more likely to be from a rural community as compared with an urban setting, which may reflect a higher tick exposure rate. In a study of dogs from Brazil, the presence of *Rh. sanguineus* ticks on dogs in the household was associated with at least one *H. canis*–infected dog per household.

Most dogs with disease due to *H. canis* are examined during the warmer months of the year when tick vectors are more abundant. In a case-control study of 100 dogs *H. canis* infections from Israel, 77% were admitted during the warm period of May through November. A follow-up study on the periodic appearance of *H. canis* gamonts in the blood of dogs in Japan indicated that the peak parasitemia was from spring to autumn. However, disease due to *H. canis* is also diagnosed during the colder months, when transmission by vector ticks is less likely, as a result of chronic persistent infection.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Most dogs infected with *H. canis* have a low level of parasitemia, with less than 5% of circulating leukocytes infected with gamonts. These dogs have a limited inflammatory reaction. About 15% of parasitemic dogs have a high level of parasitemia (>800 gamonts/μL).[23] The degree of parasitemia correlates with the severity of clinical signs; the sickest dogs may have parasitemia that approaches 100% of infected circulating leukocytes.[25] These dogs may develop hepatitis, glomerulonephritis, or pneumonitis in addition to severe anemia, fever, and cachexia.[26]

When a dog ingests the vector tick or tick parts, *H. canis* sporozoites are released in the intestine and penetrate the gut wall. The sporozoites invade mononuclear cells and disseminate hematogenously or via the lymph to hemolymphatic target organs that include the bone marrow, spleen, and lymph nodes and to other internal organs such as the liver, kidney, and lungs. Respectively, hepatitis, glomerulonephritis, and pneumonitis may

develop. Meronts, in which asexually dividing merozoites develop, are formed in the dog's tissues in the process of merogony.

Conditions that weaken the immune responses increase the susceptibility to new infection with *H. canis* or allow existing infections to reactivate. Co-infections with other pathogens such as *Ehrlichia canis, Babesia* spp., *Anaplasma* spp., *Leishmania infantum,* CPV, or CDV can influence establishment of a new *H. canis* infection as well as progression or reactivation of an existing infection. In a litter of Dalmatians that were diagnosed with *H. canis* parasitemia, pups that developed parvoviral enteritis demonstrated a significantly higher level of parasitemia than did their littermates that did not become ill. In addition, treatment of experimentally infected dogs with an immunosuppressive dose of prednisolone was followed by the appearance of parasitemia.[21]

Physical Examination Findings

Dogs with mild *H. canis* infections may have pale mucous membranes and lethargy. Dogs with high parasitemia often exhibit fever, lethargy, and severe weight loss or cachexia, even if they maintain a good appetite. Splenomegaly and lymphadenomegaly may be detected. Dogs often have physical examination abnormalities that relate to the presence of co-infections or other comorbidities.

A variety of clinical abnormalities are associated with infection, which range in severity from an incidental hematologic finding in an apparently healthy dog to a debilitating and life-threatening illness. A low level of *H. canis* parasitemia with gamonts in less than 5% of neutrophils is the most common finding. This is usually associated with subclinical to mild disease. A high-level parasitemia that can approach 100% of infected neutrophils with leukocytosis is usually associated with severe disease. High parasitemia rates are frequently found in association with marked neutrophilic leukocytosis, as high as 150,000 cells/μL of blood.[25,26] The mechanism leading to this leukocytosis has not been elucidated.

In a case-control study of 100 dogs with disease caused by *H. canis*, dogs were categorized into low and high parasitemia groups. Of these, 85% had a low parasitemia level and 15% had a high number of circulating parasites. Dogs with low parasitemia were more anemic and had lower platelet counts than did the control dogs with other disease conditions. However, dogs with high circulating parasite numbers suffered mainly from fever, lethargy, weight loss, anemia, and hyperglobulinemia. A study of canine hepatozoonosis from Turkey also found an association between the severity of clinical signs and the level of parasitemia. Dogs with severe disease had higher parasitemia levels than dogs showing moderate or mild clinical signs.[26]

High numbers of circulating *H. canis* gamonts (e.g., 50,000 to 100,000 gamonts/μL of blood) signify significant tissue parasitism. Tissue meronts produce the numerous merozoites that eventually invade leukocytes. The load of blood and tissue parasites present in dogs with high-level parasitemia demands nutrients and exerts tissue injury. This subgroup of affected dogs typically exhibit weight loss with cachexia and profound lethargy. A study of 185 dogs from Thailand found a significant positive correlation between the number of gamonts in *H. canis* infected dogs and the plasma protein level.[30]

Concurrent infections involving *H. canis* and other canine pathogens are common. Some co-infecting organisms, including *E. canis* (see Chapter 44) and *Babesia vogeli* (see Chapter 97), are also transmitted by *Rh. sanguineus*, and are likely to be found in dogs with tick infestations in areas where these diseases are endemic in the dog population. Other pathogens reported to be involved in concurrent infections include CPV, CDV, *Anaplasma phagocytophilum*, *Anaplasma platys*, *T. gondii*, and *L. infantum*. Young puppies with hepatozoonosis and other concurrent infections may develop more severe disease. Co-infections may influence the susceptibility to establishing a new infection or the progression of an existing one. In the case of concurrent infection, clinical signs attributed to *H. canis* infection must be interpreted cautiously.

DIAGNOSIS

The pathogenesis, vector capacity, tissue tropism, and clinical signs associated with *H. canis* infection differ from those of *H. americanum* infection (see later discussion). *Hepatozoon canis* is found primarily in hemolymphatic tissues, whereas *H. americanum* infects mainly muscular tissues, causing myositis and lameness.[1,2,10] The principal differences between these two infections are summarized in Table 99.1.

Laboratory Abnormalities

Complete Blood Count

The most common laboratory finding in *H. canis* infection is anemia, which is usually normocytic, normochromic, and occasionally regenerative. Platelets are decreased about one third of the time, but this may be due to concurrent infection with *E. canis* or other disease. The white blood cell count is typically normal in cases with low parasitemia but is elevated in dogs with high parasitemia. Some dogs have neutrophil counts of 50,000 to 150,000/μL with close to 100% of these cells containing gamonts.[31]

Serum Chemistry Profile

Common serum chemistry findings in *H. canis* infection include hyperproteinemia, hyperglobulinemia, and hypoalbuminemia. The hyperglobulinemia is due to a polyclonal gammopathy. Increases in the activities of ALP and CK are usually present.

Urinalysis

Urinalysis findings are not known to be affected by *H. canis*, but because some dogs have evidence of glomerulonephritis, proteinuria may be possible.

Diagnostic Imaging

In *H. canis* infection, radiographic bone lesions are rare. Periostitis has been described in reports from Japan, India, and Italy, and in an experimental infection in Israel.

Microbiologic Tests

Diagnostic assays currently available for hepatozoonosis in dogs are described in Table 99.2.

Cytologic and Morphologic Diagnosis

In most dogs with *H. canis* infections, gamonts are found on blood smear examination in 0.5% to 5% of neutrophils and monocytes. Parasitemia may approach 100% in heavy infections. Gamonts may also be identified in dogs that are apparently healthy.

Microscopic detection of *H. canis* gamonts in Giemsa- or Diff-Quik-stained blood smears is the most common method for diagnosis. The gamonts are ellipsoidal and measure approximately 11 μm × 4 μm (Fig. 99.6) and are found in the cytoplasm of neutrophils and rarely in monocytes. Gamonts are enveloped in a thick membrane (Fig. 99.7) and are often situated in the center of the neutrophil and compress its lobulated nucleus toward the cell membrane. Examination of buffy-coat smears is more sensitive than routine blood smears for detection of the organism; however, nucleic acid amplification tests (see later discussion) are even more sensitive and specific.

Hepatozoon canis meronts can be detected in cytologic preparations made from aspirates or touch impressions of hemolymphatic tissues. With cytologic examination, meronts are round to oval and approximately 30 μm in diameter. Immature meronts appear as

TABLE 99.1 Comparison Between *Hepatozoon canis* Infection, American Canine Hepatozoonosis, and Feline Hepatozoonosis

	Hepatozoon canis Infection	American Canine Hepatozoonosis	Feline Hepatozoonosis
First described	India, 1905	Texas Gulf Coast, 1978	India, 1908
Etiologic agent	*Hepatozoon canis*	*Hepatozoon americanum*	*Hepatozoon felis, Hepatozoon silvestris, Hepatozoon canis*
Primary vector	*Rhipicephalus sanguineus* (brown dog tick), *Rhipicephalus turanicus, Ambylomma ovale*	*Amblyomma maculatum* (Gulf Coast tick)	Unknown
Route of transmission	Ingestion of tick (not a tick bite)	Ingestion of tick (not a tick bite)	Probably ingestion of tick or other hematophageous vector
Additional routes of transmission	Transplacental from dam to puppy	Ingestion of cystozoites in transport hosts; transplacental is likely	Possibly transplacental
Affected mammalian hosts	Dogs, foxes, jackals, other carnivores	Dogs, coyotes, possibly bobcats, ocelots, and other wildlife	Domestic cats, wild felids
Geographic distribution	Africa, Middle East, Asia, southern Europe, Central and South America, United States, Australia	Primarily southern and south-eastern United States	India, Africa, Israel, Brazil, Spain, France, Italy, Cyprus, Turkey, Thailand, United States
Severity of disease	Subclinical to mild; occasionally severe, especially if immunosuppressed	Usually severe, even in absence of immunosuppression	Typically subclinical unless immunosuppressed
Principal target organs	Spleen, bone marrow, lymph node	Skeletal muscle, myocardium	Myocardium, skeletal muscle, lungs, bone marrow
Major clinical signs	Lethargy, fever, weight loss	Fever, pain, lameness, ocular discharge	Nonspecific
Common laboratory abnormalities	Anemia; extreme leukocytosis is rare but may occur with high parasitemia	Marked leukocytosis (20,000–200,000 cells/μL), anemia, elevated ALP activity, low glucose concentration	Elevated CK activity
Radiographic lesions	Nonspecific; rare periostitis	Common; periosteal bone proliferation	Not reported
Histopathology findings	Hepatitis, splenitis, glomerulonephritis, pneumonitis associated with *H. canis* meronts No muscle lesions	Myositis, onion-skin cysts, pyogranulomas, and meronts in skeletal muscle	Meronts in myocardium and skeletal muscle
Unique morphologic features	"Wheel-spoked" meronts, small monozoic splenic tissue cysts	Large onion-skin cysts in muscle	
Blood smear findings	Gamonts common; parasitemia of 1%–5% is typical; rarely see parasitemia of 5%–100%	Rarely observed gamonts; parasitemia is usually < 0.1%	Parasitemia is rare; when present usually < 1% of neutrophils
Human health significance	None known	None known	None known

ALP, alkaline phosphatase; *CK,* creatine kinase.

TABLE 99.2 Diagnostic Assays Currently Available for Hepatozoonosis in Dogs

Assay	Specimen Type	Target	Performance
Cytologic examination	Whole blood smears	*Hepatozoon* spp. gamonts in leukocytes	False negatives are common because of low circulating numbers of gamonts, especially in clinical *Hepatozoon americanum* infections.
Antibody serology (ELISA or immunofluorescent antibody)	Serum	Antibodies to *Hepatozoon canis*	Positive test results indicate exposure but do not indicate the presence of the organism in circulating leukocytes and do not correlate with clinical disease.
Real-time PCR assays	Whole blood	*H. americanum* or *H. canis* DNA	Sensitivity and specificity may vary depending on assay design, but in general PCR assays are more sensitive than cytology. False-negative results may occur when organism levels are very low, such as early in disease or in very chronic infections.
Histopathology	Muscle biopsy specimens	*H. americanum* cysts, meronts, and pyogranulomas	Reliable method in both acute and chronic cases of *H. americanum* infection, but requires anesthesia.

ELISA, enzyme-linked immunosorbent assay; *PCR,* polymerase chain reaction.

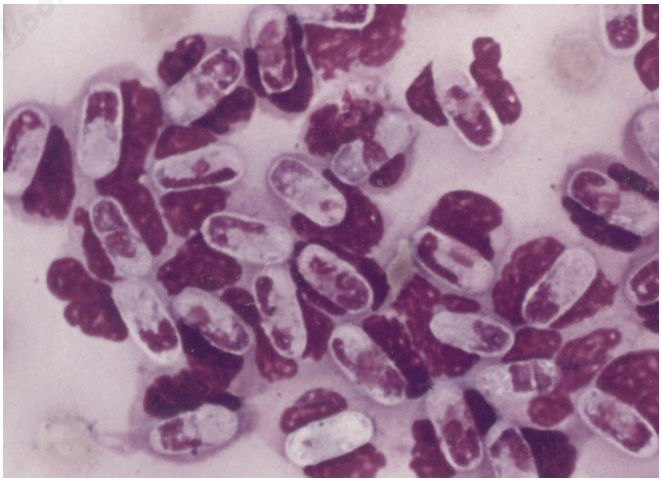

Fig. 99.6 Feathered edge of a blood smear from a dog with leukocytosis and a high *Hepatozoon canis* parasitemia. Close to 100% of the neutrophils are parasitized with gamonts (Giemsa stain, 1000× magnification).

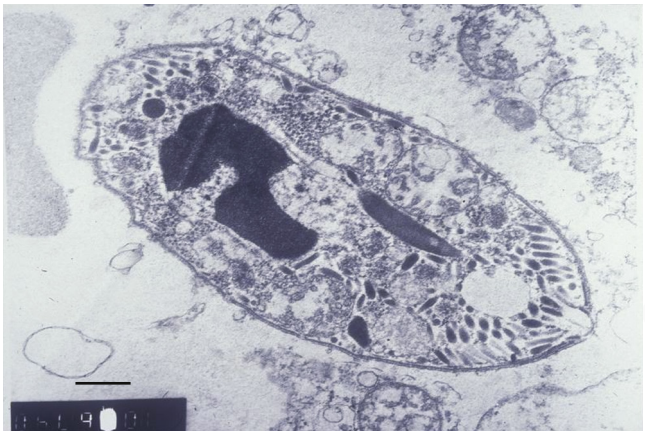

Fig. 99.7 A transmission electron microscopic image of *Hepatozoon canis* gamont from the blood of a naturally infected dog. Note the conoid at the anterior end of the parasite. A three-layer membrane envelopes the gamont (bar = 1μm).

round opacities filled with globular foam-like material. As the meront matures, basophilic-staining chromatin material forms as either two to four larger macromerozoites (Fig. 99.8) or more than 20 micromerozoites (Fig. 99.9). The micromerozoites align in a circle close to the meront wall around a central opaque core.

Hepatozoon canis can also be identified in ticks. Mature oocysts can be seen even without magnification as small white globular forms in wet preparations of the hemocoel. The observation of oocysts is verified and differentiated from the tick's organs and salivary glands by microscopy of hemocoel smears as unstained wet preparations or as Giemsa-stained specimens (Fig. 99.10). The oocysts are enveloped in a fragile membrane and contain hundreds of smaller oval sporocysts. Free sporocysts are often scattered outside the oocyst, and infective sporozoites are packed as elongated slender forms within the sporocysts.

Serologic Diagnosis

Both IFA and ELISA assays for *H. canis* antibodies have been developed. Positive serologic test results indicate exposure but do not prove active infection or correlate with clinical disease. Thus, serologic testing is mostly of use for epidemiologic studies. Both IgM and IgG antibodies were detectable in the sera of experimentally infected dogs as

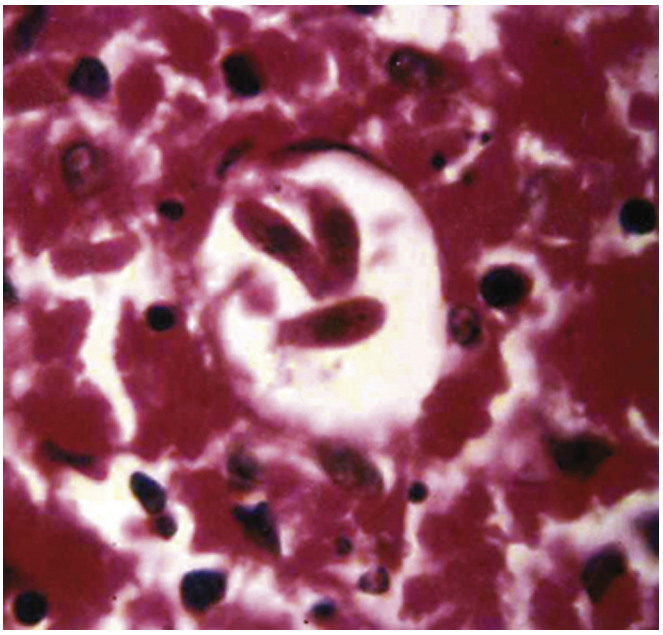

Fig. 99.8 *Hepatozoon canis* meront containing three macromerozoites in splenic tissue.

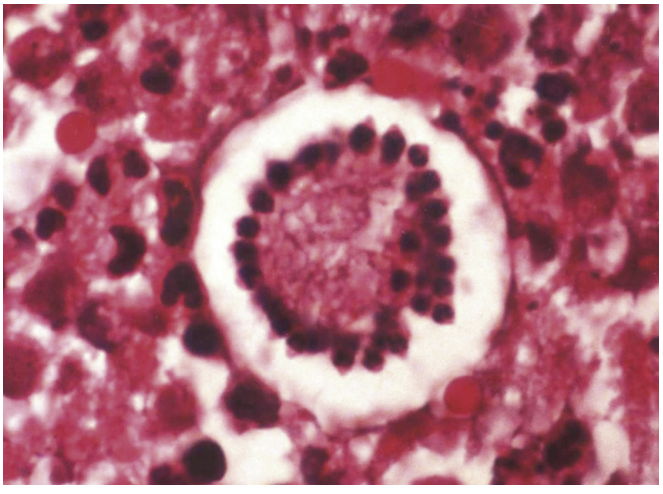

Fig. 99.9 *Hepatozoon canis* meront containing micromerozoites forming a "wheel-spoke" shape in splenic tissue (hematoxylin and eosin stain, 400× magnification).

early as 16 and 22 days postinoculation, respectively, peaked at 7 to 9 weeks, and persisted for more than 7 months.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays for the detection of *Hepatozoon* DNA have been mostly based on amplification of fragments of the *18S rRNA* gene.[6,7,32] Some of the PCR assays originally developed to detect piroplasms such as *Babesia* spp. also amplify *Hepatozoon* DNA; however, the amplified products are of different size, and their identities can be further verified by sequencing. Studies that compared the detection of *Hepatozoon* by blood smear microscopy and endpoint PCR from the same blood samples indicated that PCR was considerably more sensitive. In one study, smears were positive in 2.6% of cases versus 11.4% by PCR, in another 10.6% versus 25.8%, and in a third, 11.3% versus 53.3%, respectively. Quantitative (real-time) PCR assays for *Hepatozoon* are very sensitive and specific and have the potential to provide an estimate

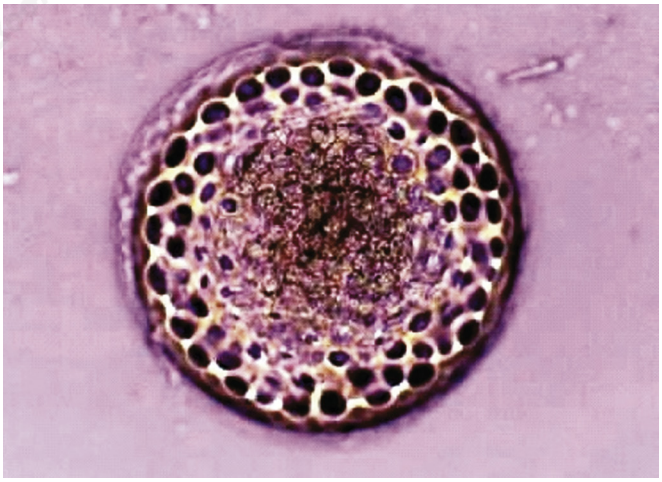

Fig. 99.10 Unstained *Hepatozoon canis* oocyst containing numerous sporocysts from the hemocoel of an adult-stage *Rhipicephalus sanguineus* tick (200× magnification).

of the parasite load in submitted specimens.[7] A loop-mediated isothermal amplfication technique for the detection of *H. canis* infection at POC has been developed.[33]

Pathologic Findings

Gross Pathologic Findings

Pathologic descriptions of infected dogs range from reports on infrequent tissue meronts termed as incidental findings to severe and occasionally fatal multiorgan involvement. A considerable variation is found in the spectrum of lesions and the number of parasitic life forms. The major macroscopic lesions found in dogs with heavy infections include splenomegaly and hepatomegaly, with a diffuse pattern of small white necrotic foci 1 to 2 mm in diameter. Necrotic foci may be larger and nodular in appearance and are also found in other tissues including the pancreas and on the pleura. Pneumonia may be evident, and lymph nodes are typically enlarged.

Histopathologic Findings

Histopathologic findings include a varying number of developing or mature meronts in tissues. "Wheel-spoke" meronts are approximately 30 µm in diameter (see Fig. 99.9). Meronts can be found in small numbers as an incidental finding in dogs from enzootic areas.

Meronts can be associated with a mild to severe inflammatory response. Focal splenic necrosis is associated with *H. canis* merogony in red and white pulp regions, with white pulp necrosis located primarily in lymphoid follicles. Hepatitis with Kupffer cell hyperplasia and mononuclear and neutrophil infiltration is associated with developing meronts in the liver. The presence of *H. canis* in the lung is associated with interstitial pneumonia and thickening of alveolar septa with inflammatory cell infiltrates. Renal lesions include glomerulonephritis and interstitial nephritis with multifocal necrosis. Mild to extensive parasitism with meronts and developing gamonts in the lymph nodes and bone marrow may also be evident.

TREATMENT AND PROGNOSIS

The current treatment protocol for *H. canis* infection is imidocarb dipropionate at 5 to 6 mg/kg, SC or IM, every 14 days, until gamonts are no longer present in blood smears. It has been recommended that all dogs, even those with only mild disease, be treated because parasitemia may increase over time. One or two injections may suffice; however, the elimination of gamonts in heavy infections using imidocarb dipropionate may require treatment for 8 weeks or longer. Doxycycline at 10 mg/kg/day, PO, for 21 days is frequently used in combination with imidocarb dipropionate to treat potential or identified rickettsial vector-borne co-infections.

Despite the clinical improvement or clearance of the parasite in the blood by microscopic methods, PCR methods may still detect the organism during follow-up evaluation after treatment. Successful treatment with the combination of toltrazuril at 10 mg/kg/day PO for 5 days followed by 5 mg/kg/day for additional 10 days, and trimethoprim-sulfonamide at 15 mg/kg PO q12h for 30 days was described in one dog. Addition of toltrazuril or clindamycin does not seem to provide any additional benefit to imidocarb therapy.

Despite lack of a parasitologic cure, clinical cure is achieved in many dogs. The rate of survival of treated dogs with a low *H. canis* parasitemia is generally good and is frequently dependent on the prognosis of any concurrent disease, if present. The prognosis for dogs with a high parasitemia is guarded. Only 7 of 15 dogs (47%) with a high parasitemia survived 2 months despite specific treatment.

IMMUNITY AND VACCINATION

Infection with *H. canis* elicits a distinct humoral immune response during the early stages of the disease.[34] No information is available on the cellular response to infection; however, because *H. canis* is an intracellular parasite, CMI probably plays a major role in the immune mechanism mounted by the host.

Current treatments do not cure infection, so dogs remain susceptible to relapse of disease, especially if immunosuppressed. In experimental *H. canis* infection, treatment with an immunosuppressive dose of glucocorticoids was followed by the appearance of parasitemia. Vaccines for *H. canis* infection are not available.

PREVENTION

Hepatozoon spp. have not been shown to be transmitted through blood transfusion, and the parasite needs to pass through the tick in which the sporozoites, the infective stage of the parasite, are produced in order to complete its life cycle. However, there is no knowledge whether tissue stages that may be infectious may circulate in dogs' blood, and therefore it seems logical that dogs infected with *Hepatozoon* species be avoided as blood donor dogs.

Prevention of *H. canis* infection should consist of an effective control of vector ticks on dogs and in the environment using external parasiticides. Dogs must be prevented from ingesting ticks while grooming or scavenging. Until the certainty that *H. canis* infection may be transmitted by ingestion of infected tissues is reached, dogs in endemic areas should be prevented from eating raw or prey meat.[5]

PUBLIC HEALTH ASPECTS

The spectrum of natural hosts for *H. canis* and *H. americanum* is not currently known. There is only one report of infection with a *Hepatozoon* spp. in a person from the Philippines. This patient was anemic and icteric, and gamonts were detected in the blood. However, no parasites were found in liver and bone marrow biopsies. The danger of direct transmission from dogs to humans is apparently low. *H. canis* is transmitted by tick ingestion rather than a tick bite, and tick ingestion is an unlikely route of transmission for humans.

Although the zoonotic importance of *Hepatozoon* spp. is not known, and it is unlikely to be a significant pathogen in immunocompetent people, caution should be used when handling infected dogs infested with ticks or when removing ticks from dogs as there is a possibility that known human pathogens may also be present.

HEPATOZOON AMERICANUM INFECTION

ETIOLOGY AND EPIDEMIOLOGY

Hepatozoon americanum, the cause of American canine hepatozoonosis (ACH), was first described in 1978 in a Texas coyote. Reports of infections in domestic dogs in Texas and additional southern states occurred over the next two decades, but the parasite was mistaken for *H. canis* due to the similar morphology of the intraleukocytic gamont stage.[1,2] However, based on several criteria including demonstrated tick definitive host, clinical manifestations in infected dogs, and genetic and antigenic differences from *H. canis*, *H. americanum* was recognized as a novel species infecting canids in North America in 1997.[1,10]

ACH is an emerging disease that is spreading north and east from where it was originally detected, which may be due to the geographic expansion of the tick definitive host, *Amblyomma maculatum,* the Gulf Coast tick.[10,35] The geographic distribution of ACH aligns closely with the range of the Gulf Coast tick. Although this tick is endemic in the states that surround the Gulf of Mexico, its range is expanding and it has been found in arid regions of Arizona and as far north as Kansas, Illinois, Kentucky and the Mid-Atlantic states of Virginia, Maryland, and Delaware.[35–37]

Hepatozoon americanum infection is predominantly diagnosed in south-central and south-eastern states, but occasional cases have been identified in diverse locations across the United States, including California, Nebraska, Vermont, Virginia, and Washington. Because infection may be chronic, ACH is occasionally diagnosed in dogs with a history of travel to and from endemic areas.[7] Although initially thought only to be present in North America, recent molecular data suggest that *H. americanum* or a genetically close species infects canids in Brazil.[38] There are isolated reports of DNA of a *Hepatozoon felis*–like organism detected in a dog from southern California and a *H. americanum*–like organism in an immunocompromised cat in Oklahoma, but the clinical significance and epidemiology of these infections are unknown.[32]

Significant variation in 18S rDNA sequences of *Hepatozoon* spp. that infect dogs in the United States has been identified, indicating that the species infecting dogs in North America may be more diverse than previously recognized.[6] As research using molecular diagnostics and genetic sequencing continues, it is possible that additional species will be identified.

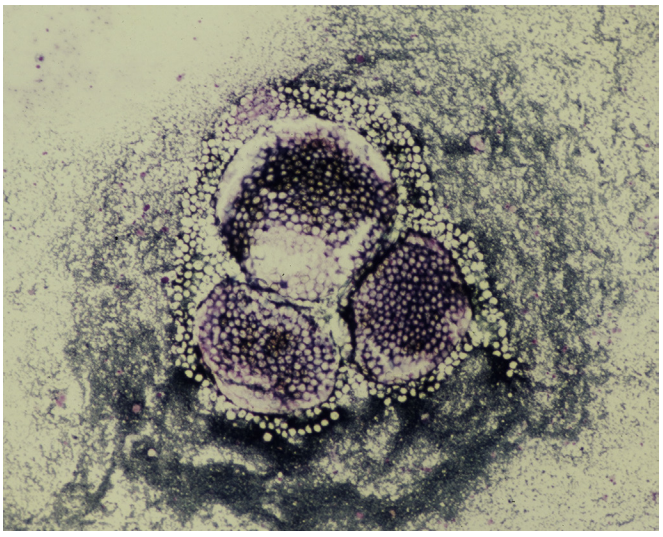

Fig. 99.11 *Hepatozoon americanum* oocysts from the hemocoel of an *Amblyomma maculatum* tick. Hundreds of small, round sporocysts are present within each oocyst. Each sporocyst contains 10 to 26 infective sporozoites.

The true prevalence of *H. americanum* infection is not entirely clear. In 2007, a collaborative molecular survey study using real-time PCR on whole blood detected *H. americanum* in 27.2% of 614 dogs with signs suggestive of hepatozoonosis from 28 states in North America, predominantly in the southeast. Accurate estimates of the prevalence of *H. americanum* infection are difficult due to the lack of available serologic tests and the insensitivity of molecular methods to detect *H. americanum* DNA in infected dogs that have no detectable parasitemia. Infections have also been reported in dogs from Alabama, Georgia, Louisiana, Mississippi, Oklahoma, New Jersey, and Virginia; a few dogs have had mixed infections with *H. americanum* and *H. canis*.[6,8,32]

Because dogs or other vertebrates serve as intermediate hosts, a vector is needed to complete the sexual phase of the life cycle of *Hepatozoon* species. In the case of *H. americanum*, the vector is the Gulf Coast tick, *A. maculatum.* Experimentally the disease has not successfully been transmitted with *Amblyomma americanum, Dermacentor variabilis,* or *Rh. sanguineus* ticks. As it feeds on an infected dog, the larval or nymphal Gulf Coast tick ingests circulating blood macrophages that contain gamonts. Within the tick's gut, the gamonts are freed from the cells and undergo further development before fertilization occurs. The resulting zygote divides through sporogony and develops into an oocyst within the hemocoel of the tick (Fig. 99.11). Oocysts mature while the tick molts to the nymphal or adult stage. Each mature oocyst contains hundreds of sporocysts, with each sporocyst containing 10 to 26 infective sporozoites.[2]

Once a dog ingests an infected tick, whether through grooming or preying on a tick-infested animal, exposure of the parasite to bile in the dog's GI tract results in release of sporozoites, which penetrate the intestinal epithelial wall and are transported to target organs and tissues, likely within mononuclear cells. In *H. americanum* infections, infected cells preferentially travel to skeletal muscle where each organism develops within its monocytic host cell, which becomes lodged between myocytes (Fig. 99.12). Concentric layers of mucopolysaccharide are

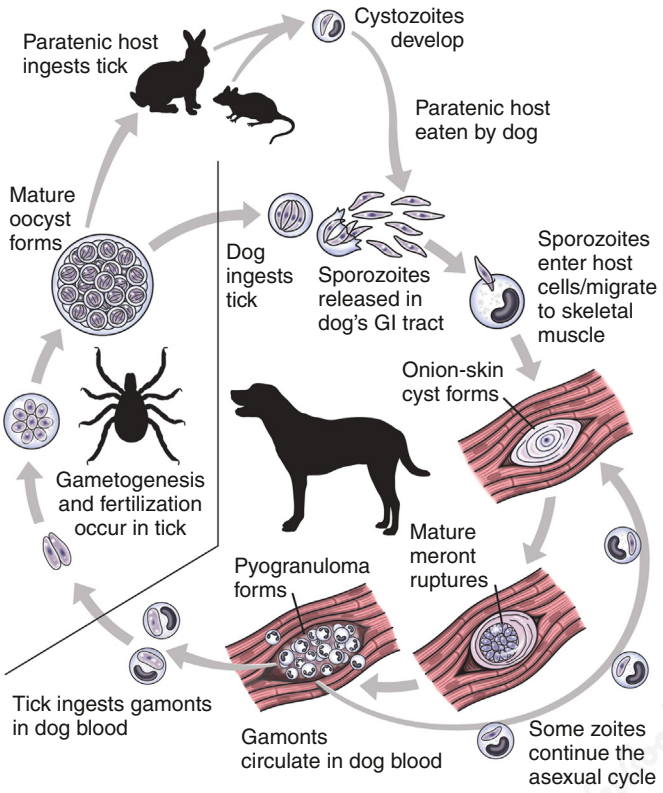

Fig. 99.12 Life cycle of *Hepatozoon americanum.*

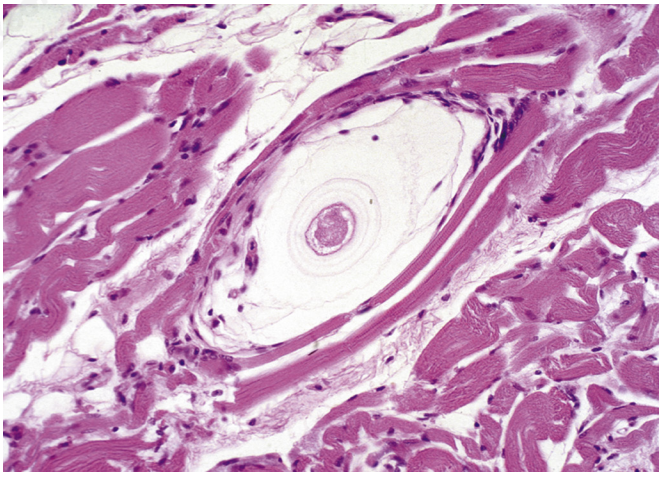

Fig. 99.13 "Onion-skin cyst" of *Hepatozoon americanum*. Concentric layers of mucopolysaccharide material produced by the host cell protect the developing organism from the host's immune system (hematoxylin and eosin stain, 400x magnification).

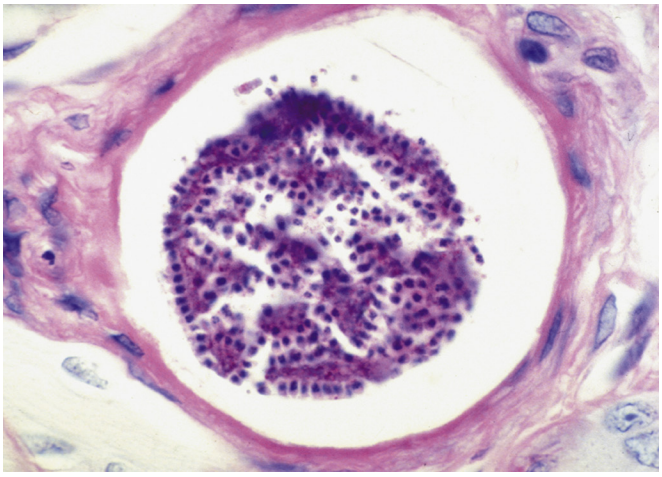

Fig. 99.14 A mature *Hepatozoon americanum* meront just before release of merozoites. Note the lack of inflammation surrounding the cystic structure (hematoxylin and eosin stain, 1200× magnification).

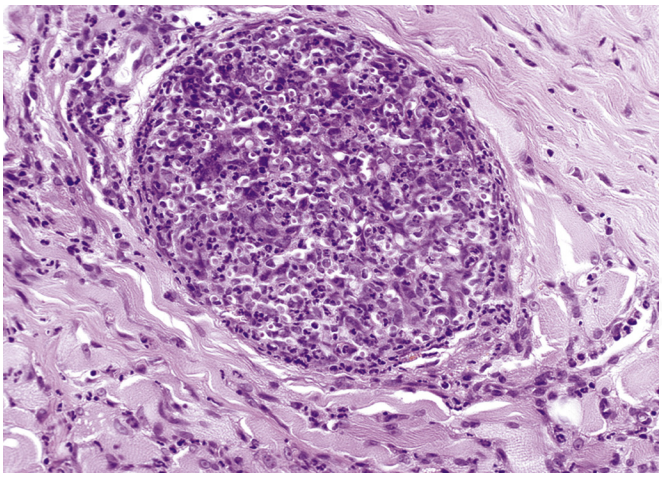

Fig. 99.15 Pyogranuloma associated with the invasion of zoites released from a meront in skeletal muscle of a dog infected with *Hepatozoon americanum*. Zoites displace the nucleus in several of the inflammatory cells.

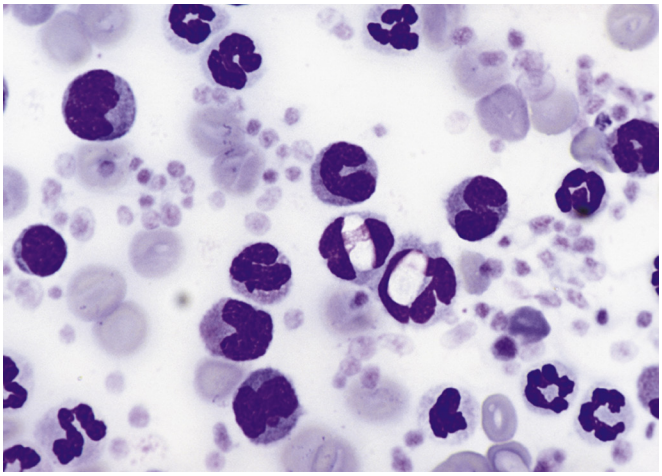

Fig. 99.16 Gamonts of *Hepatozoon americanum* in circulating neutrophils appear identical to *Hepatozoon canis* gamonts. (Giemsa stain, 1200× magnification).

laid down by the host cell to form a large "onion-skin cyst," which may protect the organism from the host immune response (Fig. 99.13). Merogony occurs within the cyst, and on maturation of the meront, the cyst ruptures and merozoites are released (Fig. 99.14). This elicits a severe inflammatory response, with recruitment of neutrophils and macrophages to the area. A pyogranuloma develops in the space where the cyst existed (Fig. 99.15). Many macrophages become infected with a single zoite. Angiogenesis within the pyogranuloma results in a highly vascular structure from which the infected cells can reenter circulation. Two morphologic forms of organism have been observed in macrophages within the pyogranulomas or peripheral blood: circulating merozoites continue the asexual cycle by redistributing to tissues to initiate repeated asexual cycles, while gamonts in peripheral blood macrophages are ingested by feeding ticks, thus completing the life cycle (Fig. 99.16).[2]

Some of the onion-skin cysts within muscle lie dormant for varying lengths of time; their activation is responsible for the waxing and waning nature of ACH as well as relapse of clinical signs that can occur months after perceived clinical cure. Cysts have been found in muscle biopsies taken from dogs for up to 5 years after the initial infection, and an experimentally infected dog remained infective to ticks for over 5 years.[2] In experimental infections, completion of the life cycle from ingestion of infected ticks to development of circulating gamonts can occur in as few as 32 days.[39] In the nymphal tick, approximately 40 days are needed for the organism to develop into mature oocysts that are present in the hemocoel of newly molted adults. Larval *A. maculatum* can also acquire *H. americanum* when they feed from infected dogs, and then support the parasite's development through the molting period. Experimental infections have been produced in both dogs and coyotes by feeding them infected *A. maculatum* ticks.[2]

Other modes of transmission also occur in hepatozoonosis. Transplacental transmission from dam to puppies has been documented for *H. canis* infections and may occur in *H. americanum* infections, although not experimentally demonstrated. Carnivory may play an important role in *H. americanum* transmission in enzootic areas, as has been demonstrated for *Hepatozoon* spp. infecting snakes, lizards, and frogs.[26] Experimentally, cotton rats, mice, and rabbits fed *H. americanum* oocysts developed inflammatory lesions that contain cystozoites (one to two merozoites within small tissue cysts). Gamonts or meronts did not develop, and illness was not documented. Morphologically, cystozoites were similar to tissue stages observed in

TABLE 99.3 Frequency of Clinical Signs in 22 Dogs with American Canine Hepatozoonosis

Clinical Sign	Number of Dogs (%)
Fever	19 (86)
Weight loss	18 (82)
Mucopurulent ocular discharge	17 (77)
Low tear production	8 (36)
Muscle atrophy	14 (64)
Pain	
All types	14 (64)
Joints	2 (9)
Lumbar	4 (18)
Cervical	5 (19)
Generalized	3 (14)
Stiffness	12 (55)
Generalized weakness	9 (41)
Pelvic limb paresis and ataxia	5 (19)
Inability to rise	5 (19)
Anorexia	5 (19)

From Vincent-Johnson NA. American canine hepatozoonosis. *Vet Clin North Am Small Anim Pract*. 2003;33:905–920. Data from Macintire DK, Vincent-Johnson N, Dillon AR, et al. Hepatozoonosis in dogs: 22 cases (1989-1994). *J Am Vet Med Assoc*. 1997;210:916–922.

snakes with hepatozoonosis which are infective to predatory reptiles that ingest them. The cystozoite-laden rabbit and rodent tissues fed to naïve dogs resulted in *H. americanum* infections with classic clinical signs. Thus, it is suspected that dogs may also become infected with this organism by predation on an as-yet unidentified reservoir host in nature. In support of this, an investigation of a natural outbreak in a pack of hunting beagles revealed that clinical signs of ACH developed 4 to 6 weeks after some of the dogs were allowed to consume a wild rabbit carcass, whereas dogs not allowed to consume the rabbit did not develop clinical signs.[26] Larval and nymphal stages of *A. maculatum* may feed on a variety of vertebrate hosts including coyotes, but preferentially feed on ground-dwelling birds and small mammals, lending credence to the supposition that noncanid reservoir hosts may serve as a source of infection to feeding ticks and predatory dogs.[2,10,40]

However, surveys of wildlife in ACH-endemic areas have detected *Hepatozoon* spp. that are related but not identical to *H. americanum* in small rodents and rabbits.[26] Bobcats, fox, ocelots, and raccoons are also documented wildlife hosts of *Hepatozoon* spp. in North America.[2,32,41]

Coyotes have long been recognized as harboring *H. americanum* in endemic areas. In a 2013 study, nearly 80% of coyotes sampled from six total locations in Oklahoma and Texas were infected with *Hepatozoon* spp. by histologic and/or molecular methods.[42] Dogs may be an aberrant, rather than natural, host of *H. americanum* due to the severity of disease that develops. Adult coyotes are reported to tolerate *H. americanum* infection better than domestic dogs, and may represent a reservoir host.[2,43] However, the severity of disease in coyotes may be influenced by age and/or infective dose. Coyote puppies developed higher-level parasitemia, more numerous parasite-induced muscle lesions, and more commonly experienced bony changes after oral administration of 50–100 oocysts than did adult coyotes in the same experiments.[44]

Although a noncanid reservoir species has not been identified, the diversity of wildlife species that could potentially serve as reservoir hosts and the persistence of the organism in infected tick populations may explain why *H. americanum* infection is recognized as an emerging disease that is infecting increasing numbers of dogs, as well as expanding its geographic distribution in the United States.[10,35,37]

The occurrence of hepatozoonosis appears to be seasonal in the warmer months or in early fall when dogs are most likely to be exposed to ticks. There is no sex or breed predilection for ACH, but hunting dogs, rural dogs, and dogs allowed to roam are most at risk.[26] Once infected, dogs typically exhibit waxing and waning clinical signs that occur throughout the year as repeated cycles of asexual reproduction and pyogranulomatous inflammation take place.[1,2,10]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In contrast to *H. canis*–infected dogs, most dogs with *H. americanum* infection exhibit moderate to severe clinical signs even in the absence of concurrent disease or immunosuppression.[1,41] Clinical signs of *H. americanum* infection are associated with the strong inflammatory response that occurs when meronts rupture, leukocytes are recruited, and pyogranulomas form in skeletal muscle. The earliest lesions occur 3 weeks after infection.[39] As the organisms multiply, the infection disseminates, which results in more severe inflammation that waxes and wanes over time. The inflammation causes fever and myositis, which is associated with locomotor abnormalities and hyperesthesia (Table 99.3).[10] The clinical signs can mimic those of meningitis or discospondylitis.[1,41]

Many affected dogs also develop bone lesions that are evident radiographically and resemble lesions seen in hypertrophic osteopathy, except they are proximal rather than distal in distribution (Fig. 99.17). It is unknown whether the bone lesions result from nearby localized muscle inflammation or from humoral factors.[2,10]

Dogs infected with *H. americanum* usually have bilateral mucopurulent ocular discharge that may be caused by pyogranulomatous inflammation of the extraocular muscles or of the lacrimal gland (Fig. 99.18). Return of ocular discharge is frequently the first clinical sign indicative of a relapse following treatment.[2,10,41]

Dogs with ACH frequently maintain a fairly normal appetite; however, weight loss, cachexia, and muscle atrophy occur over time, likely as a result of the increased caloric demands associated with a prolonged inflammatory state.[2,10] There may be a history of polyuria and polydipsia that is due to glomerulonephritis or amyloidosis, which can occur secondary to long-standing inflammation in chronic infections. Nephrotic syndrome and thromboembolic complications may ensue. Less common clinical signs include diarrhea, mucosal pallor, cough, abnormal lung sounds, and lymphadenomegaly.[1,41]

Physical Examination Findings

With *H. americanum* infection, fever (up to 105.6°F or 40.9°C) that does not resolve with antibiotic therapy is common, although because of the waxing and waning nature of the disease, body temperature may be normal at any given time.[45] Many dogs are treated for a fever of unknown origin before it is evident that abatement of clinical signs is not in response to antibiotic therapy, but attributable rather to the cyclic nature of ACH.[1,10]

Because of the myositis, dogs are typically evaluated for gait abnormalities, which range from lameness or stiffness to recumbency and an inability or unwillingness to rise. Pain from myositis is common and may appear as cervical, back, joint, or generalized pain. The stiffness and reluctance to move cause many dogs to assume a "master's voice"

Fig. 99.17 Radiograph of the pelvic limb of a dog with *Hepatozoon americanum* infection. There is smooth periosteal proliferation on the cranial aspect of the femur. (From Vincent-Johnson NA. American canine hepatozoonosis. *Vet Clin North Am Small Anim Pract.* 2003;33:905–920.)

Fig. 99.18 Rottweiler with *Hepatozoon americanum* infection. Note the hunched appearance, muscle atrophy, and mucopurulent ocular discharge.

stance. Hyperesthesia, stiffness, neck guarding, and fever can easily be mistaken for meningitis or discospondylitis, but sensory deficiencies and analysis of CSF are usually unremarkable, indicating that nervous system involvement is unlikely. Generalized polymyopathy may be detected using electromyography.[1,45] Lethargy is common, and cachexia and generalized muscle atrophy may be apparent. Mucopurulent ocular discharge is often present; approximately one third of dogs with matted eyes have decreased tear production on a Schirmer tear test.[41,43] Other ocular lesions seen in ACH patients on occasion include focal retinal scars or hyper-reflectivity, increased retinal pigmentation, papilledema, and uveitis with active inflammatory fundic lesions. Mucosal pallor and lymphadenomegaly may also be present.[43]

DIAGNOSIS

A high degree of suspicion based on consistent clinical signs, radiographic findings, and laboratory abnormalities is key to the diagnosis of *H. americanum* infection. Diagnosis is most often confirmed by histopathologic findings of muscle biopsy or positive PCR assays on blood.[10,41,46]

Laboratory Abnormalities

Complete Blood Count

The most consistent laboratory abnormality in *H. americanum* infection is leukocytosis, which is often, but not necessarily, extreme (Table 99.4). White cell counts are typically 20,000 to 200,000 cells/μL, with reported means of 76,807 and 85,700 cells/μL.[1,41,43] The leukocytosis is due to a mature neutrophilia, although sometimes there is a mild to moderate left shift. A mild normocytic, normochromic nonregenerative anemia is typical. Platelets are usually normal to increased, sometimes with thrombocytosis up to 916,000 platelets/μL. When thrombocytopenia is evident, concurrent tick-borne diseases such as ehrlichiosis, RMSF, and babesiosis should be considered.[1,41,43]

Serum Chemistry Profile

In *H. americanum* infection, a mild increase in the activity of serum ALP is typical, possibly due to periosteal new bone formation. Serum glucose concentration is often decreased (40 to 60 mg/dL) and occasionally as low as 5 mg/dL. This is not a true hypoglycemia, but rather a laboratory artifact due to utilization of glucose in the specimen by the high number of white blood cells. Blood glucose values are typically in reference range if sodium fluoride is used as the anticoagulant to block glucose metabolism by leukocytes. Hypoalbuminemia is common and may be due to chronic inflammation, decreased protein intake, or renal loss from secondary glomerulonephritis or amyloidosis. Chronic inflammation causes increased production of acute-phase proteins and macroglobulins, resulting in downregulation of albumin synthesis. Hyperglobulinemia is relatively uncommon. Except in dogs with significant renal damage, serum urea nitrogen concentration is often low. The combination of increased activity of serum ALP and low glucose, serum urea nitrogen, and albumin concentrations may mislead the clinician to suspect liver disease. Serum bile acid concentrations are normal or only slightly elevated. Surprisingly, the activity of serum CK is consistently within the normal range even though *H. americanum* infection causes severe myositis.[1,41,43]

Urinalysis

Urinalysis may be normal but in patients with chronic *H. americanum* infection, proteinuria of varying degrees is a frequent finding due to the occurrence of secondary glomerular disease, protein-losing nephropathy, or amyloidosis. These dogs have decreased concentrating ability, resulting in isosthenuria and an elevated protein-creatinine ratio.[41,43]

Diagnostic Imaging

Plain Radiography

Many dogs with *H. americanum* infection show radiographic abnormalities of the skeletal system; therefore, radiographs of the pelvis or long bones can be useful to support a clinical diagnosis of ACH.[10,43,46] Young dogs are more likely to show bone lesions than older dogs. In experimental infections, bone lesions are recognizable histologically

TABLE 99.4 Frequency of Laboratory and Radiographic Findings in 22 Dogs with American Canine Hepatozoonosis

Finding	Number of Dogs (%)
Moderate to marked leukocytosis[a]	22 (100)
Mature neutrophilia	15 (68)
Mild left shift	7 (31)
Elevated ALP activity	22 (100)
Hypoglycemia	20 (91)
Hypoalbuminemia	19 (86)
Periosteal proliferation on radiography	18 (82)
Anemia (nonregenerative)	14 (64)
Hypocalcemia	14 (64)
Normal platelet count	11 (50)
Thrombocytosis	9 (41)
Hyperphosphatemia	7 (32)
Low BUN concentration	7 (32)
Hyperglobulinemia	4 (11)
Hypercalcemia	2 (9)
Elevated CK activity	1 (5)

[a]Minimum white cell count was 27,800 cells/μL.
ALP, alkaline phosphatase; BUN, blood urea nitrogen; *CK,* creatine kinase.
From Vincent-Johnson NA. American canine hepatozoonosis. *Vet Clin North Am Small Anim Pract.* 2003;33:905–920. Data from Macintire DK, Vincent-Johnson N, Dillon AR, et al. Hepatozoonosis in dogs: 22 cases (1989-1994). *J Am Vet Med Assoc.* 1997;210:916–922.

within 5 weeks postexposure.[2] Disseminated, symmetric periosteal new bone formation occurs most frequently and most markedly on the diaphysis of long bones, but occurs to a lesser degree on flat and irregular bones.[2,10,46] The radiographic appearance can vary from subtle irregular periosteal exostoses to thick parallel pseudocortices. Morphologically resembling hypertrophic osteopathy, the bone lesions of *H. americanum* infection typically affect the more proximal bones while sparing the distal ones.[10,41]

Sonographic Findings

Abdominal ultrasound examination of dogs with *H. americanum* infection is generally unremarkable, although dogs with secondary glomerulonephritis, interstitial nephritis, or amyloidosis may have renal hyperechogenicity and abnormalities in kidney size according to the chronicity of the condition. Ultrasound findings in the skeletal muscle have not been described in the literature, although subtle disruption in the normally well-organized muscle echotexture may be expected due to the presence of onion-skin cysts, pyogranulomas, and myositis.

Microbiologic Testing

Diagnostic assays currently available for hepatozoonosis in dogs are described in Table 99.2. Blood smears from dogs suspected to have ACH can be stained and examined for rare gamonts in circulating leukocytes. PCR assays on whole blood are more sensitive.[7]

Cytologic Diagnosis

The gamont of *H. americanum* appears as a light blue to clear oblong structure containing a faintly staining nucleus within the cytoplasm of circulating monocytes stained with Diff-Quik or Giemsa. The gamonts look nearly identical to those of *H. canis*, although those of *H. americanum* are slightly smaller, measuring 8.8 × 3.9 μm.[41,43]

In dogs with *H. americanum* infection, gamonts are rarely found on peripheral blood smears. When present, infected cells rarely exceed 0.1% of the circulating leukocytes; several thousand cells may have to be examined before an infected cell is found. The chance that gamonts are detected can be increased by examination of buffy-coat smears. Neither bone marrow nor lymph node aspirates are of much value in making a definitive diagnosis of *H. americanum* infection; organisms are not usually seen in these specimens.[10,41,43]

Serologic Diagnosis

An ELISA assay for detection of antibodies to *H. americanum* sporozoites was developed at Oklahoma State University for research purposes, but the assay is not available commercially to veterinary practitioners.[10]

Molecular Diagnosis Using Nucleic Acid–Based Testing

A quantitative, real-time PCR assay that detects *Hepatozoon* spp. is available commercially to veterinary practitioners through the Auburn University Molecular Diagnostics Laboratory and various veterinary diagnostic laboratories. The assay performed at Auburn University detects as few as seven genomic copies of *Hepatozoon* spp. per milliliter of blood and distinguishes between infection with *H. canis* and *H. americanum*. Although highly sensitive and specific and useful for detection of early infections (from around 42 days PI), false negatives can occur early in the course of infection or in chronic disease where the numbers of circulating gamonts are extremely low or absent. Muscle biopsy should be performed in dogs suspected to have *H. americanum* infection but that have negative PCR assay results.[7]

Pathologic Findings

Gross Pathologic Findings

In dogs with *H. americanum* infection, muscle atrophy and cachexia are consistent findings on gross necropsy examination. Pyogranulomas may appear as multiple 1- to 2-mm–diameter white-tan foci.[43] These are scattered diffusely throughout skeletal and cardiac muscle but may also be observed in other tissues. Roughening and thickening of bone surfaces are often present. Less common findings include lymphadenomegaly, congestion of the gastric mucosa, splenic coagulative necrosis, and pulmonary congestion.[1,43]

Histopathologic Findings

Muscle biopsy has long been considered the most reliable method for diagnosis of *H. americanum* infections. Muscle specimens (approximately 2 cm × 2 cm) can be obtained from the biceps femoris or semitendinosus muscles under general anesthesia.[10,41] Submission of multiple specimens increases diagnostic sensitivity, especially for low-level infections. Muscle lesions consist of large onion-skin cysts, pyogranulomas, and myositis. The cysts are round to oval and have mean cross-section dimensions of 186 × 150 μm.[1] At the center of the cyst is a host cell nucleus and protozoan, but depending on the plane of the cut surface, these may or may not be visible. Surrounding the center of the cyst are concentric layers of mucopolysaccharide. Occasionally meronts in various stages of development are observed within these cystic structures. The highly vascular pyogranulomas are packed with neutrophils and macrophages, many of which contain a single zoite. Myositis is characterized by muscle necrosis and atrophy with infiltration of neutrophils, macrophages, and occasional lymphocytes between muscle fibers.[47]

Although consistently identified in skeletal and cardiac muscle, *H. americanum* cysts, meronts, and pyogranulomas can sporadically

TABLE 99.5 Antimicrobial Drugs Indicated for Treatment of American Canine Hepatozoonosis

Drug	Dose[a] (mg/kg)	Route	Interval (Hours)	Duration (Days)
TCP combination:				
Trimethoprim-sulfonamide *and*	15	PO	12	14
clindamycin *and*	10	PO	8	14
pyrimethamine *and*	0.25	PO	24	14
decoquinate[b]	10–20	PO	12	730
Ponazuril regimen:				
Ponazuril *and*	10	PO	12	28
decoquinate[b]	10–20	PO	12	730

[a]Dose per administration at specified interval.
[b]Use the decoquinate 6% (27.2 g/lb) powder, Deccox (Alpharma Inc., Fort Lee, NJ). One teaspoonful is equivalent to approximately 180 mg decoquinate. Administer at a rate of 1 teaspoon per 10 kg of body weight and feed q12h mixed into moist dog food.
TCP, trimethoprim-sulfadiazine, clindamycin, and pyrimethamine; *PO*, oral.

be found in adipose tissue, intestinal smooth muscle, pancreas, liver, lymph node, spleen, skin, salivary gland, lung, and kidney.[43] The wheel-spoked meront typical of *H. canis* infection is not identified in dogs infected with *H. americanum*. Renal damage is common and manifests as focal pyogranulomatous inflammation with mild glomerulonephritis, lymphoplasmacytic interstitial nephritis, mesangioproliferative glomerulonephritis, or occasionally amyloidosis. Amyloid deposits have also been found in the spleen, lymph nodes, small intestines, and liver of affected dogs. Various organs can show vascular changes, which include fibrinoid degeneration of vessel walls, mineralization and proliferation of the vascular intima, and pyogranulomatous vasculitis.[1,2,41]

TREATMENT AND PROGNOSIS

Most dogs will die within 1 year after infection without treatment.[1,2,10,41,43] No treatment effectively eliminates the tissue stages of *H. americanum*, but remission of clinical signs can be achieved using either a combination of trimethoprim-sulfa, clindamycin, and pyrimethamine (TCP) or ponazuril (Table 99.5).[48] Response to therapy is usually dramatic, with resolution of clinical abnormalities within a week of initiating therapy. Either of these protocols must be followed by long-term administration of decoquinate in order to prevent relapse.[41,48] Without the addition of decoquinate, relapse occurs in most dogs 2 to 6 months following treatment.[41] Although these dogs generally respond well to another round of combination therapy, subsequent relapses occur more frequently, and eventually disease may become refractory to treatment.[43,49]

Persistent infections and multiple relapses lead to complications such as glomerulonephropathy, amyloidosis, vasculitis, and cachexia, which carry a guarded to poor prognosis. Decoquinate, a livestock anticoccidial agent, apparently breaks the asexual recycling of infection by arresting the development of the merozoites after their release from meronts through disruption of electron transport in the parasite's mitochondrial cytochrome system. Two years of daily decoquinate therapy is recommended.[48,49]

Alternatively, a PCR assay can be performed every 3 to 6 months, and when the results of PCR testing becomes negative, treatment can be discontinued. However, with this approach, some dogs have required treatment for longer than 2 years because of persistent positive test results. Mild relapses can occur even during treatment with decoquinate. If clinical signs are severe, another course of TCP combination therapy or ponazuril is indicated. Long-term administration of decoquinate very often results in extended survival times and excellent quality of life with a good prognosis. During the initial few days of treatment with either antiprotozoal regimen, administration of an NSAID at standard dosages can provide relief from fever and pain.[48,49]

IMMUNITY AND VACCINATION

Current treatments do not cure *H. americanum* infections, so dogs remain susceptible to relapse of disease, especially if immunosuppressed.[1,41,43] Vaccines for *H. americanum* infections are not available.

PREVENTION

Since *H. americanum* is transmitted by ingestion of ticks, the administration of topical or oral acaricides to dogs, use of environmental acaricides, and immediate removal of ticks from dogs are the most important means of prevention.[1,10,41,43] Because the organism can also be transmitted through ingestion of cystozoites in muscle from other animals, dogs should not be allowed to roam, scavenge, or engage in predatory behavior. Dogs should not be fed uncooked or undercooked game meat.[26,41]

PUBLIC HEALTH ASPECTS

See Public Health Aspects under the *H. canis* section for the discussion on this subject.

HEPATOZOON SPP. INFECTIONS IN DOMESTIC CATS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Feline hepatozoonosis occurs primarily in areas where canine hepatozoonosis exists. It has been reported in a number of countries, including India, South Africa, Nigeria, Brazil, Israel, Italy, Japan, Spain, France, Portugal, Turkey, Austria, Cyprus, Cape Verde, and Thailand.[50] In the United States, there is one report of hepatozoonosis in a domestic cat from Hawaii and an immunocompromised cat from Oklahoma. The main species of *Hepatozoon* infecting cats is *H. felis*, which primarily targets striated muscle tissues and the myocardium.[3] Another species, *Hepatozoon silvestris*, was described in Bosnia and Herzegovina in five European wild cats (*Felis silvestris silvestris*) based on molecular and morphologic characteristics.[51] The organism is found in the heart, spleen, and skeletal muscle, and is only 96% genetically similar to *H. felis* and its tissue meronts differ from those of *H. felis* in size, number, and orientation. In this same survey study, *H. felis* was also identified for the first time in wild felids in Europe.[51] Another study identified *H. felis*, *H. silvestris*, and *H. canis* infections in domestic cats in Italy.[52] Another case of a fatal infection with *H. silvestris* in a domestic cat was reported from Switzerland.[53]

A survey of blood specimens from stray cats in Bangkok, Thailand, showed that 32.3% were positive by PCR for a *Hepatozoon* sp. most closely related to *H. canis*, whereas only 0.7% of the cats had gamonts observed on blood smears. In Israel, *Hepatozoon* DNA was amplified from the blood of 36% of 152 cats, and infected cats were more likely

to have access to the outdoors.[3] The vast majority of cats were infected with *H. felis*, although two cats were infected with *H. canis*. Most infections were subclinical. A survey study of 644 client-owned and stray cats in Spain documented *H. felis* infection in 1.4% of cats and *H. canis* infection in one cat.[54] Another survey from Cyprus documented that 38% of the surveyed cats were positive for *H. felis* and there was significant association for co-infection with *L. infantum* and "*Candidatus* Mycoplasma haemominutum."[55]

The vectors that transmit *Hepatozoon* spp. to domestic cats are also unknown. However, based on *Hepatozoon* spp. infecting other vertebrates, transmission of feline *Hepatozoon* spp. may be via the ingestion of an arthropod definitive host and vertebrate paratenic host tissues, and possibly transplacental transmission.[3]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Cats with hepatozoonosis are commonly immunosuppressed because of infection with FIV or FeLV. Alternatively, they may be co-infected with other vector- or blood-borne pathogens such as hemotropic mycoplasmas and/or *L. infantum*.[55,56] FIV or FeLV was detected in four of six cats with hepatozoonosis from Israel and in two cats from France.

Hepatozoonosis in cats is associated with infection of muscle tissues. *Hepatozoon* meronts have been identified in the myocardium and skeletal muscles of domestic and wild felids. Elevated activities of serum CK were found in the majority of cats with hepatozoonosis in a retrospective study, and in three cats reported from a rural area in Brazil.

A variety of clinical signs have been described in infected cats. In a parasitemic cat from Israel, weakness, hypersalivation, lingual mucosal ulceration, and lymphadenomegaly were observed. Two parasitemic cats from France that also had positive test results for FeLV had lethargy, anorexia, anemia, and thrombocytopenia. A cat from Hawaii had weight loss, ulcerative glossitis, pyrexia, progressive anemia, serous ocular discharge, and icterus. The cat also had cytologic evidence of liver infection consistent with hepatozoonosis. A cat from Cyprus had multiple ulcerated skin nodules associated with *L. infantum* infection, in addition to co-infection with *H. felis* and "*Candidatus* M. haemominutum."[55]

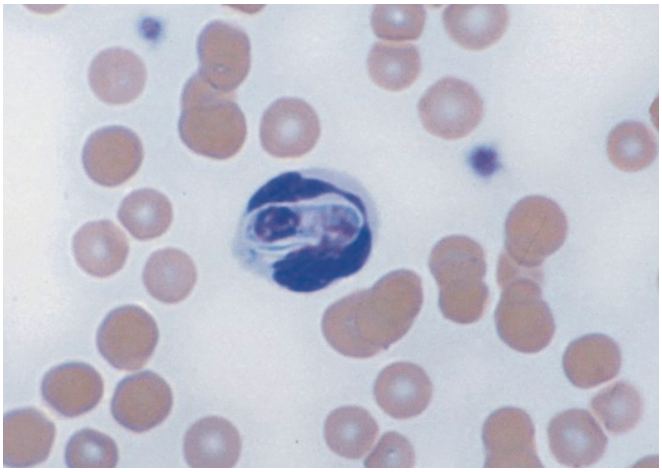

Fig. 99.19 *Hepatozoon* sp. gamont in the cytoplasm of a neutrophil from a domestic cat. The blood smear was stained with Giemsa (500× magnification).

DIAGNOSIS

The diagnosis of feline hepatozoonosis is usually performed by detection of gamonts in stained blood smears. Gamonts are located in the cytoplasm of neutrophils, have an ellipsoidal shape, and possess a round or pleomorphic nucleus (Fig. 99.19). The level of parasitemia is frequently low with less than 1% of the neutrophils containing gamonts. Application of PCR assays can be used to confirm infection.

TREATMENT AND PROGNOSIS

No controlled studies that evaluate treatment outcomes for cats infected with *Hepatozoon* spp. are documented. In rare case reports, feline hepatozoonosis has been treated with doxycycline, 5 mg/kg, PO, with no clear benefit or oxytetracycline at 50 mg/kg, PO, q12h with a single dose of primaquine (2 mg/kg, PO) with a successful outcome. A cat from Austria infected with *H. felis* was treated successfully with imidocarb dipropionate at 6 mg/kg repeated after 14 days and doxycycline 5 mg/kg twice daily for 4 weeks.[57]

CASE EXAMPLE

Fig. 99.20 "Pepper," a 1.5-year-old male miniature schnauzer with *Hepatozoon americanum* infection.

Signalment

"Pepper," a 1.5-year-old male miniature schnauzer from Opelika, AL (Fig. 99.20).

History

Pepper was seen for a 1-month duration of illness characterized by intermittent fever (104.0°F to 105.0°F [40.0°C to 40.6°C]), lethargy, and ocular discharge. The dog's owner reported that Pepper had also been stiff and reluctant to move. Despite a fairly good appetite, he had lost weight and muscle mass. The fever and other clinical signs had been nonresponsive to antibiotics, which included enrofloxacin and doxycycline, prescribed at the onset of illness. Pepper was a house dog but spent time outdoors in a rural environment. No vomiting, coughing, or sneezing had been reported, but he had had mild diarrhea at the onset of illness that resolved after a week. He had also had a mild increase in thirst and urination. He was fed a high-quality commercial dry dog food, received monthly heartworm preventive, and was current on all vaccinations, including CDV, hepatitis, CPV, and rabies vaccines. He had not traveled outside of the local area. The owner mentioned that she had another dog that died about 1 year earlier after exhibiting similar clinical signs, but a diagnosis was not made.

Current medications: Aspirin 11 mg/kg, PO, q12h for pain.

Continued

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 7.6 kg.

General: Quiet, slightly lethargic, but responsive. Reluctant to walk or stand; appeared painful. T = 103.8°F (39.9°C), HR = 96 beats/minute, RR = 32 breaths/minute, mucous membranes pink, CRT = 1.5 seconds.

Integument: The skin and haircoat appeared normal with no evidence of ectoparasites.

Eyes, ears, nose, and mouth: A moderate amount of mucopurulent ocular discharge was present bilaterally. No other abnormalities were identified.

Musculoskeletal: BCS was 3/9 with moderate generalized muscle atrophy. The dog exhibited hyperesthesia during palpation of trunk, head, neck, and limb muscles. The dog's gait was very stiff and slow.

All other systems: Apart from abdominal splinting on palpation of the abdomen, no clinically significant abnormalities were present.

Ophthalmic Examination

Pupillary light reflex (direct and consensual): Normal.

Conjunctiva: Injected bilaterally, mucopurulent discharge bilaterally.

Cornea and lens: Normal.

Schirmer tear test: Right eye = 18 mm; left eye = 16 mm (normal > 15 mm).

Fluorescein stain: Negative.

Tonometry: Normal.

Fundoscopic examination: A small grayish, slightly raised focal lesion was identified in the right fundus.

Laboratory Findings

CBC: PCV 38.7% (37%–55%), MCV 68.7 fL (60–77 fL), MCHC 35.4 g/dL (32–36 g/dL), WBC 39,200 cells/μL (6,000–17,000 cells/μL), neutrophils 35,672 cells/μL (3,000–11,400 cells/μL), lymphocytes 1,176 cells/μL (1,000–4,000 cells/μL), monocytes 1,952 cells/μL (150–1,200 cells/μL), eosinophils 0 (100–750 cells/μL), platelets 607,000 platelets/μL (200,000–400,000 platelets/μL).

The clinical pathologist's blood smear review showed no evidence of microorganisms.

Serum chemistry profile: BUN 8 mg/dL (10–25 mg/dL), creatinine 0.6 mg/dL (0.3–1.0 mg/dL), ALP 142 U/L (19–50 U/L), ALT 37 U/L (17–66 U/L), CK 148 U/L (92–357 U/L), total bilirubin 0.3 mg/dL (0.1–0.3 mg/dL), glucose 52 mg/dL (80–100 mg/dL), sodium 153 mmol/L (146–160 mmol/L), potassium 4.7 mmol/L (3.5–5.9 mmol/L), chloride 118 mmol/L (108–125 mmol/L), calcium 10.3 mg/dL (9.5–11.8 mg/dL), phosphorus 3.9 mg/dL (3.3–5.8 mg/dL), total protein 6.4 g/dL (5.1–7.3 g/dL), albumin 2.7 g/dL (2.6–3.5 g/dL), globulin 3.7 g/dL (3.6–5.0 g/dL), total CO_2 21.8 mmol/L (13.9–31.5 mmol/L).

Urinalysis: SpG 1.035; pH 8.0, protein 1+, bilirubin negative, hemoprotein negative, glucose negative, 0 WBC/HPF, 0 RBC/HPF, no crystals, moderate lipid droplets.

Imaging Findings

Pelvic radiographs: Bilateral smooth periosteal bone formation was present on the ilium and femurs.

Abdominal ultrasound examination: No abnormalities were detected.

Bone Marrow Aspirate

The bone marrow smears were highly cellular with many particles. Megakaryocytes were adequate. In a 500-cell count, the M:E ratio was 1.7 (reference range 1.3–2.1) with normal maturation sequences in both red and white series. Multiple smears examined showed no evidence of microorganisms.

Muscle Biopsy

Histopathology showed infiltration of neutrophils and monocytes between muscle fibers. There were rare onion-skin cysts and one focal pyogranuloma. Many of the monocytes and neutrophils within the granuloma contained a single zoite. Findings were consistent with *H. americanum* infection.

Cytology Findings

Although negative at the initial evaluation, blood smears and buffy-coat smears performed a few days later showed oblong "jellybean" inclusions in the cytoplasm of < 0.1% of the leukocytes. These were characteristic of *Hepatozoon* gamonts.

Diagnosis

ACH (*H. americanum* infection).

Treatment

Triple combination therapy consisting of (1) pyrimethamine 0.25 mg/kg, PO, q24h for 14 days; (2) sulfadiazine/trimethoprim 15 mg/kg, PO, q12h for 14 days; and (3) clindamycin 10 mg/kg, PO, q8h for 14 days. This was associated with resolution of fever within 24 hours. According to his owner, Pepper was back to normal within 7 days. After the 14-day course of triple combination therapy was completed, Pepper was started on decoquinate 15 mg/kg, PO, q12h with food. At day 74, the owners ran out of decoquinate and Pepper missed 2 days of treatment before a refill was obtained. Eight days later, the owners called to say that Pepper was doing poorly, could not get up, and his eyes were matted shut with a yellow-green discharge. Physical exam and CBC findings were similar to initial findings. Another 14-day course of triple combination therapy with pyrimethamine, sulfadiazine/trimethoprim, and clindamycin was prescribed. Once again, Pepper's clinical signs resolved within a few days. Pepper has continued on the decoquinate twice daily with no further breaks in doses and no more relapses.

Comments

ACH was suspected in this dog because of the geographic location in an endemic area of the south-eastern United States, a waxing and waning fever, muscle pain, ocular discharge, leukocytosis, and other laboratory findings. As initially occurred in this case, organisms often cannot be seen on blood smear or buffy-coat exam. Muscle biopsy has been considered the most reliable way to diagnose infection, although PCR is also a very sensitive and specific diagnostic tool. This case illustrates the typical relapsing nature of the disease and the need for continuous long-term decoquinate therapy. After missing only a few doses of decoquinate, this dog suffered a relapse days later. He made a quick recovery with a second round of triple combination therapy. Effective treatment requires daily decoquinate therapy with no breaks for at least 2 years or until PCR of whole blood becomes negative.

Trypanosomiasis

Sarah A. Hamer, Ashley B. Saunders, Karen F. Snowden, Jane E. Sykes

KEY POINTS

American Trypanosomiasis (Chagas disease)

- First Described: Chagas disease (American trypanosomiasis) was first described in humans in 1909 by Dr. Carlos Chagas.[1] The first canine Chagas disease cases in the United States were diagnosed in the early 1970s in Texas.[2]
- Cause: *Trypanosoma cruzi,* a protozoan parasite (order Kinetoplastida, family Trypanosomatidae).
- Affected Hosts: Dogs, cats, humans, horses, nonhuman primates, and other domestic and wild mammalian species.
- Geographic Distribution: Endemic across the Americas including South and Central America, Mexico, and the southern United States.
- Mode of Transmission: Contact with infected feces from, or ingestion of, triatomine (kissing bug) vectors, primarily *Triatoma* species. Transmission through blood transfusion and vertical transmission can occur.
- Major Clinical Signs: Infected dogs may be subclinically infected. Clinical disease manifests as lethargy, inappetence, mucosal pallor, lymphadenopathy, splenomegaly, arrhythmias, heart failure, or sudden death. Neurologic signs such as pelvic limb ataxia and exaggerated spinal reflexes may also occur.
- Differential Diagnoses: The differential diagnoses for suspected Chagas myocarditis include dilated cardiomyopathy, parvoviral myocarditis in puppies, canine monocytic ehrlichiosis, babesiosis, and leishmaniosis. The primary differential diagnoses for suspected Chagas meningoencephalitis in puppies are CDV infection and neosporosis, but other infectious and inflammatory causes of meningoencephalitis should also be considered.
- Human Health Significance: Chagas disease is a neglected tropical disease with as many as 8 million humans infected. Infected animals may be sentinels for human disease risk when there are infected triatomine vectors in the environment. Direct transmission from infected dog to human has not been shown. Transmission to humans has the potential to occur after needlestick injuries; caution is advised when handling tissues or clinical specimens from dogs with suspected trypanosomiasis.

African Trypanosomiasis

- First Described: Reports of African trypanosomiasis date back to Egyptian times. Trypanosomes were identified as the cause in 1895, when they were detected in cattle by a Scottish microbiologist, David Bruce (after whom *Brucella* was named).[3]
- Cause: *Trypanosoma brucei rhodesiense, Trypanosoma congolense, Trypanosoma evansi* (protozoan parasites, family Trypanosomatidae).
- Affected Hosts: Dogs and a variety of other mammalian host species. Humans are infected with *Trypanosoma brucei gambiense* and *T. brucei rhodesiense.*
- Geographic Distribution: Central Africa *(T. brucei, T. congolense)*; *T. evansi* is found in Africa as well as in Asia, Latin America, and the Canary Islands in Spain.
- Mode of Transmission: A bite from the tsetse fly *(T. brucei* or *T. congolense)* or mechanical transmission by hematophagous flies *(T. evansi).*
- Major Clinical Signs: Lethargy, inappetence, weight loss, pallor, peripheral edema, ascites, hematemesis, hemorrhagic diarrhea, uveitis, corneal edema, neurologic signs due to meningoencephalitis.
- Differential Diagnoses: These include canine monocytic ehrlichiosis, babesiosis, leishmaniosis, and systemic immune-mediated diseases. CDV infection and neosporosis are important differential diagnoses in dogs with meningoencephalitis.
- Human Health Significance: Although most *Trypanosoma* species that cause African trypanosomiasis in dogs do not infect humans, *T. brucei rhodesiense* does, so caution is advised when handling tissues or clinical specimens from dogs or cats with suspected trypanosomiasis.

Trypanosomes, which cause trypanosomiasis, are hemoflagellate protozoans of the order Kinetoplastida and family Trypanosomatidae. The disease has been divided into American and African forms of disease because of the biologic differences in the two forms of infection (e.g., stercorarian versus salivarian transmission), different parasite species, and their tendency to exist in separate geographic regions. However, infections with African-type trypanosomes have been identified as indigenous foci in South America. These latter infections are mentioned under Epidemiology in the section on American trypanosomiasis because of their geographic location; however, the biology and treatment of these diseases are covered in more detail under the heading of African Trypanosomiasis.

AMERICAN TRYPANOSOMIASIS

ETIOLOGY AND EPIDEMIOLOGY

Chagas disease, or American trypanosomiasis, is caused by the flagellated protozoan *Trypanosoma cruzi*, and exists in several morphologic forms. In the mammalian host, the extracellular spindle-shaped trypomastigote or blood form is 15 to 20 μm long, with a central vesicular nucleus. A single, free flagellum originates from a basal body near the large posterior subterminal kinetoplast and an undulating membrane passes along the body to project anteriorly (Fig. 100.1). The second mammalian form is an oval intracellular amastigote approximately 1.5 to 4.0 μm in diameter

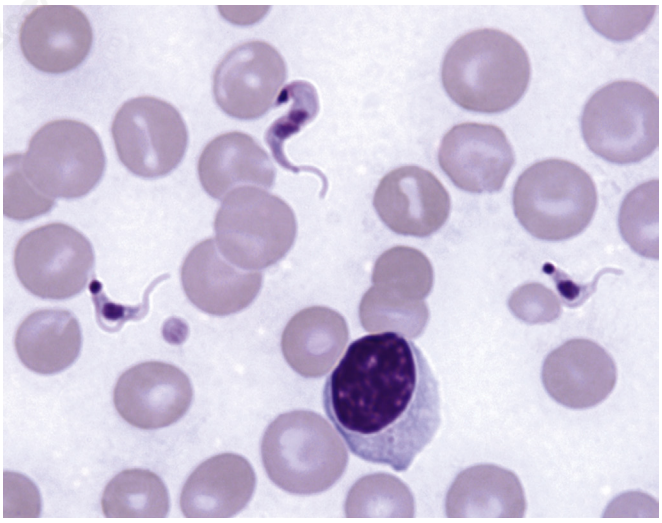

Fig. 100.1 Trypomastigotes of *Trypanosoma cruzi* in a blood smear of a dog. Wright-Giemsa stain, 100× oil magnification. (From Barr SC. Canine Chagas' disease [American trypanosomiasis] in North America. *Vet Clin North Am.* 2009;39:1055–1064.)

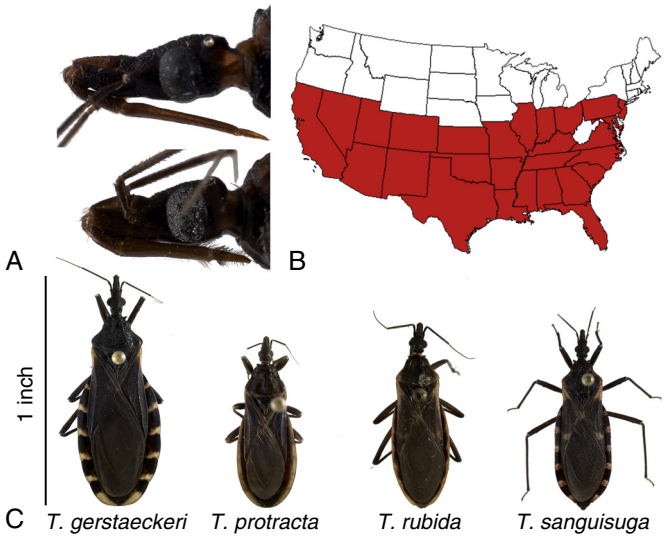

Fig. 100.2 (A) Side view of head and mouthparts of triatomine bugs. (B) Triatomine bug distribution in the United States. (C) Dorsal view of various *Triatoma* species.

that contains a large, round nucleus and rod-like kinetoplast similar to that of *Leishmania*. Epimastigotes, the third morphologic form, are found in the triatomine insect vector (Hemiptera: Reduviidae), commonly known as the *conenose bug* or *kissing bug*. This flagellated and somewhat pleomorphic form (15 to 20 μm) has a kinetoplast situated adjacent to the nucleus with a short undulating membrane and a single anterior flagellum. Six genotypes of *T. cruzi* have been identified (TcI through TcVI, also known as *discrete typing units* or *DTUs*), plus a bat-associated genotype (TcBat), which appear to differ in their vector preferences and the extent to which they cause disease.[4] Triatomine vectors are established across the southern half of the United States, with 11 species reported.[5] *Trypanosoma cruzi*–infected bugs have been reported from the majority of southern US states (Fig. 100.2).[6]

Stercorarian transmission occurs when the infected bug defecates on or near the host during or shortly after feeding and the fecal material containing trypomastigotes is subsequently rubbed into the bite wound, skin abrasions, or mucosal tissue (Fig. 100.3). Oral ingestion of infected insects will cause infection in opossums, raccoons, and wood rats and is a probable route of infection in dogs.[7–9] Other less common sources of infection in humans and possibly in dogs include blood transfusion, congenital transmission, or ingestion of meat or milk from infected lactating animals.[10] Trypomastigotes usually enter macrophages and myocytes, either locally or systemically, after hematogenous spread. Once they are intracellular, trypomastigotes transform into amastigotes, which multiply by binary fission (see Fig. 100.3). These amastigotes transform into trypomastigotes before rupture of and release from the cell. Rapid intracellular multiplication cycles ensure a rapid rise in parasitemia before effective immunity develops. The bug vector becomes infected by ingesting circulating trypomastigotes that transform to epimastigotes and multiply by binary fission. Transformation of the epimastigotes back into trypomastigotes occurs in the vector's hindgut before the trypomastigotes are passed in the feces.

Trypanosoma cruzi infection has been documented in a wide variety of dogs including 48 breeds in a medical records review in Texas.[11] Sporting and working breed groups may have lifestyle factors that increase the dogs' exposure to infected triatomine vectors, such as confinement in outdoor kennels. However, no evidence for a breed predilection for the pathogen was found in studies across diverse ecoregions in Tennessee or Texas.[12,13] Although cross-reactivity with *Leishmania* spp. is a concern in *T. cruzi* serologic surveys, histopathologic or parasitologic confirmation of *T. cruzi*

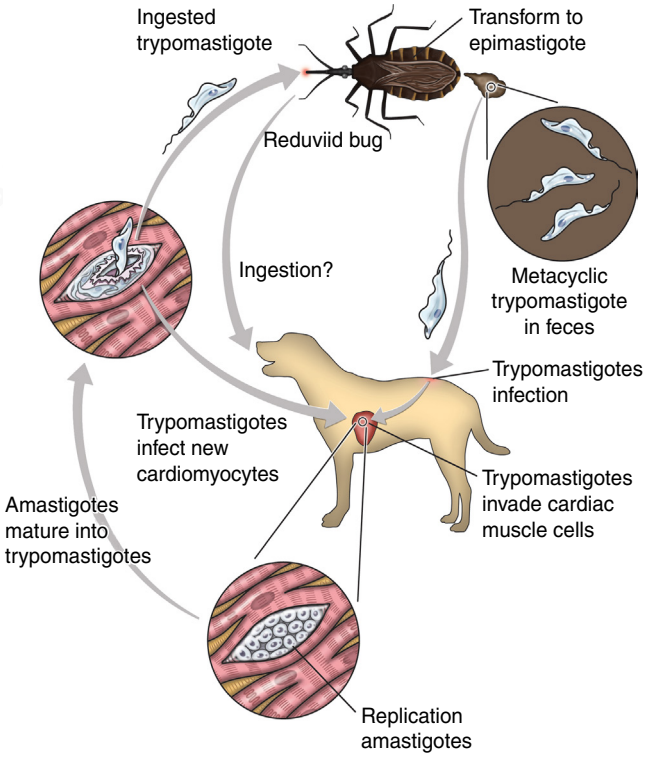

Fig. 100.3 Life cycle of *Trypanosoma cruzi.* Dogs are infected when a triatome (reduviid bug) defecates at its bite site, and possibly when dogs ingest infected triatomes. Other routes of transmission may also predominate in the United States (see text). Trypomastigotes infect cardiomyocytes (as well as other tissues) and form amastigotes, which replicate locally, leading to myocarditis.

infection has been reported in dogs from at least five states, providing further evidence of active and widespread canine Chagas disease transmission in the southern United States (Fig. 100.4).[11,14–20] An incidence of 30.7 *T. cruzi* infections per 100 dogs per year was documented in a 2021 longitudinal study of dogs across 10 kennels in Texas over a 12-month period.[21] A study of 284 shelter cats from southern Louisiana found a seroprevalence of 7.3% and blood samples from 24.6% of cats were PCR positive.[22]

As in humans, transplacental transmission in dogs may contribute to the prevalence of Chagas disease in this species. Transplacental and transmammary transmission was documented in experimentally infected dogs in very early studies.[19,23] Natural infection in eight pups born to a Walker hound female dog in Virginia with a positive serum antibody titer was suggestive of transplacental or transmammary infection due to the lack of vector presence or exposure to infected wild mammalian tissues.[14] Data from canine field studies in Argentina showed that 10% of offspring born to dams with positive serum antibody titers were also infected as determined by serologic testing compared with 4% of offspring born to seronegative dams.[24] Experimental *T. cruzi* infection of a male and female mongrel dog pair that later mated resulted in positive *T. cruzi* serology in all four pups that were born; after weaning all pups had weakness, progressive weight loss, and chronic diarrhea with cardiac dilation evident on necropsy.[25]

Fig. 100.4 (A) Approximate distribution of Chagas disease in humans in the Americas, showing states where autochthonous human transmission has occurred in the United States. (From Lynn MK, Bossak BH, Sandifer PA, et al. Contemporary autochthonous human Chagas disease in the USA. 2020;205:105361.) (B) States within the United States where Chagas disease is most prevalent in dogs. Occasional cases have been reported in other southern states and as far north as Virginia and Missouri.

Trypanosoma cruzi infection in mammalian wildlife hosts has been reported from most areas of the southern United States and other regions of the Americas where the disease is endemic. The principal sylvatic reservoir hosts of *T. cruzi* in the southern United States include opossums, raccoons, and armadillos.[18,26–31] Recent analysis of hunter-harvested coyotes, fox, and bobcats from central Texas found that 12%–14% of these animals had *T. cruzi*–infected heart tissue, whereas over 70% of raccoons from the same counties were infected.[32] Similarly, in Maryland,[33] Oklahoma,[34] North Carolina,[28] South Carolina,[35] and Georgia,[35–38] raccoons and opossums are the main reservoir hosts. In the southwestern states, *T. cruzi* infection has been detected in various rat, mouse, and squirrel species.[30,38,39] Triatomines distributed from the western half of Texas to California are frequently found in the nests of wood rats. Consequently, a significant percentage of wood rats in field surveys have been found to be infected with *T. cruzi* and probably serve as reservoirs in those regions.[18,40,41] Because experimental inoculation of *T. cruzi* isolates from opossums and armadillos into dogs produces a disease similar to that described in naturally acquired cases of acute and chronic canine trypanosomiasis, dogs in natural settings are likely infected with the same parasite strains as those sylvatic hosts.[42–44] Across several biomedical research facilities in the southern United States, nonhuman primates have seroconverted presumably from exposure to vectors in outdoor cages, leading to Chagas cardiomyopathy and diminishing the value of the infected animals as biomedical models.[45] Chagas disease was diagnosed in a horse in Texas with neurologic signs of ataxia and pelvic limb weakness. Amastigotes were found in the thoracic spinal cord; this constituted the first report of clinical *T. cruzi* infection in an equid.[46]

CLINICAL FEATURES

Pathogenesis, Clinical Signs and Physical Examination Findings

The host-parasite interactions in *T. cruzi* infections are complex, and it is likely that both parasite and host response contribute to the progressive cardiac damage.[47] In experimental canine infections, the intensity of inflammatory infiltrate and fibrosis in the heart varied based on the strain of the parasite in both acute and chronic phases of infection.[43,47,48] In medical literature reporting pathologic changes in acute Chagas disease in humans, a microangiopathy has been described, and an ischemic vascular component to the cardiac destruction has been suggested.[47]

The mechanism by which progressive cardiac damage occurs may be linked in part to host immune responses to the parasite. In experimentally infected beagles, high levels of the anti-inflammatory cytokine IL-10 were consistently detected in animals that showed less severe cardiac pathology during chronic infection.[49] The role of various antiparasite immunoglobulin subclasses in contributing to cardiac damage is unclear. In one study, an elevated IgG1 isotype was reported in dogs with an increased cardiac index and myocarditis.[50] Conversely, in another study, low IgG1 levels correlated with cardiomegaly in chronically infected dogs.[49]

In a review of Chagas-associated human pathology, it was hypothesized that a balance of cell-mediated immune response and inflammatory response was maintained in the indeterminate phase of

infection.[47] The progressive cardiac damage and inflammation in chronic disease was attributed to mediation by cytotoxic CD8+ T cells, although the mechanism of cell-mediated myocardial damage was not clearly elucidated. An autoimmune component in cardiac damage has been proposed, especially because there is a lack of correlation between intracellular amastigote numbers and the degree of chronic myocarditis with fibrosis.

Dogs

The course of *T. cruzi* infection in dogs appears to follow the cardiac disease pattern in humans, with an acute phase, followed by an "indeterminate" or latent phase with normal clinical presentation, and a chronic phase of cardiac damage.[14,31,43,48,51,52]

Acute disease in young dogs is often sudden in onset, with signs of myocarditis, cardiac arrhythmias and heart failure, or sudden collapse and death of a previously normal young dog. Acute myocarditis results from cell damage and inflammation as trypomastigotes rupture from cardiomyocytes. Lethargy, fever, inappetence, generalized lymphadenopathy, slow capillary refill time with pale mucous membranes, and, in some cases, splenomegaly and hepatomegaly are the main signs in puppies. A weak pulse with deficits, tachyarrhythmia, and terminal hypothermia and respiratory distress are common. In some dogs over 6 months of age, parasitemia develops more slowly and clinical signs are often much less severe or not apparent at all. Sudden death, presumably from cardiac muscle failure or to malignant arrhythmias, may also occur. In adult dogs, these acute manifestations are sometimes less severe, with only transient mental depression and parasitemia.[53] The reason for variation in intensity of illness with age is unclear; however, it may relate to inherent age-related host immunity.

In one retrospective study of dogs with confirmed *T. cruzi* infections in Texas, 50.5% of the infected dogs were less than 1 year of age.[11] In that study, 42% died acutely (n = 86 dogs) and the diagnosis of Chagas disease was determined using histopathology after necropsy.[10]

In addition to cardiac manifestations, dogs may exhibit other signs of acute disease. Generalized lymphadenomegaly, anorexia, and diarrhea are common during acute illness and may precede cardiac manifestations. Although less common than signs referable to cardiac abnormalities, neurologic signs referable to meningoencephalomyelitis as a direct result of parasitic invasion of the neurologic system may also occur. Weakness, paresis, pelvic limb ataxia, and upper motor neuron (hyperreflexive) spinal reflexes have rarely been described in naturally and experimentally infected dogs.[43,54]

Survivors of acute myocarditis become aparasitemic and without overt clinical signs in the "indeterminate" or "latent" phase. Parasitemia becomes cytologically undetectable at about 30 days PI, although it can still be demonstrated by blood culture. During the long subclinical period between acute and chronic disease in the dog, ECG readings may be within reference limits, except for intermittent occurrence of ventricular arrhythmias, which can be exacerbated by exercise or excitement.[55] Sudden death during this phase can occur and is thought to be caused by fatal cardiac arrhythmias.

Although not all dogs exhibit signs of chronic disease, many develop chronic myocarditis with cardiac dilatation over a variable length of time. In experimental studies of young dogs, the onset of chronic disease was documented over an 8- to 36-month period postinoculation.[43,44] In the chronic phase, cardiac dilatation occurs, ECG abnormalities become more prevalent, and clinical signs referable to right-sided and/or bilateral cardiac failure occur. ECG abnormalities detected in naturally infected dogs in the chronic phase have included supraventricular and ventricular arrhythmias and atrioventricular block.[56,57] In experimentally infected dogs with chronic infection, clinical signs included pulse deficits, ascites, pleural effusion, hepatomegaly, and jugular venous congestion.[41] In two retrospective studies of naturally infected dogs, the most common clinical history and physical examination abnormalities included exercise intolerance, lethargy, anorexia, ascites, respiratory difficulties (tachypnea and cough), bradycardia, heart murmurs, and hepatomegaly.[11,58] Chronic *T. cruzi*–induced myocardial disease in dogs is difficult to distinguish from chronic dilative cardiomyopathy of noninfectious origin, and misdiagnosis may occur until serologic evaluation for exposure or histologic detection of parasites is available.[14,42,52]

In chronic infections, electrical conduction disturbances along with variable cardiomegaly can sometimes be overlooked. In a Texas study reviewing case records, 21.3% of dogs had electrical conduction disturbances, and a number of animals were being evaluated for pacemaker implantation.[11] A variety of electrical conduction abnormalities have been reported.[44,53] Parasite-associated damage to parasympathetic innervation in the heart and subsequent conduction disturbances are probably responsible for the cardiac arrhythmias. In experimental infections in both rats and dogs, a reduction in autonomic neurons has been documented, along with a variable intensity of inflammatory changes in histopathologic studies.[59,60] Trypanosomiasis should be considered in any dog with signs of myocarditis, cardiomyopathy, or electrical conduction disturbance in the heart. There is little information available on survival times of dogs. In a review of 11 dogs identified with chronic *T. cruzi* infection, survival times ranged from 0 to 60 months.[58]

Humans with Chagas disease can also develop severe megaesophagus or megacolon due to parasympathetic denervation,[61] but these syndromes have not been described in dogs. Morphometry of the myenteric esophagus was not altered in dogs with experimentally induced chronic *T. cruzi* infection.[62]

The most common physical examination findings in puppies with Chagas disease are lethargy, generalized lymphadenomegaly, splenomegaly, pallor, and arrhythmias. Generalized subcutaneous edema has also been reported.[63] Dogs with chronic Chagas disease may show signs of right- and/or left-sided congestive heart failure, with tachypnea, ascites, or jugular pulses. Cardiac murmurs and arrhythmias may be detected during auscultation of the heart.

Cats

Field studies in Mexico and South America (Brazil and Argentina) have documented significant levels of serum antibody reactivity to *T. cruzi* in cats and have implicated this species as a potential reservoir in the domestic transmission cycle.[64–66] Unfortunately, data on the clinical course of disease in cats are lacking in the published literature. A total of 42% of seropositive cats from shelters in Texas had evidence of myocardial inflammation and fibrosis.[67] In Louisiana, 7.3% of 234 cats were seropositive for *T. cruzi*, with 24.6% testing PCR-positive.[22] Serologic testing for *T. cruzi* antibodies in cats is not generally available in commercial diagnostic laboratories, complicating detection of infection in this host species. In the authors' experience, cats with unknown clinical disease in households with seropositive dogs and positive triatomine vectors can test positive for the presence of anti-*T. cruzi* antibodies using unvalidated assays.

DIAGNOSIS

The key to diagnosis of Chagas disease is a high degree of clinical suspicion. Chagas disease should be considered in any dog with signs of myocarditis or cardiomyopathy, particularly if it lives or has lived at any time—even years before evaluation—in an endemic region. Diagnosis of dogs in regions without endemic triatomines (e.g., the northern United States) may reflect travel histories.[68] The odds of

TABLE 100.1 Diagnostic Assays Currently Available for Trypanosomiasis in Dogs and Cats

Assay	Specimen Type	Target	Indications and Limitations
Cytologic examination	Aspirates of lymph nodes, spleen, bone marrow, blood smears, or buffy-coat preparations	*Trypanosoma* trypomastigotes or, less commonly, amastigotes	Organisms may be few in number and in chronic trypanosomiasis are often not found.
Trypanosoma culture	Blood or buffy-coat preparations, bone marrow	*Trypanosoma* spp.	Requires special techniques, laboratory biosafety containment, and expertise that are not widely available. Sensitivity may be low in chronic infections.
Antibody serology (indirect fluorescent antibody or ELISA)	Serum	Antibodies to *Trypanosoma* spp.	Most infected dogs test positive, although acutely infected dogs may test negative. Not all infected dogs will develop disease, so results must be interpreted in light of clinical signs. False positives can occur in dogs exposed to *Leishmania* or those vaccinated with *Leishmania* vaccines.
PCR assay	Whole blood, buffy coats, splenic or lymph node aspirates, CSF	*Trypanosoma* DNA	Negative results may occur in infected animals because duration of parasitemia is short. May be useful in dogs with suggestive clinical signs in which organisms cannot be found cytologically. Sensitivity and specificity depend on assay design. Limited availability.

CSF, cerebrospinal fluid; *ELISA,* enzyme-linked immunosorbent assay; *PCR,* polymerase chain reaction.

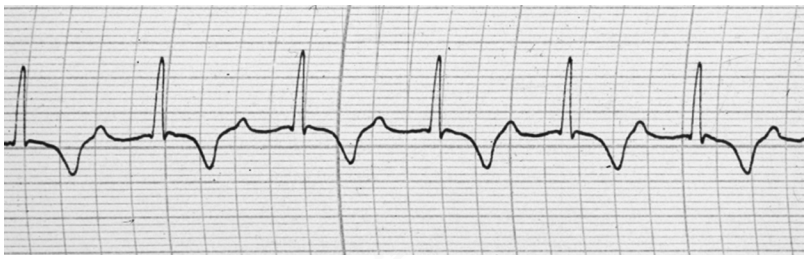

Fig. 100.5 Electrocardiogram showing second-degree heart block and depressed QRS complexes often present in dogs with acute Chagas' disease. (From Barr SC. Canine Chagas' disease [American trypanosomiasis] in North America. *Vet Clin North Am.* 2009;39:1055–1064.)

being infected with *T. cruzi* are higher in dogs with an infected littermate or housemate.[69] Diagnostic assays for trypanosomiasis are described in Table 100.1.

Laboratory Abnormalities

Complete Blood Count

Hematologic abnormalities are of little specific diagnostic value for Chagas disease. During the acute phase of infection, the CBC of some dogs may reveal anemia, leukocytosis due to a neutrophilia, eosinophilia, monocytosis, and lymphocytosis.[70–72] Thrombocytopenia, leukopenia, and/or lymphopenia have also been documented.[73] Dogs in the chronic phase of infection may have no hematologic abnormalities.

Serum Biochemical Tests

Serum ALT activity, AST activity, and creatinine and urea nitrogen concentrations can be elevated in dogs with *T. cruzi* infection, especially those that are at risk of death from severe acute myocarditis. Rarely, moderate to severe hypoalbuminemia with or without hyperglobulinemia occurs in acutely affected dogs.[63,73] Elevation in serum troponin I levels has been reported as a nonspecific indicator of myocardial damage.[56,57,69,74]

Electrocardiography

The ECG of dogs with Chagas myocarditis may show any combination of arrhythmias or conduction disturbances including sinus tachycardia, decreased R-wave amplitude, axis shifts, supraventricular and ventricular arrhythmias, and conduction abnormalities including atrioventricular block and right bundle branch block (Fig. 100.5). Ventricular arrhythmias alone or in combination with other ECG abnormalities are most often detected in seropositive dogs.[69] The damage to the myocardium and conduction system from parasites, inflammation, and fibrosis provide a substrate for the ECG abnormalities (for instance, damage to the ventricular myocardium resulting in ventricular arrhythmias).

Diagnostic Imaging

Thoracic radiography is of value in the diagnosis of cardiomegaly and congestive heart failure (pleural effusion, pulmonary edema) (Fig. 100.6).[58,75] Echocardiographic abnormalities are variable depending on the location of myocardial damage and can include enlargement of all four heart chambers and reduced ventricular systolic function (Fig. 100.7).[57,58]

Microbiologic Tests

Cytologic Examination

During acute disease, trypomastigotes may be detected on stained blood smear examination (see Fig. 100.1). In experimental infections in puppies, parasites could be detected in circulation as early as 3 days postinoculation, and parasitemia peaked about day 17, approximately at the time that clinical signs of acute myocarditis and lymphadenomegaly appeared.[53] In those animals, parasitemia persisted for up to 30 days. However, in chronic infections, parasitemia is often so low that

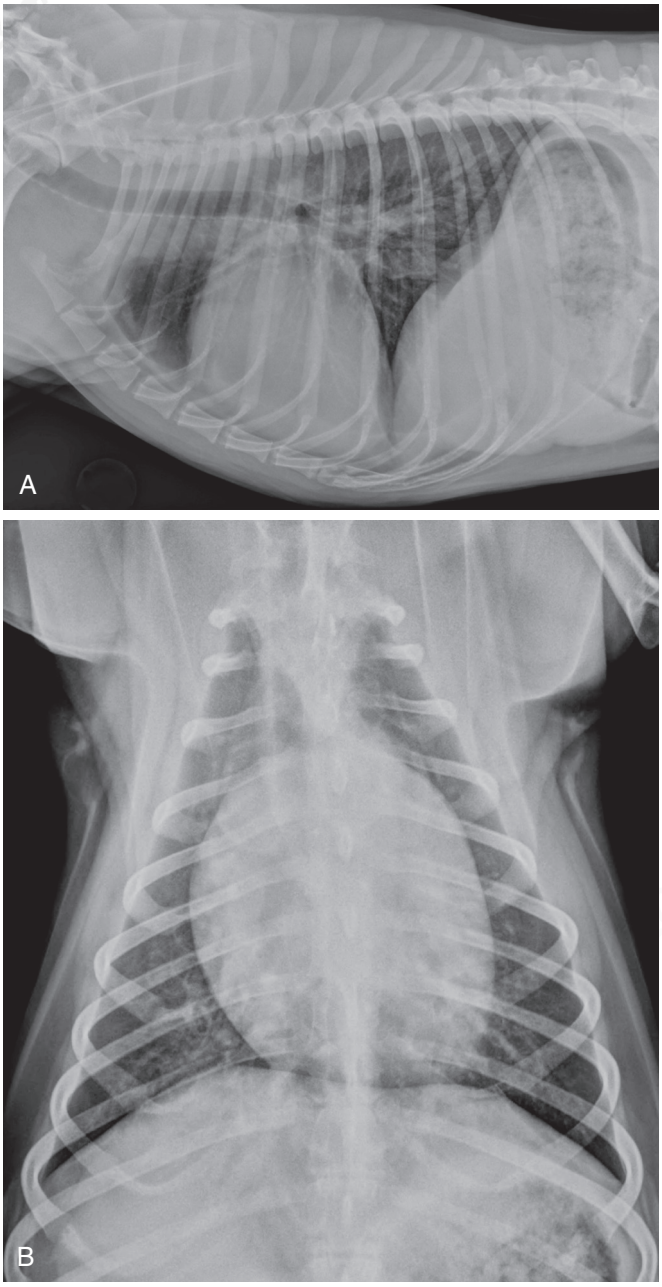

Fig. 100.6 Lateral (A) and dorsoventral (B) thoracic radiographic images of a dog with trypanosomiasis and mild generalized cardiomegaly. The pulmonary veins are mildly larger than the corresponding artery, and a slight interstitial pattern was present throughout the lungs.

organisms may be difficult to identify during routine examination of Wright-stained blood films. To concentrate parasites and increase the sensitivity of detection, a thick-film buffy coat smear can be stained with Wright or Giemsa stain and examined microscopically, or a buffy coat specimen may be examined as a wet preparation for trypomastigote movement.[75] Stained lymph node aspirates or impression smears may contain amastigotes, even when parasitemias are very low.[75] The larger the volume of the blood specimen collected, the greater the likelihood that organisms will be detected. Trypomastigotes may also be found on cytologic examination of lymph node aspirates and in abdominal effusions. Amastigotes were described in the lymph node of one affected dog that were cytologically indistinguishable from those of *Leishmania*.[63]

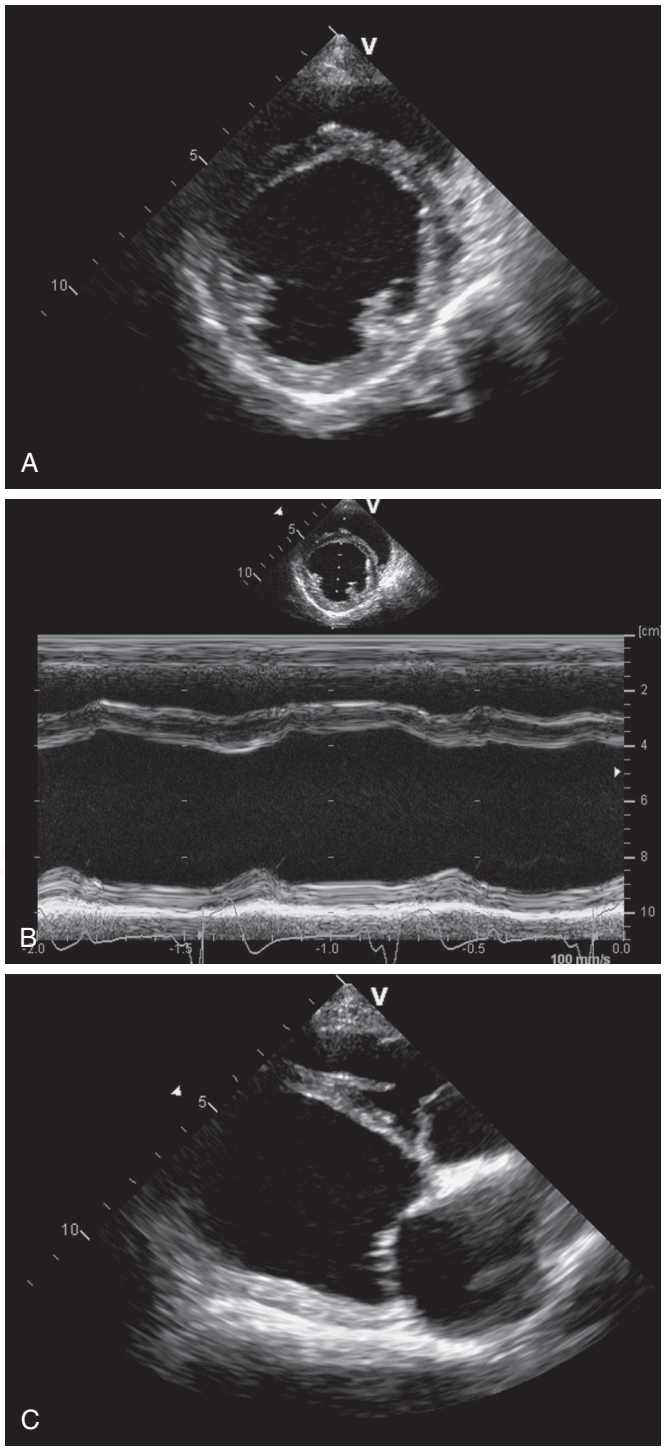

Fig. 100.7 Two-dimensional (A) and M-mode (B) transthoracic echocardiogram images obtained in a right parasternal short axis view and long axis view (C) documenting significant left ventricular enlargement and mild right ventricular enlargement.

Parasite Culture and Xenodiagnosis

Culture of trypanosomes is a specialized procedure that is not routinely available in veterinary diagnostic laboratories. *Trypanosoma cruzi* can be cultured from blood in liver infusion tryptose (LIT) growth medium or other media; however, 2 to 20 weeks may be needed for the results to become positive for epimastigotes.[14,43] In one naturally infected dog, parasite cultures were established using lymph node

aspirates inoculated into serum-supplemented Dulbecco's modified Eagle's medium and maintained at room temperature to yield replication of the flagellated epimastigote stage of parasite.[63]

Xenodiagnosis involves feeding colony-reared, parasite-negative triatomine vectors on suspected infected hosts and subsequently testing the vectors in order to diagnose infection in the host, and is thought to measure infectiousness of a host to vectors. These methods are used primarily in a research setting and have limited application in making a clinical diagnosis. Although specificity of bug feeding is high, the sensitivity may be low. Results of one study were only an 11% detection rate in bugs fed serially on experimentally infected dogs.[76]

Serologic Diagnosis

Serologic testing for *T. cruzi*–specific serum antibodies is the predominant diagnostic tool for detection of canine *T. cruzi* infections. A positive result, in association with clinical signs, is considered supportive for the diagnosis of *T. cruzi* infection in dogs. Due to variation in sensitivities and specificities among assays, two different serologic assays should be used to confirm a positive titer, especially in regions of low prevalence, although very few veterinary diagnostic laboratories currently offer assays for diagnosis of canine *T. cruzi* infection. In experimental infections, antibodies are usually first detected by 3 weeks PI, at the time when parasitemia is declining, and positive titers persist for the life of the animal.[27] Many apparently healthy dogs are diagnosed as positive for *T. cruzi* based on serology findings, and the prognosis is currently unknown.[13]

Antibody detection methods used by commercial diagnostic laboratories include IFA and ELISA tests. However, there may be confusion due to significant cross-reactivity and cross-infection with the closely related parasite *Leishmania*.[77,78] Depending on the clinical history and geographic location of the animal, positive serum antibody test results for *T. cruzi* should be confirmed by additional testing for antibodies to *Leishmania* to determine which organism yields the higher titer.[79]

Several immunochromatographic POC "dipstick" tests have also been developed for use in humans and show promise in canine epidemiologic research[13,80–82] but are not currently approved for canine diagnosis in the United States. These test kits have potential as rapid, simple screening tools in a clinic setting that can be used in conjunction with additional confirmatory tests.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR testing can be used to detect DNA of *T. cruzi* in various clinical specimens including specimens that can be acquired antemortem (blood, lymph node aspirates, or ascites fluid) as well as cardiac and other organ tissues acquired at necropsy. PCR assays can be highly specific for *T. cruzi* but can have variable and sometimes low sensitivity for diagnosis of chronic infections unless multiple specimens are tested.[83] In a clinical setting, the utility of PCR may be limited in animals that are in the indeterminate state of infection when the parasite is not circulating in the blood. PCR may be useful to confirm infection when organisms are not seen on blood smears. In a research study using experimentally infected dogs, parasite DNA was easily detected in the acute phase of infection in 12 animals, but the sensitivity of the test decreased during the chronic phase of infection depending on the strain of parasite.[84] Currently, PCR assays for *T. cruzi* are not widely available from veterinary diagnostic laboratories on a commercial basis, but have been used for diagnosis of canine Chagas disease.[63,85]

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with Chagas disease include generalized lymphadenopathy, evidence of congestive heart failure (ascites, pleural effusion, or congestion of viscera), and biventricular cardiac enlargement with thinning of the ventricular wall. Subendocardial and subepicardial hemorrhages, as well as multiple yellow to white myocardial spots and streaks may be observed.[16,60,74]

Histopathologic Findings

Histopathologic findings in acute Chagas disease include a severe diffuse granulomatous myocarditis with myocardial necrosis, often with large numbers of parasitic pseudocysts containing intracellular amastigotes, and minimal fibrosis (Fig. 100.8). Typically, the heart is the primary organ with significant lesions, but amastigotes can be identified in lymph nodes and other organs including liver, spleen, and brain.[63,74] IHC does not distinguish *Leishmania* from *Trypanosoma* amastigotes because of serologic cross-reactivity.[63] In chronically infected dogs, multifocal coalescing areas of lymphoplasmacytic inflammation and mild necrosis with extensive loss of myocardial fibers and severe interstitial fibrosis occur.[47,53] A progressive, destructive process occurs in the heart, including damage to uninfected cardiomyocytes, which has been described in infected humans.[50] In chronic infections, organisms may uncommonly be evident in cardiac muscle, and are occasionally found in other tissues.[86]

TREATMENT

Antiprotozoal Treatment

Therapeutic options for treating *T. cruzi* infections in dogs are limited. The drugs available for treatment of Chagas disease in humans include benznidazole and nifurtimox; however, neither of these drugs is available for animal use in the United States. In the United States, benznidazole was FDA-approved for pediatric use in 2017; otherwise these drugs are only available for human use through the CDC, under an investigational drug-use license. The marketing of nifurtimox has been discontinued in many countries.

In humans, these drugs are primarily effective in the acute phase of infection, and significant toxic adverse effects[87] and drug resistance[88] have been reported for both. Some early success was reported in treating experimental and natural cases of canine trypanosomiasis with nifurtimox, but severe adverse effects limited its use.[89] In one study, benznidazole was shown to induce cure in acute (63%) and to a lesser extent in chronic (39%) experimental infections in dogs.[90] However in a more recent study, benznidazole resulted in a temporary, short-term reduction in parasite load but did not prevent myocardial damage in an infected canine model.[91] The efficacy of chemotherapy in clearing *T. cruzi* infection appears dependent on an adequately functioning immune system.[92,93]

Numerous medications have been evaluated as therapeutic agents for Chagas disease with high adverse effect profiles or disappointing results in clinical trials, particularly in chronic disease.[94] Medications

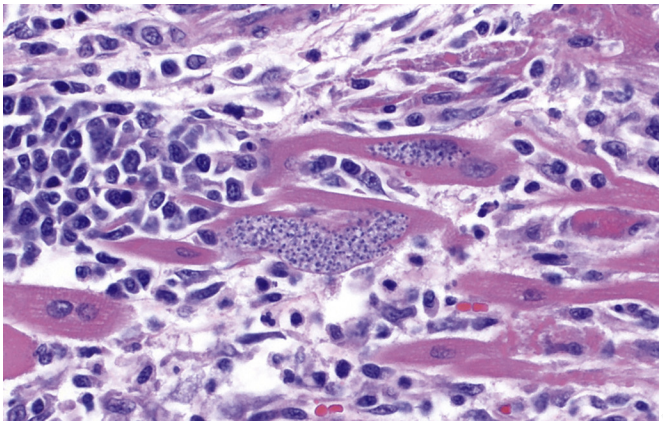

Fig. 100.8 *Trypanosoma cruzi* amastigotes in a pseudocyst within the cardiac muscle of a dog. Inflammatory cells are present as well (hematoxylin and eosin stain, ×1000).

including gossypol, allopurinol, and multiple triazole class of drugs (albaconazole, ketoconazole, itraconazole, posaconazole) have been investigated for treatment, but drug efficacies for some are less than convincing.[95–100] In some experimental models, the drug may be effective in suppressing parasite proliferation and death in infected humans or dogs; but treatment failure occurs and cure is not achieved.[93,97,99] Current research is exploring alternatives including combinations of medications and sequential therapies.[100] In a study of 105 dogs with *T. cruzi* infection, treatment with a combination of itraconazole and amiodarone for 12 months resulted in survival times that were on average 7 months longer than those of the 16 dogs in a control group.[85]

Because there is no available effective parasiticide, clinically affected animals should be managed using appropriate supportive therapy. Diuretics and positive inotropes/inodilators may be indicated in dogs with reduced ventricular systolic function that have developed congestive heart failure. Cardiac arrhythmias may require specific antiarrhythmic therapy for tachyarrhythmias and pacemaker implantation for bradyarrhythmias.[101]

PROGNOSIS

The prognosis for dogs that develop Chagas disease is often poor because of the lack of effective treatments. Dogs diagnosed at an older age (mean of 9 years) survive longer (30 to 60 months) than dogs diagnosed at a younger age (mean of 4.5 years), which survive only up to 5 months post diagnosis.[59] In a study of 44 client-owned dogs evaluated at Texas A&M University, identification of right ventricular enlargement was strongly associated with decreased time to death in a multivariable model.[57]

IMMUNITY AND VACCINATION

No vaccine is available for Chagas disease in dogs. Protective immunity was not documented in experimentally infected dogs that received five repeated infections over a 3-year period. Over time, dogs developed diminishing parasitemias and increased antibody titer results, with a progressive myocarditis similar to control animals.[102]

PREVENTION

Chagas disease prevention is centered on vector control. Implementing integrated pest management methods to reduce encounters between dogs and infected vectors will likely have the greatest effect. These measures could include housing dogs indoors at night in areas with doors and screens to exclude bugs, limiting the use of yard lights to reduce attraction of insects, and optimizing pesticide regimens. There are no pesticides in the United States specifically labeled for control of triatomine bugs. However, residual spray formulations of synthetic pyrethroids, such as deltamethrin, have proven to be very effective at killing the triatomine vectors in Latin America[103] and are available in the United States. Applications of fipronil on the coats of dogs do not appear to prevent infections in dogs or reduce the feeding of vectors,[104] but deltamethrin-treated collars do reduce feeding by *Triatoma infestans*.[105,106] Isoxazolines (fluralaner and afoxolaner) were also shown to induce triatome mortality when given as a single oral dose to dogs that were then exposed to triatomes 2, 7, 21, 34, and 51 days after treatment,[107] and in another study, fluralaner was shown to significantly reduce infestations with pyrethroid-resistant triatomes when compared with placebo.[108]

Kennels and surrounding structures (chicken houses, wood piles) in endemic areas can be sprayed monthly with a residual insecticide. Dog housing and surrounding habitats should be upgraded to remove vector nesting sites. Woody debris and other habitat that may serve as refuge for triatomine vectors or wildlife hosts (wood rats, raccoons, opossums, armadillos) should be removed from the immediate vicinity of dog kennels. Serologic testing of breeding females is advised in areas where *T. cruzi* is endemic, so the risk of transplacental and transmammary transmission can be considered. Dog-to-dog transmission, through exposure to infected blood while fighting or during rough play, has not been documented but may be possible if the infected dog is parasitemic. Although *T. cruzi* organisms were detected in the urine and saliva of dogs after experimental administration of an extremely high infective dose, transfer of parasites through these body fluids has not been documented in natural settings.[109] Limiting exposure to potentially infectious tissues of wild mammalian reservoirs may reduce disease transmission in dogs. Finally, *T. cruzi* antibody screening of canine blood donors residing in endemic areas should be considered to reduce potential blood transfusion transmission.

In the United States, it is not known if dogs with seropositive test results are significant parasite reservoirs in the vector-borne transmission cycle. The importance of dogs as reservoir hosts has been well documented throughout South America and appears to be influenced by parasite strain, infectious dose, and host health attributes such as nutritional status.[103,110,111]

PUBLIC HEALTH ASPECTS

American trypanosomiasis is a major human health problem in South and Central America and Mexico.[112,113] It is primarily a problem in impoverished regions where humans live in rural areas. Dogs are considered a reservoir for human infection in these regions because they maintain high levels of parasitemia and are a preferred host for triatomine insects. Cats may also act as a reservoir for human infection in South America.[114] Fewer than one third of infected humans ultimately develop Chagas disease.[61] More information about triatome bug species that may transmit *T. cruzi* to dogs and humans in South America and the importance of dogs as reservoirs and sentinels has become available in recent years with application of serologic and molecular methods as part of a One Health approach. Seroprevalences that exceed 30% and PCR prevalences that reach 57% have been reported in dogs in South America.[115–118]

The human health burden of Chagas disease in the United States is largely unknown, but it is estimated that over 235,000 people in the United States are infected, the majority of whom are immigrants from Chagas-endemic areas of Central or South America or Mexico.[119] At the time of writing, the CDC indicates that it is a reportable disease in humans in six states (Arkansas, Arizona, Louisiana, Mississippi, Tennessee, and Texas). Reports of cases associated with transmission by blood transfusion continue to rise.[120–122] Autochthonous cases in humans in the United States are rare, but increasingly recognized especially in Texas.[123,124] The generally higher standards of housing in the United States relative to other endemic regions may limit the degree to which vectors from colonize human dwellings. It is likely that many human cases of Chagas disease in the United States may be overlooked because of a low level of suspicion.

Although the risk of a human acquiring infection directly from an infected dog is extremely low, the presence of an infected dog often signals a landscape where infected triatomines occur, and so there is a human health risk due to the presence of infected vectors. The severity and difficulty of treating disease in humans makes this disease of considerable public health significance. Veterinarians should be careful when handling blood samples from infected dogs and warn laboratory staff of the potential infectivity of the samples. Accidental needle-stick injuries when administering therapy to or collecting specimens from infected dogs should be reported immediately to healthcare providers.

TRYPANOSOMA CANINUM INFECTION

Trypanosoma caninum has only been identified in dogs primarily from Brazil, many of which have been apparently healthy.[125–128] The

pathogenicity of this organism requires further study. Importantly, infection with *T. caninum* leads to false-positive serologic test results for *Leishmania*, which can confound control methods that rely on culling of dogs that are seropositive for *Leishmania* (see Chapter 96).

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is caused by *Trypanosoma brucei* and *Trypanosoma congolense*. These organisms are transmitted by tsetse flies (*Glossina* species), which are only found in Africa. *Trypanosoma brucei* includes three subspecies: *Trypanosoma brucei, T. brucei gambiense,* and *T. brucei rhodesiense,* which are indistinguishable morphologically and are referred to as "*T. brucei* complex" organisms. *Trypanosoma evansi* also belongs to this group (see later). The epidemiology, host range, and clinical features of disease caused by these *T. brucei* complex organisms differ. *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* cause "sleeping sickness" in humans from Africa (West African and East African trypanosomiasis, respectively) (Fig. 100.9). A variety of animal reservoirs of *T. brucei rhodesiense* have been established, and although naturally occurring infections of domestic animals and wildlife hosts with *T. brucei gambiense* have been identified, the relative importance of animals as reservoir hosts for this pathogen has been less clear.[129] Naturally occurring, clinical and subclinical infections of domestic dogs with *T. brucei rhodesiense*, and more recently with *T. brucei gambiense*, have been reported.[129–132] *Trypanosoma brucei* and *T. congolense* cause trypanosomiasis in a variety of domestic animal species ("nagana") but do not infect humans. Dogs are especially susceptible to *T. congolense* infection, and evidence of co-infections with *T. congolense* and *T. brucei rhodesiense* or *T. brucei* was identified using molecular methods in indigenous hunting dogs from eastern Zambia.[130] Three groups of *T. congolense* have been identified—savannah (East and West Africa), forest, and kilifi—which vary in pathogenicity, with savannah being the most pathogenic and kilifi causing mostly subclinical infections in cattle.[133] There are several reports of travel-related infections with *T. congolense* in dogs,[134–138] sometimes in association with a long period of latency.[136] Both savannah-type and forest-type infections have been identified.[132,134,135] African dogs may exhibit a degree of "trypanotolerance," whereas dogs imported into Africa may be more susceptible to infection and disease.[139]

African trypanosomes exist only as a trypomastigote in the blood of the mammalian host; in contrast to Chagas disease, there is no amastigote phase. Epimastigotes develop in the salivary glands of the tsetse fly, and the organism is transmitted in saliva when it feeds on the mammalian host. Transmission to the mammalian host results in hemolymphatic spread of the organism over weeks to months with signs that relate to proliferation of mononuclear phagocytes and increased vascular permeability. *Trypanosoma brucei* complex organisms are well known for their ability to evade the host immune response through extensive variation of their outer surface glycoproteins (known as *variant antigen types,* or *VATs*). The hemolymphatic phase may be followed by the development of meningoencephalitis in some animals. In humans, meningoencephalitis is most apparent with *T. brucei gambiense* infections and results in tremors and progressive daytime somnolescence (hence the term "sleeping sickness"). Pancarditis with arrhythmias and congestive heart failure is a more typical outcome of *T. brucei rhodesiense* infection in humans.

The clinical signs of canine African trypanosomiasis include persistent fever, lethargy, anorexia, weight loss, pallor, mucopurulent oculonasal

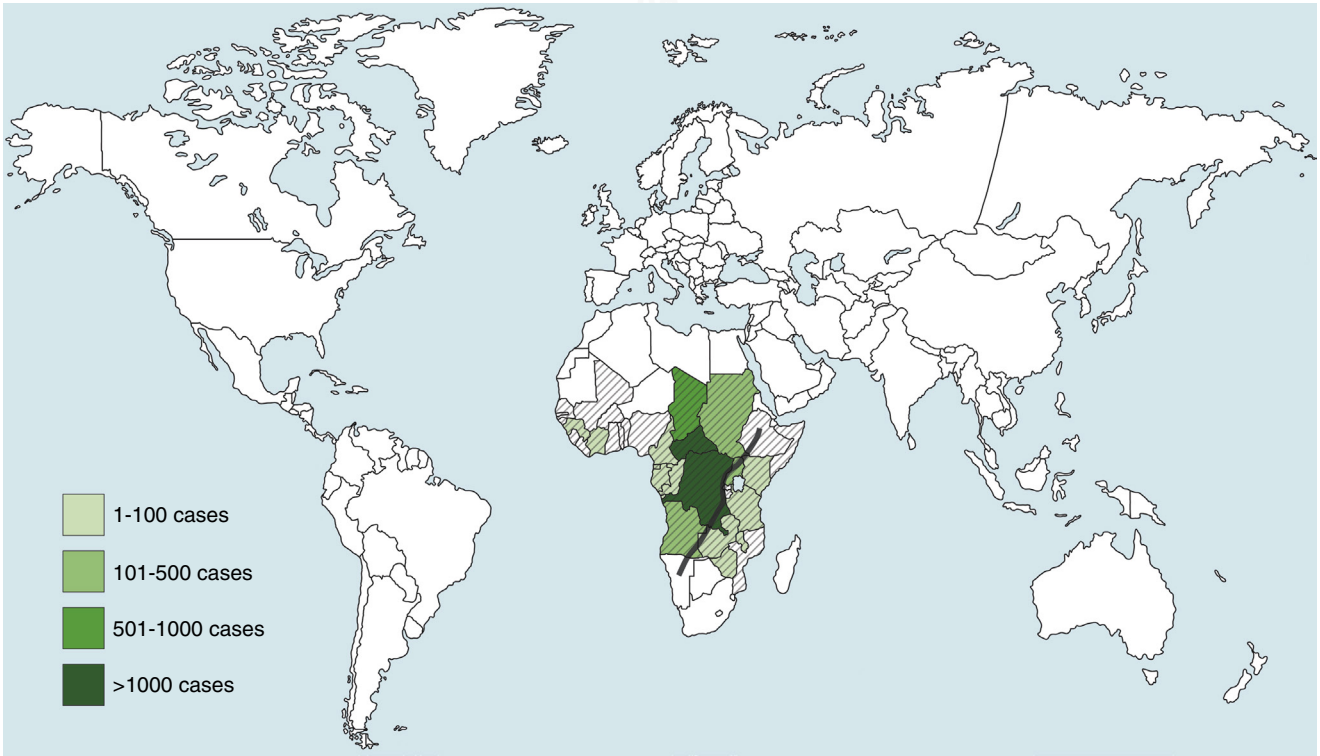

Fig. 100.9 Map showing geographic distribution of human African trypanosomiasis *(green countries)* and the number of cases reported in natives in the year 2009. *Trypanosoma brucei gambiense* is found in western Africa and *Trypanosoma brucei rhodesiense* is found in eastern Africa. The line divides the geographic distribution of the two forms of disease. *Trypanosoma brucei brucei,* which also infects dogs, occurs throughout both regions. The *hashed lines* indicate the countries in which tsetse flies are found. (Modified from Brun R, Blum J. Human African trypanosomiasis. *Inf Dis Clin North Am.* 2012;26:261–273.)

discharge, lymphadenopathy, hepatosplenomegaly, variable peripheral edema, abdominal distention due to ascites, petechial hemorrhages, signs of pancarditis, and ocular signs such as unilateral or bilateral uveitis, corneal edema, and/or keratitis (which can mimic "blue eye" due to canine adenovirus-1). In a study of indigenous hunting dogs from eastern Zambia that used a LAMP assay to detect trypanosomes in blood, bilateral corneal opacity was associated with infection (Fig. 100.10); affected dogs were infected with *T. brucei* (one dog), *T. brucei rhodesiense* (two dogs), or both *T. congolense* and *T. brucei rhodesiense* (one dog).[130] Clinical signs that include lymphadenomegaly and blindness associated with bilateral keratitis have also been described in dogs from Nigeria infected with *T. brucei gambiense*.[132] Hemorrhagic vomiting and diarrhea can occur in dogs infected with *T. congolense*.[137,140] Neurologic signs (seizures, tremors, opisthotonos, and hyperreflexia) due to meningoencephalitis have also been described in dogs infected with *T. congolense*.[137,140] In one dog, seizures were associated with severe hypoglycemia.[134]

Laboratory abnormalities in dogs with African trypanosomiasis have been most well described for *T. congolense* infections. The most common findings are regenerative or nonregenerative anemia, leukocytosis or leukopenia, and thrombocytopenia.[134–137,140] Serum biochemistry findings include increased serum liver enzyme activities, azotemia, hypoglycemia, hyperglobulinemia, and hypoalbuminemia,[134–137] but one dog had no significant abnormal serum biochemistry findings.[138] Severe and refractory hypoglycemia in another dog was thought to be secondary to massive consumption of glucose by replicating trypanosomes.[134]

Fig. 100.10 Bilateral corneal opacities/keratitis in an indigenous dog from eastern Zambia with canine African trypanosomiasis. (From Lisulo M, Sugimoto C, Kajino K, et al. Determination of the prevalence of African trypanosome species in indigenous dogs of Mambwe district, eastern Zambia, by loop-mediated isothermal amplification. *Parasit Vectors*. 2014;7:19.)

The primary means of diagnosis is cytologic detection of the organism in aspirates, body fluids, or blood smears. Identification of the infecting species requires PCR and sequencing. The treatment of choice for dogs is diminazene aceturate, but this may not always be effective or available. Treatment of the hemolymphatic disease in humans is with pentamidine isethionate *(gambiense)* or suramin *(rhodesiense)*, whereas disease of the CNS is treated with the arsenical melarsoprol, but these drugs can have significant adverse effects. Pentamidine was used with apparent success to treat dogs with African trypanosomiasis (Table 100.2).[134,141] Prevention is through the use of insect repellants and indoor housing. Isometamidium (Trypamidium, Boehringer Ingelheim) is also used every 2 months (1 mg/kg, IM) as chemoprophylaxis for military dogs in sub-Saharan Africa, especially French working dogs in the Côte d'Ivoire,[135] although disease was reported in one dog despite use of this drug in addition to deltamethrin collars. Complete eradication of *T. congolense* forest type was reported in a dog seen in Austria following treatment with IM isometamidium chloride; before that, clinical improvement with imidocarb and miltefosine treatment was described.[142]

TRYPANOSOMA EVANSI INFECTION

Trypanosoma evansi causes surra (= "rotten") and is endemic in large parts of Asia, Africa, Latin America, and the Canary Islands of Spain. It causes disease in a variety of mammalian host species that include horses, cattle, dogs, and cats, but not humans. *Trypanosoma evansi* is very closely related to *T. brucei* and may have derived from *T. brucei* as a result of partial or complete loss of kinetoplast DNA, which stops it from developing within the insect vector. Instead, the organism is transmitted mechanically by biting flies. Ingestion of infected meat may also lead to infection. Because populations of biting flies are greatest during the rainy season, a seasonal incidence of disease has been observed in dogs.[143] Travel-related disease has been described.[144,145] The disease has an acute course; clinical signs and laboratory abnormalities resemble those of African trypanosomiasis, with lethargy, fever, anorexia, weight loss, pallor, lymphadenomegaly, hepatosplenomegaly, vomiting, arrhythmias, conjunctivitis, uveitis, corneal edema, and peripheral edema, as well as leukopenia, thrombocytopenia, and anemia on the CBC.[143–149] Hyperglobulinemia, hypoalbuminemia and proteinuria have also been reported.[17,24] Some dogs develop neurologic signs late in the course of disease due to nonsuppurative meningoencephalitis.[144] Definitive diagnosis of infection is based on cytologic examination of blood smears and/or PCR assay. A variety of antiprotozoal

TABLE 100.2 Antimicrobials Used To Treat African Trypanosomiasis in Dogs[a]

Drug	Dose (mg/kg)	Route	Interval	Duration (days)
Diminazene aceturate	3–5[b]	Deep IM	Give once or repeat 72 to 96 hours later	NA
Pentamidine isethionate	8 mg/kg on day 1, then 4 mg/kg	IM or IV infusion over 2 to 3 hours	24	10
Suramin	10–20	IV infusion over 3 minutes	Repeat every 7 days	2 months

[a]The availability of these drugs is limited and varies with country. None are readily available in the United States. The optimal dosing protocols, safety, and efficacy for these drugs for treatment of African trypanosomiasis are not well understood in dogs. Neither pentamidine nor suramin penetrate the blood-brain barrier well and so may not be effective for CNS infections. Pre-treatment with antihistamines or nonsteroidal anti-inflammatory drugs may be used to reduce adverse reactions that follow administration.

[b]Diminazene was used successfully to treat *Trypanosoma evansi* infection in cats at 3.5 mg/kg IM daily for 7 days without adverse effects in one study.

CASE EXAMPLE

Signalment
"Duke," a 5-year-old male beagle mix dog from south Texas.

History
Duke's owner reported a 7-day history of inappetence, lethargy, and decreased exercise tolerance. Two months earlier, the dog had been diagnosed with dirofilariasis and was treated with melarsomine dihydrochloride using a split protocol. He had not traveled out of his local area. He was up to date on vaccinations, which included vaccines for distemper, hepatitis, parvovirus, and rabies.

Current medications: Monthly oral ivermectin/pyrantel heartworm preventative.

Physical Examination
Body weight: 19.9 kg.

General: Lethargic. T = 101.7°F (38.7°C), HR = 142 beats/minute, RR = 48 breaths/minute, mucous membranes pink, CRT = 1 second.

Integument, eyes, ears, nose, and throat: Full, shiny haircoat. No evidence of ectoparasites was detected. No other significant abnormalities were noted.

Musculoskeletal: BCS was 6/9.

Cardiovascular: An irregular rhythm and a grade 3/6 systolic left apical murmur were detected on thoracic auscultation. Strong femoral pulses were palpated bilaterally.

Respiratory: Mild tachypnea was identified with normal breath sounds and normal respiratory effort.

GI, genitourinary, and lymph nodes: No abnormalities were detected.

Laboratory Findings
CBC: PCV 48.3% (31%–56%), MCV 66.4 fL (60–77 fL), MCHC 35 g/dL (32–36 g/dL), WBC 13,100 cells/μL (6,000–17,000 cells/μL), neutrophils 8,777 cells/μL (3,000–11,500 cells/μL), lymphocytes 2,096 cells/μL (1,000–4,800 cells/μL), monocytes 1,179 cells/μL (150–1,250 cells/μL), platelets 238,000 platelets/μL (200,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 144 mmol/L (139–147 mmol/L), potassium 3.9 mmol/L (3.3–4.6 mmol/L), chloride 118 mmol/L (107–118 mmol/L), bicarbonate 22 mmol/L (20–28 mmol/L), phosphorus 3.6 mg/dL (2.9–6.2 mg/dL), calcium 9.8 mg/dL (9.3–11.8 mg/dL), BUN 19 mg/dL (5–29 mg/dL), creatinine 1.27 mg/dL (0.3–2.0 mg/dL), glucose 108 mg/dL (60–135 mg/dL), total protein 5.5 g/dL (5.7–7.8 g/dL), albumin 2.6 g/dL (2.4–3.6 g/dL), globulin 2.9 g/dL (1.7–3.8 g/dL), ALT 136 U/L (10–130 U/L), ALP 103 U/L (21–147 U/L), GGT 11 U/L (0–25 U/L), cholesterol 199 mg/dL (120–247 mg/dL), total bilirubin 0.2 mg/dL (0–0.8 mg/dL), magnesium 2.1 mg/dL (1.7–2.1 mg/dL).

Urinalysis: SpG 1.012; pH 7.5, trace protein (SSA), no bilirubin, no glucose, no WBC/HPF, 0–1 RBC/HPF.

Heartworm antigen test: Negative.

Cardiac troponin I: 0.69 ng/mL (<0.2 ng/mL).

Chagas indirect fluorescent antibody titer: Positive at 1:160.

Imaging Findings
Thoracic radiographs: The cardiac silhouette was mildly, generally enlarged. The pulmonary veins were mildly larger than the corresponding artery. A mild pulmonary interstitial pattern was present.

Echocardiogram: The left ventricular internal dimensions were enlarged, and systolic function was reduced (fractional shortening 16.1%, area shortening 26.9%; normal is >25% and >50%, respectively). Moderate mitral regurgitation was documented, and the left atrium was enlarged. The right ventricle was mildly dilated. Pulmonic and aortic velocities were within normal limits. No heartworms were visualized.

Additional Testing
Electrocardiogram: Sinus rhythm with frequent, multiform ventricular premature complexes. Sinus beats conduct with a long PR interval (0.16 seconds) consistent with first-degree atrioventricular block.

Blood pressure: Systolic blood pressure was 115 mmHg.

Diagnosis
American trypanosomiasis (Chagas disease).

Treatment
Medication to address cardiac enlargement, dysfunction, and arrhythmias included pimobendan (0.25 mg/kg, PO, q12h), enalapril (0.5 mg/kg, PO, q12h), and sotalol (1 mg/kg, PO, q12h). This was associated with improvement in clinical signs within 1 week of starting treatment.

Comments
This dog was diagnosed with trypanosomiasis based on an index of suspicion in the presence of ventricular enlargement and dysfunction in combination with multiform ventricular arrhythmias. Infection by *Leishmania* could also have caused the positive serologic test result, but this was considered unlikely based on the geographic location and clinical signs. Antiprotozoal drugs were not used to treat this dog because they do not appear to alter outcome in chronic Chagas disease and they are not available. The dog did very well clinically while being managed with cardiac medications including antiarrhythmics along with routine evaluation. After 2.5 years, ventricular arrhythmias increased in severity and were more difficult to control with antiarrhythmic therapy. He died suddenly at home 5 days after reevaluation.

treatments have been used, especially with diminazene aceturate or suramin, although diminazene aceturate is considered less effective against *T. evansi* than against *T. congolense* infection, and some affected dogs have died or had relapse of parasitemia despite treatment.[144,148,149] In one study that involved an outbreak of infection with a high mortality rate in 38 dogs on a farm in rural Brazil, clinical improvement was reported for 15 of 18 dogs treated with diminazene aceturate (3.5 mg/kg, IM, once).[149]

Giardiasis

Valeria Scorza, Michael R. Lappin

KEY POINTS

- Cause: *Giardia duodenalis* (multiple genetic assemblages); a flagellate protozoan (phylum Sarcomastigophora).
- First Described: Trophozoites that were likely *Giardia* spp. were first described in 1681 by Antonie van Leeuwenhoek and the genus was established in the early 1900s. Infections of dogs and cats were first described in the 1960s.[1,2]
- Affected Host Species: Dogs and cats are the definitive hosts for several different *Giardia* assemblages and pass either trophozoites (diarrhea) or cysts (diarrhea or normal stool) in feces.
- Intermediate Hosts: Although there are no intermediate hosts, there are multiple potential transport hosts that may carry *Giardia* spp. cysts and indirectly infect dogs or cats.
- Route of transmission: Fecal-oral.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Most dogs and cats harbor subclinical infections. Acute watery diarrhea that can contain mucus can occur. Steatorrhea can be observed. Chronic or intermittent diarrhea and weight loss may be noted in animals with concurrent infections or immunocompromise.
- Differential Diagnoses: All causes of small bowel diarrhea including *Cystoisospora* spp., *Cryptosporidium* spp., bacterial infections such as salmonellosis, nematode infections, dietary intolerance, exocrine pancreatic insufficiency, and inflammatory bowel disease.
- Human Health Significance: *Giardia duodenalis* assemblages that infect dogs (assemblages C and D) or cats (assemblage F) are usually not associated with clinical disease in humans but can be detected in the feces of immunocompromised people.[3] Human assemblages A and B can be found in feces of dogs and cats when animals share human environmental features (such as contaminated water). However, it is unlikely that new human infections with *G. duodenalis* assemblage A or B infections are acquired from the feces of dogs or cats.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Enteric protozoa covered in this book are limited to four protozoan genera: *Giardia*, *Tritrichomonas*, and *Entamoeba* in the phylum Sarcomastigophora (having flagella or pseudopodia); and *Balantidium* in the phylum Ciliophora (having cilia). For perspective, salient characteristics of these organisms and the diseases they may cause are presented in Table 101.1. A detailed coverage of laboratory methods for diagnosis of enteric protozoal infections is presented in Chapter 5, and more information on treatment can be found in Chapter 12.

Giardia duodenalis is a protozoan parasite with worldwide distribution that infects a variety of mammals. Several other species of *Giardia* exist that infect other hosts (Table 101.2). Molecular characterization studies report that *G. duodenalis* is a species complex comprising eight assemblages (A to H). Some of the assemblages have been detected in animals and humans, but some others are species-specific. Dogs usually harbor the species-specific C-D assemblages, and cats usually harbor the cat-specific assemblage F (Table 101.3 and Fig. 101.1). Assemblages A and B have been reported in humans and other mammals including cats and dogs (Table 101.3).[4-8] Many studies have evaluated the prevalence of *Giardia* spp. infection and different assemblages in dogs and cats worldwide, and prevalences vary widely depending on the test used and the population studied (Tables 101.4, 101.5, 101.6, and 101.7). A meta-analysis showed that *Giardia* spp. estimated pooled prevalence rates of 15.2% and 12% for dogs and cats, respectively.[9]

Giardia spp. occur in two forms, the trophozoite and the cyst form. The trophozoite (15 μm long and 8 μm wide) is the active, motile form that is found in the intestinal tract (Figs. 101.2 and 101.3). The trophozoites can be identified under light microscopy by the "smiling-face" appearance, which is formed by the two nuclei in the anterior third forming the eyes, the axonemes passing longitudinally between the nuclei forming the nose, and the median bodies located transversely in the posterior third forming the mouth; four pairs of flagella complete the shape.[10] Trophozoites are susceptible to inactivation by many environmental conditions, and are usually not responsible for spread among animals.

The cyst (12 μm long and 7 μm wide) form is the resistant stage that is mainly responsible for transmission. The cyst contains two incompletely separated but formed trophozoites, their axonemes, fragments of the ventral discs, and as many as four nuclei (Fig. 101.4). *Giardia* spp. are transmitted by the direct ingestion of fecal cysts or by indirect ingestion of contaminated water, food, transport hosts, infected prey species, or fomites (Fig. 101.5). Many infected hosts excrete fecal cysts for months, but infections may also be self-limited in 27 to 35 days in dogs and cats.

CLINICAL FEATURES

Pathogenesis And Clinical Signs

Although the pathogenesis of *Giardia* infection is not completely understood, it is suggested that is multifactorial with a combination of intestinal malabsorption and hypersecretion as the primary mechanisms associated with the development of diarrhea. *Giardia* colonize the lumen and epithelial surface but do not invade deeper mucosal layers. *Giardia* infection causes disruption of tight junctions and cytoskeleton proteins resulting in increased intestinal permeability and decreased transepithelial resistance.[11] The host-parasite interaction leads to the upregulation of genes involved in the apoptotic cascade and in the formation of reactive oxygen species.[12] The induction of

TABLE 101.1 Comparison of Some Enteric Protozoa in Dogs and Cats

Organism	Stage	Average Size (μm)	Natural Hosts	Organ Parasitized	Pathogenic Mechanisms	Clinical Signs
Giardia[a]	Tr Cy	15 × 10 × 3 10 × 8	D, C, H, other mammals	Small intestine	Damage to glycocalyx and microvilli on intestinal epithelium; inhibition of some digestive enzymes; host elicits inflammatory response	None to chronic diarrhea, continuous or intermittent, malabsorption
Entamoeba histolytica	Tr Cy	25 (diam) 12 (diam)	D, C, H, NHP	Large intestine	Invades colonic wall, producing ulcers; may spread to extraintestinal sites	None to diarrhea; dysentery
Balantidium coli	Tr Cy	60 × 35 50 (diam)	D, P, H, NHP	Large intestine	Invades colonic wall, producing ulcers, dissemination (rare)	None to diarrhea; dysentery
Pentatrichomonas hominis	Tr	8 × 5, five flagella	D, C, H, other mammals	Large intestine	Probably none; considered harmless commensal but may be opportunistic pathogen	None to diarrhea
Tritrichomonas blagburni	Tr	8 × 5, three flagella	D, C, Ca, P	Genitalia (cattle) Intestine, nasal (swine) Large intestine (cat)	Epithelial adherent, elaboration of cytotoxins and enzymes; host elicits inflammatory response	Large bowel diarrhea in cats; infertility and fetal loss in cattle

[a]Some *Giardia* species can be microscopically indistinguishable.

TABLE 101.2 *Giardia* Species and Their Corresponding Hosts[91]

Giardia Species	Host
Giardia agilis	Amphibians
Giardia ardae	Birds
Giardia microti	Muskrats and voles
Giardia muris	Rodents
Giardia psittaci	Birds
Giardia varani	Lizards
Giardia duodenalis	Mammals

TABLE 101.3 Host Distribution and Taxonomy of the Eight Currently Recognized Assemblages within *Giardia duodenalis* Species Complex[5]

Assemblage	Proposed Species Name	Main Host
A	*Giardia duodenalis*	Humans and other mammals
B	*Giardia enterica*	Humans and other mammals
C	*Giardia canis*	Domestic and wild canids
D	*Giardia canis*	Domestic and wild canids
E	*Giardia bovis*	Hoofed animals
F	*Giardia cati*	Cats
G	*Giardia simondi*	Rodents
H	None proposed	Pinnipeds

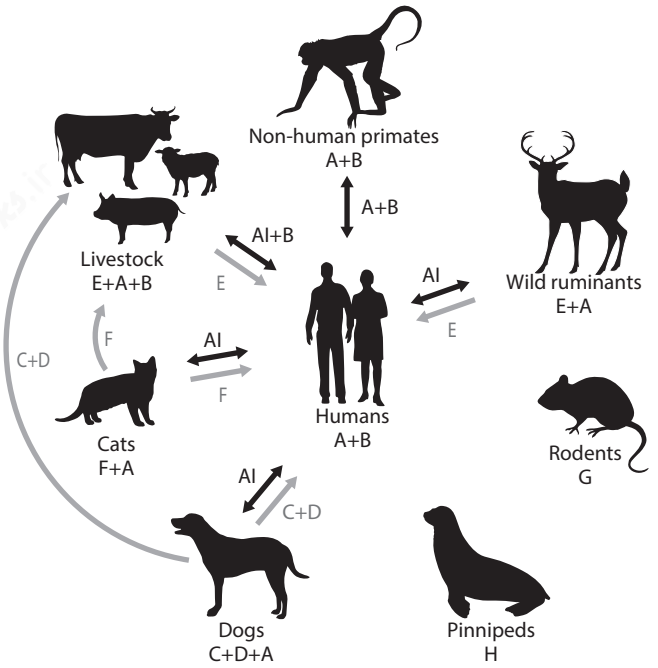

Fig. 101.1 Assemblages and transmission cycles of giardiasis. Most human infections are anthroponotic, and involve sub-assemblages AI, AII, BIII, and BIV. Sub-assemblage AI has zoonotic potential, and involves livestock, wild ruminants, nonhuman primates, cats, and dogs. Occasional reports of transmission of assemblages C, E, and F have been reported, likely originating from the animals predominantly infected by these assemblages. (Modified from Caccio, et al. *Infect Genetics Evol.* 2018: 66; 335-345.)

apoptosis increases GI permeability, allowing luminal antigens to activate host immune–dependent pathologic pathways.[12] Parasite proteins cause cellular damage affecting the intestinal permeability and cells of the adaptive immune system. *Giardia* infection stimulates chloride secretion and results in a diffuse loss of brush border microvillus length, which causes epithelial maldigestion and malabsorption of glucose, sodium, and water and reduced disaccharidase activity.[12]

The reason as to why *Giardia* can cause clinical signs in some individuals and not in others is not completely elucidated. Parasite strains, host nutritional status, the composition of intestinal microbiota, co-infection with other enteric pathogens, and immunological response are important factors that influence disease manifestations.[11] It is unknown if the different assemblages vary

in their disease-producing properties and induce a respective range of severity of clinical signs in cats and dogs. A higher prevalence of symptomatic giardiasis is observed in human infants, especially in those with pre-existing nutritional deficits, due to an immature adaptive immune system.[11] In HIV/AIDS patients, *Giardia* is not a common opportunistic pathogen, suggesting that not all forms of immunosuppression predispose to severe disease.[11] Recent findings suggest that some protozoa parasites can colonize the human gut for long periods without provoking symptoms, challenging their definition as a "pathogen" or "commensal."[13] *Giardia* and intestinal microbiota may produce persistent dysbiosis that could potentially predispose to GI disorders post infection to people with giardiasis.[13] *Giardia* colonization may cause a metabolic shift among the intestinal microbial community, and as a consequence the altered microbiota could contribute the clinical signs during the infection.[14] In dogs, the composition of the fecal bacterial microbiome was significantly different in clinically ill and subclinical *Giardia* infections.[15]

Although many cats and dogs that excrete *Giardia* do not show clinical signs of disease, *Giardia* can cause illness in other animals. Younger, immunosuppressed animals and those living in crowded environments are at the highest risk of showing clinical disease.[9,16-20] Shelter dogs showed a higher prevalence of protozoa l infections and a lower prevalence of helminth infections when compared with hunting dogs.[21] The

primary clinical signs of giardiasis include acute or chronic diarrhea and weight loss. Acute diarrhea occurs frequently in very young animals; in older cats and dogs the diarrhea can be acute, intermittent, or chronic. The diarrhea is usually mucoid, pale, and soft and has a strong odor; steatorrhea may be present as well. The organism is not usually enteroinvasive, and so blood is uncommon. Most infected cats and dogs are afebrile and do not vomit. Co-infection with other parasites is common. *Giardia/Cryptosporidium* and *Giardia/Tritrichomonas blagburni* co-infections may often be found in association with diarrhea.[22,23]

DIAGNOSIS

A variety of different *Giardia* detection tests have been evaluated for use in cats and dogs. Despite the improved specificity, there is no one test that can be performed on a single fecal specimen that has 100% sensitivity. Even more problematic is the lack of an assay with high etiologic predictive value for clinical giardiasis due to the high prevalence of infection in clinically healthy animals.

Laboratory Abnormalities

Giardia spp. infection alone is rarely associated with CBC or serum biochemical panel abnormalities.

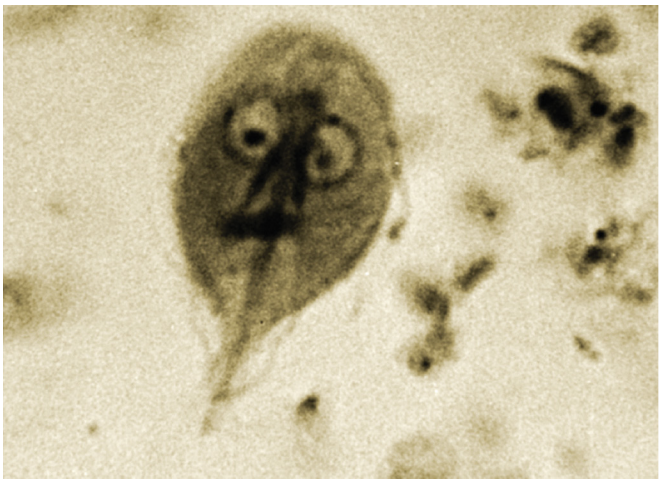

Fig. 101.2 *Giardia* trophozoite in a fecal smear stained to enhance the characteristic organelles (iron hematoxylin, ×2000.)

Diagnostic Imaging

Abdominal radiographic abnormalities are uncommon and nonspecific and, when present, are suggestive of diffuse enteritis.

Microbiologic Tests

Diagnosis Using Fecal Examination

Giardia is one of the most commonly misidentified parasites.[24] Pseudoparasites or yeasts are easily mistaken for *Giardia*, and cysts

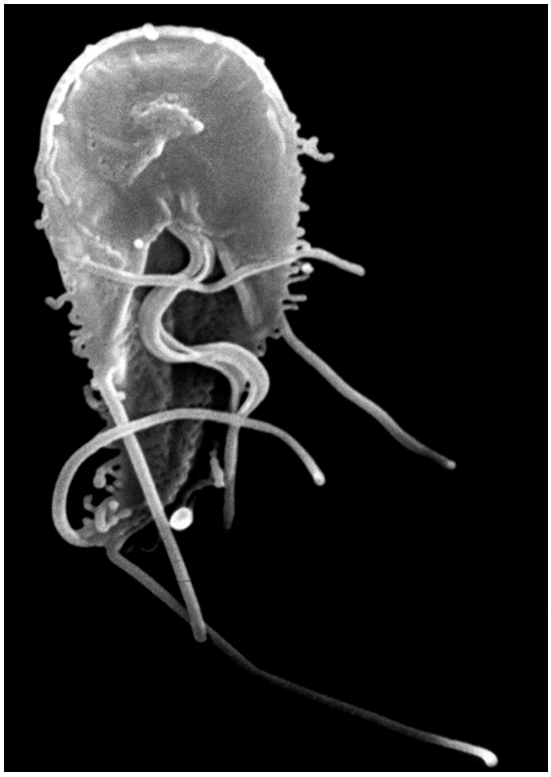

Fig. 101.3 Electron micrograph of a *Giardia* trophozoite. (Courtesy of Bayer Animal Health. In: Tangtrongsup S, Scorza V. Update on the diagnosis and management of *Giardia* spp. infections in dogs and cats. *Top Comp Anim Med.* 2010;25:155-162.)

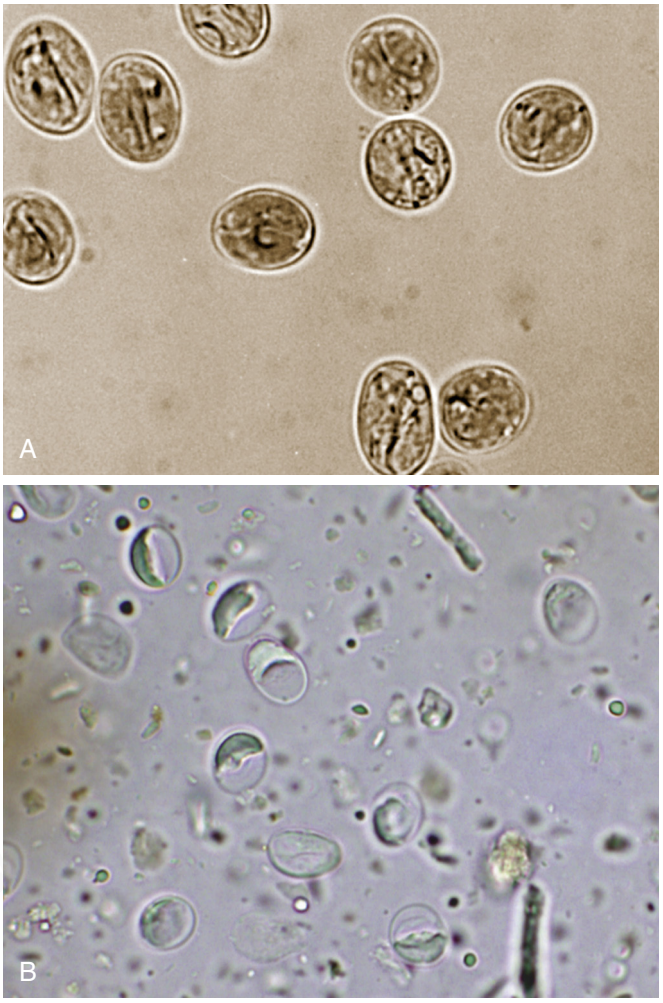

Fig. 101.4 *Giardia* cysts concentrated from the feces of a cat by the zinc sulfate centrifugal flotation technique. (A) Cyst wall, nuclei, axonemes, and median bodies are apparent in several of the cysts (iodine, ×1100). (B) Unstained with numerous cysts showing concavity (×1100).

can deteriorate in fecal flotation solutions, leading to false positive and false negative results, respectively.[24]

Direct Smear. *Giardia* trophozoites can be observed in direct smears of unstained fecal specimens using light microscopy. Trophozoites are rarely found in formed feces, refrigerated specimens, or specimens that are examined several hours after collection.[25] Although *Giardia* trophozoites can be confused with tritrichomonads that are similar in size, the latter may be differentiated by the presence of an undulating membrane, a rolling form of motility, the lack of a concave surface, and a single nucleus.[26] Further testing with *Giardia* antigen tests or fecal culture or PCR for *T. blagburni* can be used for differentiation. Once *Giardia* is detected, further cytologic examination should be performed on a fresh specimen. Although they also inactivate the parasites, the application of Lugol's solution, methylene blue, or acid-methyl green to the wet mount helps in the visualization of the internal structures of the trophozoites.[26] Examination of fresh feces on 3 different days detected 40% of the *Giardia*-infected dogs.[27]

Concentration Techniques. If trophozoites are not seen on a direct smear, examination for cysts should be performed.[24] If fecal specimens cannot be examined immediately, storage at 4°C for several days is acceptable, but specimens should not be frozen. *Giardia* cysts are best detected by Sheather's sugar centrifugation and the zinc sulfate centrifugation technique ($ZnSO_4$) (see Fig. 101.4, *B*).[26] If the feces contain much fat, formalin-ethyl acetate sedimentation is the best technique for cyst detection. The zinc sulfate centrifugation technique has also been superior to passive fecal flotation for detection of helminths and *Giardia* cysts. Flotation methods detected only 6.5% to 14.7% of samples with *Giardia* cysts, as compared to those found to contain cysts using $ZnSO_4$.[28,29] The zinc sulfate centrifugation technique recovered seven times more *Giardia* cysts than sodium nitrate when used in a commercial flotation device (StatSpin Ovatube, Iris Sample Processing, Inc., Westwood, MA, USA).[30] Barium sulfate, several proprietary antidiarrheals, and enemas administered before the collection of the feces may interfere with the detection of the cysts.[25] Because of the intermittent pattern of excretion, it is recommended that if fecal flotation alone is to be used, at least three specimens be examined over a period of about 1 week before ruling out the presence of *Giardia*.[24,25,27] Additionally, in general, dogs and cats often are not excreting large numbers of *Giardia* cysts. Another factor to consider is the type of laboratory to submit the specimen to for the diagnosis of *Giardia* infection via fecal centrifugation flotation. In one study, the frequency of *Giardia* detection was significantly lower when performed at a commercial laboratory than when it was performed at a university laboratory.[31]

Immunochemical Detection with Fluorescent Microscopy. A monoclonal antibody–based direct FA assay (Merifluor Cryptosporidium/*Giardia*, Meridian Diagnostics, Cincinnati, OH) is used to detect *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts in feces. The assay has been evaluated for detection of *Giardia* infections of dogs and cats in multiple studies.[32,33] Because the assay gives both immunologic confirmation (fluorescence) and morphologic evaluation (size and shape), it is usually considered a reference standard in test comparison studies.[34] This FA assay was more sensitive and specific than zinc sulfate flotation but comparable to other antigen-detection techniques when used on refrigerated feline fecal

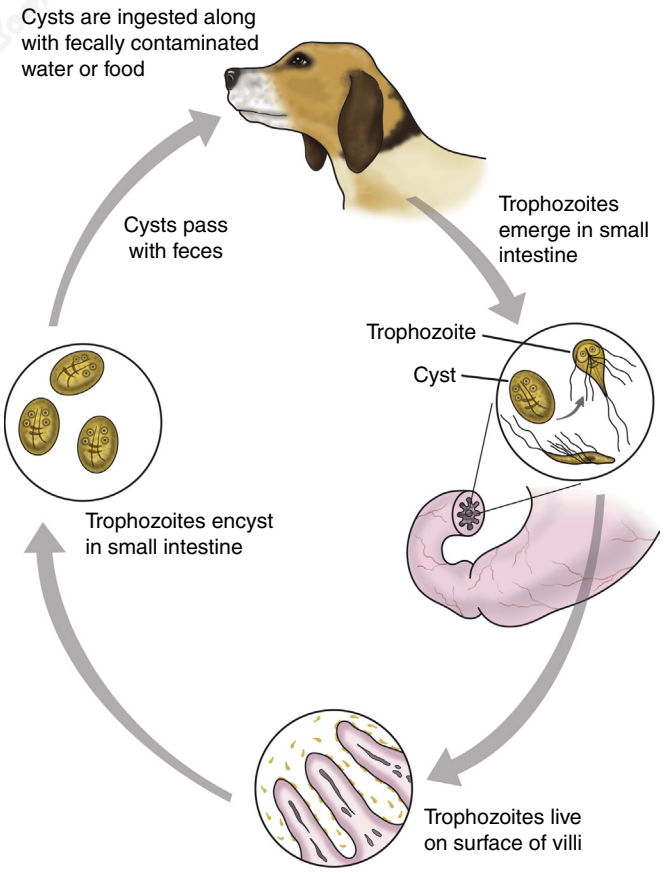

Fig. 101.5 Life cycle of *Giardia duodenalis*.

specimens and in fecal specimens from shelter dogs.[26,35] In addition, it detects *Cryptosporidium* spp., which can be found as co-pathogens. A fluorescence microscope is needed to read the FA slides, therefore this assay is usually only performed in diagnostic laboratories. Specimens can be stored at 4°C for several days but should not be frozen.

Fecal Antigen Assays

There are several POC ELISA-based kits available for the detection of *Giardia* spp. antigen in human feces, and one kit is licensed for use with dog and cat feces (SNAP *Giardia*, IDEXX Laboratories, Portland, ME). Results vary depending on the test kits used, and inconsistent results have been reported with some *Giardia* antigen tests when compared to other non–ELISA-based techniques.[9,36-42] In cats, the ELISA-based kit licensed for use with canine or feline feces had similar sensitivity and specificity when compared to $ZnSO_4$ flotation, and when the results of the two techniques were combined, the overall sensitivity was 97.8%.[43] In dogs, using the direct FA as the gold standard test, at a prevalence rate of 10%, the *Giardia* antigen assay was estimated to have a positive predictive value (PPV) and negative predictive value (NPV) of 51.0% and 97.0%, respectively, which were similar to those for $ZnSO_4$ flotation.[34]

In a study using Bayesian statistical approach, the IDEXX POC kit (SNAP *Giardia*) showed a sensitivity of 88.9% and a specificity of 95.8% with PPV and NPV of 89.6% and 95.4%, respectively, when used on dog specimens.[44] A study compared the results of $ZnSO_4$ flotation and the SNAP *Giardia* antigen test (IDEXX Laboratories Inc., Netherlands) in dog fecal specimens with the results of two additional POC ELISA-based tests: Single Antigen Rapid *Giardia* Ag and the Triple Antigen Rapid CPV-CCV-*Giardia* Ag (BioNote).[45] At a high prevalence rate in the dog population, the specificities and PPV of both tests were 100%. However, the sensitivities were 48% and 83% for the single and triple test, respectively, and the NPV was 55% and 80% for the single and triple test, respectively.[45] At lower prevalence rates, both tests showed high PPVs (100%) and the NPVs were higher with the Triple (96% to 99%) than the Single (88% to 96%) Rapid test.[45] The direct FA assay, $ZnSO_4$ flotation, SNAP *Giardia* test, ProSpecT *Giardia* EZ Microplate assay, and PCR were evaluated in fecal specimens from 136 young dogs.[42] Comparisons among the tests were done using FA as a gold standard and also using Bayesian analysis.[42] *Giardia* was detected in 41% of the specimens by FA, and $ZnSO_4$ flotation was positive in 37% of specimens with a relative sensitivity and specificity of 86% and 98%, respectively. The SNAP *Giardia* test was positive in 40% of the specimens, with a relative sensitivity and specificity of 91% and 96%, respectively. The ProSpecT test was positive in 51% of the specimens, with a relative sensitivity and specificity of 100% and 83%, respectively. The PCR was positive in 55% of the specimens, with a relative sensitivity and specificity of 58% and 56%, respectively. When the Bayesian approach was performed, the conclusions remained the same although sensitivity and specificity changed.[42] The ProSpecT was the most sensitive test, but it is not designed for dogs and is more expensive than the other tests. In another study, specimens from 573 dogs were tested by centrifugation sedimentation flotation coproscopical analysis, direct FA, the SNAP *Giardia* test, and a qPCR assay.[46] Bayesian analysis was used to evaluate test performance characteristics.[46] All tests were highly specific. The highest specificity was with the SNAP *Giardia* (99.6%) and the lowest was with qPCR (85.6%).[46] The qPCR assay had the highest sensitivity (97.0%) and centrifugation sedimentation flotation had the lowest sensitivity (48.2%). Direct FA was more sensitive than SNAP *Giardia*, but slightly less specific.[46]

Another study compared the performance of the VetScan Canine *Giardia* Rapid Test (Abaxis), Anigen Rapid CPV-CCV-*Giardia* Antigen Test (BioNote), SNAP *Giardia* Test (IDEXX), and Witness *Giardia* Test (Zoetis), ova parasite examination and the ProSpecT Microtiter Plate ELISA to FA as the gold standard.[47] The sensitivities of the SNAP, Anigen, Witness, VetScan, ova and parasite examination, and ProSpecT assays were 87.1%, 80.2%, 73.3%, 70.0%, 81.2%, and 94.1%, respectively.[47] The specificities were 93.4%, 80.3%, 71.1%, 85.5%, 93.4%, and 97.4%, respectively.[47] Although information is limited regarding detection of *Giardia* assemblages C, D, or F, in one study of four assemblage C isolates and 13 assemblage D isolates, all were positive by the SNAP *Giardia* antigen assay.[47]

The CAPC recommends that fecal antigen tests be used as an addition to fecal flotation only during the evaluation of dogs and cats with diarrhea, and not with clinically healthy pets or to follow therapy, because the clinical and zoonotic impact of an antigen result-positive, cyst presence result-negative healthy pet is unknown.[48] It is also unknown as to how long *Giardia* antigen assay results remain positive after resolution of diarrhea. Therefore, if a veterinarian chooses to assess the success of the treatment for giardiasis in cats and dogs, only fecal flotation is recommended for follow-up evaluation.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Many veterinary diagnostic laboratories offer PCR diarrhea panels that include *G. duodenalis* for the detection of common enteric pathogens. However, if genotyping is desired, other PCR assays may be required.[49] At the time of writing, one diagnostic laboratory has begun to offer a PCR panel that detects nucleic acid from 20 different parasites, and differentiates zoonotic assemblages of *Giardia* (A and B) from other assemblages of *Giardia* (assemblage non-specific assay) (KeyScreen GI Parasite PCR, Antech Diagnostics, USA). A 2019 article reported that the sensitivity and specificity of a real-time PCR assay for *G. duodenalis* that was incorporated as a component of a diarrhea panel was 95.1% and 92.1%, respectively, when compared with a reference real-time PCR assay.[50] However, *Giardia* PCR assay results can also be falsely negative because of the presence of PCR inhibitors in feces. In one study, false negative results were obtained in 41% (11/27) specimens using a

real-time PCR assay in comparison with direct FA or fecal flotation.[31] Therefore, PCR should not be used as the sole means of confirming *G. duodenalis* infection. The authors recommend to test initially with $ZnSO_4$ centrifugal flotation and then follow with an antigen test.

Pathologic Findings

Gross Pathologic Findings

Giardia spp. infection may cause mild intestinal thickening, and it is not enteroinvasive, so blood is generally not present within the intestinal lumen unless co-infections are recognized. Animals with chronic clinical signs of disease may be emaciated.

Histopathologic Findings

In clinically affected animals with *Giardia* infection, a diffuse loss of brush border microvillus length may be noted on histopathology of the small intestine. Increased numbers of intraepithelial lymphocytes and mast cell hyperplasia may also be present. However, diarrhea has been associated with giardiasis in dogs, cats, and people with normal intestinal biopsy results.

TREATMENT AND PROGNOSIS

Effective and approved drugs to treat giardiasis in humans include 5-nitroimidazoles and benzimidazoles derivatives, quinacrine, furazolidone, paromomycin, and nitazoxanide.[51] In veterinary medicine, many drugs can reduce the parasite burden and speed resolution of clinical signs (Table 101.8). Metronidazole has been widely used for the treatment of giardiasis in naturally and experimentally infected cats and dogs, even though controlled studies are lacking.[52,53] Central nervous system toxicity had been associated with the administration of metronidazole in some dogs and kittens but this is usually avoided by staying below 50 mg/kg total daily dose and only using the drug for days rather than weeks.[52,54] The CAPC suggests a maximum dose of 25 mg/kg, PO, q12h for 5 days.[48] Treatment for longer than 7 days should never exceed 30 mg/kg per day. Metronidazole hydrochloride is the United States Pharmacopeia (USP) formulation in tablets, which causes cats to salivate, while the benzoate form that is available in some countries is less likely to cause this problem.[55] When metronidazole benzoate was administered to cats with subclinical giardiasis, cyst excretion ceased over the time period of the study, and signs of toxicity did not develop. Use of drugs in the nitroimidazole class may also add the benefit of correcting bacterial overgrowth, which may also contribute to diarrhea. However, one study demonstrated that dogs with acute diarrhea continue to have dysbiosis and altered metabolic profiles after treatment with metronidazole for 28 days.[56] Other nitroimidazoles including ipronidazole, ronidazole, and tinidazole had been used for the treatment of giardiasis in a small number of animals. Ipronidazole added to water was effective for the treatment of giardiasis in two dogs.[57] The administration of a single dose of secnidazole at 30 mg/kg eliminated diarrhea and *Giardia* cyst excretion in 11 naturally infected cats; however, one cat showed elevation of liver enzymes.[58] This drug is not available in most countries except as a compounded formulation.[58]

Nitazoxanide was approved by FDA for the treatment of *Cryptosporidium* and *Giardia* infections in humans, it has also been used to treat some cats and dogs infected with cryptosporidiosis and giardiasis.[59] A salicylanide derivative of nitrothiazole, nitazoxanide is effective against a broad spectrum of parasites and bacteria.[60] Diarrhea resolved in some infected cats and dogs after the administration of nitazoxanide at 25 mg/kg, PO, q12h for at least 5 days.[23] Nonetheless, nitazoxanide is a GI irritant and often causes vomiting and it is not effective in the absence of an appropriate immune response.

One study of dogs that were naturally infected with *Giardia* involved administration of nitazoxanide at different dosages (37.5, 75, and 150 mg/kg) on days 0 and 14.[61] In the same study, another group of dogs were treated PO with a combination of pyrantel, praziquantel, and febantel for 3 consecutive days; another group of dogs were untreated control dogs.[61] Although *Giardia* excretion reduced in all treatment groups, fecal consistency did not improve. However, this study lacked an uninfected control group and some of the dogs were co-infected with other parasites.

Fenbendazole has been evaluated for the treatment of giardiasis in a number of studies of dogs and cats.[10,62-64] Fenbendazole also has activity against other parasites that have the potential to be co-pathogens. The CAPC recommends a dose of fenbendazole of 50 mg/kg, q24h, for 5 days for cats and dogs, or a combination of this dosage of fenbendazole and metronidazole (25 mg/kg, q12h, for 5 days). However, when fenbendazole was administered to cats concurrently infected with *Giardia* and *Cryptosporidium parvum*, *Giardia* cyst excretion ceased in only four of eight cats.[63] When fenbendazole was administered to naturally infected shelter dogs, the percent persistence of cyst counts per gram of feces were 84% and 78% when feces were rechecked 9 and 16 days, respectively, after treatment.[64] Fenbendazole (50 mg/kg, PO, q4h for 10 days), bathing and moving dogs into disinfected kennels while disinfecting their original kennels with a quaternary ammonium solution, and then raising the temperature in the room for 24 hours to promote drying of *Giardia* cysts, eliminated *Giardia* excretion in 34 dogs.[65]

TABLE 101.8 Treatment for Giardiasis and Other Enteric Protozoal Infections

Drug	Species	Dose	Route	Interval (Hours)	Duration (Days)

[a]Elanco. See manufacturer's label for dosing recommendations based on tablet size. Some dosages noted here are based on studies where combination products were used off-label.
[b]In drinking water and given ad libitum.
[c]In suspension, 200 mg/day maximum. Has been used in children and has the ability to inhibit cyst formation. Not available in some countries. maximum recommended dosages are used for treatment of enteric protozoal infections. Neurotoxicity has been observed at levels of hydrochloride salt at ≥ 60 mg/kg per day. To facilitate the dosage to smaller animals, the 250- or 500-mg tablets may be ground, or smaller tablet size (50 to 100 mg) may be used. This may be placed in a palatable base. For cats, metronidazole benzoate formulations (62% metronidazole base) are better tolerated orally than hydrochloride formulations, but dosage needed would be 1.6 times listed.
B, both dog and cat; *C,* cat; *D,* dog; *feb,* febantel; *PO,* oral; *praz,* praziquantel; *pyr,* pyrantel.

In cats, fenbendazole was safe when administered to healthy, adult, nonpregnant cats at a dosage five times higher than the approved dosage.[66] Other benzimidazoles used in some studies of giardiasis are albendazole, oxfendazole, and febantel. Albendazole has been effective in dogs; however, because of bone marrow suppression, it is not recommended.[66,67] Oxfendazole used in conjunction with other control measures led to resolution of diarrhea and cyst excretion in one study of kenneled dogs with giardiasis.[68]

A combination of febantel, pyrantel, and praziquantel (FPP) (Drontal Plus Tablets, Bayer, Shawnee Mission, KS), using a variety of dosage protocols, has had variable results in the treatment of giardiasis in dogs and cats.[40,69-75] Two different formulations of the drug exist (see Table 101.8), and dose differences may be responsible for some of the discrepancies between results of efficacy studies. In one report of seven healthy *Giardia*-infected dogs, organisms were not detected again in 3 days after 3 consecutive days of treatment with FPP.[69] However, 6 days after the last treatment, some dogs began to excrete organisms again, probably from reinfection.[69] The efficacy of the treatment of dogs naturally infected with *Giardia* spp. for 5 consecutive days with the European formulation was not significantly better than treatment for 3 consecutive days.[74] Another study implied that when FPP was used to treat dogs with giardiasis, bathing the animal and changing its environment after treatment may be more important for preventing reinfection than duration of treatment.[40,48]

When FPP was administered at the empiric dosage of two "small dog" tablets per cat, PO, for 5 days, to six cats, a significant decrease in cyst excretion was observed in the treated group in comparison to the untreated control group.[75] In addition, four of the six treated cats had evidence of infection after administration of two immunosuppressive doses of repositol glucocorticoids.[75]

Azithromycin (10 mg/kg PO q24h for 5 days) was used for the treatment of an 8-month-old dog that had persistent diarrhea after being treated with fenbendazole and metronidazole for giardiasis.[76] After treatment the diarrhea stopped, and no adverse reactions were observed. *Giardia* cysts and DNA were not detected after examination of fecal smears and PCR of fecal samples on days 2, 4, and 6 after therapy.[76] However, azithromycin has failed to lessen *Giardia* attachment or growth *in vivo*, and so use of this drug for treatment of giardiasis in animals needs additional study.[77]

Other drugs used historically to treat giardiasis in dogs or cats included quinacrine, furazolidone, and paromomycin; however, controlled efficacy studies are lacking.[23,59,61,78]

Auranofin is a gold-containing drug that was approved by the FDA in 1985 for the treatment of rheumatoid arthritis, and it could be a promising new agent for the treatment of giardiasis. Auranofin showed anti-*Giardia* activity *in vivo* and *in vitro* at a low concentration and was effective against multiple metronidazole-resistant strains *in vitro*.[79] Auranofin inhibits the activity of a protozoal enzyme that contributes to normal protein function and that combats oxidative damage. Auranofin has activity against both the *Giardia* cyst and the trophozoite stages. It has been administered to shelter dogs with diarrhea due to *Giardia* infections alone and *Giardia* and *Cryptosporidium* co-infections.[80] No adverse effects have been observed in these dogs using a dose of 0.3 mg/kg and upwards to a maximum dose of 6 mg/day, q24h for 5 days, and dogs ceased excreting cysts and had normal stools after 5 to 10 days of treatment.[80]

Although controlled studies in dogs and cats are generally lacking, other adjunctive therapies, including fiber, silymarin, and probiotics, have been administered to some dogs or cats with giardiasis on the basis of work with other species. Although all dogs who received metronidazole, with or without silymarin, stopped excreting *Giardia* cysts, the addition of silymarin appeared to help to compensate for weight loss and increased the levels of serum total proteins and albumin when compared to dogs administered metronidazole alone.[81] Dietary fiber reduced *Giardia* infection rates in a gerbil model and controlled studies assessing the benefit in dogs are ongoing.[82] While the probiotic *Enterococcus faecium* SF68 enhanced *Giardia* immune responses in mice, positive effects on cyst excretion, fecal antigen excretion, fecal IgA concentrations, or leukocyte phagocytic activity were not recognized in samples from adult dogs with chronic subclinical infections.[83] Further work is required before these adjunctive therapies can be routinely recommended.

Common questions about treatment of *Giardia* spp. infection in dogs and cats include which drug to start with and whether dual therapy is required for treatment success. Dual therapy with fenbendazole and metronidazole has been suggested for the treatment of giardiasis in dogs and cats by some veterinarians and the combination was shown to be synergistic in a recent study in mice.[84] However, while metronidazole has adverse effects on the GI microbiome and the benzimidazole drugs fenbendazole and febantel do not, monotherapy with a benzimidazole first may be prudent with dual therapy only used in resistant cases.[56,85]

Because *Giardia* infection may be difficult to eliminate in dogs and cats, the primary goal is to resolve diarrhea. The treatment protocol used may need to be varied according to each individual patient. Additionally, control measures should be instituted to attempt to avoid reinfection. Resistance to metronidazole, nitazoxanide, albendazole, furazolidone, and quinacrine has been described in humans.[51] In dogs and cats with persistent diarrhea and detection of *Giardia* in feces after appropriate treatment, an extensive work-up should be undertaken to evaluate for other underlying disorders that may perpetuate clinical disease such as co-infections with other parasites (*Cryptosporidium* spp., *T. blagburni*), inflammatory bowel disease, bacterial overgrowth, and exocrine pancreatic insufficiency.

Although immunization has been used in the past, both the canine and feline *Giardia* vaccines previously licensed for use in dogs or cats in the United States have been discontinued.[86] However, *Giardia* vaccines are commercially available in Latin American countries for prevention of clinical illness and reduction of parasite excretion.[87] An oral vaccine with the complete repertoire of variant-specific surface protein (VSP) antigens hindered establishment of infection by trophozoites or cysts, in experimental and domestic animals (gerbils, dogs, and cats).[88] The administration of this vaccine also decreased clinical signs and reduced contamination of the environment with cysts.[88]

PREVENTION

In controlled environments (cattery or kennel situation), four main approaches should be employed to control *Giardia*: (1) decontamination of the environment, (2) antiprotozoal treatment, (3) cleaning of cysts from coats, and (4) preventing reintroduction of infection.[89]

Animals should be treated (preferably with fenbendazole or the FPP combination) before moving them into catteries or kennels. Cages or runs should be steam or chemically cleaned after all fecal material has been removed before disinfection. Five percent sodium hypochlorite (1:30 dilution) and quaternary ammonium–containing disinfectants inactivate *Giardia* cysts.[90] Quaternary ammonium compounds lose activity in the presence of organic matter, which makes it impossible to decontaminate environmental areas such as soil and grass. The kennel should be allowed to dry thoroughly after cleaning (cysts are extremely susceptible to drying) and preferably left dry and empty for several days. Animals should be bathed with a general pet shampoo to remove fecal material from their coats, rinsed, and then bathed with quaternary ammonium compounds.[40] Quaternary ammonium compounds can irritate skin and mucous membranes with repeated or prolonged exposure but appear to produce no adverse effects when applied for 3 to 5 minutes followed by thorough

rinsing. The coat is allowed to dry thoroughly before returning the animal to the clean area. Animals should then be treated again, preferably with a different compound than the one initially used, once back in the clean facility. Theoretically, the only way *Giardia* can be reintroduced into a clean area is by an infected animal or by fomite transmission. Fomite transmission can be avoided by donning shoe covers before entering the facility or cleaning boots with a quaternary ammonium compound footbath. Fecal specimens should be periodically checked using $ZnSO_4$ centrifugal fecal flotation in order to determine whether the process has been effective.

PUBLIC HEALTH ASPECTS

Giardia is the most common parasite infecting humans worldwide; it is estimated that it causes approximately 280 million cases of human illness per year.[12] The majority of infections are acquired by drinking water or swallowing contaminated water while swimming in natural bodies of water or swimming pools.[12,91,92] Most dogs harbor dog-specific assemblages. However, potential zoonotic assemblages A and B have also been reported (see Table 101.6).[93-103] Assemblages A and B are subtyped into four sub-assemblages (AI-IV and BI-IV).[99,104] Human isolates mostly belonged to AI, AII, BIII, and BIV whereas isolates from animals belonged to AI, AIII, AIV, BI, and BII.[105] Nevertheless, assemblage AII has also been described in a small number of dogs worldwide. Additionally, sub-assemblages BIII and BIV were observed in 27% and 73% of dogs and 56% and 44% of humans, respectively.[4,7,93,104,106] Numerous isolates from *G. duodenalis* from animals and humans have been genetically characterized.[106-108] However, few studies have genetically compared *Giardia* isolates from animals and humans sharing the same household.[102,104,110,111] In India, assemblage A or B was found in humans and dogs living in the same household. In Brazil, a child and a dog in the same household were both harboring sub-assemblage BIV. Only a few studies have reported cat- and dog-specific assemblages in humans, but these findings were based on the detection of *Giardia* DNA and not on viable protozoa.[112,113] The fact that similar genotypes are dispersed in different hosts and that humans and pets in the same household share the same genotypes is not certain evidence of zoonotic transmission. Assemblage BIV was detected in humans, dogs, and vegetables showing a connection in the transmission dynamics of *G. duodenalis* in Southern Brazil.[98] More molecular epidemiologic studies on giardiasis in humans, animals, and the environment are needed to completely clarify the occurrence of zoonotic transmission.[4,98]

Several studies have reported an association between dogs attending dog parks and the presence of enteropathogens.[31,114] However, off leash activity showed a positive association with the transmission of *Giardia* infections, rather than attending the park alone.[115] *Giardia duodenalis* was detected in 3.8% and 9% of the dogs attending dog parks in Colorado and in California, respectively. In Colorado, dogs visiting dog parks were more likely than the control dogs to be positive for *Giardia* feces.[31,114] The *Giardia* isolates from both studies typed as dog-specific assemblages C and D.[31,114] The benefits of attending dog parks outnumber the disadvantages for both owners and dogs, therefore owners are advised to be responsible in ensuring proper disposal of dog feces, minimizing environmental contamination.

CASE EXAMPLE

Signalment
"Giada," a 3-month-old female papillon from Fort Collins, Colorado.

History
Giada was brought to a referral veterinary clinic with a history of intermittent diarrhea, weight loss, and lethargy.

Physical Examination
The dog was dehydrated and lethargic. Rectal examination revealed feces that were soft and contained traces of blood.

Laboratory Findings
The initial hemogram showed mild non-regenerative anemia.

Imaging Findings
Thoracic radiographs: Possible interstitial pneumonia and mild distention of the cervical esophagus were identified.

Fecal examination
$ZnSO_4$ centrifugal fecal flotation: Positive for *Giardia* spp. cysts.

Diagnosis
Giardiasis and possible pneumonia.

Treatment
The dog was treated wiith IV fluids (0.45% NaCl and 2.5% dextrose), sucralfate, famotidine, and cefazolin. The next day the dog improved and so was discharged with instructions to administer metronidazole (25 mg/kg, PO, q12h for 7 days) for the *G. duodenalis* infection, amoxicillin-clavulanate (21 mg/kg, PO, q12h for 7 days) for suspected interstitial pneumonia, sucralfate for the hemorrhagic diarrhea, and a vitamin supplement. After 10 days, the diarrhea was still present and grossly appeared to contain blood and mucus. The dog was active but hardly eating and drinking; metronidazole was administered for another week. After 2 weeks of metronidazole administration, the dog was still positive for *Giardia* spp. on fecal flotation and *Strongyloides* larvae were also detected. After administration of metronidazole for another 5 days, fenbendazole (50 mg/kg PO q24h) for 5 days was added to the dog's food. Thoracic radiographs at that time showed that the pneumonia was resolving. The next fecal flotation was still positive for *G. duodenalis* and so fenbendazole was prescribed for an additional 14 days. The referring veterinarian also added psyllium to the food and recommended cleaning the environment with a quaternary ammonium compound. Two weeks later the fecal flotation remained positive for *G. duodenalis* cysts and so the dose of metronidazole was increased to 35 mg/kg, PO q12h for 5 days while continuing the fenbendazole. A CBC and a chemistry panel were performed in order to assess for evidence of underlying immunodeficiency. Abnormalities noted included a lymphocytosis (5311/μL; N = 690–4500/μL) and hypoproteinemia (total protein 4.7 g/dL: RR, 5–7.4 g/dL). Treatment with amoxicillin-clavulanate (for an additional 14 days), metronidazole (for an additional 5 days), and fenbendazole (for an additional 14 days) was continued. In the meantime, the consistency of the feces was still soft. Continued treatment with fenbendazole for 90 days was begun. However, the stool consistency remained soft and the next fecal flotation remained positive for *G. duodenalis*. At that time one of the authors (MRL) was consulted and it was recommended that the dog be evaluated for *Cryptosporidium* spp. co-infection. An FA confirmed that the dog was co-infected with *G. duodenalis* and *Cryptosporidium* spp. and tylosin was administered (11 mg/kg, PO, q12h for 28 days). By day 9 of treatment, stools were normal, and the dog was negative for both parasites by FA. The medication was discontinued and a week later the dog appeared to be healthy.

CASE EXAMPLE—cont'd

Comments

In general, giardiasis is more common in young, shelter and immunosuppressed animals. The dog described here was young and had evidence of pneumonia as well as the diarrhea which may have suggested the presence of an underlying immunodeficiency. Diarrheic dogs had a higher prevalence of co-infection with enteric pathogens whereas the non-diarrhea dogs had only single infections. Certain combinations of co-pathogens tend to arise, possibly associated with common factors that promote environmental survival, similar patterns of transmission, and/or host immunodeficiency factors. For example, co-infections with *G. duodenalis* and *Cryptosporidium* (dogs and cats) or *T. blagburni* (cats) have been commonly observed. Additionally, the pathogenic mechanisms and transmission routes of *G. duodenalis* and *Cryptosporidium* are similar.

Trichomonosis

M. Katherine Tolbert

KEY POINTS

- Cause: *Tritrichomonas blagburni* (also known as *Tritrichomonas foetus*); flagellate protozoan (phylum Sarcomastigophora, order Trichomonadida, class Parabasalia).
- First Described: Trophozoites that were likely to be *T. foetus* have been recognized in cat feces for many years, but *T. blagburni* was not definitely recognized as the primary cause of trichomonal diarrhea until 2003 (Levy).[1]
- Affected Host Species: Cats. Clinical signs of disease are most common in purebred or young cats that are housed or originate from high-density housing environments.
- Geographic Distribution: Although infections have not been documented in all countries, *T. blagburni* infection of cats is thought to have a worldwide distribution.
- Primary Mode of Transmission: Fecal-oral. There are no proven intermediate hosts, but *T. blagburni* can survive outside the host for several hours as well as survive transit through slugs, and so transport hosts are possible.
- Major Clinical Signs: Subclinical infections are common in high-risk cats. Continuous or intermittent large bowel diarrhea is most common in young, purebred cats. Swelling of the anus and fecal incontinence can occur.
- Differential Diagnoses: All causes of large bowel diarrhea, including *Cystoisospora* spp., food responsive disease, and inflammatory bowel disease. If motile trophozoites are noted on wet mount examination of feces, infections with *Giardia* spp. and *Pentatrichomonas hominis* are differential diagnoses.
- Human Health Significance: There are no known significant human health risks associated with *T. blagburni* infections of cats. However, two case reports of immunocompromised humans with *T. foetus* infections thought to be cattle or swine genotype suggest a zoonotic potential of trichomonads. Thus, cat feces should always be handled as if the possibility of zoonosis exists.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Members of the order Trichomonadida are flagellates that reproduce by binary fission and do not form true cysts (Fig. 102.1).[2,3] The trophozoite of *Tritrichomonas blagburni* is 10 to 26 µm long and 3 to 5 µm wide, spindle-to-pear shaped, and has three anterior flagella and a posteriorly directed flagellum (Fig. 102.2). A rigid, rod-shaped axostyle bisects the trichomonad and protrudes from the posterior end. In vertebrates, trichomonads are parasites of microaerophilic environments including the GI system, the reproductive system, and the upper portions of the respiratory tract. *Tritrichomonas blagburni* infects the reproductive tract of both cows and bulls and can cause abortion and other reproductive abnormalities. The organism resides as a commensal or parasite within the GI system of the cat and can be associated with diarrhea. Genetic characterization of bovine and feline *Tritrichomonas* spp. isolates has been performed, and minor differences exist.[4–6] Feline isolates of *T. blagburni* remained in the reproductive tract of heifers but did not cause the same pathologic changes as a bovine isolate in one study.[7] Similarly, a bovine isolate of *T. blagburni* did not cause diarrhea in cats as successfully as feline isolates.[8] Although a proposed name change has not been adopted by the American College of Veterinary Parasitologists, this lack of host specificity has led investigators to propose that the feline trichomonad is an entirely different species and should be renamed *Tritrichomonas blagburni*.[9] However, experimental infection of cats with the feline isolate also does not reliably reproduce disease.

Tritrichomonas blagburni is presumed to be transmitted by the direct fecal-oral route. The organism can survive for short periods of time in contaminated water, urine, feces, and cat litter,[10,11] although they do not persist under clean, dry, and aerobic conditions. Shared food bowls and litter boxes and mutual grooming likely contribute to transmission from one cat to another. In one study, the organism was shown to survive 30 minutes on dry cat food, several hours in moist cat food, and hours to days in cat feces.[10] The organism also survived transit through the GI tract of two types of slugs, which are known to eat cat feces.[12]

Cats that harbor *T. blagburni* infection have now been documented in multiple countries.[13–28] Cats in crowded environments and purebred catteries are commonly colonized; the organism is uncommon in feral cats. In one of the first large prevalence studies in the United States, 31% of 117 cats owned by 89 different breeders at an international cat show were colonized.[29] In the United Kingdom, 16 (14.4%) of 111 diarrhea specimens were positive for *T. blagburni* by PCR assay.[18] *Tritrichomonas blagburni*-associated diarrhea is most common in kittens and young cats, but adult cats can also be affected.[18,29] Catteries with a recent history of refractory diarrhea, adult cats with *Cystoisospora* spp. infections, and cats living in a facility with a small number of square feet per cat were more likely to be infected with *T. blagburni* in some studies.[18,29] Other co-infections, such as those with *Giardia* spp. and *Cryptosporidium* spp., may also increase the potential for disease.[30] Proximity of a cattery to agricultural species (pigs, cattle, horses), feeding of raw meat, type of water source, outdoor contact, or history of travel have not been identified as significant risk factors for *T. blagburni* infection in cats.

T. blagburni infection has only been identified in two dogs; these dogs were concurrently infected with *Giardia* or *Pentatrichomonas hominis*, respectively.[31,32] Thus, dogs are not considered to be natural hosts for *T. blagburni*.

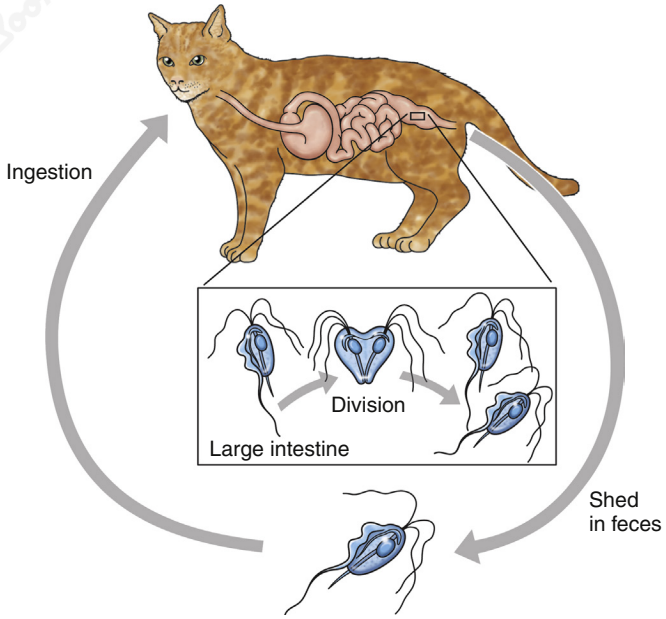

Fig. 102.1 Life cycle of *Tritrichomonas blagburni*. The organism has a direct life cycle, and the parasite replicates by binary fission.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Tritrichomonas blagburni is an obligate parasite, which like other trichomonads, resides in a nonsterile environment because it lacks many of its own metabolic pathways and, therefore, relies on the host and resident microorganisms for provision of nutrients. In experimentally infected cats, the location of *T. blagburni* is restricted to the terminal ileum, cecum, and colon where bacterial density is the highest.[33,34] Fluctuations in the colonic microflora or genetic and environmental factors may be necessary to produce the clinical signs in association with *T. blagburni* infection. The organism can persist in cats without diarrhea, and diarrhea can worsen without a change in the number of organisms present, suggesting that the underlying mechanisms that lead to diarrhea are multifactorial.[33] Other pathogenic factors associated with *T. blagburni* include adherence to host epithelium and elaboration of cytotoxins and proteolytic enzymes.[35–40] The organism adheres to the intestinal epithelium and incites a lymphoplasmacytic and neutrophilic inflammatory response.[34] An increased number of *T. blagburni* organisms and increased severity of diarrhea were associated with co-infection with *Cryptosporidium* spp. in one study.[33] However, co-infections are not always present in *T. blagburni*–associated diarrhea. There is little information available as to whether immunosuppression predisposes to chronic infection with *T. blagburni*. Administration of prednisolone did not change the fecal consistency or the frequency of positive results on direct fecal exams in one study.[33]

The clinical signs of trichomonosis are variable and range from subclinical infection to chronic intractable diarrhea. The signs often are intermittent and can resolve with antimicrobial drug treatment, only to recur after treatment is discontinued. The diarrhea is most commonly waxing and waning and large bowel in origin; characterized by increased frequency of defecation and passage of semi-formed to liquid, often foul-smelling feces, sometimes with fresh blood and mucus. When the diarrhea is severe, the anus may become edematous and fecal incontinence may develop (Fig. 102.3). Although diarrhea may persist, most affected cats maintain a good appetite and body condition score. Less frequently, but especially with poor care or housing conditions or co-infections, infected cats can have other clinical signs such as vomiting, dysrexia, abdominal pain, depression, and weight loss.[30]

Tritrichomonas blagburni was detected in the uterine contents of a cat with endometritis and pyometra.[41] However, the organism was not associated with infection or disease of the reproductive tract in a separate study of cats with *T. blagburni* infection that were housed in catteries.[42] The organism has also been identified in the nose of a young cat with chronic rhinitis.[43]

Physical Examination Findings

Cats solely infected with *T. blagburni* are generally in good body condition. Cats with co-infections or comorbidities may have poor body condition, abdominal pain, or depression.

DIAGNOSIS

Laboratory Abnormalities

Tritrichomonas blagburni infections are only rarely associated with systemic laboratory abnormalities. However, if the diarrhea is severe, decreases in potassium, sodium, and chloride concentrations may be present as a result of GI losses. Evaluation for co-infections and comorbidities in cats with more severe clinical signs or laboratory abnormalities is recommended. Further diagnostic evaluation of infected cats may include CBC; serum biochemical analysis; urinalysis; tests for viral infections such as FeLV, feline panleukopenia virus, and FIV; fecal flotation; *Giardia*-specific antigen testing; fecal direct FA for *Cryptosporidium*; molecular genetic testing for other feline enteric pathogens; and colonic mucosal biopsies. Commercial assays that detect fecal *Giardia*-specific antigen do not cross-react with antigens of *T. blagburni*.

Diagnostic Imaging

Abdominal radiographic or ultrasonographic abnormalities associated with *T. blagburni* infection are uncommon, nonspecific, and, when present, suggestive of diffuse colitis.

Microbiologic Tests

Trichomonads cannot be detected with fecal flotation methods. A direct wet mount cytology using fresh, unrefrigerated feces should be performed for all cats with large bowel or mixed diarrhea to evaluate for the presence of *T. blagburni* trophozoites (Table 102.1), using the technique described for *Giardia* (see Chapter 101). *Tritrichomonas blagburni* is similar in size to *Giardia* but can be differentiated by the presence of an undulating membrane, pear shape, a rapid forward motion, the lack of a concave surface, and a single nucleus. The trophozoite and its undulating membrane may also be identified on fecal smears stained with Diff-Quik stain using the high-dry (40-50× objective) or oil immersion microscopy. The sensitivity of direct cytology using specimens from naturally infected cats was only 14% in one study.[33] The sensitivity can be improved by analyzing multiple fresh fecal smears and by obtaining the fecal specimen from the proximal colon through fecal collection loop or colonic flush. Video clips that demonstrate how to perform the colonic flush technique and of the classic motility of the parasite can be found online (https://cvm.ncsu.edu/research/labs/clinical-sciences/tfoetus/#tabsPnl1-tab-1). *Tritrichomonas blagburni* is difficult to distinguish from *P. hominis*; however, infection with *T. blagburni* is more common, and *P. hominis* is generally easily eliminated with a short course of metronidazole.

If *T. blagburni* infection is still suspected after the initial work-up, culture can be performed using a commercially available culture system (InPouch TF, BioMed Diagnostics, White City, OR, USA). In this

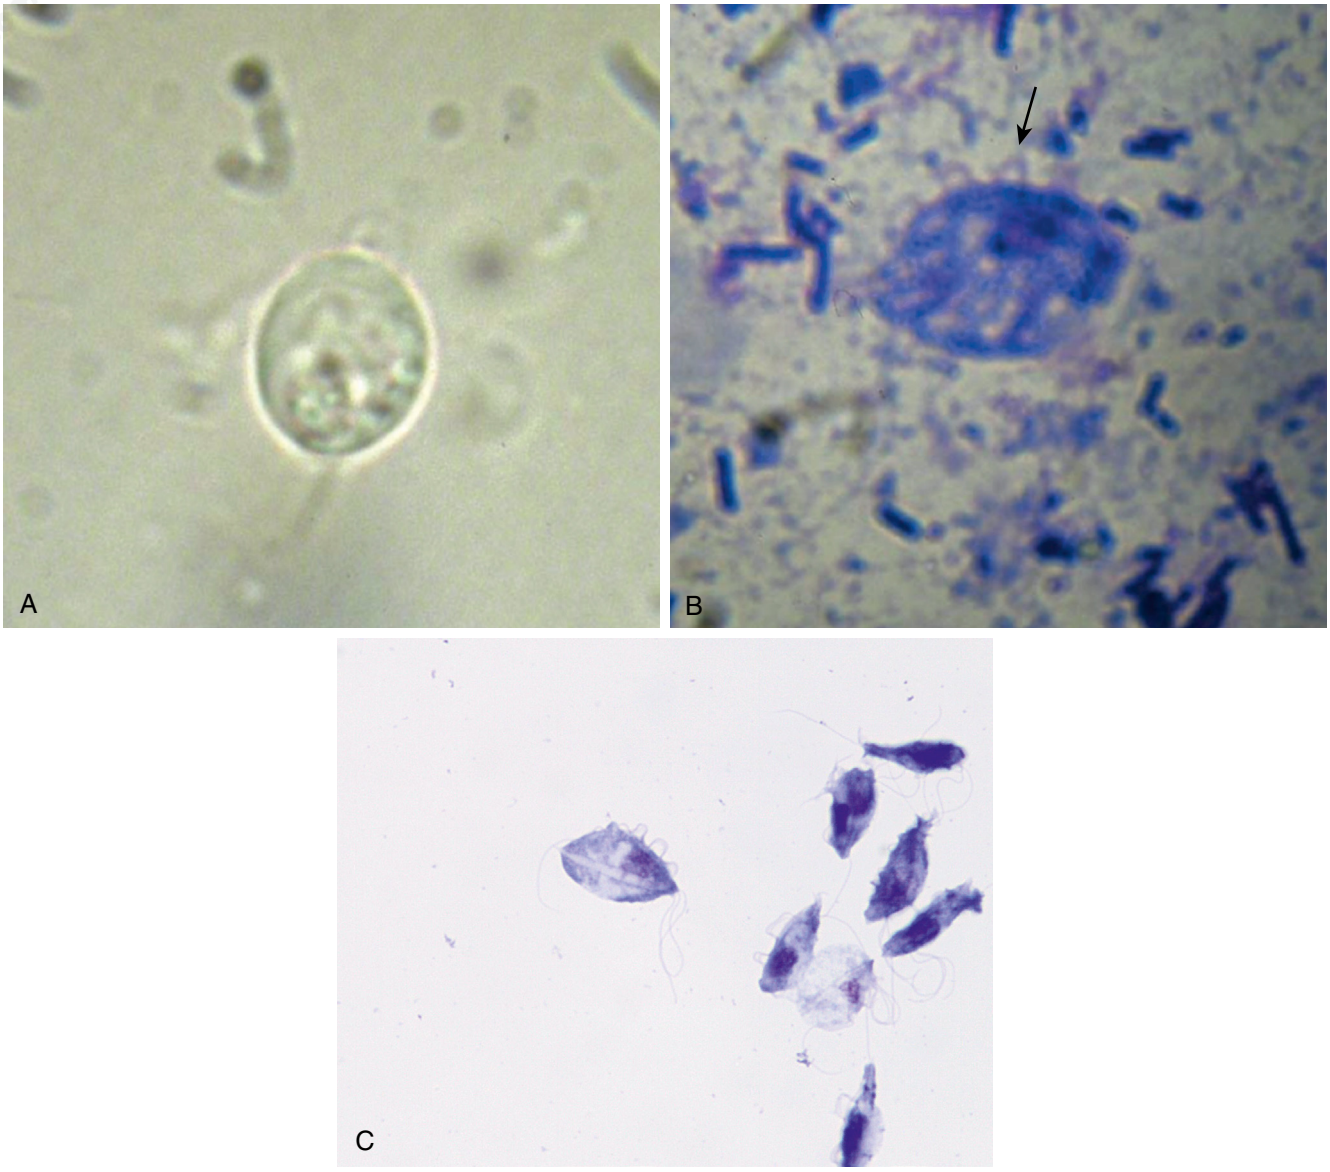

Fig. 102.2 (A) *Tritrichomonas blagburni* trophozoite seen on a saline wet mount of a fecal specimen. The organism can be recognized by its progressive forward, rolling motility. (B) Diff-Quik stain. The undulating membrane can be clearly visualized coursing along the lateral aspect of the trophozoite *(arrow)*. (C) Diff-Quik stain of a sample taken from an InPouch fecal culture. Several trichomonads can be observed. The undulating membrane, axostyle, and flagella can all be seen.

system, a tiny amount of fresh feces (~50 mg), obtained by the methods described above, is inoculated into the culture pouch. Inoculation with more feces than this can overwhelm the antibacterial agents in the culture pouch and bacteria will overgrow leading to a false-negative result. Shipment of fecal specimens to external laboratories is not recommended as the culture requires viable organisms and trichomonads often die in transit. If a fecal specimen must be transported to the clinic or diagnostic laboratory, removal of adherent litter and dilution with saline (3 mL 0.9% saline per 2 g of feces) is recommended to extend trichomonad survival.[16] The specimen should be evaluated within 6 hours of collection to preserve diagnostic sensitivity.[11] The culture pouch is incubated in an upright position in the clinic at room temperature, or preferably in a 37°C incubator, and examined daily by microscopy for evidence of protozoal growth. Positive results can occur within hours when incubated at 37°C or after several days (up to 12) when incubated at room temperature. The medium used does not support the growth of *Giardia* spp. and positive test results generally suggest infection by *T. blagburni*.[35] Rarely, *P. hominis* can be cultivated with the InPouch system.[44] Thus, positive results should be confirmed with microscopic visualization of the trichomonad (see Fig 102.2) (*P. hominis* has 5 anterior flagella) or by PCR. PCR assays are considered to be the gold standard method to diagnose *T. blagburni* infection. These assays are recommended for assessment of fecal specimens that were found negative by microscopy and fecal culture and to confirm that microscopically observed or cultivated organisms are *T. blagburni*.[31] Specimens obtained from non-diarrheic or dry stools are not suitable for use in testing for *T. blagburni* and rarely yield positive test results even if infection is present. Several PCR-based assays that are specific for *T. blagburni* and that do not amplify *Giardia* or *P. hominis* DNA are commercially available.[45] Thus, a positive PCR result from a reputable lab should be interpreted as positive for the infection. PCR can detect both viable and non-viable organisms and has a very good analytical sensitivity. The assay can detect as little as 10 *T. blagburni* organisms per 100 mg fecal specimen. However, PCR assays are

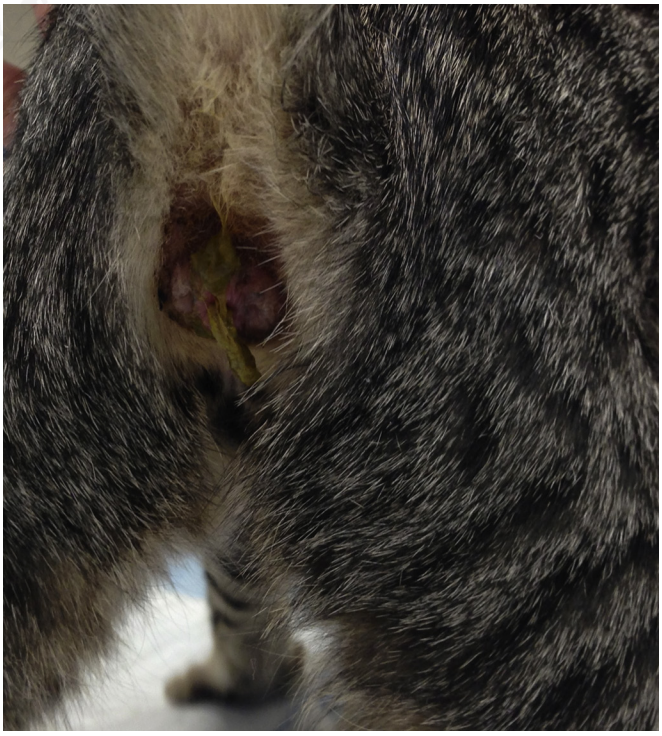

Fig. 102.3 Anal swelling and evidence of fecal incontinence in a kitten with suspected *Tritrichomonas blagburni* infection.

TABLE 102.1 Diagnostic Assays Available for Trichomonosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Feces	*Tritrichomonas* trophozoites	False negatives are common and occur when specimen size is small or low numbers of organisms are present, or because of intermittent shedding. The sensitivity of this method is < 20%.
Culture (InPouch test)	Feces	*T. blagburni*	May take days for the organism to grow. The sensitivity of this method is approximately 55%. False negatives can occur if feces are dried out, because of intermittent shedding or recent treatment with antiprotozoal drugs, or if the pouch is overgrown by intestinal bacteria.
PCR assays	Feces	*T. blagburni* DNA	The sensitivity and specificity of assays vary depending on assay design. Well-designed assays have the highest sensitivity of all diagnostic test methods, but false negatives can occur if specimen size is small or as a result of PCR inhibitors in feces.

TABLE 102.2 Drugs Commonly Used for Treatment of *Tritrichomonas blagburni* Infection in Cats

Drug	Dose	Route	Interval (Hours)	Minimum Duration (Days)
Ronidazole	30 mg/kg	PO	24	14
Tinidazole	30 mg/kg	PO	24	14

not 100% sensitive. In cases with a high index of suspicion for infection, repeat testing is recommended. For all microbiologic testing, the feces should be diarrheic, devoid of litter, and the cat should not have received antimicrobials (e.g., metronidazole, fenbendazole) within the 1–2 weeks before testing. Co-infections with organisms such as *Giardia* spp. in cats infected with *T. blagburni* are common; therefore, a positive result with any diagnostic test for *T. blagburni* does not preclude the possibility of a co-infection.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings associated with *T. blagburni* infection in cats are nonspecific and associated primarily with the colon and terminal ileum. The colon may be normal or appear mildly thickened with or without hyperemia.

Histopathologic Findings

Lesions associated with *T. blagburni* infection in cats are most prominent in the colon but can also be identified in the terminal ileum and cecum. The organisms are noted in most experimentally infected cats, but not in all sections.[34] Thus, if colonoscopy is performed, multiple specimens should be collected for histopathologic evaluation. The organisms are usually close to the mucosal surface and are associated with mild to severe lymphoplasmacytic and neutrophilic infiltrates; crypt epithelial cell hypertrophy, hyperplasia, and increased mitotic activity; loss of goblet cells; crypt microabscesses; and attenuation of the superficial colonic mucosa.[34] In some cats, *T. blagburni* may be detected in the lumen of colonic crypts and, less commonly, can invade the lamina propria. However, trichomonads are fragile and often difficult to preserve in intestinal biopsy specimens. It is advisable to indicate that *T. blagburni* is a diagnostic consideration when submitting specimens, as a minimum of six tissue sections should be examined to achieve at least 95% confidence that trichomonads will be identified.[34] *In situ* hybridization techniques have been used to identify *T. blagburni* and *P. hominis* in biopsy specimens.[46,47]

TREATMENT AND PROGNOSIS

The treatment of choice for *T. blagburni* infections is the nitroimidazole drug ronidazole (Table 102.2). Before ronidazole was discovered as an effective treatment, multiple other treatment regimens had been attempted in cats with *T. blagburni* infections with generally poor responses.[16,48] In some cases, temporary improvement was noted with a variety of drugs, but relapse was invariable. Some of the apparent clinical improvement may have been due to secondary effects of drugs on the intestinal bacterial flora, although treatment may also prolong trophozoite shedding.

A number of drugs have also been tested *in vitro* to determine *T. blagburni* susceptibility patterns.[49,50] Ronidazole has been the most effective drug used clinically to date and is currently recommended at a dose of 30 mg/kg, PO, q24h for 14 days.[51] Clinical signs can relapse after

administration of ronidazole, but generally resolve again after the treatment regimen is repeated. The pharmacokinetics have been determined for ronidazole in cats.[52,53] Higher doses of ronidazole and twice-daily dose regimens can result in neurologic signs such as ataxia and seizures.[54] This likely relates to the high oral bioavailability and slow elimination of the drug by cats.[52] Even with lower doses and once-daily regimens, cats should be monitored closely. To date, all reported cases of ronidazole-related neurotoxicity have been reversible, but irreversible neurotoxicity can occur in some cats. Signs of neurotoxicity may be easier to observe if the treated cat is engaged each day in a playful activity (e.g., chasing a laser pointer) that requires coordination and agility. If signs of toxicity are observed, owners should be advised to discontinue treatment with ronidazole. Continuing treatment after signs of toxicity are observed could result in life-threatening complications. If treatment must be discontinued because of neurotoxicity, the cat should be retested for *T. blagburni* infection. Many of these cats have received sufficient ronidazole, by the time toxicity ensues, to have cleared the infection.

Not all cats treated with high doses of ronidazole develop toxicity. In one study, a dose of 50 mg/kg, PO, q12h was used in research cats with no reported adverse effects.[55] Ronidazole is not approved by the US FDA for use in companion animals and is banned for use in food animals because of its teratogenic potential in humans. Accordingly, due diligence is required to protect humans from exposure to ronidazole, and veterinarians are advised to prescribe the drug only in cases of confirmed *T. blagburni* infection after obtaining the owner's informed consent. Ronidazole should not be used to treat pregnant or lactating queens or very young kittens. Likewise, caution is recommended with pregnant clients. Ronidazole should be obtained from a reputable compounding pharmacy and not pigeon supply warehouses because the latter may provide poor-quality preparations. Compounded chemical grade ronidazole is available from several online pharmacies. Compounding into gelatin capsules rather than liquid is recommended to avoid stability and taste concerns. A delayed-release (guar gum) formulation offers promise for targeted delivery of ronidazole to the colon and reduced likelihood of systemic adverse effects in cats.[53]

Some strains of *T. blagburni* are resistant to ronidazole.[56] Based on previous studies, approximately 60% of cats that are treated with ronidazole will have improvement or resolution of clinical signs.[57] Poor compounding can be another reason for failure of treatment in some situations. Other reasons for ronidazole failure include insufficient dose or duration of therapy, compliance failure, or re-infection from another cat in the household who may be asymptomatic. Other cats in the household/cattery should also be tested for *T. blagburni*. Ronidazole also has activity against *Giardia*.[58] However, to lessen the potential for selection of resistant strains, ronidazole should be reserved for use for *T. blagburni* infections, because multiple other drugs are effective for treatment of giardiasis.

Tinidazole, administered at 30 mg/kg for 14 days, suppressed *T. blagburni* shedding to undetectable levels in two of four cats during a 33-week period post-treatment.[49] However, this drug is currently considered inferior to ronidazole because infection was not eliminated in all cats. Veterinarians should be cautious in embracing the success of other antimicrobial drugs for treatment of *T. blagburni* infection because many drugs merely suppress detection of the organisms rather than eradicate them. Investigation into other treatments for feline trichomonosis including novel probiotics and protease inhibitors are ongoing. If owners elect not to treat for *T. blagburni* infection, the diarrhea will eventually spontaneously resolve in most cats (88%); however, this can take as long as 2 years.[16] Unfortunately, 55% of these cats remain infected based on positive PCR results for *T. blagburni* and, therefore, may be sources of infection for other cats. Owners of only one cat may find this outcome satisfactory if the cat remains healthy in other respects. However, in a cattery environment, subclinical carriers may perpetuate the infection.

IMMUNITY AND VACCINATION

Immunity to reinfection by *T. blagburni* does not occur in the short term after recovery. However, although intestinal infection can be prolonged, the development of effective immune responses as kittens mature can be followed by resolution of clinical disease. Vaccines for prevention of *T. blagburni* infection in cats are not currently available.

PREVENTION

Kittens in crowded environments are more susceptible to infection due to stress or immunologic immaturity. Thus, minimizing stress and reduction of population-dense housing conditions will likely reduce the chances of exposure to *T. blagburni*. Protocols for eliminating infections or lessening signs of *T. blagburni* infection in catteries involve testing, isolation or removal of cats that test positive, and retesting. Treatment with ronidazole does not guarantee cure even if repeated PCR assays are negative, and relapse of infection (or re-infection) can occur months after discontinuation of treatment. For this reason, re-introduction of treated cats to a cattery is not recommended.

PUBLIC HEALTH ASPECTS

Only two case reports of immunosuppressed humans infected with *T. foetus* have been reported.[59,60] The parasite was isolated from a bronchoalveolar lavage specimen in a patient with *Pneumocystis* pneumonia and from the bile of a patient with acquired agammaglobulinemia. The authors did not rule out the possibility of a human host-adapted strain of *T. blagburni*. However, because of the apparent poor host specificity of *T. blagburni* and the close contact between cats and humans, zoonotic transmission should be considered and infected kittens with diarrhea should be handled with care. In addition, the possible presence of other zoonotic pathogens should always be considered in cats with diarrhea.

CASE EXAMPLE

Signalment

"Belle," a 14-week-old intact female pixie-bob cat from Seattle, WA, United States.

History

Belle was considered a pet quality pixie-bob and so was sold into a private home at 14 weeks of age. The cattery had three queens and one tom and had bred at least six litters over the previous 2 years. No significant health problems were reported to the adoptive owner, and the cattery was retrovirus free. Belle appeared healthy the day the adoption was completed and was also pronounced healthy by the new attending veterinarian. The breeder had administered one dose of a vaccine for prevention of FHV-1, FCV, and FPV and a dose of pyrantel pamoate at 7 and 10 weeks of age. The veterinarian administered an attenuated live FVRCP vaccine subcutaneously, gave one dose of pyrantel pamoate, discharged Belle with selamectin to be applied monthly, and scheduled a re-check at 16 weeks of age for rabies vaccination. Belle was taken to her new home by car for 4 hours and then housed in her private room while attempting to socialize to the two black Labrador retrievers living at the new home. The kitten was not allowed to see the dogs the first 2 days, but the dogs were allowed to sniff under the door of the room Belle was housed in and occasionally

CASE EXAMPLE—cont'd

barked. On day 3, Belle began having diarrhea that the owner reported to be "pea soup" consistency, with white strands and fresh blood. Tenesmus was also noted.

Physical Examination

Body weight: 2.1 kg.
General: Quiet, alert, and responsive. Ambulatory on all four limbs. Body weight was 2.1 kg and BCS was 4/9. T = 101.3°F (38.5°C), HR = 180 beats/minute, RR = 24 breaths/minute, mucous membranes pink, CRT = 1 second. The only abnormality detected on physical examination was that the cat postured to defecate, and passed a small volume of diarrhea with streaks of blood and mucus when the caudal abdomen was palpated. Intestinal palpation was unremarkable.

Microbiologic Testing

Fecal wet mount examination: Motile flagellates noted with morphology and motility consistent with that of *T. blagburni*.
In-house *Giardia* ELISA assay (SNAP Giardia, IDEXX Laboratories): Negative.
Zinc sulfate centrifugal fecal flotation: Negative.
Tritrichomonas blagburni PCR: Positive.

Diagnosis

Tritrichomonas blagburni infection.

Treatment

Ronidazole at 30 mg/kg, PO, daily for 14 days was prescribed. The stool normalized 3 days later, and ultimately, Belle learned to tolerate Labrador retrievers. She was clinically healthy at the visit 2 weeks later for rabies vaccination. The breeder was informed of the findings, and it was recommended that the breeder discuss management of this agent in the cattery with a veterinarian.

Comments

The findings were characteristic of a stress-activated *T. blagburni* infection associated with moving to the new home and first contact with dogs. Many cats in catteries maintain subclinical infections that may be followed by clinical signs of large bowel diarrhea when the infected cats are subjected to stress. While *T. blagburni* can be amplified by PCR assay or grown from feces of dogs, it is unlikely that healthy adult dogs will become clinically ill, and so no tests or treatments were performed on the family dogs.

Cryptosporidiosis and Cyclosporiasis

Valeria Scorza, Michael R. Lappin

KEY POINTS

Cryptosporidiosis

- First Described: The genus *Cryptosporidium* was first described in 1910 by Tyzzer, who in 1912 also described *Cryptosporidium parvum* in the small intestine of mice.[1]
- Cause: *Cryptosporidium* is a ubiquitous coccidian genus in the phylum Apicomplexa, suborder Eimeriorina, family Cryptosporidiidae, which inhabits the epithelium of the respiratory and digestive systems of reptiles, birds, and mammals. Based on extensive biological and molecular data, *Cryptosporidium* has been recently transferred from the Coccidia, to a new subclass, Cryptogregaria, with gregarine parasites.[2]
- Affected Hosts: Mammals, birds, and reptiles.
- Intermediate Hosts: Although there are no intermediate hosts, there are multiple potential transport hosts that may carry *Cryptosporidium* spp. oocysts and indirectly infect dogs or cats.
- Geographic Distribution: Worldwide.
- Route of Transmission: Direct contact with infected humans and animals, drinking contaminated water during recreational activities, or by eating or drinking contaminated food.
- Major Clinical Signs: *Cryptosporidium* spp. have been detected in dogs and cats with and without GI signs of disease. Clinical signs include diarrhea, usually small bowel characterized by high volume, low-frequency stools, and significant weight loss.
- Differential Diagnoses: Dietary, nematode parasitic, viral, and bacterial diarrhea.
- Human Health Significance: *Cryptosporidium parvum* was the cause of numerous waterborne outbreaks. The majority of the infections in humans are caused by *Cryptosporidium hominis* and *C. parvum*. However, *Cryptosporidium canis* and *Cryptosporidium felis* DNA has also been amplified from the feces of people, and so the potential for zoonotic transmission exists (see Public Health Aspects).

Cyclosporiasis

- Causes: *Cyclospora* (phylum Apicomplexa, suborder Eimeriorina, family Eimeriidae) was first described in 1993.[3]
- Affected Hosts: Although *Cyclospora cayetanensis* oocysts have also been identified in animals, currently *C. cayetanensis* is the only species known to infect humans.
- Geographic Distribution: *Cyclospora* infections have been described worldwide. In many non-industrialized countries, infections are endemic. Sporadic reports associated with outbreaks occur in industrialized countries.
- Primary Mode of Transmission: Ingestion of contaminated food and water.
- Major Clinical Signs: Clinical illness, if any, in dogs and cats is uncertain, because definitive oocysts have been documented only in human feces. Infected humans can develop anorexia, nausea, watery diarrhea, flatulence, fatigue, abdominal cramping, low-grade fever, fatigue, and weight loss after *C. cayetanensis* infection; the most severe symptoms develop in children and in humans with HIV/AIDS.
- Differential Diagnoses. Dietary, nematode parasitic, viral, and bacterial diarrhea.
- Human Health Significance: *Cyclospora cayetanensis* seems to be the only species detected in humans, and they seem to be its specific host. However, contact with animals was considered a risk factor for human infection in many studies worldwide.

CRYPTOSPORIDIOSIS

ETIOLOGY AND EPIDEMIOLOGY

The majority of *Cryptosporidium* spp. are host-adapted and have a narrow spectrum of natural hosts (Tables 103.1, 103.2, and 103.3). Most studies report that dogs and cats are infected with the host-specific *Cryptosporidium canis* and *Cryptosporidium felis*, respectively. *Cryptosporidium muris* and *Cryptosporidium ubiquitum* have also been detected in the feces of naturally infected dogs.[4-6] More recently, the DNA of *Cryptosporidium hominis* was detected in the feces of a dog in Spain.[7] *Cryptosporidium parvum*, *C. muris*, *Cryptosporidium ryanae,* and a novel genotype related to *Cryptosporidium* rat genotype III were detected in a small number of cats.[8-12]

Prevalence rates of *Cryptosporidium* spp. in cats and dogs vary worldwide depending on the test used and the population studied (Tables 103.4 and 103.5). Infection occurs after oocysts are ingested directly (coprophagia or grooming) and indirectly (ingesting the oocysts in contaminated food or water, or after ingesting infected prey species). After ingestion, oocysts excyst in the GI tract, releasing infective sporozoites, which become enclosed as trophozoites within parasitophorous vacuoles of the microvillous surface of enterocytes (Figs. 103.1 and 103.2).[13] The trophozoites proliferate asexually by merogony to produce, sequentially, two types of meronts. Type I meronts leave the parasitophorous vacuoles to invade other epithelial cells where they develop into more type I meronts or type II meronts. Type I meronts are capable of recycling indefinitely and type II meronts produce sexual reproductive stages. The zygotes formed by sexual reproduction form either thick-walled or thin-walled oocysts, each containing four sporozoites. Approximately 20% of the oocysts produced in the gut are "thin-walled" oocysts that fail to form an oocyst wall. Instead, a series of membranes surround the developing sporozoites. Thus, *C. parvum* appears to have two autoinfective cycles: by continuous recycling of type I meronts, and by sporozoites released from ruptured thin-walled

TABLE 103.1 *Cryptosporidium* Species and Host Range

Host	Tier 1 Species	Tier 2 Species	Tier 3 Species
Humans	*Cryptosporidium hominis*, *Cryptosporidium parvum*	*Cryptosporidium meleagridis*, *Cryptosporidium felis*, *Cryptosporidium canis*, *Cryptosporidium ubiquitum*, *Cryptosporidium cuniculus*, *Cryptosporidium viatorum*, chipmunk genotype I, *Cryptosporidium muris*	*Cryptosporidium andersoni*, *Cryptosporidium suis*, *Cryptosporidium bovis*, horse genotype, *Cryptosporidium xiaoi*, skunk genotype, mink genotype, *Cryptosporidium erinacei*, *Cryptosporidium fayeri*, *Cryptosporidium scrofarum*, *Cryptosporidium tyzzeri*
Cats	*C. felis*	*C. muris*	*C. parvum*, *Cryptosporidium ryanae*, rat genotype III
Dogs	*C. canis*	*C. parvum*, *C. muris*	*C. scrofarum*, *C. ubiquitum*, *C. hominis*
Cattle	*C. parvum*, *C. bovis*	*Cryptosporidium ryanae*, *C. andersoni*	*Cryptosporidium occultus*, *C. xiaoi*, *C. ubiquitum*
Sheep and goats	*C. xiaoi*, *C. ubiquitum*	*C. parvum*	*C. andersoni*
Pigs	*C. suis*, *C. scrofarum*	*C. muris*	
Camels	*C. andersoni*, *C. muris*	*C. parvum*	
Horses and donkeys	Horse genotype, *C. parvum*, *C. hominis*	*C. andersoni*	*C. muris*, *C. tyzzeri*, *C. felis*(?), *C. proliferans*
Rabbits	*C. cuniculus*	-	-
House mouse	*C. tyzzeri*, *C. muris*	*C. parvum*	-

Tier 1 species: *Cryptosporidium* spp. that are responsible for over 90% of infections in the specified host.
Tier 2 species: *Cryptosporidium* spp. that have been each reported in at least five cases.
Tier 3 species: *Cryptosporidium* spp. for which detection has been each reported in fewer than five cases.

C. canis (2), *Cryptosporidium scrofarum* (1)	Greece[150]
C. parvum (7), *C. canis* (1)	Italy[160]
C. canis (15)	Japan[161-163]
C. canis (7), *Cryptosporidium hominis* (1)	Spain[7,153]
C. canis (2)	Thailand[155]
C. canis (7), *C. parvum* (1)	United States[15,74,155,164]

oocysts.[13] The thick-walled oocysts are passed in the feces and into the environment.

Cryptosporidium spp. oocysts are sporulated when passed in feces, so they are immediately infectious. *Cryptosporidium felis* oocysts are excreted in the feces 3 to 6 days after infection. The number of oocysts excreted by cats as estimated by quantitative PCR ranges from 175 to 1.1×10^5 oocysts/g of feces with a median of 3.5×10^3 oocysts/g.[12] *Cryptosporidium felis* and *C. canis* oocysts are similar in size; *C. felis* oocysts are 5 μm × 4.5 μm and *C. canis* oocysts are 4.95 μm × 4.71 μm.[14,15]

Risk factors for excretion of *Cryptosporidium* oocysts are living in crowded environments (shelters, pet shops), living in the same household of a cat excreting *Cryptosporidium* oocyts and *Giardia* cysts, contact with livestock, and drinking untreated water.[16-22]

Specific pathogen–free cats developed chronic infection after being inoculated with *C. parvum* but these cats showed minimal clinical signs of disease, even after the administration of glucocorticoids.[23]

Cryptosporidium parvum infection (of bovine origin) developed in inoculated dogs and cats.[24] Dogs experimentally infected with *C. muris* oocysts rarely developed infections.[25] However, when *C. muris* was administered to three kittens, a large number of oocysts were excreted for extended periods.[14] In another study, puppies and kittens experimentally inoculated with *C. parvum* excreted oocysts after a prepatent period of 2 to 14 and 2 to 11 days, respectively.[26] Patent periods lasted 3 to 33 days in puppies and 2 to 25 days in kittens. None of the infected animals showed clinical illness.[26] In a 2018 study, immunocompetent dogs, immunocompromised dogs, and mice were experimentally infected with *C. canis* oocysts.[27] *Cryptosporidium canis* was not infective for immunocompetent dogs or mice with severe immunodeficiency syndrome, and immunosuppressed dogs started excreting oocysts on day 3 PI with levels peaking on days 10 and 17 PI.[27] In the same study, only the immunocompromised dogs showed lethargy and diarrhea around day 8 PI.[27]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

There is little information regarding the pathogenesis of *C. felis* or *C. canis* in cats and dogs. Most evidence is from research done in humans, mice, and cattle after infection with *C. parvum*. *Cryptosporidium* spp. cause diarrhea by intestinal malabsorption of electrolytes and nutrients with hypersecretion of chloride and water.[28] The pathologic changes are caused by both the parasite factors and the host immune response against the organism. *Cryptosporidium* causes damage by attaching to host cells, penetrating the epithelium, altering the cytoskeleton, inducing apoptosis, and secreting virulence factors.[29] After infection, *Cryptosporidium* sporozoites attach to the intestinal epithelium between the cell membrane and the cell cytoplasm; this extracytoplasmic location may explain their resistance to chemotherapy.[30] Different proteins are involved in adhesion, binding, invasion, and attachment of the epithelial cells.[31] *Cryptosporidium* is intracellular but can be considered "minimally invasive," because it does not penetrate into deeper mucosal layers. However, in immunosuppressed individuals infection can spread to the epithelial cells of the biliary tract, pancreatic duct, stomach, esophagus, and respiratory tract.[29] It was suggested that *Cryptosporidium* parasites regulate gene expression of the host cells by modulating apoptosis, inhibiting the process at the trophozoite stage, and promoting it at the sporozoite and merozoite stages.[32] Cellular damage is also caused by loss of barrier function, increased rates of cell death, and the release of several enzymes and hemolysins.[29] Some protozoan parasites carry small double-stranded RNA (dsRNA) viruses, which might influence the virulence of the parasites that carry them.[29] *Cryptosporidium parvum* carries the virus *Cryptosporidium parvum* virus 1 (CSpV1) (genus *Cryspovirus*, family *Partitiviridae*) and is considered to be associated with fecundity and virulence.[33]

Regarding the host immune response, recognition of *Cryptosporidium* by receptors activates the immune response leading to induction of the expression of proinflammatory cytokines and chemokines. IFN-γ is an important cytokine secreted early in infection by natural killer (NK) cells, macrophages, and dendritic cells, which are thought to play a major role in arranging the innate and adaptive immune responses.[34] In addition, the intestinal microbiota is essential in maintaining intestinal homeostasis. A study that compared the gut microbiota of *C. parvum*–infected mice and controls reported that the parasite causes slight but significant alteration of the native intestinal microbiome.[35] The severity of cryptosporidiosis is highly dependent on the host immune response. The prevalence is usually higher in young individuals due to their immature immune system; however, not all forms of immune suppression lead to increased severity of cryptosporidiosis. Individuals with T cell immunodeficiency disorders are particularly at risk. In contrast, immune deficiencies that affect B cell function have not been associated with increased severity of cryptosporidiosis.[29]

Cryptosporidium spp. have been detected in dogs and cats with and without GI signs of disease. Host immunity is likely important in the development of infection and clinical illness following exposure to cryptosporidia, although the association with risk factors has been confusing. Because of the isolation of cryptosporidia from clinically healthy animals, finding the organism in an animal with clinical illness must always be viewed with caution as an indication of a direct role of the parasite. Clinical signs include diarrhea, usually small bowel characterized by high volume, low-frequency stools, and significant weight loss (Fig. 103.3). Fresh blood, tenesmus, and discomfort can be reported in some chronic cases.[14,36-39] Vomiting is uncommon in cats with cryptosporidiosis unless concurrent abnormalities exist. Most of the published cases with diarrhea and *Cryptosporidium* spp. infection have been immunosuppressed, had preexisting disease of the intestines, co-infections, or chronic diarrhea.[40-44] In cats with co-infections, it was difficult to determine if *Cryptosporidium* spp. were the primary cause of the observed clinical signs. *Cystoisospora* spp., *Toxocara cati,* coronavirus, *Giardia*, *Tritrichomonas blagburni*, and *Campylobacter* have been documented as co-pathogens in cats with *Cryptosporidium* spp. in feces and diarrhea.[43,45-49] However, co-infection with other parasites also has been reported in healthy cats with *Cryptosporidium* spp. infections.[45] Non-infectious diseases associated with cryptosporidiosis in cats are lymphoma and inflammatory bowel disease.[40,50]

Cryptosporidium was detected in puppies with diarrhea that had co-infections with CPV, CDV, and parasites, as well as dogs with lymphoma.[51-53] Intestinal malabsorption was reported in an adult dog with cryptosporidiosis.[54] *Cryptosporidium muris* infection was identified in the stomach of a dog that had a chronic history of vomiting and profuse diarrhea that was observed during physical examination.[55] The histopathologic findings of stomach biopsy revealed gastritis associated with cryptosporidia and bacteria compatible with *Helicobacter* spp. The dog was treated empirically for gastric helicobacteriosis with metronidazole and omeprazole and had clinical improvement during a 6-week follow-up period.

Physical Examination Findings

Most dogs or cats colonized with *Cryptosporidium* spp. have a normal physical examination. On abdominal palpation, small intestines may feel slightly thickened. Because some dogs or cats with *Cryptosporidium* spp. infection and diarrhea have had underlying

TABLE 103.6 Diagnostic Assays Available for Cryptosporidiosis in Dogs or Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Feces	*Cryptosporidium* oocysts	Modified acid-fast staining has an approximately 70% sensitivity and so false negatives are common. However, the technique is more sensitive than fecal flotation.
$ZnSO_4$ centrifugal fecal flotation	Feces	*Cryptosporidium* oocysts	The small size of the oocysts and small numbers shed by dogs and cats makes this an inadequate screening procedure. The sensitivity is unknown but may be as low as 10%.
Direct FA assay	Feces	*Cryptosporidium* oocysts	Direct FA assays are available that detect both *Cryptosporidium* spp. oocysts and *Giardia* cysts. Morphology as well as fluorescence can be evaluated and so this assay is considered by most to be the gold standard. The assay appears to detect *C. felis* and *C. canis*. The sensitivity of the assay is > 70% but false negatives can occur because oocysts numbers fluctuate.
PCR assays	Feces	*Cryptosporidium* DNA	The sensitivity and specificity of assays may vary depending on assay design. Well-designed assays have the highest sensitivity of all diagnostic test methods, but false negatives can occur if low numbers of oocysts are shed, the specimen size is small, or as a result of PCR inhibitors in feces. Use of PCR as a screening assay will result in detection of many subclinical infections.

diseases or co-infections, physical examination findings may reflect the presence of these conditions.

DIAGNOSIS

The etiologic predictive value of all assays for *Cryptosporidium* spp. is low since there is a relatively high prevalence of infection in healthy dogs and cats. Diagnostic tests for *Cryptosporidium* spp. infection are summarized in Table 103.6.

Microbiologic Testing

Fecal Microscopic Examination

Cryptosporidium oocyst shedding can be sporadic, so a negative assay result does not exclude the infection. Cats and dogs generally shed relatively few oocysts. Naturally infected cats with and without diarrhea shed approximately 1817 oocysts/g of feces and 191 oocysts/g of feces, respectively.[46] In comparison, infected calves, less than 21 days old, shed a mean of 90,867 oocysts/g of feces.[56]

Concentration techniques. The threshold of detection of *Cryptosporidium* oocysts was 10^6 oocysts/g of feces using unconcentrated fecal smears.[57] Oocyst concentration procedures such as Sheather's sucrose flotation, zinc sulfate flotation, and saturated sodium chlorine methods are needed to increase the test sensitivity.[58] The consistency of the feces also affects the detection rate. For 100% test sensitivity in formed fecal specimens, 50,000 oocysts/g of feces were needed for positive results with FA examination, whereas 500,000 oocysts/g of feces were needed for acid-fast stain detection.[59] However, cats and dogs generally only shed 10^3 oocysts/g of feces, and even concentration procedures are considered insensitive for detecting infection.

Nonspecific direct oocyst staining techniques. Because oocysts are slightly smaller compared with erythrocytes, and because they are transparent, unstained preparations using conventional light microscopy make accurate identification difficult (Fig. 103.4). The stains more commonly used are safranin-methylene blue stain, Kinyoun, modified Ziehl-Neelsen (MZN), and dimethyl sulfoxide carbol fuchsin (Fig. 103.5). The average detection limit using MZN stain after concentration of human feces was 5×10^5 oocysts/g.[59] However, since cats and dogs shed only low numbers of oocysts, this technique may not be very sensitive in those species.

Immunostaining methods. Direct FA detection procedures, using monoclonal antibody reagents, can be more sensitive and specific than acid-fast or other staining methods. In one study using human feces, the average detection limit using MZN was 5×10^5 oocysts/g of feces and the threshold of detection using direct FA was 5×10^4 oocysts/g of feces.[59] The disadvantage compared to other staining procedures, is that direct FA has a higher cost and requires a fluorescent microscope.

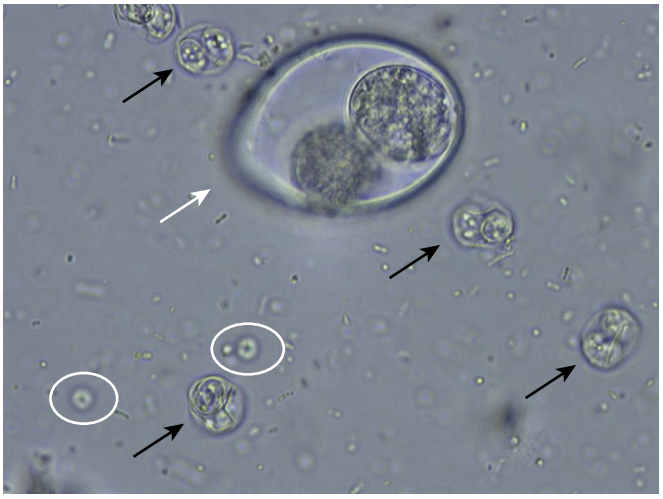

Fig. 103.4 Fecal flotation from a cat that was co-infected with *Toxoplasma gondii*, *Cystoisospora felis*, and *Cryptosporidium felis*. The image is magnified approximately 2000×. The *black arrows* are sporulated *T. gondii* oocysts; the *white arrow* shows *Cystoisospora felis*; the *white circles* surround *Cryptosporidium felis* oocysts.

A commercially available direct FA test kit (Merifluor *Cryptosporidium/Giardia*, Meridian Bioscience, Inc., Cincinnati, OH), which simultaneously detects *Giardia* cysts and *Cryptosporidium* oocysts, has been evaluated for use in dogs and cats. In one study, this assay had a lower sensitivity than MZN staining when a single fecal specimen from a cat was tested.[60] However, the sensitivity of direct FA was the same as that of MZN when 2 to 4 consecutively collected specimens were tested. In this study, oocyst fluorescence intensity varied from an intense apple-green to a weak green fluorescence. This direct FA test has been titrated using *C. parvum* oocysts in human feces, and the variation in oocyst fluorescence may be due to antigenic diversity within *Cryptosporidium* spp. or to infection with more than one *Cryptosporidium* species.[60] Unfortunately, the

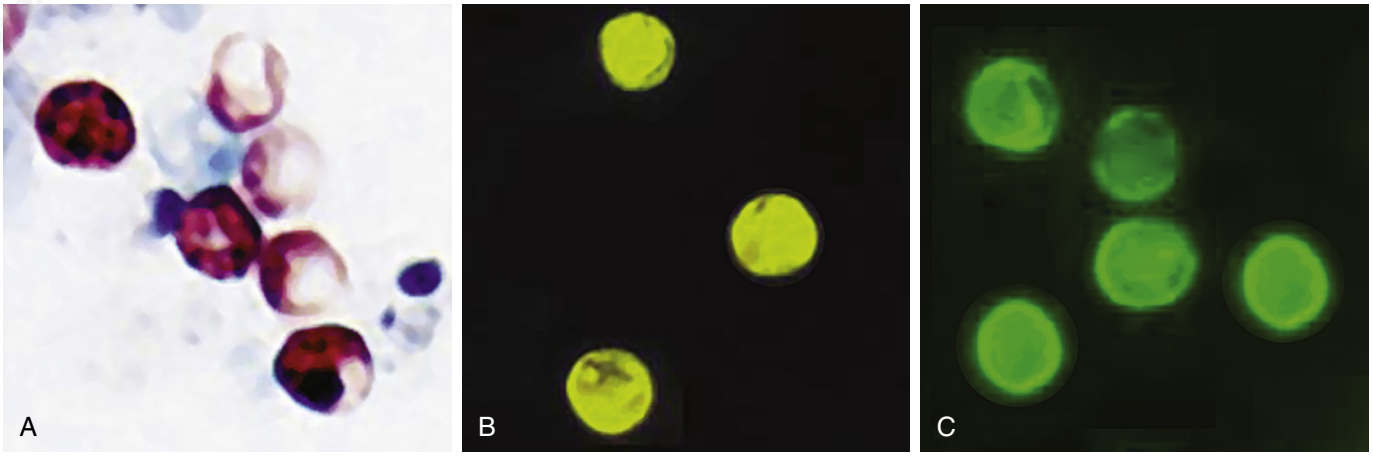

Fig. 103.5 *Cryptosporidium* is detected by demonstration of organisms in fecal specimens. This can be done using immunoassays for antigen, by microscopic detection of the organisms, or by nucleic acid amplification. Because the organisms are similar in size and shape to erythrocytes and yeasts that are normally found in feces, differential stains are required to identify the organism. These can include modified acid-fast stains (A), which stain oocysts red because they retain carbol fuchsin after decolorizing with alcohol; fluorescent stains, such as auramine-rhodamine (B), or immunofluorescent antibody stains (C) (green organisms). (From the Centers for Disease Control and Prevention).

Cryptosporidium species infecting the cats in that study were not determined. However, when the same feline specimens were tested with a polyclonal antibody, a higher sensitivity was achieved, indicating that antigenic differences exist among *C. parvum* of humans and species infecting cats.[60]

The direct FA method had a sensitivity threshold of around 10^4 to 10^5 oocysts/g of feces when used with *C. parvum*–spiked feline feces.[23]

Fecal Antigen ELISA-Based Assays

A number of different ELISA-based tests are available for detection of *C. parvum* antigen in feces. The available assays were titrated for use with human feces; therefore, sensitivity and specificity of each assay for use with dog or cat feces is unknown. The sensitivity of three fecal ELISAs and direct FA tests were compared to MZN staining.[61] Using specimens collected on day 1 of the study, the sensitivity of the three ELISA methods were 89%, 80%, and 15%. The sensitivity of these assays increased when specimens from two consecutive days were examined.[60] In another study, a comparison was made between the sensitivity of a fecal ELISA kit and carbol fuchsin stain in the detection of *Cryptosporidium* in canine and feline specimens.[62] Of 270 dog specimens, 26 (9.5%) had positive test results for *Cryptosporidium* by microscopy and 8 (3.0%) specimens had positive test results with the fecal ELISA.[62] In the same study, none of 100 cats had positive results for *Cryptosporidium* using microscopy, but 22 of 100 cats had positive results using fecal ELISA. Since observation of organisms using microscopy is considered the reference standard, it is unknown whether the ELISA results of this study were falsely positive.[38,39,62] In general, in humans, ELISA methods have had lower specificity (90.3% to 100%) when compared to direct FA.[63] When human-based ELISA test kits were applied to cat specimens, specificities were high (> 99%), but sensitivities ranged from 72.7% to 91.2% compared to direct FA.[64] Two lateral-flow POC devices for detection of *C. parvum* in human feces were insensitive for the detection of *Cryptosporidium* spp. in feline feces.[65] This may relate to antigenic differences between *C. felis* and *C. parvum*.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Some studies report increased sensitivity of PCR when compared to microscopy and immunological-based techniques in clinical specimens from humans.[57,66-68] PCR has been used to amplify *Cryptosporidium* spp. DNA in feline feces, and was more sensitive than IFA.[23,57,67] A variety of PCR assays are available for detection of *Cryptosporidium* spp. DNA in feline and canine feces, including quantitative PCR panels that also detect other common GI pathogens. A positive test result does not prove that *Cryptosporidium* cause illness, because subclinical infections are common. Therefore, PCR is not considered valuable as a first-choice test for diagnosis of cryptosporidiosis in dogs or cats with diarrhea. In addition, nucleic acid–based assays are not recommended for diagnosis of *Cryptosporidium* spp. infection in clinically healthy dogs or cats (see also Public Health Aspects, later).

Serologic Diagnosis

Detection of serum antibodies has been used in a limited number of prevalence studies.[69-71] In experimentally infected cats, *C. parvum*–specific IgG was detected 4 weeks post inoculation.[71] When the results of this ELISA were compared with the presence of oocysts in feces by zinc sulfate flotation and acid-fast staining, the sensitivity, specificity, positive predictive value, and negative predictive value were 50%, 85.5%, 7.7% and 98.6%, respectively.[72] In the same study, 26 of 170 cats (15.3%) had seropositive results for *C. parvum* IgG, but only 4 of 170 cats (2%) had oocysts in feces.[72] Many cats with acute infection and diarrhea are likely to be seronegative, and it is feasible that *Cryptosporidium* IgG titers will persist for months or years as the organism is difficult to eliminate.[72] Thus, the presence of *C. parvum*–specific IgG in cat serum suggests prior infection but does not correlate highly with oocyst excretion. *Cryptosporidium* spp. infections often persist at low levels for years in some animals and so it is possible that antibody test results do not correlate to presence of oocysts in studies because of false-negative test results in fecal assays. In dogs, antibodies to *Cryptosporidium* were detected by indirect FA in 16 of 20 (80%) blood samples in one study suggesting that exposure to the

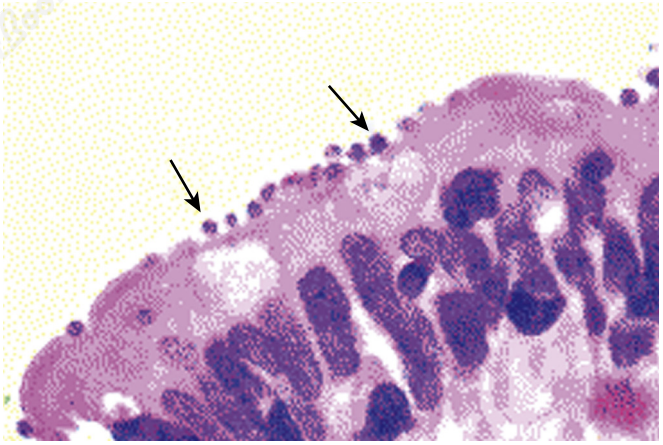

Fig. 103.6 *Cryptosporidium (arrows)* in intestine from an infected human is characteristically located at the microvillous border (hematoxylin and eosin stain). (From Petri WA. Therapy of intestinal protozoa. *Trends Parasitol.* 2003;19:523-526.)

TABLE 103.7 Drug Therapy for *Cryptosporidium* Infections in Cats and Dogs

Drug[a]	Species	Dose[b]	Route	Interval (Hours)	Minimum Duration (Days)
Azithromycin[c]	D	5–10 mg/kg	PO	12	5–7
	C	7–15 mg/kg	PO	12	5–7
Nitazoxanide	B	25 mg/animal	PO	12	5
Paromomycin[d]	B	125–165 mg/kg	PO	12–24	5
Tylosin	B	10–15 mg/kg	PO	8-12	21

[a]See Chapter 10 for specific information on drugs.
[b]Dose per administration at specified interval.
[c]Dose for systemic infections; effective level for the disease has not been established.
[d]Can be nephrotoxic and of uncertain efficacy. Never use where bloody diarrhea is observed, because the drug may be absorbed systemically.
B, both dog and cat; *C*, cat; *D*, dog

organism may be common.[71] There is no information available concerning the use of *C. canis* or *C. felis* as the antigen source in different antibody assays as previous studies used either *C. parvum* or unknown *Cryptosporidium* spp.

Intestinal Biopsy

Intestinal biopsy is costly, time-consuming, and lacks sensitivity for diagnosis of cryptosporidiosis. Specimens may be fixed in Bouin's or formalin solutions within hours after being collected. Giemsa and routine H&E stains are effective in highlighting organisms (Fig. 103.6). In naturally infected cats, loss of microvilli, degeneration of host epithelial cells, and atrophy of the villi in heavy infections, which may predispose to malabsorption or other GI dysfunction, have been documented.[40,41,73] Moderate small intestinal lymphocytic infiltrates were detected in one cat infected with *Cryptosporidium* spp. with no evidence of concurrent infection.[40] Histological findings in infected dogs included severe crypt damage with hyperplasia, dilation, marked villous atrophy, and loss of glands from the mucosa; the lamina propria has been infiltrated with lymphocytes, plasma cells, and neutrophils.[27] In dogs that were experimentally infected with *C. canis* and treated with dexamethasone acetate (6 mg/day 5 days PI), histopathologic changes consisted of epithelial metaplasia and dilation and damage to the integrity of the intestinal mucosal epithelial cells with widespread cilial atrophy.[27] Using scanning electron microscopy, *C. canis* in various developmental stages was found adherent to the surface of the duodenum and jejunum.[27] No parasites were found in the ileum, cecum, or stomach[27]; however, in one report involving an infected puppy, *C. canis* was most predominantly found within the stomach.[74]

TREATMENT AND PROGNOSIS

Treatment options for cryptosporidiosis remain limited. Many compounds with potential anti-*Cryptosporidium* activity have been evaluated in people, cattle, and mice and none consistently controlled clinical signs of disease or eliminated infection. One of the reasons proposed for lack of drug activity appears to be the unique location of the parasite in the parasitophorous vacuole, which separates it from the epithelial cell cytoplasm.[75] Because of this, supportive care and restoration of host immune response remains the mainstay of treatment in human patients.[75]

There are only a few published reports of treatment for cryptosporidiosis in cats and dogs. As a result, treatment suggestions described here are anecdotal (Table 103.7). Furthermore, some clinical responses to treatment may be due to drug activity on co-pathogens in naturally exposed cats since the presence of cryptosporidia can be an incidental finding. Therefore, only drugs with known anti-cryptosporidial activity are listed in Table 103.7. Clindamycin hydrochloride (25 mg/kg PO q24h) was administered to a cat with chronic cryptosporidiosis and lymphocytic duodenitis.[40] After 60 days of therapy there was no further improvement in stool consistency and oocysts were still detected. Tylosin was then administered (11 mg/kg PO q12h for 28 days) and stools were normal within a week of initiating therapy; *Cryptosporidium* spp. oocysts were no longer detected over a period of 6 months, intestinal inflammatory lesions resolved, and the cat remained apparently healthy for a follow-up time of 2 years after treatment. Other cats with presumed cryptosporidiosis were treated with tylosin (10 to 15 mg/kg PO q12h for 21 days), and diarrhea had resolved in about 50% of animals.[76] These observations are uncontrolled, and the signs in affected cats may have resolved spontaneously. Because tylosin has only questionable antiprotozoal effect, it is possible that its anti-inflammatory or antibacterial effects played a role in the beneficial clinical responses. Neither clindamycin nor tylosin are generally recommended as therapy for cryptosporidiosis.

Azithromycin has been evaluated in animal models of infection and in some humans with cryptosporidiosis with encouraging preliminary results.[77-80] Administration of azithromycin to dairy cows infected with *Cryptosporidium* reduced oocyst shedding and improved clinical signs of diarrhea.[77] Azithromycin is well tolerated by cats and has been administered at 10 mg/kg PO q24h for a minimum of 10 days for treatment of cryptosporidiosis with variable response.[80] The optimal duration of therapy is unknown but frequently several weeks of therapy is required for diarrhea to resolve.

Elimination of *Giardia* using drugs such as fenbendazole may have the potential to resolve *Cryptosporidium* spp. infections. Administration of ivermectin to mice co-infected with *Giardia* spp. and *Cryptosporidium* spp. decreased excretion of both parasites even though the drug has no known activity against *Cryptosporidium*.[81]

Paromomycin is an aminoglycoside antibiotic that is poorly absorbed across the gut epithelium but can be absorbed in small quantities by the apical membrane surrounding the extracytoplasmic parasite.[79,82] Studies of immunocompromised humans concluded that paromomycin alone

was only partially effective for the treatment of cryptosporidiosis.[82-85] However, when paromomycin was used in combination with azithromycin, infection was cleared.[82] When paromomycin was administered to some naturally and experimentally *Cryptosporidium*-infected cats, oocyst excretion decreased to below the detectable limits of the assays used.[72,86] Paromomycin should never be administered to animals with bloody diarrhea because it can be absorbed systemically resulting in renal toxicity and ototoxicity. When cats infected with *Tritrichomonas* were treated with paromomycin, 4 out of 32 cats developed acute renal failure and three of the four cats became deaf.[84]

Nitazoxanide is the only drug approved by the US FDA for the treatment of diarrhea caused by *Cryptosporidium* in humans.[87] Nitazoxanide, a salicylanide derivative of nitrothiazole, has activity against a broad spectrum of parasites and bacteria.[88] The anti-*Cryptosporidium* activity of nitazoxanide have been proven *in vitro*, in some animal models, and in human clinical trials.[87] Nitazoxanide does not seem to be beneficial in the treatment of cryptosporidiosis in malnourished children and the immunocompromised.[34] Nitazoxanide has been used to treat some cats and dogs infected with cryptosporidiosis and giardiasis.[89] Diarrhea has resolved in some dogs and cats following administration of nitazoxanide at 25 mg/kg PO q12h for at least 5 days.[76] Nonetheless, nitazoxanide is a GI irritant, often causes vomiting, and is not effective in the absence of an appropriate immune response.

Auranofin, a gold-containing drug that was approved by the FDA in 1985 for the treatment of rheumatoid arthritis, has shown promise for the treatment of protozoal and gram-positive bacterial infections.[90] Auranofin's *in vitro* activity against *C. parvum* was similar to nitazoxanide.[90] It has been administered to shelter dogs with diarrhea due to *Giardia* infection or *Giardia* and *Cryptosporidium* co-infection (0.3 mg/kg to a maximum dose of 6 mg/d q24h for 5 days) without adverse effects.[91] Stool specimens tested negative and were formed after 5 to 10 days of treatment.

In humans, combination therapy (azithromycin and paromomycin; azithromycin, paromomycin, and nitazoxanide) has been used to reduce oocyst excretion and improve clinical signs in some individuals.[92,93]

The optimal duration of therapy for feline and canine cryptosporidiosis is uncertain, and clinical signs in some animals treated with the dosing regimens described in this chapter (Table 103.7) may improve but may not resolve by the end of the suggested treatment period. In these animals, continued treatment may be indicated if gradual improvement is noted. Animals co-infected with *Cryptosporidium* spp. and *Giardia* spp. appear to be more difficult to treat than animals infected with either organism alone.[76]

Molecular-based immunotherapy against *Cryptosporidium* and the effects of probiotic bacteria have been studied, but neither of the two protocols eradicated the parasite.[78] The use of highly active antiretroviral therapy in humans with AIDS has significantly reduced the severity of cryptosporidiosis, probably due to the recovery of the host immune responses and also due to a direct effect of protease inhibitors of host cell invasion and parasite development.[75,94,95]

Parenteral fluid replacement is indicated if dehydration is severe. Antibiotic therapy for secondary bacterial infection may be necessary. Oral rehydration solutions that contain glutamine may be helpful since absorptive-cell surface epithelium is lost and development of glutamine-dependent epithelium prevails.[96]

PREVENTION

Cryptosporidium spp. oocysts are resistant to most frequently used disinfectants, such as commercial bleach (5.25% sodium hypochlorite, see Chapter 14). Routine chlorination of drinking water does not affect oocyst viability.[97] Because filtration of this small organism is difficult, the organism can enter treated municipal water supplies. Formol saline (10% solution) and ammonia (5% solution) destroyed oocyst viability, but the required contact time was 18 hours. Concentrated ammonia solutions (50%) inactivate *Cryptosporidium* oocysts after 30 minutes.[98] Formaldehyde and hydrogen peroxide also have activity against oocysts.[99] Moist heat (steam or pasteurization [over 55°C]), freezing and thawing, or thorough drying are more practical means of disinfection. Swimming pools can be disinfected by using high chlorine concentrations for long periods (3 mg/L of water for 53 hours or 8 mg/L for 20 hours).[100] Housing dogs and cats indoors and feeding processed foods also may reduce the potential for infection since *Cryptosporidium* DNA was amplified from some raw meat diets.[101] Exceptional sanitation and use of boiling water for the cleaning of water and food bowls should decrease the possibility of contamination within crowded environments. When a human is infected with cryptosporidiosis, it is advisable to exclude that individual from work place, school, or other institutional setting until 48 hours after the last diarrhea episode.[102] This last preventive measure might be prudent for infected cats or dogs.

PUBLIC HEALTH ASPECTS

Humans become infected when they consume contaminated food and water, as well as contaminated water during recreational activities. Person-to-person or animal-to-person spread can also occur. Cryptosporidiosis in humans is generally caused by *C. hominis* and *C. parvum.*[34] Infection may be subclinical or lead to fever, severe abdominal pain, nausea, decreased appetite, weight loss, vomiting, and voluminous watery diarrhea. In developed countries, disease has occurred in association with swimming in contaminated water (such as swimming pools where fecal accidents have occurred), day-care center transmission, and less often as a result of food-borne spread.[75]

Cryptosporidium parvum is one of the few *Cryptosporidium* species with a broad host range and high genetic heterogeneity; genotyping has revealed nearly 20 subtype families, some of which are adapted to humans and some adapted to animals.[4] *Cryptosporidium hominis* is largely a human-specific *Cryptosporidium* species. However, it had been occasionally detected in cattle, sheep and goats, rodents, and dogs.[4,7]

In 2021, the AVMA reported that in 2020, there were 83.7 million dogs and 60 million cats; 45% of households owned at least one dog and 26% of households owned cats. (see also Chapter 75, Bite and Scratch Wound Infections). *Cryptosporidium felis* and *C. canis* are occasionally found in feces from humans.[97,103,104] *Cryptosporidium canis* and *C. felis* have been reported mainly in children in studies in developing countries, and these species account for 3.3% and 4.4%, respectively, of the overall *Cryptosporidium* cases.[34,105] In England, contact with dogs and cats was not a risk factor for cryptosporidiosis.[106] Furthermore, the prevalence of fecal oocyst excretion by dogs and cats owned by humans with cryptosporidiosis was no higher than that by dogs and cats owned by noninfected humans within the same studied population.[107] However, a study reported a possible case of zoonotic transmission of *C. felis* from a cat to a human living in the same household.[104] A weak statistical association was found between pediatric cryptosporidiosis and contact with dogs and cats in Guinea-Bisseau and Indonesia.[108-110] In another report, *C. canis* was detected in a dog and two children in the same environment.[111] However, even when *C. canis* or *C. felis* oocysts have been reported in the same household in humans and pets, it is difficult to establish the direction, or a common source, of the infection.[92] The cross-species transmission of *Cryptosporidium* spp. among dogs or cats and their owners has been a long-standing controversy. A report from 2021 used new typing tools to identify several subtype families within

both *C. canis* and *C. felis*.[112] Five subfamilies have been detected within both *C. felis* and *C. canis*; two of these subtype families in each of *C. felis* and *C. canis* have been detected in humans and cats and in humans and dogs, respectively. The use of these subtyping tools will be useful in elucidating the importance of zoonotic transmission of *Cryptosporidium* spp. from cats and dogs.

In immunocompromised individuals, such as those with AIDS and malnourished children, diarrhea can become chronic and life-threatening.[34] Life-threatening disseminated infections involve the respiratory tract, gall bladder, liver, and pancreas in addition to the GI tract. Currently, there is no effective treatment for cryptosporidiosis. Nitazoxanide, the only FDA-approved drug to treat cryptosporidiosis, does not improve clinical signs in AIDS patients and malnourished children.[34] The most beneficial treatment for these individuals has been reversal of underlying immunosuppression with highly active anti-retroviral therapy (HAART).

Since there is no effective treatment for cryptosporidiosis, prevention and risk reduction are the most important interventions, particularly for those that are immunosuppressed. Immunosuppressed individuals should be advised on prevention measures. Rigorous hand washing after handling animals, potential contact with human feces (changing diapers), and contact with soil before eating and before food preparation can reduce the risk of diarrhea in HIV-infected humans.[96] Immunosuppressed individuals also should avoid contact with animal feces, especially those of stray pets or pets less than 6 months of age. Gloves should be worn when cleaning areas that could be contaminated with pet feces. Humans with AIDS should also avoid direct exposure to calves and lambs. They should not drink water directly from lakes, canals, or rivers[96,113,114] and they should avoid accidental swallowing of water during recreational activities like swimming in public pools.[115]

The creation of dog parks has generated concerns regarding transmission of infectious agents among veterinarians, dog owners, and public health authorities. In one study, dogs attending dog parks were more likely to be positive for *Giardia* or *Cryptosporidium* than non–dog park-attending dogs. However, the only *Cryptosporidium* isolate in that study was typed as *C. canis*, which is of low risk for zoonotic transmission.[116] Since the benefits of attending dog parks outnumber the disadvantages for both owners and dogs, owners are advised to responsibly dispose of dog feces, minimizing environmental contamination of the parks.

CYCLOSPORIASIS

ETIOLOGY AND EPIDEMIOLOGY

Cyclospora cayetanensis (subclass Coccidia, phylum Apicomplexa) infects humans and animals in warm or tropical climates worldwide. *Cyclospora* are small (8 to 10 µm) obligate intracellular coccidian parasites that infect the mucosal epithelium of the intestine or bile duct of a variety of vertebrate hosts. *Cyclospora* was first identified in 1977 in Papua New Guinea as a human pathogen. The name "cyanobacterium-like bodies" was initially suggested for the organism because of its similarity to members of the blue-green algae.[117] Later the parasite was isolated from human feces and the oocysts were induced to sporulate, yielding two sporocysts that each contained two sporozoites. The parasite was considered a coccidian and named *C. cayetanensis*.[117-119] *Cyclospora cayetanensis* is closely related to *Eimeria* spp.[120] Like *Cryptosporidium*, *Cyclospora* are transmitted via the fecal-oral route by exposure to contaminated water, food, or soil.

Although the life cycle of *Cyclospora* spp. is not fully characterized, it appears to be monoxenous, requiring a single human host to complete the entire life cycle. Oocysts are passed in a noninfective form and must survive long enough to sporulate and to be ingested by a susceptible host. Depending on climate factors, oocysts may require days to weeks to sporulate and can persist and maintain infectivity for long periods in the environment even when exposed to harsh conditions.[120] Oocysts are spherical with a diameter of 7.7 to 9.9 µm. The minimum infectious dose is unknown, but it is likely that it is very low, ranging between 10 and 100 oocysts.[121]

After ingestion, sporulated oocysts excyst in the small bowel and enter epithelial cells. Asexual replication occurs in the small bowel with extruded merozoites penetrating new epithelial cells. Sexual reproduction occurs in the small-bowel epithelium and culminates with the passage of unsporulated oocysts in the feces.[122]

Outbreaks of cyclosporiasis in humans living in endemic areas usually occur during the warm and rainy season. In the United States and Canada, food-borne outbreaks related to eating contaminated raspberries also occurred during the warm rainy season.[123,124] The role that animals may play in the transmission of cyclosporiasis is controversial. Experiments conducted on nine strains of mice, rats, sand rats, chickens, ducks, rabbits, gerbils, hamsters, ferrets, pigs, dogs, and three types of monkeys have been unsuccessful in establishing an animal model for study of this parasite.[125] However, oocysts morphologically similar to *C. cayetanensis* have been detected in feces from dogs, chickens, ducks, and primates.[121] The organisms have been confirmed as *Cyclospora* only in primates. Oocysts that resembled *Cyclospora* were observed in feces from two dogs in Sao Paulo, Brazil and in one dog in Egypt.[126,127] However, another study of 140 stray dogs in the same area in Sao Paulo, Brazil, did not report evidence of such oocysts in feces.[128] The DNA of *C. cayetanensis* was amplified by PCR from feces from one chicken, two dogs, and one monkey.[129] In Mexico, oocysts morphologically and biologically similar to *C. cayetanensis* were detected in poultry feces, but not in cat feces.[130]

CLINICAL SIGNS

Clinical illness, if any, in dogs and cats is uncertain, because definitive oocysts have been documented only in human feces. Infected humans can develop anorexia, nausea, watery diarrhea, flatulence, fatigue, abdominal cramping, low-grade fever, fatigue, and weight loss after *C. cayetanensis* infection; the most severe symptoms develop in children and in humans with HIV/AIDS.[120] Asymptomatic infections are more common in endemic areas.[120] Biliary disease has also been reported in some patients with cyclosporiasis, and co-infections with *Cryptosporidium*, and other intestinal pathogens have also been described.[120]

DIAGNOSIS

Cyclospora oocysts can be identified by phase-contrast microscopy or bright-field microscopy (Table 103.8). The oocysts are spherical, refractile bodies with a central morula (Fig. 103.7A). Because the organisms are passed unsporulated in fresh feces, they can be confused with fecal yeasts. If fecal specimens are stored at 23° to 30°C for 7 to 15 days, the oocysts will sporulate and contain two sporocysts. The oocysts can also be stained with MZN acid-fast stain (Fig. 103.7B), and thus can be confused with *Cryptosporidium* and *Cystoisospora*. Some oocysts can have variable staining, with some being dark red, pale pink, or unstained.[120] Better results have been observed when the slides were heated by microwave treatment or heated to 85°C for 5 minutes in a water bath during staining (Fig. 103.7C).[120] PCR assays have been used for outbreak investigations or research; they are more sensitive than microscopy.[131-137] However, one PCR assay designed to detect *C. cayetanensis* as part of a multiplex panel was positive on a stool specimen from a dog with diarrhea in Korea; when the DNA was sequenced, the organism was identified as *Cystoisospora ohioensis*.[138] Of interest, the panel, which was reported to detect 23 enteric pathogens that were predominantly canine

TABLE 103.8 Comparison of Some Coccidial Oocysts Features and Transmission Potential

	Cyclospora	*Cryptosporidium*	*Cystoisospora*	*Toxoplasma*
Definitive Host	Humans, possibly animals	Humans, dogs, cats, other animals	Humans, dogs, cats, other animals	Cats
Intestinal Biopsy Findings				
Intracellular stages	T, S, M	T, S, M, G	T, S, M, G	T, S, M, G
Intracellular location	Deep seated	Intramembranous, extracytoplasmic	Deep seated	Deep seated
Size in tissue (μm)	4–16	2–5	3–15	3–15
Fecal Analysis				
Oocyst size (μm)	8–10	4–6	10–19 × 20–30 Varies with species	12 × 10
Sporulated Oocyst Features				
Number of sporocysts	2	0	2	2
Number of sporozoites per sporocyst	2	4 per oocyst (naked)	4	4
Acid-fast staining	Variable	Yes	Yes	Yes
Ultraviolet autofluorescence, 365-nm filter	Blue-green circles	None	Yes	None
Auramine fluorescence	Weak	Bright	Variable	Variable
Infectivity in fresh feces (already sporulated)	No	Yes	No	No
Zoonotic transmission	Unknown	Many animals	None, host-specific	Cats
Host-to-like-host transmission	Unknown	Yes	Yes	Yes, uncommon via oocyst

Light and electron microscopic identification of *Cyclospora* species in the small intestine: evidence of the presence of asexual life cycle in human host. *Am J Clin Pathol*. 1996;105:216-220.

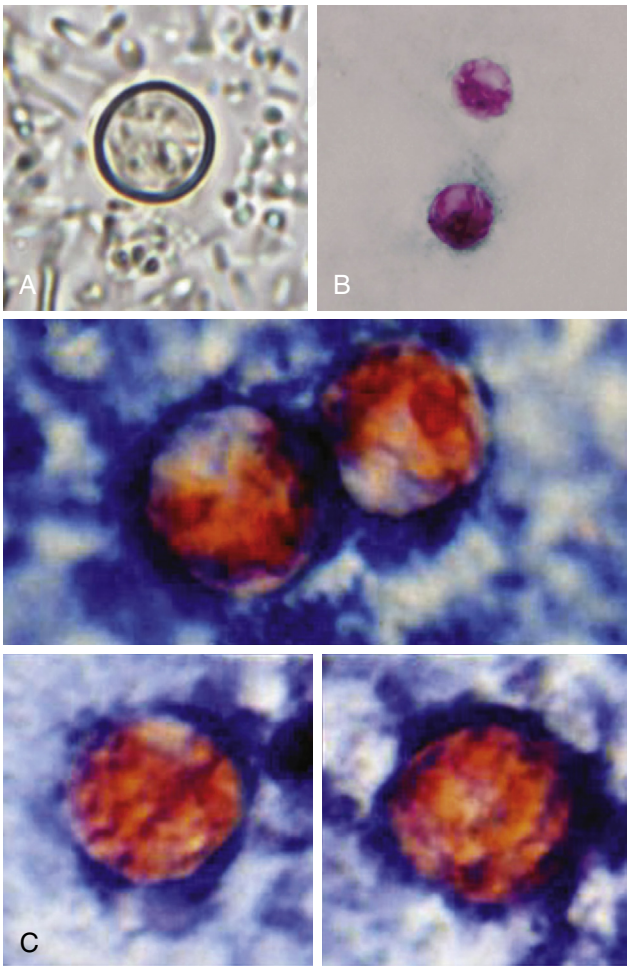

Fig. 103.7 *Cyclospora* oocysts visualized using different staining methods. (A) Wet mount. (B) Variable staining with modified acid-fast stain. (C) Uniform staining with modified safranin stain. Modification consists of heating in a microwave during staining to improve stain penetration. (From DPDx Image Library, Centers for Disease Control and Prevention, Atlanta, GA. In Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA; Elsevier: 3184-3191.)

(e.g., CDV) but sometimes human pathogens (*Lawsonia intracellularis*), did not include *Cystoisospora* spp. This underscores the importance of careful analysis of the components of "diarrhea panels" and the potential meaning of a positive or negative result for each pathogen included in the panel.

TREATMENT

The drug of choice for treatment of humans with cyclosporiasis is trimethoprim-sulfonamide, which generally leads to resolution of diarrhea after 3 to 7 days.[136,139] Ciprofloxacin was reported as an alternative for patients who are allergic to sulfonamides, but anecdotal treatment failure with this drug has also been reported.[140,141] Nitazoxanide was also effective in the treatment of cyclosporiasis in patients with sulfonamide hypersensitivity.[142,143] If a dog or cat is diagnosed with clinical cyclosporiasis, or is clinically healthy but poses a potential risk for human infection, routine dosages of trimethoprim-sulfonamide can be administered (see Chapter 10).

PUBLIC HEALTH ASPECTS

Cyclospora cayetanensis seems to be the only species detected in humans, and they seem to be its specific host. However, contact with animals was considered a risk factor for human infection in many studies worldwide.[144] Amplification of *C. cayetanensis* DNA from feces of two dogs by PCR assay increases the evidence that dogs can be exposed. However, it is unknown whether the dogs had natural infection or were just passing oocysts in feces after eating feces of another natural host. Direct human-to-human or animal-to-human transmission is unlikely, because the oocysts need a considerable amount of time to sporulate outside the host.[144] Humans tend to acquire their infection from consuming contaminated water or unwashed produce. To prevent infection, health education including personal hygiene, changing eating habits, proper sanitary infrastructures, and safe drinking water are needed. As with other coccidians, sodium hypochlorite is not an effective disinfectant for *Cyclospora* spp. oocysts. See Public Health Aspects, under *Cryptosporidia* previously, for further information on decontamination.

CASE EXAMPLE

Signalment

This case report describes the clinical management of two cats suspected to have diarrhea from *Cryptosporidium* spp. and *Giardia* spp. co-infection diagnosed by FA. Cat 1 (1-year-old, domestic longhair, male, neutered) and cat 2 (3.5-month-old, domestic longhair, male, neutered) lived in the same home in north-central Colorado.

History

The source of the cats was unknown. Both cats had been administered several conventional treatments (drugs and doses unavailable) but the diarrhea did not resolve.

Physical Examination Findings

Physical examinations were normal in both cats. Because of the dual infection and chronic diarrhea, the cats were evaluated for evidence of immunodeficiency by performing a CBC, serum biochemical panel, urinalysis, and CD4+ and CD8+ cell counts.

Laboratory Findings

The only abnormalities detected were mild neutrophilia (12,500/μL; N = 2000–12,000/μL) and a slight increase in serum ALP activity (75 IU/L; N = 7–65 IU/L) in cat 1.

Diagnosis

Prior to treatment, three fecal specimens per cat were collected (pretreatment) for evaluation for *Cryptosporidium* spp. DNA in feces by PCR, *Cryptosporidium* spp. oocysts, and *Giardia* spp. cysts by FA, and trophozoites of *Giardia* spp. and *Tritrichomonas blagburni* by wet mount examination. Specimens were then collected daily during the treatment period (intra-treatment), and then three times per week during the week after treatment (post-treatment).

Treatment

Azithromycin was administered at a dose of 10 mg/kg PO q24h for 14 days. Diarrhea did not resolve in either cat, both cats remained positive for *Cryptosporidium* DNA by PCR, and for *Giardia* spp. cysts by FA. Paromomycin was then administered at 500 mg/cat PO q24h for 5 days. After treatment, the consistency of the feces of both cats was normal and both cats were negative for *Giardia* spp. cysts by FA testing, but both cats remained positive for *Cryptosporidium* spp. DNA by PCR. In an attempt to resolve *Cryptosporidium* spp. oocyst excretion, paromomycin was administered again 1 month later. After administration of paromomycin, follow-up fecal tests were performed over 4 weeks (seven specimens) and 1 week (two specimens) for the first and second treatment periods, respectively. After treating the cats with both azithromycin and paromomycin, both cats became negative for *Giardia* spp. and *Cryptosporidium* spp. by FA but remained PCR positive for *Cryptosporidium* spp. DNA in feces. Although parasitologic clearance was not achieved, fecal consistency improved. Approximately 4 years after the administration of the last treatment, the owner reported that cats 1 and 2 were healthy and they did not have any other episodes of diarrhea.

Comments

Animals with co-infections may be more difficult to treat successfully than animals infected with either organism alone. It is possible that no drug will be generally effective for the treatment of these infections. Some treatments can help improve the clinical signs but infection may be unlikely to clear. In general, cats and dogs harbor the host-specific *Cryptosporidium* and *G. duodenalis* genotypes; currently there is no information if different assemblages might have different drug susceptibilities. Consequently, the drug and protocol should be varied according to each individual patient. In chronic cases, the possibility of underlying disorders should also be considered. Additionally, infection with *G. duodenalis* and *Cryptosporidium* does not appear to cause permanent immunity and so re-infections are likely to occur.

Cystoisosporiasis and Other Enteric Coccidioses

Michael R. Lappin, Jitender P. Dubey

KEY POINTS

- First Described: Coccidian parasites were first described in dogs and cats in the 1800s; the organisms were placed in the genus *Isospora* spp. in 1906.[1] Once it was discovered that the parasites have an extraintestinal phase, the genus was transferred to *Cystoisospora*.
- Cause: *Cystoisospora* spp., protozoan coccidian parasites (phylum Apicomplexa).
- Mode of Transmission: Fecal-oral; ingestion of intermediate/paratenic hosts.
- Affected Host Species: Dogs and cats are the definitive host of different *Cystoisospora* spp. The sexual phase of the organism is completed in the small intestine, which culminates in the passage of oocysts in feces.
- Intermediate Hosts: Most vertebrates can serve as intermediate/paratenic hosts (whereby the parasite encysts but does not multiply); invertebrates can serve as transport hosts by carrying *Cystoisospora* spp. oocysts.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Most dogs and cats harbor subclinical infections. Watery diarrhea that can contain blood occasionally occurs in puppies and kittens.
- Differential Diagnoses: These include other protozoal infections (e.g., *Giardia, Tritrichomonas blagburni*), enteropathogenic bacterial infections (e.g., *Clostridium perfringens, Campylobacter* spp.), and nematode infestations.
- Human Health Significance: *Cystoisospora* spp. of dogs and cats do not infect humans.

CYSTOISOSPORIASIS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Cystoisospora spp. are protozoan coccidian parasites that have been recognized for years as potential pathogens in dogs and cats.[2-5] The sexual phase of reproduction occurs in the intestines of dogs and cats and culminates in the passage of oocysts in feces (Table 104.1). Cats are the definitive hosts for *Cystoisospora felis* and *Cystoisospora rivolta. Cystoisospora canis*, *Cystoisospora ohioensis, Cystoisospora neorivolta,* and *Cystoisospora burrowsi* are described in dogs.[2] There is some overlap in the size of oocysts among *C. ohioensis*, *C. neorivolta*, and *C. burrowsi*. While *C. ohioensis* is distinct from the other species based on the location of intestinal endogenous stages, *C. neorivolta* and *C. burrowsi* currently cannot be distinguished and so it is proposed that these agents be referred to as *C. ohioensis*-like organisms.[6]

Cystoisospora spp. are host specific and have worldwide distribution.[4] Infections are very common, particularly in young animals. In the United States, the Companion Animal Parasite Council reports that prevalence rates for *Cystoisospora* spp. infection in dogs and cats vary from 3% to more than 30%.[7] In a study of more than one million fecal specimens from dogs in the United States, 4.4% contained *Cystoisospora* spp. oocysts.[8] Another study of 2586 fecal specimens from cats submitted to the veterinary parasitology laboratory at Oklahoma State University over a 12-year period noted that "*Cystoisospora* spp. oocysts was the most common parasite stage (9.4%)[9]; in fecal specimens from dogs it was the second most common parasite stage (5%) after *Ancylostoma* eggs (8.2%)."[10] In a study of 1355 cats in the United Kingdom, *C. felis* oocysts were detected in 3%.[11] Gender and breed do not usually influence *Cystoisospora* spp. excretion rates, but young animals are usually more likely to be excreting oocysts than adults. For example, in one Austrian study, 8.7% of dogs less than 2 years of age were infected; 78% of the positive specimens were in puppies less than 4 months of age.[12] In the study from the United Kingdom, *C. felis* was found in the feces of 9% of cats less than 6 months of age.[11]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Infection by *Cystoisospora* spp. in dogs or cats is initiated by ingestion of sporulated oocysts in the environment or by ingestion of tissues of other infected vertebrate or transport hosts (Fig. 104.1).[12,13] Infection can also occur if the dog or cat ingests sporulated oocysts carried mechanically by flies, cockroaches, or dung beetles.[14] The enteroepithelial phase occurs in the small intestine of infected animals and culminates in the passage of unsporulated oocysts in feces. The prepatent period (time between infection and appearance of oocysts in the feces) and patent period (time that the organism can be detected in the body) vary slightly by the species. In one study of dogs experimentally infected with *C. canis,* the mean prepatent period was 9.8 days (range, 9 to 11 days, n = 22 dogs), the patent period was 8.9 days (range, 7 to 18 days, n = 20 dogs), and all of the puppies developed diarrhea.[13] In contrast, the prepatent period for *C. ohioensis* in one study was 6 to 7 days, and diarrhea was variable.[12] The number of oocysts excreted by infected animals can vary dramatically.[12,13] Depending on the environmental conditions, sporulation can occur in as little as 12 hours.

Cystoisospora can invade extraintestinal tissues of cats, dogs, and other animals and can encyst (at a stage known as the *tissue cyst*) but does not multiply in this location or cause tissue damage. However, dogs or cats can become infected by eating tissues of these infected

animals (*paratenic hosts*). In addition, invertebrates (such as cockroaches) can mechanically transport oocysts in the environment.

Clinical disease is most common in young, debilitated, and immunocompromised animals. All the different *Cystoisospora* spp. replicate in the small intestine, but the regions with the heaviest infection vary by species. The presence of co-infections may increase potential for clinical illness associated with *Cystoisospora* spp.[15] Fecal microbiome differences were detected between cats with and without *Cystoisospora* spp. oocysts in feces; whether this finding is associated with development of clinical disease will need to be assessed further.[16]

Cystoisospora spp. infections are generally only associated with disease in puppies and kittens. However, adult animals treated with immune-suppressive drugs may also have activated cystoisosporiasis and resultant disease.[17] Clinically ill puppies and kittens can show signs of vomiting, abdominal discomfort, inappetence, and watery diarrhea that sometimes contains blood. Depending on the age of the animal and the parasite burden, severe dehydration and death can occur. Puppies and kittens with subclinical infection can repeat shedding and clinical signs of disease during periods of stress.

TABLE 104.1 *Cystoisospora* spp. Oocyst Characteristics After Detection by Centrifugal Fecal Flotation

	Oocyst Dimensions
Cats	
Cystoisospora felis	30 × 40 μm
Cystoisospora rivolta	20 × 25 μm
Dogs	
Cystoisospora canis	30 × 38 μm
Cystoisospora ohioensis and *C. ohioensis*-like	19 × 23 μm

DIAGNOSIS

When illness from cystoisosporiasis occurs, diarrhea is most common and so proving the presence of the agent in feces is the most important part of the diagnostic plan. However, because *Cystoisospora* spp. can be

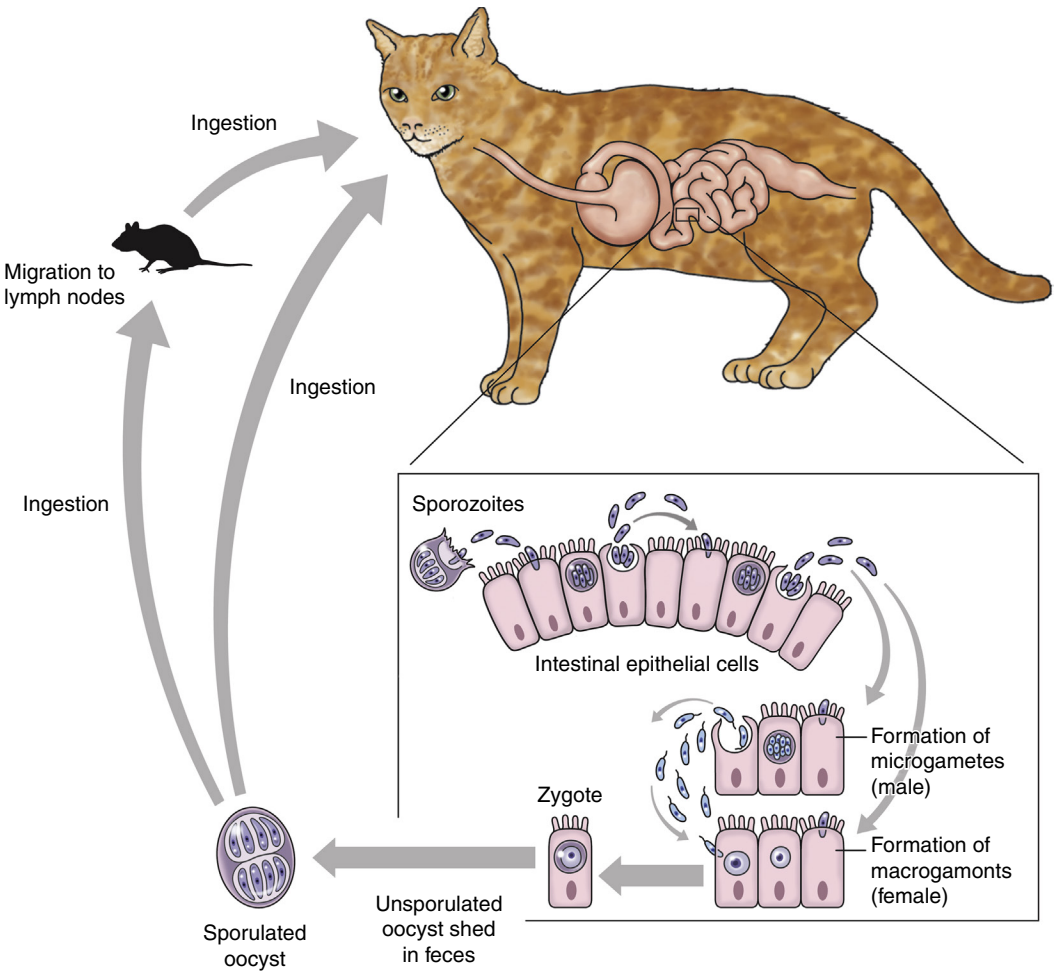

Fig. 104.1 Life cycle of *Cystoisospora* spp. The host species (in this case, cats) can be infected by ingestion of sporulated oocysts or ingestion of prey that have organisms encysted in their mesenteric lymph nodes. Oocysts shed in the feces can sporulate in as little as 12 hours under optimal environmental conditions.

detected in the feces of normal animals, a positive test result does not prove the agent is the cause of the clinical abnormalities.

Laboratory Abnormalities

Cystoisospora spp. infections only rarely lead to systemic laboratory abnormalities. In theory, regenerative anemia could develop from blood loss in puppies or kittens with heavy parasite loads. Other CBC abnormalities are uncommon. Decreases in serum total protein, albumin, and globulin concentrations can occur concurrently with blood loss. If diarrhea is severe, potassium, sodium, and chloride concentrations may decrease as a result of GI losses.

Diagnostic Imaging

Abdominal radiographic abnormalities in puppies and kittens with cystoisosporiasis are uncommon and nonspecific and, when present, are suggestive of diffuse enteritis.

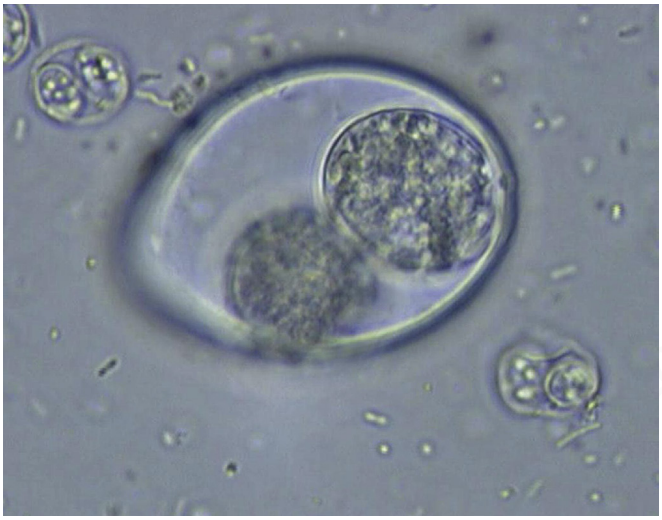

Fig. 104.2 Oocysts of *Cystoisospora felis* from a kitten with diarrhea (1000× magnification). (From Lappin MR. Update on the diagnosis and management of *Cystoisospora* spp. infections in dogs and cats. *Top Companion Anim Med.* 2010;25:133-135.)

Microbiologic Testing

The definitive diagnosis of coccidiosis can be made by demonstrating oocysts in fecal specimens from affected animals. *Cystoisospora* spp. oocysts are large and often numerous and so are generally easy to identify on microscopic examination of feces after centrifugal fecal flotation (Fig. 104.2). However, as discussed, animals with normal stool can pass *Cystoisospora* spp. oocysts, and so positive test results do not prove a disease association. False-negative fecal flotation results are uncommon in clinically infected animals, but occasionally clinical signs precede oocyst shedding, and so a second fecal flotation may be needed to prove infection in some cases.

Molecular diagnostic assays can be used to amplify the DNA of *Cystoisospora* spp. in feces. The detection of parasite DNA in feces will be used more in the future as a diagnostic test for cystoisosporiasis.[18-20] However, careful assay design is important in order to ensure that the DNA of related organisms is not amplified[20]; laboratories should be able to provide evidence that the assay is specific for detection of *Cystoisospora* spp. DNA. In one small study of experimentally inoculated kittens, fecal PCR results were positive in several specimens that were negative for oocysts after fecal flotation.[21]

Pathologic Findings

Clinically affected puppies and kittens may be emaciated. Other parasites such as roundworms or hookworms may be noted. The small intestines of clinically ill puppies and kittens may be hyperemic, edematous, or thickened. Microscopic lesions observed in some infected animals include villous atrophy, sloughing of villi in the intestinal lumen, dilation of lacteals, and hyperplasia of lymph nodes in Peyer's patches.

TREATMENT AND PROGNOSIS

Coccidiosis is generally self-limited, and clinical signs in most puppies and kittens resolve without therapy. However, treatment can hasten resolution of clinical disease and may lessen environmental contamination and the potential for infecting other, in-contact animals, particularly if the coccidiocidal drugs (see Chapter 12) ponazuril or toltrazuril are used (Table 104.2).[22-25]

In the United States, ponazuril is licensed for the treatment of *Sarcocytis neurona* infection in horses and has been used most frequently in this country for the treatment of canine or feline

TABLE 104.2 Drugs Used for the Treatment of *Cystoisospora* spp. Infections[a]

Drug	Species	Dose	Route	Interval and Duration
Amprolium	C D	60–100 mg total 300–400 mg total	PO	q24h for 5 days
Furazolidone	C, D	8–20 mg/kg	PO	q12-24h for 5 days
Ponazuril	C, D	50 mg/kg	PO	q24h for 3 days
Toltrazuril[b]	C, D	9 mg/kg	PO	Once
Sulfadimethoxine	C, D	50–60 mg/kg	PO	q24h for 5 to 20 days
Trimethoprim-sulfonamide	C, D	15–30 mg/kg	PO	q12–24h for 5 days
Amprolium-sulfadimethoxine	D	150 mg amprolium and 25 mg/kg sulfadimethoxine	PO	q24h for 14 days

[a]Sulfadimethoxine is the only approved drug for the treatment of coccidiosis in the United States. Sulfonamides or trimethoprim-sulfonamide combinations can cause macrocytic anemia, keratoconjunctivitis sicca, type III hypersensitivity reactions (primarily Doberman pinschers), and acute hepatic necrosis. See also Chapter 10.

[b]In Europe, toltrazuril has been available in combination with emodepside (Procox Oral Suspension for Dogs, Bayer Animal Health) for treatment of cystoisosporiasis and roundworm infections in puppies over 2 weeks of age. The suspension contains 18 mg/mL of toltrazuril.

C, cats; *D,* dogs.

cystoisosporiasis. Several treatment protocols have been recommended over the years. In one study, the optimal protocol was to administer 50 mg/kg, PO, daily for 3 days.[23] In Europe, toltrazuril has been available in combination with the anthelmintic emodepside (Procox Oral Suspension for Dogs, Bayer Animal Health) for treatment of cystoisosporiasis and roundworm infections in puppies over 2 weeks of age (see Chapter 12 for additional information). The only approved treatment for coccidiosis in the United States is sulfadimethoxine. Other drug regimens have been used with some success, and these include trimethoprim-sulfa (30 to 60 mg/kg of trimethoprim daily for 6 days in animals >4 kg; or 15 to 30 mg/kg trimethoprim daily for 6 days in animals <4 kg) and a variety of protocols using amprolium alone or in combination with sulfadimethoxine. Amprolium can cause anorexia, diarrhea, lethargy, and CNS disease due to induction of thiamine deficiency. However, these other drugs have only static effects and so are inferior to ponazuril or toltrazuril.

Use of prebiotics (food ingredients that stimulate the growth or activity of beneficial bacteria), or probiotics and/or dietary manipulation may speed up resolution of diarrhea, but controlled data are lacking.[16]

Most *Cystoisospora* spp.–infected dogs and cats survive infection, and so the prognosis is considered good to excellent.

IMMUNITY AND VACCINATION

Dogs previously infected with *C. canis* and challenged with *C. canis* did not show any signs of illness.[26] In contrast, dogs previously infected with *C. ohioensis* excreted *C. canis* oocysts and some developed diarrhea. These results suggested some immunity to repeat infection by the homologous species. However, the duration of immunity is likely not permanent because repeated excretion, clinical signs, and infection can occur. While *Cystoisospora* spp. infestation can be prolonged, immune responses usually block the development of clinical disease as puppies and kittens grow older. Vaccines for *Cystoisospora* spp. that infect dogs and cats are not currently available.

PREVENTION

Cystoisospora spp. oocysts are resistant to environmental conditions and disinfectants. The key to control is to provide good sanitation, including prompt removal of feces before oocyst sporulation. Steam cleaning can be used to destroy oocysts that contaminate surfaces, provided the water is hot enough (> 70°C) when it reaches contaminated surfaces. Treatment of dams and queens with anticoccidials before parturition can lessen the occurrence of coccidiosis in young animals. In environments with heavy infections, treatment of all in-contact animals, particularly puppies and kittens, could be considered. Ponazuril administered to all at-risk puppies and kittens on intake to shelters may aid in the control of coccidiosis.

PUBLIC HEALTH ASPECTS

Cystoisospora spp. of dogs and cats do not infect people. However, some infected animals are co-infected with other parasites with potential for zoonotic transfer to people, such as *Cryptosporidium* spp. and *Giardia* spp. Thus, a complete diagnostic workup should be completed for animals with diarrhea.

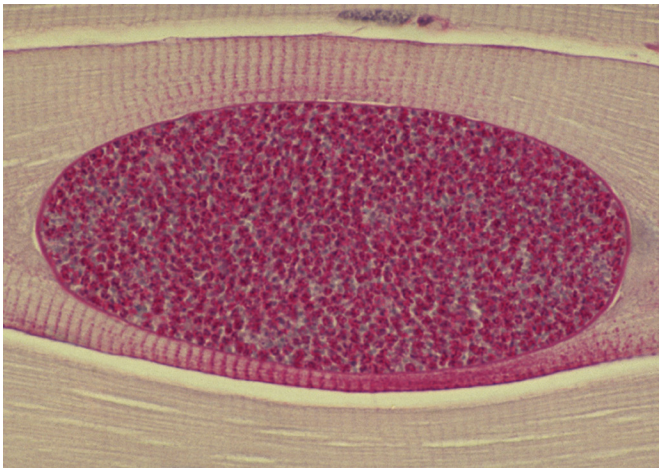

Fig. 104.3 *Hammondia hammondii* tissue cyst in skeletal muscle of a mouse. Note the thin cyst wall enclosing hundreds of PAS-positive bradyzoites (PAS stain, ×750).

OTHER ENTERIC COCCIDIOSES

Other enteric coccidia that infect the intestines of dogs and cats include *Hammondia*, *Besnoitia*, a variety of intestinal *Sarcocystis* species (see Chapter 95), *Toxoplasma gondii* (see Chapter 93), and *Neospora caninum* (see Chapter 94).

Hammondia species, unlike *Isospora* species, have obligatory two-host life cycles. Domestic cats and the European wildcat (*Felis sylvestris*) are the definitive hosts of *H. hammondii*; goats and rodents are natural intermediate hosts, but a number of other warm-blooded animals have been infected as intermediate hosts experimentally. *Hammondia hammondii* does not invade extraintestinal tissues of the cat, and cats are infected only by eating tissue cysts. Intermediate hosts become infected when they ingest sporulated oocysts, which resemble those of *T. gondii*. Sporozoites excyst in the intestinal lumen, invade the intestinal wall, and multiply as tachyzoites in the intestines, mesenteric lymph nodes, and other tissues. The parasite then encysts principally in muscles (Fig. 104.3).

The life cycle of *Hammondia heydorni* is not fully known but appears similar to that of *H. hammondii*. Dogs and other canids are definitive hosts; cattle, sheep, goats, deer, and a variety of other herbivores are intermediate hosts. In dogs, the oocyst of *H. heydorni* resembles that of *N. caninum* (Fig. 104.4).

Hammondia spp. are largely thought to be nonpathogenic in dogs and cats. However, there have been some reports that have suggested an association between *H. heydorni* infection in dogs and diarrhea (see also Fig. 104.4).[27-29] In addition, *H. heydorni* or a closely related *Hammondia* species was associated with cholangiohepatitis in an 11-year-old Jack Russell terrier mix from a horse farm in Wisconsin, USA.[30] Another dog with intrahepatic biliary coccidiosis was also reported from the United States, although the organism could not be identified to the species level.[31]

Cats are the definitive host for several *Besnoitia* species, including *Besnoitia darlingi* (intermediate hosts: opossums and possibly lizards), *Besnoitia wallacei* (rodents), *Besnoitia oryctofelisi* (rabbits), and *Besnoitia neotomofelis* (woodrats). The life cycle is similar to *T. gondii*; schizonts may be found not only in intestinal tissues but also in extraintestinal organs. The oocysts are difficult to distinguish from those of *T. gondii*. *Besnoitia* spp. infections are considered nonpathogenic in cats.

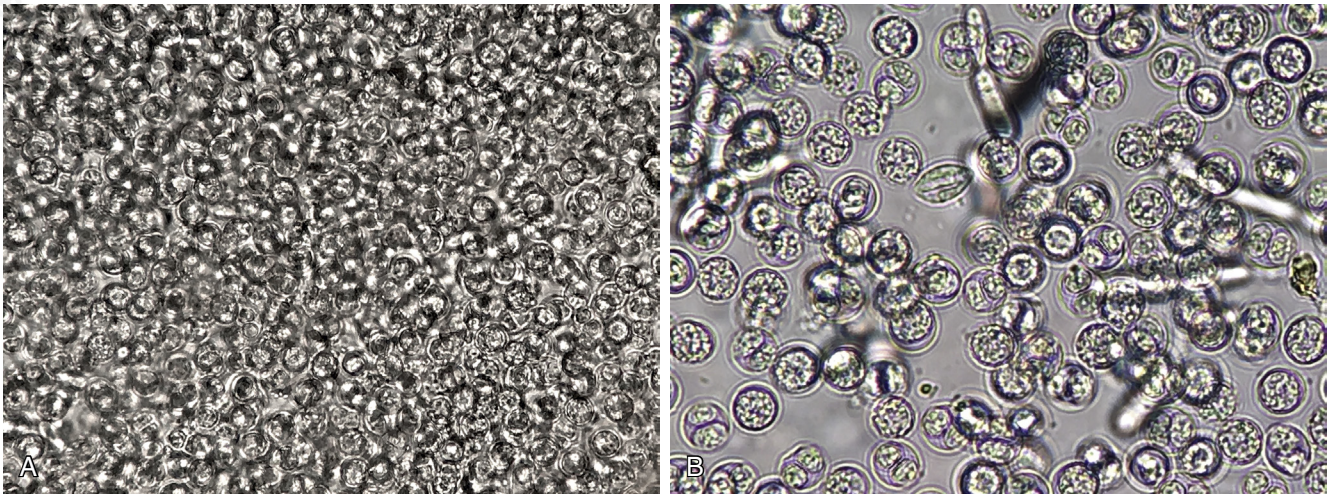

Fig. 104.4 Massive numbers of both sporulated and unsporulated *Hammondii heydorni* oocysts in a fecal flotation from a 7-year-old Great Dane with acute vomiting, diarrhea, and weight loss. The oocysts were initially thought to be *Neospora caninum*, but were later identified as *H. heydorni* using molecular methods. (Courtesy Dr. Lauren Camp, Veterinary Parasitology Service, University of California, Davis.)

CASE EXAMPLE

Signalment

"No-name," an 8-week-old, intact male, domestic shorthair cat from a pet store in Fort Collins, CO.

History

No-name was housed in a pet store. The kitten appeared small for his age and weighed 25% less than the littermates also housed at the pet store. Although he was eating well, he was thin. Small bowel diarrhea was the other historical complaint, and stool character varied from soft to watery with occasional flecks of what appeared to be fresh blood but no mucus. The source of the kitten was not disclosed. His first vaccine (an attenuated live vaccine for prevention of FHV-1, FCV, and FPV infections) had been administered subcutaneously 2 weeks previously. He had been fed a commercial processed food followed by a bland diet with no improvement noted in body weight or diarrhea. The other littermates were normal according to the pet store owner. The kitten was administered pyrantel pamoate once on entry to the pet store; no other treatments had been administered.

Physical Examination

Quiet, alert, and responsive. Ambulatory on all four limbs. Body weight was 1.1 kg and body condition score was 3/9. T = 101.3°F (38.5°C), HR = 180 beats/min, RR = 24 breaths/min, mucous membranes pink, CRT = 1 s. The cat's haircoat was dull but there was no evidence of ectoparasites. Abdominal palpation revealed mild diffuse thickening of the small intestinal loops. No other significant abnormalities were detected.

Results of Microbiologic Testing

FeLV antigen ELISA assay: Negative.
FIV antibody ELISA assay: Negative.
Fecal wet mount examination: No motile flagellates were noted.
Fecal flotation: Oocysts that were morphologically consistent with *C. felis* were noted.

Diagnosis

Cystoisospora felis infection.

Treatment

Ponazuril at 20 mg/kg PO q24h for 2 days; the littermates were treated as well. A commercially available intestinal diet was administered until the stool normalized 5 days later.

Comments

The findings were characteristic of *Cystoisospora* spp. infection. Although the littermates were clinically normal, ponazuril was administered to try to lessen oocysts shedding into the pet store environment and lessen the potential for reinfection.

Emerging and Miscellaneous Protozoal Diseases

Mary Marcondes, Marc Kent, Elizabeth W. Howerth, Jane E. Sykes

KEY POINTS

Rangeliosis

- Cause: *Rangelia vitalii*, a protozoan parasite of the phylum Apicomplexa, class Aconoidasida, order Piroplasmida; phylogenetically close to the family Babesiidae.
- First Described: 1908, in dogs from Brazil (Carini, 1908).[1]
- Affected Hosts: Domestic dogs and wild canids (the crab-eating fox *Cerdocyon thous*, and the pampas fox *Lycalopex gymnocercus*).
- Geographic Distribution: South America, especially in the south and south-east of Brazil, Argentina, and Uruguay.
- Mode of Transmission: *Amblyomma aureolatum* ticks.
- Major Clinical Signs: Lethargy, inappetence, weakness, weight loss, fever, pallor, jaundice, splenomegaly, lymphadenomegaly, pelvic limb edema, and hemorrhagic disorders including persistent hemorrhage from the tips and external surface of the pinnae, nose (epistaxis), oral cavity (including hematemesis), venipuncture sites, and GI tract (hemorrhagic diarrhea).
- Differential Diagnosis: Other tick-borne diseases (e.g., canine babesiosis and canine monocytic ehrlichiosis), leptospirosis, leishmaniosis, immune-mediated disorders.
- Human Health Significance: There is no evidence that *R. vitalii* can infect humans.

Amebiasis and Balantidiasis

- Cause: Nonenteric (free-living) amebiasis in dogs is caused by organisms belonging to the genera *Acanthamoeba* and *Balamuthia.* Amebic keratitis caused by *Acanthamoeba* spp. has rarely been reported in companion animals. GI amebiasis in dogs is rare and caused by *Entamoeba histolytica*. Balantidiasis is also rare and caused by *Balantioides coli* (formerly *Balantidium coli*)
- Affected Hosts: Domestic dogs.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Unclear, but inhalation (systemic disease) or ingestion (systemic or GI disease) from environmental sources are suspected.
- Major Clinical Signs: The major clinical signs of canine systemic amebiasis are lethargy, inappetence, weakness, weight loss, fever, and a variety of neurologic signs. Rare cases of localized amebic keratitis have been described in dogs with chronic keratoconjunctivitis sicca treated with topical immunosuppressive drugs. GI amebiasis may be characterized by signs of large bowel diarrhea and inappetence.
- Differential Diagnosis: Systemic amebiasis must be differentiated from other viral, bacterial, protozoal, and fungal pathogens that cause chronic progressive CNS signs; and noninfectious diseases of the CNS (see Chapter 129). Differential diagnoses for amebic keratitis include squamous cell carcinoma, leishmaniosis, and toxoplasmosis. GI amebiasis and balantidiasis must be differentiated from other subacute and chronic infectious and inflammatory causes of large bowel diarrhea.
- Human Health Significance: GI ameba and *Balantioides* can cause mild to severe diarrhea in humans, and systemic ameba can cause life-threatening disease. However, there is no strong evidence for a role of companion animals in zoonotic transmission.

RANGELIOSIS

Mary Marcondes

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Rangeliosis is a severe tick-borne hemorrhagic disease of dogs caused by *Rangelia vitalii*, a protozoan parasite of the phylum Apicomplexa, class Aconoidasida, order Piroplasmida; phylogenetically close to the family Babesiidae.[2,3] *Rangelia vitalii* infection has been reported only in domestic and wild canids.[4-14] The taxonomy of *R. vitalii* is not completely understood.[15] Molecular phylogenetic analyses of *R. vitalii*, based on fragments of the 18S rRNA and heat shock protein 70 (*hsp70*) genes, demonstrated that *R. vitalii* forms a new branch of piroplasms, which is located in the *Babesia* spp. *sensu stricto* clade.[2,3,16] Analysis of 18S rRNA gene sequences shared the highest degree of sequence identity (95%) with *Babesia* spp., and 92% to 94% sequence identity with *Babesia canis* and *Babesia gibsoni*, while DNA sequences of the *hsp70* gene shared the highest degree of sequence identity (87%) with *Babesia bigemina* and only 82% to 86% sequence identity with *B. canis* and *B. gibsoni*.[3] However, further analysis is needed for a clearly defined phylogenetic classification of *R. vitalii*.[3,17] What is known about life cycle and host cell tropisms of *R. vitalii* also differ from those of organisms in the *Babesia* spp. *sensu stricto* clade.

The first reference in the literature to rangeliosis in dogs was by Antônio Carini in 1908.[1] Two years later, in 1910, the Brazilian protozoologist Bruno Rangel Pestana published two articles describing a disease that affected dogs in several parts of the country that was known

as "nambiuvú," (which means "bleeding ears" in the indigenous language Tupi-Guarani), "bleeding plague," or "yellow fever of dogs."[18,19] According to Pestana, the disease was possibly caused by a novel piroplasm, which he named *Piroplasma vitalii* in honor of the Brazilian scientist Vital Brazil.[19] Despite the similarities with other piroplasms, namely *Piroplasma canis* (a former synonym of *Babesia canis*), its status as a new species relied on its additional intracellular presence within endothelial cells, which has never been reported for any other canine piroplasm. In 1914, Carini and Maciel studied this same disease and reached similar conclusions to those described by Rangel. The authors stated that a tick was probably the source of the infection and, as a tribute to Rangel Pestana, proposed that a new genus of protozoan was created, designated *Rangelia*. From that time, the etiologic agent became known as *Rangelia vitalii* and the disease was called rangeliosis.[20]

Over the years, clinical signs of rangeliosis characterized by ear margin bleeding, epistaxis, anemia, jaundice, and a history of tick exposure were erroneously associated with numerous diseases, including visceral leishmaniosis, babesiosis, ehrlichiosis, hepatozoonosis, and toxoplasmosis,[5,21] or were described using various names throughout Brazil.[22,23] Veterinarians did not consider *R. vitalii* in their differential diagnosis as most were unfamiliar with this pathogen, and almost no information about it was published between 1948[24] and 2003,[23] after which more studies and clinical cases were reported.[4,6,17,25-27] Canine rangeliosis is now recognized as a reemerging disease in Brazil.[22]

At the time of writing, canine rangeliosis has been reported only in dogs from South America, especially in the south and south-east of Brazil,[2,4,6,7,17,22,23] Argentina,[16,28] Uruguay,[29] and Paraguay.[30] Among the three piroplasmids recognized to infect dogs in South America (*Babesia vogeli*, *B. gibsoni,* and *R. vitalii*), *R. vitalii* is the only one that has not been found outside South America.[12] In the southern part of Brazil the disease has been identified not only in rural areas, but also in the outskirts of cities, where dogs have direct access to forest and mountain areas, and where tick species that infest dogs are present.[5]

Although *Amblyomma aureolatum* (commonly known as the yellow dog tick) and *Rhipicephalus sanguineus* (brown dog tick) are the ixodid ticks that have been found on dogs infected with *R. vitalii*,[3,5,22] vector competence for *R. vitalii* has only been confirmed for *A. aureolatum*, which transstadially transmits the agent from nymph to adult.[31,32] *Rangelia vitalii* DNA has also been detected in *Amblyomma sculptum* ticks that were found on crab-eating foxes (*Cerdocyon thous*) in endemic areas.[33] The distribution of *A. aureolatum* includes southeastern and southern Brazil, northeastern Argentina, and Uruguay; this reflects the distribution of rangeliosis (Fig. 105.1).[29,34] In an experimental study of dogs exposed to infected ticks, clinical signs appeared after the engorged females had dropped off the dogs, around 14 to 19 days post infestation. Since the period of engorgement of *A. aureolatum* ranges from 9 to 15 days, female ticks found on dogs with signs of rangeliosis are not necessarily those that transmitted the agent to the dog. This explains the fact that some dogs have no ticks at the time they develop clinical signs.[31]

Rangelia vitalii has been described infecting two species of wild canids—the crab-eating fox (*C. thous*) and the pampas fox (*Lycalopex gymnocercus*); these are possible natural reservoirs of the parasite in Brazil.[9,10,12-14] Although the first confirmed *R. vitalii* infection in crab-eating foxes was reported in six subclinically infected animals, disease was reproduced in a domestic dog inoculated with blood and bone marrow from one of those foxes, suggesting a higher pathogenicity of the parasite in domestic dogs than in *C. thous*.[12] However, severe rangeliosis was also documented in a captive crab-eating fox in Brazil, indicating that disease can also occur in this species.[35]

There is limited information about the seasonality of canine rangeliosis. Although the disease is described throughout the year, the highest number of cases appear to occur in the summer, when ticks are more abundant.[5] *Rangelia vitalii* affects mainly young dogs, although adult dogs may also be affected, especially those in rural areas. Hunting dogs may be predisposed due to increased exposure.

Fig. 105.1 Geographic distribution of *Amblyomma aureolatum* (and canine rangeliosis). (Modified from Guglielmone AA, Estrada-Pena A, Mangold AJ. *Amblyomma aureolatum* (Pallas, 1772) and *Amblyomma ovale* Koch, 1844 (Acari: Ixodidae): hosts, distribution and 16S rDNA sequences. *Veterinary Parasitology.* 113;2003:273-288.)

CLINICAL FEATURES

Pathogenesis and Clinical Signs

There is little information on the pathogenesis of *R. vitalii* infection. Spontaneously occurring disease may have a clinical course of a few days to up to 3 months. In early reports, the disease was classified as an acute or icteric form, a subacute or hemorrhagic form, and a mild and benign chronic form.[18-20] However, overlap of these clinical forms can occur.[5,23] Experimental studies showed that the clinical course can range from 3 days (acute form) to 8 to 15 days (subacute form) or up to 18 to 25 days (chronic form).[5] Infected dogs often have nonspecific clinical signs such as lethargy, anorexia, chronic weight loss, and intermittent fever. Mucosal pallor, jaundice, generalized lymphadenomegaly, and splenomegaly are usually noted. Pelvic limb edema may occur. Hemorrhagic disorders, such as petechiae and ecchymoses of mucosal membranes, persistent bleeding from the tips and external surface of the pinnae, planum nasale, venipuncture sites, GI tract (including hematemesis and hemorrhagic diarrhea), and epistaxis are commonly observed.[4-6,8,17,22] The pathogenesis of the hemorrhagic disorders is still unclear.[17] Consumptive coagulopathy related to DIC secondary to endothelial damage caused by the intracellular replication of this organism may be one mechanism. The observation of microthrombi in the lumina of small blood vessels supports this possibility.[5,17] Another possible cause of bleeding is thrombocytopenia related to other mechanisms such as immune-mediated destruction.[6,17,36] Additionally, thrombocytopenia may be related to possible altered enzymatic activity of the purinergic system.[37] Trauma inflicted by hematophagous flies feeding on the tips of the ears, and the vigorous scratching and head shaking to alleviate the pain and irritation of these areas, may also contribute to auricular hemorrhage.[17]

The infection in dogs consists of an intraerythrocytic and an extraerythrocytic phase that occurs in endothelial cells of internal

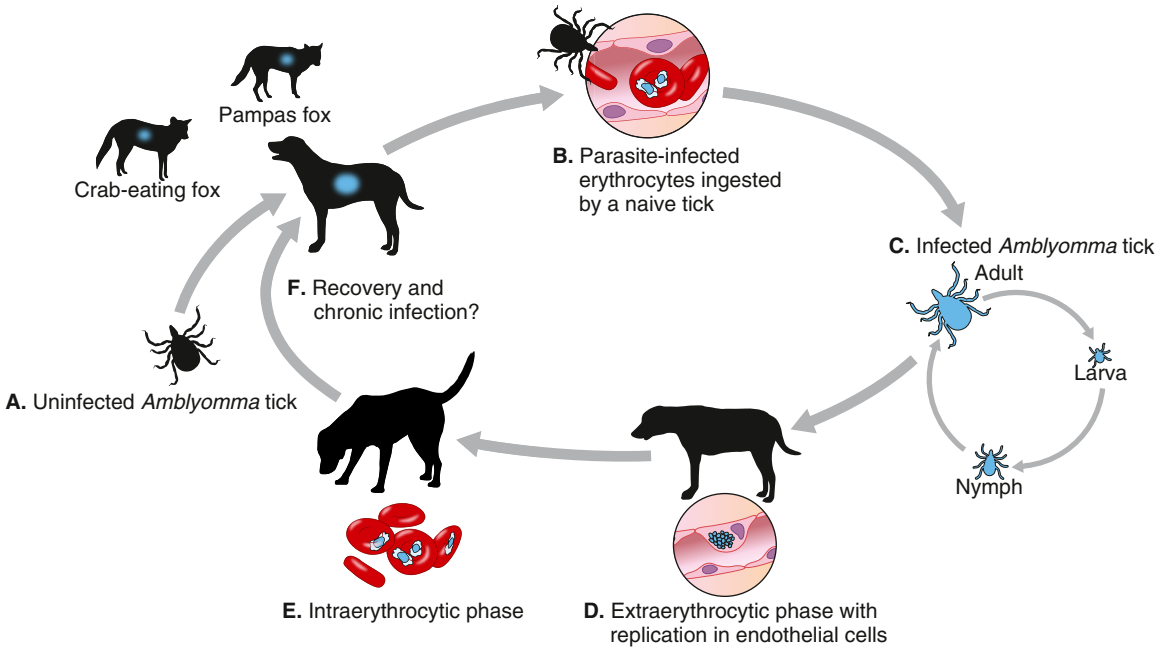

Fig. 105.2 Possible life cycle of *Rangelia vitalii*. (A) Uninfected ticks feed on infected dogs and possible wild canids (acting as reservoir hosts) and (B) ingest parasite-infected blood cells. (C) Transovarial transmission of *R. vitalii* occurs in female ticks. Inoculation of domestic dogs with *R. vitalii* during tick feeding leads to disease (D and E). Two phases of replication occur in the canid host, an extraerythrocytic phase that involves infection of endothelial cells (D), and an intraerythrocytic phase that involves infection of erythrocytes (E). Surviving dogs may remain subclinically infected and serve as reservoirs for infection of new ticks.

organs (tissue phase) (Fig. 105.2).[17,22] Although some authors state that the intraerythrocytic form of the parasite is mostly observed during the acute stage of the disease,[18-20] the tissue phase appears to occur before the intraerythrocytic stage.[31] Thrombocytopenia precedes detection of the parasites in a blood smear, leading to the belief that infection of the vascular endothelium is pre-erythrocytic, and that thrombocytopenia could be the result of platelet consumption in vascular lesions caused by the protozoan exiting the vascular endothelium.[31] The severe anemia may reflect IMHA, leading to prehepatic jaundice.[4,6,22,23] Evidence for an immune-mediated process includes the presence of regenerative anemia, spherocytosis, erythrophagocytosis in the blood, spleen and lymph nodes, and a favorable response to corticosteroids during treatment;[4,6,22,23] however, the Coombs test has not been evaluated in affected dogs. The presence of hemosiderophages in the bone marrow is also consistent with an excessive erythrocyte breakdown.[17]

Physical Examination Findings

Physical examination abnormalities in most dogs with rangeliosis include lethargy, weakness, dehydration, intermittent fever, mucosal pallor, jaundice, generalized peripheral lymphadenomegaly, splenomegaly on abdominal palpation, pelvic limb edema and hemorrhagic disorders that most often occur as persistent bleeding from the tips and external surface of the pinnae and planum nasale (Fig. 105.3), and epistaxis and excessive bleeding from venipuncture sites. Petechiae and ecchymoses of mucosal surfaces can also be observed.[4-6,8,17,22] The severe bilateral pinnal hemorrhage is a characteristic (but not pathognomonic) clinical sign.[22] The outer surface of the ears or planum nasale may show extensive hemorrhagic crusting.[4-6,17]

DIAGNOSIS

A presumptive diagnosis of rangeliosis is based on history, typical clinical signs, and hematological changes. Ticks may have detached from the dog by the time the animal is examined.[17] Definitive diagnosis requires detection of parasites in peripheral blood smears or in tissues, through histopathological evaluation,[3,4,6,17,26] or molecular diagnostics.[3,15,28] Differential diagnoses include babesiosis, leptospirosis, monocytic ehrlichiosis, and leishmaniosis.[5,17,33,34]

Laboratory Abnormalities

Complete Blood Count

CBC findings in canine rangeliosis include severe regenerative anemia and mild to severe thrombocytopenia.[4,6,8,22,23,31] In experimental infections, *R. vitalii* reduced platelet aggregation.[37] A normocytic, normochromic anemia is usually observed in the first days of infection, which becomes macrocytic and hypochromic as the disease progresses. Reticulocytosis, anisocytosis, polychromasia, metarubricytosis, and Howell-Jolly bodies are common findings on blood smears. Spherocytosis, microscopic agglutination of RBCs, and erythrophagocytosis are also noted.[4-6,23,25] The plasma can be icteric and, in some cases, macroscopic erythrocyte agglutination can be seen in the blood collection tube.[4,23] Leukocyte abnormalities are inconsistent but may include leukocytosis, neutrophilia, lymphocytosis, monocytosis, or neutropenia.[4,6,8,23,25,31]

Serum Chemistry Profile and Urinalysis

Increased activities of ALT, AST, and CK are reported in experimental infections with *R. vitalii*.[38] An increase in serum bilirubin concentration due to extravascular hemolysis may also occur.[39] In experimentally

Fig. 105.3 Physical examination findings in dogs with rangeliosis. (A) Yellow discoloration of the oral mucosa (jaundice); (B) hyphema and epistaxis; (C) petechiae and ecchymoses scattered throughout the oral mucosa, and mucosal pallor (anemia); (D) severe bleeding on the outer surface of the right pinna and on a venipuncture site on the right forelimb. (From França, RT et al. Canine rangeliosis due to *Rangelia vitalii*: from first report in Brazil in 1910 to current day – a report. *Ticks and Tick-borne Diseases*. 2014;5:466–474. Elsevier. Figure 4). *Continued*

infected dogs, total protein, albumin, alpha-2 globulin, and beta-2 globulin concentrations decreased, while there was an increase in alpha-1 globulin and gamma-globulin levels.[40] Urinalysis may reveal bilirubinuria and hemoglobinuria.[39]

Microbiologic Tests

Rangeliosis can be diagnosed by microscopic identification of the parasite and/or molecular diagnostic assays. To date, there are no serologic tests for detection of antibodies to *R. vitalii*.

Cytologic Diagnosis

Examination of peripheral blood smears for *R. vitalii* is insensitive, because in many cases the number of circulating parasites is low.[41] The parasite can be found free in plasma or inside erythrocytes, neutrophils, and monocytes (Fig. 105.4). The probability of finding the parasite is higher when blood is collected during an episode of high fever in the acute stage of the disease.[5,18-20] Parasitized erythrocytes tend to be found on the feathered edge of blood smears.[22] Depending on the study, parasites were seen in blood smears in 11% to 71% of cases.[4,6] Within cells, *R. vitalii* is a round, oval, or teardrop-shaped organism found singly or in pairs.[22] The zoites of *R. vitalii* are 3 µm long and 2 µm wide (nucleus 1 µm long and 0.8 µm wide).[42] In blood smears stained with Giemsa, intraerythrocytic merozoites have a pale basophilic cytoplasm and an eccentric magenta nucleus.[3]

Diagnosis Using Nucleic Acid–Based Assays

A quantitative PCR assay to detect and quantify a fragment of the 18S rRNA gene of *R. vitalii* in canine blood samples has been validated,[15] but there are no commercial veterinary diagnostic laboratories performing PCR analysis for *R. vitalii*.

Pathologic Findings

Necropsy findings commonly observed in dogs with rangeliosis include diffuse pallor or jaundice, splenomegaly, hepatomegaly, generalized enlargement of peripheral and visceral lymph nodes, and enlarged tonsils. Diffuse subcutaneous edema of the pelvic limbs and multiple petechiae and ecchymoses are observed on the serosa of many organs and the mucous membranes. There may be pulmonary and cardiac hemorrhage. Lungs are edematous, heavy, and fail to collapse. The stomach and intestines can be filled with blood. Mild to moderate hydrothorax, hydropericardium, and ascites can also be noted.[4,17,22,23]

Microscopic findings include the presence of zoites in endothelial cells of blood capillaries in many organs; the zoites are located inside intracytoplasmic membrane-bound parasitophorous vacuoles.[4,17,22,23]

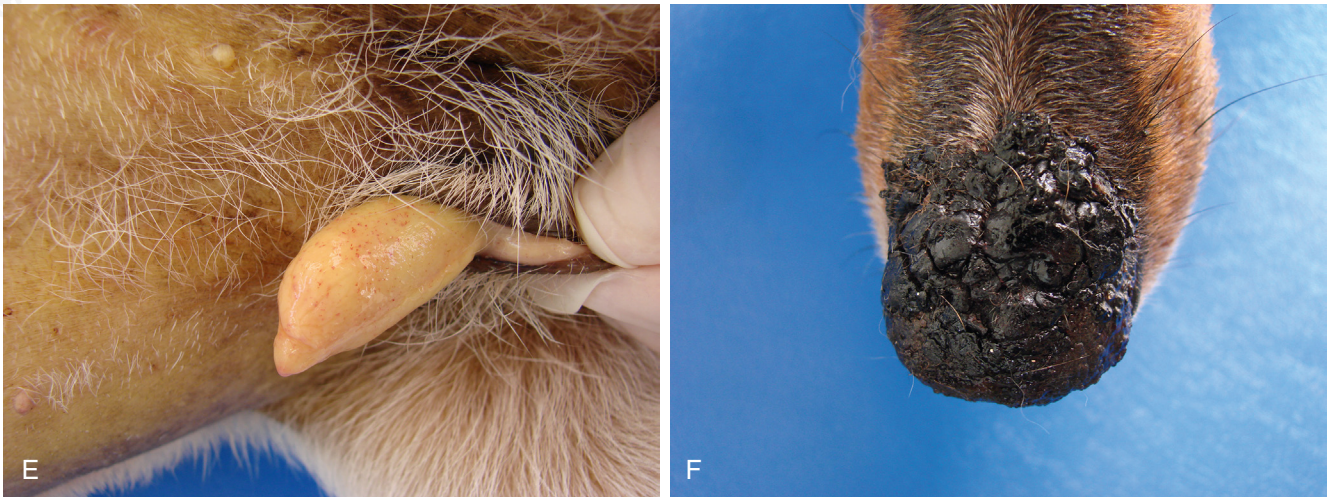

Fig. 105.3 cont'd. (Courtesy of Rafael Fighera, UFSM, Santa Maria, Brazil.)

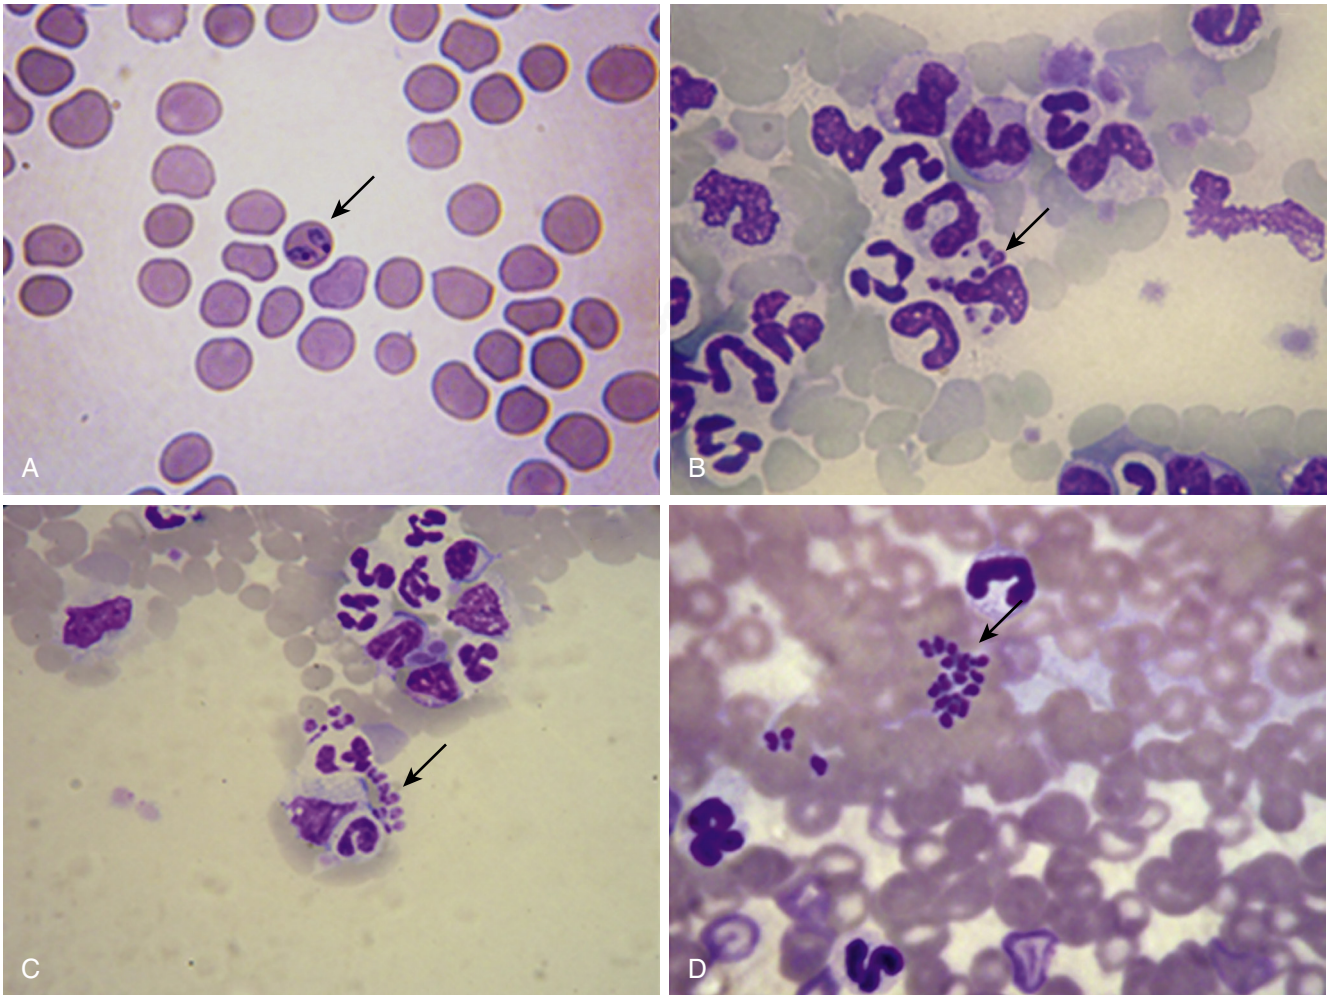

Fig. 105.4 Blood smear from a dog with rangeliosis showing intraerythrocytic *R. vitalii* piroplasms (arrows). (A), inside leukocytes (B), and (C and D) free in the plasma. (From França, RT et al. Canine rangeliosis due to *Rangelia vitalii*: from first report in Brazil in1910 to current day – a report. *Ticks Tick Borne Dis.* 2014;5:466-474. Elsevier. Figure 1.)

The organisms are round or oval, homogeneous and basophilic with H&E, and are found most often in peripheral lymph nodes, liver, tonsils, bone marrow, kidneys, lungs, adrenal medulla, and choroid plexus (Fig. 105.5).[4,17,22,23] The cytoplasm of the parasites is pale with a prominent basophilic and eccentrically located nucleus.[17] Parasitized endothelial cells can be markedly distended by organisms.[17]

Tissues often show a mononuclear inflammatory infiltrate, predominantly plasmacytic, of variable severity.[4,17,22] Reactive hyperplasia of the lymph nodes with prominent secondary follicles, multinucleated giant cells, and erythrophagocytosis within medullary sinuses are often observed (Fig. 105.5).[4,17] Follicular hyperplasia of the splenic white pulp is observed in many cases.[17] There is also increased cellularity of the red

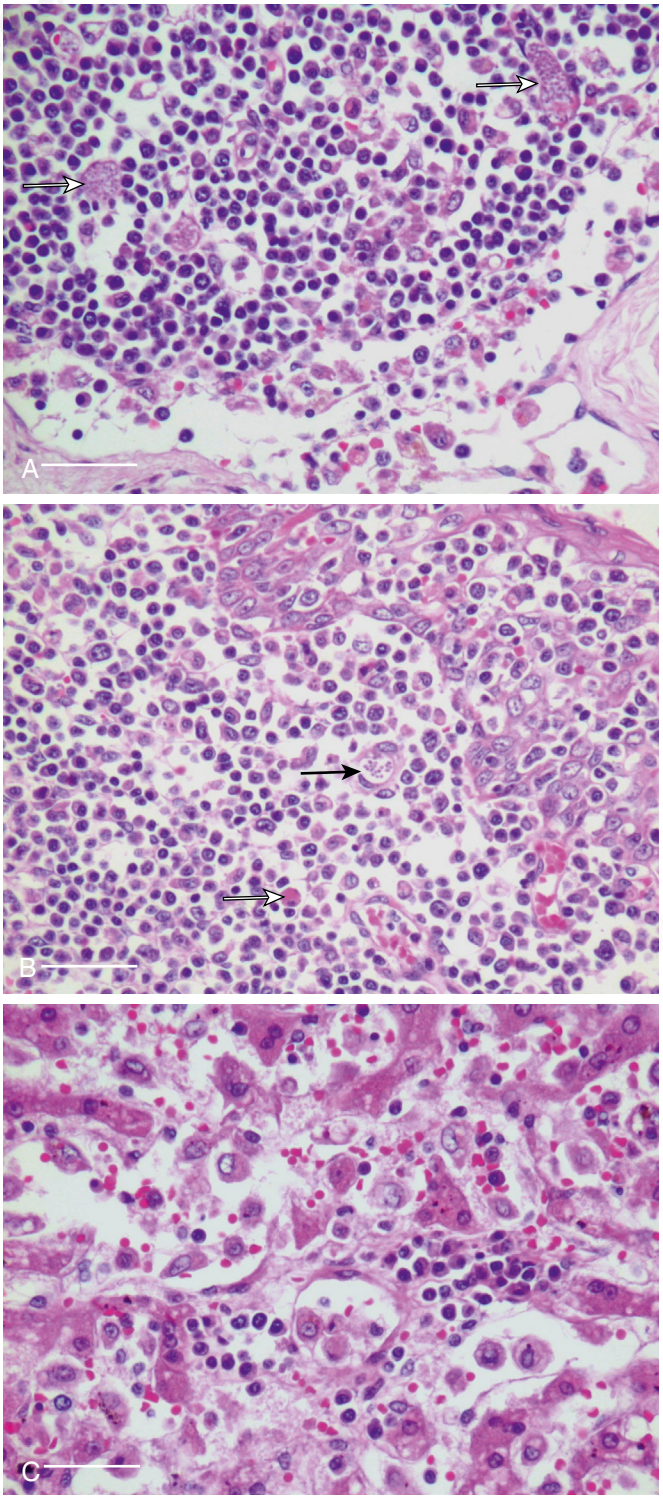

Fig. 105.5 Histopathologic findings in canine rangeliosis. There are multiple zoites of *R. vitalii* within capillary endothelial cells *(arrows)*. (A) Lymph node showing plasmacytic hyperplasia within the medullary cords with sinus histiocytosis. (B) In the tonsil, there is lymphoid and marked plasmacytic hyperplasia; a Mott cell is present in the center of the image *(black arrow)*. (C) Lymphoplasmacytic hepatitis with marked Kupffer cell hyperplasia (hematoxylin and eosin stain, bar = 100 μm). (Courtesy of Rafael Fighera, UFSM, Santa Maria, Brazil.)

pulp, due to proliferation of plasma cells and extramedullary hematopoiesis.[4] In the liver, there may be periportal inflammation, or less often, inflammation surrounding central veins, extramedullary hematopoiesis, and Kupffer cell hyperplasia (Fig. 105.5). There may also be centrilobular or midzonal necrosis, microthrombi, and evidence of biliary stasis.[4,17]

Renal changes include cortical and occasionally medullary interstitial inflammation, evidence of acute tubular necrosis, and accumulation of hemosiderin in tubular epithelial cells.[4,17,22] Mononuclear cell infiltrates surround glomeruli, and *R. vitalii* may be seen in capillary endothelial cells. Hyperplasia of all cell lines may be observed in the marrow. Hemosiderin-laden macrophages can be seen.[17]

Other changes may include myocarditis; pulmonary edema and interstitial inflammation with lymphocytes, plasma cells, and macrophages; and meningitis.[4,17,23]

TREATMENT AND PROGNOSIS

Drugs used for treatment of rangeliosis have included diminazene aceturate, imidocarb dipropionate, doxycycline, and trypan blue (Table 105.1).[5,25,28,42,43] Diminazene aceturate (3.5 mg/kg IM, once) was used successfully to treat dogs with experimental infection with *R. vitalii*.[25,42] Blood smears were negative for *R. vitalii* within 24 hours, and 9 days after treatment, all dogs were PCR negative for the parasite.[25] Nevertheless, diamizene aceturate has a low therapeutic index and neurotoxicosis has been reported.[6,17,44] The toxicity of the drug is cumulative and usually dose-related, but individual variation in susceptibility and idiosyncratic reactions can occur. Repeat administration should be avoided for at least 2 weeks after the first injection, and attention should be paid to the animal's body weight to avoid overdosing and toxicosis.[44] Imidocarb dipropionate (5 mg/kg) has been used as a single dose or as two doses given at 2-week intervals, alone or in combination with doxycycline.[6,17,28,29] Anticholinergic adverse effects of imidocarb, such as vomiting, diarrhea, salivation, and muscle tremors, can be controlled with atropine (0.005 mg/kg SC).[44] Doxycycline (5 mg/kg q12h for 28 days) has been used with apparent success.[5,6,17] Trypan blue was used in the first reported cases of the disease; however, it is no longer used. The drug must be administered IV and, in case of perivascular extravasation, can cause tissue necrosis.[5,43]

Glucocorticoids have been used to address the immune-mediated consequences of the disease (i.e., IMHA and ITP) in some cases.[5,6,17,42] Blood transfusion and supportive fluid therapy are necessary in those cases in which anemia is severe.[5,17] If not properly treated, rangeliosis is usually fatal.[22]

IMMUNITY AND VACCINATION

Dogs that recover spontaneously or are treated for rangeliosis may develop immunity against a new infection by *R. vitalli*, but parasite persistence for months in the face of subclinical infection has also been documented.[17] Vaccines for *R. vitalii* infection are not available.

PREVENTION

Prevention relies on avoidance of tick-infested areas and the use of appropriate ectoparasite preventives. Routine inspection of dogs and rapid removal of ticks after outdoor activities, such as hunting, can help to prevent the infection.

PUBLIC HEALTH ASPECTS

There is no evidence that *R. vitalii* can infect humans.

NONENTERIC (FREE-LIVING) AMEBIASIS

Marc Kent, Elizabeth W. Howerth

INTRODUCTION

Amebas that belong to the genera *Acanthamoeba, Balamuthia*, and *Naegleria* are free-living, amphizoic, and opportunistic protozoa that are ubiquitous in nature. Infections with these amebae are rarely reported in

TABLE 105.1 Antimicrobials Used in the Treatment of Rangeliosis

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration
Diminazene aceturate	3.5	IM	Once	NA
Imidocarb dipropionate	5	IM	Once	Repeat in 14 days
Doxycycline	5	PO, IV	12 hours	28 days
Trypan blue	10	IV	Once	NA

IM, intramuscular; NA, not applicable; PO, oral.

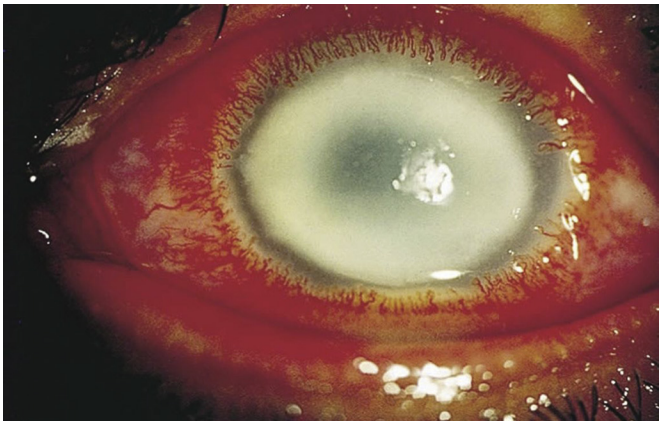

Fig. 105.6 *Acanthamoeba* keratitis with characteristic corneal ring infiltrate in a human patient. The disease can be sight-threatening and lead to corneal perforation. (From Garg P, Rao GN. Corneal ulcer: diagnosis and management. *J Comm Eye Health.* 1999;12:21.)

humans and companion animals. Infections often are disseminated, with frequent involvement of the CNS; the respiratory system and kidneys may also be involved. Localized corneal infections with *Acanthamoeba* occur in humans, most often associated with contact lens or corneal trauma, as well as following LASIK procedures (Fig. 105.6). *Acanthamoeba* spp. keratitis has also rarely been reported in dogs and cats. In humans, CNS infections with *Acanthamoeba* spp. and *Balamuthia mandrillaris* are referred to as *granulomatous amebic encephalitis* (GAE), whereas infections with *Naegleria* are referred to as *primary amebic meningoencephalitis* (PAM) in an effort to denote restriction of the infection to the CNS. Systemic infections with *Acanthamoeba* spp. and *B. mandrillaris* have only been described in dogs and not cats, and PAM has not been reported in companion animals.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Acanthamoebae are ubiquitous free-living amebae found in a multitude of water sources including fresh and salt water, as well as soil, dust, and sewage.[45-51] The classification of the genus *Acanthamoeba* and separation from the closely related genera have had a confusing history that is becoming resolved only with the use of molecular techniques.[52] Acanthamoebae are classified as distinct genera based on morphologic differences in the trophozoite shape and cyst wall structure, nutritional requirements, and serologic responses by infected hosts.

Acanthamoeba spp. have been divided into three morphologic groups (I, II, and III) based on trophozoite and cyst size and structure. Although this morphologic classification is used, genetic comparisons have suggested the need for additional taxonomic reevaluation. Twenty different genotypes (T1 to T20) exist based on rRNA sequencing.[53] The majority of infections in human beings (those not in association with ocular keratitis) involve the T4 genotype.[51,54] Too few cases have been reported in dogs to identify a common genotype. The T4 genotype has been documented in dogs with and without disease.[55-59] Interestingly, the T1 genotype also has been documented in affected dogs.[60,61] All the pathogenic ameba are known to harbor obligate intracellular prokaryotes including bacteria, chlamydiae, and viruses. The role of these endosymbionts in the production of disease or transport of these organisms is uncertain.

The life cycle of *Acanthamoeba* involves two stages: one, a dormant free-living cyst in the environment, and the other, a vegetative trophozoite form capable of parasitizing and feeding in host tissues. The vegetative replicating trophozoite has two distinct phagotrophic niches: (1) feeding on bacteria in aquatic habitats and (2) acting as opportunists of host cells in the body. The cyst phase is often able to resist adverse environmental conditions, including desiccation and possibly host immune responses. Cysts can survive exposure to temperatures between −20°C and +42°C and a pH of 3.9 to 9.75.[62]

In the environment, *Acanthamoeba* species are omnipresent and abundant. They have been isolated from all fresh-water sources and vegetation. In the atmosphere, they are carried on pollutants, and their concentrations have been used as potential monitors of air quality. After ingestion, they may be inhabitants of the GI tracts of many animals and human beings and can be found in their feces.[63]

Several *Acanthamoeba* species are pathogenic for animals and human beings. They can subclinically colonize superficial epithelial surfaces but can also produce ocular surface infections and may disseminate in immunocompromised individuals. Disseminated infections usually involve the CNS. *Parachlamydia acanthamoebae,* a chlamydial endosymbiont of *Acanthamoeba* spp., has been associated with pneumonia in human beings.[64] *Parachlamydia acanthamoebae* has also been detected in topical ocular specimens from human beings[65,66] and cats[67,68] with conjunctivitis with or without keratitis. The prevalence of infection was similar in cats with or without corneal disease, indicating that clinically healthy cats may harbor this organism.[69] Cats in this latter study also had an equal prevalence of infection whether they were kept indoors or outdoors. Furthermore, they harbored *P. acanthamoebae* without *Acanthamoeba* spp. being detected.[69]

Three related amebae, *B. mandrillaris, Naegleria fowleri,* and *Sappinia pedata,* also cause meningoencephalitis or encephalitis in human beings and nonhuman primates (also known as "brain-eating ameba").[70] Of these organisms, disseminated infection with *B. mandrillaris* has been reported in several dogs with granulomatous meningoencephalitis,[71-74] one with concurrent granulomatous nephritis[72] and another with concurrent pneumonitis.[73] One dog had a history of exposure to stagnant water.[74] Systemic infections with *Acanthamoeba* spp. develop in immunocompromised human beings; however, those caused by *N. fowleri* and *B. mandrillaris* spp. can affect immunocompetent humans. Infection with *N. fowleri* is acquired through swimming in contaminated waters, with the infection spreading through the olfactory neuroepithelium to the CNS, and reports typically involve children. In contrast, infections with *Acanthamoeba* and *B. mandrillaris* are subacute infections that may also follow hematogenous spread of organisms from pulmonary or cutaneous sites to the CNS. Most human infections with *B. mandrillaris* in the United States have come from California, followed by Texas and Arizona.

In dogs, epizootics of acanthamebiasis have been observed in greyhounds.[75] Affected greyhounds ranged from 4 to 13 months of age. During outbreaks, organisms are thought to be acquired from a common environmental source rather than from other animals. However, most reported cases of acanthamebiasis involve a single dog. Young dogs appear to be most susceptible. Affected breeds reported include two German shepherd dogs, one 6 months old and one 4 years old;[76,77] a 1-year-old Labrador-type dog;[60] an immunosuppressed Akita;[78] an immunosuppressed 10-month-old boxer;[61] and a 22-month-old Spanish water dog.[58] While most are disseminated infections, *Acanthamoeba* infection with genotype T4 was reported in the prostate of a 10-year-old mixed breed dog.[56] *Balamuthia* spp. infections have

been reported in a golden retriever (Melbourne, Australia), Australian blue heeler (Melbourne, Australia), great Dane (northern California, USA), and Siberian husky dog (Oklahoma, USA).[71-74]

The source of infection and the incubation period in dogs are unknown. Immunosuppression is likely involved in the development of most infections. In one dog infected with *Acanthamoeba castellanii,* T cell function was abnormal based on lymphocyte blastogenesis in response to various mitogens, consistent with immunosuppression or T cell–mediated immunodeficiency.[78] Although immunocompetency is often not evaluated, affected dogs often have been treated with immunosuppressive drugs when infection was diagnosed.[61] In other cases, infection has occurred in dogs obtained from shelters.[60,77] Concurrent acanthamebiasis and distemper in affected dogs further supports the role of an incompetent immune system in the pathogenesis of the infection.[79]

Acanthamoeba infection is rare in cats. Despite this, strains consistent with *A. castellanii* genotype T4 were isolated from 10 of 64 cats with clinical signs of keratoconjunctivitis.[80]

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

The pathogenesis of nonenteric amebiasis in dogs is unknown. In humans, routes of infection may include inhalation of organisms from water while swimming or from contaminated air. The organisms can replicate in the upper or lower respiratory tract after inhalation, or may replicate in skin or other tissues after penetrating injuries and then spread to the CNS by hematogenous means. Alternatively, infection of the cornea and nasal passage might lead to a spread to the nervous system via optic and olfactory nerves, respectively. In one dog with acanthamebiasis, distribution of the brain lesions suggested penetration of the cribriform plate.[77] Experimentally, *Balamuthia* has been shown to infect the brain via the olfactory nerves in immunodeficient mice,[81] and this may be a likely route for natural infection.

Acanthamoeba sp. infection was identified in two dogs from Florida with preexisting chronic keratoconjunctivitis sicca treated with topical immunosuppressive drugs that developed localized granulomatous keratitis, which was evident on ocular examination as fleshy mass lesions.[82] Clinical manifestations of systemic canine acanthamebiasis often include mild ocular and nasal discharge, anorexia, lethargy, and fever.[60,74,78] In many dogs, acute onset of respiratory distress and neurologic dysfunction are present.[61] Neurologic signs include incoordination, head tilt, stumbling, dysmetria, and seizures. Severely affected dogs are tetraplegic and in lateral recumbency. Cough and dyspnea may be observed together with neurological signs, or respiratory signs may develop a few days after the onset of neurological signs. In one dog, progressive neurologic signs developed as a result of meningoencephalitis, as well as the syndrome of inappropriate antidiuretic hormone secretion (SIADH).[77]

A dog with disseminated balamuthiasis developed lethargy, anorexia, diarrhea, and hematuria followed by neurologic dysfunction, including intermittent seizures, rotary nystagmus, recumbency, and coma.[72] Another dog had an 8-month history of generalized seizures that had been controlled with phenobarbital.[73] Two months before referral, the dog had been evaluated for deafness, a left-sided head tilt, and circling. A diagnosis of CNS lymphoma was suspected based on CSF analysis, which revealed a lymphocytic pleocytosis with atypical lymphocytes. The dog was treated with glucocorticoid and lomustine therapy. Four weeks later, the dog was evaluated for respiratory distress and hypotension and was euthanized.[73] In one dog with no previous history of illness, acute signs of left-sided central vestibular dysfunction developed. Balamuthiasis localized to the cerebellum was observed at necropsy.[74] Acute onset of seizures was reported in another dog that had right cerebral frontal cortex involvement at necropsy.[71]

DIAGNOSIS

Laboratory Abnormalities

Laboratory abnormalities in animals with systemic amebiasis are nonspecific. The CBC often reveals a neutrophilic leukocytosis. In some animals, leukopenia is observed. Leukopenia in greyhounds is a result of marked lymphopenia and in other breeds is caused by a reduction in all types of blood leukocytes.[76,78] Similar laboratory findings have been documented in dogs with *B. mandrillaris* infection. On the serum biochemistry panel, increased serum liver enzyme activities and renal azotemia may be observed if kidney and liver involvement is present. Azotemia may also reflect dehydration.

Cerebrospinal Fluid Analysis

In dogs with neurological signs, CSF may have a pleocytosis and elevated protein concentration. The degree of pleocytosis has ranged from 234 nucleated cells/μL to 2,925 nucleated cells/μL and has been characterized by a mixture of nondegenerative neutrophils and large mononuclear cells and lymphocytes.[74,77] Protein concentration may be greater than 1 g/dL.[77]

Diagnostic Imaging

Plain Radiography

In one dog with pulmonary infection, thoracic radiographs disclosed a diffuse bronchial to interstitial pattern.[61]

Sonographic Findings

Nonspecific changes are observed on abdominal ultrasound examination which likely reflect infection involving organs such as the liver and kidney. In a dog with *Acanthamoeba* infection localized to the prostate, multiple cysts in the prostate were identified.[56]

Advanced Imaging

Too few cases with neurological signs have undergone advanced imaging using CT or MRI examinations to characterize lesions. In one dog, CT disclosed a ring-enhancing lesion in the cerebellum.[74] In another dog, MRI disclosed a heterogenous mass that was ring-enhancing following contrast administration.[79]

Microbiologic Tests

Cytological Diagnosis

Antemortem diagnosis of amebic infection is rare; the diagnosis necessitates the identification of trophozoites or cysts. Organisms are rarely observed in CSF. Despite the lack of clinical reports that document evidence of infection in specimens obtained from the respiratory tract, it may be possible to make a diagnosis using BAL or lung biopsy in animals with respiratory disease.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Because these amebae are difficult to distinguish morphologically, PCR testing offers the most specific and reliable means of species identification.[57,58,70,83,84] PCR-based assays have been used frequently on isolates in culture as well as from necropsy specimens. Demonstration of *Acanthamoeba* and *Balamuthia* have been documented in archived, formalin-fixed, and paraffin-embedded specimens using molecular techniques.[84]

Cell Culture

Acanthamoeba spp. can be easily cultured on non-nutrient agar plates coated with bacteria such as *Escherichia coli* or *Enterobacter aerogenes*.[51]

Amebae demonstrate a preference for nonencapsulated and nonpigmented bacteria as the mucoid capsules of the bacteria inhibit phagocytosis by the ameba and bacterial pigments may be toxic.[51] Early in the cultivation process, plaque-like clearings in the bacterial lawn may be observed; once the bacteria have been consumed, amebae encyst.[51] Cysts remain viable for prolonged periods of time, especially if the agar plate is sealed to prevent drying and kept at a reduced temperature.[51] Isolation of the parasitic amebae is possible using fresh frozen (−70°C) tissue that has been stored for up 2 months.[60] Cultivation using bacteria-free medium is also possible.

Pathologic Findings

Gross Pathologic Findings

A definitive diagnosis of systemic amebiasis is almost always made at necropsy. In dogs with acanthamebiasis, lung and brain lesions have been observed grossly in almost all reports, but small nodules that range in color from white to reddish-brown may be observed in the kidney and liver.[60,61] Lung lesions vary from light-tan to deep-red, raised, semisolid nodules distributed uniformly throughout all lobes.[61,76,78] The nodules have a tendency to coalesce, and intralesional cavitations have been noted. Brain lesions may be large, multifocal, and visible on the meningeal surfaces of the cerebrum and cerebellum and vary from red to tannish-brown as a result of recent hemorrhage or necrosis.

Histopathologic Findings

Microscopically, multifocal necrotizing and often hemorrhagic meningoencephalitis and pneumonia with purulent, pyogranulomatous, or granulomatous inflammation and intralesional amebic trophozoites and cyst forms, sometimes in macrophages, are seen (Figs. 105.7 and 105.8). In brain lesions, sometimes the amebae are best visualized in perivascular and subarachnoid spaces, because in the neural parenchyma they are often masked by the presence of infiltrating inflammatory cells. Similar necrotizing and purulent to granulomatous foci containing amebae may be seen in other tissues, including kidney, heart, liver, adrenal, lymph node, and pancreas.[60,61,76-78] Histopathology of biopsy specimens obtained from the two dogs with localized amebic keratitis revealed chronic granulomatous superficial keratitis with intralesional trophozoites and cysts.[82] Histologic and direct fluorescent antibody methods can be used to demonstrate and identify the organism in tissues. Free-living pathogenic amebae are difficult to differentiate microscopically from certain mammalian cells, especially macrophages.[85] The diagnostic feature of *Acanthamoeba* in histologic sections, which should help differentiate them from macrophages, is the eccentric nucleus with a large centrally located nucleolus (*targetoid karyosome*) and vacuolated cytoplasm. Gomori's methenamine silver and PAS stains can be used to help demonstrate the organism, but they only stain the cyst wall. Trophozoites are 15 to 50 µm in diameter, and cysts are 15 to 25 µm, depending on species.[51] The cysts have an outer wrinkled cyst wall and a variably shaped, PAS-positive inner wall. Direct fluorescent antibody staining is specific and reliable on deparaffinized sections of formalin-fixed tissue and, with specific conjugates, can be used to distinguish among the various species of *Acanthamoeba*. Nucleic acid–based assays have been used to document infection and for strain genotyping.[60,61,72,82]

In dogs with *B. mandrillaris* infection, grossly visible granulomas have been present in the kidneys, lung, and brain (Figs. 105.9 and 105.10).[15,16] In one dog, the kidneys had marked interstitial edema and necrosis with perivascular granulomatous inflammation (Fig. 105.11), and the brain had fibrinoid necrosis of vessels with marked perivascular pyogranulomatous inflammation mixed with fibrin and malacia surrounding the affected vessels. Trophozoite and fewer cyst forms were admixed with the perivascular infiltrates. Trophozoites are 15 to 45 µm in diameter and round to oval, with short cytoplasmic pseudopodia (Fig. 105.12) and a centrally located nucleus with one or two nucleoli. Cysts are 15 to 20 µm in diameter and surrounded by a double wall with an outer undulating wall and a thick round inner wall (Fig. 105.13). In a second dog, there was embolic pneumonia with small numbers of neutrophils and macrophages and large numbers of amebic trophozoites and fewer cysts, whereas the brain had chronic multifocal nonsuppurative meningoencephalitis in which amebic forms outnumbered inflammatory cells. Immunohistochemistry, fluorescent antibody staining, and PCR have been used on paraffin-embedded tissue for diagnosis.

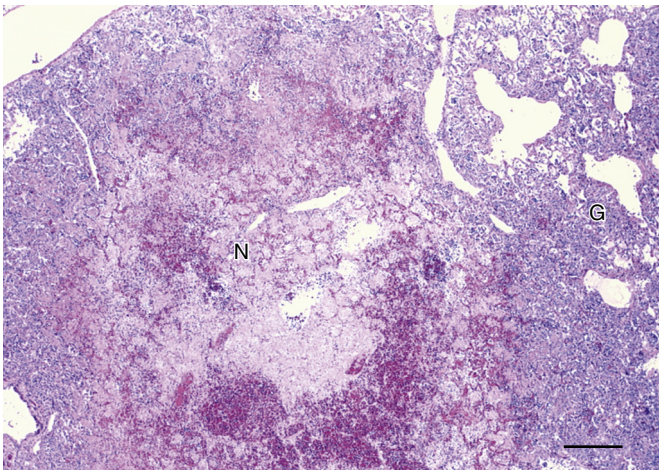

Fig. 105.7 Lung from a greyhound with acanthamebic pneumonia characterized by necrosis and hemorrhage (*N*) surrounded by pyogranulomatous inflammation (*G*) (hematoxylin and eosin stain, bar = 0.3 mm).

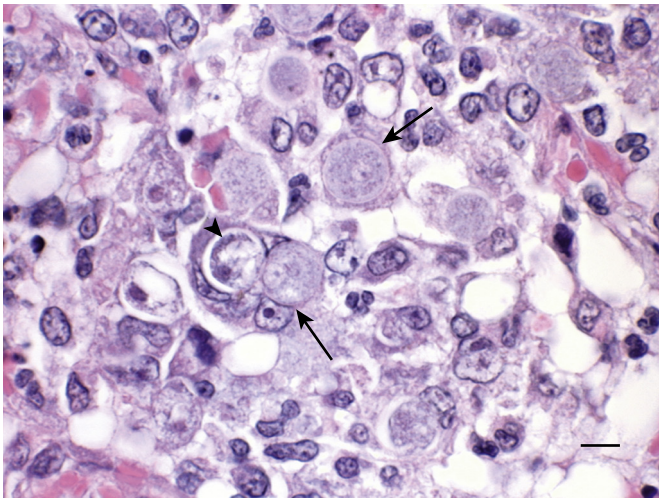

Fig. 105.8 Lung from a greyhound with acanthamebic pneumonia. *Acanthamoeba* trophozoites (*arrows*) and developing cysts (*arrowhead* shows mature cyst) are present in pyogranulomatous inflammation in an alveolus (hematoxylin and eosin stain, bar = 30 µm).

TREATMENT AND PROGNOSIS

Information on treatment of topical and systemic amebic infections in animals is lacking, and most infections are diagnosed at necropsy. Amebic keratitis was reported in one dog when topical tacrolimus for keratoconjunctivitis sicca was switched to topical 2% cyclosporine, and in another dog following topic treatment with 0.02% chlorhexidine digluconate and 0.02% polyhexamethylene biguanide.[82]

No therapeutic regimen for systemic acanthamebiasis in humans has been well established, and drug susceptibility has been inconsistent. Only a small number of humans have survived CNS involvement

worldwide. Drugs active against *Acanthamoeba* and some other amebae *in vitro* include polyene antifungals (amphotericin B); azoles (ketoconazole, fluconazole, and voriconazole); trimethoprim-sulfamethoxazole; and flucytosine.[47,50,86,87] Multidrug therapy is most often employed.[47,50,86-88] Of the azole drugs, voriconazole may be considered a first-line treatment for *Acanthamoeba* infection and is often used in multidrug regimens in humans.[86]

In addition to traditional antimicrobials such as voriconazole, the use of a statin drug with voriconazole may be effective.[89] This combination may cause cell death through apoptosis rather than necrosis and consequently provoke less of an inflammatory reaction which may lessen the morbidity associated with CNS inflammation.[89] Of note, voriconazole appears less effective against *B. mandrillaris*.[90,92] Instead, other medications including amlodipine, loperamide, and prochlorperazine have shown *in vitro* activity against *B. mandrillaris*.[92] Given the time it takes for identification and susceptibility testing, several combinations of medication have shown *in vitro* activity against both *Acanthamoeba* and *B. mandrillaris*. These combinations include prochlorperazine plus loperamide; prochlorperazine plus apomorphine; and procyclidine plus loperamide.[87] Such combinations may be used along with traditional antimicrobials (i.e., azole and trimethoprim-sulfamethoxazole). Despite the knowledge of *in vitro* susceptibility, it is unknown whether or not such medications would be effective in veterinary patients. Most drugs used for treatment are amebistatic with few being amebicidal, therefore successful treatment likely necessitates months or years of therapy.[47]

Early detection seems crucial to successful treatment in humans. In humans surviving infection, early diagnosis of cutaneous infection may enable implementation of treatment before dissemination occurs. In humans, skin lesions often precede CNS infections by weeks to months.[47] To date, successful therapy in dogs has not been described due to advanced disease at presentation, with dissemination to the CNS.

PREVENTION

As these ameba species are ubiquitous in the environment, prevention is difficult. It is likely that dogs are exposed to low numbers of *Acanthamoeba* organisms throughout their lifetimes. Because these amebae are free-living, infection prevention may involve avoiding access to contaminated water especially in animals with a compromised immune system.

PUBLIC HEALTH ASPECTS

Human infections are believed to originate from exposure to free-living amebae in the environment such as soils and water sources. Transmission from an infected animal to another is unlikely. However, the dog is sentinel for human infection because of common environmental exposure. Strains infecting dogs have been genotypically identical to those infecting humans.

GASTROINTESTINAL AMEBIASIS AND BALANTIDIASIS

Jane E. Sykes

Ameba species that belong to the genus *Entamoeba* and the ciliate protozoan *Balantioides coli* (formerly *Balantidium coli*) (da Silva et al, 2021) can infect the colon of dogs and cats.[92] Balantidiasis has been reported very rarely in dogs but not cats. Dogs with balantidiasis showed signs of large bowel diarrhea with hematochezia and tenesmus, although co-infections with *Trichuris* have been reported.[93,94] Cysts and occasionally trophozoites can be seen in fecal flotations, as well as in colonic biopsy specimens using histopathology (Fig. 105.14).

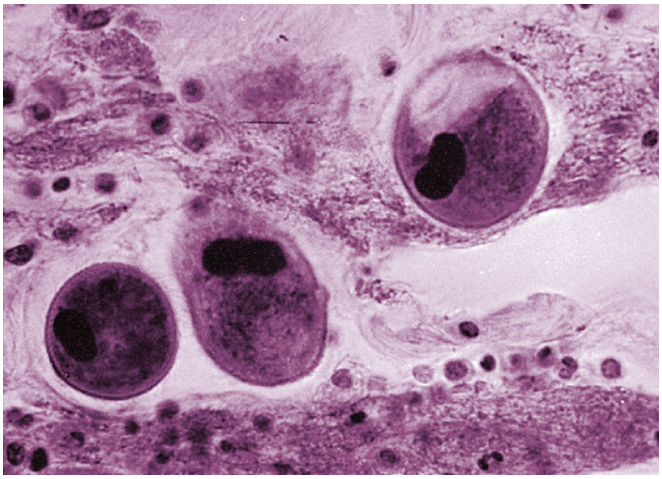

Fig. 105.14 *Balantioides coli* trophozoites in a section from the wall of a human colon. Note the prominent parasite macronuclei and the surrounding inflammatory response (hematoxylin and eosin stain, ×250).

There are several species in the genus *Entamoeba,* but only *Entamoeba histolytica* is recognized as a pathogen; in humans, *Entamoeba dispar* is considered a commensal and the pathogenic potential of *Entamoeba moshkovskii* is unclear. *Entamoeba histolytica* infection occurs worldwide and is an important cause of disease in humans and nonhuman primates. The life cycle of the organism as it relates to human infections is shown in Figure 105.15. Infection has also been described in both dogs and cats. A high prevalence of infection in dogs in Malaysia with *E. histolytica*, *E. moshkovskii* and *E. dispar* was documented in one study using PCR.[95] Most *Entamoeba* infections are subclinical, but large bowel diarrhea and anorexia can also occur.[96,97] Diagnosis is based on the finding of trophozoites in feces (Fig. 105.16) or in colonic biopsies using histopathology (Fig. 105.17). Dogs and cats may acquire infection from humans in the household, so the owners of pets diagnosed with *E. histolytica* infection should be referred to their physician for medical advice.

BLASTOCYSTOSIS

Jane E. Sykes

Blastocystis spp. are waterborne protozoal organisms that inhabit the intestinal tracts of humans and a wide variety of vertebrate animals. Analysis of the small subunit (SSU) rRNA gene suggests that they belong to the stramenopiles, a diverse group of protists that include the brown algae and diatoms; however, analysis of other portions of the genome indicates that they are related to *E. histolytica*. Analysis of the SSU rRNA gene also has identified 28 different subtypes (ST1 to ST32)[98]; ST1 to ST4 are the most frequently found in humans.

The significance of *Blastocystis* spp. lies in the fact that it is the most prevalent protozoa found in human fecal specimens worldwide, but its role in GI disease remains controversial because they are found widely as commensals. In humans, they have been incriminated as contributing to acute or chronic diarrhea, flatulence, irritable bowel syndrome, refractory ulcerative colitis, and colorectal cancer.[99] However, a large metagenomic study found no clear association between infection and disease among organisms worldwide, instead finding a higher prevalence of infection in healthy individuals.[100]

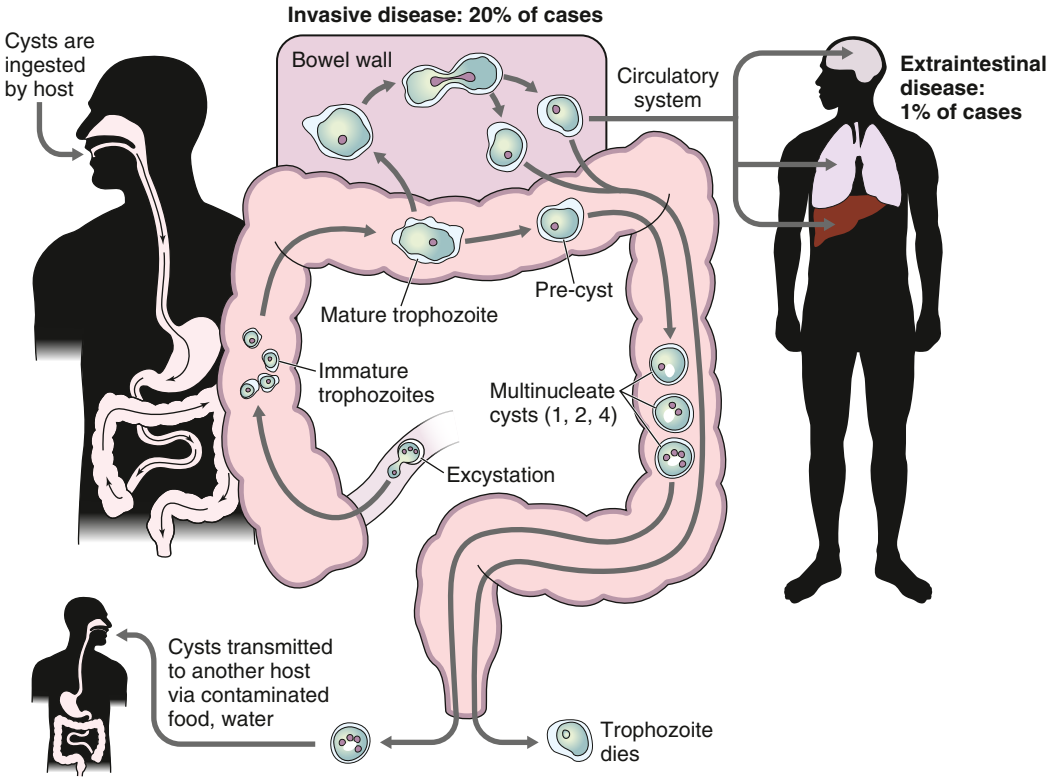

Fig. 105.15 Life cycle of *Entamoeba histolytica*. Infection is normally initiated by the ingestion of fecally contaminated food or water that contains cysts. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites form. In most infections, trophozoites aggregate in the intestinal mucin layer and form new cysts, which results in self-limited and asymptomatic infection. In some cases, however, adherence to and lysis of colonic epithelium leads to invasion of the colon by trophozoites. Extraintestinal spread to the peritoneum, liver, and other sites may follow.

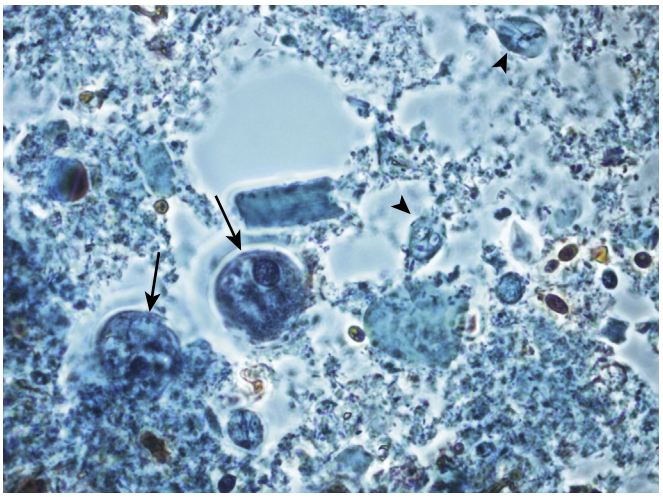

Fig. 105.16 Fecal smear from a woman who had recently traveled to India and developed severe diarrhea. Trophozoites of *Entamoeba histolytica (arrows)* and *Giardia (arrowheads)* are present. Trichrome stain. (Courtesy Dr. Patricia Conrad.)

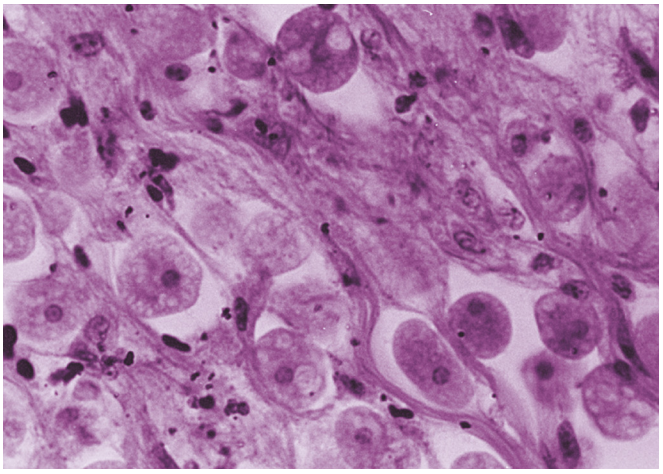

Fig. 105.17 Numerous *Entamoeba histolytica* trophozoites in a section from the wall of a human colon. Each organism contains a single, darkly stained nucleus; in some of the trophozoites, pale vacuoles are apparent (hematoxylin and eosin stain, ×540).

The life cycle is believed to involve ingestion of a cyst form, with excystation in the large intestine. The cyst then transforms into a vacuolar form which then encysts and is excreted. Risk factors in humans for infection have included immunocompromise, travel to and residence within developing countries, and exposure to contaminated food and water. Several investigators have examined subtypes of *Blastocystis* spp. in companion animals because of interest in the possibility of zoonotic transmission.[101,102] Cysts can be identified in wet mounts as irregular structures (2–25 μm in diameter) with barely discernable organelles, an outer rim of cytoplasm, and a central vacuole (Fig. 105.18A). They can be stained with Lugol's iodine, Wright, or trichrome stains (Fig. 105.18B). The internal structures are more discernable using electron microscopy (Fig. 105.18C). PCR-based assays have also been developed for their detection. Identification of *Blastocystis* spp. organisms in canine and feline fecal specimens should be considered an incidental finding.

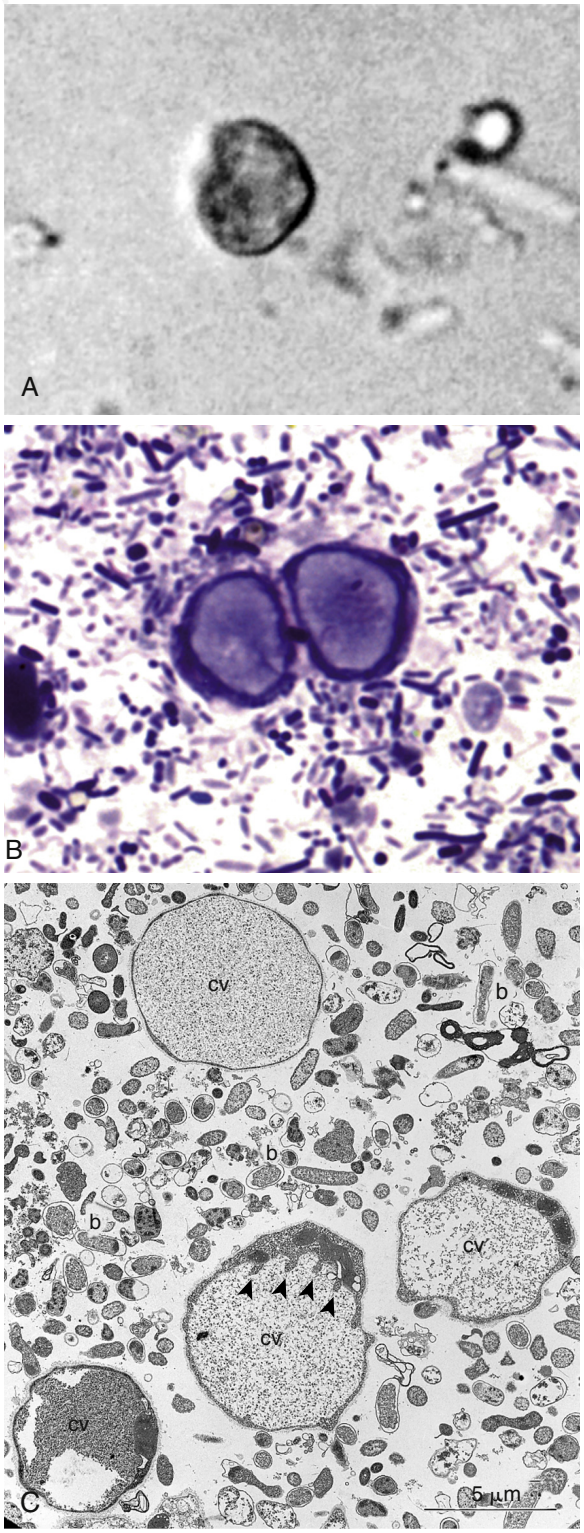

Fig. 105.18 *Blastocystis* sp. in canine fecal material. (A) Unstained wet mount (×1000). (B) Diff-Quik stain (×1000). (C) Transmission electron micrograph showing cell morphology. Variability is noted in the central vacuolar (*cv*) contents. One cell shows projections of the cytoplasm (*arrowheads*) into the central vacuole. Numerous bacteria (*b*) are present in the culture. CASE EXAMPLE

Signalment
"Luna", 10-month-old female German shepherd dog from Porto Alegre, RS, Brazil.

History
Luna's owner reported a 6-day history of lethargy and progressive inappetence. Two days before evaluation the owner noted diarrhea containing fresh blood, and bleeding from the tips of Luna's ears. Luna lived on a hobby farm with frequent exposure to ticks, and her owner had removed some engorged ticks from Luna before taking her to the clinic. She had never traveled out of her local area, and was up to date on vaccinations.

Physical Examination Findings
Luna was weak and quiet, and estimated to be 10% dehydrated. T = 104.5°F (40.3°C), with icteric mucous membranes. There was no evidence of ectoparasites. Peripheral lymphadenomegaly was present. Abdominal palpation revealed splenomegaly and a fluid-filled intestinal tract. Bloody diarrhea was present on the thermometer. There was extensive hemorrhagic crusting on the outer surface of the pinnae, and excessive bleeding from a venipuncture site was noted.

Laboratory Findings
CBC: HCT 20% (40–55%), MCV 80 fL (65–75 fL), MCHC 32.5 g/dL (33–36 g/dL), WBC 11,900 cells/µL (6000–13,000 cells/µL), neutrophils 6188 cells/µL (3000–10,500 cells/µL), lymphocytes 3808 cells/µL (1000–4000 cells/µL), monocytes 1904 cells/µL (150–1200 cells/µL), platelets 58,000 platelets/µL (150,000–400,000 platelets/µL). Blood smear evaluation revealed intraerythrocytic merozoites consistent with *Rangelia vitalii*.

Diagnosis: Rangeliosis

Treatment
Diminazene aceturate (3.5 mg/kg IM, single dose), immunosuppressive doses of glucocorticoids for 1 week and supportive treatment.

Comments
Rangeliosis was suspected in this case because of the geographic location (southern Brazil), clinical signs (especially bleeding from the tips of the pinnae), and history of tick exposure. Although examination of peripheral blood smears is not a sensitive diagnostic procedure, the diagnosis was confirmed in this case based on cytological examination. The probability of finding the parasite is higher when blood is collected during an episode of high fever, as was present in this case. After 36 hours Luna showed clinical improvement, and made a full recovery in 3 weeks.

SECTION 5

Metazoan Parasites and Parasitic Diseases

Susan E. Little

Metazoan parasites include some of the most common and medically important pathogens of dogs and cats. In the absence of careful, consistent control strategies, both external parasites (e.g., fleas, ticks, mites; Chapters 106–110) and internal parasites (e.g., intestinal helminths, heartworm; Chapters 111–118) can quickly become established in companion animals, leading to poor body condition, disease, and, in severe cases, death. Fortunately, well cared for pets maintained on preventives are unlikely to develop clinical disease due to parasites; however, because many dogs and most cats are not routinely treated, the conditions caused by these preventable infections and infestations remain familiar to those in general practice. In addition, less commonly encountered parasites of dogs and cats, including gastrointestinal nematodes like *Physaloptera* or *Strongyloides stercoralis*, lungworms, and trematodes (Chapter 116–118) occasionally infect and cause clinical signs in pets. Diagnosis of a parasitic infection or infestation is readily achieved by identifying the organisms directly; examining skin scrapes, blood, or feces by microscopy; or detecting antigen using widely available commercial tests (Chapter 5).

The goal of Section 5 is to convey the relevant features of epidemiology and natural history that lead to the presence of each of the most common types of parasites in dogs and cats and to explain some key strategies for effective diagnosis, treatment, and prevention. These organisms can also create a zoonotic risk, so public health issues associated with parasites are discussed in each chapter. A related risk not always fully appreciated in clinical practice is the damage parasites can cause to the human-animal bond; because most pet owners find metazoan parasites unpleasant or repulsive, effective control strategies are critically important in fostering and maintaining a close relationship between pets and their owners. Ideally, pets would be protected from parasites through careful management to limit infection risk and routine use of preventives. However, because these organisms are almost ubiquitous, and because many pets do not receive veterinary care, eliminating infection risk is all but impossible. Thus, although prevention is the preferred strategy, a second goal of Section 5 is to provide an overview of the best treatments currently available to clear parasites from pets when they occur and to limit, to the extent possible, the pathology caused by these infections and infestations. Parasite treatment is also covered comprehensively in Chapters 12 and 13.

VetBooks.ir

Fleas and Lice

Susan E. Little

KEY POINTS

Fleas

- First Described: Familiar since antiquity, fleas (*Pulex irritans*, *Tunga penetrans*) were first described in the 10th edition of *Systema Naturae* published by Linnaeus in 1758. *Ctenocephalides canis* was first described by Curtis in 1826, *Ctenocephalides felis* by Bouché in 1835, *Echidnophaga gallinacea* by Westwood in 1875, and *Pulex simulans* by Baker in 1895.
- Cause: *Ctenocephalides felis* (cat flea) most common on dogs and cats worldwide; also *Ctenocephalides canis* (dog flea), *Echidnophaga gallinacea* (sticktight flea), *Pulex* spp. (human flea), *Xenopsylla cheopis* (rat flea) (family Pulicidae, order Siphonaptera); *Tunga penetrans* (chigoe flea, jigger) (family Hectopsyllidae (formerly Tungidae), order Siphonaptera).
- Affected Hosts: Dogs, cats, other domestic animals, and peridomestic wildlife.
- Geographic Distribution: Most fleas of companion animals (*Ctenocephalides* spp., *Pulex* spp., *E. gallinacea*) are found worldwide, sparing high altitude and arid regions; *T. penetrans* is native to the Caribbean, Central America, and South America, and has been introduced to and established in sub-Saharan Africa, especially East Africa, and India.
- Primary Mode of Transmission: Infestations are most often acquired through direct contact with emerging fleas from pupae in the environment. Fleas are persistent or permanent ectoparasites of the host; although considered a secondary infestation route, a few fleas may occasionally move directly from an infested animal to another animal in close, prolonged proximity.
- Major Clinical Signs: Pruritus; anemia; flea allergy dermatitis consisting of tail head or abdominal alopecia, seborrhea, pyotraumatic dermatitis, and secondary infections (dogs); or miliary dermatitis especially around the neck (cats). Pruritus may be the primary clinical sign or, in some flea-infested animals, absent. Direct evidence of flea infestation (fleas, flea frass) is absent in the majority of dogs and cats with flea allergy dermatitis. Fleas also serve as vectors for common pathogens, including *Bartonella* spp. and *Dipylidium caninum.*
- Differential Diagnoses: Atopic dermatitis; dermatophytosis, bacterial pyoderma, *Malassezia* dermatitis, mite infestations (*Cheyletiella* spp., *Demodex* spp., *Notoedres cati*, *Otodectes cynotis, Sarcoptes scabiei, Lynxacarus radovskyi*), lice infestation, mosquito allergy, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: Humans, especially those sharing a home with infested pets, are at risk of experiencing flea bites, particularly on the feet, ankles, and lower legs. The bites occur when adult fleas emerge from pupae and feed on humans instead of pets. Children less than 10 years of age are particularly likely to develop a localized allergic reaction to the bites.

Lice (pediculosis)

- First Described: *Trichodectes canis* was first described in 1778 by De Geer. *Linognathus setosus* was described in 1816 by von Olfers, and *Heterodoxus spiniger* by Enderlein in 1909. *Felicola subrostratus* was first described in 1838 by Burmeister as *Trichodectes subrostratus* and moved to a newly erected genus, *Felicola*, by Ewing in 1929.
- Cause: Dogs: *Trichodectes canis*, *Linognathus setosus*, *Heterodoxus spiniger*; cats: *Felicola subrostratus* (family T*richodectidae* [*T. canis*, *F. subrostratus*], *Boopiidae* [*H. spiniger*], and *Linognathidae* [*L. setosus*], order Psocodea, clade Phthiraptera.
- Affected Hosts: Dogs and closely related wild canids (coyotes, wolves) are infested with *T. canis* and *L. setosus. Heterodoxus spiniger* evolved on dingo hosts but is now found on domestic dogs and other wild canids (jackals, coyotes, wolves, foxes), and occasionally on cats, primarily in warmer areas of the world. Domestic cats are hosts for *F. subrostratus.*
- Geographic Distribution: Lice are found on dogs and cats worldwide although prevalence and species composition vary by geography and climate. Lice are more common in free-roaming populations and in dogs and cats not regularly treated with ectoparasiticides. Some species (e.g., *T. canis*) are more common in colder areas, while others (*H. spiniger*) predominate in warmer regions.
- Primary Mode of Transmission: Infestations are acquired through direct contact between animals, including from dam to nursing young in the neonatal period. Lice may also be spread through fomites (e.g., brushes, bedding). All stages of the louse life cycle are found on the host.
- Major Clinical Signs: Pruritus; alopecia; anemia (*L. setosus*); presence of eggs (nits) adherent to and different stages of lice grasping the hair shaft.
- Differential Diagnoses: Flea allergy dermatitis; atopic dermatitis; dermatophytosis, bacterial pyoderma, *Malassezia* dermatitis, mite infestations (*Cheyletiella* spp., *Demodex* spp., *Notoedres cati*, *Otodectes cynotis, Sarcoptes scabiei, Lynxacarus radovskyi*), mosquito allergy, cutaneous adverse food reactions, autoimmune disease.
- Human Health Significance: None. Lice are host-specific parasites, and people acquire lice from other people, not from pets or from an environment with pets.

FLEAS: *CTENOCEPHALIDES* SPP.

ETIOLOGY AND EPIDEMIOLOGY

Despite decades of safe, effective control products, the cat flea (*Ctenocephalides felis*) remains the most important ectoparasite of dogs and cats and infestations are commonly seen even in well-cared-for pets.[1] Dogs are sometimes also infested with *Ctenocephalides canis*, the dog flea, and subspecies of *C. felis* have been described, but *Ctenocephalides felis felis* predominates on both dogs and cats in most regions worldwide and will be the focus of this chapter.[2,3] Adult *C. felis*, like all fleas, are obligatory blood feeders in the order

Fig. 106.1 Adult female *Ctenocephalides felis,* lateral view and en face showing genal *(G)* and pronotal *(P)* comb. (From the National Center for Veterinary Parasitology.)

Siphonaptera. They are small (1–2 mm), laterally compressed, and reddish-brown in color. Both a genal ctenidium (comb) on the anteroventral aspect of the head and a pronotal ctenidium on the first thoracic segment are present (Fig. 106.1). Although morphologically very similar, *C. felis* can be distinguished from *C. canis* by the relative length of the first genal spine, shape of the head, and number of tibial teeth.[4,5] Fleas live in the haircoat of infested animals, rarely leaving once they have located a host, and both males and females feed on capillary blood.[6,7] Fleas begin feeding almost immediately after acquiring a host, with 25% of fleas engorged after 5 minutes and all fed in the first hour.[8]

Mating occurs within 8 to 24 hours of initial infestation and most females are mated by 34 hours. Egg production can be initiated as soon as 24 to 36 hours after the first blood meal and peaks 4 to 9 days after infestation, with each female producing 40 to 50 eggs per day during peak reproduction. If not removed by host grooming, 85% of females and 58% of males will survive on the host at least 50 days, and a few continue to persist for more than 100 days.[2,6,9] However, host grooming is a major source of flea mortality, with approximately 4% to 18% of fleas removed each day. Accordingly, the longevity of fleas on the host averages 7.8 days.[10] Flea-allergic cats remove a higher number of fleas than nonallergic cats; egg production is also reduced in female fleas fed on allergic cats.[11]

Eggs begin to fall from the host once dry (~2–8 hours after oviposition occurs), accumulating in the carpet, soil, or other substrate where the pet spends most of its time. The first instar larvae hatch and molt to second and third instars in the environment, feeding on flea feces that has also fallen from the haircoat. Flea eggs are also a major source of nutrition for maturing larvae, with some estimates suggesting that each larva may consume more than 20 eggs as it develops.[12,13] Larvae usually develop near where eggs are deposited, with most migrating < 15 cm; larvae are susceptible to desiccation and negatively phototactic, burrowing to the base of carpet or below sandy soil to develop. Mortality of immature stages is high; a majority do not develop to adult fleas.[2] Once fully mature, third instar larvae develop a pupal case to which debris often adheres (Fig. 106.2) and begin the process of metamorphosis to the adult flea. Adults emerge from the pupal case upon sensing host cues such as warmth or mechanical pressure. Females usually emerge before males. Newly emerged adults immediately seek a host and begin to feed and mate.[2] The timing of the life cycle is variable but can be completed in 3 to 8 weeks. Development from egg to adult fleas is faster in warmer

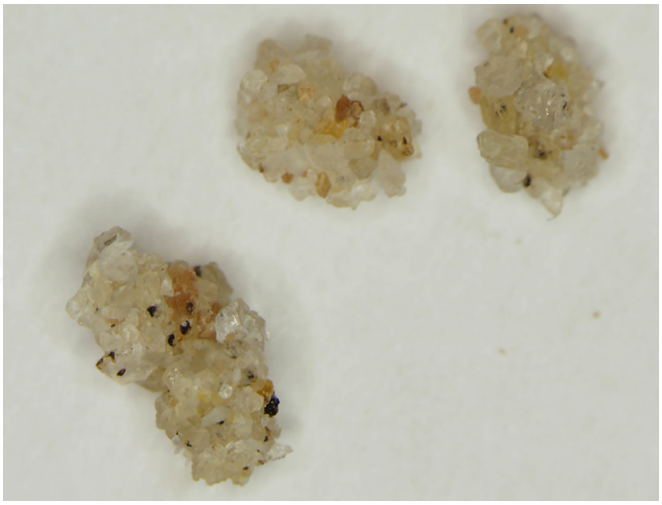

Fig. 106.2 Pupae of *Ctenocephalides felis.* Note the debris adherent to the pupal case. (From the National Center for Veterinary Parasitology.)

months (20 to 24 days) than in the winter (36 to 50 days); if protected in the environment under soil, vegetation, or leaf litter, pupae can survive frosts and some adults may emerge > 5 months after egg production.[14,15] In warmer areas, larvae can also survive outdoors year-round.[15,16] Several excellent comprehensive reviews of biology and life history of cat fleas are available.[1–3,6,15]

In most surveys, *C. felis* is the most common ectoparasite collected from free-roaming and pet dogs and cats. In warmer areas, prevalence of infestation in free-roaming animals exceeds 50% and, for some populations, approaches 100% (Tables 106.1 and 106.2); in temperate areas, 9.2%–25.6% of pet cats and 4.4%–16.3% of pet dogs seen at veterinary practices have evidence of flea infestation.[17–20] Prevalence of infestation is usually higher in cats than in dogs in the same region, and although seasonal patterns are evident and infestations peak in summer and early fall, fleas can be found throughout the year.[18,20–22] Risk factors for infestation in pet dogs and cats include outdoor access, failure to administer any flea control product, and multipet households.[18,20,23,24] In areas where *C. felis* occurs, flea allergy dermatitis (FAD) is often the most common allergic dermatologic disease of dogs and cats seen.[25–27]

Ctenocephalides felis is also commonly identified on peridomestic wildlife including opossums, foxes, coyotes, raccoons, bobcats, mustelids, and hedgehogs.[6,15] Historically, *C. canis* was identified more widely; predominance of *C. canis* persists in a few regions, including at higher altitudes.[5,18,28] Where *C. canis* is found, both *C. canis* and

Fig. 106.3 *Pulex irritans,* the human flea, and the morphologically similar *Pulex simulans,* can be distinguished from *Ctenocephalides* spp. by the absence of genal and pronotal combs. (From the National Center for Veterinary Parasitology.)

C. felis may be recovered from dogs, while primarily *C. felis* (and some other flea genera, see below) is identified on cats.[29] In some areas, low humidity and temperatures reduce flea populations dramatically and *Ctenocephalides* spp. are rarely found. Other fleas are occasionally found on pets. Brief summaries of *Echidnophaga gallinacea*, the sticktight flea, and *Tunga penetrans*, the chigoe flea, are provided at the end of this section. Other species sometimes reported from pets or free-roaming dogs and cats but considered of minimal clinical significance include *Pulex* spp. (Fig. 106.3), *Xenopsylla cheopis*, *Cediopsylla simplex*, *Leptopsylla segnis*, *Nosopsyllus fasciatus*, and *Rhopalopsyllus lutzi*.[17,21,30,31] Representative surveys documenting the prevalence of different flea species on dogs and cats are summarized in Tables 106.1 and 106.2.

PATHOGENESIS

Adult male and female fleas feed on blood. Female *C. felis* consume 13.6 μL daily, more than 15 times their body weight, with much of it excreted incompletely digested as flea frass and available as a nutrient source to larvae in the environment.[32] Intense infestations lead to blood loss and severe, iron deficiency anemia, particularly in young kittens, puppies, and small-breed dogs; fatalities can occur.[2,3,15] Feeding fleas also inject saliva that contains histamine-like compounds and other proteins which induce localized dermal inflammation at the bite site. Histologically, a perivascular eosinophilic dermal infiltrate develops; endothelial swelling, edema, and vesicles are evident.[27]

In animals with FAD, compounds in flea saliva induce type I (immediate), type IV (delayed), and cutaneous basophil hypersensitivity reactions; up to 30% of dogs only experience a delayed reaction.[15,27] Histologic changes are nonspecific and include edema and perivascular infiltration of eosinophils.[33] In dogs, basophils may be present, peaking 4 to 18 hours after exposure.[34,35] Flea-allergic dogs also have a higher number of mast cells before flea exposure, greater eosinophil infiltration after exposure, and a higher number of IgE+ cells after exposure than nonallergic dogs.[36] Cats with FAD demonstrate antigen-induced wheal formation and infiltration of lymphocytes and mast cells in response to flea antigen.[37]

Fleas are also important disease vectors, and infested pets are at risk of infection with *Bartonella* spp. (see Chapter 70), flea-borne *Rickettsia* spp. (see Chapter 46), *Acanthocheilonema reconditum* (see Chapter 111), and *Dipylidium caninum* (see Chapter 115). *Dipylidium caninum* was detected in 2.2% and 5.2% of individual *C. felis* collected from cats and dogs, respectively; 3.1% of *C. canis* from dogs were infected.[29] Distinct canine and feline genotypes of *D. caninum* have been identified by molecular comparison of proglottids shed by dogs and cats. When cysticercoids were present in fleas collected from animals, almost all *C. felis* (>95%) and all (100%) *C. canis* and *Pulex irritans* from dogs harbored *D. caninum* canine genotype. Similarly, when infected, almost all *C. felis* (>95%) recovered from cats carried the *D. caninum* feline genotype.[38,39]

CLINICAL FEATURES

Fleas are a major cause of pruritus and allergic dermatitis. In warmer areas with high humidity, fleas can be responsible for most dermatology issues seen in primary practice. All flea bites induce some local inflammation; true FAD, or an exaggerated response to antigen in flea saliva, develops in a subset of infested animals dependent on the frequency of flea exposure and degree of hypersensitivity in a given patient.[40] Intermittent flea exposure, as occurs with irregular use of flea control, is thought to promote development of FAD.[15,27] In an animal model, both intermittently and continuously exposed dogs developed FAD although erythema developed earlier and persisted longer with intermittent exposure.[41] In dogs with simple pruritus associated with flea infestation, fleas or flea frass can often be identified at physical examination (see Diagnosis). Skin lesions vary from mild irritation to pyotraumatic dermatitis. In contrast, direct evidence of flea infestation is lacking in the majority of dogs with FAD.

No breed or sex predisposition is seen with FAD. Although age can be affected, most dogs that develop FAD are between 2 and 5 years old. Atopy may also be present, and mixed signs of atopic dermatitis and FAD are common.[27,42] In some patients, addressing the flea infestation can support resolution of other allergies.[27] Classic lesions include erythema and alopecia in the lumbosacral area and base of the tail that extend down the pelvic limbs (Fig. 106.4); in canine FAD patients, the abdomen or caudomedial aspects of the pelvic limbs may also be affected. Excoriations, crusts, lichenification, or hyperpigmentation develop over time. Many nonallergic cats tolerate flea infestations well and remain subclinically infected. Cats with FAD are more likely to be pruritic, groom excessively, and often develop miliary dermatitis on the neck and head as well as alopecia at the base of the tail, in a stripe along the dorsum, on the face, and on the legs. Eosinophilic granuloma complex can develop—indolent ulcers are present in a majority of flea-allergic cats.[27,43] In temperate areas, lesions often resolve in winter months and recur in summer and early fall.[15,27,42]

Kittens, puppies, and small-breed dogs with flea anemia are usually covered with hundreds of fleas when examined. Entire litters may be affected and the diagnosis is readily confirmed by evaluating PCV. The history often includes outdoor exposure; housing in a shed, barn, or other open structure; and lack of flea control in the dam.[15] Flea-infested animals can also develop secondary bacterial or fungal dermatitis (see Chapters 79 and 119), flea-transmitted bacterial infections (see Chapters 46, 70, and 73), or present with *A. reconditum* microfilaremia (see Chapter 111) or *D. caninum* proglottids in the feces (see Chapter 115).

DIAGNOSIS

Direct Microscopic Examination

Although many animals with pruritus due to FAD do not present with direct evidence of fleas, infestation can be confirmed in some pets by identifying adult fleas or flea frass ("flea dirt"). Close examination of the haircoat and skin is required; recovery of fleas is facilitated by use of a fine-toothed comb (32 teeth/inch) and by systematic examination of the top of head, dorsal neck and midline, left and right lateral

Fig. 106.4 A 5-year-old mixed breed dog with lumbosacral alopecia, excoriations, and pruritus consistent with flea allergy dermatitis.

thorax, ventral neck, and ventral midline. On cats, most fleas are found on the head and neck and the lowest number are on the tail and legs.[44] Adult fleas are approximately 3- to 4-mm long and can be adhered to clear tape and examined with a microscope. *Ctenocephalides* spp. have both a genal and pronotal comb and rounded head (see Fig. 106.1). If specific identification is desired, fleas should be placed in 70% ethanol and submitted to a parasitology laboratory. Flea frass is often present on infested pets even when adult fleas are not identified. This dark, granular or coiled material can be confirmed to be the dried blood of flea feces by placing on a white paper towel and wetting slightly to reveal the dark-red color. Glistening white eggs approximately 0.5-mm long are occasionally found on pets with an active infestation.[3,15,45]

Serology

Flea-specific IgE can be measured in serum samples although levels do not necessarily predict severity of clinical disease due to FAD. In dogs continuously exposed to fleas, IgE concentrations correspond to clinical signs of FAD, but in dogs intermittently exposed, significant IgE titers may not develop even in patients for which FAD is confirmed.[41,46]

Laboratory Abnormalities

Anemia or eosinophilia can develop in animals heavily infested with or allergic to fleas, respectively. However, these changes are less likely to be seen in dogs. In an evaluation of a canine model for FAD, blood values remained normal despite clinical, serologic, and intradermal confirmation of flea allergy.[4] In contrast, in an animal model of feline FAD, cats developed eosinophilia, and a multiyear study documented FAD in 20.5% of cats with eosinophilia.[47,48] Cats also may be more prone to anemia from fleas. In a survey of urban cats submitted to a spay/neuter program in Brazil, 12.7% of cats were anemic, most anemic cats (78.4%) were infested with fleas, and there was a significant association between anemia and flea infestation.[49]

Flea allergy can be evaluated by intradermal or blood IgE tests although a treatment trial with a highly effective flea control product is more commonly used to confirm a diagnosis in practice.[46] At least 3 months of flea control is recommended prior to intradermal skin testing for other possible allergens.[46,50] A majority of dogs with FAD have both immediate and delayed positive skin test reactions to flea antigen; approximately 30% have only mild, delayed reactions. Some normal dogs also react.[27]

Gross Pathologic Findings

Flea feeding activity on dogs results in pruritic, erythematous wheals and papules which are often crusted. Erythema is variable, and moist, pyotraumatic dermatitis or acral lick granulomas may be present.[3,15] Dogs with acute FAD develop erythematous macules, papules, which are often crusted, and self-induced alopecia due to the persistent chewing induced by the intense pruritus. Lesion pattern (lumbosacral region, base of tail, caudolateral pelvic limbs) is distinct. When FAD is chronic and untreated, lichenification and hyperpigmentation occur due to chronic pruritus.[3,15,46] Cats infested with fleas may appear normal or show evidence of mild dermal reactions and pinpoint lesions where fleas have fed. Cats with FAD also develop erythematous wheals, crusted papules, and dorsal or lumbosacral alopecia as well as miliary dermatitis on the neck and head; erythema is absent and the abdomen is usually spared.[3,15,48] Kittens and puppies with flea anemia present with pale mucous membranes.[3,15]

TREATMENT AND PROGNOSIS

Elimination of mild to moderate flea infestations can be achieved by consistently treating pets with highly effective flea adulticides; in certain situations, severe infestations may warrant also treating the environment to reduce the burden of fleas likely to emerge and speed resolution of a home infestation. When almost all adult fleas on the pet are rapidly killed, and when insecticidal efficacy of pet-administered compounds persists for several weeks, ensuring new fleas acquired from the environment will also be killed, treating the pet alone is adequate. Environmental treatment becomes important when efficacy of persistent products wanes. Numerous field studies demonstrate that pet treatment alone controls home flea infestations as long as highly effective products are consistently administered.[50–65] Several studies conducted in the same region (west central Florida, United States) over the past 25 years provide incontrovertible evidence that pet-only treatments reduce or eliminate active, severe home infestations in challenging environments although efficacy of specific compounds may have shifted over time (Table 106.3).[50–58] Resistance to some older insecticides has been described in fleas although laboratory confirmation can be difficult. When using current flea control products, lack of efficacy is more likely due to issues with administration, compliance, and continued emergence of fleas from the environment.[66]

Flea control products are discussed in detail in Chapter 13. Compounds with activity against adult fleas include fipronil, indoxacarb, isoxazolines (e.g., afoxolaner, fluralaner, lotilaner, sarolaner), neonicotinoids (e.g., dinotefuran, imidacloprid, nitenpyram), pyrethrins, pyrethroids (e.g., deltamethin, permethrin), selamectin, and spinosyns (e.g., spinetoram, spinosad). Significant adulticidal activity persists for as short as 1 day to as long as 8 months depending on the compound and formulation. Care must be taken to ensure that all pets in the household are treated; untreated pets provide a reservoir supporting continued infestation. Similarly, free-roaming dogs or cats or peridomestic wildlife can increase flea populations around the home, allowing reintroductions to occur. Insect growth regulators (e.g., methoprene, pyriproxyfen) and insect development inhibitors (e.g., lufenuron) provide added

support to flea control efforts by limiting development of immature fleas in the environment. Some flea adulticides also reduce production or development of eggs or larvae.[1,15] Essential oils and other plant-derived flea products have poor or unknown efficacy.[1] Several essential oils have documented toxicity and should not be applied to pets.[67–69]

Kittens and puppies with flea anemia can be treated with fast-acting, mild insecticides, and combed to remove fleas. Depending on severity, management of anemia may require supportive care, iron supplementation, or blood transfusion to allow recovery; fatalities are reported.[3] Management of FAD in both dogs and cats requires consistent administration of highly effective flea control products to all animals in the household. The identification of bacteria using skin cytology sometimes supports prescription of antimicrobials to manage secondary infections associated with FAD. If pruritus is intense, a short course of oral glucocorticoids may be helpful. When effective, persistent insecticides are used, environmental treatment is not usually necessary; skin lesions and pruritus associated with FAD are significantly reduced by flea treatment alone.[54–65] Environmental cleaning to remove immature stages can be helpful for reducing the overall flea population, allowing more rapid eradication of the infestation. When owners consistently administer effective flea control to all pets in the home, dramatic reduction or elimination of flea populations is readily achieved.

IMMUNITY

Cats and dogs do not acquire natural immunity to flea infestations, and development of a vaccine for fleas, and for arthropods in general, is challenging.[1,15,70] One study showed a modest reduction (32%–46%) in flea egg hatching success following vaccination with recombinant antigens, suggesting immunity may be able to reduce flea populations over time.[71] Immunotherapy that combines antigens from flea saliva and T-cell suppression proteins reduced FAD in cats but is not commercially available.[1,48]

PREVENTION

Preventing flea infestations on pets involves consistent use of flea control products; when flea control is not administered, active infestations lead to environmental burdens of immature fleas, including pupae, which provide a source of infestation for several months. The CAPC recommends all pets be routinely treated throughout the year. All pets in the home that can support cat fleas (i.e., dogs, cats, rabbits, ferrets) should be treated to eliminate reservoirs. Keeping cats indoors and limiting roaming in dogs reduces acquisition of new fleas from contaminated outdoor areas. Exclusion of wildlife and free-roaming dogs and cats from the area immediately surrounding the home further decreases the likelihood of introduction of fleas. Routine use of insect development inhibitors or insect growth regulators, vacuuming areas where pets spend the majority of their time, and frequent cleaning of pet bedding limits accumulation of immature stages in the environment. Premise infestations can be avoided at shared animal facilities (e.g., boarding kennels, dog day care, veterinary practices) by requiring evidence of flea control or treating animals at intake to eliminate fleas.[2,3,15]

PUBLIC HEALTH ASPECTS

Cat fleas readily feed on people that share a home environment with infested pets or come in contact with areas where adults are emerging from pupae. Feeding by *C. felis* induces pruritus and erythematous-edematous papules on the lower legs of people; bites are often clustered and vesiculobullous lesions may be present.[72] Lesions are moderately or intensely pruritic and often excoriated.[73] In sensitized individuals, particularly children, papular urticaria may develop as a delayed hypersensitivity reaction.[72] Antihistamines and 1% hydrocortisone cream are helpful for symptomatic relief, but eradicating the infestation is key to preventing future bites.[73]

Treatment of all pets in the home that can serve as a source of *C. felis* (e.g., dogs, cats, rabbits, ferrets) with safe, label-approved, persistent insecticides is critical to control flea populations and protect

public health. In all but the most extreme situations, pets should not be removed from a home with fleas as treated pets will attract fleas that will then be killed; removing pets drives newly emerging fleas in the environment to feed on the humans that remain. When homes are heavily infested, environmental cleaning (thorough vacuuming and immediate removal and disposal of vacuum bags) followed by environmental application of insect growth regulators or compounds to desiccate flea larvae can reduce the immature stages that constitute the majority of the flea population. Environmental efforts should focus on pet resting areas where immature flea stages are most likely to accumulate.[2,3,15]

Fleas also transmit potentially zoonotic infections.[74] Cats are the reservoir for *Bartonella henselae*, the causative agent of cat scratch disease, and *C. felis* is the primary arthropod vector maintaining feline infection (see Chapter 70). Fleas that feed on bacteremic cats will shed *B. henselae* in their frass; the organisms are transmitted to the cat's teeth or claws during normal grooming behavior and humans become infected when bitten or scratched.[75] Treating cats for fleas prevents *B. henselae* transmission.[76,77] Similarly, fleas shed *Rickettsia typhi* and *Rickettsia felis* in their feces (see Chapter 46) that can be transmitted to humans when inoculated into flea bite wounds or mucous membranes.[78] Although *R. typhi* is historically associated with *X. cheopis*, a rat flea, a cycle involving *C. felis*, opossums, domestic animals, and human disease has been described in the United States.[79] Plague is also associated with infestation with *X. cheopis* and other rodent fleas; *C. felis* is considered a poor vector for *Yersinia pestis* (see Chapter 73). Cats can become infected with *Y. pestis* from rodents while hunting. Flea control and keeping cats indoors to prevent hunting are recommended for prevention.[74] *Dipylidium caninum* can be transmitted to humans, usually young children, by accidental ingestion of fleas containing cysticercoids (see Chapter 115). Infections are usually asymptomatic or associated with mild anal pruritus.[80]

FLEAS: *ECHIDNOPHAGA GALLINACEA*

Commonly known as the sticktight flea or the stickfast flea, *Echidnophaga gallinacea* is a semi-permanent, sedentary ectoparasite; fertilized adult females attach to the host with serrated laciniae, feeding for prolonged periods of time. Preferred sites include the skin of the comb, wattle, and around the eye of chickens; many other domestic and peridomestic birds are also infested although the extensive host list leads some to suggest that mammals may be a more common host than birds.[81] Eggs are deposited by females while still attached to the host and develop in the environment. While not common on pets, *E. gallinacea* is occasionally found on dogs in rural areas worldwide (see Table 106.1), often in association with domestic poultry, and attaches to less haired areas around the eyes, margins of the pinna, between the toes, on the scrotum, and the perianal region.[82,83] Surveys in Georgia and Florida, United States, documented that 3.7%–6.9% of fleas removed from dogs were *E. gallinacea*.[84,85] Stickfast fleas account for as many as 16.6% of fleas from dogs in Western Australia although they were not recovered on dogs or cats in the rest of the country.[86,87] Attached *E. gallinacea* can be removed by securely grasping with forceps and applying rearward traction. Sticktight fleas are smaller than *C. felis* and *C. canis*, lack pronotal and genal combs, and have a sharply angular head (Fig. 106.5).[5]

Ulcerative lesions develop at *E. gallinacea* attachment sites due to laceration by flea mouthparts and secondary infections; hypersensitivity reactions are also described. Female fleas remain attached for as long as 19 days. A related species in Australia, *Echidnophaga myremecobii*, can transmit the myxamotosis agent to rabbits although European rabbit fleas (*Spilopsyllus cuniculi*) are more important vectors.[5] Treatment of infested pets is achieved by physical removal of attached fleas and use of insecticides. Flea control products are not label-approved for *E. gallinacea*, but standard options (e.g., fipronil, isoxazolines, neonicotinoids, spinosad) would be expected to be effective. Dead fleas may remain attached to the host after treatment. Sticktight fleas occasionally attach to humans in contact with areas frequented by domestic poultry, wild birds, or other hosts.[88–90]

Fig. 106.5 The sticktight flea, *Echidnophaga gallinacea*, is usually found attached to hosts and has a distinct angular head; combs are absent.

FLEAS: *TUNGA PENETRANS*

The chigoe, jigger, or sand flea, *T. penetrans* is a very small (~1 mm) burrowing flea with an angled head similar to *E. gallinacea*. Fertilized females invade host skin and increase dramatically in size, resulting in formation of a nodule approximately 4–10 mm in diameter. The female genital aperture protrudes through an opening in the skin to allow eggs to be deposited in sandy soil in the environment for development. Originally native to South America, *T. penetrans* is now found throughout many tropical regions, including Latin America, the Caribbean, sub-Saharan Africa, and southern India.[5] Cases have been associated with translocation of infested dogs to other areas of the world.[91]

Dogs, cats, and humans in resource-limited areas are commonly infested although people in affected regions are more aware of human tungiasis than animal infestations.[92] Dogs are considered an important animal host; pigs and cats are also frequently infested.[93–95] In two communities in northeastern Brazil, *T. penetrans* was found in 52.1% and 54.4% of people, 30.9% and 67.1% of dogs, and 32.4% and 49.6% of cats surveyed.[96] Prevalence is high throughout the year, with one study showing 62.1% of dogs infested in August and 82.2% in November; sex and age were not associated with infestation risk.[97] In dogs, most lesions (89.1%) develop on the toe pads; other affected areas include the nipples, abdomen, testicles, elbows, and nose pad (Fig. 106.6). Lesions are often painful and erythematous. Hyperkeratosis, deep fissures, onychogryphosis, and lameness can develop, leading to progressive debilitation. Lesions commonly cluster and higher numbers are seen in younger dogs.[98]

Treatment of dogs with imidacloprid/permethrin insecticides reduced canine infestations and may help decrease distribution of eggs in the environment, thereby preventing human infestations.[99] Prevalence of human tungiasis is reportedly higher in homes with infested dogs or cats, and early recognition and treatment of infestations in dogs has been recommended as an important public health measure.[94,98] Frequent inspection of dog paws in endemic areas allows lesions to be recognized early and treatment instituted.[98] Repellents and protective clothing (i.e., shoes) are recommended for people to prevent skin penetration.[100,101] In people with only a few lesions, surgical extraction of the fleas can be used for treatment.[102]

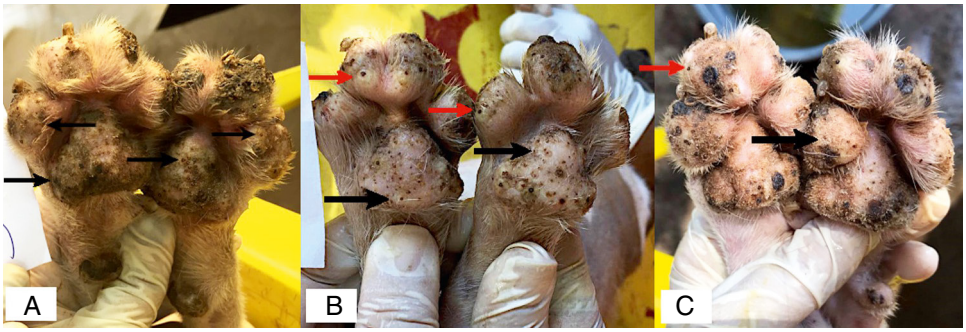

Fig. 106.6 *Tunga penetrans* lesions on a dog's paws. Multiple active *Tunga penetrans* flea lesions on a dog's paws in varying stages of development (examples shown with black and red arrows). Each panel shows evolution of lesions on days 0 (A), 7 (B) and 21 (C). (From dos Santos KC, Chiummo RM, Heckeroth AR, et al. Efficacy of oral fluralaner (Bravecto) against *Tunga penetrans* in dogs: A negative control, randomized field study in an endemic community in Brazil. *PLoS Negl Trop Dis*. 2022;16:e0010251)

LICE

ETIOLOGY AND EPIDEMIOLOGY

Lice infestations in dogs and cats may be caused by chewing lice (*Trichodectes canis* and *Heterodoxus spiniger* in dogs, *Felicola subrostratus* in cats) or blood-sucking lice (*Linognathus setosus* in dogs). Historically, chewing lice, also referred to as "biting lice," were grouped together in an order or suborder referred to as "mallophaga" but subsequent analysis has shown that the taxa are not monophyletic. Both *T. canis* and *F. subrostratus* are in the suborder Ischnocera, family Trichodectidae, while *H. spiniger* is in the suborder Amblycera, family Boopiidae. A single species of blood-sucking lice, *L. setosus* (suborder Anoplura), is also found on dogs in some regions. Chewing lice have prominent mandibles and feed on skin scales, hair, and tissue fluids; *H. spiniger* is an exception in that it primarily feeds on blood released by chewing activity.[103,104] As a blood-sucking louse, *L. setosus* mouthparts are adapted to pierce skin and imbibe blood directly from capillary beds.[27,103]

The life cycle of lice occurs entirely on the host. Females cement the eggs to hair shafts. First-stage nymphs hatch from the eggs in approximately 1 to 2 weeks depending on the species by dislodging the operculum on the anterior end of the egg. The nymphs then molt through two subsequent nymphal stages before developing in to adults. The entire life cycle can be completed in 3 to 4 weeks. Infestations are more commonly identified in young, aged, or debilitated animals. Infestations of *L. setosus* and *F. subrostratus* are more common in long-haired breeds and in cats that do not self-groom.[105] Reported predilection sites for *T. canis* include the head, neck, tail, and perianal region; in wolves, *T. canis* is most commonly found in the dorsal hindquarters and the inguinal region.[103,106] *Linognathus setosus* is more commonly found on the back, ears, and neck, especially below the collar.[103,107] Both *H. spiniger* and *F. subrostratus* may be found anywhere on the host.[103]

In most surveys, lice are recovered less commonly than fleas from dogs and cats. Prevalence of lice in domestic dogs ranges from 1% to 10% depending on lifestyle of the population considered and geographic location (see Table 106.1). Similarly, surveys reveal *F. subrostratus* infestations on less than 1% of pet cats to as many as 14% of free-roaming cats (see Table 106.2). However, although under-reported, lice infestations of pets may be common in colder climates, perhaps due in part to reduced use of routine insecticides for flea control.[108,109] In Finland and Sweden, *L. setosus* predominates on dogs and is most common in the winter months.[109] In other regions, *T. canis* is the most common species found on dogs.[110] *Trichodectes canis* infestations are also frequently identified in coyotes and wolves in colder regions of North America, with per animal infestation intensity ranging from 14 to an estimated 80,000.[106,111,112] *Heterodoxus spiniger* is more common in warmer or tropical climates and, although reported, is considered rare in North America.[113]

PATHOGENESIS

Lice are active on hosts, feeding on skin or blood and causing irritation. Common chewing lice (*T. canis, F. subrostratus*) abrade host skin with mandibles and then feed on skin cells, broken hairs, or tissue fluids. Although also chewing lice, *H. spiniger* are facultative hematophages that scrape the host skin until it bleeds and then ingest the blood. Blood-sucking lice (*L. setosus*) insert stylets through the skin to puncture a capillary, secrete saliva with anticoagulants, and imbibe blood.[103] Regardless of the method, lice feeding induces pruritus, increasing host grooming activity. Alopecia and skin damage from host scratching results in excoriations and secondary bacterial infections. If blood loss is severe, anemia may develop, particularly in malnourished young animals with multiple parasitic infections and infestations.[27] Lice also transmit pathogens to dogs. Although fleas (*C. felis*) are considered epidemiologically more important, chewing lice (*T. canis*) can serve as an intermediate host for *D. caninum* (see Chapter 115) and *H. spiniger* can be an intermediate host for *A. reconditum* (see Chapter 111).[103,114]

CLINICAL FEATURES

Animals with lice present with moderate to intense pruritus. History usually reveals an absence of insecticide use. On long-haired animals, eggs are often evident but the motile nymphs and adults cluster at the base of the hair shaft near the skin surface; parting the hair to allow closer examination is necessary. The hair is often matted and may have a fetid odor. Lice are more commonly seen in animals that have not received regular veterinary care, are housed in conditions of poor sanitation, and have frequent contact with other animals. Young animals with intense *L. setosus* infestations may be anemic, lethargic, and debilitated. Adult *L. setosus* tend to move more slowly and are readily collected for examination; adult *T. canis* and *F. subrostratus* move quickly through the haircoat, making collection more difficult.[27,103]

DIAGNOSIS

Direct Microscopic Examination

Lice are dorsoventrally flattened and can be collected for examination by combing or by adhering to clear tape; collecting nits is facilitated by clipping hair. Unlike with fleas, lice are invariably present on infested animals although close inspection may be needed to recover specimens for microscopic examination.[27] Chewing lice (*T. canis, H. spiniger*) have a head that is broader than the thorax (Fig. 106.7); antennae of *T. canis* project posteriorly and maxillary palps are absent, whereas *H. spiniger* antennae are within lateral grooves and distinct maxillary palps bearing post-palpal processes are evident.[103] In canine blood-sucking lice (*L.*

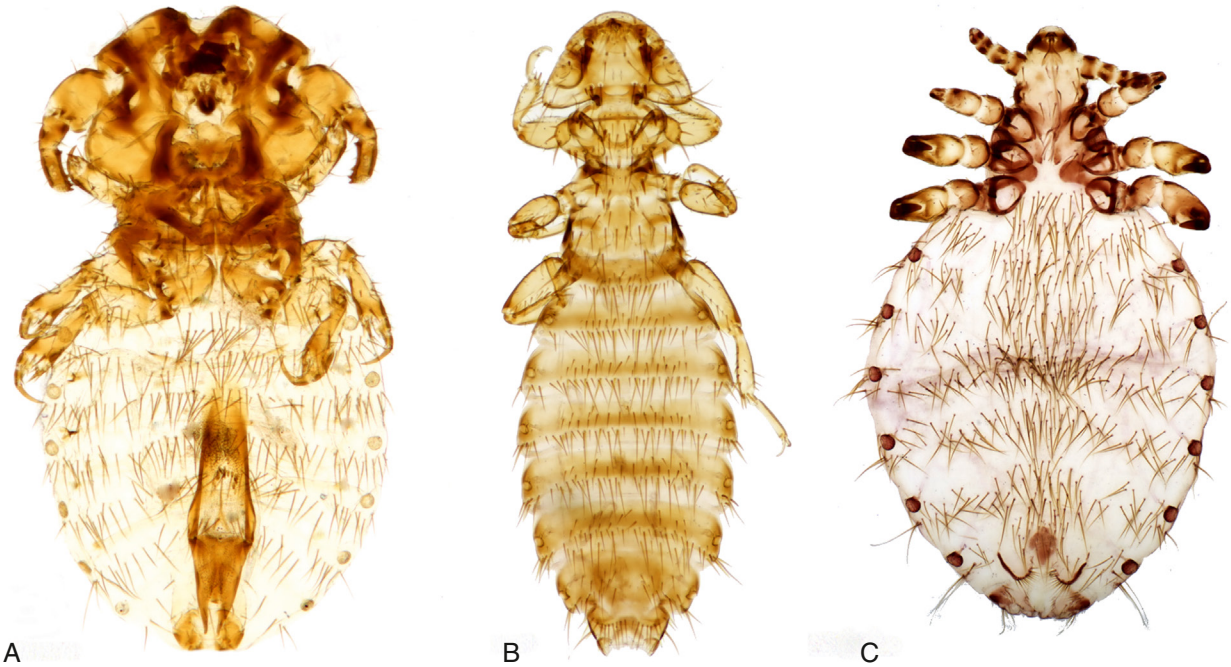

Fig. 106.7 Lice of domestic dogs. (A) *Trichodectes canis*, (B) *Heterodoxus spiniger*, (C) *Linognathus setosus*. (Photographs by Lorenza Beati and Lance A. Durden. In: Mullen GR, Durden LA. *Medical and Veterinary Entomology.* 3rd edition. Academic Press; 2019:79–106.)

setosus), the head is narrower than the thorax and the segmented antennae project laterally or anteriorly. Blood-sucking lice are larger than chewing lice and if fed may be dark red. *Felicola subrostratus* resembles *T. canis* but has a triangular rather than rounded head (Fig. 106.8). In most regions, *F. subrostratus* is the only feline louse present, although *H. spiniger* has been rarely reported from cats in tropical areas.[115,116]

Laboratory Abnormalities

Heavy infestations of puppies with *L. setosus* and *H. spiniger*, both of which feed on blood, may lead to anemia.[27,103]

Gross Pathologic Findings

Damage to the hair coat including broken hairs due to self-trauma caused by host scratching or chewing is often present. Alopecia and self-excoriations may be evident. When infestations are chronic, papules, crusts, and secondary dermatitis may develop; skin discoloration can occur, but deep pyoderma is rare. Lesions can resemble FAD in dogs or miliary dermatitis in cats.[27]

Fig. 106.8 Adult *Felicola subrostratus* from a cat. This chewing louse feeds on superficial tissue debris. (From the National Center for Veterinary Parasitology.)

TREATMENT AND PROGNOSIS

Although not all are label-approved for this purpose in all regions, lice infestations are readily treated with insecticides commonly used in dogs and cats for flea control including dinotefuran, fipronil, imidacloprid, and selamectin.[117–122] In dogs, high-concentration permethrin can be used.[107,123] Fluralaner is effective at eliminating blood-sucking lice (*L. setosus*) from dogs, and a selamectin/sarolaner combination product is label-approved for the treatment of biting lice (*F. subrostratus*) in cats in Europe.[124] Bathing with a neem-seed extract has also been shown to be effective.[125] Traditional treatments using lime sulfur, pyrethroid, organophosphate, or carbamate dips, or the off-label use of high-dose large animal macrocyclic lactone products, are no longer necessary or recommended to eliminate lice infestations.

When a large number of nits are evident or the fur matted, the hair should be clipped to reduce the infestation; bathing may also be indicated to address dermatitis and secondary infections. In severely anemic animals, supportive care, including blood transfusions, should be considered. Off-host survival of lice is limited, but washing bedding and grooming tools in hot water can be helpful to reduce their role as fomites.[27,126,127] In a multi-animal home or facility, all contact animals of the same species should be treated. When infestations are intense, multiple treatments, and, depending on the product used, more frequent application may be indicated. The prognosis is excellent; although lice are very contagious between dogs or between cats, insecticide treatment readily eliminates the infestations.[27,45]

IMMUNITY

Lice infestations are more common in young, debilitated animals, suggesting immune restriction plays a role in limiting infestations.[27] *Trichodectes canis* prevalence in dogs decreases with increasing age.[128]

PREVENTION

Lice infestations can be prevented by routine use of insecticides as is recommended for flea control. In areas where flea control is commonly used, lice are rare in well-cared-for pets and usually only encountered by veterinarians who work with shelter, rescue, or free-roaming animals. In colder climates where flea control may not be as widely practiced, lice infestations may be seen in pets, particularly in dogs that attend dog day care or those allowed to roam; avoiding direct contact with other dogs and cats, especially those not on control products, and with wildlife hosts, limits risk of infestations. Shelters and multi-animal facilities should routinely treat all new animals, especially young puppies and kittens, with insecticides during quarantine to avoid introducing lice into the larger population. When lice are diagnosed in a pet, infestation of all pets of that species in the home should be assumed, regardless of findings on clinical examination, and all same-species contacts treated.[126,127]

PUBLIC HEALTH ASPECTS

Lice from pets are not zoonotic, and pets play no role in the maintenance or transmission of human lice. Humans, particularly children, are commonly infested with head lice (*Pediculus capitis*) worldwide; body lice (*Pediculus humanus*) are less common and primarily seen when conditions of poverty, war, or homelessness prevail. Transmission occurs following direct contact with an infested person, or, less commonly, through shared fomites (e.g., hairbrushes, clothing).[129] Pubic lice (*Phthirus pubis*) usually infest the groin and perianal region, but infestations are also described from facial hair, eyelashes, eyebrows, and, occasionally, the scalp.[130] People acquire pubic lice through direct, intimate contact with other infested individuals; humans are the only host.

CASE EXAMPLE

Signalment

"Grover," a 4-week-old intact male domestic shorthair cat from northern California.

History

Grover is an orphan kitten that was rescued with no known medical history. He was brought to the University of California-Davis, VMTH, with signs of an upper respiratory tract infection.

Physical Examination

Body weight: 268 g.

General: Dull, rectal temperature too low to read, R = 30, HR = 130 beats/minute, BCS 2/9, CRT = 2 seconds, pale/white mucous membranes, 8%–10% dehydrated, sternally recumbent for most of the examination but ambulatory.

Integument: Full haircoat with large numbers of fleas and flea frass over the entire body.

Eyes, ears, nose, and throat: Eyes crusted closed with dry discharge. Moderate to severe mucopurulent ocular discharge OU and nasal discharge. Mild ceruminous debris in both ears.

Cardiovascular: Regular cardiac rhythm with no murmurs auscultated.

Respiratory: Normal breath sounds.

All other systems: No clinically significant abnormalities noted.

Laboratory Findings

PCV: 11%, blood glucose 283 mg/dL.

Venous blood gas: pH 7.267, pCO_2 47.9 mmHg, pO_2 40.8 mmHg, bicarbonate 21.1 mmol/L, CO_2 total 22.6 mmol/L, base deficit –4.7 mmol/L, sodium 149 mEq/L, potassium 3.8 mEq/L, ionized calcium 1.44 mmol/L, chloride 117 mEq/L, glucose 150 mg/dL, lactate 0.8 mol/L, creatinine 0.2 mg/dL, anion gap 14.5 mmol/L.

Diagnosis

Anemia likely secondary to severe flea infestation, feline URTD (conjunctivitis neonatorum).

Treatment

Nitenpyram (5.7 mg PO); doxycycline (5 mg/kg, PO, q12h); famciclovir (90 mg/kg, PO, q12h), topical ofloxacin (1 drop OU, q12h), IV lactated Ringer's solution. Grover was also given a transfusion with 6 mL packed RBCs (Fig. 106.9A) after which his PCV was 22% and total protein was 6 g/dL. After 5 hours in the intensive care unit, Grover's mentation improved significantly and he began to eat. He was discharged the following day. At a recheck 2 months later, he was bright and alert and weighed 1.8 kg; mucous membranes were pink and CRT was < 2 seconds. Ocular examination was normal (Fig. 106.9B). There were no fleas or flea frass noted on examination of the haircoat. An FeLV antigen and FIV antibody test was negative.

Fig. 106.9 (A) A 1-month-old intact male domestic shorthair kitten receiving a packed red blood cell transfusion to treat anemia secondary to flea infestation. The kitten's eyelids are glued together by crusty exudate secondary to feline upper respiratory tract disease. (B) A recheck examination 2 months later after treatment with antimicrobials and oral famciclovir showed only mild serous ocular discharge and no clinical evidence of anemia. (Courtesy of University of California Davis Veterinary Medical Teaching Hospital.)

Continued

CASE EXAMPLE—cont'd

Comments

Although the cause of this kitten's anemia was not proven to be flea infestation, this seemed most likely based on the large numbers of fleas present and the kitten's small size. Other differentials that were considered were retrovirus infection or hemoplasmosis; however, typically the incubation periods for these diseases are longer than 4 weeks and hemoplasmosis is rare in kittens. Antimicrobial therapy for the upper respiratory tract infection was clearly indicated based on the presence of mucopurulent ocular discharges and systemic illness. Differentials for the upper respiratory tract disease included FHV-1, FCV, *Bordetella bronchiseptica*, or *Chlamydia felis* infection; multiple pathogens may be present in some cases. FHV-1 has most often been associated with conjunctivitis neonatorum, hence the decision to treat with famciclovir. Treatment with antimicrobials and famciclovir was continued for 3 weeks, and the owner was instructed to continue regular flea prevention year-round.

Mosquitoes and Other Blood-Feeding Flies

Meriam N. Saleh

KEY POINTS

- First Described: Aristotle gave true flies their name "Diptera" (two-winged) in the fourth century BC. In Aristotle's *History of Animals* (335 BC), he accurately observed "the diptera have the sting in the front" and "no insect with only two wings has a sting in the rear." The earliest Diptera appeared in the Triassic period ca. 240 million years ago.[1]
- Causes: A variety of blood-feeding flies feed on dogs and cats in North America, including members of the families Culicidae (e.g., mosquitoes), Simuliidae (e.g., black flies), Psychodidae (e.g., sand flies), and Muscidae (e.g., stable flies).
- Affected Hosts: Blood-feeding flies feed on a wide variety of reptiles, birds, and mammals, including dogs and cats.
- Geographic Distribution: Mosquitoes, black flies, and muscid flies are found on every continent except Antarctica. Sand flies can be found throughout tropical and subtropical Europe, Asia, Africa, and in parts of the Americas.
- Primary Mode of Transmission: Fly bites occur upon contact with environments where blood-feeding flies are present. The specific environment of risk varies with each particular fly species.
- Major Clinical Signs: Blood-feeding flies cause skin lesions leading to irritation, erythema, pruritus, inflammation, hypersensitivity reactions, and anemia. In addition, blood-feeding flies transmit numerous pathogens as biologic (e.g., *Dirofilaria immitis*) or mechanical (e.g., anthrax) vectors.
- Differential Diagnoses: Skin lesions from other ectoparasites including ticks, mites, fleas, and lice; other cutaneous hypersensitivities (e.g., atopic dermatitis); eosinophilic plaque; autoimmune disorders; photoinduced dermatitis (e.g., solar dermatitis, photosensitive dermatitis).
- Human Health Significance: Many species of blood-feeding flies readily feed on humans.

ETIOLOGY AND EPIDEMIOLOGY

True flies (Diptera) are among the most varied order of insects. Approximately 158,000 species have been described with great diversity in their biology and life histories.[2] Historically the order was divided into three major suborders: Nematocera containing mosquitoes, black flies, sand flies, and gnats; Brachycera containing horse flies and deer flies; and Cyclorrhapha containing the house flies, flesh flies, tsetse flies, and keds. However, major taxonomic revision has led to most current studies classifying the true flies into five infraorders: Culicomorpha (mosquitoes and black flies), Psychodomorpha (sand flies), Brachycera (horse flies, deer flies, and house flies), Bibionomorpha (gnats), and Tipulomorpha (crane flies).[2,3] This chapter focuses on families that contain blood-feeding Diptera known to feed on dogs and cats: Culicidae and Simuliidae of the infraorder Culicomorpha, Psychodidae of Psychodomorpha, and Muscidae of Brachycera.

Like other insects, the body of adult Diptera are divided into three parts: the head, thorax, and abdomen. The head contains the eyes, antennae, and specialized mouthparts that vary greatly among species. Variation in antennae structure and number, along with mouthpart morphology, play an important role in taxonomy and species distinction. Blood-feeding Diptera have specialized mouthparts made for piercing or biting the skin to imbibe blood meals.[4,5] Hematophagous flies first appeared in the Jurassic period,[6,7] and only a minority of known Diptera (approximately 11,000 species) have evolved to feed on blood.[8] Most Diptera have two wings (one pair) as adults, although there are some species of wingless adults. True flies have modified structures called halteres rather than hind wings; these club-shaped organs are used for balance and are present even in the wingless Diptera.[8] Wing venation is also important for identification and classification of different species. The abdomen consists of 11 or fewer segments, with the posterior segments modified for copulation or ovipositing.

All Diptera have a complex life cycle and undergo complete metamorphosis with egg, larval, pupal, and adult stages. The larval stages are commonly referred to as maggots, while the pupal stage usually involves development within a cocoon.[8] In most blood-feeding species, only the female imbibes blood from the host. However, there are some examples where both sexes take blood meals (e.g., stable flies). Feeding behavior is a major component of a blood-feeding fly's ability to serve as a vector for a pathogen, and differences in host preference or feeding patterns directly influence vector potential. Table 107.1 provides examples of different pathogens that can be transmitted to dogs or cats by members of each family.

Culicidae (Mosquitoes)

Adult mosquitoes are delicate flies (Fig. 107.1) with long segmented antennae and an extended proboscis containing a bundle of stylets used in feeding. Mosquitoes persist and thrive in a variety of environments. They feed on dogs, cats, people, and many other animals worldwide; mosquitoes also transmit a wide variety of human and veterinary disease agents. Important genera that readily feed on and transmit pathogens to dogs and cats include *Aedes, Anopheles, Culex,* and *Psorophora*.[9,10]

The mosquito life cycle is depicted in Fig. 107.2. Mosquitoes oviposit in aquatic environments or in dry areas that flood seasonally, with some species being able to utilize moist soil.[11] A small body of water (e.g., a backyard puddle) can provide a suitable habitat for a large number of eggs. In some species, eggs remain dormant in dry

TABLE 107.1 Blood-Feeding Diptera of Dogs and Cats and Associated Pathogens

Family	Common Name	Important Genera	Examples of Pathogens Transmitted	Affected Species
Culicidae	Mosquito	*Aedes, Anopheles, Culex,* and *Psorophora*	*Dirofilaria immitis*	Dogs and Cats
Simuliidae	Black fly	*Simulium*	*Onchocerca lupi*	Dogs and Cats
Psychodidae	Sand fly	*Phlebotomus* (Old World) *Lutzomyia* (New World)	*Leishmania* spp.	Dogs and Cats
Muscidae	Stable fly	*Stomoxys*	*Coxiella burnetti* *Trypanosoma evansi* (mechanical)	Dogs

Fig. 107.1 Female mosquito (***Aedes aegypti***). Note the delicate appearance and long proboscis.

conditions for months, hatching only after an area is inundated by floods or heavy rain. Several abiotic factors, particularly temperature and moisture, play a role in determining when eggs will hatch or when pupae become adults.[11,12] After hatching, mosquito larvae molt four times within an approximately 2-week period before pupating. The pupae may persist from 2 days to a week depending on the species (Fig. 107.2).

Only the female mosquito takes a blood meal, which is required for oviposition, while the males feed on plant nectar.[13] In some species the female undergoes autogeny (production of eggs without a blood meal), but most only do so for an initial clutch.[11] The female mosquito takes blood meals every few days and rests and develops eggs between feedings.[14,15] After oviposition the female seeks a new host. Repeated feeding on new hosts contributes greatly to pathogen transmission.

Mosquitoes utilize complex behaviors that support the location of a host and subsequently a blood meal. Chemical cues such as the detection of carbon dioxide, lactic acid, and acetone from the skin, sweat, and breath may be used.[16,17] Mosquito mouthparts have evolved to efficiently pierce skin and obtain a blood meal.[13] Mosquito saliva contains anticoagulants that are injected into the wound during feeding;[13] if not interrupted, feeding is usually concluded within 3 to 4 minutes.[18] Abdominal stretch receptors alert the nervous system when adequate blood has been consumed and feeding stops.[15]

Simuliidae (Black flies)

Black flies are among the smallest of the blood-feeding Diptera, measuring 1 to 6 mm in length. Black flies have stout bodies with short segmented antennae and they vary in color from black or gray to a yellow-brown. Sometimes referred to as the humpback fly because of the shape visible in profile behind their head (Fig. 107.3), black flies are a major pest of poultry and livestock, and livestock deaths from hypersensitivity reactions, anemia, or toxin from fly saliva have been reported.[14] Black flies also readily feed on dogs and cats and can cause pruritic bloody lesions.[14] In areas where black flies are common, reports often describe dogs plagued by swarms during the summer months.[19,20] Black flies are also considered a putative vector of *Onchocerca lupi* in dogs and cats in the United States.[21,22]

Like mosquitoes, black flies also use water to complete their life cycle (Fig. 107.4). Female black flies deposit eggs in clear, running water in natural areas.[23] Larval and pupal stages are adapted to an aquatic environment, and only the females imbibe a blood meal while the males feed on plant nectar, similar to mosquitoes.[23] Black flies are notorious for their aggressive feeding and markedly large swarms involving huge numbers of flies; asphyxiation of livestock has reportedly occurred following inhalation due to the extreme abundance of black flies at certain times of the year.[24,25] Females oviposit on the water's surface or on partially submerged objects.[14] Species differ in seasonality and annual fecundity. In areas of North America with mild climates, some species are multivoltine (produce multiple broods annually) and can complete seven or more generations per year.[23] The eggs of multivoltine species hatch in a few days, but eggs of univoltine species (one brood of eggs per year) will not hatch until the following year. In some species of black flies, females can reproduce without taking a blood meal; for these species the mouthparts lack teeth and cannot cut the host's skin.[23]

Black flies feed during the day, and their activity is highly seasonal in temperate areas, with more feeding occurring during the spring and summer.[8] Several host attractants have been identified, including carbon dioxide, host shape, size, and color.[16] The black fly has short mouthparts consisting of serrated stylets that cut into host skin.[8] Stylets enter the host's skin and anchor the mouthparts; blood then begins to pool at the feeding site and is imbibed from the pool.[23] The saliva contains anticoagulants and local anesthetic to enhance vasodilation.[26] Black flies are persistent feeders and often do not leave a host until completing their blood meal, which can require as long as 3 to 6 minutes; this behavior renders them poor mechanical vectors as they do not take multiple interrupted feedings.[23]

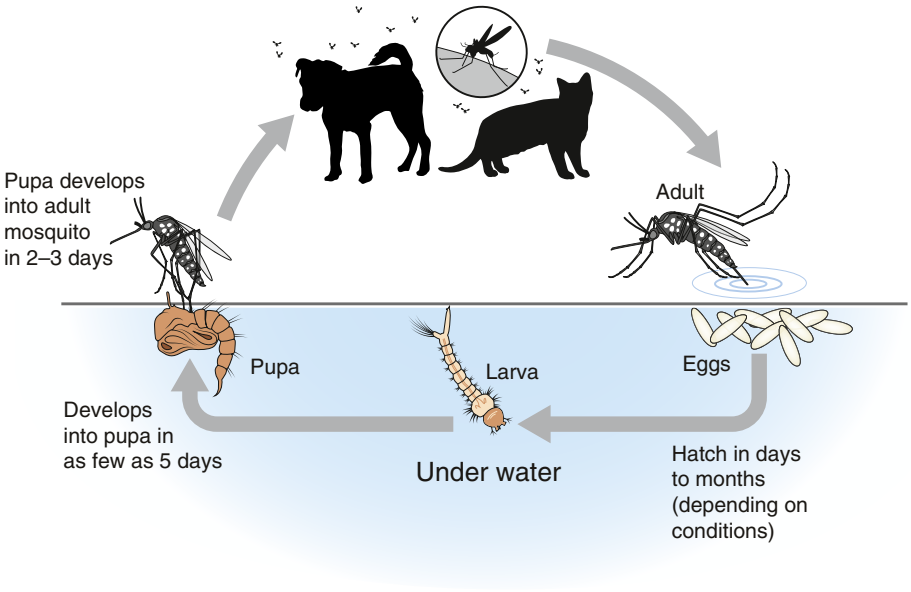

Fig. 107.2 Mosquito life cycle. Female mosquitoes oviposit in aquatic environments or in dry areas that flood seasonally. Eggs are deposited either in clusters called a raft or singly depending on species. Larvae hatch and molt four times before pupating. The pupae are a nonfeeding stage and can persist from 2 days to a week depending on the species. Once development is complete, adults emerge and rest on the water surface to dry and then fly off to find a blood meal.

Fig. 107.3 Black fly (*Simulium* sp.). Note the hump behind the head and the short segmented antennae. (Courtesy of Dr. Brian Herrin, Kansas State University.)

Psychodidae (Sand flies)

Sand flies of veterinary importance are in the subfamily Phlebotomine. These small fuzzy-appearing flies have long legs and antennae (Fig. 107.5) and are readily distinguished from other Diptera by wings held above the body forming a vertical "V" shape.[27] The adults are weak fliers and are mainly active at night. Sand flies can typically be found near breeding and resting sites such as tree hollows, plant leaves, cracks and crevices between rocks or other masonry, and other dark humid sites that offer shelter.[28] The sand fly life cycle is depicted in Figure 107.6. Breeding and ovipositing occur in humid and terrestrial areas.[28] Sand flies are vectors of the protozoan parasite *Leishmania* spp. (see Chapter 96).

Only female sand flies feed on blood. As is the case with Culicidae and Simuliidae, some sand fly species are autogenous, but females of these species need to imbibe blood meals for successful oviposition. Blood feeding generally occurs on exposed skin such as ears, nose, lips, and feet.[28] The sand fly has tiny mouthparts (less than 0.6 mm) and mandibles with teeth that cut like scissors, creating a small pool of blood from which to imbibe (similar to black flies).[27] Less is known about the host-seeking behavior and cues of sand flies compared to mosquitoes.[29]

Muscidae (Stable Flies)

Most Muscidae adults do not imbibe blood, but one subfamily, the Stomoxyinae, contains several blood-feeding species.[30] The stable fly, *Stomoxys calcitrans*, is a filth fly and a blood feeder of medical and veterinary importance. Stable flies closely resemble the common house fly (*Musca domestica*), but the mouthparts differ (Fig. 107.7A). Stable fly mouthparts bear a nonretractable, long, sharp proboscis for piercing the host skin and imbibing blood (Fig. 107.7B). Unlike many other blood-feeding flies, both males and females imbibe blood. As a filth fly, stable fly eggs are laid in decaying organic material such as damp hay, lawn clippings, or animal manure. The complete life cycle is illustrated in Figure 107.8. The adults mate in the air and do not spend significant time on the host.

Stable flies are usually active and attacking hosts on warm days and often stop seeking hosts and blood meals during cold weather.[14] Livestock are the primary hosts, but stable flies will often feed on people and dogs, so much so that in some areas they are commonly referred to as the dog fly or kennel fly, as dogs are often repeatedly bitten.[30] Stable flies are a common cause of allergic fly bite dermatitis in

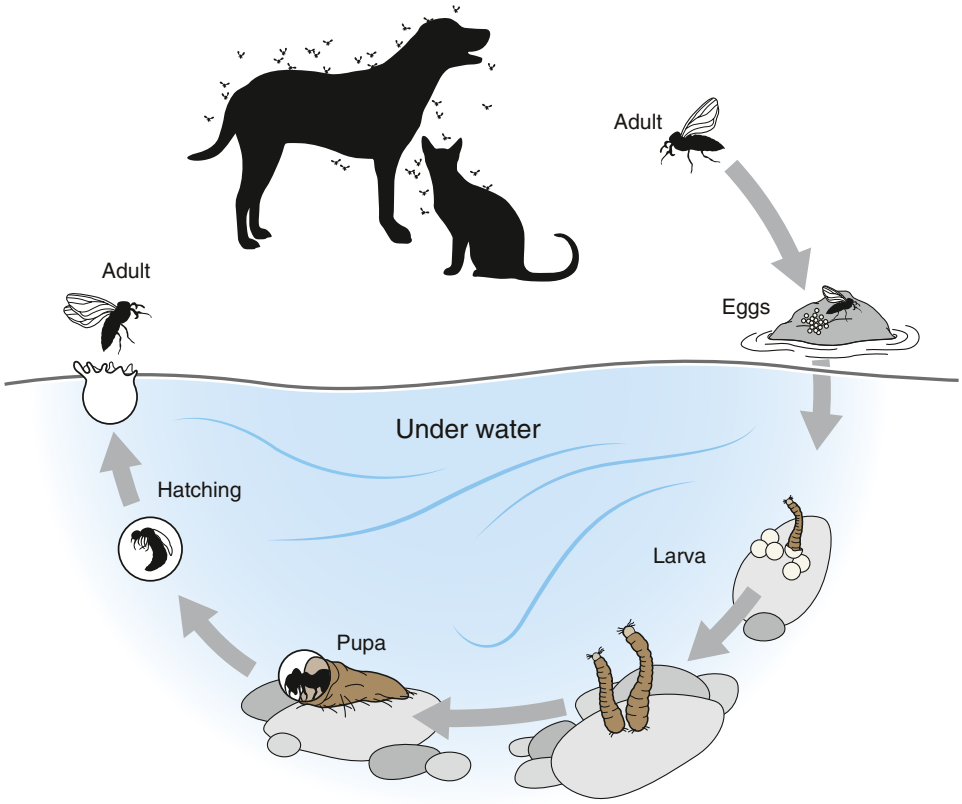

Fig. 107.4 Black fly life cycle. Female black flies oviposit after taking a blood meal, depositing their eggs in clear running water. The larval stages are adapted to an aquatic lifestyle and anchor themselves to rocks, vegetation, or other debris and feed on organic matter in the current. After passing through several instars (4–9 depending on the species), the larvae spin cocoons and pupate underwater. Pupae are attached to the substrate via a silken thread. Adults emerge from the pupae underwater and are carried to the surface in a bubble of air. The mature adult then searches for a blood meal.

Fig. 107.5 Old World sand fly (*Phlebotomus perniciosus*). Note the long legs relative to the body and the fuzzy appearance. (Courtesy of Dr Emilie Bouhsira, National Veterinary School of Toulouse, France.)

dogs, particularly in dogs housed in outdoor kennels where they cannot readily escape the flies.[31] Mechanical transmission of *Trypanasoma evansi* and *Coxiella* spp. by *Stomoxys* spp. has been documented.[32]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Blood feeding by flies causes a wide range of effects, from no reaction by the host, to general annoyance, the appearance of pruritic bloody spots at the feeding site, and the potential for pathogen transmission. Fly feeding injuries often result in mechanical damage to the host skin and immediately underlying tissues. A wound can form at the feeding site causing further irritation, erythema, dermatitis, papular eruptions, and, in some cases, hypersensitivity reactions.[33] Stable flies can cause necrotic dermatitis on the ear tips of dogs as well as exudative dermatitis.[34] Hypersensitivity reactions to mosquito feeding are particularly common in some cats resulting in eosinophilic dermatitis that can lead to nodules, scaling, and alopecia.[33,35]

Excessive blood feeding by flies can result in significant blood loss and subsequent anemia. Mosquitoes can ingest up to three times their body weight when taking a blood meal,[36] and heavy swarms have caused the death of cattle and horses,[37,38] therefore exsanguination of smaller mammals is also possible, although rare. The saliva of a biting fly contains anticoagulants, toxins, and other secretions that aid in blood flow at the wound site and allow the fly to continue to successfully feed.[30] For example, sand flies inject a particularly powerful vasodilation peptide into the feeding site which results in a pool of blood for feeding.[39] Salivary components also stimulate an immune

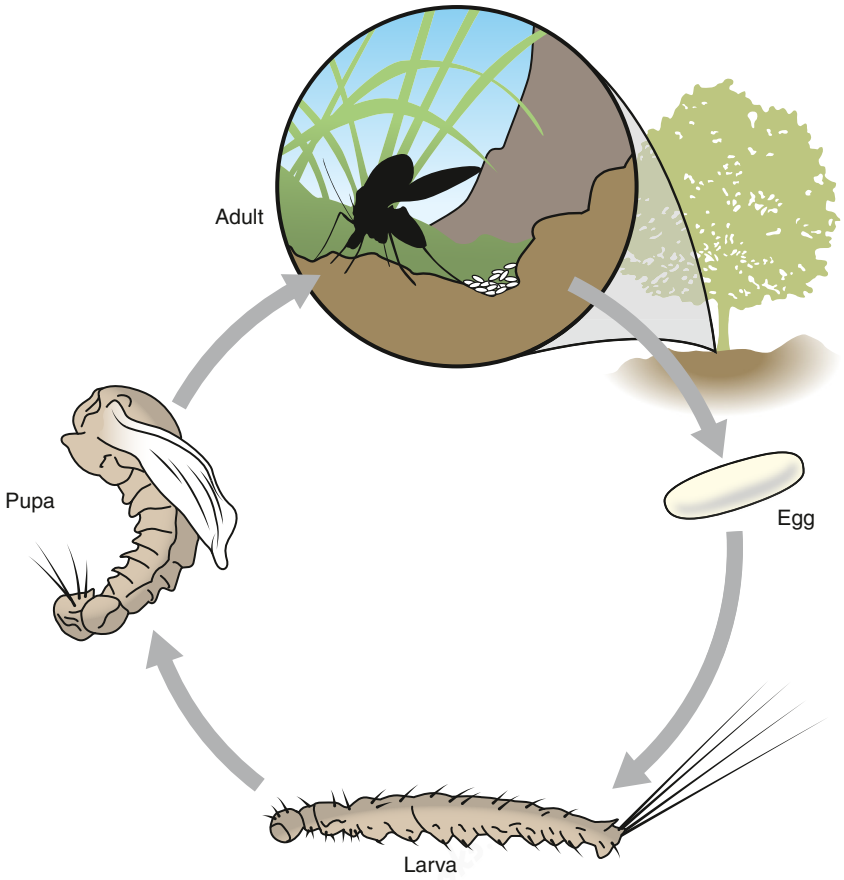

Fig. 107.6 Sand fly life cycle. Female sand flies oviposit after a blood meal and deposit eggs in cracks and crevices between rocks or other masonry, tree hollows, or other dark humid areas that offer shelter. Sand flies progress from egg, to larva going through four instars before pupating and the emergence of adults. Unlike mosquitoes and black flies, the immature sand fly stages are not aquatic.

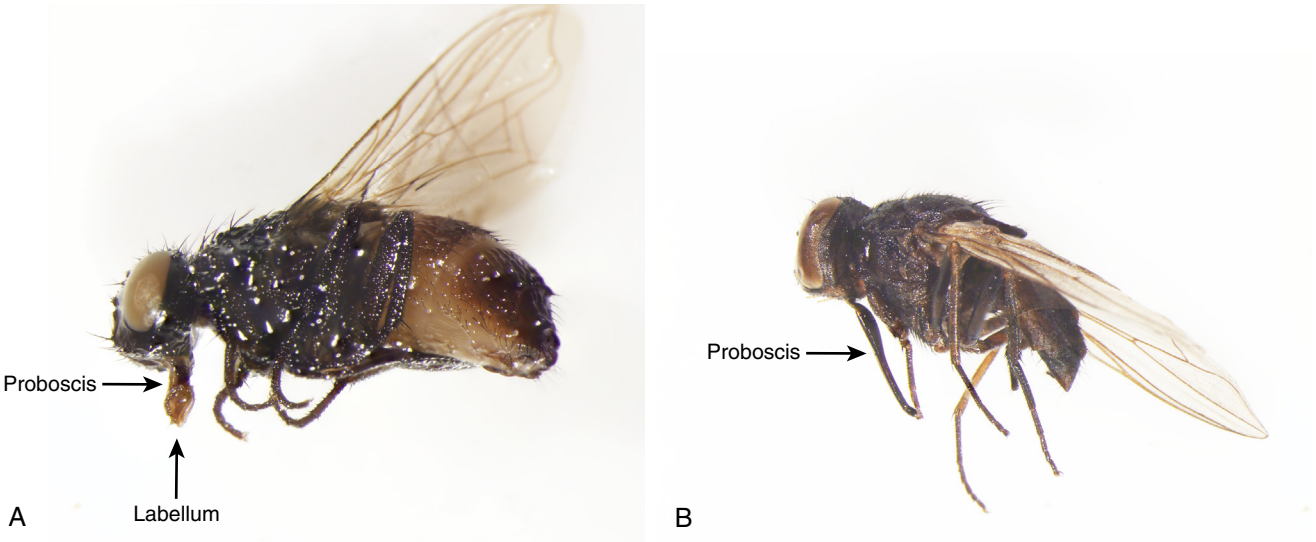

Fig. 107.7 (A) House fly (*Musca domestica*) with retractable proboscis and labellum. (B) Stable fly (*Stomoxys calcitrans*) with long, pointed proboscis.

response that often results in local inflammation. In some instances, individual dogs or cats may become hypersensitive, developing more severe reactions as they encounter more flies.

Physical Examination Findings

Blood feeding by flies is often painful, although reactions vary greatly among individual animals. Inflammatory reactions and pruritus at the bite site are common. Local inflammation triggered by blood-feeding flies may result in the formation of wheals and papules with a central puncture wound that may or may not be bleeding.[40] Cats with mosquito bite hypersensitivity develop lesions primarily on the haired skin of the nose, pinnae, and margins of the paws (Fig. 107.9).[33,35,40] These lesions initially appear as erythematous papules that, over time, become crusts, erosions, areas of alopecia, or ulcers and may be either hyper- or hypopigmented.

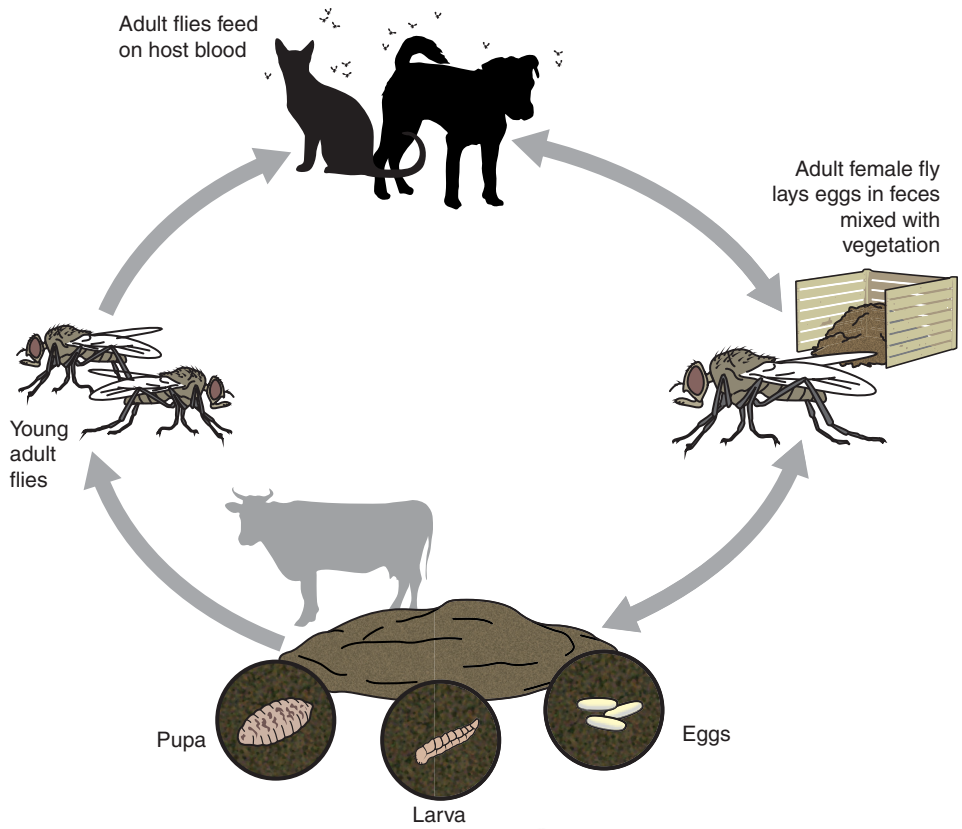

Fig. 107.8 Stable fly life cycle. Stable flies deposit eggs in moist, decaying organic matter such as feces. The adult female deposits multiple clutches of eggs, with each clutch requiring a separate blood meal. Eggs hatch into the first instar larvae, which feed and mature through three instars. The third instar larvae pupate in the organic material and adult stable flies can fly within an hour of emerging.

DIAGNOSIS

Definitive diagnosis can be achieved by identifying flies directly; however, observing flies feeding on pets is unlikely. Because flies are usually not present on examination, a detailed history—including attention to the season and awareness of arthropods commonly active in a given habitat and geographic region—is necessary to help identify the cause of the skin lesions. The identification of a specific vector-borne disease or pathogen transmitted by the biting fly also would indicate a previous fly bite. Differential diagnoses for blood-feeding flies include other arthropod bite wounds such as those induced by ticks, mites, fleas, lice, and bed bugs as well as a number of different skin conditions. Reactions to food and environmental antigens, head and neck excoriations, photoinduced dermatitis, and autoimmune conditions can result in similar lesions.

Biting flies that readily feed on dogs or cats can be differentiated from other ectoparasites morphologically. Diptera bodies are differentiated into head, thorax, and abdomen. The head contains the eyes, antennae, and specialized mouthparts adapted for blood feeding that can vary greatly among species; the thorax bears six legs and a pair of wings; and the abdomen contains the reproductive organs.[4,5]

Morphologic keys are available to identify all stages of biting flies.[41-43] If the adult fly is available and the specimen is not damaged, an identification can be made by a trained parasitologist or medical entomologist using morphologic keys.[14,30,44]

LABORATORY ABNORMALITIES

Most bloodwork findings on animals with fly bites are unremarkable. When massive blood loss from feeding has occurred, anemia can be present.

Pathologic Findings

Histopathologic Findings

Early fly bite lesions may include a central area of epidermal necrosis surrounded by edema and dermal hemorrhage; in some cases, a hemorrhagic crust covers the necrotic area. Mixed mononuclear, neutrophilic, and eosinophilic inflammatory infiltrates may be present, along with intraepidermal eosinophils, sometimes contained within eosinophilic pustules.[44] The histologic findings of feline mosquito bite hypersensitivity include extensive superficial and deep perivascular and interstitial eosinophilic and mixed dermatitis. Focal areas of degranulated eosinophils with eosinophilic folliculitis and furunculosis may also be present.[44]

TREATMENT AND PROGNOSIS

Animals with hypersensitivity or other dermatologic reactions to blood-feeding flies should be treated as their clinical signs dictate. Feline mosquito bite hypersensitivity can be addressed by keeping the cat housed indoors and administering immunomodulatory drugs

such as glucocorticoids and antihistamines until lesions resolve.[45] In the case of feline mosquito bite hypersensitivity, as long as mosquitoes are kept from biting, the reaction can be contained and the prognosis for recovery is good, but the reappearance of mosquitoes and subsequent bites will lead to continued hypersensitivity reactions.[45] As for all blood-feeding flies, preventing contact with flies is crucial for a good prognosis. Repellents containing permethrin can be helpful in limiting bites from mosquitoes, sand flies, and *Stomoxys* on dogs but cannot be used safely on cats.[46] Some studies have documented reduced transmission of heartworm to dogs when a mosquito repellent is used; this approach should always be combined with consistent use of heartworm preventive (see Chapter 111).[47] Dogs and cats that are routinely pestered by blood-feeding flies, particularly by persistent and aggressive feeders such as black flies or *Stomoxys* spp., should be kept indoors to limit contact with the offending flies.

IMMUNITY AND VACCINATION

The immune response to a biting fly is largely directed against salivary proteins. The saliva of blood-feeding flies contains numerous enzymes to assist in blood meal acquisition and minimize the host immune response, including kinases that destroy bradykinin, which is responsible for mediating pain and itch in the host, as well as other histamine-binding proteins.[48] Fly feeding activity induces both a Th1 and Th2 response in the host. The Th1 respsonse is stimulated by salivary components that do not function as antigens because of their low molecular weight, but instead bind to collagen and other skin proteins of the host, acting as haptens.[48] Repeated exposure to these haptens can induce delayed hypersensitvity reactions.

Mosquito saliva has been shown to elicit an immune response that leads to Type 1 and Type 4 hypersensitivity reactions as well as IgE-mediated reactions and antibody-independent T-cell reactions.[49] Mast cells also play a key role in the hypersensitivity reactions caused by exposure to mosquito saliva. The adaptive immune response to biting fly saliva can also impact pathogen transmission. Immunity to sand fly saliva can lead to strong protection against *Leishmania* spp. infection by limiting parasite proliferation.[50] Numerous salivary proteins from different sand fly species have been evaluated as potential candidates for vaccines against leishmaniosis.[51] A phase I clinical trial in humans showed that a mosquito vaccine appeared to be safe and incited an immune response when adjuvanted.[52] However, at the time of writing no commercially available vaccine exists for mosquitoes, sand flies, or any other biting flies for any species.

PREVENTION

Keeping pets indoors and limiting contact between the pets and blood-feeding flies are particularly helpful in preventing fly bites. However, some biting flies, especially certain endophilic mosquito species, will readily enter the home or other buildings.[15] Ensuring that windows and doors are properly screened will help prevent access by mosquitoes. In addition, removing any potential breeding sites, such as standing water for mosquitoes or decaying vegetation associated with compost piles for *Stomoxys* spp., can limit populations of biting flies in the environment.[53,54]

In dogs, some topical pyrethroids have efficacy as mosquito, sand fly, and stable fly repellents and can reduce the feeding activity of these biting flies.[55-58] In areas where vector transmission of pathogens is common, permethrin or deltamethrin repellents are used to protect pets from fly feeding and can reduce transmission risks.[59] Pyrethroid repellents have also been shown to prevent sand flies from transmitting *Leishmania* spp. to dogs in endemic areas.[57,60] An effective prevention strategy combines the use of safe, effective repellents with lifestyle management (habitat avoidance) to limit the contact with blood-feeding flies, and barriers to prevent mosquitoes and other blood-feeding flies from gaining entry into the home. Isoxazoline insecticides will kill mosquitoes and sand flies after feeding; although their use does not prevent feeding altogether, killing the flies does reduce the overall population and limit transmission to the next host.[61,62]

PUBLIC HEALTH ASPECTS

Mosquitoes and other biting flies also are of significant human health importance. People often develop localized reactions from arthropod feeding as well as hypersensitivity resulting in erythema, pruritus, and edema.[63] Biting flies also transmit a number of pathogens to people. Recommended protection methods include habitat modifications to reduce fly populations, avoiding areas with actively feeding flies, wearing protective clothing, and using repellents containing permethrin or N, N-diethyl-meta-toluamide (DEET). No DEET-containing products are labeled for veterinary use and DEET should not be used in pets as seizures may result, especially in cats.[14] In leishmaniosis-endemic regions, dogs can serve as a reservoir host; sand fly control on dogs has been shown to limit transmission risk to people (see Chapter 96).

CASE EXAMPLE

Signalment

"Tom," a 3-year-old male neutered domestic shorthair from Glen Ellen, California, USA.

History:

Tom was evaluated in June for multiple skin nodules and ulcerations on his nasal planum and pinnae that first appeared in April (2 months previously). He had a similar problem last spring that began as a few small nodules on his nose and ears. His owner reported that the nodules increase in number and eventually ulcerate if untreated. The lesions were nonpruritic. Last spring, he was treated with a glucocorticoid injection, ivermectin IM, and possibly antimicrobials. The lesions resolved completely until this episode. Tom is an indoor/outdoor cat that lives on a half-acre of land with a dog, goats, and chickens. None of the other animals have skin conditions.

Current Medications:

Topical monthly flea prevention (owner unaware of name).

Other Medical History:

Previous medical problems included transient pyrexia of unknown origin a year previously, and a migrating plant awn in the inguinal fat pad a month previously that was removed surgically. At that time the skin lesions were present. He was treated with cefovecin sodium SC, but there was no change in the skin lesions after the injection.

Physical Examination

Body weight: 6.2 kg

General: Bright, alert, hydrated, responsive. Mucous membranes pink, HR 190, RR 50, temperature 100°F (37.8°C)

CASE EXAMPLE—cont'd

Integument: There was focal alopecia, crusting, and ulceration on the bridge of the nose and multiple crusted nodules on both pinnae (see Fig. 107.9A and B). A thickened area of skin was present in the inguinal fat pad where surgery had been performed a month previously. No ectoparasites were evident.
Eyes, ears, nose, and throat: Mild gingivitis was present.
No other clinically significant findings were found on physical examination.

Cytology Findings

Cytology of a skin scraping revealed increased numbers of neutrophils and cocci.

Serology

A feline heartworm antibody test was negative.

Diagnosis:

Suspected mosquito bite hypersensitivity.

Treatment

Tom was treated with a tapering course of prednisolone (1 mg/kg q12h PO for 5 days, then q24h for 5 days, then 0.5 mg/kg q24h for 5 days then q48h for 5 days). He was also treated with clavulanic acid-amoxicillin (10 mg/kg q12h PO). Monthly treatment with topical selamectin was commenced. The lesions resolved completely.

Comments

A presumptive diagnosis of mosquito bite hypersensitivity was made in this cat based on the seasonality of disease, the cat's lifestyle and geographic location, and the suggestive appearance and distribution of lesions. The owner was offered a biopsy but declined. Other diagnostic tests that could be considered in this case are retrovirus testing as well as a heartworm antigen test (see Chapter 111).

Myiasis

Jane E. Sykes, Lindsay Merkel, Susan E. Little

KEY POINTS

- First Described: Myiasis in humans and animals has been recognized for centuries. The most well-accepted description of myiasis was reported in 1965 by Fritz Zumpt, a German entomologist.[1] Infestations with *Cuterebra* spp. in cats in the United States were first described in the late 1800s.[2]
- Cause: A variety of fly species that obligately or facultatively infest the skin of vertebrates. The most common species that infest dogs and cats belong to the order Diptera; families Oestridae (bot flies or warble flies), Calliphoridae (blow flies), Sarcophagidae (flesh flies), and Muscidae (house flies). Examples include *Cuterebra* spp., *Hypoderma* spp., *Dermatobia hominis,* and *Oestrus* spp. (Oestridae); *Cochliomyia hominivorax*, *Lucilia* spp., and *Chrysomya* spp. (Calliphoridae); *Sarcophaga* spp. and *Wohlfahrtia* spp. (Sarcophagidae); and *Musca domestica* (Muscidae).
- Affected Hosts: Dogs, cats, and a large number of other vertebrate host species, especially livestock and wildlife species.
- Geographic Distribution: Worldwide, although the geographic distribution of individual fly species varies.
- Route of Transmission: For *Cuterebra* spp., eggs or larvae that are normally deposited around rodent or lagomorph burrows contaminate the skin and migrate into tissues. For most other fly species, eggs or larvae are deposited directly on to the vertebrate host. This may be where wounds or skin maceration are present, around body orifices (e.g., nasal cavity, perianal region), or on intact skin of weak or debilitated animals that are unable to groom.
- Major Clinical Signs: Cutaneous ulceration, which may have a putrid odor; subcutaneous masses ("warbles"), which may be pruritic or have evidence of larval movement; upper respiratory signs (e.g., sneezing, nasal discharge, stertorous respiration); neurologic signs (e.g., seizures, paralysis); ophthalmologic signs (impaired vision, uveitis, corneal edema, ocular discharge, distortion of the globe).
- Differential Diagnoses: Depend on parasite location and include a variety of other infectious diseases and neoplasia of the skin, ocular tissues, upper respiratory tract, and CNS; and migrating foreign bodies (e.g., plant awns). Aberrant CNS migration by *Cuterebra* spp. has been identified as a cause of feline ischemic encephalopathy in some regions.
- Human Health Significance: Humans can be infested by some of the same Diptera species that infest dogs and cats; myiasis is more often seen in impoverished people living in unhygienic conditions, travelers returning from tropical jungles, and children. Infestations are not directly transmitted from dogs and cats to humans. Blow fly larvae, especially *Lucilia sericata*, are also used as a recognized treatment in humans for debridement of necrotic wounds.

INTRODUCTION

Myiasis is defined as the infestation of live human and vertebrate animals with dipterous larvae, which, at least for a certain period, feed on the host's dead or living tissue, liquid body-substances, or ingested food. Myiasis has been divided into *obligatory myiasis*, where a living host is required for fly development, and *facultative myiasis*, where flies that normally use carrion or decaying organic matter for development occasionally infest macerated tissue or wounds of living hosts. *Pseudomyiasis* is when maggots are found in the intestinal or urogenital tract as passersby; they have accidentally been swallowed or migrated into these areas without actually feeding on tissues.

Myiasis may also be defined based on the anatomic region infested: cutaneous, auricular, ophthalmic, neurologic, urogenital, GI, and nasopharyngeal. Cutaneous myiasis includes *furuncular (subcutaneous) myiasis*, *traumatic (superficial cutaneous) myiasis*, and *creeping obligatory myiasis.* Creeping obligatory myiasis is when dipteran larvae create burrows in the skin and is usually caused by *Gasterophilus* spp. To date, this has not been reported in dogs or cats.

Ophthalmic myiasis has been divided into three types depending on the location of affected ocular tissues: *ophthalmomyiasis externa* (orbital or external ocular tissues), *ophthalmomyiasis interna posterior* (posterior portion of the globe), and *ophthalmomyiasis interna anterior* (anterior chamber).

A large number of fly species have been implicated in myiasis, which can be broadly grouped into the families Oestridae (bot flies or warble flies), Calliphoridae (blow flies), Sarcophagidae (flesh flies), and Muscidae (house flies). Often the exact species of Diptera involved is not identified in clinical cases. However, examples of species that have been identified in dogs and cats are listed in Table 108.1.

CUTEREBRA SPP. INFESTATIONS (CUTEREBRIASIS/CUTEREBROSIS)

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Cuterebra spp. (family Oestridae) are large, bee-like flies (bot flies) that normally deposit their eggs in or around rodent (depending on

TABLE 108.1 Examples of Fly Species Implicated in Obligatory or Facultative Myiasis in Dogs and Cats

Species	Common Name	Normal Hosts	Geographic Distribution	Site of Egg/Larval Deposition	Comments
Oestridae (bot flies, warble flies)					
Cuterebra spp.	Rodent bot fly, rabbit bot fly	Rodents, rabbits	North America (especially northeastern United States and southeastern Canada), northern Central America	E	Large larvae capable of causing significant respiratory, ocular, CNS, or cutaneous lesions
Dermatobia hominis	Human bot fly Torsalo American warble fly	Humans	Tropical and subtropical Central and South America	H	Large flies that resemble bumblebees. Important cause of furuncular myiasis in impoverished humans. Eggs may be vectored to tissues by mosquitos or muscoid flies
Hypoderma spp.	Heel fly Gad fly Warble fly	Cattle, deer	Northern hemisphere, 25–60 degree latitude; especially North Africa, India	H	Rare. Primarily lays eggs on cattle. Can cause furuncular, CNS, and ocular myiasis in humans
Oestrus spp.	Nasal bot Sheep bot fly	Sheep and to a lesser extent deer, goats	Worldwide	H	Normally deposits first-stage larvae in nostrils of sheep, sporadically affects the nasal cavity of humans and dogs
Calliphoridae (blow flies)					
Cochliomyia hominivorax	New World screw-worm fly	Warm-blooded animals including humans	Southern North America, Central and South America; largely eradicated from North America	H	Adults lay hundreds of eggs in exposed host flesh; wound disturbance causes maggots to invade more deeply
Chrysomya spp., especially *Chrysomya bezziana*	Old World blow fly Old World screw-worm fly (*Ch. bezziana*)	Warm-blooded animals especially livestock	Tropical Africa, southeast Asia, Middle East, India, Papua New Guinea	H	*Ch. bezziana* adults lay 150–200 eggs in wounds and mucous membranes; larvae feed on living (rather than necrotic) tissue of animals, sometimes causing permanent tissue damage. Importation into nonendemic regions has been a concern
Cordylobia spp., especially *Cordylobia anthropophaga* ("human eater")	Tumbu fly, mango fly	Warm-blooded animals, especially dogs and rodents	Subtropics of Africa	E	Larvae penetrate host skin and cause furuncles
Lucilia spp., especially *Lucilia sericata*	Common green bottle fly Sheep blow fly (United Kingdom, Australia)	Sheep, other warm-blooded animals	Temperate and tropical regions worldwide	H	Eggs laid in carrion and sometimes wounds or macerated skin of living hosts. Maggots have been used for wound debridement therapy
Sarcophagidae (flesh flies)					
Sarcophaga spp., e.g., *Sarcophaga haemorrhoidalis*	Flesh fly Red-tailed flesh fly	Carrion	Worldwide	H	Usually lay eggs on carrion but can cause wound myiasis in debilitated hosts; aural, nasal, and gastrointestinal (rectal) myiasis have been described in humans
Wohlfahrtia spp., e.g., *Wohlfahrtia magnifica*	Spotted flesh fly	Primarily livestock and horses	Tropical and subtropical regions worldwide	H	Most species lay eggs on carrion but can cause wound myiasis; *W. magnifica* is obligatory parasite; cases of aural, nasal, genital, and oral myiasis have been described
Muscidae (house flies)					
Musca domestica	House fly	Decomposing organic matter in the environment	Worldwide	H	Rare cause of wound myiasis in debilitated hosts

E, environment; *H,* host.

the *Cuterebra* species, various squirrels, chipmunks, woodrats, house mice) (subgenus *Cuterebra*) and lagomorph burrows (subgenus *Trypoderma*). They are the most common cause of furuncular myiasis in North America. Approximately 34 different species have been identified in North America, with approximately 12 species in the subgenus *Cuterebra* and 22 in the subgenus *Trypoderma*.[3] Adult flies, which live only a few weeks, lay 5 to 15 eggs per site (one to several thousand per lifetime) on vegetation during the summer months, and in response to heat from vertebrate hosts and optimal environmental conditions, eggs hatch and release first-stage larvae, which are 2 to 4 mm long (Fig. 108.1A). The sticky larvae then adhere to the fur of their target hosts and penetrate the host body by entering natural orifices. Often this is the upper respiratory tract, especially the nasopharyngeal or tracheal mucosa. Larvae then migrate through pleural and peritoneal tissues to a subcutaneous location. After about a week, the larva molts to the second instar, penetrates the epidermis, and creates a small air pore ("warble pore") by which it uses to breathe and excrete waste. The second-stage instar is gray to white and about 5 to 10 mm long. After another week, development to a third-stage larva occurs, then the larva enlarges the pore, emerges, drops to the ground, burrows into detritus and soil, and pupates. At the pre-pupal stage, third-stage larvae may be 2 to 4 cm long, are dark, thick, have two black mouth hooks, and are covered in cuticular spines (platelets) (Fig. 108.1B). The spines of *Cuterebra* species that prefer rodents have been described as flattened and plate-like, occasionally somewhat conical, usually bifid to many pointed in the anterior and posterior bands of spines on most segments. In contrast, species that prefer lagomorphs have conical, single-pointed spines, especially in the anterior and posterior bands on most segments.[4] Precise species determination is not possible based on larval morphology and requires molecular assays or pupation in the laboratory environment; unfortunately, larvae recovered from aberrant hosts often will fail to pupate to adults. The total time for larval maturation, from infection to exit from the warble, ranges from 3 to 8 weeks. The time required for the adult fly to emerge from the pupal case may be a month to several years.

Dogs, cats, humans, and a variety of other wildlife species such as raccoons and skunks are accidental or atypical hosts, developing more severe clinical disease than rabbits and rodents, sometimes with aberrant larval migration to sites such as the CNS and upper respiratory tract. It has been suggested that most infestations in dogs and cats involve *Cuterebra* spp. with a preference for lagomorph burrows.[5] Most affected dogs and cats documented in the literature have been from the midwestern and northeastern states of the United States, where only six different species of *Cuterebra* exist (Table 108.2). However, many cases have also been reported from eastern Canada,[6,7] along with isolated cases from other states of the United States (e.g., Georgia, Louisiana, Florida, Kansas, Texas), where other species of *Cuterebra* are present, potentially with slightly different host species as well as target site predilections. For example, in a case report of ophthalmomyiasis externa in an 8-week old Scottish terrier puppy, it was

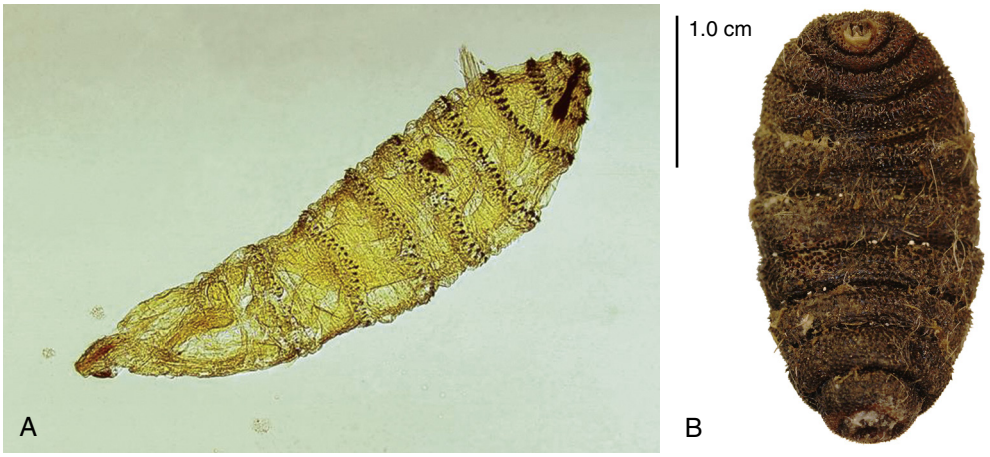

Fig. 108.1 *Cuterebra* spp. larvae. (A) First-stage larva. Note the rows of anterior hooklets that can anchor the feeding larva to the dermis. (B) Third-stage larva. (A, From Diaz JH. Myiasis and tungiasis. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases.* Philadelphia, PA: Elsevier; 2020:3492–3496. B, Modified from Lara-Lagunes N, Jaume-Schinkel S, Ibáñez-Bernal S. An incidental case of gastric pseudomyiasis in *Canis latrans* (Carnivora: Canidae) by a rabbit bot fly *Cuterebra* sp. (Diptera: Oestridae). *Rev Mex de Bioversidad.* 2017;88:410–414.)

TABLE 108.2 *Cuterebra* Species of the Northeastern United States

Subgenus	Order of Preferred Host	Species	Common Name	Preferred Host
Cuterebra	Rodentia	*Cuterebra emasculator*	Tree squirrel bot fly	Squirrels, chipmunks
		Cuterebra fontinella	Mouse bot fly	White-footed mouse (*Peromyscus leucopus*)
		Cuterebra americana[a]	Woodrat bot fly	Eastern woodrat (*Neotoma floridana*)
Trypoderma	Lagomorpha	*Cuterebra abdominalis*	Rabbit bot fly	Cottontail rabbit (*Sylvilagus floridanus*)
		Cuterebra buccata		
		Cuterebra cuniculi[b]		

[a]Found primarily in southeastern states as far south as Florida.
[b]Found primarily in southeastern coastal regions (Florida and southern Georgia); other species can be found throughout the east.

suggested that *Cuterebra jellisoni* might be involved, a species in the region that typically targets the head of rabbits, especially periocular tissues.[8] Although unpublished in the peer-reviewed literature, cases are common in Colorado (Jane Sykes, personal communication),[9,10] and occasional cases occur in the western United States (author's personal observations).[11,12]

Infestations are usually recognized in late summer to early fall; 90% of 42 cases (20 dogs and 22 cats) in one study that included cases from Michigan (United States) and Ontario (Canada) were seen in July and August, and the remainder in September.[6] A similar temporal pattern of infection has been noted in cats with CNS cuterebriasis.[13,14] The mean body weight of affected dogs in the series from Michigan and Ontario was 4.1 kg, and 80% of dogs were ≤ 4.5 kg; only one dog weighed > 9.1 kg. Eight of the dogs were Yorkshire terriers, and this breed was significantly overrepresented. A Yorkshire terrier with cerebral cuterebriasis confirmed molecularly to be *C. abdominalis* was also described from Texas.[15] However, anecdotally, small-breed white-coated dogs such as West Highland white terriers are most often affected in Colorado. Mean age of the dogs was 55.7 months (range, 8–110 months) and that of the cats was 17.8 months (range, 1–97 months); median age of 11 cats with CNS cuterebriasis was 2 years.[14] No sex predisposition has been noted. Both indoor-only, indoor/outdoor, and exclusively outdoor animals were affected; however, free roaming increases risk for infection. Although only one larva is usually identified, occasionally multiple larvae are removed; the presence of multiple larvae has most often been reported in kittens,[6] which also have the potential to be infected by larvae transferred from the fur of a queen.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Furuncular myiasis in dogs and cats may occur when *Cuterebra* spp. larvae penetrate wounds or migrate following inhalation or ingestion to a subcutaneous location, forming subcutaneous masses (furuncles or "warbles") with a 2 to 4 mm air pore with well-defined margins. The exact route of migration to subcutaneous tissues in domestic animals is unknown, but evidence of migration through muscle and the peritoneal cavity has been identified in some animals, suggesting a similar pattern of migration to that in rabbits or rodents.[6] Secretion of collagenase, proteases, and other digestive enzymes by the larva facilitates migration. Migrating larvae may also carry bacteria into tissues that leads to secondary bacterial infection. Furuncles are usually located on the head, neck, or trunk. The pore may ooze serosanguinous fluid such that the hair covering the furuncle becomes matted. Occasionally, the larva may also be observed to intermittently extrude from the pore.

Aberrant migration of larvae can involve the nasal cavity, pharynx, trachea, eye, and CNS. Occasionally, animals exhibit systemic signs in association with infection, such as inappetence or lethargy. Fever may also be present, possibly resulting from secondary bacterial infection or toxins excreted by the migrating larva. DIC, sepsis, and anuric renal failure secondary to acute tubular necrosis have been documented in dogs, but not cats.[6] Animals with infection of the upper respiratory tract or pharynx typically show signs that include epistaxis, sneezing, stertor, nasal discharge, gagging, cough, or inspiratory stridor and dyspnea with tracheal involvement.[6,12,16] Occasionally a larva is sneezed out of the nasal cavity, coughed or vomited out, or extrudes from the nares. Other physical examination findings include decreased nasal airflow, and swelling of the soft palate or pharynx. Ocular cuterebriasis is associated with ocular discharge, corneal edema, periocular swelling or masses, chemosis, blepharospasm, uveitis, and sometimes blindness.[17,18] A larva may be observed in periocular masses (ophthalmomyiasis externa) or within the anterior or posterior chambers (ophthalmomyiasis interna).[17] Involvement of the anterior chamber appears to incite more inflammation than involvement of the posterior chamber. CNS migration (cerebrospinal cuterebriasis) is most often reported in cats, but also has been described in a small number of dogs.[19–21] Based on the frequent finding of *Cuterebra* spp. in the olfactory bulbs or peduncles and cribriform plate at necropsy, it is suspected that larvae gain access to the brain from the nasal cavity.[14] The neurologic signs that follow depend on the path of larval migration. Acute onset of seizures (documented in approximately 25% of cats), head tilt, nystagmus, circling, falling to one side, central blindness, evidence of cranial nerve dysfunction, head pressing, obtundation, ataxia, abnormal placing reactions, pelvic limb weakness, behavioral changes, thermoregulatory disturbances, vomiting, and vocalization have been described.[11,13,14,21–23] Signs are often lateralizing (and in one study, left lateralizing),[14] typically progress rapidly and end in death due to ischemic necrosis and inflammation; rarely, recovery with or without residual neurologic signs occurs. Rarely larvae are found within the spinal canal.[24] Respiratory signs (especially sneezing) often precede CNS signs, most often by 1 to 2 weeks, but occasionally 4 to 10 weeks.[4] CNS cuterebriasis has been suggested as the cause of feline ischemic encephalopathy, based on a similar geographic distribution and seasonality as well as findings on CNS histopathology[11]; it has also been suggested as a possible cause of feline idiopathic vestibular disease.[14,23]

DIAGNOSIS

Cuterebra spp. larvae have a characteristic appearance as described above, and because other causes of myiasis in North America are rare, in most cases, a diagnosis of cuterebriasis is made presumptively, without confirmation of their identity by a parasitologist. If a larva is not visualized in the eye or extruding from the air pore in the skin or upper respiratory tract, diagnosis can also be made following biopsy. Clipping the hair over cutaneous furuncles may be required in order to visualize the pore. Cerebrospinal cuterebriasis is usually diagnosed at necropsy, although findings on MRI examination of the brain may be supportive of the diagnosis. In endemic regions, a history of respiratory signs (especially sneezing) before the onset of neurologic signs should raise suspicion for cerebrospinal cuterebriasis, especially in the summer or early fall. Cryptococcosis is an important differential diagnosis in cats with this history.

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, Urinalysis, and Clotting Function

Findings on routine blood work and urinalysis in dogs and cats with cuterebriasis are nonspecific and may be normal. Neutrophilic leukocytosis, eosinophilia, thrombocytopenia, increased serum liver enzyme activity, azotemia, hypoalbuminemia, and hyperglobulinemia have been described in some animals.[6,14] In the study of dogs and cats from Michigan and Ontario, proteinuria was documented in all 13 animals that had urinalysis performed; urine protein-to-creatinine ratios (UPCRs) that were performed in six dogs were consistent with the magnitude expected with glomerular proteinuria (3.2 to 16). Some animals have granular casts in the urine.[6] Clotting function is usually normal, but evidence of DIC may be present in infestations that are complicated by SIRS or sepsis.

Cerebrospinal Fluid Analysis

The CSF in dogs and cats with cerebrospinal cuterebriasis may have evidence of hemorrhage and pleocytosis, in some cases with a predominance of eosinophils.[14,19,23] Total protein concentration may be moderately to markedly increased.[19,21] Given that some animals

have had evidence of increased intracranial pressure, collection of CSF may carry some risk for brain herniation; however, this has not been reported in the literature.

Diagnostic Imaging

Plain radiography of affected tissues can reveal soft tissue submucosal or subcutaneous masses, sometimes with evidence of chitinous larval fragments, which appear as radiodensities.[6] Brain MRI of dogs and cats with cerebrospinal cuterebriasis can reveal single tubular lesions (tracts) that course through the brain parenchyma; these have been described as hyperintense with a hypointense rim on T2-weighted images, and hypointense on T1-weighted images, relative to normal gray matter. In one case report, the hypointense rim enhanced strongly with gadolinium on T1-weighted images, and T2-weighted and FLAIR sequences revealed evidence of edema surrounding the tract (hyperintense signal).[19] Brain lesions extended from the cribriform plate, suggesting entry through the nasal cavity. One cat had evidence of subtentorial and transforaminal brain herniation, with intraparenchymal T2-hyperintense, T1-contrast-enhancing meandering tracts that correlated with eosinophilic tract lesions on histopathology.[23] Few descriptions exist of the larvae themselves, but blooming artifacts have been described on T2* (T2-star) sequences in humans with CNS myiasis that have the potential to be caused by larval materials rather than hemorrhage (Fig. 108.2).[25]

Rhinoscopy and tracheoscopy in animals with respiratory involvement allow direct visualization of warbles or larvae and in some cases, endoscopic removal of larvae (Fig. 108.3). Larvae may be observed to intermittently extrude from a warble.[12]

Parasitologic Tests

Serologic Diagnosis and Molecular Diagnosis Using Nucleic Acid–Based Testing

No serologic tests are commercially available for diagnosis of cuterebriasis in dogs and cats. However, development of an ELISA assay that detects IgG antibodies to *Cuterebra* spp. antigen was reported which showed some promise for aiding diagnosis when larvae could not be visualized, especially in the case of cerebrospinal cuterebriasis.[24] Unfortunately, for unclear reasons, some cats with large larvae remained seronegative, and no further developments on this assay have been reported at the time of writing. PCR-based assays have been used to differentiate fly species causing myiasis in livestock (including *Cuterebra* spp.)[26,27] and humans,[3] but

Fig. 108.3 Endoscopic image of the trachea of a 6-year-old intact female wire-haired dachshund that was seen for lethargy, cough, apparent odynophagia, intermittent fever, and inappetence. On one instance hemoptysis was observed. A *Cuterebra* sp. larva was visualized on the left ventrolateral trachea. The larva was removed using suction. A large erosion remained on the tracheal mucosa. Recovery was uneventful.

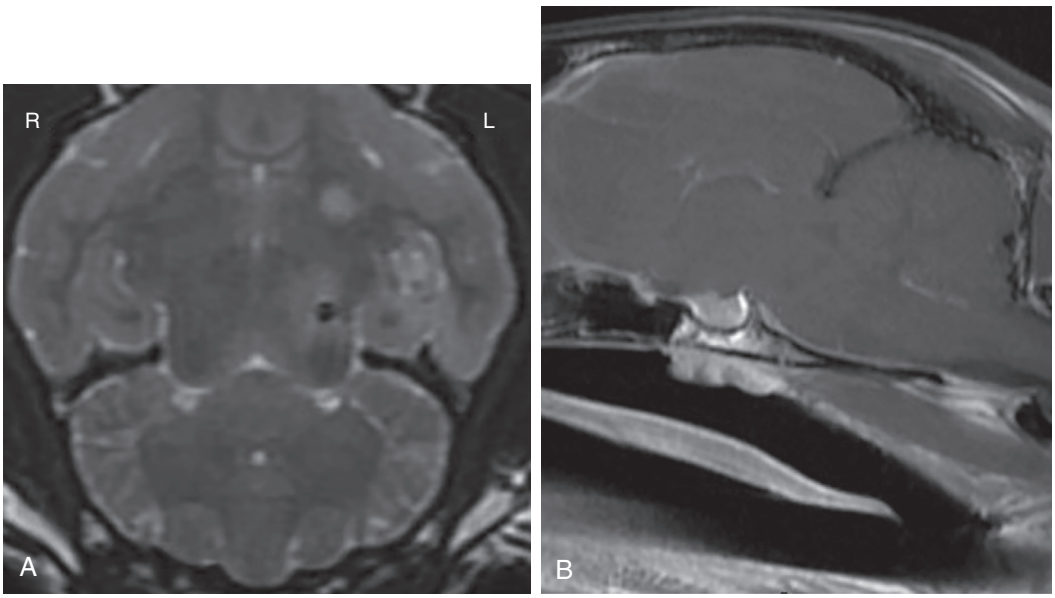

Fig. 108.2 MRI images from a 1-year-old intact female domestic shorthair cat with presumptive cerebrospinal cuterebriasis. (A) Multiple T2-weighted hyperintense lesions are present throughout the cerebral parenchyma. (B) T1-weighted post-contrast image showing markedly contrast-enhancing lesion in the nasopharynx suspected to be the site of a furuncle.

these have only recently been applied for identification of larvae recovered from companion animals.[15] However the dearth of accurately identified specimens for reference purposes makes molecular confirmation difficult in many cases.[3,24]

Pathologic Findings

Gross pathology of the brain in dogs and cats with CNS involvement can reveal focal or multifocal areas of yellow discoloration (malacia) and hemorrhage, often within the olfactory bulbs or peduncles, with a single intralesional larva (Fig. 108.4).[13] Histopathology may reveal a larva within the brain parenchyma accompanied by neutrophilic and or eosinophilic meningoencephalitis. However, larvae are not found in many cases.[14]

Parasitic migratory tracts have most often been identified in or near the caudate nucleus and thalamus in cats, and have been characterized by spongy degeneration, cerebral infarction, and hemorrhage; cerebrocortical necrosis; astrogliosis; and focal granulomatous encephalitis surrounding a larva.[13,19,21] Larvae have also been found at necropsy in association with the optic nerve, cribriform plate, or ventral cranial cavity.[13] It has been suggested that a larval toxin may induce some of the pathology found within the brain that resembles that described for feline ischemic encephalopathy.

TREATMENT AND PROGNOSIS

Treatment of furuncular cuterebriasis or infestations that involve the respiratory tract or eye involves removal of the larva using forceps as well as broad-spectrum antimicrobial therapy for secondary bacterial infection. It has been recommended not to squeeze or disrupt the larva during removal as release of antigens has the potential to trigger an anaphylactic reaction, and residual fragments may lead to a foreign body reaction and abscessation. However, this is anecdotal and in practice, gentle compression of the base of a cutaneous furuncle to extrude the larva rarely has adverse consequences. The area should be debrided as much as possible, lavaged with copious amounts of saline, and allowed to heal by granulation. In human medicine, asphyxiation of the larvae by covering the air pore with petrolatum jelly or other fatty substances has been advocated to trigger spontaneous extrusion of the larva, rather than removing it surgically. Such treatments have not been documented in the veterinary literature. A short (72-hour) course of NSAIDs may help to reduce pruritus following extraction of cutaneous larvae, and for cases that involve the nasopharynx or trachea, a tapering course of glucocorticoids should be administered if there is severe swelling that obstructs respiration. Where multiple larvae are identified, administration of ivermectin should be considered (e.g., 100 to 400 µg/kg, PO, once). Application of topical fluralaner or oral sarolaner was used to successfully treat furuncular myiasis caused by *Dermatobia hominis* in cats and dogs, respectively.[28,29] Larvae located within the respiratory tract may be removed using endoscopic guidance.[16,30] Descriptions exist of surgical approaches to remove larvae of various stages from the tracheal submucosa[12,16] and in cases of ophthalmomyiasis interna by keratotomy or vitrectomy techniques.[12,17,31,32] IV fluid therapy and other supportive care measures may be required for debilitated animals. Angiotensin-converting enzyme inhibitors and low-dose aspirin have been used to treat animals with secondary protein-losing nephropathy.[19]

The optimal treatment for suspected cerebrospinal cuterebriasis is not known. Ivermectin has been the most commonly reported antiparasitic treatment, with doses that range from 20 to 400 µg/kg SC or PO; in some cases, more than one treatment was given at intervals ranging from q24h, q48h, and 14 days.[14,19,23] Ivermectin normally does not penetrate the blood-brain barrier; its use has been based on the assumption that barrier disruption occurs secondary to larval migration and inflammation and evidence of efficacy for treatment of other cerebrospinal myiases.[19] Death of larvae may trigger a type I hypersensitivity reaction, and so pretreatment with diphenhydramine (4 mg/kg IM) 1 to 2 hours before ivermectin (400 µg/kg, SC, q24h for 3 treatments) and dexamethasone (0.1 mg/kg IV) has been used in some cases.[14,19] It may be necessary to continue treatment with tapering anti-inflammatory doses of glucocorticoids to reduce brain edema and inflammation. Mannitol may also be indicated if increased intracranial pressure is suspected. Surgical removal of a migrating larva by craniotomy was attempted in one dog, but the larva was not identified, and instead biopsy was performed.[19] This dog ultimately recovered following treatment with an escalating dose of ivermectin (20 µg/kg on day 1, 25 µg/kg on day 2, and 30 µg/kg on day 3) and methylprednisolone sodium succinate (30 mg/kg IV q24h). Recovery without ivermectin treatment also has been described.[21] Anticonvulsants such as phenobarbital have been used to manage seizures acutely, and were required for long-term management of residual cluster seizures in one otherwise recovered dog.[19] An overall mortality rate of 17% was reported among 42 dogs and cats with cuterebriasis from North America.[6] Only 1 of 22 cats died, and this was as a result of suspected septic peritonitis secondary to larval migration through the peritoneal cavity. In contrast, 6 of 20 dogs died; all weighed ≤ 4.5 kg and had SIRS, DIC, or both.

PREVENTION

Keeping cats indoors, limiting roaming of pets, and maintaining yards to reduce long grass and rodent/lagomorph habitats can help reduce infection. It is possible that the use of heartworm prophylaxis and flea control, including systemic insecticides (e.g., isoxazolines), may also reduce the risk of infection, but this has not been evaluated experimentally.[6]

PUBLIC HEALTH ASPECTS

Human cases of cuterebriasis have been reported in North America, including cases of ophthalmomyiasis, respiratory infections, and cutaneous furunculosis.[33] Most cases occur in the northeastern

United States, with humans encountering eggs or larvae when they engage in outdoor activities. The rabbit bot fly species *Cuterebra buccata* has been identified as the cause of a small number of human myiasis cases in the United States; however, as with dogs and cats, the species is rarely identified.[3] Furuncles are most commonly identified in lesions of the scalp, face, and neck down to the upper torso. Cutaneous and respiratory infestation with *C. buccata* was described in a 74-year-old man from Connecticut who reported doing yard work, including mowing his lawn, without a shirt.[3] Similar lesions occur with *Dermatobia hominis* infestations (New World or human bot fly), which occurs in the Caribbean, Central America, and South America. Although theoretically animals could bring first-stage *Cuterebra* spp. larvae adherent to their coats into close proximity with humans, human disease is extremely rare and no human case has been linked to contact with companion animals.

WOUND MYIASIS (MAGGOT INFESTATION)

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

In North America, most maggots found associated with skin wounds are facultative parasites that feed on decaying, necrotic tissue and include members of the Calliphoridae (blow flies), Sarcophagidae (flesh flies), and, rarely, Muscidae (house flies). In other regions of the world, a few species are obligatory parasites that feed on healthy tissue. Examples of obligatory myiasis flies include the primary New World screwworm fly, *Cochliomyia hominivorax*; the Old World screwworm fly, *Chrysomya bezziana*; the tumbu fly, *Cordylobia anthropophaga;* and the spotted flesh fly, *Wohlfahrtia magnifica*. The latter two species are non–bot fly agents of furuncular myiasis not present in the Americas.[34]

Diptera associated with wound myiasis have a similar life cycle. Females deposit eggs or larvae on the edge of a wound or, for some species, on a moist mucous membrane. For obligatory myiasis flies, a wound as small as a tick bite may be adequate. In some patients, no primary trauma is identified.[34] Larvae feed on necrotic tissue and decaying organic material (e.g., feces, vegetation) adherent to the skin or, in the case of primary screwworm larvae and other obligatory myiasis flies, healthy tissue. After 3 to 10 days on the host, fully developed larvae drop to the environment and pupate in the soil. Environmental development, activity of adult flies, and fecundity are species, temperature, and humidity dependent. Some species thrive in more tropical areas, whereas others are found seasonally in temperate regions. At lower temperatures, flies may remain in the pupal stage for several months.[34]

Adult New World screwworm flies are two to three times larger than house flies, metallic blue to blue-black, and have three stripes along the dorsal surface; the center stripe of *Co. hominivorax* is shorter than the outer ones, and in *Cochliomyia macellaria* all stripes appear to be of the same length.[35] Larvae of *Co. hominivorax* grow as long as 17 mm and can be identified by the presence of pigmented tracheal trunks. Tissue destruction by feeding *Co. hominivorax* may attract other blow flies resulting in a mixed population of maggots. The primary screwworm can only survive in areas with mild (warm) temperatures and adequate humidity, and, although historically found in the southern United States, has been eradicated from North America and most of Central America.[36] Populations remain in southern Panama, South America, and in some Caribbean islands with occasional re-introductions into North America reported.[37,38] Adult female *Co. hominivorax* only mate once; large-scale release of sterile male flies allowed initial eradication and continues to be employed when re-introductions occur.[36,38] The Old World screwworm fly, *Ch. bezziana*, is found in tropical areas in Southeast Asia, Africa, the Middle East, and some Pacific islands. Adults are metallic green or blue. Larvae have pigmented tracheal trunks, but the pattern differs from that of *Co. hominivorax*.[35] Other *Chrysomya* spp. (*Chrysomya rufifacies*, *Chrysomya putoria*) primarily develop in carcasses but are also involved in some cases of facultative myiasis.[34] *Cordylobia anthropophaga* is unusual in that larvae hatch from eggs deposited in the environment and then directly penetrate the skin to develop in furuncles prior to emerging to pupate in the environment, similar to bot flies.[34]

Like *Chrysomya* spp., *Lucilia* spp., *Calliphora* spp., and *Phormia* spp. are referred to as bottle flies due to the dramatic metallic green or blue color of the adults. *Lucilia sericata*, the common green bottle fly, is found worldwide and thrives in warm humid areas although it can also survive in drier regions. Although associated with sheep, *L. sericata* will also deposit eggs on necrotic tissue on dogs and cats, resulting in fly strike.[39] Other *Lucilia* spp. (e.g., *Lucilia* [*Phaenicia*] *eximia*), *Calliphora* spp. (e.g., *Calliphora vicina*), and *Phormia* spp. (e.g., *Phormia regina*) can also be involved.[40–43]

Adult flesh flies (Sarcophagidae: *Sarcophaga* spp., *Wohlfahrtia* spp.) are large, greyish flies approximately twice as large as house flies and can be recognized by the distinct checkerboard pattern (*Sarcophaga* spp.) or rows of oval black spots (*Wohlfahrtia* spp.) on the abdomen.[34] Female *Sarcophaga* spp. deposit fully formed larvae (or, for some species, hatching eggs) onto decaying flesh; development to mature larvae can proceed in as little as 3 to 4 days. Several *Sarcophaga* spp. (*Sarcophaga pernix* [= *haemorrhoidalis*], *Sarcophaga argyrostoma*, *Sarcophaga tibialis*) have been reported in cases of facultative myiasis in dogs and cats.[43] Larvae of *W. magnifica* are obligatory parasites that infest wounds or natural body orifices (nares, ears, eyes, genitals) of mammals and birds in southern Europe, Asia, and the Middle East. As with *Sarcophaga* spp., female *Wohlfahrtia* spp. deposit formed larvae. Canine infestations are often associated with livestock, especially small ruminants, but infestations in shelter dogs have also been reported.[44–46] *Wohlfahrtia* spp. in North America (*Wohlfahrtia vigil*, *Wohlfahrtia opaca*) normally infest wildlife (fox, rabbits) and have been historically reported in dogs and cats but are presently considered rare causes of furuncular myiasis in the region.[47,48] House flies (*Musca domestica*) occasionally lay eggs in decaying tissues but are not a common cause of wound myiasis.

Wound myiasis disproportionally affects animals in poor condition that are kept outside.[49] Feral cats, and dogs and cats that experience trauma and are not presented for treatment, are at increased risk; ages vary and intact males are overrepresented.[50–53] Fight-related wounds are considered particularly high risk.[53] Other identified risk factors include paresis and obesity.[41,43] An association with exposure to livestock is evident in many case reports, and cases of myiasis are more likely in months with warm, humid weather when fly activity is highest.[45,49]

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Facultative myiasis flies are attracted to dogs and cats by the presence of adherent blood, feces, or decaying tissue. Obligatory species seek out pets kept outdoors regardless of overall condition, although debilitated animals may be more susceptible. Female flies deposit eggs or larvae directly onto animals, selecting warm, moist regions such as wounds, which may be as minor as arthropod feeding lesions, or mucous membranes. Predisposing, traumatic conditions that attract female flies include wounds that develop following a fight, fall, or vehicular collision; untreated surgical incisions; abrasions from a collar; dermatitis associated with infection, which may be secondary to fecal and urine contamination of skin or matted fur; ectoparasite infestation; or decubitus ulcers secondary to prolonged immobility.[39]

Dogs and cats infested with maggots are malodorous and often debilitated. Stabilizing the patient may be necessary prior to instituting therapy. The extent of the infestation may be obscured by the hair-coat, particularly in long-haired or dense-coated animals, or by other material adherent to the wound. Careful inspection, including clipping the hair, is usually necessary to adequately assess overall condition; sedation with analgesia may be required to allow full examination of affected areas. A complete history that includes questions about recent injuries, pre-existing conditions, housing conditions, and, for potentially introduced species of myiasis flies, travel, can be helpful in formulating an effective treatment plan.

DIAGNOSIS

In animals with wound myiasis, maggots are usually grossly apparent on ulcerated skin lesions. To confirm the etiology, a representative sample of larvae should be removed with forceps, placed in 70% ethanol, and submitted to a diagnostic laboratory.[54] Mixed infestations commonly occur, including with primary screwworm fly; submitting several larvae (20–30) collected from different areas is recommended. Third-stage larvae are more readily identified; when possible, larger larvae should be selected for submission. In cases of furuncular myiasis, larvae are removed from subcutaneous cysts for identification as described for cuterebriasis.

Laboratory Abnormalities

Complete Blood Count, Serum Chemistry Profile, Urinalysis, and Clotting Function

Findings on routine blood work and urinalysis in dogs and cats with wound myiasis may be normal or, if abnormal, associated with either the infestation or the underlying condition. Dogs infested with *W. magnifica* had neutrophilic leukocytosis, but all other parameters were normal.[45] Some case reports of wound myiasis describe increased serum hepatic enzyme activities, increased CK concentration, and hypergammaglobulinemia, as well as mild anemia, decreased serum albumin concentration, and decreased serum albumin-to-globulin ratio.[55–54] Evidence of dehydration due to fluid loss may be present in dogs and cats with advanced wound myiasis lesions.

Parasitologic Tests

Larval identification is made by examining the spiracles, cuticular spines, and, for *Co. hominivorax*, tracheal trunks.[54] If primary screwworm flies are suspected, representative specimens should be placed in 70% ethanol and submitted to a diagnostic parasitologist for confirmation of identification. In many areas of the world, including North America, primary screwworm flies must be promptly reported to regulatory agencies.[38,58] The identity of larvae in ethanol can also be evaluated using molecular assays; formalin distorts some morphologic features and reduces utility for subsequent molecular assays. Morphologic identification of larvae of some fly species can be challenging, and appropriate keys should be used by a trained, boarded entomologist or veterinary parasitologist. Many larvae cannot be identified to species based on morphology alone, and molecular data are not available for all species. In these cases, partnering with a specialist to collect live larvae and rear them to adults can allow identification.

Pathologic Findings

Wound myiasis is usually present in ulcerated, necrotic tissue. Invasion of major organs or sepsis following secondary infections may occur.[59] Because wound myiasis is grossly apparent, histopathology is not usually pursued. Examination of otic discharge and preputial lavage fluid from dogs with *W. magnifica* infestations revealed bacterial cocci, neutrophils, and epithelial cells; *Staphylococcus aureus* and coagulase-negative staphylococci were isolated.[45]

TREATMENT AND PROGNOSIS

Treatment of wound myiasis involves a combination of insecticidal and manual removal of fly larvae followed by wound management. The hair should be clipped to visualize the extent of the infestation. Systemic insecticides useful for treatment of wound myiasis include nitenpyram, spinosad, sarolaner, afoxolaner, milbemycin oxime, and other macrocyclic lactones. Nitenpyram administered twice, 6 hours apart, to dogs infested with *Co. hominivorax* resulted in expulsion of 86% of larvae by 6 hours and 94% by 18 hours; all larvae were killed as well as expelled.[60,61] Administration of spinosad to dogs infested with *Co. hominivorax* resulted in expulsion of most (70%) larvae by 6 hours after treatment although not all larvae were killed; sarolaner expelled fewer larvae than spinosad but all (100%) larvae in sarolaner-treated dogs were dead 24 hours after treatment.[62,63] A combination spinosad/milbemycin treatment killed all larvae by 7 hours post-treatment. In groups receiving afoxolaner or spinosad, all larvae were killed within 24 hours.[61] Other approved isoxazolines (fluralaner, lotilaner) are also considered effective.[64] Historically, topical organophosphates or pyrethroids were applied to wounds, but their use has largely been supplanted by systemic insecticides.[65] Any remaining larvae in the wound after insecticide treatment should be manually removed. Larvae can be removed from affected tissues with forceps and the tissue lavaged and cleaned with chlorhexidine and povidone-iodine.[54]

Insecticide treatment and manual removal of larvae alone are not adequate for resolving cases of wound myiasis; careful wound management, treatment of underlying conditions, and change in owner care practices are also necessary. Once larvae are removed, necrotic tissue should be debrided and other issues caused by larvae or responsible for initial wounds appropriately addressed (e.g., skin resection, complete excision to allow primary closure, enucleation, amputation). Pain management (e.g., meloxicam, 0.2 mg/kg q24h until resolved) and both systemic and topical antibiotic therapy should be provided as indicated; continuing antibiotics for at least 2 weeks past clinical resolution is recommended.[54,62,63] Larvae involved in furuncular myiasis (e.g., *W. magnifica, Co. anthropophaga*) can be removed with forceps and the skin lesion managed as described for cuterebriasis.[34] Prognosis is dependent on the extent of the lesions at presentation, the body systems affected, any underlying conditions, and the ability of the owner to provide appropriate housing and follow-up care. Uncomplicated cases or those in which co-morbidities can be readily addressed are likely to recover, even when infestations are severe.

PREVENTION

Keeping dogs and cats indoors and protected from flies, particularly when debilitated or if skin wounds are present, largely eliminates risk of myiasis. Outdoor pets should be routinely bathed, groomed to remove mats, and kept in clean, dry areas free of fecal debris or other decomposing material (e.g., garbage, compost) that will attract flies; screening kennels if possible is strongly encouraged.[54] Postsurgical discharge instructions should advise owners to house pets indoors and protected from flies until wounds are completely healed, particularly during warmer months. Pets with skin lesions, including pyotraumatic or atopic dermatitis, or those infested with mites, lice, ticks, or fleas, are at increased risk. Addressing other health issues, such as incontinence or malodorous dermatitis or otitis externa, that might lead some owners to house animals outdoors or in structures unprotected from flies (e.g., sheds, barns) supports prevention. Risk is higher for older,

Fig. 108.5 Forearm exit site wound of a third-stage (instar) New World screwworm fly larva, *Cochliomyia hominivorax*. (From Seppänen M, Virolainen-Julkunen A, Kakko I, et al. Myiasis during adventure sports race. *Emerg Infect Dis*. 2004;10:137–139.)

debilitated dogs that may develop decubital ulcers and for intact dogs and cats allowed to roam and thus prone to trauma or fight wounds. Accordingly, neutering indirectly reduces risk.[53] Routine use of macrocyclic lactones for heartworm prevention and insecticides for flea control, including systemic isoxazolines, would be expected to limit wound myiasis, but this has not been evaluated experimentally.

PUBLIC HEALTH ASPECTS

In areas where the flies are endemic, primary screwworm fly larvae (*Co. hominivorax*, *Ch. bezziana*) feed on human as well as animal tissues (Fig. 108.5). Myiasis caused by both species can result in extensive tissue destruction, including bone loss; in severe cases and without treatment, fatalities occur.[66–68] A systematic review of 291 cases revealed that human infestation with *Ch. bezziana* usually occurs in concert with poor hygiene, low socioeconomic status, advanced age, substance abuse, or the presence of underlying diseases including infections, age-related diseases, and noninfectious chronic diseases.[67] Similar factors have been identified in analysis of human cases of *Co. hominivorax*, with infestations more common in warmer months and associated with poor hygiene, psychiatric disorders, substance abuse, and co-infestation with lice or scabies; older men are overrepresented.[68,69] In Africa, humans acquire *Co. anthropophaga* larvae from the environment, developing furuncular myiasis on the arms, abdomen, and lower back; other species of *Cordylobia* described from humans include the Lund's fly, *Cordylobia rodhaini*.[70]

Facultative wound myiasis readily develops on humans and is usually associated with lack of access to housing, neglect, and the presence of co-morbidities, including substance abuse and peripheral vascular disease. Cases of wound myiasis in the United States are more common in older men (average age 60 years, male-to-female ratio 5.5:1).[59] *Lucilia sericata* is the most common species, but other blow flies and flesh flies have been described in people. A majority of patients are homeless and present with larvae from late spring through early fall.[59] In Brisbane, Australia, where *Lucilia cuprina* was the most commonly identified species, cases similarly occurred during warm weather and disproportionately affected elderly, ill, and debilitated patients.[71] do not contribute to the risk of facultative wound myiasis in humans. Dogs are considered a reservoir of *Co. anthropophaga* in Africa, and translocation of infested pets is a potential source for re-introduction and geographic spread of primary screwworm flies, but dogs and cats are not epidemiologically important in the life cycle of any other obligatory or facultative myiasis flies.[34,38]

ACCIDENTAL MYIASIS (PSEUDOMYIASIS)

Accidental myiasis refers to the presence of larvae (maggots) in feces or vomit of animals following ingestion of fly eggs or larvae in food, carrion, or garbage.[54] Common species include any of the blow fly or bottle fly larvae that invade carcasses (*Lucilia* spp., *Calliphora* spp., *Phormia* spp.) or muscid flies whose larvae develop in decomposing food materials (e.g., *Musca* spp., *Muscina* spp.). *Sarcophaga* spp. have also been detected in feces following ingestion in carrion.[34] The larvae are present due to dietary indiscretion, not because of ongoing development in the GI tract. Since the pet is not infected, treatment is not indicated.[54] Accidental myiasis would be expected to be more commonly seen in free-roaming pets that are likely to encounter and ingest decomposing carcasses or rotting food with fly larvae. Confirmation of pseudomyiasis can be achieved by confining the pet for 2–3 days and feeding only fresh, commercial food; larvae will no longer be evident in the feces.

Pseudomyiasis can also occur when larvae are found in feces submitted for parasite examination because specimens are collected from the environment rather than per rectum. Female flies oviposit on uncovered feces in the environment almost immediately after it is deposited, and larvae rapidly develop but are not of diagnostic significance.[72] When confirmation of the absence of larvae is desired, a fresh fecal specimen can be collected and examined.

In humans, accidental myiasis is commonly associated with *Piophila casei*, the cheese skipper, following ingestion of cured or smoked meats and cheese on which the flies have fed.[34,73] The condition has also been reported in children and adults that ingest *Drosophila* spp. on produce, meat with *Sarcophaga* spp., and in a child fed overripe bananas with *Muscina stabulans*.[34,74,75]

CASE EXAMPLE

Signalment
"Prim," a 1-year-old intact female domestic shorthair from Minneapolis, MN, United States.

History
Prim was evaluated by the University of Minnesota Small Animal Emergency Service on July 6 for acute onset of ataxia and possible loss of vision. The owner noted that she was disinterested in food, she appeared to be walking very cautiously with a low stance, her pupils were enlarged, and she was not responsive to voice or other stimuli.

Current Medications
None.

Other Medical History
Prim was an indoor cat that was allowed outdoors but only with supervision. She was up to date on core vaccinations, including rabies.

Physical Examination
Body weight: 3.5 kg.

Continued

CASE EXAMPLE—cont'd

General: Bright, alert, and responsive. T = 102.6°F (39.2°C), HR = 160 beats/minute, RR = 80 breaths/minute, mucous membranes pink and moist, CRT < 2 seconds.

All other body systems: No clinically significant findings.

Neurologic examination: Decreased withdrawal reflex for the left pelvic limb and absent withdrawal reflex for the right thoracic limb. Menace response was normal OS but not OD. All other aspects of the neurologic examination were unremarkable.

Laboratory Findings

CBC: HCT 35.3% (29.5%–47%), MCV 40.5 fL (37.4–50.4 fL), MCHC 34.7 g/dL (32.1–39.7 g/dL), WBC 13,280 cells/μL (1,830–16,270 cells/μL), neutrophils 11,820 cells/μL (1,200–13,200 cells/μL), eosinophils 400 cells/μL (0–1,900 cells/μL), basophils 0 cells/μL (0–300 cells/μL), lymphocytes 660 cells/μL (200–9,400 cells/μL), monocytes 400 cells/μL (0–800 cells/μL), platelets clumped but adequate. Rare reactive lymphocytes.

Serum chemistry profile: Sodium 145 mmol/L (147–158 mmol/L), potassium 4.2 mmol/L (3.9–5.3 mmol/L), chloride 111 mmol/L (113–123 mmol/L), bicarbonate 14.2 mmol/L (12–20 mmol/L), phosphorus 4.1 mg/dL (3.3–7.8 mg/dL), calcium 9.9 mg/dL (8.3–10.9 mg/dL), BUN 13 mg/dL (12–39 mg/dL), creatinine 1.0 mg/dL (0.5–2.1 mg/dL), glucose 209 mg/dL (74–143 mg/dL), total protein 7.0 g/dL (5.9–8.2 g/dL), albumin 3.8 g/dL (2.4–4.1 g/dL), globulin 3.2 g/dL (2.5–5.3 g/dL), ALT 70 U/L (16–127 U/L), AST 84 U/L (14–42 U/L), ALP 32 U/L (2–88 U/L), creatine kinase 3285 U/L (54–744 U/L), GGT < 3 U/L (0–3 U/L), cholesterol 118 mg/dL (56–226 mg/dL), total bilirubin 0.2 mg/dL (0–0.3 mg/dL), magnesium 1.9 mg/dL (1.6–2.4 mg/dL).

Urinalysis: not available.

Imaging Findings

MRI: Multiple T2-, T2 FLAIR-hyperintense and poorly-defined lesions were identified throughout the cerebral parenchyma: specifically, within the left frontal lobe, left thalamus, left midbrain, and left hippocampus (see Fig. 108.2A). With the exception of mild contrast enhancement associated with the left hippocampal lesion, these lesions were not contrast-enhancing. However, there was mild left pachymeningeal enhancement that extended from the forebrain to the occipital lobe. Associated with the lesions within the hippocampus and left midbrain is ill-defined T2-hypointensity, T1- and isointensity with a susceptibility artifact on the T2* (T2-star)-weighted image, compatible with acute hemorrhage. Within the dorsal aspect of the left cerebellar hemisphere is similar patchy T2-hyperintensity with minimal patchy contrast enhancement. The caudal fossa is slightly crowded and the cerebellar vermis is mildly flattened and displaced caudally without overt herniation.

Extra-calvarial structures: Originating from the dorsal aspect of the mid nasopharyngeal wall was a broad-based, 0.5 × 1 cm, T1-, T2-isointense (to gray matter) and markedly contrast-enhancing structure (see Fig. 108.2B). Both medial retropharyngeal lymph nodes were moderately generally enlarged and markedly heterogenously contrast-enhancing.

Conclusions: multifocal intra-axial lesions affecting the forebrain, midbrain, and cerebellum with mild pachymeningeal enhancement. Broad-based structure within the dorsal aspect of the nasopharynx of uncertain etiology but could be related to the intracranial lesions if this is parasitic. Crowding of the caudal fossa is likely secondary to increased intracranial pressure. Medial retropharyngeal lymphadenopathy that is likely reactive is present.

CSF Analysis

Total protein, 41 mg/dL; RBC, 163 cells/μL; total nucleated cells, 9 cells/μL. Total nucleated cells comprised 70% neutrophils, 7% small mononuclear cells, 19% large mononuclear cells, and 4% eosinophils. The neutrophils were largely non-degenerate although occasional hyper-segmented and rare degenerate forms were identified. The large mononuclear cells were often vacuolated. No infectious agents were noted.

Diagnosis: Minimal mixed (neutrophilic and eosinophilic) pleocytosis.

Serologic Tests

FeLV/FIV serology (IDEXX SNAP, IDEXX Laboratories, ME, USA): Negative for FeLV antigen and FIV antibody.

Toxoplasma gondii IgG/IgM: Negative.

Diagnosis

Presumptive cerebrospinal cuterebriasis.

Treatment

Ivermectin (300 μg/kg PO, two doses, 48 hours apart), prednisolone (0.7 mg/kg PO q12h), clindamycin (20 mg/kg q12h for 7 days.)

Comments

Although not confirmed, a diagnosis of CNS cuterebriasis seemed likely in this cat based on the geographic location, time of year, left lateralizing CNS signs, MRI findings (including the structure in the nasopharyngeal wall, which may have represented a furuncle), and negative *T. gondii* titers. Upon recovery from the MRI, two partial seizures were observed, 12 hours apart, that involved the face. Following treatment, Prim made a full recovery although the seizures continued and were managed with zonisamide (7 mg/kg, PO, q12h). Three years later, at the time of writing, she is still alive and otherwise apparently healthy.

Ticks

Jennifer E. Thomas, Mason V. Reichard

KEY POINTS

- First Described: The earliest written records of ticks date to ancient Greek literature. Homer mentioned ticks in his poem Odyssey (800 BC) as did Aristotle in the *History of Animals* (335 BC). *Rhipicephalus sanguineus* adults and nymphs were recovered from a mummified dog dating to Roman Egypt.[1] Occurrence of ticks in the fossil record indicate the parasites originated during the Cretaceous period (65–146 mya).[2]
- Causes: Ticks that infest dogs and cats belong to two taxonomic families, the Ixodidae or hard ticks, and the Argasidae or soft ticks. The most common ticks found on dogs and cats in North America are hard ticks and include *Amblyomma americanum* (lone star tick), *Amblyomma maculatum* (Gulf Coast tick), *Dermacentor andersoni* (Rocky Mountain wood tick), *Dermacentor occidentalis* (Pacific Coast tick), *Dermacentor variabilis* (American dog tick), *Haemaphysalis longicornis* (longhorn tick), *Ixodes pacificus* (western black-legged tick), *Ixodes scapularis* (deer tick; black-legged tick), and *Rhipicephalus sanguineus* (brown dog tick; kennel tick). The soft tick most commonly encountered in dogs and cats is *Otobius megnini* (spinose ear tick). However, other soft ticks including *Ornithodoros* spp. can also infest dogs and cats.
- Affected Hosts: All dogs and cats are susceptible to tick infestation.
- Geographic Distribution: Worldwide with the highest abundances in tropical and temperate climates.
- Primary Mode of Transmission: Contact with environments contaminated with ticks. Intrastadial transfer of ticks from one infested animal to another.
- Major Clinical Signs: Painful bite, erythema, pruritus, inflammation, swelling, ulceration, hypersensitivity reactions, otitis externa, paralysis, and anemia. Ticks are vectors of several pathogens capable of resulting in severe disease with variable clinical signs in dogs and cats.
- Differential Diagnoses: Other ectoparasites including mites, fleas, lice, and bed bugs. For tick paralysis, key differential diagnoses include botulism, polyradiculoneuritis, acute peripheral neuropathies, snakebite, and hypokalemia.
- Human Health Significance: Several species of ticks (e.g., *A. americanum* and *I. scapularis*) readily bite and feed on humans. Pets that are not maintained on tick control can transport ticks indoors increasing the risk of exposure to humans. Owners removing embedded ticks from infested pets with improper technique or without protection risk infections with tick-borne pathogens.

ETIOLOGY

Ticks (Acari: Ixodida) are obligate parasites that feed on the blood of vertebrates. There are about 900 extant species of ticks known.[3] These species are divided into three families: Ixodidae (hard ticks; ca. 700 species), Argasidae (soft ticks; ca. 200 species), and Nuttalliellidae (one species, *Nuttalliella namaqua*). *Nuttalliella namaqua* occurs only in southern Africa and exhibits biology related to both hard and soft ticks as well as traits specific to itself. This tick primarily infests lizards[4] and has not been reported from dogs or cats.

Numerous species of ticks feed on dogs and cats throughout the world (Table 109.1).[5] The focus of this chapter will be ticks in North America[6] but the chapter will also mention important ticks from other parts of the world. The ticks most commonly recovered from dogs and cats include *Amblyomma americanum*, *Amblyomma maculatum*, *Dermacentor andersoni*, *Dermacentor occidentalis*, *Dermacentor variabilis*, *Haemaphysalis longicornis*, *Ixodes pacificus*, *Ixodes scapularis*, *Rhipicephalus sanguineus*, and *Otobius megnini* (Tables 109.1 and 109.2; Figs. 109.1 and 109.2).[5,7,8] Ticks are highly specialized arachnids with three distinct regions to their bodies[9]: the gnathostoma (or capitulum), idiosoma (body), and segmented appendages (legs). The gnathostoma contains the mouthparts (e.g., palps, chelicerae, hypostome, basis capituli). The idiosoma is the largest part of a tick and contains the internal organs. Legs connect to the anterior half of the idiosoma through coxae. The tarsus of the first pairs of legs contains Haller's organ. Haller's organ is a sensory structure used to locate hosts by detecting odors, temperature, humidity, and possibly other external stimuli.[9] Ticks also contain chemoreceptors in their palps that help them sense their environment.[9,10]

Hard and soft ticks differ in several key characteristics. The most conspicuous difference is that hard ticks possess a scutum. The scutum is a sclerotized plate that covers nearly the entire dorsal surface of males and the anterior half of females and immature stages (larvae and nymphs). Soft ticks lack a scutum and have a cuticle covered in mammillae. When examining hard ticks from the dorsal aspect, mouthparts project anteriorly. The mouthparts do not project beyond the anterior margin of the body in adult soft ticks and can be visualized only from the ventrum.

EPIDEMIOLOGY

There are four developmental stages in the life cycle of ticks: eggs, larvae, nymphs, and adults. There is little variation on this basic developmental plan for hard ticks in that each motile, feeding stage (i.e., larvae, nymphs, and adults) feeds once on a host. Soft ticks are more variable having more than one nymphal stage and feeding multiple times as adults; the number of nymphal stages is not consistent across species.

Hard ticks are categorized as one-, two-, or three-host ticks. Three-host ticks are the most common and comprise the majority of ticks that infest dogs and cats. Three-host ticks are defined by each feeding

TABLE 109.1 Ticks that Commonly Infest Dogs and Cats

Continent	Tick	Common Name
Africa	*Haemaphysalis elliptica*	African yellow dog tick
	Haemaphysalis leachi	Yellow dog tick, African dog tick
	Ixodes spp.	Various depending on species
	Otobius megnini	Spinose ear tick
	Rhipicephalus gertrudae	–
	Rhipicephalus sanguineus	Brown dog tick, kennel tick
Antarctica	None that infest dogs and cats	
Asia	*Haemaphysalis longicornis*	Asian longhorn tick, bush tick
	Rhipicephalus haemaphysaloides	–
	Rhipicephalus sanguineus	Brown dog tick, kennel tick
Australia	*Amblyomma triguttatum*	Kangaroo tick
	Haemaphysalis bancrofti	Wallaby tick
	Haemaphysalis longicornis	Asian longhorn tick, bush tick
	Ixodes cornuatus	Southern paralysis tick, Tasmanian paralysis tick
	Ixodes holocyclus	Eastern paralysis tick
	Ixodes tasmani	Tasmanian possum tick
	Rhipicephalus sanguineus	Brown dog tick, kennel tick
Europe	*Dermacentor reticulatus*	Meadow tick, marsh tick, ornate cow tick
	Haemaphysalis concinna	Bush tick, relict tick
	Haemaphysalis punctata	Red sheep tick
	Ixodes ricinus	Sheep tick, castor bean tick
	Ixodes canisuga	Dog tick, fox tick
	Ixodes hexagonus	Hedgehog tick
	Rhipicephalus sanguineus	Brown dog tick, kennel tick
North America	*Amblyomma americanum*	Lone star tick
	Amblyomma maculatum	Gulf coast tick
	Dermacentor variabilis	American dog tick
	Haemaphysalis longicornis	Asian longhorn tick, bush tick
	Ixodes pacificus	Western black-legged tick
	Ixodes scapularis	Black-legged tick, deer tick
	Otobius megnini	Spinose ear tick
	Rhipicephalus sanguineus	Brown dog tick, kennel tick
South America	*Amblyomma aureolatum*	Yellow dog tick
	Amblyomma ovale	–
	Amblyomma triste	–
	Rhipicephalus sanguineus	Brown dog tick, kennel tick

stage taking a blood meal from a host, falling off that host, molting to the next stage, and then finding another host. For the common three-host ticks of dogs and cats, adult ticks feed and mate on the third host after which replete (fully fed) females drop off the host and lay eggs in the environment. Larvae hatch from the eggs and the cycle is repeated. For two-host ticks, fed larvae are retained on the first host, molt to the nymphal stage, feed, and then drop off and molt to adults. Adults find the second host where they feed and mate. Larvae, nymphs, and adults of one-host ticks all feed on the same individual host animal without spending time in the environment (off the host), between stages.

In general, soft ticks utilize a multitude of hosts in their life cycle. In addition to having multiple nymphal stages, soft ticks display biology that distinguish them from hard ticks. Soft ticks visit their vertebrate hosts only to take a blood meal and they feed quickly (15 to 30 minutes). In some instances, soft ticks may not take a blood meal before molting to the next life stage. Soft tick females lay several clutches of eggs from a single blood meal and may take multiple blood meals at various stages. In comparison, hard ticks attach and feed on their hosts from days to just over a week depending on species and life cycle stage, only take one blood meal per motile stage, and females deposit one clutch of eggs from their single blood meal.

Ticks persist in two environments: on hosts and off hosts. Ticks infest a wide variety of vertebrates including amphibians, reptiles, birds, and mammals. Host predilection is the host preferred by a tick species. Host range is the variety of hosts that a tick species can utilize for a blood meal. Different stages of ticks and tick species often have different host predilections and ranges (see Table 109.2). Relatively few tick species feed on dogs and cats[11-14] with the majority parasitizing wildlife species.[6,15] Understanding the preferred host and the host range of ticks is critical to understanding population dynamics of ticks, tick-borne diseases, and the risks to pets and humans.

Dogs are significant hosts for ticks throughout the world.[16] Examination of dogs seen at veterinary hospitals in 339 US cities across 40 states from 2002 to 2004 demonstrated that ticks were observed during 42,090 of 8,088,288 dog visits.[17] That is, the prevalence of dog visits in which ticks were found was 0.52% (95% CI, 0.51–0.53%). The highest prevalence of dogs with ticks were in Oklahoma (2.5%; 2.3–2.7%), Arkansas (2.4%; 2.1–2.7%), Connecticut (1.4%; 1.2–1.6%), West Virginia (1.3%; 1.1–1.6%), and Rhode Island (1.2%; 1.0–1.5%). States with the lowest prevalence of ticks on dogs included Michigan (0.03%; 0.02–0.06%), Utah (0.04%; 0.03–0.06%), Nevada (0.05%; 0.04–0.07%), Colorado (0.1%; 0.09–0.1%), and Washington (0.2%; 0.1–0.2%). The highest prevalence of ticks on dogs were observed late spring into summer during April, May, June, and July. The lowest prevalence was during winter in November, December, January, and February. Factors that increased the risk for infestation were age of 6 months to 1 year (OR [95% CI] = 1.54 [1.47–1.62]), male sex (OR [95% CI] = 1.08 [1.06–1.10]) and being sexually intact (OR [95% CI] = 1.46 [1.43–1.49]).[17] These factors likely indicate time before client compliance with ectoparasite preventive regimens and a tendency of intact animals to roam, increasing contact with environments harboring ticks. Similarly, dogs less than 1 year of age from Mexicali, Mexico were found to be 2.8 times more likely to be infested with *Rh. sanguineus* when compared with dogs over one year of age.[18] A comparison of the prevalence of ticks among dog breeds demonstrated that toy-breed dogs were least likely to be infested.[17] It is likely that the lower prevalence of ticks on toy-breed dogs is reflective of the dog's lifestyle and being less exposed to environments with ticks than toy-breed dogs being less susceptible to infestation with ticks.

Less information is known about ticks on cats, and primary literature reports of cats naturally infested with ticks are limited to a

TABLE 109.2 Common Ticks of Dogs and Cats in North America—Preferred Hosts, Geographic Distribution, and Examples of Pathogens Transmitted to Dogs and Cats

Tick	Common Name	Preferred Hosts	Geographic Distribution	Examples of Pathogens Transmitted (Chapter Number)
Amblyomma americanum	Lone star tick	Larvae: Medium-sized and larger mammals including dogs, cats, deer, cattle, other domestic and wild animals Nymphs: Medium-sized and larger mammals including dogs, cats, deer, cattle, other domestic and wild animals Adults: Large mammals including dogs, cats, cattle, deer, other domestic and wild animals	Southeastern and southcentral US north to southern Michigan. Atlantic Coast of US from Florida to southern Maine	*Cytauxzoon felis* (98) *Ehrlichia chaffeensis* (44) *Ehrlichia ewingii* (44) *Francisella tularensis* (74)
Amblyomma maculatum	Gulf Coast tick	Larvae: Small mammals and ground-dwelling birds Nymphs: Small mammals, ground-dwelling birds, and larger mammals Adults: Medium- and large-sized mammals including dogs	Gulf Coast states of US inland to southern Kansas. North along the Atlantic Coast to Virginia	*Hepatozoon americanum* (99)
Dermacentor andersoni	Rocky Mountain wood tick	Larvae: Rodents Nymphs: Rodents Adults: Medium- to large-sized mammals	Rocky Mountain states and provinces of US and Canada from elevation of 4000 to 15,000 feet (1219 to 4572 m)	*Rickettsia rickettsii* (46) *Francisella tularensis* (74)
Dermacentor occidentalis	Pacific Coast tick	Larvae: Small rodents Nymphs: Small rodents Adults: Larger mammals including dogs and cats	Pacific Coast of US	*Francisella tularensis* (74) *Rickettsia rickettsii* (46)
Dermacentor variabilis	American dog tick	Larvae: Small rodents Nymphs: Small- and medium-sized mammals Adults: Medium-sized mammals	Prairie states and provinces of US and Canada east of the Rocky Mountains to the Atlantic Coast. California coast of US to southern Oregon	*Cytauxzoon felis* (98) *Francisella tularensis* (74) *Rickettsia rickettsii* (46)
Ixodes pacificus	Western black-legged tick	Larvae: Lizards, birds, and small mammals Nymphs: Birds, small mammals, and lizards Adults: Large and medium-sized mammals	Pacific Coast of US	*Anaplasma phagocytophilum* (45) *Borrelia/Borreliella* (*incertae sedis*) *burgdorferi* (69)
Ixodes scapularis	Deer tick; black-legged tick	Larvae: Rodents, birds, and reptiles Nymphs: Rodents, birds, reptiles, dogs, and cats Adults: Medium- and large-sized mammals including dogs and cats	Southcentral and southeastern US north along the Atlantic Coast into the northeastern US and Canada. Upper Midwest of US	*Anaplasma phagocytophilum* (45) *Borrelia/Borreliella burgdorferi* (69)
Otobius megnini	Spinose ear tick	Larvae: Medium- and large-sized mammals Nymphs: Medium- and large-sized mammals Adults: None, adults are free living	Southern Canada through the US. Also found in Central America, South America, Africa, and India. In the US, most common in arid regions of the west	None known
Rhipicephalus sanguineus sensu lato	Brown dog tick; kennel tick	Larvae: Dogs Nymphs: Dogs Adults: Dogs	Cosmopolitan throughout the world	*Anaplasma platys* (suspected) (45) *Babesia canis* (97) *Babesia gibsoni* (not confirmed in North America) (97) *Ehrlichia canis* (44) *Hepatozoon canis* (not confirmed in North America) (99) *Rickettsia rickettsii* (46)

handful.[6,19-26] The importance of ticks infesting cats is often overlooked possibly due to the misperception that cats are not suitable hosts and are fastidious groomers. A survey of ectoparasites on feral cats in Florida[20] only recovered a few adults of *A. americanum*, *D. variabilis*, *I. scapularis*, and *Rh. sanguineus*. A comparable survey of free-roaming cats in Oklahoma[25] also demonstrated adults of *A. americanum*, *D. variabilis*, *I. scapularis*, and *Rh. sanguineus* on 18.7% (15.9–21.9%) of the cats examined. However, larvae and nymphs comprised 54.7% of

Fig. 109.1 Size and morphological comparisons of life stages of unengorged (A) *Amblyomma americanum*, (B) *Amblyomma maculatum*, (C) *Dermacentor variabilis*, (D) *Dermacentor andersoni*, (E) *Ixodes scapularis*, and (F) *Rhipicephalus sanguineus*. Scale bar is 5.0 mm, magnification is 1.25×. (Courtesy of the National Center for Veterinary Parasitology.)

the ticks (mostly *A. americanum*) recovered from infested cats. Ticks were found infesting cats in all months surveyed.[25]

Three-host hard ticks are intermittent parasites and spend 95% of their lifespan in the external environment.[27] In general, soft ticks spend even more time in the external environment and only visit hosts briefly to feed. *Otobius megnini* is an exception. This is a soft tick whose larvae and two nymphal stages are parasitic in the ear canal of dogs, cats, and other animals.[28] Adult *O. megnini* are free living and do not feed.

Hard ticks thrive in habitats rich with vertebrate hosts, like mammals, lizards, and ground-dwelling birds. The preferred habitats for most wildlife ticks are brushy, wooded, or weedy areas, especially moist woodlands and vegetated areas at the edge of forests, along animal and hiking trails and in overgrown weedy or grassy fields. One hard tick, *Rh. sanguineus*, is more likely to be found in or around homes or kennels with dogs. Soft ticks are generally found in animal burrows, dens, caves, or dilapidated human dwellings such as huts, cabins, or sheds. In addition, soft ticks readily thrive in hot and dry conditions. Dogs and cats become infested with ticks through contact with contaminated environments. Pets may also become infested with ticks through intrastadial (same life stage) transfer from one infested animal to a naïve one (e.g., an adult tick transfers from one dog in the household to another pet).[29]

In the external environment, tick survival is dependent upon a multitude of factors including climate, vegetation, host availability, photoperiod, and human activities.[30] Ticks that are off hosts are most susceptible to arid conditions and temperature extremes.[27] Mortality of ticks in the external environment results from freezing in winter, dehydration during arid summers, overheating during summer, drowning in floodwater, and exhaustion of energy resources because they fail to find a host.[31] Nonetheless, ticks are well adapted to survive off hosts and live longer than any other arthropod without food or water.[27] Ticks can become active at temperatures not thought to be conducive to tick activity and they can occur in locations considered atypical by most pet owners presenting

Fig. 109.2 Nymph of *Otobius megnini* recovered from an infested dog. Note spiny protuberances (mamillae) covering the body. Magnification 2.4×.

unforeseen risks to pets. For example, the threshold temperature in which *I. scapularis* adults quest is 4°C (32°F).[32] *Rhipicephalus sanguineus* is adapted to completing its life cycle indoors but can also survive outdoors in mild climates if hosts and environmental refuges are available.[33] With the ability to survive and reproduce indoors, as well as the ability to transmit *Rickettsia rickettsii* (causative agent of Rocky Mountain spotted fever), *Rh. sanguineus* presents a significant public health concern.[34]

Current thinking suggests that human development and population growth, movement of wild and domestic animals, and climate change will all have an impact on tick distribution and abundances.[35,36] What that impact will be has yet to be determined. Within recent history, we have seen an expansion of the ranges of *A. americanum*, *A. maculatum*, *D. variabilis*, and *I. scapularis*. *Amblyomma americanum*, historically found in the southeastern and southcentral United States, has expanded rapidly in the northeast and Midwest.[37] *Amblyomma maculatum* was historically found within a couple hundred miles of the Gulf of Mexico. Over the last two decades, the geographic range of *A. maculatum* has expanded northward along the Atlantic coast to Maryland as well as north into mid-western states including Arkansas, Oklahoma, Kansas, and southwestern Tennessee. *Dermacentor variabilis*, historically found in prairie states and provinces east of the Rocky Mountains, has moved westward and northward in Canada.[38] and is now commonly found infesting dogs and cats in Rocky Mountain states.[44] Finally, *Ixodes scapularis* (historically found in the southcentral, southeastern, northeastern, and upper Midwest) has expanded into Canada.[40] The distribution of *I. scapularis* in the United States has also shifted. Since 1998 the number of counties in the United States reporting *I. scapularis* has increased by 44.7%.[31] Moreover, the greatest increase in the number of counties reporting *I. scapularis* occurred in the northeastern states and upper Midwest. It has been suggested that the historic foci of *I. scapularis* populations in New England states and upper Midwest are converging in the Ohio River Valley.[31] *Haemaphysalis longicornis* was initially found in the United States on sheep in New Jersey in late 2017[41] and has since been found in at least 17 states throughout the eastern and southcentral United States.

CLINICAL FEATURES

Pathogenesis

Insertion of mouthparts and feeding activities may result in mechanical injury, irritation, inflammation, hypersensitivity reactions, transmission of pathogens, and toxicosis (see tick paralysis). A tick bite lesion is created upon insertion of the tick's chelicerae and hypostome into the host's skin.[42] Once a tick finds a suitable location, insertion of the mouthparts occurs in four phases: surface coursing, superficial attachment, cheliceral insertion, and hypostomal envelopment.[43] Ticks may remain attached at one location or they may remove their mouthparts and reattach at a different site. Insertion of chelicerae and the hypostome are not adequate holdfast organs to support the extended duration needed for ixodid ticks to feed. Most ixodid ticks secrete cement proteins[44] for extended attachment. Tick cement is a latex-like substance secreted by the tick within 5 to 30 minutes of attachment.[42] The cement hardens quickly forming a gasket between the tick's mouthparts (Fig. 109.3) and the host's epidermis, securing the attachment. Soft ticks do not produce cement[42] and feed rapidly by inserting their mouth parts deeply into their hosts.

Insertion of a tick's mouthparts damages capillaries and small blood vessels creating pools of extravasated blood that is ingested. While on hosts, ticks are in a gorging state[27] and must modulate the host's defenses in order to successfully feed. A variety of bioactive proteins and lipids are produced to combat host hemostasis, tissue repair at the feeding site, and development of an anti-tick response. Over 3500 putative salivary proteins have been identified from a variety of tick species.[45] These substances include anticoagulants, antiplatelet aggregators, vasodilators, anti-inflammatories, and immunomodulators that allow ticks to feed successfully to repletion.[46] Ticks are important vectors of pathogens and transmit a greater variety of disease agents (Table 109.2) than any other arthropod vector group.[16] Transfer of pathogens from ticks to hosts most commonly occurs through the passage of contaminated saliva during feeding.[47] However, tick-borne pathogens may also be transferred to hosts through regurgitation, coxal fluid, tick feces,[48] and ingestion of infected ticks as seen with *Hepatozoon americanum* and *Hepatozoon canis* (see Chapter 99).[49]

Galactose-alpha-1,3-galactose Hypersensitivity Reactions

In humans, an association has been made between bites of certain tick species and subsequent development of delayed (3 to 8 hours) anaphylactic reactions to red meat. In 2009, it was reported that bites from *A. americanum* induced a delayed anaphylaxis to red meat in humans due to IgE antibodies against galactose-alpha-1,3-galactose (alpha-gal) in the US.[50,51] Alpha-gal is a carbohydrate naturally produced in all mammals besides humans, great apes, and new-world monkeys. It is a carbohydrate moiety of post-translational modification of proteins for proper protein folding and stability as well as intracellular movement of proteins. The mechanism by which this antibody response develops has yet to be determined. Possibilities include, but are not limited to: the presence of alpha-gal in ticks to which hosts are exposed; host antibody development against a non-alpha-gal carbohydrate or protein which is cross-reactive with

alpha-gal; and host exposure to alpha-gal ingested from a previous blood meal, including from the blood meal of the previous motile life stage. This phenomenon has also been demonstrated in Europe (*Ixodes ricinus*), Australia (*Ixodes holocyclus*), Asia (tick species not identified), and Central America (*Amblyomma cajennense* suspected).[52] Food allergy as a result of anti-alpha-gal antibodies is not likely to develop in dogs and cats as these species naturally produce alpha-gal. Production of anti-alpha-gal antibodies would represent a catastrophic autoimmune disorder, unlikely to be overlooked.

Tick Paralysis

Tick paralysis results from the inoculation of toxins present in tick saliva into hosts. Dogs, cats, and numerous other animals are susceptible to these toxins.[53–55] Tick paralysis in animals and humans occurs worldwide.[56] Most tick bites do not result in paralysis and the condition is rare in North America. Approximately 70 species of hard and soft ticks have been implicated in, or suspected to cause, paralysis in hosts.[57] Most cases of tick paralysis in dogs, cats, and humans in North America are due to infestation with *D. andersoni* or *D. variabilis*.[57] However, all of the ticks common on dogs and cats in North America are capable of causing tick paralysis.[54–57] Other medically important ticks that cause paralysis are *I. holocyclus* (eastern paralysis tick) and *Ixodes cornuatus* (southern paralysis tick) in Australia[58,59] and *Ixodes rubicundus* and *Rhipicephalus evertis* in Africa.[60] A third *Ixodes* species in Australia, *Ixodes hirsti*, has been reported as a cause of paralysis in cats.[59] The onset of paralysis coincides with rapid engorgement of female ticks regardless of the species.[57] Feeding of male ticks does not result in paralysis likely as a result of lower levels of saliva injected during feeding compared to females.[61] Large numbers of larvae or nymphs are believed to cause toxicosis. For *Dermacentor* species, rapid engorgement of females occurs after mating with a male after about 5 days of attachment and feeding. In cases of tick paralysis in humans, ticks are commonly found attached to the scalp, behind the ear, the neck, and the groin.[56] In veterinary medicine, it is commonly believed that ticks attached to the head, base of the skull, or along the spine are most likely to result in paralysis. The ability of *D. andersoni* adults to cause paralysis is a heritable trait and virulent strains of ticks can be selected.[60]

Paralysis due to *I. holocyclus* results from a temperature-dependent inhibition of acetylcholine release from the neuromuscular junction.[62] Muscle paralysis can be experimentally induced by inhibiting the dependence of transmitter release on extracellular calcium.[58] Direct cardiotoxicity and GI signs (vomiting and regurgitation), with aspiration pneumonia, have also been identified in dogs. The exact mechanism of paralysis caused by *D. andersoni* is not known and is thought to be distinct from that of *I. holocyclus*.[57] Feeding *D. andersoni* females are known to affect neurons of the efferent pathway but not the afferent; the neuromuscular junction of peripheral nerves is targeted through inhibition of acetylcholine release from the synapse, suggesting a presynaptic target.[63]

Clinical Signs

Tick bites are painful and irritating. They incite local inflammatory reactions and pruritus. The attachment of a few ticks is well tolerated by most dog and cat hosts. However, severe infestations can lead to anemia[64] and possibly death by exsanguination. It is important to remember that tick burden is relative to patient size and concurrent morbidities. A female tick will ingest between 0.5 and 1.5 mL of blood from the host, depending on tick species.[65] Hypersensitivity reactions to tick attachment and feeding may result in focal areas of necrosis and ulceration; erythematous macules or nodules that may or may not be pruritic and ulcerated; and pruritic pododermatitis.[66] Ticks that feed in or around the ears (e.g., *O. megnini*) may cause secondary otitis externa[67] and pruritic or painful ear disease (head tilt, altered pinnal carriage). Cases of tick paralysis present as acute, symmetric, ascending paresis/paralysis. The longer the inciting tick(s) remains attached, the higher the likelihood that ascending neuromuscular paralysis will lead to respiratory failure and death. Unilateral facial paralysis and anisocoria have been noted in dogs and cats presenting with tick paralysis due to *I. holocyclus*.[53] Additional signs include cough; gagging; hypersalivation; inappetence; urinary incontinence due to sphincter incompetence; and dyspnea and increased breath sounds due to pulmonary edema, congestive heart failure, or aspiration pneumonia.[68,69] Hypothermia may occur in moribund animals. Physical examination findings can be confounded if a tick-borne disease is also present. Sudden death may also occur.

Physical Examination Findings

Physical examination findings of dogs and cats infested with ticks are highly variable. Cases with only a few ticks attached will be subclinical. Infestation by only a few ticks or by immature ticks can be easily missed during physical examination.[25] Ticks can be found attached anywhere on a dog or cat requiring close inspection of the entire surface of a pet, as well as mucous membranes. If tick infestation is severe enough to lead to anemia, expected findings may include dull mentation, generalized weakness, pale mucous membranes, tachycardia, tachypnea, and poor peripheral pulses.[64]

Cutaneous lesions include erythematous macules, papules, or nodules around the site of tick attachment (Fig. 109.4). These lesions may be up to 2 cm in diameter. Surface ulceration/erosion and crusting will develop after tick detachment and may be subtle. Self-induced trauma may make the lesions more dramatic. After a tick detaches or is removed, acute feeding lesions of 1 to 2 mm deep and 1 to 3 mm wide remain (Fig. 109.5). Tick bite lesions typically heal in about 3 weeks but may be complicated by secondary infection. Granuloma formation at the bite site has been described in humans and domestic animals, and may persist for months to years.[70,71]

Dogs and cats with tick paralysis have generalized lower motor neuron signs (including ataxia, lateral recumbency, decreased withdrawal reflexes) and may also have signs related to the respiratory and GI tract described earlier. Respiratory signs may predominate in cats.[68]

DIAGNOSIS

Diagnosis is achieved by identifying ticks recovered from infested pets during physical examination. The burden of ticks on pets can range from a few that are subclinical to severe infestation that results in anemia requiring a blood transfusion.[64] Thorough examination of infested animals is often necessary to locate immature stages of ticks that are easily missed because of their small size.[25] Utilization of a flea comb can help recover ticks but combing is not efficient for recovering small, attached, unengorged (i.e., flat) ticks aligned close to the surface of the pet's skin. By examining dogs during peak activity times of *A. americanum*, *D. variabilis*, *I. scapularis*, and *Rh. sanguineus* activity, predilection sites have been described for each species.[72] Adult *A. americanum* were evenly distributed on dogs including the perianal region and between the pelvic limbs. However, 43% of *A. americanum* adults were recovered from the ears, head, and neck of infested dogs. The majority (80%) of adult *D. variabilis* were also recovered from the ears, head, and neck of infested dogs. Adult *I. scapularis* were most commonly recovered from anterior body regions of infested dogs. Adult *Rh. sanguineus* were retrieved from all body regions of dogs with

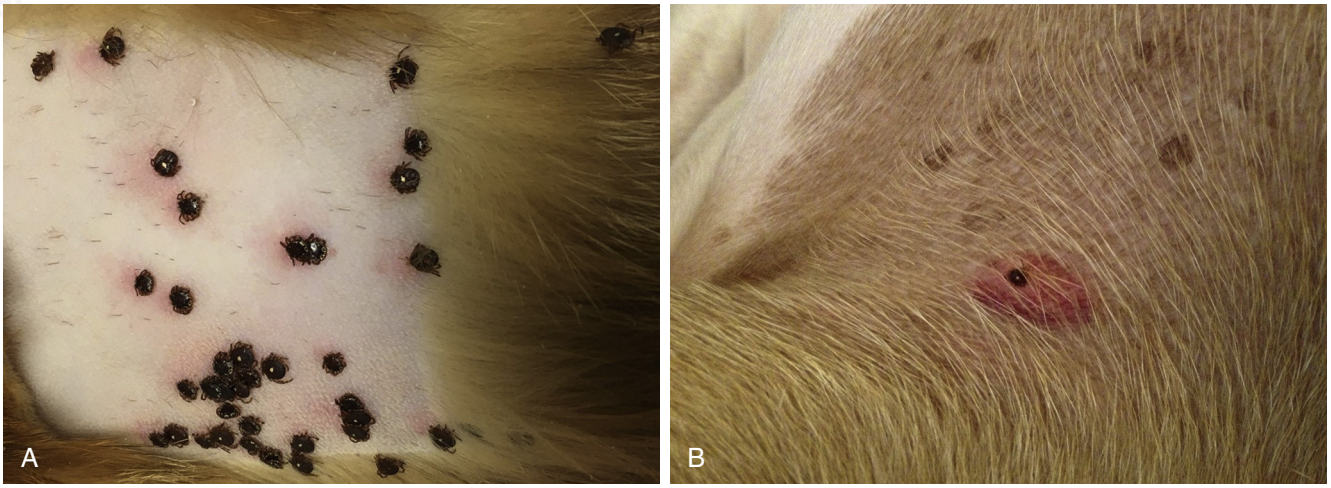

Fig. 109.4 Erythema associated with attached ticks. (A) Poorly defined erythematous macules around feeding *Amblyomma americanum* adults on an artificially infested cat. (B) Markedly erythematous, semi-fluctuant epidermal swelling around an attached female *A. americanum* in the axilla of a 5-year-old dog.

Fig. 109.5 Erythematous papules with central hemorrhagic crusts remaining after a large number of *Amblyomma americanum* adults were removed. Tick frass (feces) can still be observed around feeding sites. Hair clipped for improved visualization of lesions.

the head, neck, and back being most commonly infested.[72] Larvae and nymphs of *Rh. sanguineus* were evenly distributed on infested dogs with the fewest on the dorsum. Predilection sites of ears, head, interdigital spaces, back, inguinal region, and axilla were also reported for *Rh. sanguineus*.[33]

Differential diagnoses for acariasis includes infestation with other parasites such as mites, fleas (especially *Echidnophaga gallinacea*, the sticktight flea), lice, and bed bugs. Ticks are arachnids that can be easily differentiated from other ectoparasites.[13,73] Arachnids do not have wings, have four pairs of legs in the adult stage, and undivided bodies. Insects (e.g., fleas and lice) have bodies divided into three regions (head, thorax, and abdomen), six pair of legs, and mouthparts outside the head capsule. Mites (see Chapter 110) are also arachnids but can be easily distinguished from ticks. Ticks are larger than mites, and have a leathery cuticle and spiracles near the coxa of the fourth pair of legs.[6]

Ticks are identified based on the morphology of key anatomical structures. Dichotomous keys are available for identification of adults,[74,75] nymphs,[75–78] and larvae.[75,78–81] However, dichotomous keys are problematic in that they are often limited to specific taxa, life stage, or geographic location. Identification of immature ticks to species can be challenging and is not practical in a clinical setting. Common adult hard ticks (see Fig. 109.1) and *O. megnini* (see Fig. 109.2) can be readily identified in clinic with the aid of a magnifying lens or dissecting microscope. Websites are available[82,83] to assist in gross identification of common adult ticks found on pets and humans.

Amblyomma americanum is a medium-sized, reddish-brown bodied, ornate tick with long mouthparts and festoons.[84] The female *A. americanum* is distinguished by a white spot (hence the name "lone star" tick) on the posterior margin of the scutum. Male *A. americanum* are readily identified having white spots on the festoons. *Amblyomma maculatum* is a medium- to large-sized, reddish-brown bodied, ornate tick with long mouthparts and festoons.[85] This tick is distinguished from other ticks based on its large size and diffuse pattern of white on the scutum of both males and females.

Dermacentor andersoni, *D. occidentalis*, and *D. variabilis* are morphologically similar. They are medium- to large-sized, reddish-brown bodied, ornate ticks with short mouthparts, a square basis capitulum, and festoons. A primary difference among these ticks is the geographic locales where they are most abundant. *Dermacentor andersoni*, the Rocky Mountain wood tick, is found in the Rocky Mountains in western North America.[86] *Dermacentor occidentalis*, the Pacific Coast tick has a range restricted to far western North America.[87] *Dermacentor variabilis*, the American dog tick, is widely distributed in North America east of the Rocky Mountains and some areas along the Pacific Coast (see Fig. 46.1 for maps). The coloration and patterns of adult *Dermacentor* spp. look most similar to those of *A. maculatum* and the ticks may be confused for each other in areas where their distributions overlap. Nonetheless, *Dermacentor* spp. are readily differentiated from *A. maculatum* due to their short mouthparts.

Haemaphysalis longicornis is an inornate, reddish-brown, medium-sized tick with rectangular basis capitulum, short mouth parts, and lateral projection of the second palpal segment.[88] Morphologically, *H. longicornis* is most similar to and easily mistaken

for *Rh. sanguineus*. However, upon close inspection under magnification, one can easily identify the flared second palpal segment of *H. longicornis* as compared to the flared basis capitulum of *Rh. sanguineus* (see following text).

Ixodes pacificus and *I. scapularis* are morphologically similar ticks. *Ixodes pacificus*, the western black-legged tick, is found along the west coast of the United States.[31] *Ixodes scapularis*, the black-legged tick or deer tick, is widely distributed in eastern North America with dense populations in the northeast and upper Midwest (see Fig. 45.2).[31] As their common names suggest, the legs of these adult ticks are black as is their scutum. They have long mouthparts and an anal groove located anterior to the anus; this is also true for other ticks that belong to the *Ixodes persulcatus* complex.

Rhipicephalus sanguineus, the brown dog tick or kennel tick, is found throughout the world.[33] *Rhipicephalus sanguineus* is a brown tick that is inornate and has a flared basis capitulum and short mouthparts.

Otobius megnini, the spinose ear tick, is the soft tick that is most commonly encountered in dogs and cats.[7] This tick has no scutum and only larvae and nymphs of *O. megnini* are parasitic, infesting the ears of their hosts.[28] Larvae of *O. megnini* resemble tiny shriveled grapes[7] and nymphs are covered in spines, conveying its common name. *Otobius megnini* is most commonly found in arid areas of western North America.[7,89]

Tick paralysis is diagnosed when acute onset of ascending paralysis is accompanied by tick infestation. Inciting tick(s) may be difficult to locate on the affected animals necessitating a complete and thorough search of the pet. Ticks may be attached in areas not typically considered including deep within the ears, in the mouth (both mucosa and transverse palatine ridges of the hard palate), preputial sheath, vulvar folds, and perianal folds. Clinical laboratory tests are not available outside of research labs to aid the veterinary practitioner in diagnosing tick paralysis nor infestation with ticks. Diagnosis is confirmed by resolution of clinical signs following tick removal. Clinical scoring systems have been developed to classify neurologic and respiratory signs in canine[69,90] and feline[68,91] tick paralysis patients for prognostication purposes and to monitor recovery.

Laboratory Abnormalities

Responses of cats and dogs to infestation with ticks are non-specific and variable. Most cases of infestation in which only a few ticks are attached are unremarkable. Laboratory abnormalities range from no abnormalities to eosinophilia, hypoproteinemia, and non-regenerative or regenerative anemia. No significant difference in CBC findings were detected in dogs repeatedly infested with >50 adult *Rh. sanguineus* versus non-infested dogs.[92] Two dogs severely infested with nymphal and adult *Rh. sanguineus* (i.e., thousands of ticks) were described with severe regenerative anemia, hypoproteinemia, and leukocytosis.[64]

Pathologic Findings

Histologic lesions of tick bites include congestion, edema, and sometimes focal hemorrhage (Fig. 109.6). Inflammation consists of perivascular to diffuse accumulations of neutrophils, eosinophils, and basophils.[93] After about 24 hours of infestation with *A. americanum*, there is mild, focal epidermal necrosis with a minimal increase in dermal cellular infiltrates. The tick bite lesion extends through the epidermis into the dermis. By 48 hours post infestation, the predominant patterns include a moderate perivascular neutrophilic dermatitis with extension into the dermis and subcutis, and a moderate diffuse neutrophilic panniculitis. Coagulated collagen degeneration is observed by 48 hours. By 96 hours post infestation, a focally severe neutrophilic dermatitis and panniculitis is observed, with focal areas of necrosis and fibrin deposition extending through the subcutis into the muscle band of the deep subcutis. The most intense cellular infiltration into the dermis and epidermis is by 96 hours post infestation. Mast cells and mononuclear leukocytes are also present.[94]

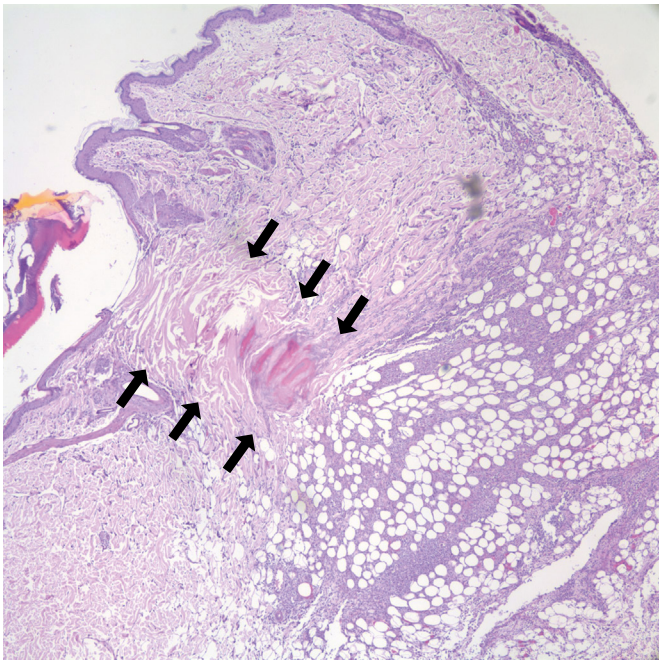

Fig. 109.6 Histologic section showing lesion created from a tick bite on a domestic cat with focally severe, perivascular neutrophilic dermatitis and panninculitis associated with tick feeding. Focal areas of necrosis and fibrin deposition extend through the deep subcutis. Coagulated collagen degeneration is present in the dermis, prominently in the central feeding lesion. Feeding lesion, which extends into the deep dermis, denoted by arrows (hematoxylin and eosin stain).

TREATMENT AND PROGNOSIS

All attached ticks should be removed from infested pets as quickly as possible to minimize pathogenesis and reduce the likelihood of pathogen transmission. For pets with only a few ticks attached, manual removal of ticks with gloved hands is indicated. Ticks are easily removed using fine-tipped tweezers. The tick should be grasped as close to the surface of the skin as possible and pulled perpendicular to the skin with steady, even pressure. Jerking or twisting should be avoided as this will increase the likelihood of breaking off the tick's mouthparts. If mouthparts do break off, they should be removed from the skin with fine-tipped tweezers. Ticks should not be squeezed or crushed as this may cause the tick to regurgitate gut contents or stimulate salivary gland secretion. After ticks are removed, the lesion should be cleaned to reduce risk of secondary bacterial infection, using dilute chlorhexidine or iodine, rubbing alcohol, or soap and water.

Other popularized remedies suggesting that attached ticks be removed by some method of burning (e.g., lit match or cigarette), suffocation (e.g., painting with fingernail polish, petrolatum jelly, oils), or chemical irritation (e.g., alcohol, oils, perfume, diatomaceous earth) do not work, are ill-advised, and could increase the risk of pathogen transmission to hosts.

Live, motile ticks can be secured by placing them in a sealed plastic bag or adhering between two layers of tape. Secured ticks

should be disposed of in the trash. Ticks are also killed by long-term submersion in alcohol or freezing at −20°C for a minimum of 24 hours. Ticks can be tested for specific pathogens at various commercial laboratories. Testing ticks for the presence or absence of pathogens should not be used as a proxy for the clinical assessment of a patient. It is impossible to tell if a pathogen was transmitted from a tick to a host by testing the tick after it has been removed from the host. Tick pathogen screens are, by nature, not comprehensive for all pathogens the tick may carry.

Pets heavily infested with ticks can be treated with an approved acaricide (Table 109.3 and Chapter 13). Depending on the level of infestation and the amount of injury that results, severely infested animals may require treatment for secondary skin infections, topical or systemic glucocorticoid therapy, fluid therapy, and/or blood transfusion.[64] Historically, it was recommended to bath severely infested pets with warm water and an acaricide-containing shampoo, sometimes daily until all ticks were removed.[64] However, the majority of acaricide-containing shampoos and dips available in the US market contain pyrethrins, pyrethroids, and their synergists. As of 2021, amitraz dip for dogs is not currently being manufactured in the United States. Clinicians should weigh the risks of dermal irritation of exposing broken and damaged skin to these compounds, along with potential risks of increased dermal absorption of these compounds in highly infested animals. Similar clinical judgment should be used when considering topical sprays. Common topical acaricidal sprays in the US market may contain a variety of active ingredients, including: pyrethrins, pyrethroids, fipronil, etofenprox, and tetrachlorvinphos (see Table 109.3). Acaricidal powders are generally avoided in small animal medicine due to risk of respiratory irritation, eye irritation, and exposure to veterinary staff and clients. A clinician may elect to use an effective systemic acaricide for the patient, and determine if the addition of an EPA-approved topical product is necessary.

Routine treatment and control of ticks on dogs and cats is accomplished through regular and continuous use of approved acaricides (see Table 109.3). Year-round use of acaricides on dog and cats is warranted because pets are host to several tick species that have varying degrees of activity throughout the year, ticks can be active in colder months of the year, common ticks that infest dogs and cats are expanding in distribution, and because *Rh. sanguineus* can infest homes and kennels and be active indoors throughout the year. All animals in close association with an infested animal should be treated and maintained on an approved acaricide.

In the United States, ectoparasiticides are regulated by the Environmental Protection Agency (EPA) or the FDA. As a general rule, if a product is applied topically to an animal to treat ectoparasites, and the compound is not absorbed systemically, it likely falls under the jurisdiction of the EPA. If a product is administered orally, by injection, or if it is applied topically for systemic absorption, it likely falls under the jurisdiction of the FDA. This distinction is important for practitioners to recognize, because there is no legal extra-label use of products regulated by the EPA. Label directions must be followed regarding species treated, product concentration, product dosage, individuals allowed to administer application, and re-treatment interval. Because products regulated by the FDA are approved animal drugs, extra-label use may be allowed under the Animal Medicinal Drug Use and Clarification Act (AMDUCA).

Acaricides currently approved for use in cats and dogs are formulated for topical ("spot on" products, collars, sprays) or oral administration (see Table 109.3). Care must be taken to use acaricides only on or in the host species for which they are approved. Dog products should not be administered to cats, and vice versa. In areas where ticks are abundant and there is increased risk of infestation to pets, practitioners can combine tick treatment and control products, alternating and overlapping application of products yet keeping within label directions. Acaricide resistance has been documented in various locations throughout the world, predominately in livestock.[95] The continued use and in some cases misuse of acaricides would be expected to select for ticks that are drug-resistant. Resistance of *A. americanum* to benzene hexachloride (BHC)/cyclodienes; *D. variabilis* to BHC/cyclodienes and

[a]Product names which appear in italics are no longer being manufactured, though EPA estimates that they will remain available for sale through 2020 or later, and in households for use. Note: The EPA no longer permits the manufacturing of propoxur-containing flea and tick collars in the US. In 2020, the EPA determined that tetrachlorvinphos in powder for use on companion animals or kennels poses unacceptable risks, but remains acceptable for on-pet use according to revised residential exposure and risk assessments in collar and spray formulations.
C, cat; *D*, dog; *F*, flea; *F&T*, flea and tick; *IGR*, insect growth regulator; *T*, tick. MGK 264 (n-octyl bicycloheptene dicarboximide) and PBO (piperonyl butoxide) are pyrethrin/pyrethroid synergists.

DDT; and *Rh. sanguineus* to amitraz, BHC/cyclodienes, and organophosphates has been reported.[96] *Rhipicephalus sanguineus* removed from dogs in Florida and Texas were resistant to permethrin and tolerant to fipronil.[97] *Rhipicephalus sanguineus* from dogs in Yucatan, Mexico were resistant to amitraz and cypermethrin,[98] and ivermectin.[99]

IMMUNITY AND VACCINATION

Both innate and acquired immune defenses are involved in the response of hosts to tick attachment and feeding. Tick feeding induces a complex array of host immune responses involving antigen-presenting cells, T cells, B cells, antibodies, cytokines, complement, basophils, mast cells, eosinophils, and a number of other bioactive molecules.[100] Hosts show varying degrees of susceptibility to ticks. Some hosts can develop resistance to ticks after repeated infestations. Dogs are less likely to acquire resistance to the host-adapted *Rh. sanguineus*[101] but do develop a cutaneous,[102] immediate[92] hypersensitivity reaction induced by the tick's attachment and feeding.

In naïve hosts, local reactions to tick bites are inflammatory with a predominance of neutrophils; in contrast, in sensitized hosts, rapid and more intense reactions occur locally and cutaneous lesions present at a greater distance from the site of attachment with basophils,

eosinophils, and neutrophils present in the epidermis and dermis.[93] Cutaneous basophil hypersensitivity, a form of delayed-type hypersensitivity (DTH), plays an important role in immunity to ticks.[93] Acquired resistance to ticks manifests in reduced engorgement weight, increased duration of feeding, decreased numbers of eggs, reduced viability of eggs, inhibition of moulting, and death of engorged ticks.[100]

Ticks counteract innate and acquired host defenses by producing a complex array of pharmacologically active proteins differentially expressed over the course of tick feeding.[100] Distinct differences occur in the composition of secreted proteins for different tick species.[103] Molecules produced in the salivary glands of ticks function for vasodilation, platelet aggregation inhibition, anticoagulation, fibrinolysis, complement inhibition, immunosuppression, immunomodulation, chemokine binding, delayed wound healing, and angiogenesis.[46]

No commercial vaccine exists for use in dogs and cats to prevent ticks from attaching and feeding. A tick vaccine was developed and commercialized in the early 1990s for control of *Rhipicephalus* (*Boophilus*) *microplus* (a one-host tick) on cattle in several Latin American countries and in Australia.[104] The vaccine contained recombinant *Rh.* (*Boophilus*) *microplus* gut antigens and showed efficacy by reducing the number of engorged female ticks, their weight, and reproductive capacity.[104] Despite demonstrated efficacy when combined with strategic acaricide application and integrated tick management, the vaccine experienced a number of difficulties in commercialization.[104] Tick vaccines still offer promise for reducing tick burdens on animals while concurrently reducing dependence on acaricides. Current research efforts in tick vaccine development target the unique physiology of ticks and their dependence on a parasitic lifestyle, modern molecular biology techniques, and bioinformatics.[105]

PREVENTION

Veterinarians and pet owners should not rely solely on the application of approved acaricides to pets to prevent infestation. No compound is 100% effective all of the time. Combining a tick treatment and control plan for pets with other control strategies to formulate an integrated tick management (ITM)[106] program provides the most comprehensive and successful approach to prevent infestation with ticks. The goal of an ITM program is to reduce the risk of tick infestation on pets. This is accomplished by:

1. Maintaining all pets in a household on approved acaricides for the entire year. Thoroughly checking pets each day for ticks and removing any ticks as quickly as possible.
2. Modifying the habitat where pets reside to become less suitable to ticks while off hosts. This includes keeping the yard mowed, removing leaf litter, and trimming bushes and trees that are overgrown to let in more sunlight.
3. Excluding other animals from the backyard where pets spend their time. This includes adding secure fencing and, moving bird feeders, water baths, and woodpiles. Keep pets in managed areas to reduce the risk that they come in contact with ticks.
4. Applying approved environmental acaricides that target off-host ticks to the perimeter of a yard where natural wooded areas come in contact with the lawn. Optimal results are obtained using a trained and licensed pesticide applicator.
5. Using targeted acaricide treatment of wildlife species that are key reservoirs of ticks and tick-borne pathogens. Several devices exist that target white-tailed deer[102-104] and small rodents[110] (Tick Control Tubes, Thermacell, MA, USA) to deliver acaricides safely to wildlife and reduce the size of tick populations.

Arguably, the biggest obstacle that veterinarians face when implementing an effective tick prevention program is owner compliance. Analysis of 559 dog owners at 24 veterinary hospitals across the United States demonstrated that the average owner believed their pet needed only 10.5 months of flea and tick prevention despite their veterinarian's recommendation of 12 months.[111] Moreover, only 62% of the 559 dog owners remembered their veterinarian's recommendation of 12 months of flea and tick prevention.[111] Common causes of tick product failure include product not applied at correct frequency, product not applied to all pets in a household, product improperly applied by owner, insufficient dosing rate by owner, unrealistic expectations of owner (no compound is 100% effective all of the time), and overwhelming numbers of ticks in the environment.

PUBLIC HEALTH ASPECTS

As for pets, tick bites in humans are painful and annoying. Humans throughout the world are exposed to ticks[112] and ticks are often found on people in the United States[113] and Canada.[114,115] Most cases of tick infestation on humans are due to ixodid ticks; however, cases of argasid tick bites of humans are also reported.[112,116] Based on specimens submitted to the US National Tick Collection, 44 species of ticks (33 ixodid and 11 argasid) were recovered from infested humans. The predominant tick species on humans was variable and predictable based on geographic location in the United States.[113] All motile stages of *A. americanum* were common in the southern United States and Atlantic coastal states. Adults of *D. variabilis* and all stages of *I. scapularis* were common on people in the eastern and northern United States. In Rocky Mountain and western states, *D. andersoni* was most common whereas in far western states, adult *I. pacificus* were most commonly recovered from humans.[113] Tick paralysis in humans occurs worldwide.[56,117,118] In North America, the majority of human tick paralysis cases are in the Pacific northwest of the United States and adjacent areas of southwestern Canada.[119] However, occurrence is rare.[56] Children 2 to 5 years old are at highest risk.[120]

Humans exposed to natural areas with wildlife present are at increased risk of exposure to ticks and tick-borne diseases.[116] Outdoor activities related to contact with wood (e.g., sitting on logs, gathering wood, sitting against trees, walking, stirring and sitting on leaf litter, just sitting on leaf litter) resulted in greater acquisition of *I. pacificus* nymphs.[121] Coming in contact with wild and domestic animals infested with ticks increases the risk of tick bites to humans.[116] Maintaining pets on year-round tick prevention under the direction of a veterinarian will minimize the potential for animals to bring ticks into the home. Perhaps the biggest impact ticks have on humans globally is as pathogen vectors.[116,122] Ticks are second only to mosquitoes in this respect,[16] and they will continue to play a significant role in emerging zoonotic diseases.[123–125]

CASE EXAMPLE

Signalment

"Amos," a 2-year-old mastiff mix male dog from north-central Oklahoma.

History

The mastiff mix was reported to be roaming for 5 to 7 days and a municipality's Department of Animal Welfare was notified for pick-up. The dog was given the name "Amos" and examined by a veterinarian. After 4 days for stray hold (according to city animal welfare protocol), Amos was presented to a local animal shelter for castration and vaccination. Amos was adopted after 10 days at the shelter. There was no history of known medication.

Physical Examination

Body weight: 31 kg (68 lb).

General: Quiet, alert, responsive. Body condition score 2/9. Euhydrated. T = 101.6°C (38.7°F). P = 100 beats/min, R = 24 breaths/min, mucous membranes pink, CRT <2 s.

Integument, eyes, ears, nose, and throat: Dermatological abnormalities were limited to the sites of ectoparasite attachment. An asymmetric pattern of attached ticks was present over the patient's dorsum and convex surfaces of the pinnae (Fig. 109.7). Nodular swellings underlay each attachment point. The ticks were at various stages of rapid engorgement. Mild small, loose scale was present throughout the coat. Neither alopecia nor hypotrichosis were seen. No adult fleas were observed with flea comb exam. The interdigital webbing was normal. Ocular mucopurulent discharge was noted OU with mild hyperemia of the conjunctiva. There was mild ectropion OU. Corneas were clear. A Schirmer tear test was normal. Otoscopic examination revealed moderate brown, waxy exudate adherent to non-erythematous, non-edematous canal walls AU. Tympanic membranes intact AU. Nasal orifices free of discharge. Oral exam had no abnormalities noted.

Musculoskeletal: Ambulation was assessed by allowing the patient to roam in a small enclosure as Amos was not accustomed to walking on a leash. All joints palpated had normal range of motion with no swelling noted. There was no evidence of pain, and weight bearing was equal on all four limbs. Pain score was assessed to be 1/5.

Cardiovascular, respiratory, gastrointestinal, and genitourinary: No murmurs or arrhythmias were ausculted. All lung fields were clear on auscultation. No cough was elicited on tracheal palpation. Abdominal palpation was unremarkable. A smooth enlarged spleen was noted. Unilateral cryptorchidism was noted with the right testicle retained in the abdomen. Rectal examination was unremarkable.

Lymph nodes: Within normal limits.

Neurologic examination: Patient interacts appropriately with surroundings. No neurologic abnormalities were detected during an abbreviated neurologic examination.

Laboratory Findings

CBC: HCT 39% (36%–60%), MCV 68 fL (58–79 fL), MCHC 35 g/dL (30–38 g/dL), WBC 17,500 cells/μL (4000–15,500 cells/μL), neutrophils 9450 cells/μL (2060–10,600 cells/μL), lymphocytes 4375 cells/μL (690–4500 cells/μL), monocytes 1225 cells/μL (0–840 cells/μL), eosinophils 2450 cells/μL (0–1200 cells/μL), basophils 0 cells/μL (0–150 cells/μL), platelet 244,000 cells/μL (170,000–400,000 cells/μL).

Serum chemistry profile: Albumin 2.8 g/dL (2.7–4.4 g/dL), globulin 4.6 g/dL (1.6–3.6 g/dL), AST 37 IU/L (15–66 IU/L), ALT 71 IU/L (12–118 IU/L), ALP 73 IU/L (5–131 IU/L), GGT 2 IU/L (1–12 IU/L), total bilirubin 0.1 mg/dL (0.1–0.3 mg/dL), BUN 15 mg/dL (6–31 mg/dL), creatinine 0.8 mg/dL (0.5–1.6 mg/dL), phosphorus 4.3 mg/dL (2.5–6.0 mg/dL), glucose 96 mg/dL (70–138 mg/dL), calcium 10.1 mg/dL (8.9–11.4 mg/dL), magnesium 1.7 mEq/L (1.5–2.5 mEq/L), sodium 144 mEq/L (139–154 mEq/L), potassium 4.2 mEq/L (3.6–5.5 mEq/L), chloride 105 mEq/L (102–120 mEq/L), cholesterol 183 mEq/L (92–324 mEq/L), triglyceride 76 mg/dL (29–291 mg/dL), amylase 726 IU/L (290–1125 IU/L), precision PSL 42 U/L (24–140 U/L), CPK 138 IU/L (59–895 IU/L).

Urinalysis: Not performed

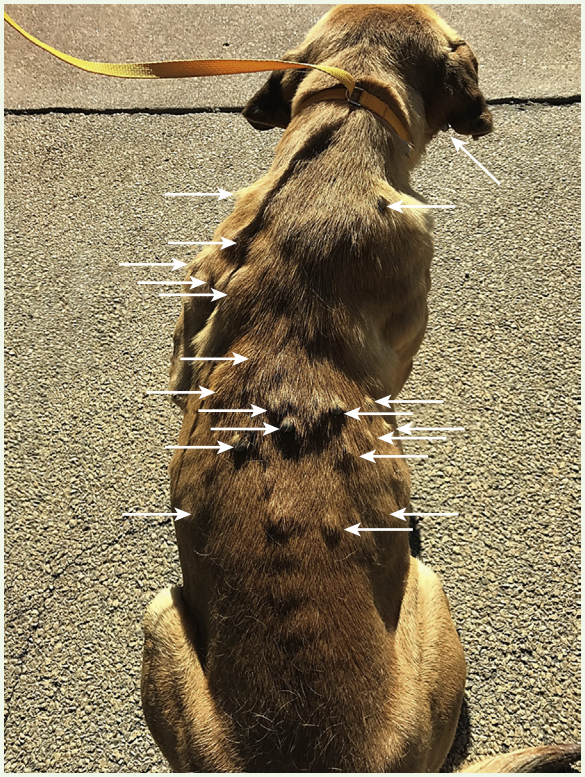

Fig. 109.7 Adult male intact mastiff mix infested with *Amblyomma maculatum* and *Dermacentor variabilis*. Engorged female ticks were first observed as "lumps" in the haircoat *(arrows)*. (Photo and case information courtesy of Dr. Katrina Meinkoth, Oklahoma State University.)

Parasitological Testing

Gross parasites identified as *Amblyomma maculatum* (Gulf Coast ticks) and *Dermacentor variabilis* (American dog ticks).

Fecal flotation (sugar with centrifugation) demonstrated moderate numbers of *Ancylostoma caninum* (hookworm) eggs.

SNAP 4Dx Plus test (IDEXX Laboratories): Negative for *Borreliella burgdorferi* antibodies; negative for antibodies to *Anaplasma* spp.; negative for antibodies to *Ehrlichia canis*, *E. ewingii*; negative for *Dirofilaria immitis* antigen.

Diagnosis

Infestation with ticks, infection with hookworms; malnutrition.

Treatment

Amos was treated with 8.80% imidacloprid + 44.00% permethrin + 0.44% pyriproxyfen (Advantix II, Bayer) for ticks and 272 μg ivermectin + 227 mg pyrantel pamoate (Heartgard Plus, Boehringer Ingelheim) for hookworms. He was vaccinated for canine distemper, canine adenovirus type 2, canine parainfluenza, canine parvovirus type 2, *Bordetella bronchiseptica*, and rabies. Amos received a balanced, commercially available dry dog food to improve his nutritional status and elevate his body condition score.

CASE EXAMPLE—cont'd

Comments

This was a typical case of a stray dog seen at an animal shelter in the south-central United States. Amos was malnourished and moderately infested with ticks. Upon further examination, he was also found to be infected with hookworms. The moderate eosinophilia and mild monocytosis was consistent with parasitic infestation and infection. The extent of eosinophilia caused by the ticks versus hookworms was not known. The likelihood that a parasite will generate an eosinophilia is proportional to the degree of tissue contact. Prolonged injection of tick saliva, migration of juvenile *A. caninum*, and feeding of adult *A. caninum* in the small intestines would all produce an eosinophilia. It is possible that infection with vector-borne pathogens was too recent for an antibody response to have developed. The presence of fully engorged female *A. maculatum* and *D. variabilis* suggested that infestation had been present for at least 7 to 10 days, which is the average amount of time required for female ticks to attach, breed, engorge fully, and detach. Both *A. maculatum* and *D. variabilis* are capable of transmitting pathogens to dogs (see Table 109.1). Due to the substantial and year-round activity of various tick species in the central United States and the potential for tick-borne pathogen transmission, the necessity of continuous administration of acaricides and control of other parasites was discussed with Amos' new owners.
