Influenza viruses are enveloped viruses with segmented single-stranded RNA genomes that belong to the family *Orthomyxoviridae* (see Chapter 25). Influenza viruses that cause disease in domestic animals belong to the genus *Influenzavirus A*, whereas influenza B and influenza C viruses primarily circulate among humans. Influenza A viruses are classified based on the genetic composition of their hemagglutinin (H) and neuraminidase (N) genes. To date, 16 H types and 9 N types have been identified, each of which are antigenically distinct.[17] The names of influenza viruses are specified as follows: influenza genus (A, B, or C)/host/geographic origin/strain number/year of

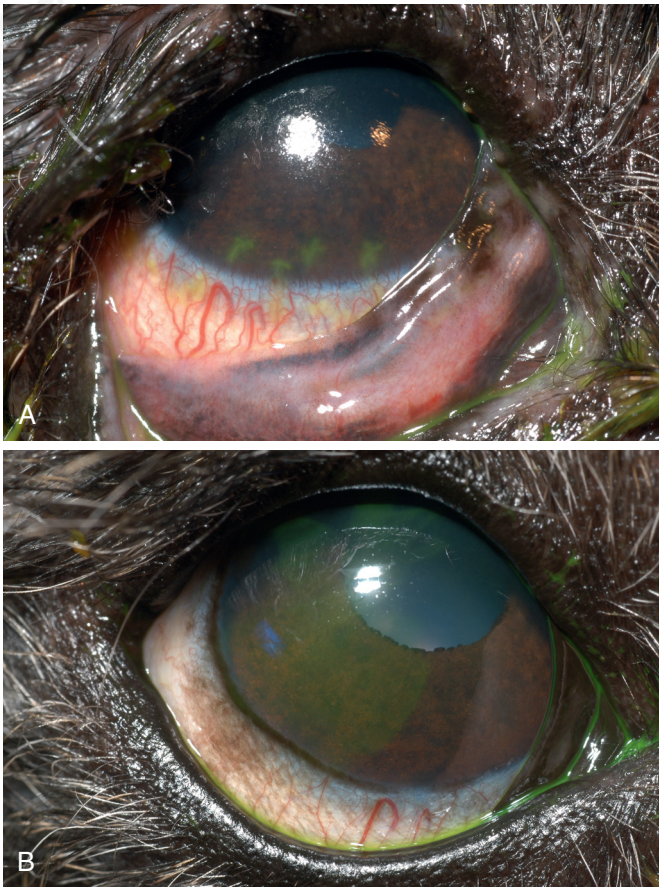

Fig. 28.1 (A) Right eye of a 10-year-old male neutered miniature schnauzer infected with bilateral conjunctivitis and dendritic ulceration associated with canine herpesvirus infection. Fluorescein uptake can be seen in a branching pattern at the limbus of the right eye. (B) The same dog 1 month later. Note diffuse stain uptake over at least 25% of the corneal surface. (Courtesy University of California, Davis Veterinary Ophthalmology Service.)

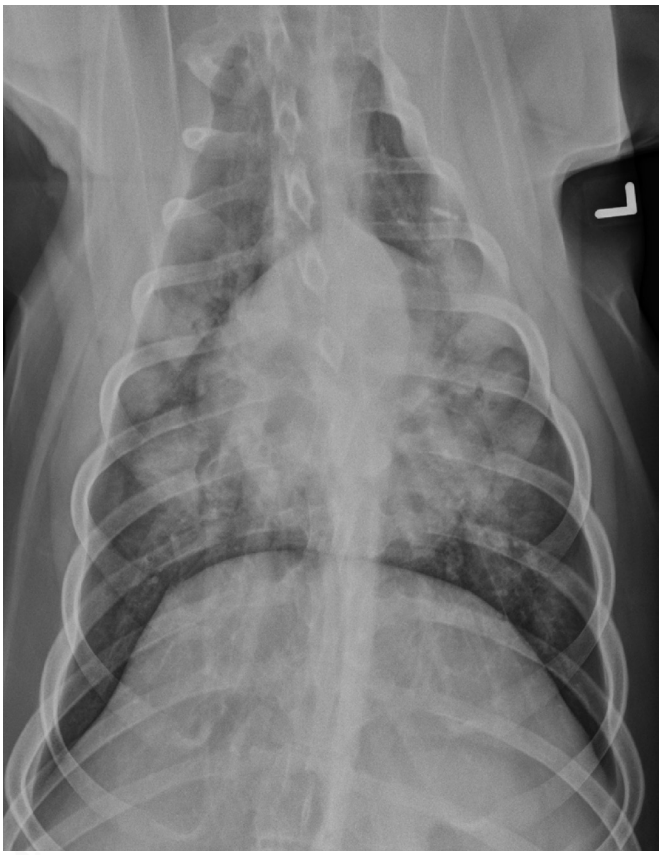

Fig. 28.2 Dorsoventral thoracic radiograph from a 2-year-old male neutered coonhound that had left a boarding facility 6 days previously with a moist, productive cough that subsequently progressed and was complicated by the development of fever and a mucopurulent nasal discharge. A complete blood count showed neutrophilia (17,840 cells/μL), increased numbers of band neutrophils (223 cells/μL), and monocytosis (3,345 cells/μL). Bronchopneumonia is present that involves the right cranial, right middle, and left cranial lung lobes. Interestingly, canine herpesvirus DNA was detected in a pooled extract from nasal, conjunctival, and oral swab specimens, as well as a whole blood sample using a PCR assay.

isolation and, in parentheses, H and N type—for example, A/canine/Florida/43/2004 (H3N8).[18] Extensive genomic rearrangements that occur within influenza A viruses allow for occasional cross-species transmission among birds and mammals. These rearrangements occur when two different viruses simultaneously infect a host, with subsequent genetic reassortment. Occasionally, cross-species transmission occurs without alteration of the viral genome.

In the United States, CIV emerged in racing greyhounds in Florida in 2003 and 2004,[18] where it caused hemorrhagic pneumonia and a high mortality. However, serologic evidence of infection in the greyhound dog population dates back to 1999.[19] Infections spread slowly and were subsequently reported in racing greyhounds and non-greyhounds in at least 38 American states. Outbreaks continued to occur in shelter situations for nearly a decade after the virus was discovered. The virus was an H3N8 virus that closely resembled an equine influenza virus, which suggested that an interspecies jump occurred without genetic reassortment.[18] Instead, accumulation of point mutations with minor amino acid changes occurred, with sustained transmission among dogs. The most significant outbreaks of disease due to CIV occurred in Florida, New England, Colorado, Wyoming, and Texas. In many other states, sustained transmission of the virus from one dog to another did not occur. The most significant risk factor for infection was indoor housing.[20] Virtually all cases to date involved dogs in kennels, animal shelters, or dog daycare facilities. Dogs of all ages and breeds are susceptible, but to date severe hemorrhagic pneumonia has occurred only in greyhounds.[21] The virus is shed for up to 7 to 10 days. CIV has retained the ability to infect horses, but horses develop only mild disease or no clinical signs.[21] The prevalence of infection as determined by real-time PCR has been gradually decreasing within the dog population. By the year 2020, some experts believed this virus was extinct or near extinction within the United States.

Avian-lineage H3N2 CIV emerged in South Korean dogs in 2007, and a similar virus was subsequently isolated from dogs in China.[22,23] Korean isolates were associated with epidemics of respiratory disease in kennels within veterinary clinics.[23] In February/March of 2015, an H3N2 virus was introduced into the Chicago area, likely as a result of importation of a dog from Korea, after which it spread to several other states within the United States, especially North Carolina and Georgia. Additional importation events may have contributed to an outbreak of infection in late 2017 in California. This virus caused more severe upper respiratory signs in dogs, and spread to a greater extent within the owned pet dog population when compared with the H3N8 virus. A novel H5N2 influenza virus was detected in a dog with respiratory

disease in China.[24] Dogs are susceptible to infection with human influenza virus H1N1[25,26] and avian H5N1[27]; however, sustained transmission of these viruses in the dog population has not been reported. Limited infection of dogs with equine H3N8 viruses was detected in hounds in England[28] and during an equine influenza outbreak in Australia.[29] In England, disease was so severe that several hounds had to be euthanized, and subacute broncho-interstitial pneumonia was detected at necropsy.[28] The Australian dogs developed inappetence, lethargy, nasal discharge, and a cough that persisted for several weeks, but dog-to-dog transmission was not identified. Experimental transmission of H3N8 influenza virus from horses to dogs was documented in Japan, but infected dogs did not show signs of illness.[30]

Dogs are susceptible to both mammalian and avian-lineage influenza viruses, and as such reassortment of viruses following co-infection poses a potentially significant zoonotic risk to humans, particularly in the western world, who have more frequent and close contact with dogs than either poultry or pigs.

Canine Parainfluenza Viruses

CDV, CPIV, and CPnV belong to the family *Paramyxoviridae*, which are enveloped RNA viruses. CPIV belongs to the genus *Rubulavirus*. The virus infects dogs worldwide, replicates in epithelial cells of the upper respiratory tract, and often causes no signs or mild respiratory illness. CPIV was the most prevalent respiratory pathogen in a large study of dogs from the United States with respiratory disease,[5] as well as 138 dogs from Italy.[31] Respiratory disease may be more severe when co-infections with other pathogens such as *B. bronchiseptica* are present.[32] Viremia seems to be uncommon, but occasionally CPIV has been isolated from the liver, spleen, and kidneys. A strain of CPIV was also isolated from a dog with neurologic signs.[33] Virus is shed for up to 10 days after infection. CPIV is discussed further in Chapter 26. CDV is now rarely associated with typical CIRD, but should be considered in the differential diagnosis, especially if respiratory signs are severe or complicated by secondary bacterial pneumonia. The concurrent presence of GI or neurologic signs are also suggestive of distemper, but sometimes these may be overlooked or absent. The immunosuppressive effects of CDV infection may also predispose an animal to infection with other respiratory pathogens, and is discussed further in Chapter 22.

Canine Respiratory Coronavirus (CRCoV)

CRCoV belongs to the *Betacoronavirus* genus of the *Coronaviridae* family, most closely related to bovine coronavirus (BoCoV) and human coronavirus OC43 (see Chapter 27).[34] The betacoronavirus SARS-CoV-2 is less closely related (see Chapter 43),[35] but similarities in the pathogenesis of, epidemiology of, and immune response to CRCoV and SARS-CoV-2 have been noted.[36] CRCoV is serologically and genetically distinct from CCoV, an alphacoronavirus, which is typically an etiologic agent of enteric disease, although pantropic CCoV have recently been identified and are discussed later in this chapter.

CRCoV was first described in 2003 during an investigation into the pathogenesis of CIRD in a large UK rehoming center.[37] This study showed a strong association between exposure to CRCoV and the development of CIRD in dogs entering the kennel. Since the initial report, the global presence of CRCoV has been demonstrated.[4,38–49] Collective findings from outbreaks and clinical cases indicate that CRCoV is associated with mild respiratory disease during the early stages of CIRD, with typical clinical signs including a dry cough and nasal discharge.[8,37,50] CRCoV has been isolated from a wide range of respiratory and respiratory-associated lymphoid tissues (trachea, palatine tonsil, nasal cavity, nasal tonsil, bronchial lymph node, apical and diaphragmatic lung lobes, and lung lavage fluids). The trachea and nasal tonsil are the most common sites of infection and are also reported to have the highest viral loads.[51,52] Indisputably, CRCoV displays a clear preferential tropism for canine respiratory tissues, particularly those of the upper airways including ciliated epithelial and goblet cells of the trachea and bronchioles.

Histologic examination of the respiratory tissues from experimentally challenged dogs showed a clear and consistent association between exposure to CRCoV and inflammation in the nares and trachea, with significant injury, such as shortening and clumping, or loss of tracheal cilia.[52] These findings support the hypothesis that CRCoV causes damage to the mucociliary clearance mechanisms of the upper airways, which may predispose dogs to secondary infections (see Fig. 27.1). Further evidence in support of this was seen in an *in vitro* CRCoV-infected canine tracheal organ culture system, in which a moderate reduction in mucociliary clearance was observed.[53]

The discovery of CRCoV and the subsequent research into its pathogenesis has highlighted the importance of viruses in CIRD, not only through direct cellular damage but also through the less obvious effects on the host immune system. Combined, these effects can result in significant morbidity whilst predisposing to other more serious secondary infections.

NOVEL CANINE RESPIRATORY VIRUSES

Viruses believed to play a role in CIRD include CPnV, pantropic CCoVs, canine hepacivirus, canine bocaviruses (CBoV), and reoviruses. A study of 138 dogs either with clinical signs of CIRD or that had been exposed to dogs recently recovered from CIRD found that CPIV was still the most commonly detected viral pathogen.[31] These results mirror similar recent studies from several European countries and Canada.[4,54–56] Interestingly some of the established viral causes of CIRD, namely CHV-1, CAdV-2, and CDV are now infrequently or rarely isolated from clinical cases with more recently discovered viruses such as CRCoV, or novel agents such as CPnV, appearing to fill this niche. In the case of CDV and CAdV-2, this is likely associated with widespread use of effective vaccines, but CPIV is also included in most primary vaccine courses and yet still appears to be a persistent problem. The picture is far from clear though, with other studies appearing to show a relatively high prevalence of CIRD pathogens such as CAdV-2 (and even CDV) in subclinically infected shelter dogs.[57] For the novel agents discussed in the following sections, no vaccines are currently available. However, for at least some of the agents, this is the subject of a great deal of active research.

Canine Pneumovirus

CPnV was first described in 2010 following a retrospective study of respiratory disease in dogs from two animal shelters in the United States.[58] It was reported that after three passages in A72 cells, a CPE uncharacteristic of viruses commonly isolated from dogs was observed. After failing to identify other common agents, a pool of monoclonal antibodies against a human respiratory pathogen (human respiratory syncytial virus) was used, and fluorescent staining was observed in infected cell cultures. Degenerate primers were used to amplify three regions of the viral genome, and sequence analysis revealed that the unknown virus was closely related to murine pneumovirus (MPV), a common pathogen of research and commercial rodent colonies.[59]

In 2011 the full genome sequence of CPnV was completed and its place within the pneumovirus genus of the subfamily *Pneumovirinae* and family *Paramyxoviridae* was confirmed.[60] CPnV is closely related to a number of important human and veterinary respiratory pathogens, including human and bovine respiratory syncytial virus, human metapneumovirus, avian pneumovirus, and most closely, MPV.

Since its initial discovery, CPnV has been detected in kenneled and pet dogs in the United States, the United Kingdom, Asia, and continental Europe.[4,31,60–62] Whilst CPnV is readily detected in dogs with respiratory disease,[58,60] its role as a causative agent of disease has been unclear. Extensive serologic surveys and surveillance studies will be required to determine the presence of CPnV globally and to establish an association with clinical disease. A large multicenter European study of kenneled and pet dogs identified CPnV in 23.4% of 572 dogs using PCR, and there was a clear association between positive test results and clinical signs of respiratory disease.[4] CPnV was the most frequent virus detected in dogs with CIRD and a similar proportion of healthy dogs from New Zealand, highlighting perhaps an inconsistent role in disease causality, and the need to ensure diagnostic assays include the more novel viruses.

The pathogenesis of CPnV infection in dogs remains to be investigated. For other pneumovirus species, transmission occurs via contact with respiratory secretions and the apical airway epithelial cells are the principal targets for infection. Indeed, following an experimental inoculation of BALB/c mice, CPnV was shown to replicate effectively in the lungs, with viral antigen detected predominantly in the epithelial cells lining the bronchioles.[63]

The host immune response, in particular neutrophil activity, has been associated with tissue damage during pneumovirus infection.[17,34,41] In the mouse model, CPnV infection was associated with the induction of a local proinflammatory cytokine response and the presence of mild multifocal perivascular neutrophilic inflammation in the lung.[18,28] Compared with MPV infections, however, there were minimal histopathological changes, reduced neutrophil infiltration of the parenchyma, and no apparent hemorrhage or edema.[64] Similar reductions in neutrophil infiltration have been observed in MPV-challenged mice deficient in type 1 IFN receptors, or in the absence of IFN-γ signaling.[65,66] Pneumoviruses have developed many immune modulation strategies, particularly mechanisms for circumventing host type 1 IFN responses. It will be interesting to establish whether these reported findings are consistent in dogs, and if so, whether they are linked to IFN signaling and immunomodulatory mechanisms of the virus.

The glycoprotein (G) of related pneumovirus species mediates attachment to host cells, and as such contains the major neutralizing epitopes. Considered an important virulence factor, a high degree of genetic and antigenic variation is shown to exist within the G protein of RSV species, which frequently gives rise to escape mutants.[67] The G protein sequences of several isolates have been reported, and this led to the designation of A and B subtypes, both of which were identified in multiple locations across the United States, and included two strains isolated from cats.[64] The study compared group A and B viruses in the BALB/c mouse model, in which virus replication was detected as early as three days post intranasal inoculation, with peak levels at day 6 PI. Local cytokine production and inflammatory responses were examined and some differential responses between A and B strains were observed.[64] Whether a clinical outcome can be linked to subtype warrants further investigation, but for human RSV infections, the findings are conflicting. In addition to *in vivo* studies, it will be important to undertake clinical surveillance and to establish the degree of variation across the CPnV genome and in particular the G protein to determine whether variation is associated with pathogenicity in the dog.

Quantitative RT-PCR assay is becoming increasingly available commercially for CPnV. The recommended diagnostic specimens include nasal and pharyngeal swabs or respiratory lavage specimens. Necropsy specimens from the lung and upper airways are also suitable for testing with this assay.

Canine Reoviruses

Reoviruses (family *Reoviridae*, genus *Orthoreovirus*) are nonenveloped viruses with a segmented, double-stranded RNA genome. Mammalian reoviruses infect a variety of host species and have a worldwide distribution. The prefix *reo-* stands for *r*espiratory *e*nteric *o*rphan virus, which highlights the tropism of reoviruses for cells of the respiratory and GI tract, and their uncommon association with disease. Despite serologic evidence of widespread exposure to reoviruses in dogs,[68] they have been found only rarely in dogs with respiratory disease[69,70] and dogs with enteritis.[71] There are three mammalian reovirus serotypes, and all three have been detected in dogs. The role of reoviruses in disease causation in dogs is unclear because disease has not been reproducible experimentally; however, they may act synergistically with other respiratory pathogens to cause disease.

Pantropic Canine Coronavirus

CCoV has traditionally been considered an enteric pathogen of low virulence which is not only frequently isolated from dogs with diarrhea but is also detected in feces of dogs displaying no clinical signs.[20,72] In 2005, an outbreak of fatal systemic disease occurred in Italy; CCoV was detected in affected dogs in a range of tissues, including the lungs, where pulmonary lesions were observed. Although the clinical signs associated with the infection have been predominantly GI and neurologic, its presence in the lungs of infected dogs may suggest a role of this tissue in the pathogenesis of CIRD. To distinguish these infections from cases with a purely enteric tropism, the term *pantropic CCoV* has been applied.

CCoV isolates are grouped into CCoV type I isolates, which are closely related to feline coronavirus (FCoV) type I, and CCoV type II isolates, which comprise types IIa and IIb.[73] CCoV type IIb is closely related to transmissible gastroenteritis virus of swine (TGEV).[74,75] CCoV type IIa is the most prevalent of the types within the canine population; however, co-infections with CCoV types I and II are also common.[76]

The pantropic variant of CCoV was first isolated from an outbreak of systemic and fatal disease in dogs in a pet shop in Bari, Italy. Dogs exhibited lethargy, vomiting, hemorrhagic diarrhea, and neurologic signs.[77] All seven affected dogs were between 45 and 56 days of age and died within a few days of onset of clinical signs. At necropsy, gross findings were hemorrhagic enteritis and serosanguinous abdominal effusion, multifocal consolidation of the lungs, superficial hemorrhages within liver and spleen, petechial hemorrhages on lymph node surfaces, and multifocal hemorrhagic renal infarcts. Histopathologic examination showed a fibrinopurulent exudate within the bronchi, bronchioles, and alveoli, degeneration of bronchial and bronchiolar epithelia, fibrinoid vascular necrosis, alveolar hemorrhage, and edema.[78] Further extraintestinal lesions included lymphoid depletion within the spleen and acute renal infarcts. In the lungs, viral antigen was detected within bronchial and bronchiolar epithelial cells and alveolar septa as well as occasional arterial walls. The authors suggested that the vascular lesions observed may have led to the renal infarcts and abdominal effusion.

CCoV type IIa was isolated from the affected tissues and was detected by RT-PCR, whereas other canine viral or bacterial pathogens were not identified. The viral isolate CB/05 had a high sequence identity with FCoV type II strain 79-1683 within the spike gene.[77] Subsequent experimental infections produced similar clinical signs to those observed during the original outbreak, with a more severe clinical course in 2.5-month-old dogs than in 6-month-old dogs.[79] Infected dogs also exhibited lymphopenia with cell counts below 60% of the initial count. Further experimental studies showed depletion of CD4+ T cells for up to 30 days PI.[80]

Since the original report, additional outbreaks have occurred in Italy,[81] France, Belgium,[82] and Greece.[83] Clinical signs exhibited by pups during five outbreaks in Belgium and France included vomiting, diarrhea, and convulsions. CCoV was detected by RT-PCR in the lungs of affected dogs in all outbreaks. Pulmonary lesions were described as subacute interstitial pneumonia and alveolar edema. In four of the five

outbreaks, CPV type 2c was detected in fecal specimens of affected dogs. Spleen and liver were tested by PCR for CPV-2c but were found to be negative. The authors suggest that infection with CPV-2c might facilitate systemic spread of CCoV. While the original pantropic isolate CB/05 is a CCoV type IIa, one outbreak in France was associated with CCoV type I.[82]

A large European surveillance study of 354 cases of fatal disease associated with clinical signs, including leukopenia, enteritis, respiratory distress, and/or neurologic signs, identified CCoV in extraintestinal tissues in 33 cases.[84] Of these, 24 were CCoV type IIa and 9 were CCoV type IIb, confirming that strains other than CCoV type IIa can cause systemic infection. In addition, similar to previous studies in France and Belgium, dogs with systemic CCoV infection were commonly co-infected with CPV-2.

Currently available inactivated vaccines against CCoV have been shown to be ineffective against challenge with pantropic CCoV type IIa[85]; the clinical signs, however, were milder in vaccinated dogs. To date, no consistent genetic marker has been identified for discrimination of enteric and pantropic CCoV strains. Of concern, a virus related to CCoV was recently detected in humans with respiratory illness in Malaysia.[86]

Canine Bocavirus

Bocaviruses contain a single-stranded DNA genome and are distinct from other members of the *Parvoviridae* family in that they possess an additional open reading frame (ORF) named NP1, between the nonstructural and structural coding regions. Most of the attention to date has focused on human bocavirus (HBoV), which is found ubiquitously worldwide, and, in particular, HBoV-1, which has been associated with respiratory disease. Initially, the frequent detection of HBoV-1 in asymptomatic individuals and the high viral co-infection rates detected in symptomatic cases indicated that HBoV-1 may exist only as a bystander. However, the application of improved diagnostics have demonstrated a high seroprevalence and a positive correlation between disease and high copy numbers of HBoV, providing increasing evidence that HBoV-1 is an important respiratory pathogen in humans.[72]

Before 2012, minute virus of canines (MVC) was the only known member of the *Bocavirus* genus to infect dogs. MVC typically causes only subclinical infection in adult dogs, but can also cause abortions in bitches and severe respiratory infections in newborn puppies.[87,88] In 2012, several novel species of CBoV were identified using novel primer walking molecular techniques.[89] Analysis of 35 CBoV variants indicated that these CBoVs represent a highly diverse group of viruses, which can be divided into three groups. Group A variants were significantly more prevalent in healthy dogs raised in controlled conditions than in diseased animals, and Group B (especially B1) and C variants were substantially more prevalent in dogs with respiratory disease.[89] The association between respiratory infections and CBoV positivity was most notable for shelter-housed dogs.

A clear relationship between CBoV and respiratory disease in dogs is yet to be established. Furthermore, it not known whether other viral pathogens were also present in the infected dogs (as is the case for HBoV-1). However, the higher prevalence of CBoV B and C variants in dogs with respiratory disease suggests that these viruses may infect diseased animals as opportunistic pathogens or enhance the severity of lesions in co-infections.[89] Evidence for the latter is provided by a study from China in which CBoV was detected in a number of fecal specimens from diarrheic dogs and often in mixed infections with other novel viruses.[90] Although bocaviruses remain only a putative cause of respiratory disease in dogs, there is currently much interest in their wider role as canine and feline pathogens.

Canine Hepacivirus

In 2011, a novel nonprimate hepacivirus (NPHV), tentatively named canine hepacivirus (CnNPHV), was identified in respiratory swab specimens collected from 9 of 33 dogs housed in rehoming shelters in the United States.[2] The dogs represented cases from five different outbreaks of respiratory disease. Six CnNHPV-positive dogs were identified in one outbreak, and three in a second outbreak in the same rehoming shelter 2 weeks later. The virus was also detected in liver specimens from five unrelated dogs which died from GI illness. A subsequent study from the United Kingdom identified the virus in the upper respiratory tract of shelter dogs with respiratory disease by RT-PCR and *in situ* hybridization, and found that it was associated with increased severity of histopathologic changes in the respiratory mucosa.[91]

Canine hepacivirus is the first NPHV to be described; subsequently, a closely related virus has also been detected in the serum samples of horses in the United Kingdom and United States.[92,93] Analysis of the NPHV sequences from dogs in the United Kingdom and United States has shown that they share a common ancestor, which existed in the 1980s, and that a cross-species transmission event may have occurred from horses to dogs around 1970.[94] Comparative phylogenetic analysis has confirmed that canine hepacivirus is the closest genetic relative of hepatitis C virus (HCV) to date.[2] HCV is associated with chronic hepatitis in humans, and the discovery of NPHVs may provide new insights into its origins. The discovery of a hepacivirus in dogs with respiratory disease is intriguing; however, a role for this novel virus in the pathogenesis of disease remains to be determined.

CASE EXAMPLE

Signalment

"Winnie," a 10-year-old male neutered miniature Schnauzer from Sacramento, CA

History

Winnie was brought to his local veterinarian because of a 1-day history of serous ocular and nasal discharge, and sneezing. Fever (103.5°F) was documented on physical examination, and enrofloxacin (2 mg/kg, PO q24h), bacitracin-neomycin-polymixin ophthalmic ointment (OU q8h) and diphenhydramine (2.2 mg/kg, PO q12h) were prescribed, which did not appear to reduce the severity of signs. A day later, he became lethargic, inappetent, polydipsic, and the owners described wheezing, continuous nasal discharge, and a moist cough, so he was brought to the UC Davis William R. Pritchard VMTH for a second opinion. Winnie had been vaccinated regularly for CDV, CAdV-2, CPV, rabies, *B. bronchiseptica*, and CPIV. He was recently cared for in a boarding facility for a week and had been home for the last 11 days. He also visited dog parks regularly and was exposed to grass awns. There were two other miniature Schnauzers at home, and both were currently well.

Current Medications

Enrofloxacin, 2 mg/kg PO q24h

Other Medical History

Increased activity of ALP was noted at a senior care visit 2 months before the onset of respiratory signs.

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 9.4 kg

General: Lethargic but hydrated. Temperature = 100.8°F, HR = 104 beats/minute, RR = 12 breaths/minute, mucous membranes pink, CRT = 1–2 seconds.

Integument: No clinically significant abnormalities.

Eyes, ears, nose, and throat: Severe chemosis, hyperemia, and mucoid ocular discharge OU, profuse bilateral serous nasal discharge and decreased nasal airflow, hypersalivation, right tonsillar enlargement.

Musculoskeletal: BCS 5/9. Ambulatory on all four limbs.

Cardiovascular: No clinically significant abnormalities.

Respiratory: Stertorous respiratory noises. Increased respiratory effort with a normal RR. Referred wheezing noises in all lung fields on auscultation.

GI: Tense abdomen, hepatomegaly detected on palpation.

Rectal examination: No abnormalities detected.

Lymph nodes: All peripheral lymph nodes normal sized.

Ophthalmologic Examination

Both eyes were open. There was mucoid ocular discharge OU. PLRs (direct and consensual) were brisk and complete OU. No evidence of anisocoria. Menace response, dazzle and palpebral reflexes all complete OU. Globe position and movements normal OU. Periorbital palpation and globe retropulsion were normal. The dog behaved as if sighted.

OS: Lids normal, third eyelid hyperemic and edematous, moderate conjunctival hyperemia and chemosis, cornea clear, anterior chamber clear, no flare, vitreous normal, dilated fundic examination normal. There was iris atrophy, lens nuclear sclerosis, and a pinpoint incipient anterior cortical cataract just ventral to the center of the lens.

OD: Lids normal, prominent secretions at meibomian gland openings, third eyelid hyperemic and edematous, moderate conjunctival hyperemia and chemosis, cornea clear, anterior chamber clear, no flare, vitreous normal, dilated fundic examination normal. There was iris atrophy, lens nuclear sclerosis, and linear pigment deposition on the anterior lens capsule at the 5 o'clock position.

Schirmer tear test: 8 mm/minute OU

Introcular pressure: 16 mmHg OS, 17 mmHg OD

Fluorescein stain: multiple dendritic ulcers at the ventral peripheral cornea OD (see Fig. 28.1).

Laboratory Findings

CBC: HCT 53.5% (40%–55%), MCV 67.7 fL (65–75 fL), MCHC 35.3 g/dL (33–36 g/dL), 1 nucleated red cell/100 WBC, WBC 14,780 cells/μL, corrected WBC 14,600 cells/μL (6,000–13,000 cells/μL), neutrophils 10,804 cells/μL (3,000–10,500 cells/μL), band neutrophils 438 cells/μL (rare), lymphocytes 1,752 cells/μL (1,000–4,000 cells/μL), monocytes 1,460 cells/μL (150–1,200 cells/μL), eosinophils 0 cells/μL (0–1,500 cells/μL), platelets 216,000 platelets/μL (150,000–400,000 platelets/μL). A few highly reactive lymphocytes were noted.

Serum chemistry profile: sodium 142 mmol/L (145–154 mmol/L), potassium 6.1 mmol/L (3.6–5.3 mmol/L), chloride 102 mmol/L (105–116 mmol/L), bicarbonate 25 mmol/L (16–26 mmol/L), phosphorus 6.7 mg/dL (3.0–6.2 mg/dL), calcium 9.5 mg/dL (9.9–11.4 mg/dl), BUN 20 mg/dL (8–31 mg/dL), creatinine 0.7 mg/dL (0.5–1.6 mg/dL), glucose 80 mg/dL (60–104 mg/dL), total protein 5.7 g/dL (5.4–7.4 g/dL), albumin 2.2 g/dL (2.9–4.2 g/dL), globulin 3.5 g/dL (2.3–4.4 g/dL), ALT 564 U/L (19–67 U/L), AST 116 U/L (21–54 U/L), ALP 1024 U/L (15–127 U/L), GGT 10 U/L (0–6 U/L), cholesterol 195 mg/dL (135–345 mg/dL), total bilirubin 0.4 mg/dL (0–0.4 mg/dL).

Urinalysis: SpG 1.009; pH 8.5, negative for protein, bilirubin, hemoprotein, glucose; rare WBC/HPF, 0 RBC/HPF, 0–3 hyaline casts/HPF, few amorphous crystals, moderate degenerated cells, and amorphous debris in the sediment.

Imaging Findings

Thoracic and cervical radiographs: A mild to moderate bronchial and interstitial pattern was identified, and was most prominent in the caudal lung fields. A prominent fissure line was identified in the left lateral thorax. Cervical radiographs were unremarkable. Impressions: Pulmonary changes more significant than those related to age, but nonspecific.

Abdominal ultrasound: The cranial pole of the right adrenal was mild to moderately enlarged. A focal area of the cranial pole of the right kidney was mineralized and there was a mild increase in renal cortical echogenicity. The liver appeared sonographically normal. A small stone that measured approximately 3 mm was identified in the urinary bladder.

Microbiologic Testing

A nasal swab was collected and submitted for real-time PCR panel for canine respiratory pathogens, which included CHV-1, CIV, CDV, CPIV, CAdV-2, and *B. bronchiseptica*. The results were available 3 days later, and the swab was positive for CHV-1 DNA.

Diagnosis

Upper respiratory disease and keratitis associated with CHV-1 infection.

Treatment

Winnie was hospitalized in isolation and treated with 0.9% NaCl (30 mL/hour, IV), nebulization for 15 minutes q8h, clavulanic acid-amoxicillin (13.5 mg/kg PO q12h) and lubricating eye ointment (1 inch OU q4h). Clinical improvement occurred a day later and electrolyte abnormalities normalized. When the dendritic ulcers were detected, idoxuridine (0.1% ophthalmic solution, 2 drops OU q4–6h) was prescribed. Unfortunately, the owner was away for the next month, and the idoxuridine was not regularly administered by the dog's caregiver. At a recheck 5 weeks after the dog was first seen, the owner reported 80% improvement in Winnie's respiratory signs although he continued to sneeze approximately six times a day and was still pawing at his eyes. There was persistent conjunctival hyperemia and a fluorescein stain showed large, superficial areas of uptake over the central cornea OU (see Fig. 28.1). STT was 13 mm/minute OS and 8 mm/minute OD. A CBC was normal and the serum biochemistry profile showed persistently increased ALP (835 U/L) and GGT activities (12 U/L) and improvement in the serum ALT activity (124 U/L). The owner was instructed to administer idoxuridine as directed for an additional 2 weeks, as well as lubricating ointment, bacitracin-neomycin ophthalmic ointment (q8h OU), and L-lysine gel (2 mL [400 mg] q12h PO), separating the ophthalmic medications with administration of the idoxuridine first. At a recheck 2 weeks later, all signs had resolved. STT results were 14 mm/minute OS and 10 mm/minute OD, and there was no uptake of fluorescein. The idoxuridine was discontinued. Winnie had another episode of respiratory signs 4 months later, at which time the STT results were 15 mm/minute OU. Treatment with lubricating eye ointment and L-lysine was continued.

Comments

This is an unusual case of ocular and respiratory herpesviral infection. The early detection of dendritic ulcers allowed a definitive connection to be made between the clinical signs and positive PCR assay result. The negative PCR assay results for other respiratory pathogens do not rule out the possibility of co-infections with these organisms, because shedding of these organisms may have ceased or be at undetectable levels. Approximately 2 years later, mild serous nasal discharge returned which progressed to depigmentation of the planum nasale. A biopsy of the nasal planum showed epitheliotropic lymphoma. He was treated with multiagent chemotherapy for over a year without recurrence of the ocular signs.

Canine Parvovirus Infections and Other Viral Enteritides

Colin R. Parrish, Jane E. Sykes

KEY POINTS

- First Described: 1978, worldwide, Appel and others.[1]
- Cause: CPV-2 variants (family *Parvoviridae,* subfamily *Parvovirinae,* genus *Protoparvovirus*)
- Affected Hosts: Dogs and other members of the order Carnivora, including coyotes, foxes, wolves, raccoons, otters, coatis, as well as occasional infections of large and small cats.
- Geographic Distribution: Worldwide.
- Route of Transmission: Direct contact with virus in feces and vomitus as well as contact with contaminated fomites.
- Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration. Sudden death or tachypnea due to myocarditis occurs rarely and only after infection of neonatal animals.
- Differential Diagnoses: CDV infection, other canine viral enteritides, dietary indiscretion, toxins, GI foreign body, enteric parasitic infections such as giardiasis and helminth infections, enteric bacterial infections such as salmonellosis, salmon poisoning disease, pancreatitis, hypoadrenocorticism, inflammatory bowel disease.
- Human Health Significance: CPV-2 variants do not infect humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

CPV is the most widely recognized cause of transmissible viral diarrhea in dogs and one of the most common infectious diseases of dogs worldwide. It is caused by variants of CPV-2, which are members of the genus *Protoparvovirus*. CPV-2 emerged in the early to mid-1970s and caused a worldwide pandemic of illness in dogs in 1978.[2] The spread of the virus worldwide occurred over a remarkable period of about 6 months. CPV-2 may have been derived from virus related to feline panleukopenia virus (FPV); the first strain recognized was replaced by a mutant that was called CPV-2a during 1979 and 1980, and there have been a number of additional mutations in the viruses, although those are of unknown significance.[3,4] The more recent strains derived from CPV-2a may occasionally cause feline viral enteritis.[5–7] Feline parvoviral enteritis is further discussed in Chapter 30. CPV-2 variants are distinct from another parvovirus—canine bocavirus (previously, canine minute virus). That virus appears to have minimal pathogenic potential, although in the past it has been suggested to be associated with abortion in pregnant dogs or occasional disease in neonatal or adult dogs.[1,8–10]

Parvoviruses are small, nonenveloped, single-stranded DNA viruses (Fig. 29.1A) that can survive for long periods (months) in the environment under cool moist conditions. As a result, environmental and fomite transmission are important, likely including mechanical transfer by insects or rodents. CPV requires the presence of mitotically active cells in order to replicate so that there is a relationship between the ages of animals and the severity of clinical disease. Young animals (6 weeks to 6 months, but especially those less than 12 weeks of age) are more likely to develop severe illness; however, disease may also occur in unvaccinated or improperly vaccinated adult dogs. In North America, certain breeds (including Rottweilers, American pit bull terriers, Doberman pinschers, English springer spaniels, and German shepherd dogs) appear to be at increased risk for development of severe parvoviral enteritis,[11,12] but this appears not to be the case in other geographic locations. A seasonal distribution of disease has been reported in some geographic locations, which may reflect times when more puppies are present, or when dogs access the outdoors and contact virus in the environment. For example, in Saskatoon, Canada, dogs were three times more likely to be admitted with parvoviral enteritis in July, August, and September, compared with the rest of the year.[12] In Australia, increased case numbers were associated with warmer weather and lower rainfall.[13] In other studies, the seasonal pattern of disease differed or was nonexistent.[14,15] For dogs older than 6 months of age, intact males were twice as likely as females to develop parvoviral enteritis.[12] Surveillance studies from Australia also found a correlation between clusters of parvoviral enteritis and regions of relative socioeconomic disadvantage, which may be associated with use of vaccines and number of vaccinations given, while the treatment given varied with the socioeconomic status of the owners.[13,14,16]

A variety of viral pathogens have been shown or suggested to be associated with enteritis and diarrhea in dogs, including CDV (see Chapter 22), canine enteric coronavirus (Fig. 29.1B), rotavirus, astrovirus, adenovirus, calicivirus, and novel viruses that include noroviruses, sapovirus, kobuvirus, and possibly also a circovirus.[17–23] While some of these viruses appear to be common infections, they vary in their ability to cause clinical disease on their own. A variety of strains of canine norovirus have been detected in young dogs with diarrhea worldwide, as well as healthy dogs, with a prevalence of infection in dogs with gastroenteritis that has ranged from 2% to 40%.[18,23] Canine enteric coronavirus primarily causes mild diarrhea in puppies that are less than 6 weeks of age and may also be found in co-infections with other viral causes of gastroenteritis, including CPV-2 variants. Rarely, it has been associated with more significant diarrhea in young dogs or neonates.[24–26] This chapter focuses on canine parvoviral enteritis, which is the most widely recognized and pathogenic viral enteritis of dogs.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Transmission of parvovirus and other viral causes of gastroenteritis occurs by the fecal-oral or oronasal routes, after exposure to virus in

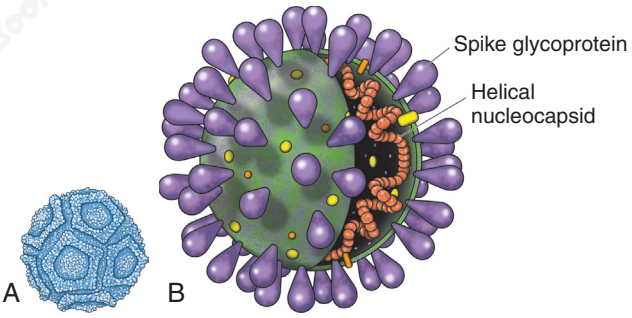

Fig. 29.1 (A) General structure of canine parvovirus. The virus is nonenveloped, 26 nm in diameter, and has icosahedral symmetry. (B) Structure of a coronavirus, which is an enveloped virus. Canine parvovirus is about one quarter the size of a coronavirus.

feces or vomit, or to virus persisting on fomites. Virus is shed for a few days before the onset of clinical signs, and shedding declines considerably after immune responses develop around 7 days.[27,28] The severity of clinical signs likely depends on stressors such as weaning and overcrowding, maternal antibody, and the presence of concurrent infections such as other enteric viral and parasitic infections. Mild or subclinical infections are probably widespread.

The incubation period for canine parvoviral enteritis is likely between 4 and 7 days. The virus initially replicates in the oropharyngeal lymphoid tissues, then free virus spreads widely in the plasma. Virus-infected lymphoid cells also may carry the virus around the body.[28] In older animals the virus will infect, replicate in, and kill rapidly dividing cells, which in puppies are found in higher proportions in the GI tract, thymus, lymph nodes, and bone marrow. Affected GI tissues include the epithelium of the tongue, oral cavity, esophagus, and intestinal tract, and especially the germinal epithelial cells of the small intestinal crypts. The destruction of the intestinal epithelium results in shortened crypts and incomplete epithelial coverage, resulting in loss of fluid regulation and diarrhea. Malabsorption and increased intestinal permeability result. Neutropenia results from not only infection of the marrow but also sequestration of neutrophils in the damaged GI tissue. Secondary bacterial infections of the GI tract, which may be followed by bacterial translocation, bacteremia, and endotoxemia play a key role in the pathogenesis of the disease. Mucosal candidiasis has also been described in puppies with parvoviral enteritis (see Chapter 85).

The outcome is clinical signs of fever, lethargy, inappetence, vomiting, diarrhea, rapid dehydration, and abdominal pain. Diarrhea is often liquid, foul-smelling, and may contain streaks of blood or frank blood. Dogs with canine parvoviral enteritis have evidence of disordered coagulation, with decreased antithrombin activities, prolonged APTT, increased thromboelastography maximum amplitude, and increased fibrinogen concentrations. Catheter and organ thrombosis may occur.[29] Secondary bacteremia may be associated with multiple organ failure and death.

Infection of the dam by CPV-2 variants early in gestation can lead to fetal infection that results in fetal death, resorption, or abortion, although these infections are rare due to the immunity that is found in most bitches by the time they are bred, which would prevent infection. Puppies infected *in utero* late in gestation or which lack maternal immunity and infected up to 2 weeks after birth may develop viral myocarditis due to viral infection of the dividing myocardial cells, which can result in sudden death or congestive heart failure.[30–32] Damage to the developing myocardium usually occurs up to the first 2 weeks of life, but clinical signs of myocardial damage may be delayed until up to 2 months of age. Cerebellar hypoplasia has been rarely reported in dogs after *in utero* infection,[33] but is more common in kittens infected

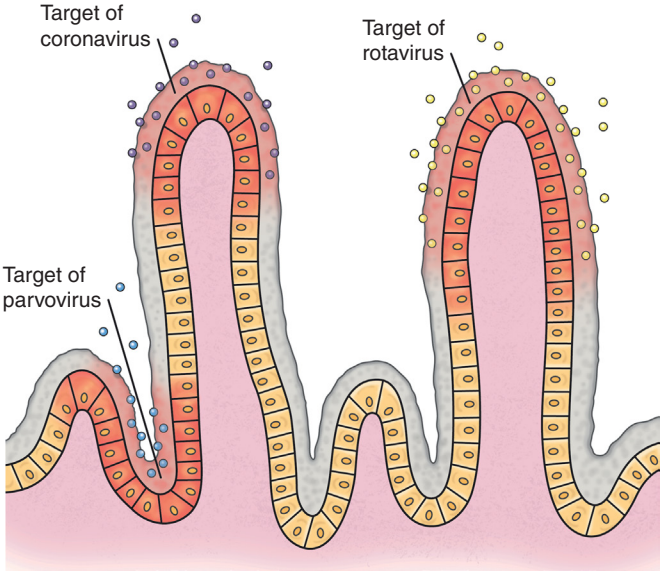

Fig. 29.2 Target sites of replication of selected enteric viral pathogens. The most pathogenic enteric viruses, such as canine parvovirus, replicate and destroy crypt epithelial cells.

with FPV (see Chapter 30). Generalized infection in neonatal puppies is rare, but when present may result in hemorrhaging and necrosis within the brain, liver, lungs, kidneys, lymphoid tissues, and GI tract.[34]

Neurologic signs in puppies with parvoviral enteritis may result from hypoxia secondary to myocarditis, hypoglycemia, or intracranial thrombosis or hemorrhage. The possibility of co-infection with CDV should also be considered.

In contrast to CPV-2 variants, the replication of less pathogenic enteric viruses is restricted to the intestinal tract, and the crypt epithelial cells are generally spared (Fig. 29.2). Canine enteric coronavirus, for example, infects the mature enterocytes at the tips of the villi. Crypt cell hyperplasia occurs to replace the damaged cells. The villi become shortened or distorted, which leads to malabsorption and diarrhea.

Physical Examination Findings

Physical examination of puppies with parvoviral enteritis often reveals fever (up to 41°C or 105°F), lethargy, weakness, dehydration, and abdominal tenderness and a fluid-filled intestinal tract on palpation (Fig. 29.3). Vomiting or diarrhea may occur during the examination, or there may be evidence of diarrhea or frank blood on the perineum or the rectal thermometer. Abdominal palpation may reveal a tubular mass as a result of intestinal intussusception. Ulcerative glossitis can occur in some puppies. Mucosal pallor, prolonged capillary refill time, or rarely hypothermia may be observed in some dogs.[35] Septic shock may be associated with tachycardia or bradycardia, mental obtundation, and poor pulse quality. Uncommonly, neurologic signs such as tremors and seizures are observed. Puppies with myocarditis may be tachypneic and have increased lung sounds as a result of congestive heart failure. Erythema multiforme has been reported in dogs with canine parvoviral enteritis; these dogs had generalized cutaneous and mucosal ulceration as well as swelling of the pinnae and paws.[36,37]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

The most common abnormalities found on the CBC are leukopenia, neutropenia, and lymphopenia (Table 29.1). Toxic neutrophils and

monocytopenia may also be present. Only around one third of dogs had leukopenia in one study.[15,35] Leukopenia can develop after the onset of GI signs when puppies are first brought for examination. Some dogs have leukocytosis due to neutrophilia and monocytosis. Although the presence of leukopenia supports a diagnosis of parvoviral enteritis, other severe GI infections such as salmonellosis can also cause leukopenia and diarrhea, so it is not specific for parvoviral enteritis. Thrombocytosis or, less commonly, thrombocytopenia may also occur.[15,35] Some puppies develop anemia as a result of GI blood loss, which may be nonregenerative or become regenerative.

Fig. 29.3 Obtundation in a 3-month-old intact male standard poodle puppy with canine parvovirus enteritis. The dog had been vaccinated for canine parvovirus at 8 and 10 weeks of age.

Serum Biochemical Tests

The serum biochemistry panel in dogs with parvoviral enteritis often shows hypoproteinemia, hypoalbuminemia, and hypoglycemia. Mild hyperglycemia has also been reported. Electrolyte abnormalities such as hyponatremia, hypochloremia, and hypokalemia may occur (Table 29.2). Occasionally severe dehydration results in prerenal azotemia. Puppies with bacterial sepsis may develop increased liver enzyme activities and hyperbilirubinemia.

Coagulation Profile

Coagulation abnormalities have been reported in a small number of dogs with parvoviral enteritis. When abnormalities occur, findings include prolonged APTT, decreased antithrombin activity, increased fibrinogen concentrations, and increased thromboelastography maximum amplitude.[29] An increase in D-dimers or fibrin degradation products has not been reported. More research is warranted to understand the range of coagulation abnormalities that can occur in parvoviral enteritis.

Diagnostic Imaging

Plain Radiography

Plain abdominal radiography in dogs with parvoviral enteritis may show poor serosal detail (often due to lack of intra-abdominal fat in puppies) and a fluid- and gas-filled GI tract. Abdominal radiography is usually performed to assess for the presence of a GI foreign body.

Sonographic Findings

Findings on abdominal ultrasonography in canine parvoviral enteritis are nonspecific but can include a thickened GI mucosa, mild peritoneal effusion, fluid distention of the GI tract, and decreased GI motility. Mild mesenteric lymphadenomegaly may be present. Abdominal

TABLE 29.3 Diagnostic Assays Available for Canine Parvoviral Enteritis in Dogs

Assay	Specimen Type	Target	Performance
Fecal antigen ELISA	Feces	CPV antigen	Specificity for detection of virus nears 100%, but weak positives based on detection of vaccine virus may occur after immunization with attenuated live vaccines. False negatives are common (low sensitivity).
Hemagglutination assay	Feces	CPV antigen	Inexpensive and rapid. Sensitivity and specificity in naturally infected dogs unknown, but high titers are diagnostic if confirmed by hemagglutination inhibition with a specific antibody.
Histopathology	Usually necropsy specimens, especially gastrointestinal tissues	Crypt necrosis (sometimes with rare intranuclear inclusions); parvovirus antigen with IHC or parvovirus DNA with *in situ* hybridization	Can be used for diagnosis at necropsy.
PCR	Feces, tissue species	CPV DNA	Sensitivity and specificity vary depending on assay design. Attenuated live vaccine virus may be detected in feces for days to weeks after vaccination. Because of the high sensitivity of some assays, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of inhibition of PCR by components of feces.
Fecal electron microscopy	Feces	Virus particles	Not widely available, turnaround time can be slow, and may be expensive. Requires the presence of large amounts of virus.
Virus isolation	Feces, tissues	CPV	Difficult, not widely available. Used as a research tool.

CPV, canine parvovirus (refers to CPV-2 variants); *ELISA,* enzyme-linked immunosorbent assay; *IHC,* immunohistochemistry.

ultrasound is useful to confirm a diagnosis of secondary intestinal intussusception.

Microbiologic Tests

Diagnostic assays for canine parvoviral enteritis in dogs are listed in Table 29.3.

Fecal Parvovirus Antigen ELISA

The most widely used assay for diagnosis of canine parvoviral enteritis is a POC fecal antigen assay, which is performed on a rectal swab specimen. Several assays are available, and those are often based on specific antibodies to capture and detect the viruses in the feces. Although the details are proprietary, tests are generally updated regularly to ensure that all currently circulating strains that vary in antigenicity are detected.[38] Sensitivities of the different tests may vary, and false negatives are common due to viral shedding being transient, and also later after infection antibodies may bind to the viral antigen in the feces and block their reaction with the antibodies in the assay.[39,40] The sensitivities of three commercially available fecal antigen assays (SNAP Parvo test, IDEXX Laboratories GmbH, Germany; FASTest Parvo Strip, Scil Animal Care Company GmbH, Germany; Witness Parvo Card, Selectavet GmbH, Germany) were 50%, 40%, and 60%, respectively,

when compared to immunoelectron microscopy, and 18%, 16%, and 26%, respectively, when compared with results of a fecal PCR assay.[38] Fecal PCR using quantitative PCR is generally more reliable, where high levels of viral DNA indicate infection (see below). A fecal antigen test for detection of CPV in specimens that contained high CPV DNA loads ($>10^5$ copies/mg of feces as determined with real-time PCR) showed 80%, 78%, and 77% positives, respectively.[38]

Comparison with PCR and immunoelectron microscopy of stool showed the specificities of the three commercially available antigen assays above were 98%, 98%, and 92%, respectively,[41] so false positives were uncommon. False-positive antigen tests can occur 4 to 8 days after vaccination with attenuated live CPV-2 vaccines, when virus is shed in feces in low amounts, but those are uncommon.[42,43]

Hemagglutination Testing

CPV agglutinates erythrocytes, and so the presence of the virus in stool can be detected with a simple hemagglutination test that involves mixing a suspension of feces with porcine or feline erythrocytes. Agglutination of erythrocytes in a microwell plate or on a slide may indicate the presence of parvovirus in the feces.[44,45] The presence of CPV as the hemagglutinating virus should be confirmed using a hemagglutination inhibition test with specific antibodies against the virus.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays for detection of CPV-2 variants and other enteric viral pathogens (such as CCoV) are now the test of choice and may detect as few as 1,000 copies of viral DNA per milligram of stool, with fast turnaround times. PCR assays will detect virus when fecal antigen tests are negative or when canine enteric coronavirus infection is a potential cause of illness. However, true-positive PCR assay results for CPV can occur in dogs without signs of gastroenteritis or in dogs with chronic diarrhea, so that confirming the role of any specific virus will depend on the quantity of viral DNA detected and other diagnostic criteria. Attenuated live vaccine virus can also be detected in the feces with PCR assays after vaccination, although assays have been designed that can differentiate between vaccine and wild-type virus.[46] False-positive PCR results occur on occasions after vaccination,[43,45] although in some of the studies conducted many of the post-vaccination viral DNA were of natural infections and not the vaccine. Quantitation of virus loads in feces using real-time PCR is helpful for interpretation of the significance of a positive PCR assay result.

Fecal Electron Microscopy

Fecal electron microscopy is still offered by some institutions for diagnosis of viral enteritis, and may also facilitate diagnosis of other viral infections such as rotavirus, norovirus, and coronavirus infections. Large amounts of virus must generally be present for results to be positive, and skilled operators are required to accurately identify viruses present.

Virus Isolation

CPV variants can be isolated in canine and feline cells, but is relatively slow and expensive compared with other methods of virus detection.

Serology

Antibodies to CPV-2 can be measured in the laboratory using HI (see Chapter 2). In addition, POC ELISA assays are available for semiquantitative measurement of antibodies to CPV-2. These assays are generally used to assess the need for vaccination, rather than for diagnosis of CPV-2 enteritis.

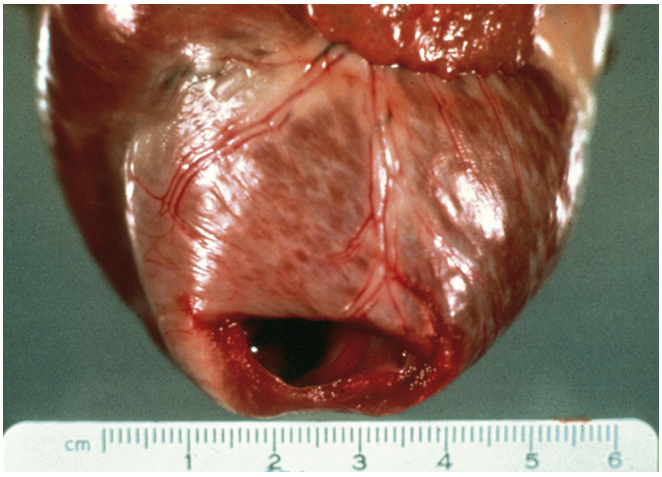

Fig. 29.5 Heart from a dog that died with canine parvovirus-2 myocarditis. Pale streaking of the myocardium is present. (Courtesy Pfizer Animal Health, Lincoln, NE.)

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with CPV enteritis include thickening and discoloration of the intestinal wall with serosal hemorrhage (Fig. 29.4) and enlarged, edematous abdominal lymph nodes. The intestine may contain bloody liquid contents, and mucosal hemorrhage may be identified. Pale areas may be seen within the myocardium of dogs with parvoviral myocarditis (Fig. 29.5).

Histopathologic Findings

The major histopathologic finding in severely affected dogs is necrosis of the crypt epithelium in the small intestine, with widespread systemic lymphoid depletion and necrosis. The crypts of the small intestine are often dilated and distended with cellular debris and mucus (Fig. 29.6), along with signs of proliferation of crypt enterocytes. Intestinal villi are collapsed, shortened, and fused, with attenuation of the epithelial lining, and there may be mild to severe fibrinous inflammation and hemorrhage. Myeloid depletion may be found in the bone marrow.

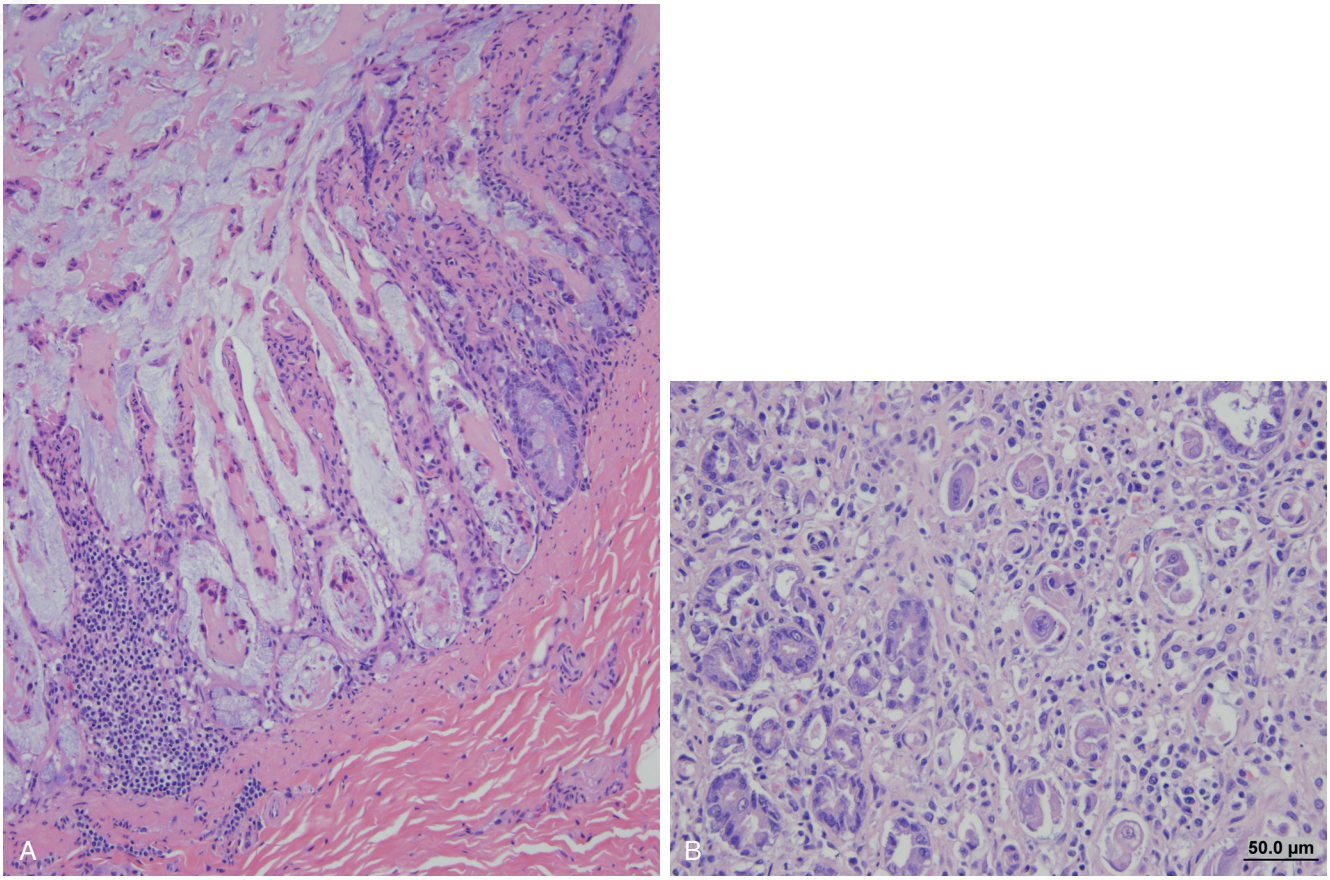

Fig. 29.6 (A) Segmental crypt necrosis in the ileum of a dog infected with a CPV-2 variant. There is severe loss of crypt epithelial cells. Hematoxylin and eosin (H&E) stain. (B) Jejunum of a dog after infection by a CPV-2 variant. Regenerating epithelial cells, which here are nested in an inflamed jejunal lamina, have a large and bizarre appearance and resemble adenoma cells. As a result, the disease has been termed *adenomatosis*. Parvovirus antigen was no longer detectable by immunohistochemistry at this stage. The crypts in the bottom left corner have a more normal appearance. H&E stain. (Courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

Parvoviral myocarditis is generally a chronic condition that develops over a few weeks and is characterized by myocardial degeneration and necrosis, with a lymphocytic inflammatory infiltrate. Myocardial fibrosis can also be present. Rarely, CNS lesions consisting of leukoencephalomalacia have been described.[47] Viral intranuclear inclusions may be visible in some cells, especially the intestinal crypt epithelium. IHC and immunofluorescence can be used to detect viral antigen in the GI tract, marrow, lymphoid tissues, and rarely in the myocardium.[28] *In situ* hybridization (see Chapter 6) can also be used to detect virus in histopathology specimens and may have greater sensitivity than IHC.[48,49]

TREATMENT AND PROGNOSIS

Antimicrobial Treatment and Supportive Care

Treatment of CPV enteritis involves supportive care and treatment of secondary bacterial infections with antimicrobial drugs (Table 29.4). Whenever possible, the patient should be hospitalized in isolation as they may be shedding high levels of virus. Appropriate fluid therapy and maintenance of adequate blood glucose concentrations are the most critical aspects of treatment. Whenever possible, fluids should be given intravenously and supplemented as needed with potassium chloride and dextrose. Blood glucose concentrations should be monitored at least twice daily, and more frequent monitoring may be indicated if hypoglycemia is present. Although not generally recommended for puppies that are vomiting or dehydrated, administration of subcutaneous fluids and antimicrobial drugs in the home can result in recovery when client finances do not permit treatment in hospital.[50] Fluids administered subcutaneously should never be supplemented with dextrose, because dextrose is hyperosmotic and can cause further dehydration, as well as injection-site reactions. In one study of an outpatient protocol, 50% of 20 puppies required dextrose supplementation and 60% required potassium supplementation.[50]

An antimicrobial drug or drug combination with activity against gram-negative and anaerobic bacteria should be administered parenterally. Injectable ampicillin or cefazolin alone may be sufficient for many dogs, but puppies that have hemorrhagic diarrhea or evidence of sepsis should probably be treated with a combination of a penicillin and a fluoroquinolone, or a combination of a penicillin and an aminoglycoside. Use of fluoroquinolones in young, rapidly growing animals has been associated with cartilage damage (see Chapter 10), but when used for the short periods of time required to treat parvoviral enteritis, this may not be of significant concern. Proper hydration is critical before aminoglycosides are used because of their potential for nephrotoxicity.

Treatment with antiemetics (such as a metoclopramide constant-rate infusion, maropitant or parenteral ondansetron), H2 blockers such as famotidine, whole blood or plasma transfusions, colloids such as hetastarch, or partial or total parenteral nutrition may be indicated

TABLE 29.4 Medications that May Be Used in Conjunction with Fluid Therapy to Treat Canine Parvoviral Enteritis

Drug	Dose (mg/kg)	Route	Interval (Hours)
Ampicillin sodium	20	IV	6
Cefazolin sodium	20	IV	8
Enrofloxacin[a]	5	IV	24
Ondansetron	0.5 to 1	IV	12
Maropitant citrate	1	SC	24
Metoclopramide	1–2 mg/kg/day	IV	CRI
Famotidine	0.5	IV	12–24

[a]Has been associated with cartilage injury in growing animals. Prolonged use (>7 days) is not recommended. See Chapter 10.
CRI, constant-rate infusion; *IV,* intravenous; *SC,* subcutaneous.

in some dogs. Maropitant (1 mg/kg IV q24h) and ondansetron (0.5 mg/kg IV q8h) were shown to have similar efficacy in parvoviral enteritis.[51] Placement of a central line or multilumen catheter may be necessary in severely ill puppies, but strict sterile technique must be adhered to because of the potential for hospital-associated infection. In general, unless absolutely necessary, invasive surgical procedures and the use of parenteral nutrition solutions should be avoided in puppies with severe neutropenia. Whether plasma or hetastarch is the treatment of choice for dogs with low colloid oncotic pressure requires further study. Plasma may offer benefit over hetastarch in that it contains antibodies from immune dogs, but titers may not be sufficient to be beneficial, and most puppies show evidence of an antibody response within 3 days after onset of clinical signs. Hetastarch has anticoagulant properties that could be beneficial in light of the hypercoagulable state that has been documented in canine parvoviral enteritis, but these effects also have the potential to increase mortality, and hetastarch has been associated with acute kidney injury in critically ill human patients.[52] Early enteral nutrition with a nasogastric feeding tube was associated with reduced hospitalization times in one study, as compared to withholding food until vomiting had ceased (Fig. 29.7).[53] Gastric suction should be performed through the tube before food is administered. One study of 28 dogs with parvoviral enteritis suggested that use of an oral recuperation fluid might be associated with a more rapid return to oral food intake and greater caloric intake when compared with use of water.[54]

Other treatments that have been investigated include anti-endotoxin sera, recombinant bactericidal permeability-increasing (BPI) protein, recombinant granulocyte colony-stimulating factor (G-CSF), recombinant feline interferon-omega (rfIFN-ω, Virbagen omega), serum from immune animals, fecal microbiota transplantation, and oseltamivir. Anti-endotoxin sera, recombinant BPI protein, and human recombinant G-CSF were not found to be beneficial. Although neutrophil counts were higher and hospital times were shorter in dogs treated with recombinant canine G-CSF, survival times in these dogs were decreased.[55] There has been concern that treatment of parvovirus infections with G-CSF might cause harm because the increased cell turnover induced by the drug might promote parvovirus replication. However, in another nonrandomized, prospective, placebo-controlled clinical trial of 62 puppies with parvoviral enteritis, administration of recombinant G-CSF (5 μg/kg daily) was associated with improvement in hematological parameters; all dogs treated with recombinant G-CSF survived, whereas 5 of 31 dogs in the placebo group died.[56] Treatment

Fig. 29.7 Puppy in Fig. 29.3 after placement of a nasogastric feeding tube.

of puppies with parvoviral enteritis with rfIFN-ω in a number of placebo-controlled trials has been associated with reduced disease severity and, in some studies, significantly reduced mortality,[57] but it has not been beneficial for treatment of FPV infections (see Chapter 30 vaccine and wild-type virus). Administration of serum from cats with antibodies to FPV to puppies with parvoviral enteritis did not appear to be beneficial.[58] In a randomized prospective clinical trial of 66 puppies with hemorrhagic diarrhea that were fecal PCR positive for CPV, fecal microbiota transplantation (10 g of feces from a healthy dog diluted in 10 mL of saline per rectum, 6 to 12 hours after admission) was associated with faster resolution of diarrhea and shorter hospitalization times when compared with standard treatment.[59]

Oseltamivir inhibits the neuraminidase of influenza viruses and does not have specific antiparvoviral activity, but it has been suggested for treatment of CPV enteritis. As CPV does not possess a neuraminidase, it has been hypothesized that oseltamivir instead may act on the neuraminidases of bacteria that are normally responsible for secondary bacterial infections in parvovirus enteritis, primarily those of the GI tract. A single prospective, randomized, masked, placebo-controlled trial of 35 dogs with parvoviral enteritis showed that dogs treated with oseltamivir (2 mg/kg PO q12h) had no significant drop in their leukocyte count, whereas untreated dogs had a significant drop in their leukocyte count in the first 5 days of hospitalization.[60] Treated dogs also gained weight during hospitalization, whereas untreated dogs lost weight. However, there was no difference in hospitalization time, clinical scores, morbidity, or mortality between the two groups, and the number of dogs in each group was small. The authors acknowledged the potential concerns that relate to administration of an oral medication to dogs with enteritis, with possible variability in drug absorption.

Given the lack of proof of efficacy of this drug, and restrictions on its use for treatment of human influenza virus infections, its use in dogs is not encouraged. More information on canine G-CSF, rfIFN-ω, and oseltamivir can be found in Chapter 9 of this book.

Prognosis

The prognosis for viral enteritis in puppies varies with the severity of illness and the owners' ability to afford appropriate treatment. Many cases of CPV-2 infection are likely mild or subclinical and not recognized. However, for those that do develop enteritis the survival rates have ranged from 9% in untreated puppies to greater than 90% with aggressive treatment in tertiary referral hospitals.[11,35,61,62] Factors that have been related to mortality include the presence of initial leukopenia or lymphopenia, monocytopenia, neutropenia, and evidence of SIRS.[15,61,63] SIRS was defined as the presence of at least three of the following four criteria: HR greater than 140 beats/minute, temperature above 102.5°F or below 100°F, and WBC counts greater than 17,000 or less than 6,000 cells/μL (see Chapter 123). A 2020 study identified a model that could predict survival based on a combination of plasma antithrombin concentration, serum AST activity, serum lipase concentration, monocyte count, and lymohocyte count.[64] Survival may also be lower in Rottweilers than in other breeds and in young puppies (less than 7 to 12 weeks of age).[60] In Australia, euthanasia was more likely to occur in summer; among pedigree dogs, in hounds, gundogs, and non-sporting breed dogs; and in puppies less than 6 months of age, and if owners were socioeconomically disadvantaged.[16,61] Vomiting and lethargy at admission as well as lymphopenia and hypoalbuminemia have been associated with prolongation of hospitalization times by approximately 2 days.[15] Positive changes in leukocyte counts (and especially lymphocyte counts) as early as 24 hours after admission have been associated with survival.[63] In general, puppies that survive the first 3 to 4 days of treatment make complete recoveries. Complications of infection include bacteremia and septic shock, intestinal intussusception, aspiration pneumonia, and esophageal strictures. Some longer-term association with chronic gastroenteritis has been reported, possibly resulting from the damage to the intestine or from the antibody treatment that is often given.[65]

IMMUNITY AND VACCINATION

Immunity that follows natural infection by CPV-2 variants appears to provide lifelong protection against reinfection, as likely does immunization with attenuated live viral vaccines. Both attenuated live and inactivated CPV vaccines are available. With the possible exception of shelter environments, attenuated live vaccines should never be administered to pregnant bitches because they may cause disease in the developing fetus. If possible, pregnant bitches introduced into shelter environments should be tested for antibody to CPV before vaccination with attenuated live vaccines, and these dogs should only be vaccinated if they test negative. The use of inactivated vaccines is not recommended because of their short duration and low levels of protection, and for breeding bitches, they provide only very low levels of maternal immunity. There is a *window of vulnerability* for CPV-2 infection in puppies, which is the period when maternal antibody interferes with the vaccine virus's ability to replicate and stimulate an effective immune response, but is unable to prevent infection with virulent field virus (see Chapter 20 for a discussion of this concept). Small quantities of attenuated live vaccine virus are shed from the intestinal tract after immunization, but this should not be relied on to immunize other in-contact animals. Protection against challenge with field virus occurs for at least 3 years and likely for life after the initial puppy series is administered (see Chapter 20). Although not documented, exposure of dogs to virus in the environment may serve to boost immunity after vaccination.

The initial immunization series should be given every 3 to 4 weeks from 6 to 8 weeks of age, until no sooner than 14 to 16 weeks (16 to 20 weeks in breeding kennels or contaminated environments) because of persistence of sufficient titers of maternal antibody in some puppies until 16 to 20 weeks of age. After that, a vaccine should be administered at 6 months or 1 year of age, and every 3 years thereafter (see Appendix). Previously, the vaccination at 6 months was recommended at 1 year of age, but as the purpose of this vaccination was to immunize dogs that still retained maternal antibody at 16 to 20 weeks of age, the WSAVA has recommended shifting this to ensure those dogs were not vulnerable for several months (see Chapter 20).[66] Puppies should be isolated in the home environment until 7 to 10 days after the last booster. Attendance at organized puppy classes has been advocated as a way to promote socialization in this period, and currently there is no evidence that such activities increase risk for parvoviral enteritis. Serum antibody titers of at least 1:80 as determined with HI correlate well with protection.

There is some minor antigenic variation among strains of CPV-2 that are circulating among dogs, which have been given various names that include CPV-2a, CPV-2b, CPV-2c, and concern has been raised that currently available CPV vaccines may not provide adequate protection against infection by all CPV strains. However, failure of protection in a successfully vaccinated dog (where the vaccine virus infected and antibodies developed) is rare, and experimental challenge studies have demonstrated strong protection between the different viruses when dogs are immunized, suggesting adequate cross-protection.[67] Whether there are differences in maternal antibody protection of dogs to the different strains is not known.

Both inactivated and attenuated live vaccines are available for prevention or reduction of canine enteric coronavirus infection, but because the disease is generally mild or inapparent and primarily occurs in puppies younger than 6 weeks of age, their use has not been generally recommended.[68]

PREVENTION

Prevention of CPV-2 enteritis requires immunization and appropriate quarantine, isolation, cleaning, and disinfection procedures. Proper immunization provides complete protection against both infection and disease, and should be a central component of any strategy for managing this virus and its infection. Puppies that have not yet been successfully vaccinated should not be introduced into environments where there has been a history of parvoviral enteritis and where adequate environmental disinfection cannot be guaranteed. Environmental decontamination is challenging, and the virus is extremely resistant to many disinfectants, but parvoviruses can be inactivated with a freshly prepared 1 in 30 dilution of household bleach; potassium peroxymonosulfate (Trifectant, Virkon S); accelerated hydrogen peroxide; or high-level chemical disinfectants such as glutaraldehyde and *ortho*-phthalaldehyde, when contact times of at least 10 minutes are used (see Chapter 14 for more information on disinfection). These disinfectants will also inactivate other enteric viruses. Steam cleaning should be used on surfaces that cannot be otherwise disinfected, and dishwashers that attain temperatures of at least 75°C should be used to wash dishes. Even if steam cleaning is not available, thorough cleaning with detergents will reduce viral loads and likelihood of exposure.

For shelters, quarantine periods of 2 weeks have been recommended before introduction of puppies that might be shedding virus because shedding rarely continues for longer than 10 days.[68] The bathing of recovered puppies can help to remove virus that persists on the haircoat. Rodent and insect vector control can also be used to prevent spread of the virus in the environment. Outdoor grassy areas and dirt are difficult or impossible to adequately disinfect, and so only immunized animals should be allowed on these areas. However, virus levels will fall as virus likely becomes bound to soil and inactivated by sunlight. The use of bleach on these areas is not recommended because of adverse environmental effects from runoff.

The prevalence and impact of enteric viral infections can also be reduced through regular removal of fecal contamination, prolonged exposure of contaminated surfaces to sunlight and drying, and elimination of stressors such as overcrowding, transport, poor nutrition, and concurrent infections such as intestinal parasites.

PUBLIC HEALTH ASPECTS

In general, enteric viral pathogens of dogs, including CPV-2 variants, do not infect humans. However, recent detection of human norovirus genogroups in dogs have suggested the possibility of zoonotic transmission. In central Thailand, an outbreak of diarrhea in kenneled dogs and children that were in contact with the dogs was described; norovirus was detected using PCR in the dogs and children, and whole genome sequencing confirmed that virus isolated from the dogs was the same as that isolated from the children (genotype GII.4).[69] Other infectious causes of gastroenteritis in puppies have the potential to be zoonotic, and co-infections with these pathogens can occur, so caution should be maintained when handling puppies with diarrhea. Precautions used in isolation should be sufficient to prevent enteric zoonoses (see Chapter 15).

CASE EXAMPLE

Signalment

"Sam," an 8-week-old intact male Hungarian vizsla puppy from northern California.

History

Sam was acquired 6 days ago from a breeder, and was eating and active at that time. The next day Sam was examined at a local veterinary clinic, and a routine fecal examination revealed infection with *Giardia* and *Isospora* spp. Treatment with sulfamethoxazole was initiated, but 1 day later the puppy developed diarrhea. The next day, lethargy and vomiting were noted. Vomiting and diarrhea occurred every few hours. The diarrhea contained fresh blood and the vomitus consisted of clear, frothy fluid. Inappetence and intermittent vomiting continued for the next 2 days.

Current Medications

None

Other Medical History

Vaccination with an attenuated live CDV, CPV-2, and CPIV vaccine was performed when Sam was 6 weeks of age. There were no other dogs in the household, only one adult cat.

Physical Examination

Body weight: 4.2 kg.

General: Quiet, alert, responsive. Estimated to be 7% to 8% dehydrated, T = 103.4°F (39.7°C), HR = 240 beats/minute, RR = 36 breaths/minute, mucous membranes pale pink and tacky, CRT = 2 seconds.

Integument: Full, shiny haircoat. No ectoparasites were seen.

Eyes, ears, nose, and throat: Enophthalmos and a dry nasal planum were present.

Musculoskeletal: BCS 2/9. The dog was ambulatory, but emaciated and weak.

Cardiovascular: Weak but synchronous femoral pulses. No murmurs or arrhythmias on auscultation.

Respiratory: No clinically significant findings.

GI: No evidence of abdominal pain on palpation. Fluid-filled intestinal tract. Full urinary bladder noted.

Rectal examination: Bloody diarrhea was present on the thermometer. Rectal examination was not performed.

Lymph nodes: All lymph nodes were within normal limits.

Laboratory Findings

CBC: HCT 31.5% (40%–55%), MCV 62.6 fL (65–75 fL), MCHC 35.6 g/dL (33–36 g/dL), WBC 530 cells/μL (6,000–13,000 cells/μL), neutrophils 16 cells/μL (3,000–10,500 cells/μL), lymphocytes 504 cells/μL (1,000–4,000 cells/μL), monocytes 11 cells/μL (150–1,200 cells/μL), platelets clumped but appeared adequate.

Serum chemistry profile: sodium 143 mmol/L (145–154 mmol/L), potassium 3.8 mmol/L (3.6–5.3 mmol/L), chloride 106 mmol/L (108–118 mmol/L), bicarbonate 23 mmol/L (16–26 mmol/L), phosphorus 4.8 mg/dL (3.0–6.2 mg/dL), calcium 10.3 mg/dL (9.7–11.5 mg/dl), BUN 6 mg/dL (5–21 mg/dL), creatinine < 0.2 mg/dL (0.3–1.2 mg/dL), glucose 133 mg/dL (64–123 mg/dL), total protein 4.3 g/dL (5.4–7.6 g/dL), albumin 2.4 g/dL (3.0–4.4 g/dL), globulin 1.9 g/dL (1.8–3.9 g/dL), ALT 22 U/L (19–67 U/L), AST 15 U/L (19–42 U/L), ALP 179 U/L (21–170 U/L), creatine kinase 274 U/L (51–399 U/L), GGT < 3 U/L (0-6 U/L), cholesterol 278 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL), magnesium 2.0 mg/dL (1.5–2.6 mg/dL).

Imaging Findings

Abdominal radiographs: The stomach wall appeared thickened. Numerous round gas opacities were present in a loop of intestine in the right cranial abdomen, which were believed to represent gas in the ascending colon or duodenum. Multiple additional gas opacities were present in a loop of intestine in the mid-right abdomen at the level of the fourth lumbar vertebra. There was reduced serosal detail compatible with the age of the animal. Changes were considered consistent with the presence of gastroenterocolitis.

Microbiologic Testing

Fecal parvovirus antigen ELISA: Negative

Fecal enteric real-time PCR panel: PCR positive for CPV in fecal specimen. PCR negative for *Clostridium difficile* toxin A and toxin B genes, *Cryptosporidium* spp., *Salmonella* spp., and *Giardia* spp. DNA.

Fecal zinc sulfate centrifugal flotation: Negative for parasite ova.

Diagnosis

Enteritis and leukopenia secondary to CPV infection.

Treatment

Sam was admitted to isolation and treated aggressively with IV lactated Ringer's solution that was supplemented with 20 mEq KCl/L, famotidine (0.5 mg/kg IV q12h), ondansetron (0.5 mg/kg IV q12h), ampicillin (22 mg/kg IV q6h), and enrofloxacin (5 mg/kg IV q24h). Because of persistent vomiting, maropitant citrate (1 mg/kg IV q24h) was added as a second antiemetic. Blood glucose concentration was monitored three times daily, but supplementation with dextrose was not required. Bloody diarrhea that contained sloughed intestinal mucosa occurred every few hours for the first 24 hours. The neutrophil count was 9 cells/μL the following day, but by day 4 of hospitalization was 261 cells/μL, with 241 moderately toxic bands/μL and a lymphocyte count of 1,226 cells/μL. There was gradual clinical improvement during this time, and Sam began to ingest small quantities of cottage cheese and rice on day 4. He was discharged from the hospital on day 5.

Comments

Despite the negative fecal antigen ELISA assay, CPV enteritis was suspected in this dog based on the history, clinical signs, and severe leukopenia. The finding of leukopenia and diarrhea is not diagnostic for parvoviral enteritis, because it can also be caused by other severe enteritides such as salmonellosis. The positive fecal real-time PCR assay for CPV supported the diagnosis, but because positive fecal PCR results can occur in healthy dogs with some assays, and also after vaccination, the fecal PCR result alone did not confirm the diagnosis of CPV enteritis. The diagnosis was therefore made on the basis of the combination of findings. The neutropenia in this dog was profound. Infection likely occurred before the owner acquired the puppy because the diarrhea began only 2 days after the puppy was purchased.

Feline Panleukopenia Virus Infection and Other Feline Viral Enteritides

Jane E. Sykes, Colin R. Parrish

KEY POINTS

- First Described: In 1928, Verge and Christoforoni, France.[1]
- Cause: Feline panleukopenia virus (synonym of feline parvovirus; FPV); also canine parvovirus (CPV); (family *Parvoviridae*, subfamily *Parvovirinae*, genus *Protoparvovirus,* species *Carnivore protoparvovirus 1*).
- Affected Hosts: Domestic and wild cats; foxes, mink, and raccoons.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Direct contact with virus in feces, vomitus, and contaminated fomites.
- Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, sudden death. Neurologic signs (primarily due to cerebellar damage) may occur after infection of neonatal kittens.
- Differential Diagnoses: Other feline viral enteritides, toxins, GI foreign body, enteric parasitic infections such as giardiasis and nematode infections, enteric bacterial infections such as salmonellosis, pancreatitis, or inflammatory bowel disease. Congenital CNS defects should be considered in cats with neurologic signs.
- Human Health Significance: FPV is not known to infect humans, but was isolated from monkeys in one outbreak.

ETIOLOGY AND EPIDEMIOLOGY

Feline panleukopenia virus (FPV) is a parvovirus that causes enteritis and panleukopenia in domestic and wild cat species worldwide.[2–4] It has also been associated with disease in raccoons, mink, foxes, and African green monkeys (one outbreak). The virus can also replicate in ferrets without causing disease. Feline panleukopenia is sometimes confusingly referred to as "cat plague" and "feline distemper"; use of these terms is discouraged due to confusion with other diseases. In raccoons and mink, FPV has sometimes been named raccoon parvovirus or mink enteritis virus. FPV is a small, single-stranded nonenveloped DNA virus that is closely related to CPV-2. In contrast to CPV-2, which emerged in the late 1970s, the disease caused by FPV has been known since at least the 1920s.[1] FPV survives for long periods in the environment and resists disinfection, and generally only replicates in dividing cells (see Chapter 29).

Feline panleukopenia most often occurs in cats younger than 1 year of age, but the virus infects unvaccinated or inadequately vaccinated cats of all ages. The ages of affected cats vary from very young (in cases of cerebellar hypoplasia), up to over a year, but average ages of affected cats tend to be lower; in one study the mean was 4 months.[5,6] However, kitten deaths have been reported despite vaccination of kittens, possibly because successful vaccination is prevented by maternal antibodies, and kittens are exposed to large amounts of virus in the environment.[7,8] Outbreaks of panleukopenia in cats correlate seasonally with increases in susceptible newborn kitten numbers. Panleukopenia occurs most commonly in multicat households, and especially in animal shelter environments which contain higher numbers of kittens, and where new kittens are introduced frequently. It can also occur in cats with outdoor exposure, such as for barn, feral, and stray cats, which are most often not vaccinated. In various studies, the prevalence of protective antibody titers to FPV in feral or owned cats has been seen to vary widely, ranging from about 25% to 80%, suggesting both low rates of exposure to the virus and vaccination in some cases.[2,9] In some animal shelters, devastating outbreaks of panleukopenia have led to high mortalities (including euthanasia) of large numbers of cats.[6,10] Contact with other cats may not be present in the history because fomite transmission is so effective.[5] FPV replicates to a limited extent in dogs, but without disease or virus shedding. Some feline panleukopenia results from infection of cats by the related mink enteritis virus or, rarely (in less than 10% of cases), by CPV.[11–13]

Other viral pathogens that have been associated with gastroenteritis in cats include feline enteric coronavirus (see Chapter 31), FeLV, rotavirus, calicivirus, reovirus, and astrovirus. A torovirus-like agent has been associated with a syndrome of diarrhea and protrusion of the nictating membranes in cats.[14] Togavirus-like and picornavirus-like particles have been identified in the feces of Australian cats. Analysis of the feline fecal virome has also revealed the presence of circoviruses, picobirnaviruses, kobuvirus, polyomaviruses, and feline norovirus.[15–17] The clinical significance of many of these viruses as they relate to diarrhea in cats remains uncertain. Feline norovirus (family *Caliciviridae*) was detected in an outbreak of gastroenteritis in a shelter in New York state, where 6/14 8- to 12-week-old cats tested positive using PCR[18]; the virus has also been detected in an apparently healthy cat from Japan[19] and diarrheic cats from South Italy.[20] In the South Italy study, 3/48 (6.2%) of diarrheic cats from shelters tested positive using PCR, whereas 0/57 healthy shelter cats tested positive.[20] In addition, experimental infection of SPF cats was followed by vomiting, weight loss, and diarrhea, with virus shedding in stool for 8 days.[19,21] Molecular characterization of this virus has shown it belongs to genogroup GVI, a genotype that does not normally infect humans. Some feline norovirus and canine norovirus isolates have had high sequence homology, raising the possibility that interspecies transmission might be possible.[22] However, considerable diversity exists among norovirus strains from dogs and cats.[22]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The pathogenesis of FPV infection is similar to that of CPV infection (see Chapter 29). Transmission is by the fecal-oral route, and indirect transmission through contaminated fomites represents the most important means of infection. Like CPV, FPV enters cells using transferrin receptor type-1[23] and replicates in cells that are in the S-phase of the mitotic cycle. Initially, the virus replicates in oropharyngeal lymphoid tissue, after which it disseminates in blood to all tissues as a free virus viremia, as well as through infected lymphocytes. Infection of lymphoid tissues leads to lymphoid tissue necrosis. Infection of the marrow is associated with leukopenia, which is compounded by neutrophil sequestration in damaged GI tissue. The virus also replicates in and kills the small intestinal crypt epithelial cells, resulting in shortening of villi, increased intestinal permeability, and malabsorption.

Subclinical infection is probably widespread, especially in young adult or adult cats. Disease severity depends on combinations of factors such as age, immune status, and concurrent infections with other bacterial, parasitic, or viral pathogens, which increase the turnover rate of intestinal epithelial cells enhancing viral replication and cellular destruction. Co-infections can occur with feline enteric coronavirus, *Clostridium piliforme, Salmonella* spp., FeLV, or astroviruses.[24–27] Disease generally occurs after an incubation period of 2 to 7 days. Infection of kittens or adult cats results in clinical signs of fever, lethargy, vocalization, weakness, and inappetence, which may progress to profound dehydration, vomiting, sometimes watery to hemorrhagic diarrhea, and rapid loss of weight. Some cats develop only anorexia and lethargy, in the absence of vomiting, diarrhea, or leukopenia.[5,10,13] Secondary bacterial infections are associated with more severe signs of disease. Death usually results from complications relating to dehydration, electrolyte imbalances, hypoglycemia, hemorrhage, or bacteremia and endotoxemia.

In the developing fetus or neonate in a nonimmune queen, FPV may replicate in a variety of tissues that are not affected in older animals. Abortion, congenital abnormalities, or infertility can result from infection early in pregnancy, although the queen is generally otherwise unaffected. Later in pregnancy or in neonates up to approximately 1 week of age, viral destruction of Purkinje cells and granule precursor cells located in the cerebellar external granular layer leads to cerebellar hypoplasia (Fig. 30.1). The severity of infection can vary between kittens in a litter. Sometimes a portion of the litter fails to survive and the remainder develop neurologic signs.[28] Signs of cerebellar ataxia are nonprogressive and are most apparent when kittens begin to walk at about 2 to 3 weeks of age, although mentation and appetite are otherwise normal, and these kittens can sometimes make acceptable pets. Other developmental CNS abnormalities have been reported less commonly, and include hydrocephalus, porencephaly (cystic lesions within the cerebral hemispheres), or hydranencephaly (complete replacement of the cerebral hemispheres with cystic lesions). These abnormalities may be accompanied by signs of forebrain damage, such as seizures and behavioral changes. Unlike CPV, FPV appears to be able to infect neurons other than the cerebellar Purkinje cells, which are terminally differentiated cells.[29,30] Ocular lesions can also develop and include retinal folding, dysplasia and degeneration, and optic nerve hypoplasia.

The DNA of FPV has been detected in the myocardium of cats with hypertrophic, dilated, and restrictive cardiomyopathy, but was not detected in a subset of healthy control cats.[31] A study of cats with endomyocardial restrictive cardiomyopathy and myocarditis revealed no evidence of parvoviral DNA in archived heart tissue.[32] Additional studies to assess the role of FPV in feline myocarditis and cardiomyopathy are needed.

Fecal shedding of virus usually lasts for several days, and in some cats, it may persist for up to 6 weeks. However, a longitudinal study of clinically affected shelter kittens showed that shedding as determined using PCR ceased after day 14, suggesting isolation for at least 2 weeks after diagnosis may be needed to control spread.[33] Viral DNA may be detected in tissues by PCR for months or years after infection, but that is likely to be residual from the earlier infection and to be noninfectious.[34]

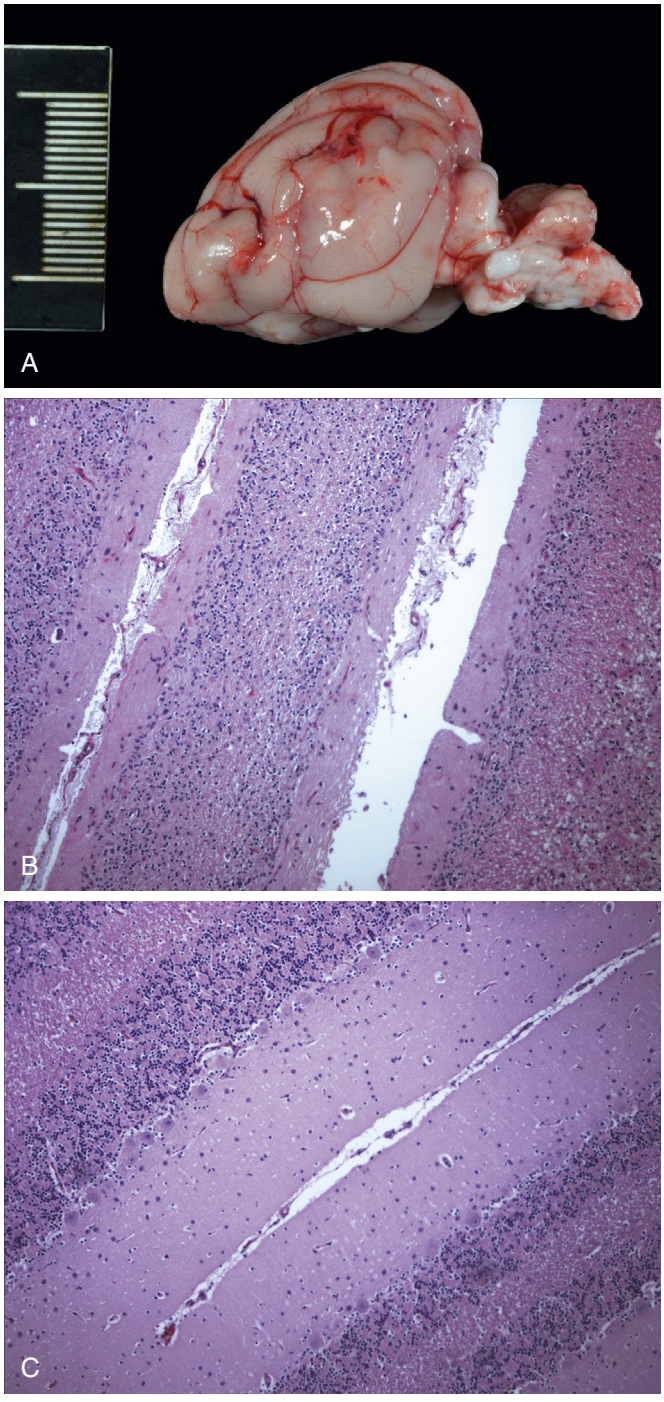

Fig. 30.1 (A) Hypoplasia of the cerebellum in an approximately 10-month-old cat that died of neurologic disease related to feline panleukopenia virus infection. (B) Severe cerebellar hypoplasia in a 1-year-old male neutered domestic short-hair cat that was euthanized for cerebellar signs and seizures. The neurologic signs had been present since the cat was found at approximately 4 months of age. There is a paucity of neurons and glial cells in all layers. (C) Normal feline cerebellum. Note the dramatically increased width of the molecular layer when compared with B. (A, Courtesy University of California, Davis Veterinary Pathology Service.)

Physical Examination Findings

The most common physical examination findings in cats with FPV infection are weakness, lethargy, and dehydration. Fever (103°F to 107°F; 39.5°C to 42.5°C) may be present early in the course of illness. Pain may be noted on palpation of the abdomen, or a hunched posture may be present. The perianal region may be contaminated with feces. Oral ulceration and mucosal pallor may be present in severely affected cats, and rarely, bacteremia may be accompanied by icterus. Terminally, affected cats may be hypothermic, bradycardic, and comatose.

Kittens with cerebellar damage are generally bright and alert but exhibit intention tremors, incoordination, ataxia, hypermetria, a broad-based stance, decreased postural reactions, a truncal sway, and absence of a menace response. Cats with forebrain disease may show abnormal behavior, such as aggression or decreased mentation. Examination of the ocular fundus may reveal folding of the retina, evidence of retinal degeneration with discrete gray spots, and optic nerve hypoplasia. Retinal lesions may be an incidental finding in older, recovered cats, which includes surviving cats with cerebellar hypoplasia.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

The most common abnormality on the CBC in feline panleukopenia is leukopenia, which is due to a neutropenia and lymphopenia (Box 30.1).[5,6,10] Total leukocyte counts may be as low as 50 cells/μL, and toxic band neutrophils may be present. However, in one study only 65% of 187 cats with panleukopenia were leukopenic, so an absence of leukopenia does not rule out FPV infection. Recovery may be associated with lymphocytosis and leukocytosis. Thrombocytopenia and mild anemia are also common. Thrombocytopenia may result from damage to the marrow or, possibly, DIC.

Serum Biochemical Tests

Serum biochemistry analysis may show hypoalbuminemia, hypoglobulinemia, and/or hypocholesterolemia; electrolyte abnormalities such as hyponatremia or hypernatremia, hypochloremia, hyperkalemia, or less commonly hypokalemia; and acid-base abnormalities (see Box 30.1). In severely affected cats, azotemia, increased serum activities of AST or ALT, or hyperbilirubinemia may be present. Hyperglycemia or hypoglycemia may also be identified.

Diagnostic Imaging

Plain Radiography

As in dogs with parvoviral enteritis, abdominal radiography in cats with panleukopenia may show evidence of poor serosal detail and a fluid- and gas-filled GI tract.

Magnetic Resonance Imaging Findings

MRI of cats with neurologic signs due to FPV may reveal evidence of cerebellar agenesis or hypoplasia. Rarely, hydrocephalus, porencephaly, or hydranencephaly can be detected.[28]

Microbiologic Tests

Diagnostic assays available for feline panleukopenia are listed in Table 30.1.

Serologic Diagnosis

Many kittens have maternal antibodies, while varying numbers of older animals have antibodies due to past infection or vaccination, so serology detecting IgG is of limited use for diagnosis of FPV-related disease. However, serologic assays that detect antibody against FPV may be used to assess the need for vaccination, in order to determine which cats are at risk for infection. The gold standard method for FPV serology is hemagglutination inhibition (HI), which measures the ability of serum to prevent agglutination of erythrocytes by the virus (see Chapter 2). Serum neutralization assays may also be used, and there is a relationship between neutralization and hemagglutination titers, with the neutralization assay being more sensitive at lower levels.[35] POC assays designed to detect antibody titers to CPV have a low sensitivity (28%) for detection of antibodies to FPV in cats.[36] A POC assay designed to detect feline antibodies (ImmunoComb Feline VacciCheck Test Kit, Biogal, Galed Labs, Israel) also had a low sensitivity (49%), although specificity was high.[36] The use of this test for risk analysis in shelter situations may therefore lead to inappropriate removal or isolation of cats with results indicating that they lack protective antibody titers (false negative), which might waste resources.[36] However, positive results should reliably indicate protection. The test can be performed quickly (30 minutes) and requires as little as 5 μL of serum or plasma, so provided it is understood that a negative result could mean either a protected or susceptible status, and a positive result equates to protection, the test still has the potential to provide useful information.

Antigen Detection Enzyme-Linked Immunosorbent Assay

FPV can be detected in feces or rectal swabs using antigen assays designed to detect CPV.[37–39] The sensitivity and specificity of these assays varies from one assay to another and with the stage of infection because virus shedding may be transient. In general, false-negative results are common with these assays, but false positives are uncommon, so a positive test result in a cat with consistent clinical signs suggests a diagnosis of feline panleukopenia. The specificity of one POC device (SNAP Parvo, IDEXX Laboratories, Westbrook, ME, USA) was high; 54 of 55 positive assay results were confirmed with a PCR assay. However, in another study, the sensitivity of this assay was low compared with fecal PCR and it was not recommended for monitoring virus shedding.[33] Another study of 52 cats with diarrhea and 148 healthy cats showed variability in the sensitivity and specificity of five different test kits when compared with fecal electron microscopy.[39] Sensitivity ranged from 50% to 80%, and specificity ranged from 94% to 100%. This study included only 10 cats with FPV as determined

BOX 30.1 Prevalence of Laboratory Abnormalities in Cats with Panleukopenia

Leukopenia: 122/187 (65%)
Thrombocytopenia: 83/153 (54%)
Anemia: 91/187 (48%)
Neutropenia: 64/137 (47%)
Lymphopenia: 53/137 (39%)
Hypoalbuminemia: 45/101 (45%)
Hypochloremia: 40/112 (36%)
Hyponatremia: 41/127 (32%)
Hypoproteinemia: 46/153 (30%)
Hyperglycemia: 48/168 (29%)
Increased AST activity: 26/98 (27%)
Hyperkalemia: 30/132 (23%)
Increased BUN: 36/168 (21%)
Hyperbilirubinemia: 19/134 (14%)
Increased ALT activity: 18/135 (13%)
Increased creatinine: 12/155 (8%)
Hypokalemia: 9/132 (7%)
Hypernatremia: 8/127 (6%)
Hypoglycemia: 10/168 (6%)

Modified from Kruse BD, Unterer S, Horlacher K, et al. Prognostic factors in cats with feline panleukopenia. J Vet Intern Med. 2010;24:1271–1276.

TABLE 30.1 Diagnostic Assays Available for Feline Panleukopenia

Assay	Specimen Type	Target	Performance
Canine parvovirus fecal antigen ELISA	Feces	Parvoviral antigen	Sensitivity varies with the assay used and the timing of specimen collection. False negatives are common, but a positive result generally indicates infection.
Histopathology	Usually necropsy specimens, especially GI tissues	Crypt necrosis with intranuclear inclusions; FPV antigen with IHC or IFA	Can be used for necropsy diagnosis
Polymerase chain reaction (PCR)	Feces, tissue samples	FPV DNA	Sensitivity and specificity varies depending on assay design. The extent to which attenuated live vaccine virus can be detected after vaccination is not well understood. Because of the high sensitivity of some assays, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of inhibition of PCR by components of feces.
Fecal electron microscopy	Feces	Virus particles	Not widely available, turnaround time can be slow, and may be expensive. Requires the presence of large amounts of virus.
Virus isolation	Feces, tissues	FPV	Difficult, not widely available. Used primarily as a research tool.

ELISA, Enzyme-linked immunosorbent assay; *FPV,* feline panleukopenia virus; *IFA,* immunofluorescent antibody; *IHC,* immunohistochemistry.

with electron microscopy. Real-time PCR is now more commonly used for laboratory diagnosis of FPV infections. Attenuated live viral vaccines may result in low levels of virus in the feces a few days after vaccination, but positive fecal antigen assay results after vaccination appear to be uncommon, but again vary with the test used.[40,41] There are a number of tests available in different regions of the world, including SNAP Parvo (IDEXX Laboratories) and the Witness Parvo (Zoetis, NJ, USA).

Fecal Electron Microscopy

Fecal electron microscopy is still offered by some institutions for diagnosis of viral enteritis. It may also facilitate diagnosis of other infections such as rotavirus, astrovirus, torovirus, calicivirus, norovirus, and coronavirus infections. Turnaround time may be slow, large amounts of virus must be present for results to be positive, and technical expertise is required to accurately identify virus in the stool. Due to its poor sensitivity and general lack of availability, it is not used for routine diagnosis.

Virus Isolation

FPV can be isolated in feline cells, but is a specialized procedure that takes several days to complete, so it is not commonly used for routine diagnosis.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Specific real-time PCR assays for detection of FPV and differentiation of FPV from CPV-2 variants are now offered by most veterinary diagnostic laboratories as the most sensitive as well as the fastest and cheapest assay. They are generally offered as part of panels that screen for several potential enteric viral pathogens. These assays may be used on whole blood or feces. The extent to which these assays detect attenuated live vaccine virus after vaccination, or residual viral DNA in recovered animals requires further study.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in cats with feline panleukopenia include thymic involution; thickening, distention, and discoloration of the intestinal wall with serosal hemorrhage (Fig. 30.2); and enlarged, edematous mesenteric lymph nodes. The intestine may contain bloody liquid contents, and mucosal hemorrhage may be identified. Hemorrhages may be visible on the surface of other organs as well. In some cats, mild pleural or peritoneal effusion is present. Cats infected

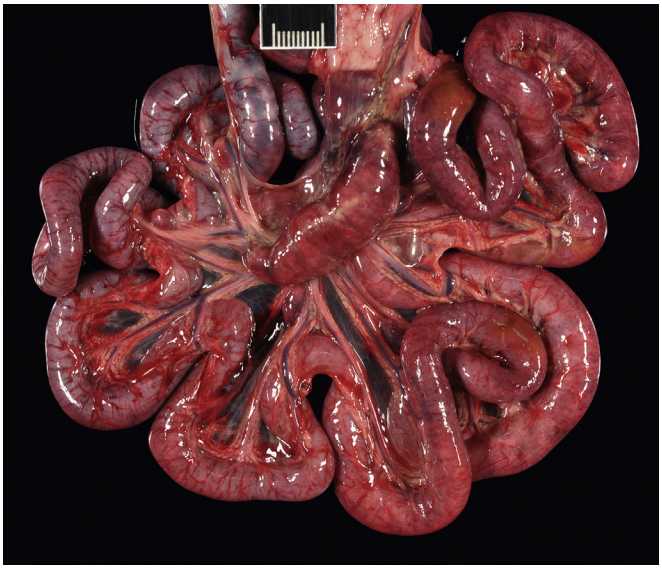

Fig. 30.2 Intestinal tract of a 2-year-old intact female domestic long-hair cat with severe feline panleukopenia. The intestinal loops are dilated and flaccid and discolored red to purple. Ruler = 1 cm.

prenatally may have cerebellar aplasia, or more commonly a small cerebellum (often half to three-quarters normal size).[42,43] Rarely other developmental CNS abnormalities such as hydrocephalus, hydranencephaly, or porencephaly are observed.

Histopathologic Findings

Histopathologic findings in the intestinal tract are similar to those described for CPV-2 infection, with crypt dilation and necrosis of crypt epithelial cells, accumulation of cellular debris, neutrophil infiltration, loss of villi, and submucosal edema throughout the small and large intestines; the jejunum and ileum are usually most severely affected (Fig. 30.3A). Acutely affected cats show widespread lymphoid depletion and there may be hyperplasia of mononuclear phagocytes. Intranuclear inclusions are found in some cats (Fig. 30.3B). Examination of the bone marrow may reveal bone marrow hypoplasia. Examination of the cerebellum shows cellular depletion; reactive astrocytosis may be present. Lymphocytic meningoencephalitis and neuronal necrosis,[44] as well as neuronal vacuolization[45] have been described in some cats. IHC or IFA may be used to document the presence of the virus within tissues (Fig. 30.3C).[46]

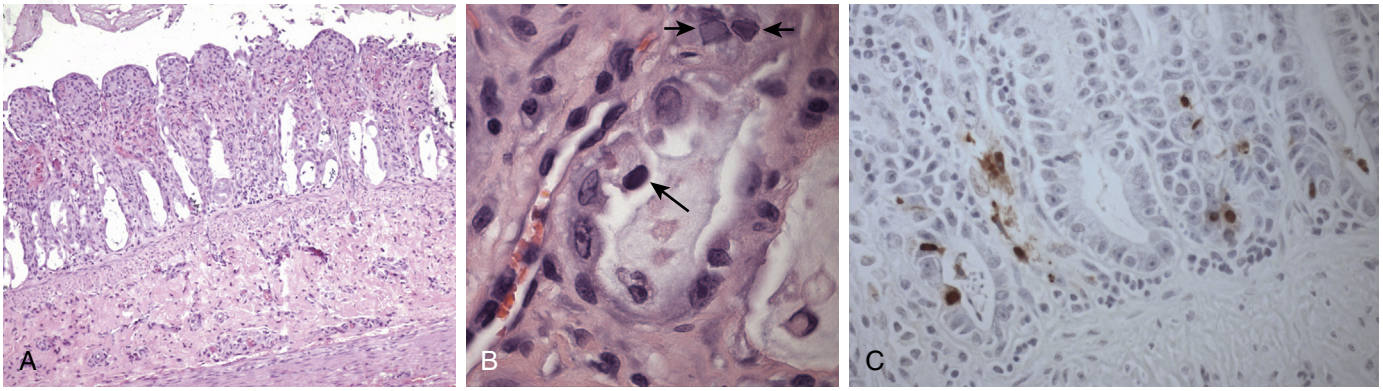

Fig. 30.3 (A) Histopathology of the jejunum from a kitten with panleukopenia. Villi are rounded and blunted with nearly complete epithelial loss and crypt dilation. Hematoxylin and eosin (H&E) stain. (B) Histopathology of the jejunum from a young barn cat that died after several days of profound weakness and neurologic signs. Six other cats in the barn died with the same signs. Mucosal crypts are dilated and contain debris, and intranuclear inclusions are present *(small arrows)*. Another cell *(large arrow)* is foamy and degenerate and has a hyperchromatic nucleus. H&E stain. (C) Same cat as in B. The presence of feline panleukopenia virus in the intestinal tract is confirmed with immunohistochemistry (brown stain). (Courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

TREATMENT AND PROGNOSIS

Antimicrobial Treatment and Supportive Care

Treatment of cats with feline panleukopenia is with supportive care, especially IV crystalloids and parenteral antimicrobial drug treatment as for CPV-2 infections (see Chapter 29). Dextrose supplementation of fluids may be required, and blood glucose concentration should be monitored. Oral intake of food and water should be withheld until vomiting has ceased. Experience with early enteral nutrition has not been reported in cats, and extreme care is warranted to prevent aspiration pneumonia. Antiemetics such as metoclopramide or ondansetron may be effective. In contrast to canine parvoviral enteritis, treatment with rfIFN-ω has not been beneficial for treatment of feline panleukopenia, although increased antibody production and a reduced acute inflammatory response was observed.[47]

Prognosis

While there are an unknown number of mild or subclinical infections, when cats present with clinical disease the prognosis varies. Cats with panleukopenia that survive the first 5 days of treatment usually recover, although recovery is often more prolonged than it is for dogs with parvoviral enteritis. In cats with feline panleukopenia, survival rates vary between around 20% and 50%.[5,6,10] In one study, nonsurvivors had lower leukocyte and platelet counts than survivors, and cats with white cell counts below 1000/μL were almost twice as likely to die than those with white cell counts above 2500/μL. Only total leukopenia, and not lymphopenia, was correlated with mortality. Hypoalbuminemia and hypokalemia were also associated with an increased risk of mortality. Total T4 concentration was the only variable associated with survival in one study, and a cutoff value of 0.82 μg/mL was proposed for distinguishing survivors from nonsurvivors.[48] In contrast to dogs with parvoviral enteritis, mortality in cats with clinical disease does not appear to be correlated with age.

Cerebellar signs in kittens with cerebellar hypoplasia typically do not progress and may improve slightly as a result of compensatory responses from other senses such as vision.[49]

IMMUNITY AND VACCINATION

Recovery from feline panleukopenia is thought to confer lifelong immunity. Effective vaccines are widely available. An intranasal FPV, FHV-1, and FCV vaccine is available; its use has been controversial, because panleukopenia is a systemic disease. An outbreak of salmonellosis and panleukopenia occurred in one cattery that used an intranasal FPV vaccine.[7] No difference was noted in seroconversion rates between five cats vaccinated with the intranasal vaccine and five cats vaccinated with a parenteral attenuated live vaccine, but the number of cats in this study was small. In other studies of larger numbers of cats that were vaccinated with the parenteral vaccines, most seroconverted with protective antibody titers on day 7 and/or 28.[8,50]

Both inactivated and attenuated live vaccine types can induce protective antibody titers after vaccination in a high proportion of cats, although the attenuated live vaccine results in higher and more prolonged protective titers than the inactivated vaccine.[9,41] Provided maternally-derived antibody (MDA) is absent, immunity is present within 1 week after a single vaccination with an attenuated live viral vaccine[8,51] and most likely lasts for life.[52] Nevertheless, two doses, 3 to 4 weeks apart, have been recommended for initial vaccination with attenuated live vaccines in the absence of information about MDA. Two injections are always required for inactivated vaccines, and maximal immunity does not occur until 1 week after the second dose. However, even with an inactivated vaccine, challenge 7.5 years after vaccination was associated with protection.[53] The routine use of inactivated vaccines is discouraged, and those should be reserved for immunosuppressed cats or colostrum-deprived neonates that are less than 4 weeks of age, or when there is a need to vaccinate pregnant cats that are expected to carry the kittens to term. In general, and particularly in shelter situations, the use of attenuated live vaccines is recommended because of the slow onset of immunity and relatively low antibody titers associated with inactivated vaccines.[54] FPV vaccines protect cats against challenge with CPV-2 strains.[55,56] However, cross-reactivity of antibodies induced by FPV vaccination to CPV-2 was lower than that to FPV as determined using HI.[57]

The most common reason for vaccine failure is interference by MDA. Maternal antibody persists from 8 until 12 weeks, and possibly longer in some cats. Virus neutralization titers above 1:10 are likely to interfere with vaccination, and kittens with titers below 1:40 are generally considered to be susceptible to infection by FPV. Kittens should be vaccinated every 3 to 4 weeks from 6 to 8 weeks of age, and it is recommended that the last vaccine in the kitten series be given no earlier than 16 to 20 weeks of age. When there is a history of an outbreak situation, the final booster could be given at 16 to 20 weeks of age.[58,59] A booster should be administered at 6 months to 1 year, and every 3 years thereafter.

Vaccination of pregnant queens with attenuated live viral vaccines can cause cerebellar hypoplasia or fetal losses. The frequency with which this occurs is unknown, as many queens are immune by the time they are bred. As a result, it has been suggested that pregnant queens only be vaccinated with attenuated live FPV vaccines if they are being introduced into a shelter, where most are spayed upon arrival. Otherwise quarantine while immunization with inactivated vaccines should be performed. Alternatively, assessment for protective antibody titers with an in-house test kit (where available) could be performed.

PREVENTION

New kittens should not be introduced into households that previously contained cats infected with FPV unless they are fully vaccinated, or until a period of at least 2 weeks has elapsed along with thorough cleanup of the facilities. In the face of an outbreak, exposed and susceptible kittens may be effectively protected for 2 to 4 weeks through SC or intraperitoneal administration of 2 mL of type-matched serum from cats with a high antibody titer.[60] However, this is only effective when administered before the onset of clinical signs, and it can interfere with subsequent vaccination. For these kittens, it has been recommended that vaccination be withheld for 3 weeks after the serum has been administered. Passive immunization may be useful when cats are introduced into a shelter situation where a known problem exists. Repeated treatment with serum should be avoided because hypersensitivity reactions may occur. Prevention of feline panleukopenia should also include proper disinfection with disinfectants that are effective against parvoviruses, such as bleach, accelerated hydrogen peroxide, or potassium peroxymonosulfate (see Chapter 14) and, in shelter situations, isolation or removal of cats that develop GI illness, and separate housing for healthy kittens (see Chapter 16).

PUBLIC HEALTH ASPECTS

Although FPV is not known to infect humans, a unique strain of FPV was recently isolated from a diarrheic monkey in China that was associated with a large outbreak among monkeys in a colony.[61] This strain was shown to cause panleukopenia in inoculated cats. Whether other enteric viruses, such as some norovirus strains, can be transmitted between companion animals and people, remains unclear. One study that looked at a diverse array of animal noroviruses concluded that there was more evidence of human noroviruses in animals than animal noroviruses in humans, suggesting the possibility of reverse zoonoses.[62]

CASE EXAMPLE

Signalment

"Callie," a 2-year-old female intact domestic long-hair cat from Woodland, CA.

History

Callie was brought to an emergency clinic for acute onset of collapse and severe illness. The current owner had fostered the cat for 1 week after she was found as a stray. The cat had been nursing a litter of kittens. The kittens were 4 weeks old, being weaned and apparently healthy. Since being fostered, the cat had exhibited a progressive decrease in appetite and thirst, and her feces had become soft and pasty. The night before she was brought to the emergency clinic, she had been bathed, and afterwards she vomited bile-stained fluid twice and was placed on a heating pad. The following morning she was found laterally recumbent and minimally responsive.

Physical Examination

Body weight: 2.3 kg.

General: Stuporous mentation, estimated to be 8% to 10% dehydrated, T < 92°F (<33°C), HR = 132 beats/minute, RR = 32 breaths/minute, mucous membranes pale and tacky, unable to assess CRT. Fecal and urinary stains were present around the perineum and on the caudal aspect of the pelvic limbs.

Musculoskeletal: BCS 2/9. Diffuse muscle wasting was present. The cat was laterally recumbent and nonambulatory.

Cardiovascular: Weak femoral pulses. No murmurs or arrhythmias were detected.

GI and urogenital: The abdomen was soft and nonpainful on palpation. Fluid-filled intestinal loops were palpated, and the urinary bladder was small (<5 cm) and soft.

All other systems: No abnormalities were detected.

Laboratory Findings

CBC: HCT 46% (30%–50%), MCV 49.8 fL (42–53 fL), MCHC 30.4 g/dL (30–33.5 g/dL), WBC 150 cells/μL (4,500–14,000 cells/μL), neutrophils 0 cells/μL (2,000–9,000 cells/μL), lymphocytes 141 cells/μL (1,000–7,000 cells/μL), highly reactive lymphocytes 6 cells/μL, monocytes 3 cells/μL (50–600 cells/μL), platelets 32,000 platelets/μL (180,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 141 mmol/L (151–158 mmol/L), potassium 4.0 mmol/L (3.6–4.9 mmol/L), chloride 111 mmol/L (117–126 mmol/L), bicarbonate 23 mmol/L (15–21 mmol/L), phosphorus 6.0 mg/dL (3.2–6.3 mg/dL), calcium 7.4 mg/dL (9.0–10.9 mg/dL), BUN 24 mg/dL (18–33 mg/dL), creatinine 0.5 mg/dL (1.1–2.2 mg/dL), glucose 68 mg/dL (63–118 mg/dL), total protein 3.2 g/dL (6.6–8.4 g/dL), albumin 1.6 g/dL (2.2–4.6 g/dL), globulin 1.6 g/dL (2.8–5.4 g/dL), ALT 125 U/L (27–101 U/L), AST 143 U/L (17–58 U/L), ALP 4 U/L (14–71 U/L), creatine kinase 2,409 U/L (73–260 U/L), GGT < 3 U/L (0–4 U/L), cholesterol 68 mg/dL (89–258 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL), magnesium 2.5 mg/dL (1.5–2.5 mg/dL).

Imaging

An abdominal ultrasound showed marked fluid distention of the small intestines.

Microbiologic Testing

In-clinic ELISA serology for FeLV antigen and FIV antibody: negative.

Treatment and Outcome

Callie was treated with active warming, and a central venous access line was placed. IV crystalloids (four warmed 60-mL boluses of lactated Ringer's solution [LRS], each given over 20 minutes) were administered, after which a venous acid-base panel showed a pH of 7.267 (7.31–7.46), bicarbonate of 17.5 mmol/L (14–22 mmol/L), base excess of –8.1 mmol/L (–4 to +2 mmol/L), pCO_2 of 39.7 mmHg (25–37 mmHg), lactate of 4.5 mEq/L (<2 mEq/L), glucose of 52 mg/dL, potassium of 3.1 mEq/L, sodium of 141 mEq/L, and ionized calcium of 1.17 (1.1–1.4 mmol/L). A dextrose bolus and ticarcillin-clavulanic acid (22 mg/kg, q6h, IV) were administered. The cat repeatedly vomited blood-tinged fluid, and so treatment with metoclopramide (0.02 mg/kg/hour) and famotidine (0.5 mg/kg, IV, q12h) was initiated. Aggressive crystalloid fluid therapy was continued (LRS supplemented with 30 mEq/L KCl and 2.5% dextrose), and treatment with hetastarch was also initiated. Systolic blood pressure (Doppler) was 60 to 90 mmHg, HR increased to 170 beats/minute, and rectal temperature increased to 100°F. When the CBC results were available, the cat was placed in the isolation ward.

Pasty diarrhea that contained sloughed mucosa occurred every 1 to 2 hours, which transitioned to liquid red feces over 24 hours. A CBC again showed absolute neutropenia and 15,000 platelets/μL. After another 24 hours, the cat's condition deteriorated despite aggressive treatment and monitoring. Partial parenteral nutrition was initiated. That evening, pyrexia developed (104.6°F) as well as tachypnea and increased respiratory effort. The owner elected euthanasia. The cat regurgitated approximately 200 mL of dark brown fluid at the time of euthanasia.

CASE EXAMPLE—cont'd

Gross Necropsy Findings

In the peritoneal cavity, 10 mL of semiopaque red fluid was present. Streaks of hemorrhage were noted throughout the skeletal muscle. Between the pylorus and the ileocecocolic junction, the serosa of the small intestinal tract was dark red to purple to black (see Fig. 30.2). The entire small and large intestinal tract was dilated and flaccid. The small intestinal mucosa was dark red to purple and contained a small amount of dark red mucoid material. The mesenteric lymph nodes were prominent, and their cut surface was discolored red to dark pink. The liver was pale yellow and extended beyond the costal arches. Numerous petechial hemorrhages were present on the serosal surface of the urinary bladder.

Histopathologic Findings

Within the duodenum, jejunum, and ileum, there was severe, subacute, diffuse necrotizing and fibrinohemorrhagic enteritis. The villi were necrotic, fused, and markedly blunted with a minimal inflammatory response. Necrosis extended into the crypts, and there was some evidence of a regenerative response that included enterocyte hypertrophy, karyomegaly, and rare mitotic figures. Mixed bacteria, which included small gram-negative rods and large numbers of gram-positive cocci, lined and effaced the denuded villi. There was diffuse lymphoid depletion in lymph nodes, as well as the mucosa-associated lymphoid tissue in the cecum and colon. Marked depletion of erythroid and myeloid precursors was present in the bone marrow. There were multifocal areas of hemorrhage in the skeletal and cardiac muscle, intestinal tract, and lungs, as well as fibrin thrombi in the lungs. FPV antigen was identified in intestinal epithelial cells using IHC. Culture of the jejunum for *Salmonella* spp. was negative.

Diagnosis

Feline panleukopenia.

Comments

The cat in this report was a stray with an unknown vaccination history, which demonstrates that severe disease can occur even in adult cats. Antemortem diagnostic testing for FPV with a fecal antigen ELISA assay or PCR assay was discussed with the owner, but was declined because of the high degree of suspicion for the disease and the lack of impact that a positive or negative result would have had on the treatment plan. Secondary bacterial sepsis was suspected. Additional co-infections with other viruses, such as FCoV, or enteropathogenic bacteria could not be ruled out. During the cat's treatment, one of the kittens in the litter died suddenly and the other developed signs of illness.

Feline Coronavirus Infections

Niels C. Pedersen, Jane E. Sykes

KEY POINTS

- First Described: 1963 (Holzworth, 1963)[1]; a viral etiology was not identified until the 1970s.
- Cause: Feline coronavirus (family Coronaviridae, genus Coronavirus).
- Affected Hosts: Cats and wild felids, especially cheetahs.
- Mode of Transmission: Fecal-oral (FECV), internal mutation (FIPV).
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, icterus, tachypnea, uveitis, neurologic signs, abdominal distention due to ascites.
- Differential Diagnoses: Toxoplasmosis, congestive heart failure, carcinomatosis, lymphoma, pancreatitis, rabies, cryptococcosis, bacterial peritonitis, pyothorax, bacterial meningitis, chronic stomatitis, multiple myeloma, FeLV or FIV infection.
- Human Health Significance: Feline coronaviruses do not infect humans.

ETIOLOGIC AGENT

Coronavirus Nomenclature

Coronaviruses have adapted themselves to many species of mammals and birds over the last 10,000 years, a brief period in the evolution of their hosts.[2] The myriad of resultant species, subspecies, clades (strains), and biotypes of coronaviruses are classified in the order *Nidovirales,* family *Coronaviridae,* and subfamily *Coronavirinae*. Members of the *Coronavirinae* are currently divided into four genera: *alpha-, beta-, gamma-,* and *delta-coronavirus.* The species *alphacoronavirus 1* contains the subspecies FCoV, the closely related CCoV, and porcine transmissible gastroenteritis virus (TGEV). SARS-CoV-2 viruses are distinct from feline coronaviruses; they belong to the *betacoronavirus* genus (see Chapter 43).

Feline coronaviruses occur in two distinct serotypes, I and II, based on virus neutralization using antisera to feline coronaviruses and canine coronaviruses.[3] It has been proposed that these be re-classified as clade A and B based on spike (*S*) gene sequencing.[4] Serotype I feline coronaviruses are distinctly of cat origin and are neutralized by antibodies to the predominant field isolates of FCoV, while type II feline coronaviruses are recombinants between type I FCoV and CCoV and are neutralized by CCoV antibodies.[5] Genetic variability in the degree of FCoV/CCoV recombination among modern isolates suggests that they are continuously occurring and evolving.[6] Seroype I feline coronaviruses predominate in Europe and the Americas, while up to 25% of feline coronaviruses from Asian countries are serotype II.[7–9] The recombination that leads to the serotype conversion involves the antibody binding site on the *S* gene that is responsible for virus neutralization and variable parts of the adjacent 3abc, E genes.

Like most RNA viruses, feline coronaviruses are undergoing constant genetic drift due to mutation and recombination, resulting in numerous closely related clades (strains) that genetically differ 10% or more from each other. These clades segregate along environmental and geographic lines.[10–12] One clade will usually predominate in environments where there is little movement of cats, such as shelters,[13] laboratory cat breeding facilities,[14] catteries, or geographic regions.[11]

The definitive classification of feline coronaviruses is the biotype (pathotype). Two biotypes exist in nature: feline enteric coronavirus (FECV) and feline infectious peritonitis virus (FIPV). The biotype names FECV and FIPV were originally assigned to these agents decades ago based on the diseases they caused. The name FECV should be used when referring to the virus found in feces of healthy cats, while the name FIPV refers to the putative virus found in tissues and effusions of cats with FIP.[15] The subspecies name FCoV should be used to describe features shared at the subspecies level. Therefore, the names FECV and FIPV will be primarily used for the rest of this discussion when describing the two vastly different diseases they cause.

Feline Coronavirus Structure and Replication

Coronaviruses acquired their name from the surface projections that resemble a corona or crown (see Fig. 29.1B). The FCoV genome contains a single positive strand of RNA containing 29,000 nucleotides, the longest among RNA viruses. The genome is made up of a single gene (1ab) that encodes for 16 nonstructural proteins involved in genome replication, four genes coding for structural proteins (S, M, N, E), and five accessory genes (3abc, 7ab). Proteins encoded by the accessory genes are not part of the virion structure and are involved in largely unknown host/virus interactions.[16] Coronaviruses employ a highly efficient replication strategy involving the creation of six nested overlapping capped RNAs that mimic cellular messenger RNA, thus enabling subversion of cellular pathways to aid in their replication.[16] Coronaviruses must convert their viral RNA to messenger RNA by an RNA-dependent RNA polymerase (replicase). Virion assembly begins in a replication-transcription complex made up of components of the endoplasmic reticulum and Golgi apparatus. Assembling virions then make their way to the cell surface through membrane structures and are released from the cell surface by exocytosis. This replication strategy is error prone and leads to mutations in single nucleotides, deletions, insertions, and recombination. Such mutations have been the source of genetically distinguishable strains, serotypes, biotypes, and even new subspecies and species.[17–19]

Coronaviruses make initial contact with their host cell membrane through a fusion peptide on the S protein followed by firm attachment between a second ligand on the S protein and a more distantly situated cellular receptor.[20] All group I coronaviruses including TGEV, HCV-229E, and serotype II feline coronaviruses use aminopeptidase N as a cellular receptor, while angiotensin-converting enzyme 2 (ACE2) is the attachment receptor for SARS-CoVs and the related human respiratory CoV NL63.[21–23] Bat and MERS coronaviruses use dipeptidyl

peptidase 4 (DPP4) as a functional receptor. The actual *in vivo* cellular receptors for non-tissue culture–adapted strains of serotype I and II FECVs for intestinal epithelium and corresponding serotype I FIPVs for peritoneal macrophages are unknown.[16] Although it is likely that FECV utilizes conventional coronavirus type receptors to infect mature intestinal epithelial cells, the inability to culture FECV has stifled the search. There is increasing evidence that FIPVs may utilize Fc type receptors to enter host macrophages as immune complexes.[24]

Host Range

FCoV seropositivity, FECV fecal shedding, and/or occasional cases of FIP have been reported in the African lion, mountain lion, leopard, cheetah, jaguar, lynx, serval, caracal, European wild cat, Sand cat, and Pallas cat.[25–32] Although not extensively studied, it is assumed that wild and domestic Felidae are infected with the same FECVs.[33] There is no evidence that either FECV or FIPV is a pathogen of humans. Coronaviruses infecting humans have evolved from animal species other than cats (e.g., HCoV-229E, -MERS, -SARS-I (and likely SARS-CoV-2) from bats and HCoV-OC43 from cattle).[18,34]

EPIDEMIOLOGY

Feline Enteric Coronavirus

FECV was first identified during studies on why healthy cats in multicat environments were seropositive to FIPV but did not develop FIP.[35] The logical assumption was that FIP was an uncommon clinical manifestation of a ubiquitous and largely nonpathogenic coronavirus. Although fecal extracts from healthy cats in such environments caused seroconversion, no cases of FIP occurred. In contrast, a pure tissue culture FIPV caused fatal FIP in 80% or more of experimental exposures.[35] This was the first evidence that FIPV and FECV were distinctly different in their disease potential. Two strains of FECV were ultimately propagated by cat-to-cat passage using fecal extracts. The original FECV strain was designated FECV-UCD[35] and a second isolate FECV-RM.[14] Both strains belong to serotype I and have been used in experimental FECV infection studies.[10,36,37] FECV has proven extremely difficult to propagate in tissue culture because of its strict tropism for mature intestinal epithelial cells.[38,39]

FECV is ubiquitous in cats throughout the world and is enzootic in virtually all larger multicat environments, especially dense urban environment, shelters, sanctuaries, and foster homes with large numbers of kittens.[40] The only place found to be free of FECV has been the Falkland Islands, and attempts are being made to quarantine these cats from outside infection.[41] Over one half of healthy cats and 80% of cats with diarrhea from high-risk environments are fecal shedders over any given time and the shared use of litter pans greatly enhances direct fecal-oral spread. Indirect transmission can occur via fomites that contaminate the fur and are then ingested during grooming. The virus is also readily transmitted via litter dust and on the clothing and person of caregivers.[14,35] Survival in the environment is likely limited to 1 to 2 days, and the virus is susceptible to destruction by routine disinfectants and detergents, as well as prolonged exposure to UV light or drying. The infection rate among strictly outdoor cat populations is unknown, but likely decreases in proportion to population density and increasing age.

Kittens born in nature do not usually shed FECV until after 9–10 weeks of age,[12,42] an age period confirmed by experimental infection studies of kittens born to infected queens.[37,43] Therefore, kittens appear to be protected by some sort of natural immunity for the first months of life, although the exact nature of this immunity is unknown. However, it is most likely to be maternal in origin as it follows the kinetics of maternal protection for other common kittenhood pathogens. Immunity to FECV infection disappears after several months and coincides with the cessation of fecal shedding.[10,37] Secondary and tertiary infections are common in denser multicat environments where kittens are both an important primary target for infection as well as a major source for recurrent infections in older cats.

Feline Infectious Peritonitis Virus

FIP was first described as an "important disorder of cats" in 1963 at the Angell Memorial Animal Hospital, Boston.[1] Cases of FIP were subsequently reported in countries throughout the world.[44] In 1966, it was first proposed that FIP was caused by a virus,[45] and subsequently, virus particles were observed in the tissues of experimentally infected cats.[15] In the early 1970s, the similarities of the virus to members of the family *Coronaviridae*,[46] the recognition of non-effusive and effusive forms of disease,[47] and the neurologic and ocular forms of FIP were described.[48] Virulent FIPV was first propagated in autochthonous macrophage cultures[49] and later in tissue culture.[35,50] FECV was first reported in 1981 in a population of cats with periodic FIP.[35] The theory that FIPV arises within an individual cat as a result of mutation of FECV ("internal mutation") was first entertained in 1987.[51] Sequence-based evidence that FIPVs arose by internal mutation in cats infected with FECV was first published in 1998.[52]

The origin of the virus that causes FIP is unclear, but, like other coronaviruses, it may have originated from a coronavirus from another host species. FIP appeared about a decade after the initial descriptions of transmissible gastroenteritis (TGE) of pigs in North America.[53] Canine respiratory coronavirus (CRCoV) also underwent a similar change in organ predisposition due to recombination with bovine coronavirus (BoCV).[54] Another scenario is that FECV existed for a long time before FIP was first documented, but evolved to a strain that was much more likely to mutate to FIPV. It is noteworthy that TGEV in pigs was replaced worldwide by a much less pathogenic pneumotropic strain within 30 years[19] through simple mutations.[55] Yet another explanation may involve changes in the popularity of cats and feline husbandry in the post-WWII era. The numbers of pet cats have greatly increased during this period, pure breeding and cattery rearing became increasingly popular, the urban and suburban cat populations increased in density, and more cats, and kittens, were present in shelters. The large indoor multicat environments created by pure breeding and sheltering of free-roaming cats are known to favor FECV infection and FIP.[37,56,57] A final explanation involves FeLV infection, which also became rampant among indoor multicat households during this same period because of the increased movement of cats from the outdoors to the indoors and resultant close cat-to-cat contact. FeLV infection was a significant cofactor for FIP, being found in up to one half of cats with FIP during the 1970s.[58,59] Although the incidence of FIP dropped after FeLV infection was controlled, it quickly rebounded and is now higher than at any time. This rebound coincides with the increased demand for pedigreed cats and larger proportion of adoptions through kitten foster/rescue.

FIP currently causes the death of 0.3% to 1.4% of all cats seen at veterinary institutions worldwide.[60–62] The incidence among kittens from foster/rescue organizations, conventional shelters, and catteries is higher. In a study that examined mortality in 274 kittens from homes, shelters, or catteries from 1986 to 2000, FIP accounted for 6.2% of overall mortality, 3.6% of deaths in shelters, and 7.8% in catteries.[63] When it occurs, FIP is a highly fatal disease that occurs mainly in cats aged 3–18 months with few cases after 7 years of age. A second peak occurs among aged cats.[64]

Risk factors for FIP fall into two general categories: 1) factors that increase severity of FECV exposure, and 2) factors that negatively affect a cat's immune system during the first weeks or months before or after initial FECV exposure and following subsequent secondary infections. In one study, the most significant risk factors for FIP in catteries were younger age, proportion of cats with high coronavirus antibody titers, and the proportion of cats shedding coronaviruses.[65] Deficiencies in passive systemic and passive local (lactogenic) immunity caused by premature separation from queens may also play a role in increased FIP morbidity, and further studies are needed to determine the effect

of early neutering, intense vaccination, over- or under-feeding, and concurrent infectious diseases. Ultimately, increased FECV replication leads to a greater number of FIPVs. Typical FECV infections generate thousands of progenies carrying at least one of the critical mutations. Innate immune responses can prevent tissue invasion and disease in situations where pathogen exposure is low. However, when exposure is high and innate immune defenses are weakened by environmental stresses, only strong adaptive immune responses will prevent disease.

The risk of FIP in kittens from different environments is closely related to the density of kittens. The highest kitten density and risk for FECV infection appears to be among foster/rescue groups, which concentrate on saving, socializing, neutering, and re-homing kittens.[40] Conventional mixed-species shelters may have a lower incidence of FIP, likely due to the increasingly common practice of intentionally or non-intentionally diverting younger kittens to foster/rescue facilities. FIP losses in high-risk environments such as dense urban environments, foster/rescue facilities, and catteries tend to occur unpredictably in clusters several weeks after spring and fall kitten seasons and can range from less than 1% to greater than 10% of kittens under 6–7 months of age.[65]

Every cattery with enzootic FECV infection is at risk of losing cats from FIP if they breed enough kittens over a long enough time. The risk of FIP appears to decrease over periods of 3 years in stable groups of cats, indicating an increase in population resistance.[66] This is most likely age related[67] and argues against the rapid turnover of breeding cats in catteries.

Pedigree cats have a higher incidence of FIP than random-bred cats.[62,68] The incidence of FIP has been followed in four typical catteries over a 5-year period.[65] Even though disease incidence was often less than 1%, spikes in mortality > 10% occurred in young cats and kittens at least once in 5 years.[65] In a study of 11,535 cats examined over a 16-year period, 1.3% of pedigreed cats developed FIP compared with 0.35% of random-bred cats.[60] Some studies show certain breeds to be more prone to FIP than others, although the exact breeds vary from one survey to another.[68,69] In a large survey of over 11,000 hospital patients, FIP was significantly higher in modern "designer"-type breeds such as Bengal, Birman, Himalayan, ragdoll, and rex than in older established breeds such as Burmese, Manx, Persian, Russian blue, and Siamese.[60] In contrast, a high incidence of FIP was reported in Burmese in Australia[69] and a low incidence in Burmese in Italy,[60] whereas Himalayan were found less susceptible in Australia[68] and more susceptible in Italy.[60] Male cats are at somewhat greater risk than females across several, but not all studies.[61]

The genetic basis for FIP susceptibility/resistance has been elusive. In one study comparing FIP deaths and pedigrees, a heritable risk for FIP accounted for up to 50% of risk.[70] Attempts to identify specific heritable genetic polymorphisms responsible for FIP susceptibility among Birman catteries naturally exposed to FIP failed to identify significant polymorphism linked to the disease phenotype.[71] Breeding for resistance by mating related resistant cats to each other increased susceptibility to experimental FIP, and it was concluded that inbreeding is the most significant genetic risk factor.[72]

CLINICAL FEATURES

Pathogenesis

Feline Enteric Coronavirus (Coronavirus Enteritis)

The pathogenesis of FIP usually begins when FECV infects kittens and presumably in older cats that have lost their immunity and become susceptible to repeat exposures. Primary FECV infection occurs in kittens at around 9 weeks of age when maternal protection is waning. Infections may also occur before 9 weeks where environmental exposures are high, and kittens are either bottle-fed or exposed to levels of virus that overcome any maternal immunity. A second group of cats over 10 years of age may also be at increased risk in association with other chronic diseases and weakening immunity (Fig. 31.1).[64]

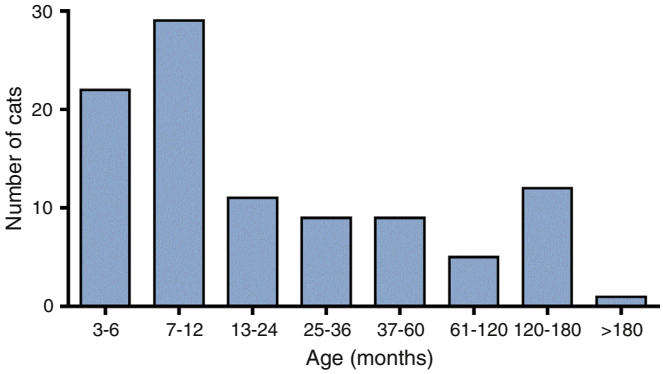

Fig. 31.1 Age distribution of 99 cats with necropsy-confirmed feline infectious peritonitis at the William R. Pritchard Veterinary Medical Teaching Hospital at UC Davis. An additional six cats were reported to be "juvenile" or kittens. There were 38 females (17 intact) and 66 males (22 intact).

Transmission of FECV is by the fecal-oral route. Infectious virions pass through the stomach intact, and there is evidence from cell cultures suggesting that trypsin and possibly other proteolytic enzymes may alter the surface spikes and play an important role in subsequent enteric coronavirus infectivity and cytopathicity.[73] FECV ultimately targets the mature apical epithelium at the tips of intestinal epithelium (see Fig. 29.2). Unlike TGEV of swine and BoCV infection of calves, which can cause severe and often fatal enteritis, FECV infection of cats is only a minimal pathogen and there is a weak statistical association with diarrhea. Its clinical importance is related to its propensity to mutate to the FIPV biotype. The comparative importance of FECV in diarrhea has been studied in shelter cats.[74] Twelve enteric pathogens were identified, including coronavirus, *Clostridium perfringens* enterotoxin A, *Cryptosporidium* spp., *Giardia* spp., *Cystoisospora* spp., hookworms, ascarids, *Salmonella* spp., astrovirus, FPV, FCV, and *Spirometra* spp. Of fecal specimens testing positive for one or more of these agents, FECV was the most common. Only FCoV was significantly ($P = .03$) more prevalent in cats with diarrhea (58%) than cats with normal feces (36%).

Virus is released when the apical epithelial cells undergo natural- or virus-induced apoptosis, with spread to adjacent and distant villi. FECV infection in 275 purebred cats from six catteries was studied by collection of fecal specimens for FECV RT-PCR every 1–3 months.[65] A large proportion of these cattery cats shed virus at any given time, but most manifested cycles of shedding and non-shedding. Similarly, all adult cats in an Abyssinian cattery shed virus in their feces at least once during the year and 4/15 cats were shedding greater than 75% of the time.[75] In a study of the persistence and evolution of endemic FECV infection in a closed cat-breeding facility, viral RNA was detected by RT-PCR in the feces of 36/42 cats (86%) tested and 4/5 cats were still shedding when tested 111 days later.[76] Two cats were then placed in strict isolation and virus shedding lasted up to 7 months in one animal. A viremic stage has not been confirmed. In a study of 50 healthy kittens and cats from a shelter that had feces tested, 28 were found to be FCoV shedders, but only two had detectable FCoV RNA in buffy coat cells.[77]

Experimental FECV infection studies were first conducted on SPF cats.[10,37,42] Clinical signs were frequently inapparent or consisted of transient diarrhea, occasionally preceded by vomiting. Fecal shedding, as determined by RT-PCR on rectal swabs, appeared within as little as 2 days[10,12] and was significantly higher in kittens than in older cats.[42] FECV was identified throughout the intestine through day 28, at which time occasional virus-positive macrophages were seen in the sinuses of reactive mesenteric lymph nodes.[12] The viral load was 10–100,000 times higher in the colon than in other sites in the intestine. FECV shedding remained at high levels for 2–10 months before eventually evolving into one of three excretion patterns: 1) persistent virus shedding at varying levels over 9–24 months; 2) periods of virus shedding interlaced with

periods of non-shedding; and 3) cessation of virus shedding after 5–19 months.[37] The colon appears to be the main site of FECV persistence.[12] Active infection is associated with the appearance and rise in FCoV antibody titers and cessation of shedding with a marked drop in titers.[37] Pregnancy, parturition, and lactation have no influence on fecal shedding by queens, and methylprednisolone acetate treatment does not appear to induce non-shedders to shed and shedders to increase shedding.[37]

Feline Infectious Peritonitis Virus (Feline Infectious Peritonitis)

FIP is caused by specific mutants that occur during FECV infection.[52] These mutant FECVs lose tropism for the intestinal epithelium and gain tropism for monocyte/macrophages. This drastic switch in tropism leads to an entirely different disease, which closely resembles other macrophage-associated diseases such as tuberculosis, leprosy, the deep mycoses, and leishmaniosis. The anatomic sites where mutations occur are not clear, but one likely site is in the lymphoid tissues regional to the primary persistent infection site in the cecum and colon.[36] In a study of the effect of FECV coinfection in FIV immunocompromised laboratory cats, mutations capable of causing FIP occurred in 11% of primary FECV infections.[78] Given an incidence of around 1%, it is apparent that only about 1 in 100 FIPV mutations actually lead to FIP. FIPVs generated by internal mutation are genetically unique to each cat and are contained solely within infected macrophages in diseased tissues and effusions and have limited access to the outside. Therefore, cat-to-cat transmission is an infrequent occurrence and when it occurs, it presents as a self-limiting epizootic caused by the same virus.

Mutations in FECVs that lead to the switch in cell tropism occur in at least three identical regions of the viral genome. The most universal mutation site involves the putative fusion peptide on the spike (*S*) gene and consists of a single nucleotide change at either nucleotide 1058 or 1060. The M1058L mutation (methionine to leucine) occurs in 91.6% of all FIPVs. The S1060A mutation (serine to methionine) occurs in 4.3% of isolates.[79] Neither mutation is found in FECVs. Unfortunately, 4% or more of FIPV isolates do not have either mutation, which makes it difficult to identify their role in FIP pathogenesis. This site is most likely involved in how FIPV and FECV enter their respective host cells. One possibility is that subtle changes in the fusion domain inhibits infection of intestinal epithelium through its normal receptor and favors internalization of FIPV by peritoneal macrophages through alternative Fc receptors.

The second most consistent mutation to be associated with the FIPV biotype is in the accessory *3c* gene.[52] Most FIPV isolates have numerous mutations leading to significant amino acid changes in the 3′ region of the gene.[11] These mutations frequently lead to truncation of the gene and a totally nonfunctional 3c gene product, and are unique for each isolate.[11,52,79–82] The function of the 3c protein is unknown. The loss of a functional 3c protein in FIPVs appears to enhance viral replication in macrophage-like cells.[83]

A third site for FIPV mutations is in the S1/S2 cleavage region, which is involved in two thirds of FIPV isolates.[84] The S1 protein is cleaved from S2 in the Golgi network by the host protease furin. Mutations at this site are again unique to each FIPV and alter the efficiency of cleavage of the S protein by furin. Because the efficiency of furin cleavage is increased in many FIPV isolates, whereas in others it is decreased or unchanged, it is also difficult to ascribe a functional significance to mutations at this region of the FECV genome.

Bone marrow–derived monocytes are recruited into the sites of peritoneal macrophage infection, most likely by the effect of macrophage-derived cytokines on nearby endothelial cell adhesion proteins. The incoming monocytes evolve into M1 macrophages, again by the action of cytokines, evoking either a protective innate and adaptive T-cell immunity and no disease, or to a persistent infection, a flamboyant cytokine storm, immune-mediated inflammation, and disease.[24] The incubation period in naïve cats is 14 to 21 days, which corresponds with the appearance of first antibodies. The epitope responsible for both antibody-dependent enhancement (ADE) and *in vitro* virus neutralization is on the S protein of FIPV.[85] Complement is also bound to virus and antibody,[86] which facilitates the uptake of FIPV by macrophages[87,88] through Fc receptor binding. Immune complex formation contributes to venulitis by evoking Arthus- or immediate-type hypersensitivity reactions. Both neutrophils and macrophages are involved in this reaction.[89] The resultant vasculitis is manifested grossly by edema, hyperemia, micro-hemorrhage, thrombosis, and fibrosis. The vasculitis associated with effusive FIP often leads to coagulation abnormalities indicative of DIC.[90] However, clinical signs of DIC are uncommon.

It has been postulated that FIP is a balance between Th1- and Th2-mediated immunity.[24] In this scenario, non-effusive FIP is associated with a strong delayed-type hypersensitivity (DTH) and weak immediate-type hypersensitivity reactions, whereas effusive FIP is a result of strong immediate hypersensitivity and weak DTH reactions. This is reminiscent of cellular immune responses in lepromatous compared with tuberculoid leprosy of humans. Evidence for the role of T-cell immunity in FIP comes from research with a coronavirus that infects mice, mouse hepatitis virus (MHV). MHV, like FIPV, exists as two biotypes, enterotropic and polytropic. Certain polytropic laboratory strains of MHV cause a disease syndrome analogous to FIP of cats when they infect IFN-γ–deficient mice.[91] Infection with enterotropic MHV in immunocompetent mice is limited to the small intestine for the first week and then to the cecum and colon for the next 2 weeks. B-cell–deficient mice exposed to enterotropic MHV develop chronic subclinical infection restricted to the GI tract that lasts for 7–8 weeks. In contrast, T-cell–deficient mice infected with the same enterotropic MHV develop a multi-systemic, lethal, FIP-like disease. These mouse studies indicate that the FIPV mutations are preventing the T-cell immune responses normally associated with FECVs.

Clinical Signs

FIP tends to occur in two distinct forms with transitions often occurring between them. The classic wet, effusive, or non-parenchymatous form of FIP is a diffuse peritonitis associated with a large outpouring of inflammatory fluid from diseased venules on serosal surfaces, mesenteries, and omentum. Similar disease may also involve the thorax. Non-effusive ("dry") FIP is manifested by more focal and organized granulomatous lesions in organs such as the mesentericlymph nodes, cecum, colon, kidney, lungs, pericardium, eyes, brain, and spinal cord, and miscellaneous sites. Disease signs may evolve over weeks, months, and rarely a year or more. Wet FIP has been likened to the lepromatous form of human leprosy.

The dry, non-effusive, or parenchymatous form of FIP has been compared to the tuberculoid form of human leprosy. Dry FIP frequently begins as a brief episode of apparent or inapparent effusive disease, whereas non-effusive FIP can morph into effusive disease. A mixture of the two forms can also be seen at necropsy. There is ample evidence that infection may incubate for days, weeks, months, and rarely years before either resolving or clinically manifesting itself. This initial infection is most likely contained to foci of infection in organs such as the cecum, ileum, and colon, and associated lymph nodes. Clinical signs in this latent period may be inapparent or associated with retardation of growth, increased susceptibility to other common pathogens, or other vague signs of ill health. Once disease becomes apparent, it is usually progressive and fatal. However, there are reports of cats that make an apparent recovery, only to have clinical signs recur months and even years later.[56,92]

Both the non-effusive and effusive forms of FIP share many of the same initial clinical signs. The earliest overt signs include a progressively worsening lethargy, inappetence, and weight loss. Kittens and adolescent cats may be smaller than normal, have poor quality coats, may be less active, and suffer recurrent bouts of vague illnesses compared with siblings or cats of the same age. A fluctuating antibiotic-unresponsive fever

is common with FIP and in one study, 22% of all cats presenting with a fever were ultimately found to have FIP.[93] Additional clinical manifestations vary greatly depending on the form and organ distribution of the inflammation. The timing of the subsequent disease course is also variable and ultimately fatal if untreated in almost all cases. Although the disease course for FIP is generally assumed to be a few days or weeks, some cats with either wet or dry FIP can survive for many weeks, months, and occasionally a year or more with just supportive care.

The effusive form of FIP is more common in kittens but also observed in adolescent, adult, and aged cats (Table 31.1). Effusions are observed solely in the abdomen in about 75% of cats, solely thoracic effusions in 10%–15%, and a mixture of thoracic and abdominal effusions in less than 10% of cases (see Table 31.1).[61] Abdominal effusions are manifested by abdominal distention and may be one of the first signs of FIP noted by the owners. Intact male cats may manifest scrotal enlargement due to inflammation of testicular tunics, whereas female cats with ascites may be considered pregnant and the disease discovered on spaying. Tachypnea may accompany thoracic effusion. Involvement of the CNS and eyes is seen in only about 10% of kittens with abdominal and/or thoracic effusions (see Table 31.1). Pericardial effusions are uncommon, either as a primary clinical manifestation or in combination with fluid accumulation in other body cavities.

About one fourth of cats with FIP have non-effusive or predominantly non-effusive FIP.[61] However, this proportion appears to be rising, either because of improved diagnosis or to an actual increase in incidence. The dry form also predominates in certain popular breeds such as the Birman[71] and Burmese.[69] The non-effusive form is also more apt to be subclinical[56,92,94] and may go unnoticed until host resistance is eventually overcome, and the disease becomes either effusive or involves the CNS and eyes. Clinical signs vary according to the organs that are involved. For instance, a disproportionate number of cats with non-effusive FIP develop neurologic and/or ocular disease (Table 31.2). A colonic form of the disease was first described in 1983 (Fig. 31.2).[95] FIP colitis is manifested by chronic diarrhea associated with mucus, fresh blood, and straining to defecate. The thickened colon, cecum, and ileocecocolic lymph nodes are readily palpated or visualized on abdominal ultrasound. FIP colitis has also been diagnosed at surgery for abdominal emergencies when a colonic pyogranuloma causes intestinal obstruction.

Neurologic disease is the sole presenting sign in about 22% of cats with non-effusive FIP, while an additional 7% is accompanied by detectable lesions in the peritoneal cavity (see Table 31.2). Ocular disease

Fig. 31.2 Section of diseased colon removed at surgery from a 7-month-old female spayed domestic shorthair with anorexia and hematochezia. Histopathology showed severe, multifocal coalescing pyogranulomatous colitis and lymphadenitis typical of the colonic form of dry feline infectious peritonitis.

occurs as the sole manifestation in 14% of non-effusive FIP cases (see Table 31.2), while ocular disease plus CNS or other organ involvement occurs in 10% of cases. CNS involvement in cats with non-effusive FIP is varied in its clinical expression. Meningitis, ependymitis, and choroiditis with extension into adjacent tissues are common lesions in cats with brain involvement (Fig. 31.3). CNS involvement can manifest in early stages by spontaneous muscle twitches, atypical limb extension and swallowing motions, and brief episodes of staring. Signs will then progress slowly or rapidly to ataxia, usually worse in the pelvic limbs. Cerebellar-vestibular signs including nystagmus, head tilt or circling may be present. Hydrocephalus, secondary to disease of the choroid and ependyma, has also been documented[96–98] and can lead to dementia, personality changes (aggression, rage, hiding/withdrawal, etc.), or seizures.

FIP is a major contributor to inflammatory/infectious disease of the spine.[99] Spinal involvement with FIP often leads to severe posterior paresis and urinary or fecal incontinence.

Once the virus enters the CNS or eyes, it is sheltered from the normal bloodborne immune responses. However, the infection is still capable of stimulating a systemic immune response as a result of lymphatic connections between the brain and cervical lymph nodes.[100] Such stimulation may explain why serum and CSF/aqueous antibody titers

are so high in this form of FIP. This compartmentalization of infection and immune responses can lead to a scenario where virus-infected macrophages outside protected sites are eliminated, whereas infection in sites such as the brain and eye persist. This may also explain why many cats with CNS disease do not have noticeable extra-abdominal lesions (see Table 31.2).

Ocular FIP is usually manifested by a varying degree of uveitis and/or retinitis[101] that often starts in one and then progresses to involve both eyes (Fig. 31.4A–C). The earliest signs of anterior uveitis may be a discoloration of the iris, aqueous flare, and keratic precipitates. Although FIP is the major cause of uveitis in young cats, it can be confused with idiopathic uveitis. In one study, the duration of disease tended to be shorter in cats with FIP than in cats with idiopathic uveitis.[102] In another study of 92 cats with uveitis from the UK, cats with FIP uveitis had the youngest age (median 1.4 years) whereas those with neoplasia (such as lymphoma) had the oldest age (median 12.8 years), and cats with FIP or lymphoma were more likely to be purebred than cats with idiopathic uveitis.[103] Microbial nucleic acids, antigens, or antibodies against a causative agent were seldom found in the blood/serum of cats with idiopathic uveitis, whereas serum FCoV titers ≥ 1:6400 were detected only in cats with FIP. Aqueous humor contained predominantly neutrophils in cats with FIP and large reactive lymphocytes and plasma cells more frequently in cats with idiopathic uveitis. However, neither clinical nor cytologic assessment of anterior chamber contents reliably differentiated idiopathic uveitis from FIP.

Retinitis is manifested by congestion of retinal blood vessels and hemorrhage that may be associated with retinal detachment and degeneration of the tapetum and optic disc. It can be unilateral or bilateral. Retinitis is often a sign of brain involvement and associated neurologic signs. Uncommon sites for extraperitoneal and extrapleural lesions, other than the CNS and eyes, include the oral cavity, nasal passages, testicles, and skin.

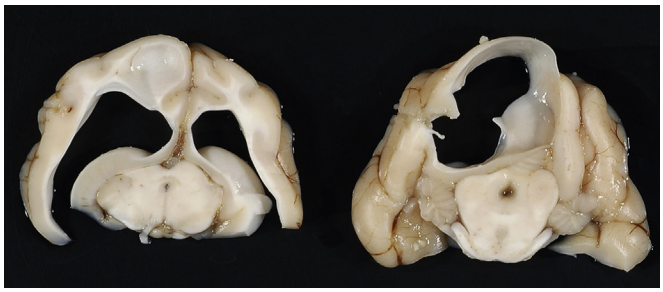

Fig. 31.3 Obstructive hydrocephalus in an 8-month-old male neutered exotic shorthair cat that developed ataxia and head tremors. Hydrocephalus and secondary cerebellar herniation were found at necropsy. Histopathology revealed severe, multifocal pyogranulomatous meningoencephalitis, choroiditis, and ventriculitis, and pyogranulomatous inflammatory lesions were also found throughout the thoracic and abdominal viscera. DIAGNOSIS

The diagnosis of FIP is based first and foremost on consideration of signalment (age, sex, and breed), environmental origin, disease history, abnormalities on physical examination (including effusions if present), and routine CBC and serum chemistry findings. There is sometimes enough evidence at this point to make a presumptive diagnosis of FIP, and whether more invasive diagnostic tests are warranted can be discussed with the owner.[104] The next step, if needed, is to choose tests that will either further increase the odds that the disease signs are due to FIP using "indirect tests" or attempt to provide a definitive diagnosis using "direct tests." It must be remembered that

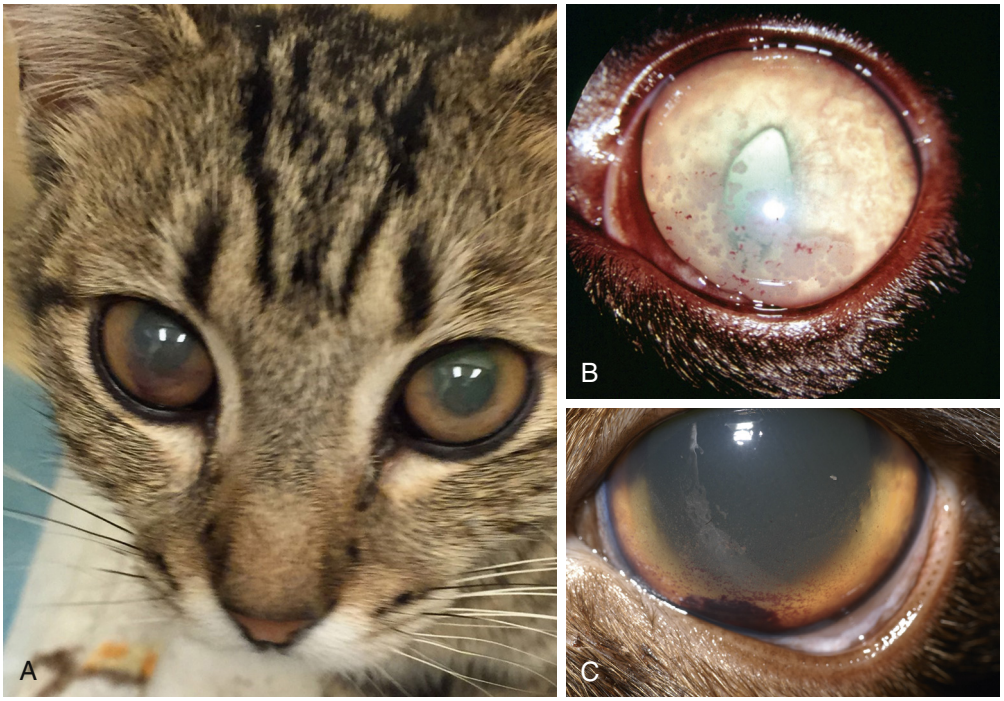

Fig. 31.4 Ocular signs associated with feline infectious peritonitis (FIP). (A) A 3-month-old male neutered domestic shorthair cat with acute bilateral uveitis associated with FIP. The anterior chamber of the left eye contains a large fibrinous clot. (B) Perivascular retinal lesions in a 7-month-old intact female domestic shorthair cat with FIP. no test is 100% sensitive and specific and that diagnostic sensitivity and specificity is strengthened by the inclusion of other supportive clinical findings.

Laboratory Abnormalities

Complete Blood Count and Serum Chemistry Profile

A CBC and serum chemistry panel that includes bilirubin, total protein, globulin, and albumin are probably the simplest and most informative indirect tests for FIP.[56,61,105] Common CBC abnormalities include nonregenerative anemia (anemia of inflammatory disease), leukocytosis with an absolute increase in neutrophils and a relative or absolute decrease in lymphocytes, and eosinopenia (Table 31.3). Occasionally, mild to moderate bandemia is present. The degree of lymphopenia is a good indicator of disease activity and severity, especially in cats with effusive FIP, whereas cats with non-effusive FIP often have low normal to normal lymphocyte counts.[106] Monocyte counts are variable and usually in the normal range.

An increased plasma total protein concentration is frequent in cats with FIP, especially in cats with non-effusive disease. Serum globulin concentration is frequently high and albumin concentration may be low (Table 31.4). This results in albumin-to-globulin ratios (A:G) ratios that are frequently below normal (<0.6).[61] Although the A:G ratio has been advocated as a useful test for FIP, the predictive value of the A:G ratio is very much dependent on the presence of other historical, clinical/physical, or laboratory abnormalities associated with the disease.[107]

FIP is perhaps the most common cause of hyperbilirubinemia in young cats, especially those with effusive FIP.[61] Hyperbilirubinemia is usually not associated with increased liver enzyme activity,[108] as the liver parenchyma is often spared in cats with FIP. Rather, bilirubin is a by-product of intravascular and extravascular destruction of RBCs by macrophages and a species deficiency in glucuronidation.[109]

Serum Protein Electrophoresis

Analysis of 155 serum specimens from cats with increased serum total protein or globulin concentration found that 136 (87.7%) had abnormal serum electrophoresis profiles, most commonly from a polyclonal increase in gamma globulins (Fig. 31.5).[110] Alpha and beta globulins are also increased in many FIP sera due to increased production of acute-phase reactants and complement proteins. The most common disease classification associated with serum protein abnormalities in the 155 feline sera was infectious/inflammatory disease (80/136; 58.8%), including 39 cats with a diagnosis of FIP. Monoclonal gammopathy was observed in four cats, including one with FIP, one with lymphoma, and two with splenic plasmacytoma.

Analysis of Effusions

The presence of a characteristic type of fluid in the peritoneal cavity and/or pleural cavity is one of the most diagnostic clinical features of FIP. Classic FIP effusions are usually yellow tinged (sometimes blue green), cloudy, high in protein (near or equal to plasma levels), and have white cell counts of 3,000 cells/μL or greater (Table 31.5). Red cells are often present but seldom in numbers that grossly tinge the fluid. The fluid color is due to the presence of bilirubin (yellow) or biliverdin (blue green). The deeper colored the fluid, the more red cell destruction is occurring and the more severe the inflammatory process. Classic FIP effusions are often viscous with an egg-white consistency, contain fibrin tags, and frequently form partial clots when placed in a serum tube.

Effusions from cats with more chronic and fibrotic disease may be clear or pale yellow, have protein content as low as 2.0 g/L, and cell counts nearer to 200 cells/μL. Such effusions are frequently and incorrectly called "modified transudates." However, they have their origin in inflammatory and not transudative processes and do not meet the established physical or physiologic criteria for a modified transudate.[111] A more appropriate term, if it existed, would be "modified exudate."

The exudate of FIP is unlike that seen in rare cases of bacterial peritonitis or in cats with pyothorax. These are much more purulent in appearance, with extremely high neutrophil counts and not as viscous or yellow tinged. The neutrophils in bacterial peritonitis are often toxic, whereas those in FIP fluid are typically mature. However, secondary bacterial infections have also been identified on occasion in cats with effusive FIP. Effusions associated with liver and heart

disease, lymphatic duct rupture (chylous effusions), and neoplasia seldom have the same overall physical and cellular characteristics as FIP effusions.

Rivalta test. The Rivalta test has been long used for diagnosing FIP-associated exudates.[105] The test involves placing a few drops of effusion into a weak acetic acid solution. The appearance of a ball ("jellyfish") of white flocculent material that moves through the solution indicates a positive test (Fig. 31.6). In a study of 497 cats with effusions, 35% of which had confirmed FIP, the Rivalta test had a sensitivity of 91% and a specificity of 66%, with a positive predictive value of 58% and a negative predictive value of 93%.[112] The diagnostic performance of the test increased when cats with lymphoma or bacterial infections were excluded, or when only cats of ≥ 2 years of age were considered. Therefore, the value of the Rivalta test for diagnosis of FIP increases as more diagnostic features of FIP are included and signs of other disorders excluded. Effusions that have low protein and cell counts, and are less inflammatory in origin, are unlikely to test positive and the interface between positive and negative is not always clear.

TABLE 31.5 Composition of Body Cavity Effusions from 21 Cats with Necropsy-Confirmed Feline Infectious Peritonitis[a]

Test	Range	Mean ± S.D.	Number of Cats Tested
Total protein (g/dL)	2.9–8.1	5.1 ± 1.8	21
RBC (cells/μL)	<100–38,600	ND	18
TNC (cells/μL)	200–13,200	3,683 ± 3,474	19
Neutrophils (%)	3–97	61 ± 28	21

Fig. 31.6 Positive Rivalta test. The appearance of a ball ("jellyfish") of white flocculent material that moves through the solution (similar to a lava lamp) indicates a positive test.

Analysis of Cerebrospinal Fluid and Aqueous Humor

The results of CSF analysis were reported on cats with necropsy-confirmed FIP from five veterinary institutions from the United Kingdom, Australia, and United States.[113] Total protein concentration was increased (mean, 9.4 g/L; median, 3.6 g/L; range, 0.85–28.8 g/L) as was total nucleated cell count (mean, 196/μL; median, 171/μL; range, 15–479/μL). Neutrophils were the dominant cell in most cats, whereas lymphocytes and a mixture of neutrophils and lymphocytes were observed in a smaller proportion (Table 31.6).

α1-Acid Glycoprotein

α1-Acid glycoprotein (AGP) has been used extensively, particularly in parts of Europe, as an indicator test for FIP. AGP is hyposialylated in cats with FIP, but not in healthy cats or in cats with other diseases.[114] One study concluded that serum AGP could be used as a discriminating marker for FIP, but only when coupled with other risk factors or test results supportive of a diagnosis of FIP.[115] AGP serum concentrations of 1.5–2 μg/mL add further support to the diagnosis when the index of suspicion is high.

Diagnostic Imaging

Plain Radiography

Plain thoracic radiography may reveal pleural effusion, enlargement of the cardiac silhouette in cats with pericardial effusion, and pulmonary nodular or peribronchial infiltrates in cats with pyogranulomatous pneumonia (Fig. 31.7). Abdominal radiographs may show loss of peritoneal or retroperitoneal detail due to peritoneal effusion, hepatomegaly, splenomegaly, renomegaly, or mass lesions associated with the GI tract or abdominal lymph nodes.

Sonographic Findings

The diagnosis of FIP often depends on the ability to identify abdominal or thoracic effusions and to obtain a fluid specimen for analysis. Ultrasound can be helpful for identification and collection of small volumes of fluid (Fig. 31.8). Ultrasound can also locate lesions such as enlarged abdominal lymph nodes, kidney masses, or infiltrative lesions of the colon or other organs. Ultrasound-guided biopsies of such lesions may be required to obtain tissues for microscopic, IHC, or PCR testing. Ultrasonography may also be helpful for diagnosis of FIP in cats with neurologic or ocular signs, as abdominal lesions such as enlarged mesenteric lymph nodes are present in most of these cats and are often not appreciated on palpation.

Ultrasonographic findings were reviewed retrospectively in 16 cats with strongly suspected effusive or non-effusive FIP.[116] The liver was normal in echogenicity in 11 (69%) cats, diffusely hypoechoic in 3 cats,

TABLE 31.6 Composition of Cerebrospinal Fluid from 10 Cats with Necropsy-Confirmed Feline Infectious Peritonitis[a]

Test	Range	Median	Reference Range	Number of Cats Tested
Total protein (mg/dL)	44–4,079	639	<25 mg/dL	4[b]
RBC (cells/μL)	3–850	340	0	9
TNC (cells/μL)	26–2,637	303	0–2	10

Lymphocytes (%)	5–89	19	NA	10
Monocytes (%)	0–20	7	NA	10

[a]Cats seen at the William R. Pritchard Veterinary Medical Teaching Hospital at the University of California, Davis.
[b]Insufficient quantity was available for protein determination.
RBC, red blood cells; *TNC,* total nucleated cell count, NA, not applicable.

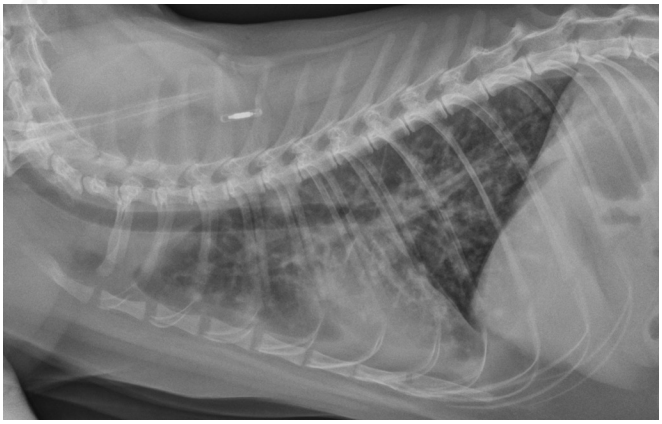

Fig. 31.7 Thoracic radiographs from a 9-month-old male neutered domestic shorthair cat with feline infectious peritonitis and pyogranulomatous pneumonia. There is a severe, diffuse, patchy alveolar and nodular interstitial pattern with thickening of the bronchial walls and mild pleural effusion.

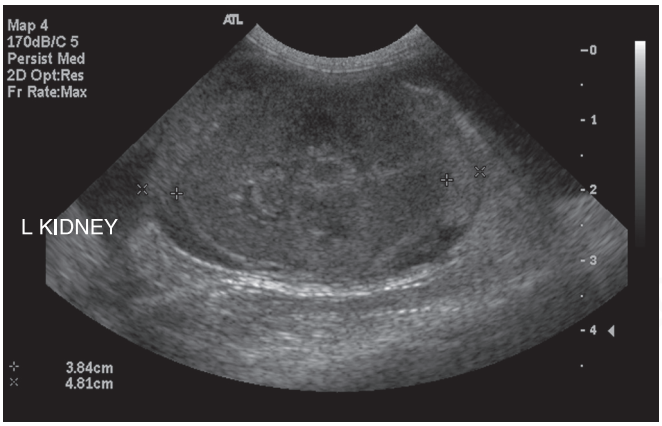

Fig. 31.8 Abdominal ultrasound of a 1-year-old male intact Scottish fold with feline infectious peritonitis. There is renal irregularity and subcapsular fluid, as well as moderate peritoneal effusion.

focally hyperechoic in 1 cat and focally hypoechoic in another. Five cats had a hypoechoic subcapsular rim in one or both kidneys. Free fluid was present in the peritoneal cavity in seven cats and in the retroperitoneal space in one cat. Abdominal lymphadenopathy was noted in nine cats. The spleen had normal echogenicity in 14 cats and was hypoechoic in 2 cats. One cat had bilateral orchitis, with loss of normal testicular architecture. The authors concluded that, while none of these ultrasonographic findings were specific for FIP, their significance was greatly increased when included with other suggestive findings.

Magnetic Resonance Imaging

MRI is a useful tool for diagnosis of neurologic FIP, particularly in combination with a compatible signalment, clinical presentation, and CSF analysis. MRI findings were described in 24 cats with necropsy-confirmed neurologic FIP.[113] Three distinct clinical syndromes were identified: T3-L3 myelopathy, central vestibular syndrome, and multifocal CNS disease. MRI abnormalities were detected in all cases and included meningeal contrast enhancement, ependymal contrast enhancement, ventriculomegaly, syringomyelia, and foramen magnum herniation (Fig. 31.9) All 24 cats were euthanized, with a median survival time of 14 days (range, 2–115) from onset of clinical signs. Histopathologic analysis identified perivascular pyogranulomatous

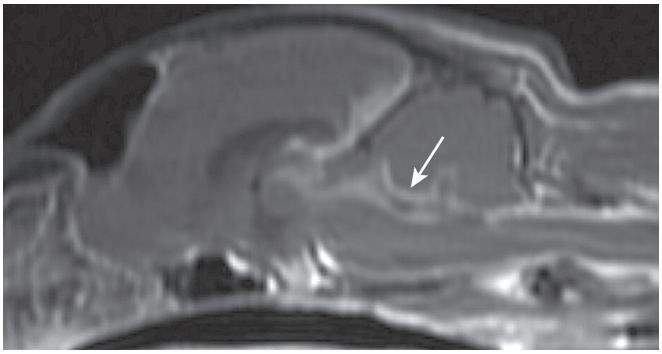

Fig. 31.9 T1-weighted post-contrast magnetic resonance imaging scan of an 8-month-old female domestic shorthair cat with neurologic feline infectious peritonitis. There was marked enhancement of the ependymal lining of the fourth ventricle *(arrow)* as well as the central canal, and moderate meningeal enhancement of the brainstem and cervical spinal cord. The feline coronavirus antibody titer was ≥ 1:20,480. A cerebrospinal fluid analysis showed marked, mixed, predominantly neutrophilic inflammation. infiltrates, lymphoplasmacytic infiltrates, or both affecting the leptomeninges, choroid plexus, and periventricular parenchyma.

Microbiologic Tests (Table 31.7)

Serologic Diagnosis

The accepted gold standard method for detection of antibodies to FCoV is an IFA using cat cell lines with tissue culture–adapted FIPV-79-1146 as the antigen.[59,64] TGEV grown on pig cells or CCoV grown on dog cells can also be used. IFA serology is accurate if properly done, but controversy still exists over its diagnostic value as FECV and FIPV evoke identical type antibodies. Although antibody titers tend to be higher in cats with FIP, they also trend high among healthy cats in the same environments that produce FIP.[43,59] Nonetheless, there is some value in determination of FCoV antibody titers. Antibodies to FCoV appear within 2 weeks of FECV infection, typically to titers of around 1:100 to 1:400 and then drop to levels of 1:25 or lower in cats that develop immunity and cease shedding.[37] Cats with antibody titers ≥ 1:400 are almost always FECV shedders, and cats with titers of ≤ 1:25 are usually non-shedders.

Rising FCoV antibody titers can also indicate progression of subclinical FIP, but the opportunity or rationale for such sequential testing is limited. FCoV antibody titers were found to rise above their baseline among a colony of cats with enzootic FECV infection that were subsequently infected with FeLV that appeared to reactivate FIP (Fig. 31.10).[59] Most healthy FECV exposed cats have titers of 1:400 or less. Only a few healthy cats have FCoV titers of 1:1600, while titers ≥ 1:3200 (provided the assay is performed correctly) are highly suggestive of FIP[105] and can be considered definitive if coupled with other signs of FIP. However, there are some cats with FIP that have low or even negative FCoV titers.[117] This means that very high titers from a reliable laboratory support a diagnosis of FIP in combination with suggestive clinical signs, but low or negative titers cannot be used to rule out FIP. A progressive rise in titer over a period of several months may also indicate that FIP is changing from a subclinical to clinical form (see Fig. 31.10).

A 7b serum ELISA antibody test was developed on a faulty premise that FECVs lack the *7b* gene and hence do not produce the 7b protein, whereas FIPVs have the *7b* gene, produce the protein, and therefore evoke a 7b antibody response. However, virtually all field isolates of FIPVs and FECVs possess an intact *7b* gene and therefore both evoke anti-7b antibodies.[118] The 7b antibody test is essentially the same as

TABLE 31.7 Assays Available for Diagnosis of Feline Infectious Peritonitis

Assay	Specimen Type	Target	Performance
Fluorescent or immunoperoxidase antibody staining	Wash or effusion specimens, tissue aspirates, tissues obtained at biopsy or necropsy	FCoV	Gold standard for diagnosis. False negatives can occur in specimens that contain low numbers of macrophages or virus particles, or when virus is complexed by antibody. Immunofluorescence is more sensitive than immunoperoxidase methods. Nonspecific staining may be interpreted as positive results by untrained personnel.
Serology	Blood, CSF, aqueous humor, effusion fluid	FCoV antibody	Positive antibody titers reflect only antibodies to a coronavirus and are not specific for a diagnosis of FIP. Most cats in multicat households test positive. Negative titers can occur in cats with advanced FIP. High titers in cats that do not reside in multicat households and that have signs suggestive of FIP support the diagnosis. Interlaboratory variation in methodology and titer reporting occurs.
RT-PCR	Blood, wash or effusion specimens, tissue aspirates, tissues obtained at biopsy or necropsy	FCoV RNA	Does not differentiate between virulent and avirulent FCoV strains, and avirulent strains may be found in tissues and blood. However, cats with high copy numbers of FCoV RNA in extraintestinal tissues are more likely to have FIP than those with low copy numbers. Sensitivity and specificity may vary depending on assay design. False-negative results may occur when virus levels are low or as a result of degradation of viral nucleic acid during specimen transport.
Histopathology	Usually necropsy specimens, but also biopsies	Inflammatory lesions induced by FCoV (pyogranulomatous vasculitis)	Biopsy is often not feasible antemortem as a result of critical illness and coagulopathies.

CSF, cerebrospinal fluid; *FCoV,* feline coronavirus; *FIP,* feline infectious peritonitis; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

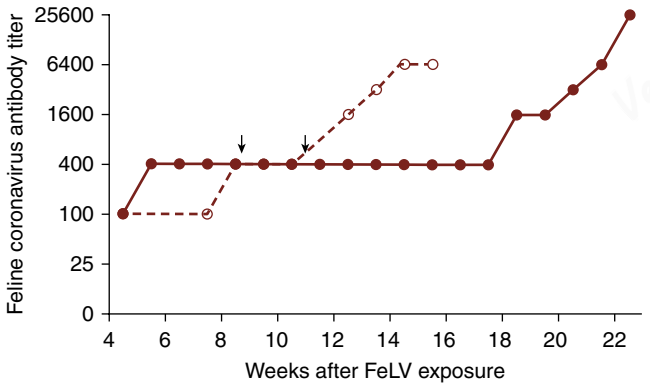

Fig. 31.10 Feline coronavirus (FCoV) antibody titers in two cats that were naturally infected with feline enteric coronavirus before being exposed to feline leukemia virus (FeLV) carriers. The FCoV titers began to rise 2 to 10 weeks after the cats became persistently FeLV viremic *(arrows)* and reached levels of 1:6400 to 1:25,600 just before death from feline infectious peritonitis (FIP). This figure demonstrates three features of FIP: (1) feline infectious peritonitis virus (FIPV) can remain dormant or subclinical for some time following FECV infection, (2) persistent FeLV infection has the potential to activate dormant or subclinical FIPV infection, and (3) rising FCoV antibody titers can be associated with disease progression.

other FCoV antibody tests. However, there are no good studies on how to interpret 7b antibody titers in context to disease status.

FCoV antibody tests have also been adapted to ELISA and rapid immunochromatographic test formats.[119,120] All are 96% to 100% sensitive in detecting antibody in blood or effusions. Serology on CSF has also been applied for diagnosis of neurologic FIP. In one study, the most useful antemortem indicators of neurologic FIP were positive IgG anti-CoV antibody titer in the CSF, increased serum total protein concentration, and MRI findings suggesting periventricular contrast enhancement, ventricular dilatation, and hydrocephalus.[96] However, in another study, CSF antibody was detected only in cats with serum titers of 1:4,096 to 1:16,384 and the investigators concluded that CSF antibodies were passively acquired.[121] In another attempt to measure local CNS antibody production in cats with FIP, an albumin quotient and IgG index were measured to determine whether proteins in the CSF were of blood or local origin. Neither the albumin quotient nor IgG index identified a pattern consistent with intrathecal IgG synthesis in cats with the CNS form of FIP.[122] In conclusion, it seems that coronavirus antibodies enter the CSF at high levels when they are also at very high levels in the serum.[123]

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR testing of feces for FCoV shedding is of limited value. The fecal virus is of the FECV biotype, even in cats with FIP. Furthermore, cats with FIP often shed FECV at low or negligible levels compared with healthy cats.[11,80,124] Routine testing of healthy cats by breeders to predict FIP problems should also be discouraged because the odds of healthy FECV shedders developing FIP are very low.[14,77] There is evidence, however, that the higher the proportion of cats in a cattery that shed coronavirus at a given time, and the higher the level of shedding, the more likely FIP will occur in the population.[65] This is an expensive and not a very accurate way of predicting future FIP risk. Testing of feces for FECV shedding can be theoretically used to eliminate FECV from a cat population such as was done in conjunction with FCoV serology in an experimental cat breeding facility.[14] However, such a use of RT-PCR must be coupled with sequential testing and proper quarantine facilities and procedures, as was done in this facility. Attempts to isolate FECV-negative kittens and cats in conventional housing with inadequate quarantine procedures are doomed to fail.

RT-PCR assays for replicating (mRNA) and non-replicating forms of FCoV were also used to screen the blood buffy coat cells and feces

of 205 healthy shelter cats to predict whether they would develop FIP later.[77] Of 205 buffy coats, 1 (0.5%) tested positive for replicating forms of viral RNA (mRNA) and 9/205 (4.4%) for non-replicating RNA, whereas 28/50 (56%) fecal specimens tested positive for mRNA. None of the 10 cats with replicating or non-replicating forms of FCoV in their blood developed FIP over the subsequent 6 months.

The *7b* gene is often used as a target for FCoV PCR because it is the most abundant viral transcript and most likely to be detected. The *M* gene has also been targeted in some PCR assays, as it is highly conserved across all isolates.[125] The use of the *7b* RT-PCR for diagnostic purposes is based on the premise that FECVs will be only found in feces of healthy cats and FIPVs only in diseased tissues and effusions of cats with FIP. Although this test has excellent sensitivity and specificity when used to detect FECV in fecal specimens of healthy cats, test results for FIP tissues and effusions have been variable. In one study of 854 cats with ascites that were suspected to have FIP based on clinical signs, 95% of ascites specimens from purebred and 79% from random-bred cats tested positive by RT-PCR. This decreased with each increasing year of age, with 70% of effusions from purebred and 42% from random-bred cats of 12–24 months of age testing positive.[123] This variation with breed or age can best be explained by the filtering effect of known risk—pedigreed cats are more likely to develop FIP than random-bred cats and younger cats are more likely to have FIP than older cats. Therefore, the specificity and sensitivity of PCR tests for FIP should always be considered along with other risk factors.[126]

The specimen type also influences the results of molecular testing. PCR was performed on peripheral blood mononuclear cells (PBMCs) of 21 cats with FIP, serum from 26 cats with FIP, and cell-free abdominal or thoracic effusions of 36 cats with FIP, and results were compared to those from a control group with other diseases.[127] PCR had a sensitivity of 29% and specificity of 100% in PBMCs, 15% sensitivity and 86%–100% specificity in serum, and 89% sensitivity and 89%–100% specificity in cell-free body cavity effusions. When fluid and cellular fractions of ascites and blood were tested from cats with experimentally induced effusive abdominal FIP, most FCoV *7b* RNA was found in the cellular pellet of ascites fluid rather than in supernatant, and viremia was not reliably detected in serum or PBMCs.[128] Similar observations were made in cats with naturally occurring FIP.[129] Viral RNA levels are too low in whole blood, plasma, or blood cells to be reliably detected. When testing effusions, a fresh cell pellet is the preferred specimen to test. Tissues to be tested should be only from lesions, and lesions from cats with non-effusive FIP would be expected to have lower viral RNA loads than lesions from cats with effusive FIP.

In one study, FCoV PCR on CSF from cats with neurologic signs and other risk factors for FIP was highly sensitive and specific.[113,127] CSF was also a useful specimen when tested for both FCoV *7b* RNA and FCoV antibody by indirect IFA.[123] CSF antibody titers of 1:640 or greater were found only in cats with FIP and were always positive by RT-PCR.

There is now a more accurate understanding of the genetic make-up of FECV and FIPV isolates and the mutations leading to the FIPV biotype. Mutations in the ORF 3c and at the S1/S2 gene cleavage site are unique to each FIPV and are therefore not good candidates for a test that differentiates FECVs from FIPVs.[84,124] However, two SNP mutations in the fusion peptide of the S protein occur in around 96% of FIPVs detected in diseased tissues but never in true FECVs.[80] An RT-PCR test has been commercialized that detects FIPV-specific mutations in the *S* gene.

In theory, the *7b* RT-PCR assay should identify any FCoV RNA in a specimen, whereas the FIPV-specific test would determine whether the RNA belonged to the FECV or FIPV biotype. However, the FIPV-specific assay has much lower sensitivity than the FCoV-specific test. In specimens with high loads of FIPV-specific RNA, both tests will be positive and the presence of an FIPV can be confirmed. However, when the starting amount of FIPV RNA is low, the more sensitive *7b* FCoV test will be positive, but the less sensitive FIPV *S* gene test may be negative. In a study of 57 cats with proven FIP and 45 control cats without FIP, identification of *S* gene- mutated FCoVs as an additional step to the detection of FCoV alone only moderately increased specificity for tissue specimens (from 92.6% to 94.6%) and specificity was unchanged for fluid specimens (97.9%).[82] However, sensitivity was significantly decreased for the FIPV-specific tests for tissue (from 89.8% to 80.9%) and fluid specimens (from 78.4% to 60%). A further complication of the *S* gene mutation test for FIPVs is that these mutations are not found in all FIPV strains from the field.[80,130]

Fig. 31.11 Gross appearance of the abdominal cavity of a 10-month-old male intact domestic shorthair cat with acute effusive abdominal feline infectious peritonitis. Pathologic Findings

Gross Pathologic Findings

Abdominal and/or thoracic effusions in cats with FIP range from a few milliliters to over a liter, and the color from nearly clear to a deep yellow (Fig. 31.11) The principal lesion is the pyogranuloma, which appears grossly as focal whitish plaques ranging from microscopic to several millimeters in diameter and most obvious on serosal surfaces of abdominal or thoracic organs and mesenteries (Fig. 31.12). The omentum and splenic mesentery are usually thickened by varying degrees of edema and fibrosis, the intestinal mesenteries cloudy, and the visceral and parietal serosal surfaces thickened with a ground-glass appearance. Focal hemorrhages are often seen in the omentum and splenic mesentery and the affected tissues stained yellow from bilirubin. Similar, but less defined, gross lesions can occur on the parietal and visceral surfaces of the chest, mediastinum, diaphragm, pericardium, heart, and lungs.

Lesions of non-effusive FIP can be classified as intra-peritoneal/pleural, extra-peritoneal/pleural, or both. They are less diffuse and more solitary than those of wet FIP, much larger, and more typical of classic, sometimes tumor-like, granulomas. The lesions are also more likely to extend down from the surface of organs into the underlying parenchyma, hence the alternative name of parenchymatous FIP. Almost 50% of cats with non-effusive FIP have disease localized to the peritoneal cavity and in 30% of cases solely abdominal lesions are present. Pleural cavity lesions occur in only 10% of cats with non-effusive FIP, usually in association with peritoneal disease. Abdominal lymph node involvement is often a primary manifestation of non-effusive FIP, especially in the subclinical form (Fig. 31.13).[56,92,94] The kidneys are also a major target (Fig. 31.14).[47] Although effusive and non-effusive FIP are considered distinct forms, they are in reality creations of opposing immediate-type hypersensitivity and DTH reactions to virus-infected macrophages and elements, and one or both reactions may be observed in individual cats.

Histopathologic Findings

The microscopic lesions of effusive FIP are characteristic, with the hallmark lesion being a vasculitis targeted at venules in the omentum,

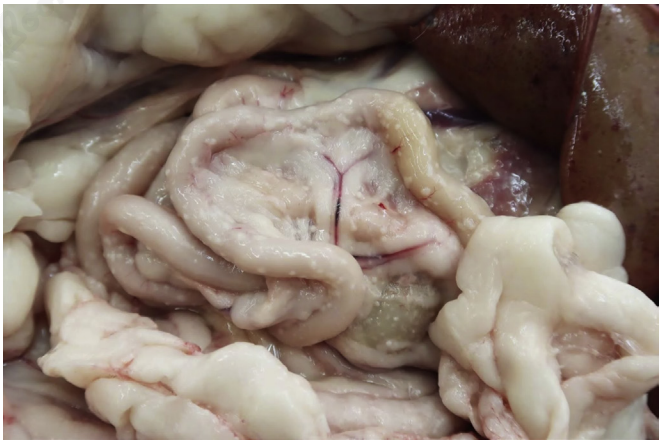

Fig. 31.12 Gross appearance of abdominal cavity of a cat with a more chronic form of effusive abdominal feline infectious peritonitis than shown in Fig. 31.11. The omentum is contracted and thickened and whitish plaques are seen on the surface of the gastrointestinal tract. (Courtesy Dr. Brian Murphy, University of California-Davis Veterinary Anatomic Pathology Service.)

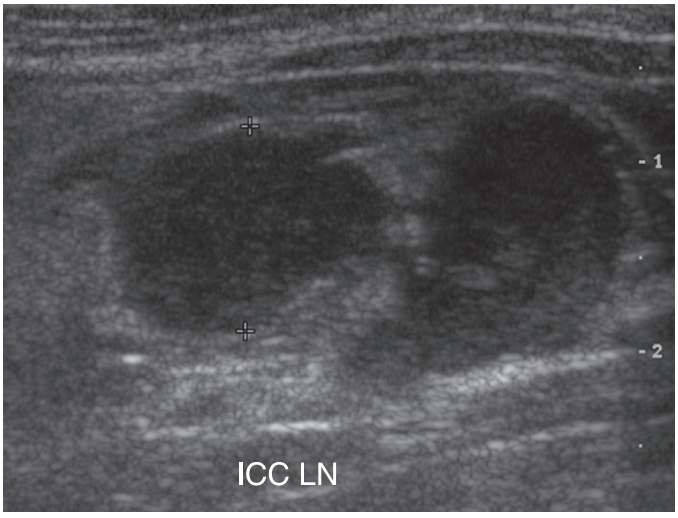

Fig. 31.13 Abdominal ultrasound image showing enlarged ileocolic lymph nodes in a 9-month-old domestic shorthair cat with non-effusive feline infectious peritonitis (FIP). Ileocolic lymph node enlargement is common to both forms of FIP and is the primary site of disease.

mesenteries and serosal surfaces of the abdomen, and pleural surfaces, mediastinum, and pericardium of the heart (Fig. 31.15A). A second characteristic lesion is the pyogranuloma, which consists of focal accumulations of macrophages and neutrophils adjacent to blood vessels. FIPV can be detected by IHC or immunofluorescence within these macrophages (Fig. 31.15B). Pyogranulomas tend to be more diffuse in acute cases and more defined with chronicity. Hyperemia and edema associated with more acute inflammation and loss of small vessel integrity is also more pronounced in severe cases, while this tends to be replaced by serous atrophy and fibrosis in more chronic cases.

Lesions of non-effusive FIP are centered around small aggregates of macrophages resembling the pyogranuloma of effusive FIP, but with a large rim of lymphocytic/plasmocytic infiltrate. Lesions tend to occur in the subcapsular parenchyma of abdominal organs such as the kidney, liver, colon, cecum, spleen, mesenteric lymph nodes, diaphragm, lungs, or pericardium rather than on the peritoneal or parietal serosa. Lesions appear to be remnants of an earlier serositis extending from the surface and into the underlying parenchyma along blood vessels. The ependyma and meninges are target tissues in the CNS and

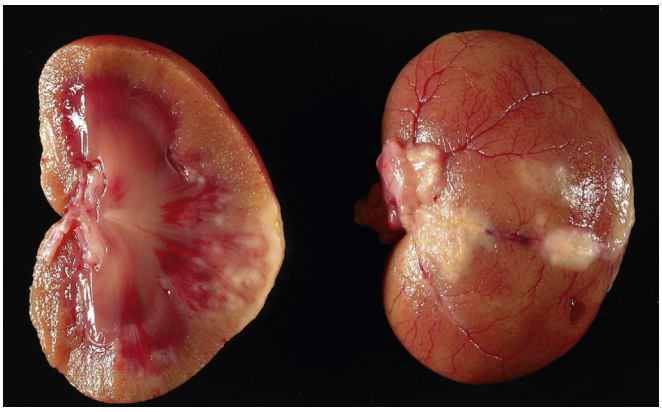

Fig. 31.14 Kidneys of the cat in Fig. 31.8. Multiple pale, tan, firm nodules expand the renal cortices and protrude from the cortical surfaces. (Courtesy D. Gasper and M. Jones, University of California-Davis Veterinary Anatomic Pathology Service.)

the uveal tract and retina in the eyes. Lesions in the skin, testicles, and nasal passages have also been described. The central pyogranulomas in non-effusive FIP are surrounded by dense infiltrates of lymphocytes and plasma cells that invade the surrounding parenchyma. The pyogranulomas contain fewer infected macrophages than those in cats with effusive FIP, which suggests that the host is better able to contain the infection in this form of FIP. Intermediate forms of effusive and non-effusive FIP may also be observed at necropsy. Intestinal[131] and renal lesions[47] of non-effusive FIP may be mistaken for neoplasia.[132] In the colonic form of the disease, foci of pyogranulomatous inflammation in the submucosa and muscularis mucosa surround pale pink-staining areas made up of collagen and sparse cells. These foci are encapsulated in turn by dense layers of fibrous tissue. FIPV antigen is found in large macrophages within the regions of active inflammation.

Immunohistochemistry. A definitive diagnosis of FIP cannot be made based solely on gross and microscopic pathologic features and requires proof of the presence of FIPV in tissues and in particular, macrophages within lesions. IHC on tissues collected at biopsy or necropsy can be as reliable as PCR, but accuracy is subject to many variables and requires excellent quality controls.[133,134] The greatest causes of false negatives and false positives include inadequate specimens, poor reagents, and reading errors. Immunofluorescence is more sensitive than immunoperoxidase staining but requires fresh frozen tissue sections with or without glycerol/resin protection medium. Immunoperoxidase staining can be performed on formalin-fixed tissues or cell pellets.

IHC of effusions from cats suspected to have FIP is strongly recommended, as effusions contain numerous virus-positive macrophages that can be concentrated onto slides. When the results of direct immunofluorescence on feline effusions were compared with histopathologic examination of tissues collected at necropsy in 17 cats, histopathology supported a diagnosis of FIP in 10/17 cases and ruled out FIP in 7/17 cases.[135] Antemortem immunofluorescence testing was positive in all 10 cases confirmed as FIP at necropsy. In the seven cats where FIP was ruled out at necropsy, IHC was negative in five cases and falsely positive in two cases. In another study, immunocytochemistry was 85% sensitive and 72% specific for the diagnosis of FIP from effusions.[136]

IHC can also be used to detect FIPV-infected macrophages within other specimens, such as CSF[137] or biopsy specimens.

TREATMENT

There is currently no approved, readily available, simple, or inexpensive treatment for FIP and the default treatment consists of drainage of fluid when necessary, anti-inflammatory doses of prednisolone, and reduction

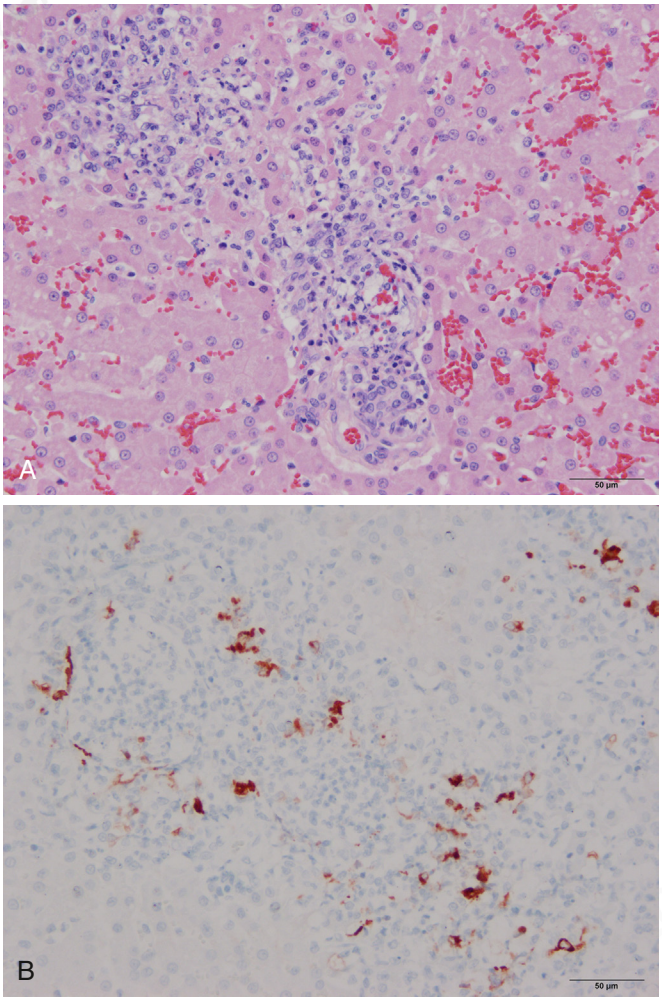

Fig. 31.15 (A) Histopathology of the liver of a cat with feline infectious peritonitis demonstrating pyogranulomatous hepatitis (hematoxylin and eosin stain). (B) Macrophages stain strongly positive for feline coronavirus antigen with immunohistochemistry. (Courtesy Dr. Patricia Pesavento, University of California-Davis Veterinary Anatomic Pathology Service)

of stress. Numerous available drugs, biologics, and nutritional supplements have been tried.[106] Antimicrobial drugs are seldom justified, as secondary bacterial infections are usually absent. Claims of cures have been made following many treatments, but these cures are uncommon and anecdotal. The problem is that there are no accurate mortality figures for FIP to evaluate any of these treatments. The only certainties are that older cats tend to live longer than younger cats and cats with non-effusive disease tend to live longer than cats with effusive FIP. Cats that are severely ill are also more likely to be euthanized upon diagnosis or shortly thereafter, whereas cats with milder disease are often treated supportively and kept alive longer, adding additional bias to mortality curves. Because of these factors, it is essential that a control population be included in studies of treatment effects on the disease. Survival time for cats with FIP also appear to be increasing over the last decade, which may relate to owner persistence with different treatments, or a true change in disease expression (either as a result of host genetics or virus factors).

Removal of abdominal effusion, except in cases where it interferes with breathing, is not recommended as it is rapidly replaced from body stores. Unnecessary removal of effusions can lead to hypoproteinemia and electrolyte disorders. Removal of thoracic effusions is frequently required to relieve dyspnea and can result in clinical improvement for several days or weeks. Removal of enlarged abdominal lymph nodes, intestinal masses, or single diseased kidney, is only indicated if life-threatening complications

TABLE 31.8 Suggested Drug Dosages for Treatment of Feline Infectious Peritonitis

Drug	Dose	Route	Interval (Hours)
Prednisolone	1–2 mg/kg	PO	12–24
Chlorambucil[a]	2 mg/cat	PO	48–72

[a]Monitor the complete blood count during treatment.

exist (e.g., intestinal blockage), as infection is almost always more widespread than clinically apparent. Other supportive care measures such as fluid therapy or placement of feeding tubes also may be required.

Anti-Inflammatory and Immunomodulating Drugs

Prednisolone and alkylating drugs such as chlorambucil have been used to reduce clinical signs in cats with FIP (Table 31.8), but there is no evidence that they significantly alter lifespan. Rather than using this less specific therapeutic approach, attempts have been made to inhibit the cytokine response. TNF inhibitors have been used to alleviate some of the signs of FIP and may decrease mortality when given in the initial stages of experimental FIPV infection.[138] Pentoxifylline has been shown to inhibit TNF-α production by macrophages and has been used to control vasculitis in humans. However, a study of 23 cats with proven FIP failed to detect an effect of a related drug, propentoxifylline, on the survival time, the quality of life, or any FIP-associated clinical or laboratory parameters.[139]

Nonspecific Immunostimulants

Anecdotal reports exist of cats presumed to be infected with FIP being cured or having their lives prolonged with a variety of non-specific immunomodulators (see Chapter 9). Polyprenyl immunostimulant (PI) is a plant extract claimed to prolong the lives, and possibly cure, some cats with mild forms of non-effusive FIP.[92,140] None of these biologics have been demonstrated to stimulate normal immune processes in healthy cats, and sufficiently powered randomized, placebo-controlled, double-masked studies of cats with confirmed FIP are lacking. A major problem is a lack of reliable survival statistics for cats treated with supportive care alone.[140]

Feline IFN-ω (Virbagen omega, Virbac) is a veterinary product widely marketed in Europe and Asia for treatment of many conditions of dogs and cats. It was proposed as a cure for cats with FIP in a study from Japan.[141] Twelve clinically ill cats were treated with a combination of a glucocorticoid and feline IFN-ω. Complete remission was observed in four cats and temporary remission in four cats. This study prompted widespread use of feline IFN-ω for treatment of FIP, except in countries where it was not approved for any veterinary use (including the United States). A subsequent double-blind, placebo-controlled study of 37 client-owned cats with predominately effusive FIP showed feline IFN-ω to lack efficacy.[142] Nonetheless, it continues to be used by some veterinarians to treat FIP and there have been anecdotal reports of occasional cats that have been cured. Human IFN-α given by injection or orally has also been used to treat cats with FIP, but it is immunogenic and is rendered ineffective after several weeks of use (see Chapter 9).

Nonspecific Viral Inhibitors

No virus disease of animals has commanded as much attention as FIP, and many drugs and biologics with inhibitory activity against FIPV in tissue culture have been studied. Many of the biologics studied inhibit FIPV by suppressing normal cellular processes that are usurped by the virus for its own replication, raising their toxicity for the cat. Others work by reacting with surface proteins and block infection in tissue culture but not in natural disease. These include cyclosporine and related immunophilins, vioporin inhibitors, pyridine N-oxide derivatives, chloroquine, plant lectins (*Hippeastrum* hybrid agglutinin, *Galanthus nivalis* agglutinin), ubiquitin inhibitors, and semisynthetic derivatives of glycopeptide antibiotics (vancomycin, teicoplanin).[83,120,143–150] Only chloroquine has

been tested for efficacy in naturally occurring disease in cats. The clinical scores of cats in groups treated with chloroquine were only slightly better than those of cats in groups not treated with chloroquine and there was evidence of hepatotoxicity.[120]

Viral inhibitory peptides and silencing RNA molecules also have been used to inhibit FIPV replication in tissue culture. In one study, five overlapping peptides that span the heptad repeat (HR) region of the S protein of a type II FIPV strain (NTU-156) were used to inhibit virus replication by blocking the intercalation of the HR1 and HR2 regions necessary for S protein-mediated fusion.[151] One of the five peptides inhibited FIPV replication by 97%, and had a synergistic effect with human IFN-α. In another study, eight small synthetic interfering RNA (siRNA) that targeted four regions of the genome were used to inhibit replication of the serotype II FIPV strain 79-1146.[152] Two of the siRNAs (targeting the 5' leader sequence and the nucleocapsid gene) resulted in a > 95% reduction in virus replication *in vitro*. Similar results were obtained by other investigators using five siRNAs that targeted the 3′ leader sequence and nucleocapsid genes.[153] These investigators then incorporated their siRNAs into infectious HIV-derived replication competent plasmids, which were then used to infect cultured feline hematopoietic stem cells.[154] The stem cells then produced anti-CoV miRNA with a reduction in FCoV replication, thus taking the application of siRNAs one step closer, but still distant, from clinical application.

Targeted Antiviral Drug Therapy

The most successful antiviral therapies have involved drugs that target viral genes that regulate key processes in virus attachment, integration, or replication. Drugs used for related and unrelated RNA virus infection of humans can target at least two FCoV genes. One is the 3C-like protease[155,156] and the second is the replicase gene responsible for RNA-dependent RNA transcription of subgenomic RNA transcripts.[157]

Viral Protease Inhibitors

GC376, a 3C-like protease inhibitor, was the first specific antiviral drug tested against both experimental[156] and naturally occurring FIP.[155] GC376 is a prodrug which is broken down to the active moiety, GC373. GC373 is virtually identical to nirmatrelvir, the active component of Paxlovid (Pfizer) for treatment of COVID-19.[158] GC373 inhibits the 3C-like protease. Structural proteins of CoV are first transcribed from mRNAs as polyproteins, which are then cleaved by 3C-like proteases into individual proteins used in virion production. Preliminary *in vitro* tests showed that GC376 was effective in inhibiting FIPV replication at levels not toxic to cells.[156] Use of GC376 to treat cats with experimental FIPV infection resulted in cures when treatment was started at the onset of disease and continued for 2 to 4 weeks.[157] A field trial using 20 cats with naturally occurring FIP and twice-daily SC injections yielded mixed results.[155] There was dramatic clinical improvement in cats without neurologic signs within a few days of starting treatment, and 6 of 20 cats developed sustained remissions after 12 weeks of continuous treatment. However, relapses that occurred during treatment or after treatment led to euthanasia of 14 of the 20 cats. Development of neurologic disease during or after treatment was the major cause of failure. Adverse drug effects were manageable and consisted of injection site reactions and impaired development of permanent teeth.[155] At the time of writing, GC376 is under development for treatment of FIP and simultaneously being evaluated as a treatment for COVID-19 by Anivive Life Sciences.[159]

Nucleoside Analogues (RNA Transcription Inhibitors)

Ribavarin is a guanosine nucleoside analogue used once in combination with IFN for the treatment of hepatitis C. It is an *in vitro* inhibitor of FIPV[160] but had no effect on experimental FIPV infection.[161]

The adenosine nucleoside analogue GS-441524, the active form of the prodrug remdesivir (Gilead Sciences) is the most promising treatment for FIP tested to date. GS-441524 and related compounds have been developed as a result of research into possible treatments for human RNA viral diseases such as Ebola, Marburg, SARS-CoV-1 and SARS-CoV-2, and MERS. GS-441524 is the parent nucleoside of remdesivir (i.e., the active metabolite of remdesivir, a prodrug). Remdesivir was originally developed to treat hepatitis C in humans and has now been used extensively worldwide to treat COVID-19. GS-441524 is taken up by cells, phosphorylated stepwise to mono-, di-, and tri-phosphate forms, which then compete with cellular adenosine nucleotide for incorporation into replicating FIPV RNA (see also Chapter 9).[162] GS-441524 given SC demonstrated favorable pharmacokinetics in laboratory cats and was effective against experimental disease.[162] A field trial of 31 cats was conducted with various non-neurologic forms of FIP and drug given SC q24h for a minimum of 12 weeks.[163] Five of the 31 cats recruited to the trial had to be euthanized during the first few days of treatment due to the severity of their disease and complications, but 26 went on to be treated for 12 weeks or longer. Of the 26 cats, 25 achieved sustained disease remission following one or two cycles of treatment with no systemic signs of toxicity. Apparent cures were described by owners in over 50% of 393 cats treated at home with GS-441524, with a mean cost of treatment of $4920 (USD).[164]

There are several limitations of drugs like GC376 and GS-441524. The passage of both drugs into the CSF and aqueous humor is impeded by the blood/brain and blood/eye barriers, respectively.[157,162] Attempts to overcome this by increasing the drug dosage have not been successful for GC376, although clinical signs were greatly decreased.[155] Higher dosages of GS-441524 can overcome the blood/brain barrier in cats with neurologic FIP.[165] A second limitation has been cost. Treatment currently costs several thousand dollars for drug alone, but this cost is expected to decrease with time.[164] A final, and more important limitation, involves legal approval for veterinary use of closely related drugs that have been developed for humans against COVID-19. These drugs currently include the nucleoside analogues remdesivir[166] and molnupiravir,[167] and the viral protease inhibitor paxlovid.[158] These drugs have only conditional approval for in-hospital use against COVID-19 at the time of writing. There is a concern among large pharmaceutical companies that concurrent use of these or closely related drugs in animals would complicate the full approval process of drugs for human use. Without FDA approval, veterinarians were initially unwilling to use drugs that were not legally produced and sold. This led initially to a situation where a cure was available for the first time for FIP but no inclination to apply it in the field. However, the desperate need of cat owners for a treatment for FIP and willingness of companies in China to provide them the drugs quickly rendered these concerns moot. People concerned about FIP, particularly those involved in foster/rescue, were quick to embrace the treatment.[164] Their efforts resulted in tens of thousands of cats from around the world being successfully cured of FIP from 2017 onward. This success convinced some academic veterinarians to become involved.[164,168] The legality of using unapproved antivirals for treatment of diseases has also been overcome in some countries by allowing veterinarians to use conditionally approved drugs like remdesivir.[169] Hopefully, such arrangements will be short-lived as drugs like remdesivir, molnupiravir and paxlovid are given full approval for coronavirus disease in people. Full approval by national entities like the FDA will allow veterinarians to use them per label or extra label fashion when no approved animal equivalent is available, provided that they are compounded from federally approved drugs. (AVMA)

PROGNOSIS

The 1-year mortality for FIP is around 95% for cats treated with various non-virus–specific medications. Younger cats, which tend to have more acute and severe forms of FIP, have the shortest survival

times, whereas older cats with less severe and more chronic forms of FIP tend to live longer. Marked pyrexia, lethargy, inappetence, weight loss, and icterus are indications of a poor prognosis. Lymphopenia is often associated with more fulminant disease, whereas higher counts are associated with more localized and less intense inflammation. Cats with pronounced abdominal effusions that are still active, eating, and maintaining weight are more likely to manifest lower-grade fever, clearer fluid, and less likely to be icteric. Apparent long-term cures have now been described for many cats treated with nucleoside analogues such as GS-441524 and remdesivir.

IMMUNITY

FECV immunity is mediated by humoral mucosal and systemic responses.[170] Secretory antibody responses in the gut most likely mirror IgG antibody levels in the blood. Antibodies measured by indirect IFA appear in the blood within 10 to 14 days of infection and rise to titers around 1:400 at the peak of shedding.[10,37] Serum antibody titers then fall to levels of 1:25 or less as virus shedding becomes intermittent and finally ceases.[37] Reinfections are common and resemble primary infections in the pattern of fecal shedding and antibody responses. Reinfection has also been observed in natural disease.[66] This pattern of infection is typical, as immunity to mucosal pathogens often requires a long period of exposure or persistence to develop and does not evoke strong memory.[171] Immunity to animal coronavirus vaccines is also notoriously poor.[172]

As noted earlier in this chapter, cellular immunity appears to be important in determining the outcome of FIPV infection. Humoral immunity is not thought to be nonprotective in FIP and contributes to disease pathogenesis. In a study of experimentally infected cats, investigators were unable to identify T-cell responses that might predict disease outcome during early infection with FIPV. However, on re-exposure to FIPV, antiviral T-cell responses appeared to be important in preventing disease.[173]

PREVENTION

Minimizing Exposure

Attempts have been made to eliminate FECV from cat populations. One approach used has been to isolate pregnant queens from all other cats and wean and isolate kittens at 4–6 weeks of age.[174] Even if the queen is shedding FECV, most kittens have sufficient maternal-derived immunity to resist infection until 9–10 weeks of age. After early weaning, kittens are strictly quarantined and tested for fecal FECV shedding at monthly intervals for several months to assure that they are free of the virus. Once free from FECV, prevention of infection requires a specific facility for noninfected cats and strict control of the movement of people to avoid introduction of the virus on fomites. It also precludes acquisition of new cats without strict testing and quarantine and limits introduction of cats, all of which defeat the purposes of pedigreed cat breeding.

FECV infection can also be allowed to burn itself out. In one study of naturally infected cats, FECV shedding dramatically decreased over 3 years, suggesting a type of herd immunity.[66] If a cattery or other multicat facility is closed to new susceptible cats, either from outside or from within (i.e., kittens bred in the facility), the proportion of fecal shedders will slowly decline. This can be facilitated through the testing of all the cats used to produce a FCoV-free population by fecal PCR or serology.[14] Cats that are negative by PCR and have low FCoV titers (≤1:25 by indirect IFA) are segregated to one facility and quarantined. Cats with strong positive PCR values and antibody titers ≥ 1:400 are eliminated, and cats with intermediate values are segregated to a second facility. This testing is repeated every month and within a year or less the result will be two separate groups of cats that should be free of infection with a minimum of loss of breeding stock. These procedures have been used to eliminate FECV infection from SPF experimental cat breeding colonies.[14]

A direct relationship exists between the extent of fecal shedding of FECV and FIP.[36,65] Cats over 3 years of age are also less apt to be FECV carriers. Therefore, the severity of FECV exposure and incidence of FIP can be diminished by reducing the numbers of breeding cats to a minimum and by decreasing the proportion of younger cats in a cat population. Breeding cats should be kept for longer periods of time to reduce the numbers of young cats introduced into the cattery. Adult cats are also less likely to shed other common pathogens, and when coupled with decreased kitten density, this can also reduce the incidence of upper respiratory and enteric infectious diseases. Catteries that remain free of FIP are often those that maintain six or less breeding queens with one or two toms. Unnecessary cats should be removed from the cattery whenever possible. Kitten production should be also minimized by more careful mate selection and breeding for quality rather than quantity.

Vaccination

Several potential FIP vaccines have been described over the last three decades.[56,57] These vaccines have had preventable fractions that range from 0% to 75%, and results from the field have been mixed.[108] Only one vaccine, Primucell FIP (Zoetis, Parsippany, NJ), has been successfully licensed and marketed in the United States and several other countries. This is an intranasal vaccine that contains a temperature-sensitive mutant of serotype II FIPV-DF2, and initial vaccination consists of two doses of the vaccine given 3 weeks apart.[175] Vaccination has not been shown to be effective when administered to cats less than 16 weeks of age, suggesting that the immune system must reach a more mature state of development than for other routinely used vaccines. The vaccine has been shown to be safe with no signs of ADE.[176] There are several aspects of the vaccine that limit its use in the field. It contains a serotype II strain of FIPV, while serotype I strains predominate in the field. Serotype I and II strains contain different virus-neutralizing epitopes. The vaccine is also without efficacy when administered to kittens less than 16 weeks of age, which is at least 6 weeks after kittens from multi-cat environments have been exposed to FECV. The vaccine may also lack efficacy in cats that have been previously exposed to FCoV.[108] In a placebo-controlled study of two high FIP–risk populations,[177] the vaccine was safe and efficacious in one population of cats that had low antibody titers to FCoV at the time of vaccination. It was concluded that vaccination could protect cats with no or low FCoV antibody titer. However, catteries with low CoV titers are at low risk for FIP, and titers are generally high among cattery, rescue, and shelter cats. Therefore, the target group for this vaccine would be cats exposed to uncommon serotype II strains of FECV, with less than a 1% risk of developing FIP after such exposure, and that are over 16 weeks of age and seronegative for FCoV exposure when vaccinated. Furthermore, vaccination of FCoV-naïve laboratory cats ≥ 16 weeks of age, was less than 70% effective against challenge exposure with a serotype II FIPV when adjusted for the survival rate of nonvaccinates.[175] As a result of these concerns, the AAFP has stated that, "at this time, there is insufficient evidence that the vaccine induces clinically relevant protection, and use of the vaccine is not recommended."[178]

Genetic Selection

Susceptibility to FIP in pedigreed cats appears to be 50% heritable in breeds studied.[70] Attempts to use positive selection in a laboratory setting to enhance resistance among random-bred cats failed, and the resultant inbreeding increased rather than decreased FIP susceptibility.[72] Genetic susceptibility appears to involve inheritance of numerous risk factors, some positive and others negative.[71,72] Because inbreeding is a much greater problem among pedigreed than random-bred cats, genetic factors play a proportionately greater role

in catteries than in kitten rescues or shelters. Other host and environmental co-factors are of greater importance in random-bred populations. The fact that some breeds and lines of pedigreed cats are at greater genetic risk for FIP is a two-edged sword. Although inbreeding and artificial genetic bottlenecks may increase FIP risk in pedigreed cats, catteries can control which toms and queens are bred and may be able to associate certain breeding combinations with development of FIP. The practice of not using cats that have produced kittens that have died of FIP or that are in closely related lines known to have problems with FIP is widely accepted. Both toms and queens contribute genetic risk factors, but because toms produce many more kittens, the culling of problem toms rather than queens can be more effective.[70] Tom cats from lines with no history of FIP can overcome genetic deficiencies in queens, while breeding genetically deficient toms with deficient queens can rapidly bring FIP problems to the forefront.

PUBLIC HEALTH ASPECTS

There is no evidence that humans can become infected with FCoV. Most human coronaviruses, including SARS-CoV-2 (the cause of COVID-19), are beta- and not alpha-CoVs. SARS-CoV-2 can infect and cause disease in cats (see Chapter 43).[179] Other coronaviruses have been shown to cause FIP-like disease in ferrets and mice. If a coronavirus emerged that could cause similar clinical manifestations and outcomes in humans as FIPV can in cats, it would clearly represent a major threat to humans, and would without doubt be the subject of intense research.

CASE EXAMPLE

Signalment

"Ricky", a 9-month-old male castrated domestic shorthair from Sacramento, CA.

History

Ricky was obtained as a stray at 8 weeks of age by a local kitten rescue group and adopted by the owner at 3 months of age. He had experienced multiple upper respiratory tract infections before being adopted but was healthy when placed in a new home with one other cat. He was an indoor cat that was sometimes walked briefly outdoors.

Ricky was brought to a local veterinary clinic at 9 months of age because of an acute onset of increased thirst and urination. A serum chemistry panel showed hyperglobulinemia (7.7 mg/dL). The urine SpG was 1.025 with inactive sediment and culture negative for aerobic bacteria. Ricky stopped eating over the next 3 days and was returned to the clinic. Laboratory abnormalities at that time included a mature neutrophilia (11,904 cells/μL), lymphocytosis (5,104 cells/μL), eosinophilia (1,536 cells/μL), hyperglobulinemia (6.9 mg/dL), and hypoalbuminemia (2.4 mg/dL) with A:G ratio of 0.35. A FCoV antibody titer was positive at 1:400. Serology for *Toxoplasma gondii* was negative. Plain thoracic radiographs showed a mild interstitial pattern. Abdominal ultrasound showed a moderately enlarged mesenteric lymph that was reactive on aspiration. Ricky's appetite recovered when cyproheptadine was initiated for several weeks, after which treatment was discontinued. Ricky remained outwardly normal over the next 3 weeks, although occasional soft feces were noticed in the litter box. The owners were concerned about the possibility of FIP. The owner suspected FIP and wanted a second opinion.

Physical Examination

Ricky was bright, alert, and active on presentation with a weight of 4.2 kg, T = 103°F, HR = 200 beats/minute, and eupneic. His eyes, ears, nose, and throat were normal, and his BCS was 5/9. Thoracic auscultation did not reveal any abnormalities, and abdominal palpation was normal.

Laboratory Findings

A CBC demonstrated a slightly low HCT at 27.3%, a normal MCV and MCHC, and a leukocytosis of 24,950 cells/μL with neutrophilia (17,141 cells/μL), high normal lymphocytes (6,886 cells/μL), a monocyte count of 724 cells/μL, eosinophils of 200 cells/μL, and a slightly elevated platelet count (518,000/μL).

A serum chemistry profile demonstrated a normal sodium, potassium, chloride, bicarbonate, phosphorous, calcium, BUN, creatinine, and glucose. However, total protein concentration was greatly elevated at 10.7 g/dL with a low normal albumin (2.6 g/dL) and high globulin (8.1 g/dL) and A:G ratio of 0.32. Serum liver enzyme activities (ALT, AST, ALP, and GGT) were normal, as were the cholesterol and bilirubin concentrations. A serum protein electrophoresis showed a polyclonal gammopathy with a mild decrease in albumin and mild increases in the α_2 and β_1 fractions consistent with the acute-phase inflammatory response.

Imaging Findings

Ultrasound of the abdomen demonstrated moderate splenomegaly and a diffuse mesenteric lymphadenopathy. An aspirate of a mesenteric lymph node showed a heterogenous population of lymphocytes, predominated by small, mature lymphocytes and low numbers of intermediate and large reactive lymphocytes with scattered plasma cells and histiocytes. Immunocytochemistry using two different monoclonal antibodies to FCoV was negative.

Microbiologic Testing

FeLV antigen and FIV antibody serology were negative, as were blood cultures for *Bartonella clarridgeiae* and *Bartonella henselae*. Ricky was also seronegative for antibodies to *Ehrlichia canis*, *Anaplasma phagocytophilum*, *Rickettsia* spp., and whole blood PCR-negative for *A. phagocytophilum*, *Anaplasma platys*, *Bartonella* spp., *E. canis*, and *Mycoplasma haemofelis*. Aerobic and anaerobic bacterial cultures of mesenteric lymph node aspirates were negative; an FCoV 7b PCR on whole blood was also negative. Serology for FCoV antibodies was positive at 1:102,400.

Diagnosis

A tentative diagnosis of FIP was made based on Ricky's background, the marked polyclonal gammopathy, and extremely high CoV titer.

Treatment and Outcome

Ricky was treated with prednisolone (5 mg, PO, q12h for 7 days, followed by 5 mg, PO, q24h thereafter), and chlorambucil (2 mg, PO, every 3 days). After 6 weeks of treatment, Ricky appeared normal and CBC variables were within normal reference ranges. However, his total protein was 8.5 g/dL with a globulin of 4.5 g/dL and an abdominal ultrasound showed persistent, but mild mesenteric lymphadenomegaly. A repeat FCoV titer was 1:25,600 and treatment with feline IFN-ω was commenced at 4.5 million units, SC, once weekly.

Ricky was next seen 3 months later, at which time he appeared playful, his appetite was normal, and his body weight had remained stable at 4.5 kg. A CBC showed mild anemia (HCT 28.5%), with low normal WBC with neutrophils at 4,439 cells/μL and lymphopenia (468 cells/μL). A serum chemistry panel and abdominal ultrasound showed no abnormalities, which prompted discontinuation of the chlorambucil and IFN-ω and continuation of prednisolone.

Ricky was next seen 12 months after his illness, at which time he was apparently healthy. CBC findings were unchanged from the previous visit and his serum globulin concentration was 4.7 g/dL. The prednisolone dose was decreased to

Continued

CASE EXAMPLE—cont'd

5 mg q48h. One month later, albumin and globulin concentrations were 3.3 and 5.1 g/dL, respectively, and the prednisolone dose was reduced to 2.5 mg q48h. Two months later, a CBC was unremarkable, but the globulin had increased to 5.7 g/dL, abdominal ultrasound showed a mild enlargement of the mesenteric lymph nodes, and the serum CoV antibody titer was 1:409,600. The prednisolone dose was returned to 5 mg, PO, q24h, and 1 month later, the serum globulin concentration was 4.9 g/dL.

Ricky was still doing well clinically 1.5 months later, but a mid-abdominal mass was palpated on physical examination and the serum globulin concentration had increased again (5.6 g/dL). Abdominal ultrasound showed several moderately enlarged and hypoechoic lymph nodes in the ileocolic region, the largest of which measured 0.9 cm in diameter. The surrounding mesentery was focally hyperechoic. There was also focal hyperechoic retroperitoneal tissue surrounding the right kidney with scant retroperitoneal fluid. Attempts to obtain aspirates from the lymph nodes were unsuccessful. The prednisolone dose was increased to 5 mg, PO, q12h, and treatment with chlorambucil was reinstituted. Ricky became lethargic and anorectic over the next week. A CBC showed worsening anemia (HCT 24.3%) and persistent lymphopenia (782 cells/μL). His globulin concentration was increased (5.8 g/dL) and albumin normal (3.3 g/dL). A fourth FCoV antibody titer was 1:25,600. Treatment with cyproheptadine was initiated and the chlorambucil and pentoxifylline discontinued. The inappetence continued, he became persistently pyrexic (103.4°F to 104°F), and hematochezia and tachypnea developed over the next few days. HCT dropped to 16.5%, and hypokalemia, hyponatremia, and hypochloremia developed. Ricky was hospitalized and treated with 1 unit of packed RBCs, IV crystalloids, and parenteral antimicrobial drugs. Thoracic radiographs showed a severe, diffuse, patchy alveolar and nodular interstitial pattern with thickening of the bronchial walls and mild pleural effusion. A tracheobronchial lavage showed marked mixed, predominantly pyogranulomatous inflammation with moderate epithelial hyperplasia and some degenerate neutrophils. Immunocytochemistry with an anti-FCoV antibody was strongly positive (Fig. 31.16). Shortly thereafter he began to seizure and was euthanized.

Necropsy Findings

A necropsy showed moderate to severe, multifocal to coalescing pyogranulomatous inflammation involving the parietal and visceral serosa of the spleen, liver, kidney, intestines, diaphragm, thoracic and abdominal walls, and pericardium. There was also multifocal pyogranulomatous splenitis, hepatitis, nephritis, meningoencephalitis, and pneumonia with pulmonary necrosis. Straw-colored effusion was present in the abdominal cavity, thoracic cavity, and pleural space. IHC was strongly positive for FCoV antigen.

Comments

This case was typical of several cats that start out with dry FIP localized primarily to the mesenteric lymph nodes. This has been previously described as the mildest clinical form of FIP. In this presentation, the host immune system can contain most of the infection to the primary target organ (i.e., the mesenteric lymph node), but the immune response is insufficient to bring about a complete cure and the disease becomes clinically apparent. In other such cases, the disease has been known to completely resolve or remain subclinical for many months and possibly years.[56,92] Although Ricky appeared to respond on several occasions to medications such as prednisolone and IFN-ω, there is reasonable evidence that none of these drugs are effective in altering the disease course,[160,163] and the ups and downs in clinical condition during these earlier stages would be as expected for this form of FIP. Ultimately, disease progressed and a diagnosis of FIP was confirmed with immunocytochemistry on a tracheobronchial lavage specimen. The terminal development of effusions is also more commonly recognized and has been referred to as 'dry-to-wet' FIP. It is often only when the disease becomes conspicuously effusive that the correct diagnosis is made. The PCR and immunocytochemistry results early during illness were false negatives, indicating that the level of virus in the samples at these early stages was below the sensitivity of the assay procedures or that sampling was inadequate. Drugs such as GC376, GS-441524, and remdesivir have shown promise for complete cure of disease in cases such as this, but were not available at the time this cat was alive.

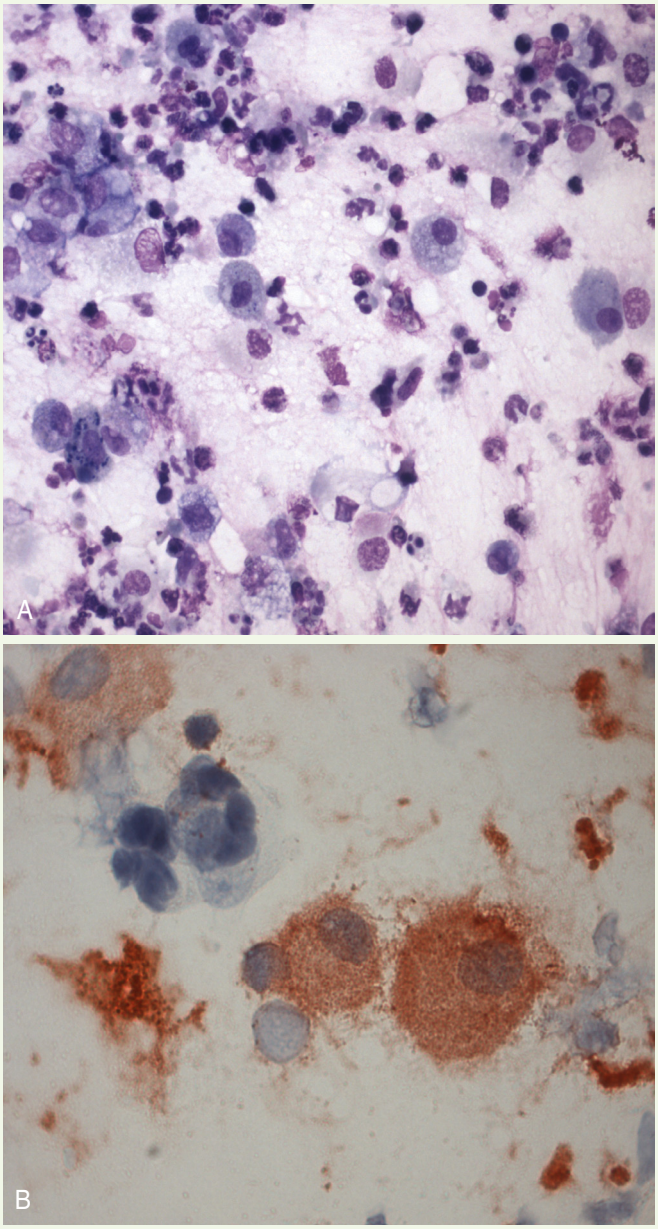

Fig. 31.16 (A) Cytospin preparation of a tracheobronchial lavage specimen from the cat in Fig. 31.7. The specimen was highly cellular (4,400 cells/μL) and the cells consisted of 42% degenerate neutrophils and nondegenerate neutrophils, 5% lymphocytes, and 53% macrophages. (B) Immunocytochemistry stain on the same specimen for coronavirus antigen showing positive staining in association with macrophages.

Feline Leukemia Virus Infection

Katrin Hartmann, Regina Hofmann-Lehmann, Jane E. Sykes

KEY POINTS

- Cause: FeLV, a gammaretrovirus of domestic cats, is a member of the *Oncornavirus* subfamily of retroviruses. It contains a protein core with single-stranded RNA protected by an envelope.
- First Described: FeLV was first described in 1964 by William Jarrett and coworkers, when virus particles were seen budding from the membrane of malignant lymphoblasts from a cat with naturally occurring lymphoma. Although clusters of lymphoma cases occurring in households had always been observed, it was not until the discovery of FeLV that an infectious etiology was finally proven.
- Affected Hosts: In nature, FeLV mainly infects domestic cats. Some wild felids are also susceptible.
- Geographic Distribution: FeLV infection occurs worldwide. For many years after its discovery, FeLV was considered to account for most disease-related deaths in pet cats, and was responsible for more clinical syndromes than any other single agent.
- Route of Transmission: Prolonged close contact with salivary secretions is the most common mode of transmission, and less frequently FeLV is transmitted through biting, transplacental transmission, transmission through milk, and through blood transfusion.
- Major Clinical Signs: Most common clinical signs include lethargy, pallor, signs of stomatitis, signs of underlying lymphoma or leukemia, signs of immune-mediated disorders, or signs of opportunistic infections.
- Differential Diagnoses: For cats with immunosuppression, FIV infection is the primary differential diagnosis; for cats with stomatitis, FCV infection or FIV infection are the differential diagnoses; for cats with immune-mediated diseases and cytopenias, primary immune-mediated disease and other bone marrow diseases are the differential diagnoses.
- Human Health Significance: FeLV does not infect humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

FeLV is a gammaretrovirus of domestic cats that belongs to the *Oncornavirus* subfamily of retroviruses. It was first described in 1964 by William Jarrett and coworkers, when virus particles were seen budding from the membrane of malignant lymphoblasts from a cat with naturally occurring lymphoma.[1-4] FeLV contains a protein core with single-stranded RNA protected by an envelope. FeLV is an exogenous agent that replicates within many tissues, including bone marrow, salivary glands, and respiratory epithelium. If the immune response does not intervene after initial infection, FeLV spreads to the bone marrow and infects hematopoietic precursor cells. All retroviruses, including FeLV, rely on a DNA intermediate for replication. The single-stranded RNA genome is reversely transcribed into DNA, which is integrated into the host's cell genome as *provirus* with the help of an integrase enzyme. After reverse transcription, synthesis of viral proteins occurs with assembly of the virions near the cell membrane and budding from the cell. Once the provirus is integrated, cell division results in daughter cells that also contain viral DNA. The ability of the virus to become part of the host's own DNA is crucial for the lifelong persistence of the virus after bone marrow infection.

Both exogenous (foreign, "pathogenic") and endogenous (inherited, mostly "nonpathogenic") retroviruses occur in cats.[5] Pathogenic exogenous viruses that can be transmitted horizontally from cat to cat include FeLV, FIV, and FFV (previously known as syncytium-forming virus, see Chapter 36), which is widespread but has a low pathogenicity.

On the basis of similarities in nucleotide sequences, it is likely that FeLV evolved from a virus in an ancestor of the rat. It is assumed that this event took place in the late Pleistocene up to 10 million years ago in the North African desert. Ancestral rats and cats roamed freely, and the virus was transmitted to cats through ingestion or a rat bite. The initial spread of FeLV among cats might have been inhibited by the aridity of the North African desert.[6]

FeLV is divided into several subgroups, but only subgroup FeLV-A is infectious and transmitted from cat to cat. The other subgroups (e.g., FeLV-B and FeLV-C) are not transmitted from cat to cat under natural circumstances but can be generated *de novo* in a FeLV-A-infected cat by mutation or recombination of the FeLV-A genome with cellular genes or genes from endogenous retroviruses in the cat's genome. The feline sarcoma virus (FeSV) also is a recombination of the FeLV-A genome with tumor-associated cellular genes (proto-oncogenes) and likewise is generated *de novo* in a FeLV-A-infected cat.

The endogenous counterparts of exogenous FeLV, termed enFeLVs, are integrated into the genome of domestic cats and closely related wild felids. EnFeLV is thought to have originated hundreds of thousands of years ago from cats that had eaten mice viremic with a murine leukemia virus (MuLV) that was able to incorporate its genome into the germline cells of the predator. This MuLV was then inherited by the feline offspring in a Mendelian manner. EnFeLVs are present in every cat and every feline cell. In contrast, more recently integrated endogenous elements can display polymorphisms among cats. As enFeLV elements are generally mutated and nonfunctional, they do not form infectious virions, although expression of short transcripts has been observed.[7] Recombination can occur between enFeLV and exogenous FeLV-A following infection, which can give rise to pathogenic viruses. Transduction of enFeLV *env* sequences encoding for the viral envelope can lead to development of FeLV-B or FeLV-D.[8-10] In addition, parts of, or the entire, *gag* genes of enFeLV have been identified in FeLV isolates from naturally infected cats.[11] Moreover, truncated envelope proteins encoded by enFeLV (FeLIX) can facilitate infection with fusion-defective exogenous FeLV by binding to the cellular receptor.[12] FeLIX activity was detected at a functional level in sera from domestic

cats.[13] EnFeLV loads can vary among different cat populations and are influenced by the breed and gender of the cat.[14] An association between enFeLV loads and FeLV-A replication but not with outcome of FeLV infection was demonstrated.[15] Full-length enFeLV elements with putative functional open reading frames have been characterized.[16] These are present in only 9% to 15% of domestic cats suggesting that they are relatively recent additions to the feline genome.[17]

Other endogenous retroviral elements are also found in cats, such as RD-114, which is most closely related to an endogenous baboon retrovirus. RD-114 elements and RD-114-related sequences (RDRSs) likely entered the cat genome hundreds of thousands of years ago as a result of predation of early primates by ancestor cats, both before and after domestication.[18,19] No loci that encode infectious RD-114 could be found in the feline genome, but a virus nearly identical to RD-114 can be produced by recombination between two defective RD-114 virus-related proviruses.[20,21] Although there is no evidence of pathogenicity of RD-114 in cats, or an immune response to the virus, it could play a role in normal fetal differentiation.[22-24] Assays to screen for RD-114 infection in cell culture, and a method to establish cell lines with reduced risk of endogenous retroviruses have been developed.[25,26]

Various recombinations of RD-114, FeLV-related sequences, and the baboon endogenous virus have been characterized, now known as endogenous retroviruses of domestic cats (ERV-DCs). Several proviral clones have been identified and numbered according to their genomic insertions, for example, ERV-DC1, and classified into genotypes I, II, and III by phylogenetic analysis. Most contain deletions and mutations that render them noninfectious, but there are several ERV-DCs that are infectious in the domestic cat and can even infect human cell lines. Some of these are fixed in the cat genome, whereas others are mobile and have the potential to eventually disappear. Approximately one-third of cats tested in Japan carried ERV-DC10 loci.[8] It is unclear whether ERV-DCs are harmful or beneficial to the host. Hosts tend to tightly control their ERVs, particularly those with high transcriptional activity, for example by promotor methylation.[27]

FeLV Subgroups

FeLV subgroups are immunologically closely related but use different cellular receptors.[28-32] The three most established FeLV subgroups are FeLV-A, FeLV-B, and FeLV-C (Table 32.1). The cell surface entry receptor for FeLV-A is a putative thiamine transporter (THTR1) which is widely expressed in cat tissues. Therefore it was speculated that FeLV-A infection could disrupt thiamine uptake with pathological consequences.[33] Thiamine uptake was indeed blocked by FeLV-A; in feline fibroblasts that naturally express feline THTR1, this blockade resulted in a growth arrest at physiological concentrations of extracellular thiamine. THTR1 is highly conserved among different feline species (Iberian lynx, Asiatic and Indian lion, European wildcat, jaguarundi, domestic cat) and thus variations in the THTR1 sequence do not explain host species susceptibility differences.[34] FeLV-B uses Pit1 and Pit2 as receptors for virus entry; Pit1 and Pit2 normally function as sodium-dependent phosphate transporters.[28,32] The FeLV-C receptor (FLVCR) is a 12-transmembrane domain surface protein that exports heme from cells. FLVCR is required for erythroid maturation.[35-37] FLVCR is also important for development and maturation of CD4+ and CD8+ T cells.[38]

Only FeLV-A is transmitted horizontally from cat to cat in nature. The other subgroups evolve in FeLV-A-infected cats by mutation and recombination between FeLV-A and cellular or endogenous retroviral sequences contained in normal feline DNA. Subgroup B originates from recombination of FeLV-A with enFeLV. In one study of a closed colony of cats, multiple FeLV-B variants were generated in more than half of the cats infected with FeLV-A; horizontal transmission was also considered possible because of a high degree of genetic similarity of the variants among cats.[39] Subgroup C is less common and is the result of mutations in the *env* gene.[2]

Replication of FeLV-B and FeLV-C is usually only possible with the help of FeLV-A, because important genomic sequences are replaced in these recombinant viruses. Proposed FeLV-A helper functions include enhanced replication efficiency, immune evasion, and replication rescue for defective FeLV-B and FeLV-C virions. However, in newborn SPF kittens, experimental FeLV-B or FeLV-C infection was established without the presence of FeLV-A.[40,41] Moreover, by screening 300 field isolates using interference assays, two isolates, FeLV-2518 and FeLV-4314, displayed the FeLV-B phenotype alone in the absence of a fully functional helper FeLV-A virus.[42] Nevertheless, naturally infected cats usually carry FeLV-A either alone or in combination with FeLV-B, FeLV-C, or both. In consequence, if immunity to FeLV subgroup A is present, the cat has immunity to infection by any FeLV subtype.

In general, the pathogenicity of FeLV-B and FeLV-C, in combination with FeLV-A, is higher than that of FeLV-A alone.[43] Envelope protein differences among subtypes have been shown to be the major determinants of pathogenicity, but the mechanisms by which these differences influence pathogenesis are not well understood. FeLV-B infection is commonly associated with malignancies, especially thymic lymphoma. FeLV-C is mainly associated with nonregenerative anemia.[44]

Other FeLV subgroups have been described more recently. FeLV-D arises from recombination of FeLV-A and the *env* gene of a feline endogenous gammaretrovirus (ERV-DC), genotype I.[8,45] FeLV-D was detected in the blood or tumor tissues of three of 283 FeLV-infected cats, but its infectivity and pathogenicity remain unclear. Receptors for FeLV-D have not yet been identified. FeLV-T is highly cytolytic for T lymphocytes and causes severe immunosuppression[46-48] but is likely not important in the field. FeLV-T also uses Pit-1 as a receptor, like FeLV-B, but for reasons that remain unclear, the host ranges of FeLV-B and FeLV-T are not exactly the same.[32] FeLV-T is fusion-defective and requires the cofactor FeLIX to infect cells. As described earlier, FeLIX is a truncated envelope protein encoded by an endogenous FeLV, which can function as either a transmembrane protein or a soluble component to facilitate infection.[12,13,49] Another subgroup that can be found experimentally, "FeLV feline-acquired immunodeficiency syndrome" (FeLV-FAIDS) virus, is composed of FeLV-A and

TABLE 32.1 Host Cellular Receptors for Major FeLV Subtypes

FeLV Subtype	Receptor	Receptor Function	Comments
FeLV-A	FeTHTR1[29]	Thiamine transporter protein	Present in all cats with FeLV infection; transmitted exogenously
FeLV-B	FePit1 or FePit2[404]	Inorganic phosphate transporter protein	Results from recombination between FeLV-A and feline endogenous FeLV-related retrovirus sequences; can facilitate development of lymphoma or enhance neuropathogenicity
FeLV-C	FLVCR[405]	Heme transporter protein	Arises from point mutations in FeLV-A *env* gene; associated with nonregenerative anemia

FePit, feline Pit; *FeTHTR1,* feline thiamine transporter 1; *FLVCR,* FeLV-C receptor.

a highly immunopathogenic variant that infects CD4+ and CD8+ T lymphocytes and B lymphocytes in blood, lymph nodes, and myeloid cells.[50] Widespread proliferation of this virus greatly impairs the host immune response. In 2016, the subgroup FeLV-TG35-2 was described, which originated from a FeLV-infected cat, TG35, in Japan;[51] a folate transporter has been identified as a possible receptor.[52]

Virus Genome and Proteins

FeLV is a typical retrovirus (Fig. 32.1). It contains a single-stranded RNA molecule that is transcribed into proviral DNA by the enzyme reverse transcriptase (RT) and subsequently integrated into the host cellular genome. The gene sequence contains long terminal repeats (LTRs), which are repeated sequences that have regulatory function and control expression of the other viral genes but generally do not code for a protein product. From the 5′ to the 3′ end, the gene order is LTR-*gag*-*pol*-*env*-LTR (Table 32.2). LTR regions play a critical role in viral tissue tropism and pathogenicity. Within the LTRs, recurrent enhancer sequences (or upstream region enhancers [UREs]) are frequently found in cats with myeloid leukemias and could play a role in oncogenesis.[53,54] For example, the U3-LTR region has the ability to upregulate the NFκB signaling pathway via activation of Ras-Raf-IκB kinase and degradation of IκB.[55] The *gag* (group-associated antigen) gene encodes internal structural proteins, including p15, p12, p27, and p10. The p27 protein is produced in amounts that exceed that necessary for assembly of new virus particles. Thus, p27 is abundant in the cytoplasm of individual infected cells and also in the blood of infected cats, which is why most available immunochromatographic tests, such as ELISA and IFA assays, are designed to detect this protein, either free in plasma or within neutrophils and platelets, respectively. Free p27 is also detectable in tears and saliva. The *pol* (polymerase) gene encodes the viral enzymes RT, polymerase, and integrase. The *env* (envelope) gene encodes the envelope components gp70 and p15E. The envelope protein gp70 defines the virus subgroup and appears to be important for inducing immunity. Antibodies to gp70 result in neutralization of the virus and immunity to reinfection. Thus, gp70 is important in natural resistance and therefore as a target for vaccine production. The transmembrane protein p15E is thought to interfere with host cell immune responses, which facilitates viral persistence.[56]

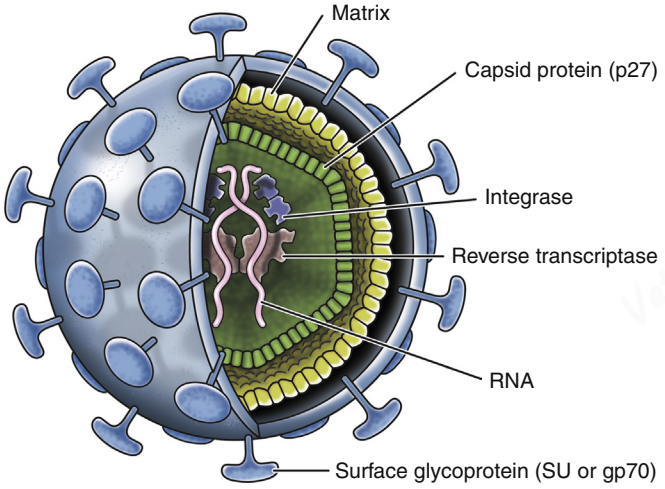

Fig. 32.1 Structure of feline leukemia virus. Gammaretroviruses contain two identical strands of RNA and associated enzymes, which include reverse transcriptase, integrase, and protease, packaged into a core composed of the capsid protein (p27) with a surrounding matrix, all enclosed by a phospholipid membrane envelope derived from the host cell. The envelope contains a gp70 glycoprotein and the transmembrane protein p15E.

Host Range

In nature, FeLV mainly infects domestic cats. Some wild felids are also susceptible. *In vitro*, FeLV also can replicate in nonfelid cell lines. FeLV-B replicates in cells derived from cats, dogs, cows, pigs, hamsters, monkeys, and humans; and FeLV-C replicates in cells of cats, dogs, guinea pigs, and humans.[1,57,58] Although certain human cell lines can be infected by FeLV-A, FeLV is not thought to pose a risk for humans; FeLV-A shed by cats carries carbohydrates on the virus envelope (α-Gal epitope) that are readily recognized by naturally occurring anti-αGal antibodies in humans, and the virus is neutralized by complement.[59] However, experimental FeLV infection with development of lymphoma could be induced in young dogs and marmosets.[60] In experimental infections with FeSV, fibrosarcomas also could be produced in nonfelids.[61] However, no reports exist on natural transmission of FeLV to nonfelids.

FeLV infection is enzootic in some wild felid populations, such as European wildcat populations. Introduction of FeLV into free-living and captive wild felid populations such as Florida panthers or the Iberian lynx has serious consequences for their health and survival. In several instances of FeLV infection in wild felids, contact with domestic cats was the source of infection. Within felids from lineage 8 (to which the domestic cat belongs), FeLV was isolated from the European wildcat (*Felis silvestris silvestris*).[62] FeLV-infected free-ranging European wildcats were reported in Great Britain, Switzerland, France, Germany, Portugal, and Spain.[63-69] Up to 49% of wildcats tested FeLV antigen–positive, but no evidence of FeLV-associated disease was found,

TABLE 32.2 Summary of the Genetic Map and Function of Feline Leukemia Virus Proteins

Gene	Location	Proteins	Function
gag	Core	p15	Matrix protein
		p12	Probably involved in the integration process
		p27	Capsid protein; used for antigen testing
		p10	Nucleocapsid protein
pol	Core	p14/PR	Protease
		p80/RT	Reverse transcriptase; enzyme copying viral RNA into complementary DNA strand
		p46/IN	Integrase
env	Envelope	gp70/SU	External surface unit; primary target for protective humoral immune response; FeLV subtype-specific antigens FeLV-A, FeLV-B, FeLV-C
		p15E/TM	Transmembrane protein; role in immunosuppression

although in one study the FeLV antigen–positive wildcats had poorer body condition than FeLV antigen–negative wildcats.[66] European wildcats that tested provirus-positive using PCR were significantly more often coinfected with feline hemoplasmas than FeLV provirus-negative wildcats.[70]

In the phylogenetic felid lineage 7 (the leopard cat lineage [genus *Otocolobus*]), FeLV antigen was detected in wild Pallas' cats (*Otocolobus* [*Felis*] *manul*) of the Daurian Steppe in Russia.[71]

FeLV has also been detected in lineage 6 felids (the puma lineage [genera *Puma* and *Acinonyx*]). Between 2002 and 2005, five Florida panthers died as a result of FeLV infection, with clinical signs of lymphadenopathy, anemia, and weight loss.[72,73] The outbreak likely originated from one cross-species transmission because the FeLV strain involved, FeLV-Pco, closely resembled a highly virulent FeLV strain of domestic cats. Due to the severity of the outbreak, a FeLV vaccination program for the Florida panthers was initiated. Evidence of FeLV infection was also detected in free-ranging Brazilian pumas,[74] free-ranging Brazilian jaguarundis (*Puma yagouaroundi*),[75] captive cheetahs (*Acinonyx jubatus*),[76,77] and 5.4% of 490 California mountain lions sampled between 1990 and 2008.[78]

In the lynx lineage 5 (genus *Lynx*), FeLV was detected in an 11-month-old captive-bred bobcat (*Lynx rufus*) that had signs of lethargy, anorexia, neutropenia, lymphopenia, and nonregenerative anemia.[79] The bobcat had been in contact with a domestic cat (surrogate mother), which was suspected to be the source of the infection. Based on sequencing analysis, FeLV-A from domestic cats was also assumed to be the source of FeLV infection in critically endangered Iberian lynxes (*Lynx pardinus*) in Southern Spain.[80] FeLV provirus in the absence of detectable circulating antigen was detected in 6 of 21 lynxes between 1993 and 2003. A subsequent study on 77 of the approximately 200 remaining free-ranging Iberian lynxes in the same area between 2003 and 2007 revealed 14 FeLV provirus-positive animals, but at that time most of the animals were also antigen-positive.[81] During a 6-month period in 2007, about two-thirds of the FeLV-infected lynxes died.[82] High-throughput sequencing of the virus suggested that the virus most likely originated from domestic cats.[83] Many domestic cats and European wildcats were FeLV antigen–positive in the same area.[68,84] Preventative measures, including surveillance and vaccination programs for the Iberian lynx have therefore been introduced. Moreover, domestic cat populations should be controlled and vaccinated in order to reduce the infectious pressure on wildlife.

FeLV infection was also confirmed in several species of the ocelot lineage 4 (genus *Leopardus*), including free-ranging kodkods (*Leopardus guigna*) on a Chilean island, a captive ocelot (*Leopardus pardalis*) and a captive oncilla (*Leopardus tigrinus*) in Brazil,[85,86] and a margay (*Leopardus wiedii*) and pampas cats (*Leopardus pajeros*) in US zoological parks.[87] The pathogenic potential of FeLV in these felid species is unknown.

No studies are available on FeLV in felids of the lineages 3 and 2 (caracal and bay cat lineages), but multiple studies suggest that FeLV infection is absent in wild felids of the panthera lineage 1 (genus *Panthera*), a lineage that is not closely related to the domestic cat. FeLV infection was not detected in many studies of African lions (*Panthera leo*), Asian lions (*Panthera leo persica*), jaguars (*Panthera onca*), and Amur tigers (*Panthera tigris altaica*).[88-95] When a recombinant subunit FeLV vaccine was used in lions and tigers (*Panthera tigris*), no antibody response was observed.[96]

Prevalence

FeLV infection exists in domestic cats worldwide. Studies report a prevalence of 2.3% to 3.3% in the United States, 0% to 8.8% in Europe, 0% to 24.5% in Asia, and 0.5% to 21% in Australia.[97-116] Only cats on some islands such as Grenada, the West Indies, Isabela Island, and the Galapagos, have been found free of FeLV infection.[117-119]

The prevalence of FeLV infection varies depending on the health status of the cat population sampled.[120] In healthy free-roaming cats, the prevalence typically ranges from 1% to 8%.[98,101,103,120,121] In sick cats, the prevalence can be as high as 38%.[97,122,123]

The overall prevalence of FeLV infection used to be decreasing in many geographic areas.[97-99,101,103-105,123,124] The Tufts Veterinary Diagnostic Laboratory, where approximately 2000 serum samples are tested yearly for FeLV antigen, reported a decrease from 8% in 1989 to 4% in 1995.[125] In Germany, a steady decrease in FeLV prevalence from 6% to 1% was observed when investigating the FeLV infection rate from 1993 to 2002.[101] A study from Switzerland found a decrease from 9% to 3% in FeLV prevalence between 1990 and 2003.[126] The decrease in prevalence is most likely the result of test and removal programs at breeding facilities, the practice of testing cats at animal shelters before adoption, and the widespread use of vaccination. However, in more recent years, the prevalence of infection has plateaued.[101,126,127]

Models have been constructed to predict the dynamics of FeLV infection in cat populations. These predicted that FeLV dynamics depend on: (1) the size of the host population, and (2) the relationship between host density and the pattern of contacts of individual cats. They found no threshold population size for virus persistence in large populations but the possibility of FeLV extinction in small populations.[128] A study that included a large number of cats from the United States revealed a higher prevalence of FIV infections in the southern and eastern United States when compared to FeLV infection. In contrast, FeLV infections were more prevalent in the western United States when compared to FIV infections.[129] In a study of FeLV prevalence in 32 European countries, seven risk factors and three protective factors were found.[110] Among the risk factors was the geographic origin of the cat: FeLV prevalence was higher in southern countries compared to northern and western parts of Europe. Other risk factors included male intact sex, indoor and outdoor or outdoor-only residence, living in large groups of five or more animals, and being an ill cat.[110] Risk factors for FeLV and FIV infections are only slightly different. The prevalence of both infections is higher in cats that roam outside[101,103] because direct contact is required for transmission. Although fighting, free-roaming, intact male cats are still considered mainly at risk for acquiring FIV infection, the same factors can facilitate FeLV infection.[101,110,130] However, being male (neutered or not) and having access to the outdoors has a stronger impact on FIV prevalence than on FeLV prevalence, while presence of clinical illness is a stronger predictor for FeLV infection.[129]

Although FeLV transmission commonly occurs among infected queens and kittens and among cats living in prolonged close contact, aggressive behavior plays a greater role than previously reported.[131] Cats that exhibit aggressive behavior have a higher risk of FeLV infection,[101] and more than 8% of cats examined by veterinarians for fighting injuries were FeLV antigen–positive in one study, a prevalence considerably higher than in the clinically healthy cat population.[131]

Although no breeds are predisposed to being infected with FeLV, infection is less commonly found in purebred cats,[110] possibly because they are more commonly kept indoors. In addition, awareness in the cat-breeder community leads to frequent testing. In older studies, young age was considered a risk factor for FeLV infection. However, a study in the United States of 18,038 cats at 345 veterinary clinics and 145 animal shelters revealed that adult cats were more likely to be FeLV-infected than young cats.[103] In a study from Europe that included 6005 cats, cats aged 1 to 6 years were at greatest risk.[110] In another study, the median age of FeLV-infected cats was not lower than that of uninfected cats.[101]

This was unexpected because of the phenomenon of age-related resistance to FeLV infection.[132,133] However, because of increased awareness, more cats are tested for FeLV, FeLV infection is being recognized earlier, and medical care is provided during the initial stage of the disease. In addition, awareness among cat breeders and animal shelters has led to routine testing of new pets entering the household or shelter.

A genetic predisposition might contribute to a susceptibility of cats to FeLV infection. Analysis of single-nucleotide polymorphisms (SNPs) in the *APOBEC3H* gene of domestic cats showed that one of the SNPs was significantly correlated with the susceptibility to FIV and/or FeLV infections.[134]

With few exceptions, FeLV prevalence studies are based on detection of FeLV p27 antigen in blood. However, free antigen can usually only be detected in the blood of viremic cats (in progressively infected cats or in the early stage of regressive infection, see Pathogenesis), because those with regressive infections only harbor provirus, with no associated antigen production.[135] In a study from Switzerland, 7% of cats had both viral p27 antigen and provirus in blood, and 10% of cats had negative results for p27 antigen and positive results for proviral DNA in blood.[136] Comparable results were also found in a study from Germany where the number of antigen-positive, provirus-positive cats was similar to the number of antigen-negative, provirus-positive cats.[100]

Transmission

FeLV spreads through close contact between virus-shedding cats and susceptible cats. The transmission of FeLV occurs primarily via saliva. Viremic cats constantly shed millions of virus particles in saliva.[137,138] The concentration of virus in saliva and blood of healthy viremic cats is as high as it is in sick cats. Fighting and biting behavior,[101,131] as well as social behavior, such as sharing food and water dishes, mutual grooming, and using common litter areas, are the most effective means of transmission of FeLV. Although the virus can enter many tissues, body fluids, and secretions, urine and feces are less likely to be a source of infection for other cats. However, FeLV is shed in small amounts in feces and urine,[139,140] so fecal shedding of FeLV cannot fully be excluded as a mode of transmission.[140] FeLV RNA has been detected in fleas and their feces,[141,142] but flea transmission does not seem to play a major role in nature. Iatrogenic transmission can occur via contaminated needles, instruments, fomites, or blood transfusions.[143,144]

The viral envelope is lipid-soluble, and FeLV is readily inactivated in the environment (usually within minutes, but sometimes up to 48 hours). Therefore close contact among cats is usually required for spread of infection. Single cats kept strictly indoors are not at risk for acquiring infection. It is only because of latency (in regressively infected cats) and reactivation that viremia is occasionally detected in middle-aged to old cats that have lived alone indoors since they were adopted as kittens. A waiting period is not needed before introducing a new cat into a household after removal of an infected cat. FeLV transmission is not a risk in a veterinary hospital or boarding kennel scenario as long as cats are housed in separate cages, and routine cage disinfection and hand washing are performed between handling cats.[145]

Vertical transmission from mother to kittens occurs commonly. Neonatal kittens can be infected transplacentally or when the queen has close contact with them. Transmission also can occur in queens with regressive infection; FeLV transmission via milk to offspring from queens with FeLV antigen–negative test results has been described.[146] If *in utero* infection occurs, fetal resorption, abortion, and neonatal death can occur, although up to 20% of vertically infected kittens can survive the neonatal period to become progressively infected adults.[123] Newborn kittens from infected queens can have negative FeLV antigen test results at birth, but can test positive over subsequent weeks to months when viral replication accelerates. Thus, if the queen or any kitten in her litter is infected, the entire litter should be treated as if infected and isolated from uninfected cats.

Susceptibility to progressive infection, which is associated with persistent viremia and culminates in FeLV-associated disease, is highest in young kittens. It is more difficult in adult cats to achieve progressive infection after experimental infection, and depending on the FeLV strain used, experimental infection does not lead to progressive infection already in kittens older than 16 weeks of age.[132] Age-related resistance to FeLV also exists in nature. It has been suggested that age-related resistance might be related to a decline in the number of cellular receptors (THTR1) available for FeLV-A to enter target cells. Maturation of macrophage function might also play a role.[147] Thus, the risk of an adult cat becoming progressively infected after a brief interaction with a FeLV-shedding cat is very low.

CLINICAL FEATURES

Pathogenesis

Although outcome of infection mainly depends on immune status and age of the cat, it is also affected by pathogenicity of the virus. The outcome of FeLV infection thus also reflects genetic variation both in the virus and the host population. Certain viral mutations can increase the speed of disease onset, whereas others change disease outcome entirely, and it has been suggested that LTR and surface unit (SU) genes mediate a rapid pathogenesis with distinctive clinical features and oncogenic mechanisms.[123]

FeLV infection can have different courses. Once integrated into the cat genome, FeLV provirus can persist for years, and recurrence of viremia and disease can occur in some cats.[148,149] However, integrated viral DNA can also elicit solid protection and long-lasting maintenance of protective immunity.[150] The currently accepted stages of FeLV infection are: (1) abortive infection, (2) regressive infection, (3) progressive infection, and (4) focal or atypical infection.[150-152]

Although cats with only integrated proviral DNA without virus replication do not shed infectious virus in saliva, proviral DNA can be infectious via blood transfusion.[144] FeLV provirus and plasma viral RNA are usually detectable by PCR within 1 week of FeLV exposure, even if FeLV antigen is not. All cats with progressive and regressive infection can undergo this phase and develop similar proviral and plasma viral RNA loads in the peripheral blood during early infection.[150] However, later in the infection, proviral loads remain high in progressively infected cats but decrease in regressively infected cats.[136]

Abortive Infection

After initial infection, which most commonly occurs via oronasal routes, virus replicates in the local lymphoid tissue in the oropharyngeal area. In some immunocompetent cats, viral replication is halted by an effective humoral and cell-mediated immune response, and viremia does not occur.[135,151,153-156] Abortive infection has been observed infrequently after experimental FeLV inoculation with low inocula and is characterized by negative test results for culturable virus, antigen, viral RNA, and proviral DNA.[152,157] Thus, cats with abortive infection have high levels of neutralizing antibody, but neither FeLV antigen nor viral RNA or proviral DNA can be detected in the blood. In these cats, virus never spreads systemically, and infection usually remains undetected. Abortively infected cats have the same life expectancy as cats that have never been exposed to FeLV.[143] They have strong immunity and are protected against new viral challenges, probably for several years if not lifelong. Protective immunity is partly humoral and partly cellular, and antibody production is not necessarily required for protection; about 2% are protected without detectable antibodies.

Regressive Infection

Regressive infection follows an effective immune response, with containment of viremia before (or shortly after) the time of bone marrow infection. After initial infection, FeLV spreads systemically within lymphocytes and monocytes.[158] During this period, cats have positive results on ELISA antigen tests and shed virus. Cats can show lethargy, fever, or lymphadenomegaly resulting from lymphocytic hyperplasia during this phase. The virus spreads to target tissue, including thymus, spleen, lymph nodes, and salivary glands. In most cats, viremia lasts only a few weeks, but in some rare cases cats can overcome viremia even after many months.[159] On the other hand, some regressively infected cats are never antigen-positive.

In some cats, hematopoietic precursor cells in the bone marrow then become infected and produce infected neutrophils and platelets that circulate in the body.[158,160] A high level of viremia develops, and lymphoid organs and salivary glands become infected with up to 1×10^6 virus particles/mL of saliva. From this time point on, viral antigen is also detectable intracellularly in platelets and granulocytes by tests that detect large quantities of intracellular antigen, such as IFA. Even if bone marrow becomes infected, some cats can clear viremia (and develop regressive infection); however, the longer the viremia lasts, the less likely it will be contained. Once bone marrow cells are infected, cats will remain provirus-positive because proviral DNA persists in bone marrow stem cells. This has previously been referred to as "latent infection" of the marrow, but is now considered a stage of regressive infection. Once virus replication is contained, no intact virus is actively produced, so cats with regressive infection have negative results from routine tests (ELISA and IFA) that detect FeLV antigen. Regressive infection can only be detected using proviral PCR or culture of bone marrow samples in the presence of high doses of glucocorticoids. Productive infection can be reactivated spontaneously or with immune suppression with viremia and therefore positive results on antigen tests. Regressive infections can also reactivate in pregnancy, with reemergence of FeLV infection in kittens. Mammary glands of regressively infected queens can produce infectious viral particles with onset of lactation.[146]

Reactivation is more likely the earlier the stress factor occurs after the viremic phase. As time passes, regressive infections become more difficult to reactivate, even with high doses of glucocorticoids. Nevertheless, regressively infected cats stay provirus-positive and reactivation can take place many years after infection.[148,154] In one SPF cat that had been experimentally infected with FIV and FeLV, regressive FeLV infection occurred and the cat remained aviremic for over 8 years. Subsequently, a genetically altered FeLV virus reappeared with reactivation of viremia. This coincided with the development of multicentric lymphoma, likely because the immune system was by then, severely depleted due to the FIV infection.[148]

It is unclear how often regressive FeLV infection can result in FeLV-related disease. One study found a high prevalence of regressive infection in older cats at necropsy and suggested an association with hematologic changes and inflammatory processes.[161] In another study, two of 37 cats (5%) with nonregenerative cytopenias and negative FeLV antigen test had positive results with bone marrow provirus PCR.[162] FeLV provirus can be detected occasionally in lymphomas of some FeLV antigen–negative cats,[163-165] but a causative association has not been made. Cats from FeLV cluster households had a 40-fold higher incidence of FeLV antigen–negative lymphoma compared to cats from the general population. Two studies reported that regressive FeLV infections occurred in 50% to 52% of antigen-negative lymphomas in older cats (> 7 years),[164,166] while other groups found evidence of provirus in only 1 of 22,[167] in 1 of 10,[166] and in 0 of 50 FeLV antigen–negative lymphomas[169] suggesting that regressive infection is only rarely involved in tumor development.

Integrated FeLV provirus has the potential to interrupt or inactivate cellular genes in infected cells, or regulatory properties of viral DNA can alter expression of neighboring genes. In addition, because bone marrow microenvironment cells (e.g., myelomonocytic progenitor cells and stromal fibroblasts) provide a reservoir for regressive FeLV infections, provirus has the potential to alter cellular functions and contribute to the pathogenesis of myelosuppressive disorders. Finally, FeLV not only contributes its genes to the host, but also has been shown to appropriate (or "steal") cellular genes, which could have the potential to contribute to viral oncogenesis.[167,170,171] Replication-defective enFeLV can recombine with FeLV and thus produce infectious oncogenic particles. However, using next-generation RNA-sequencing, no expression of FeLV has yet been detected in feline tumor samples; in fact, there was even a decreased expression of endogenous retrovirus genes in lymphoma versus control specimens.[172]

Progressive Infection

In cats with progressive FeLV infection, extensive virus replication occurs, first in the lymphoid tissues and then in the bone marrow and in mucosal and glandular epithelial tissues in most infected cats.[56] Mucosal and glandular infection is associated with viral shedding, which persists for the life of the cat. Progressive infection is characterized by insufficient FeLV-specific immunity. Progressively infected cats have low levels of detectable neutralizing antibodies.[100,168] These cats usually develop FeLV-associated diseases that can be fatal.

Young and immunosuppressed cats are at higher risk for developing progressive infection. In a cat with a first-time single contact with a FeLV-shedding cat, the risk of developing progressive infection is less than 5%. However, if a shedding cat is introduced into a naïve group of cats, and the cats are housed together for an extended period, the risk increases to about 30%.[147]

Regressive and progressive infections can be distinguished by repeated testing for viral antigen in peripheral blood.[152] Many infected cats initially have positive antigen test results within 2 to 3 weeks after virus exposure. In case of regressive infection, cats will become negative in viral antigen tests 2 to 8 weeks later or, in rare cases, months later. Both progressive and regressive infections are almost always accompanied by persistent FeLV proviral DNA in blood. However, FeLV proviral and viral RNA loads in leukocytes, as analyzed by quantitative PCR, indicate that FeLV progressive infection is associated with secondary viremia of bone marrow origin, whereas regressive cats sustain only a nonproductive viral infection in low numbers of lymphocytes.[173] During acute infection, blood proviral and viral RNA loads of cats with progressive and regressive infections are not significantly different, which, however, changes after weeks.[136,151,152] Subsequently, cats with progressive infections have higher virus loads than cats with regressive infections, and virus loads within specific leukocyte subsets differ depending on the infection outcome.[160]

Focal or Atypical Infection

Focal infections or atypical infections have been reported as a rare form of infection in both experimental and natural infections. They are characterized by persistent atypical local viral replication in certain tissues, such as the spleen, lymph nodes, small intestine, or mammary glands.[146,174] This can lead to intermittent or low-grade production of p27 antigen. Therefore these cats can have weakly positive or discordant results in antigen tests, or positive and negative results can alternate. Queens with atypical infection of their mammary glands can transmit the virus to their kittens via milk in the face of negative antigen test results.[146]

Clinical Signs

Progressive infection with FeLV can result in tumors, hematologic disorders, immunosuppression, immune-mediated diseases, and other syndromes (including reproductive disorders, fading kitten syndrome, and neuropathy). The death rate of progressively infected cats in multicat households has been described as approximately 50% in 2 years and 80% in 3 years.[23,123] However, survival time of progressively infected cats kept indoors in single-cat households with good veterinary care can be much higher. Still, FeLV infection has the greatest impact on mortality in closed households with mixed endemic viral infections.[100,175] A large study in the United States compared the survival of more than 1000 FeLV-infected cats to more than 8000 age- and sex-matched uninfected control cats[103] and found that in FeLV-infected cats, median survival was 2.4 years compared to 6.0 years for control cats.

Most cats with FeLV-associated disease are evaluated not for tumors but for anemia or immunosuppression. Of 8642 FeLV-infected cats examined at US veterinary teaching hospitals, coinfections (including FIP, FIV infection, upper respiratory infection, hemotropic mycoplasmosis, and stomatitis) were the most frequent findings (15%), followed by anemia (11%), lymphoma (6%), leukopenia or thrombocytopenia (5%), and leukemia or myeloproliferative disease (4%).[176]

Disease expression can relate to virus factors, such as the FeLV subgroup (e.g., FeLV-B is primarily associated with tumors, FeLV-C is primarily associated with nonregenerative anemia), but clinical outcome is also strongly influenced by the age of the cat at the time of infection.[132] Neonatal kittens can develop marked thymic atrophy after infection ("fading kitten syndrome"), resulting in severe immunosuppression, wasting, and early death. As cats mature, they acquire resistance to infection. When older cats become infected, they tend to have abortive or regressive infections or, if they develop progressive infection, signs are milder and they usually have a more protracted period of apparent good health.[123]

Tumors

FeLV infection is most commonly associated with lymphoma and leukemia, and less commonly with other hematopoietic tumors. In addition, unusual forms of lymphoma, such as feline neurolymphomatosis[177] or other tumors, including osteochondromas, olfactory neuroblastoma, uterine adenocarcinoma, and cutaneous horns, have been described.

Feline oncornavirus cell membrane antigen (FOCMA) is an antigen present on the surface of transformed cells. FOCMA can be found on the surface of feline lymphoma and FeSV-induced fibrosarcoma cells but not on the surface of normal feline lymphocytes.[178,179] Many cats with FeLV in cluster households have antibodies against FOCMA. Those with the highest titers are most likely to remain free of malignancies. However, some cats that are viremic with a high FOCMA antibody titer can develop lymphoma or leukemia months or years later after the titer declined.[23] Currently, FOCMA is considered a nonhomogenous group of viral antigens that can, although not always, be present on the surface of FeLV-infected cells. At the least, FOCMA antibodies indicate exposure to FeLV but since tests for the detection of FOCMA are difficult to establish and to standardize, FOCMA is not considered to be of clinical value.

Lymphoma. Lymphomas and leukemias account for about 30% of all feline tumors, the highest proportion recorded in any animal species.[180-184] Progressively FeLV-infected cats have a 60-fold increased risk of lymphoma.[185] Lymphoma can affect up to 25% of cats with progressive FeLV infection, usually within 2 years after diagnosis of the infection. FeLV-induced lymphomas are mainly T-cell lymphomas.[186] Mediastinal lymphoma is the most common form (Fig. 32.2), followed by multicentric lymphoma, although spinal, renal, ocular, and other forms of lymphoma are occasionally reported in progressively FeLV-infected cats.[187] In the past, young to middle-aged cats (median 7 years) were commonly diagnosed with lymphoma, but lymphoma is now a disease of mostly older cats with a median age of 11 years.[188] This also is likely a result of the decreasing prevalence of progressive FeLV infection as a contributing factor for development of lymphoma, as cats with FeLV-associated lymphoma are usually younger than cats with lymphoma without FeLV infection.[100] In addition, the incidence of FeLV antigen–negative lymphomas increased from approximately 18 cases per year before 1994 to approximately 32 cases per year from 1994 to 2003.[189]

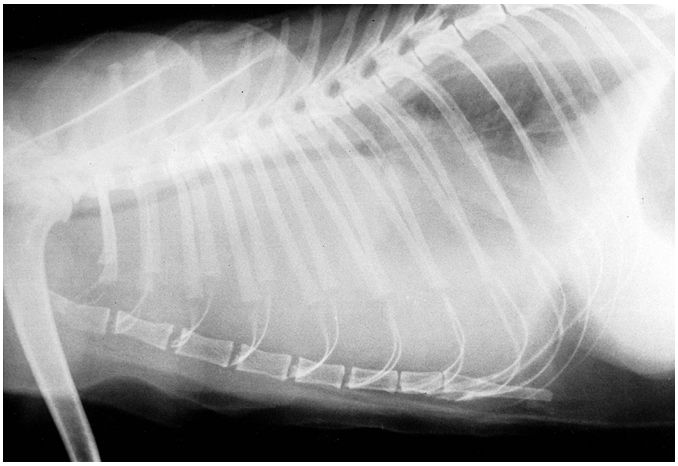

Fig. 32.2 Lateral thoracic radiograph of a cat with severe pleural effusion and mediastinal mass. The trachea is displaced dorsally, and the cardiac shadow is barely visible.

In support of the association between FeLV infection and lymphoma, lymphoma can be induced in kittens by experimental FeLV infection;[190-192] cats naturally infected with FeLV have a higher risk of lymphoma than uninfected cats;[190,193] and in the past, when the prevalence of FeLV infection was higher, most cats with lymphoma had progressive FeLV infection. Previous studies showed that up to 80% of feline lymphomas and leukemias were FeLV-related.[194-197] A study conducted at a veterinary teaching hospital in Germany showed that from 1980 to 1995, 59% of cats with lymphoma were FeLV antigen–positive, but from 1996 to 1999, only 20% were positive.[188] In a study from the Netherlands, only 4 of 71 cats with lymphoma were FeLV antigen–positive, and 22 of these cats had mediastinal lymphoma, which previously was reported to be strongly associated with FeLV infection.[198]

The most important mechanism for the development of malignancy is insertion of the FeLV genome into the cellular genome near a cellular oncogene (most commonly *myc*). This results in activation and overexpression of that gene and uncontrolled proliferation of these cells. FeLV can also incorporate the oncogene to form a recombinant virus (e.g., FeLV-B, FeSV) which contains cellular oncogene sequences that are then rearranged and activated. When they enter a new cell, these recombinant viruses are oncogenic. Thus, FeLV-induced neoplasms are caused, at least in part, by somatically acquired insertional mutagenesis in which the integrated provirus activates a proto-oncogene or disrupts a tumor suppressor gene. In a study of 119 cats with lymphoma, transduction (insertion into) the *myc* locus had occurred in 38 cats (32%).[199] Transduction of the NOTCH2 gene by FeLV was described in a naturally infected cat with multicentric lymphoma.[200] Another study suggested that the U3-LTR region of FeLV could transactivate cancer-related signaling pathways through production of a

noncoding 104-base RNA transcript that activates NF-κ B.[201] Twelve common integration sites for FeLV associated with lymphoma development have been identified in six loci: *c-myc*, *flvi-1*, *flvi-2* (contains *bmi-1*), *fit-1*, *pim-1*, and *flit-1*.[202] *C-myc* is a proto-oncogene, *bmi-1* and *pim-1* are myc-collaborators, *fit-1* appears to be closely linked to *myb*, and *flit-1* insertion was associated with overexpression of cellular genes, for example, activin-A receptor type II-like 1 (ACVRL1).[202] *Flit-1* was identified as an important proviral integration site. Of 35 FeLV-related tumors, 5 of 25 thymic lymphomas had proviral insertion within the *flit-1* locus, whereas none of four alimentary lymphomas, five of five multicentric lymphomas, and one T-lymphoid leukemia had rearrangements in this region. Some studies also show that variations in the FeLV surface glycoprotein can determine the development of tumors.[203] In one study, oncogene-containing retroviruses were experimentally generated by recombination events between viral and cellular sequences, a phenomenon called "oncogene capture," and a novel FeLV virus "FeLV-AKT" was designed that captured feline c-AKT1 in feline lymphoma. FeLV-AKT contains a *gag*-AKT fusion gene that encodes a myristoylated Gag matrix protein and the kinase domain of feline c-AKT1. It was therefore hypothesized that AKT might be involved in FeLV-associated oncogenesis.[204]

The predominant anatomical locations of lymphoma in cats in general are alimentary (approximately 50%) and extranodal (approximately 25%).[188,189,198,205,206] The majority of cats with alimentary and extranodal lymphoma (mainly kidney and nasopharyngeal) are now FeLV antigen–negative (96% and 89%, respectively),[188] suggesting most cats have other underlying etiologies, such as chronic inflammation or environmental and genetic factors. Several decades ago, 25% to 31% of renal lymphoma cases were associated with FeLV infection[195,206,207] compared with 0% to 6% in more recent studies.[163,188,198,208] A similar situation is seen in multicentric lymphoma; in the 1980s and 1990s, up to 69% of all lymphomas were multicentric, and 31% to 65% of these cats had progressive FeLV infection[164,195,206] compared with 0% to 13% of cats in more recent studies.[163,188,198,205] Mediastinal lymphoma is uncommon today (10%),[188] but many affected cats still have progressive FeLV infection with a prevalence ranging from 19% to 73%.[164,181,188,206,209] In a study from the Netherlands, where the general prevalence of FeLV was only 0.3%, 19% of cats with mediastinal lymphoma were progressively FeLV-infected, but of cats with lymphoma, all progressively infected cats had mediastinal lymphoma.[198] In a UK study, 9% of cats with mediastinal lymphoma were progressively FeLV-infected, which is higher than the general prevalence.[210]

The role of FeLV as a negative prognostic factor for lymphoma patients with regard to remission and survival times is discussed controversially, although more recent studies indicate a negative impact of FeLV infection in cats with lymphoma.[198,206,207,211] FeLV antigen–negative cats with lymphoma had significantly longer remission times (472 days) than FeLV antigen–positive cats (25 days) following treatment.[188] Median remission and survival times for FeLV antigen–positive cats were 27 and 37 days, respectively, and for FeLV antigen–negative cats, 146 and 170 days.[206] FeLV-associated lymphomas have a higher rate of mitoses than those that are FeLV-negative,[212] possibly indicating a more aggressive biological behavior that negatively affects outcome.

Leukemia. Leukemia in cats with FeLV infection most often involves lymphocytes, but all other hematopoietic cell lines can be affected, including granulocytic, erythroid, and megakaryocytic lines, resulting in myeloproliferative disease or MDS. The prognosis for cats with myeloproliferative diseases in general is poor.

Diagnosis of acute leukemia is made by CBC and bone marrow examination. Cytologic abnormalities of bone marrow include increased cellularity, megaloblastic maturation, increased myelofibrosis, and immature blast cells. FeLV variants that bear URE tandem repeats in their LTR can be associated with induction of both MDS and acute myeloid leukemia (AML) in cats. In one study, experimental infection of cats with FeLV clone33 (originating from a cat with AML) resulted in MDS in 41% of the cats, characterized by peripheral blood cytopenias and dysplastic changes in the bone marrow. Some of the cats with MDS eventually developed AML.[213]

Chronic leukemias are rare in cats and sometimes associated with FeLV.[214,215] They include well-differentiated chronic lymphocytic leukemia, chronic myelogenous leukemia, polycythemia vera, erythemic myelosis, and essential thrombocythemia. Cats with erythemic myelosis have nonregenerative or poorly regenerative anemia (12% to 15%) with normal neutrophil counts and variable thrombocytopenia. Abnormal erythrocyte stages are found in bone marrow and often in peripheral blood.[216]

Eosinophilic leukemia, polycythemia vera and essential thrombocythemia in cats have also been reported in association with FeLV infection.[217,218] Eosinophilic leukemia is difficult to distinguish from hypereosinophilic syndrome.

Fibrosarcoma. Fibrosarcomas that are associated with FeLV are caused by FeSV, a recombinant virus that develops in FeLV-A-infected cats by recombination of the FeLV-A genome with cellular oncogenes. Through a process of genetic recombination, FeSV acquires one of several oncogenes, such as *fes, fms*, or *fgr*. As a result, FeSV is an acutely transforming virus, causing a polyclonal malignancy with multifocal tumors arising simultaneously after a short incubation period. With the decrease in FeLV prevalence, FeSV has become very uncommon. FeSV-induced fibrosarcomas usually occur in young cats. Several strains of FeSV that have been identified from naturally occurring tumors are defective. They are unable to replicate without the presence of FeLV-A as a helper virus that supplies proteins (such as those coded by the *env* gene) to FeSV. The host range for FeSV depends on the helper FeLV-A. Fibrosarcoma cells express FOCMA just as lymphoma cells do. Experimental infection with FeSV causes tumors that progress in some cats and regress in others. Those in which the tumors regress have high FOCMA antibody titers.[219]

Fibrosarcomas caused by various strains of FeSV tend to grow rapidly, often with multiple cutaneous or subcutaneous nodules that are locally invasive and metastasize to the lung and other sites. Solitary fibrosarcomas in old cats are typically injection-site sarcomas and are not associated with FeSV or FeLV infection. These tumors are slower growing, locally invasive, slower to metastasize, and are occasionally curable by excision combined with radiation and/or gene therapy.

Experimentally, FeSV has also been associated with melanoma formation, showing that FeSV can transform cells of ectodermal and of mesodermal origin.[22] Intradermal or intraocular inoculation of FeSV into kittens produced melanomas in the skin or anterior chamber of the eye.[23] However, FeSV has not been associated with naturally occurring melanomas of cats.

Other Tumors. A number of other tumors have been found in FeLV-infected cats, but a link between FeLV infection and formation of these tumors has not been clearly established. Iris melanomas, for example, are not associated with FeLV infection as once was believed, as a result of one study in which 3 of 18 eyes had positive test results for FeLV-FeSV proviral DNA.[220] In a later study, however, immunohistochemical staining and PCR did not reveal FeLV or FeSV in the ocular tissues of any cats with iris melanomas.[221]

One case report described a metastatic uterine adenocarcinoma in a 2-year-old female Persian cat with progressive FeLV infection.[222] Osteochondromas (cartilaginous exostoses on flat bones) have also been described in FeLV-infected cats. Although histologically benign,

they can cause significant morbidity if they put pressure on adjacent tissues such as the spinal cord or nerve roots.[223-225] The pathogenesis of these osteochondromas is unknown. Spontaneous feline olfactory neuroblastomas are aggressive, histologically inhomogenous tumors of the nose and pharynx and have high metastatic rates. Budding FeLV particles were found in the primary tumors and lymph node metastases, and FeLV DNA was found in tumor tissue.[226] Two of three cats described had positive FeLV antigen test results. The exact role of FeLV in the genesis of these tumors is uncertain. Cutaneous horns associated with benign hyperplasia of keratinocytes have also been described in FeLV-infected cats.[227]

Hematologic Disorders

Hematologic disorders described in association with FeLV include anemia (nonregenerative or regenerative); persistent, transient, or cyclic neutropenia; panleukopenia-like syndrome; platelet abnormalities (thrombocytopenia and platelet function abnormalities); and aplastic anemia (pancytopenia) (Fig. 32.3).

Anemia. In older literature, it was estimated that more than two-thirds of all nonregenerative anemias in cats were the result of FeLV infection. This is no longer the case because of the decrease in overall FeLV prevalence. In a 2009 study of 79 anemic cats, FeLV was found in only two cats, both of which had hemolytic anemia.[228] Approximately 10% of FeLV-associated anemias are regenerative.[229] Regardless of the cause, regenerative FeLV-associated anemias usually have a favorable response to treatment. Most FeLV-associated anemias, however, are nonregenerative and result from infection of hematopoietic stem cells and supporting stroma cells. In addition to the direct effect of the virus on erythropoiesis, secondary disorders can cause nonregenerative anemia in FeLV-infected cats.

Several mechanisms contribute to anemia in FeLV-infected cats (Table 32.3). Hemolytic anemia caused by secondary infection with hemotropic mycoplasmas can occur in FeLV-infected immunosuppressed cats. FeLV-induced IMHA also has been described. Affected cats can have positive Coombs' tests, autoagglutination, and spherocytosis. In a study on IMHA in cats, 2 of 19 cats had positive FeLV antigen test results.[230] However, in another study, Coombs' positive results in cats with anemia were not significantly associated with retrovirus or hemoplasma infection.[231] Regenerative anemia secondary to blood loss can occasionally occur as a result of FeLV-associated thrombocytopenia or platelet functional defects.

Pure red cell aplasia (PRCA) is a severe, nonregenerative anemia (hematocrit [HCT] < 15%). It can be caused by infection with FeLV-C through interactions of FeLV-C with cell surface receptors in the bone marrow.[232,233] Bone marrow examination shows an almost complete lack of erythroid precursors with normal myeloid and megakaryocytic precursors and an increased myeloid-erythroid ratio.[23,123] These cats typically have macrocytosis (rarely normocytosis) but no or few reticulocytes. Whenever macrocytic anemia occurs in a cat in the absence of reticulocytosis, FeLV infection should be suspected. The macrocytosis results from skipped mitoses during erythropoiesis. These cats do not have folate or vitamin B_{12} deficiencies. Iron is present in macrophages but not erythrocyte precursors. Serum erythropoietin (EPO) levels are markedly increased, indicating that anemia is not caused by an EPO deficiency.[123] Treatment with immunosuppressive drugs can result in resolution of anemia within 3 to 5 weeks; however, relapse occurs when treatment is discontinued.[234] An atypical presentation of PRCA in a 9-month-old, female, domestic longhair kitten with progressive FeLV infection was reported. Histological examination of the bone marrow revealed an almost complete absence of erythroid precursor cells and mild to moderate myelofibrosis. The cat also had very unusual CNS defects.[235]

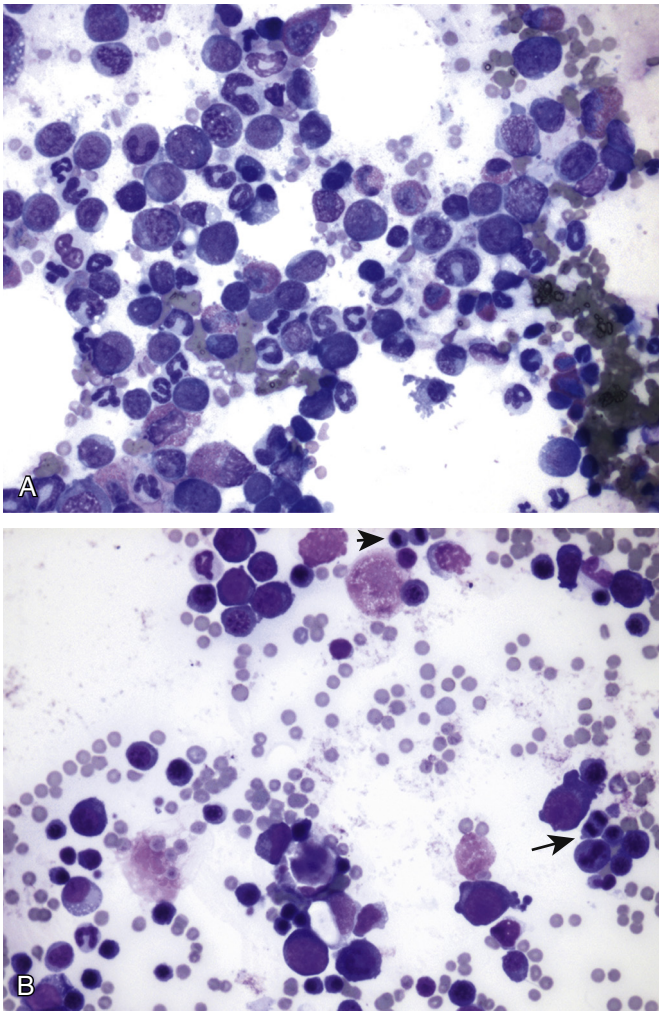

Fig. 32.3 Bone marrow abnormalities in cats with progressive FeLV infection. (A) Bone marrow aspirate cytology from a 6-month-old male neutered domestic shorthair cat that was evaluated for lethargy and fever. Acute leukemia, marked erythroid aplasia, marked granulocytic dysplasia, and increased eosinophilopoiesis are present. Megakaryocytic dysplasia was also identified. The G:E ratio was approximately 2950:1 with marked erythroid aplasia. Wright stain. (B) Bone marrow aspirate cytology from a 1-year-old male neutered domestic shorthair with progressive FeLV infection. Severe megaloblastic erythrodysplasia and mild megakaryocytic dysplasia were identified. The myeloid series was present but markedly decreased in all stages; the myeloid-to-erythroid ratio was estimated at 1:6.5 (compare with A). Nuclear to cytoplasmic asynchrony (megaloblastic change) is present, with immature nuclei in cytoplasm with hemoglobinization. Mitotic figures were present in moderate numbers and were seen in the late stages of the erythroid series *(arrows)*.

Anemia of inflammatory disease can also contribute to anemia in FeLV-infected cats, specifically in association with secondary diseases. The HCT often increases spontaneously if the secondary disease or comorbidity is treated successfully.

Hematopoietic tumors, including lymphoma or leukemia, as well as opportunistic infectious agents, such as mycobacteria, can cause anemia as a result of myelophthisis. Bone marrow suppression with anemia can also result from MDS or myelofibrosis. Diagnosis of myelofibrosis requires a bone marrow core biopsy because aspiration is typically nondiagnostic.

Aplastic anemia can be present in FeLV-infected cats and is characterized by aplasia of all cell lines with severe pancytopenia. Bone

TABLE 32.3 Mechanisms of Anemia in Cats Infected with FeLV

Category	Underlying Mechanism
Decreased RBC production	Pure red cell aplasia (FeLV-C) Aplastic anemia Leukemia (myelophthisis) Myelofibrosis Anemia of inflammatory disease
RBC loss	Thrombocytopenia secondary to immune-mediated or bone marrow disease
Increased RBC destruction	FeLV-associated IMHA Coinfection with hemoplasmas

marrow is usually hypocellular or can show necrosis cytologically.[236] Cats with pancytopenia often had positive test results for FeLV antigen in earlier times, but in a study of 13 cats with aplastic anemia from 1996 to 2004, only two were FeLV antigen–positive.[237] In FeLV-infected cats, cyclic hematopoiesis with periodic fluctuation in reticulocytes, granulocytes, and platelets can be seen. FeLV can affect bone marrow accessory cell viability, growth, production, or all of these of hematopoietic progenitor growth-regulating substances by altering cytokine mRNA levels.[238-240] Cytologic examination of bone marrow aspirates reveals few precursors, and core biopsy specimens might be needed to obtain a diagnosis. Bone marrow transplantation has not been successful in these cats, but some respond to immunosuppressive drug therapy.

Platelet abnormalities. Thrombocytopenia can occur as a result of FeLV-induced bone marrow suppression or hematopoietic tumors. Immune-mediated thrombocytopenia can accompany IMHA in cats with underlying FeLV infection. The life span of platelets is shortened in some FeLV-infected cats. Giant platelets and thrombocytosis have been observed in some progressively infected cats.[229]

White blood cell abnormalities. FeLV can reduce leukocyte numbers and function.[241-243] Lymphopenia is seen in many cats with progressive FeLV infection. Affected cats can develop thymic atrophy and depletion of lymph node paracortical zones. In some cats, lymphopenia is characterized by preferential loss of CD4+ helper T cells, resulting in an inverted CD4/CD8 ratio.[244] More commonly, substantial losses of helper cells and cytotoxic suppressor cells (CD8+ cells) occur,[245] and in long-term FeLV infection, a significant decrease in both CD4+ and, to a lesser degree, CD8+ lymphocytes was demonstrated.[246]

Neutropenia is common in FeLV-infected cats[247] and generally occurs alone or in conjunction with other cytopenias. In some cases, myeloid hypoplasia of all granulocytic stages is observed, suggesting direct cytopathic infection of neutrophil precursors. In some neutropenic FeLV-infected cats, bone marrow maturation arrest can occur at the myelocyte and metamyelocyte stages. It has been hypothesized that an immune-mediated mechanism might be responsible in cases in which neutrophil counts recover with glucocorticoid treatment ("glucocorticoid-responsive neutropenia"). Glucocorticoid-responsive cyclic neutropenia also has been reported. The cycles are usually regular, ranging from 8 to 14 days. Bone marrow cytology during the neutropenic phase can indicate either granulocytic hyperplasia or hypoplasia, with a disproportionate number of cells in the promyelocytic stage. Cats with neutropenia commonly have recurrent fever or persistent bacterial infections, and some cats have persistent gingivitis. Neutrophils of progressively infected cats can also have decreased chemotactic and phagocytic function.[241]

Feline panleukopenia-like syndrome (FPLS) or FeLV-associated enteritis (FAE) consists of severe leukopenia (fewer than 3000 cells/μL) and enteritis and destruction of intestinal crypt epithelium that mimics feline panleukopenia caused by FPV. This syndrome might actually not be caused by FeLV alone, as initially thought, but by coinfection with FPV.[248] FAE is the preferred term because clinical signs are usually enteric, and include hemorrhagic diarrhea, vomiting, oral ulceration or gingivitis, anorexia, and weight loss.[249,250]

Immunosuppression and Secondary Infections

Diseases secondary to immunosuppression account for a large portion of the morbidity and mortality of FeLV-infected cats.[251-254] Progressively FeLV-infected cats are predisposed to secondary infections primarily because of immunosuppression similar to that in HIV infection, but immunosuppression is more severe than that associated with FIV infection.

The exact mechanisms by which FeLV damages the immune system are poorly understood. Specific pathogenic immunosuppressive variants, such as FeLV-T, have been described that require a membrane-spanning receptor molecule (Pit1) and a second co-receptor protein (FeLIX) to infect T lymphocytes.[48] The latter protein is expressed from an endogenous provirus arising from FeLV-A, which is similar to the FeLV receptor-binding protein of FeLV-B.[46] Affected cats can develop thymic atrophy and depletion of lymph node paracortical zones after infection.

Reduced leukocyte numbers and function associated with infection also contribute to immunosuppression. Many immune function tests of naturally FeLV-infected cats have been reported to be abnormal, including poor response to T-cell mitogens, prolonged allograft reaction, reduced immunoglobulin production, depressed neutrophil function, and complement depletion. Interleukin (IL)-2 and IL-4 are decreased in some cats,[123,239] but FeLV does not appear to suppress IL-1 production from infected macrophages. Increased TNF-α levels have been observed in serum of FeLV-infected cats as well as in FeLV-infected cells in culture. T cells of FeLV-infected cats produce lower levels of B-cell stimulatory factors than do those of noninfected cats, which becomes progressively more severe over time.[251]

Primary and secondary humoral antibody responses to specific antigens are delayed and decreased in FeLV-infected cats. Progressively FeLV-infected cats do not consistently mount an adequate immune response to vaccines, such as rabies.[255] Therefore a need for more frequent vaccinations (e.g., yearly) has been suggested for these cats.

There are many reports of FeLV-infected cats with concurrent bacterial, viral, protozoal, and fungal infections (Fig. 32.4), but there is little evidence to demonstrate that FeLV-infected cats have a higher prevalence of infections than cats without FeLV infection, or that response to anti-infective therapies are less effective in FeLV-infected cats. Thus, although FeLV is capable of causing immunosuppression, it should not be assumed that all concurrent infections in FeLV-infected cats result from the underlying FeLV infection. Secondary diseases that can be associated with FeLV include FIP, coccidiosis, and feline upper respiratory tract disease.[256,257] A few studies have focused on the role and the influence of FeLV infection on hemoplasma infection with controversial results, because in some studies, FeLV infection was a risk factor for hemoplasma infection,[258-261] whereas in other studies it was not.[262-265] Cats that were naturally infected with FeLV were more likely to develop and not eliminate *Bartonella henselae* infection; however, the course and clinical outcome of *Bartonella* infection was the same as in cats not coinfected with FeLV.[261,263,266,267] No association is generally found between FeLV infection and feline leishmaniosis[268-270] with the exception of one study, where the presence of *Leishmania*

Fig. 32.4 Opportunistic infections in cats with progressive FeLV infection. (A) Ulceration of the nasal planum in a 6-month-old male neutered domestic medium hair cat with progressive FeLV infection as defined by positive ELISA antigen and IFA assays on peripheral blood. Chronic gingivostomatitis was also present, and FCV infection was suspected. (B) Severe nasal cryptococcosis in a Siamese cat from a cattery with endemic FeLV infection.

spp. antibodies and DNA was significantly associated with FeLV infection.[271] No association was found with rickettsial infections[272] or sporotrichosis in cats in Brazil.[273]

Skin infections occur in some FeLV-infected cats. Progressively FeLV-infected cats have a greater diversity of cutaneous and mucosal microflora compared with uninfected cats,[274] and infections associated with dermatologic conditions are usually caused by immunosuppression.[275] Traumatic injuries can be complicated by secondary bacterial infections or abscesses. Otitis externa and miliary dermatitis can be initiated by ectoparasites or allergies but persist because of secondary bacterial infections.

Most studies have not found an association between chronic gingivostomatitis and progressive FeLV infection,[276,277] although one study showed that cats with any oral inflammatory disease were more likely to be infected with FeLV than cats with healthy oral cavities.[278] One study investigated biopsy samples of oral mucosal biopsies of 27 cats with chronic gingivostomatitis and detected FeLV antigens by immunohistochemistry in the epithelium and inflammatory infiltrate of 29.6% of cats. FIV antigens were identified only in one, and FCV antigens in none of the cats using immunohistochemistry.[279]

Immune-Mediated Diseases

FeLV-infected cats can have immune-mediated diseases caused by an overactive or dysregulated immune response to the virus. Although humoral immunity to specific stimulation decreases in FeLV-infected cats, nonspecific increases of IgG and IgM have been noted. The loss of T-cell activity and the formation of antigen-antibody complexes contribute to immune dysregulation.[280] Antigens that can form antigen-antibody complexes include those associated with whole virus particles as well as free gp70, p27, or p15E proteins.[281,282] Immune-mediated diseases described in FeLV-infected cats include IMHA,[230] glomerulonephritis,[283] uveitis,[284,285] and polyarthritis.[227] A chronic polyarthritis syndrome can also be caused by FFV, and concurrent FIV infection can occur in either instance.[286] Although hyperglobulinemia is often associated with immune-mediated disorders, it does not appear to be more prevalent in progressively infected cats when compared with FIV-infected cats.[287] Hyperproteinemia is not significantly more prevalent in progressively infected cats than in uninfected cats, whereas FIV-infected cats are more likely than uninfected cats to display hyperglobulinemia.[280-282,287,288]

Other Syndromes

Other syndromes directly associated with FeLV infection include FeLV-associated neuropathy, reproductive disorders, and fading kitten syndrome.

Neuropathies. Neurologic dysfunction has been described in FeLV-infected cats. Most neurologic signs are associated with lymphoma and lymphocytic infiltrations of the brain or spinal cord, or secondary infectious diseases such as cryptococcosis, toxoplasmosis, FIP, or unusual diseases such as encephalitozoonosis or listeriosis.[289] However, in some cases an underlying cause is not apparent, even after necropsy. Anisocoria, mydriasis, central blindness, Horner's syndrome, or urinary incontinence caused by myelopathy[290] have been described in progressively FeLV-infected cats without morphologic changes. It is possible that FeLV has direct neurotoxic properties. Envelope glycoproteins of retroviruses can stimulate increased intracellular free calcium leading to neuronal death, as described in HIV-infected humans. A polypeptide of the FeLV envelope was found to cause dose-dependent neurotoxicity associated with alterations in intracellular calcium ion concentration, neuronal survival, and neurite outgrowth. The polypeptide of a FeLV-C strain was significantly more neurotoxic than the same peptide derived from a FeLV-A strain.[291,292]

Clinical signs in 16 cats with progressive FeLV infection and neurologic signs consisted of abnormal vocalization, hyperesthesia, and paresis progressing to paralysis. Some cats develop anisocoria or urinary incontinence during the course of their illness. Others have concurrent FeLV-related problems, such as myelodysplastic disease. Microscopically, white-matter degeneration with dilation of myelin sheaths and swollen axons has been identified in the spinal cord and brainstem of affected animals.[290] Immunohistochemical staining of affected tissues revealed consistent expression of FeLV p27 antigens in neurons, endothelial cells, and glial cells, and proviral DNA was amplified from multiple sections of the spinal cord.[290]

Reproductive disorders. FeLV-infected queens can transmit the virus transplacentally. Fetal resorption, abortion, and neonatal death can occur if *in utero* FeLV infection occurs. Apparent infertility is likely caused by early resorption of fetuses. Abortions usually occur

late in gestation, with expulsion of normal-appearing fetuses. Bacterial endometritis can accompany abortions, particularly in cats with neutropenia.[23]

Fading kitten syndrome. Kittens born to infected queens can become exposed to FeLV transplacentally, but exposure also occurs at birth and throughout the nursing period. Some kittens become immune, but most become progressively infected and die at an early age with fading kitten syndrome, characterized by failure to nurse, dehydration, hypothermia, thymic atrophy, and death usually within the first 2 weeks of life.[123]

Physical Examination Findings

Physical examination findings in cats with progressive FeLV infection vary dramatically depending on the stage of infection and the secondary disease process present.[293,294] There might be no abnormalities, or cats can show signs of lethargy, fever, mucosal pallor, petechial hemorrhages, dehydration, peripheral lymphadenomegaly, thin body condition, stomatitis, subcutaneous abscesses, or upper respiratory tract disease. Anemic cats can have a hemodynamic heart murmur, tachypnea, or tachycardia, or can be icteric. Cats with severe anemia can be laterally recumbent or comatose and hypothermic. Cats with thymic lymphoma can be tachypneic and have decreased lung and cardiac sounds on thoracic auscultation as a result of pleural effusion, or heart sounds can be displaced caudally. Decreased compressibility of the cranial thorax can also be detected. Splenomegaly, hepatomegaly, renomegaly, intestinal masses, and/or abdominal lymph node enlargement can be detected on abdominal palpation of cats with multicentric lymphoma. Neurologic signs are detected infrequently when compared with signs of anemia or thoracic or abdominal lymphoma and include ataxia, anisocoria, and mydriasis. Although also relatively uncommon, uveitis can be identified, or there might be other ocular abnormalities as a result of intraocular lymphoma or coinfections with other pathogens.[293-295]

DIAGNOSIS

General Statement about Diagnostic Tests

Testing for FeLV and consequently preventing exposure of healthy cats to FeLV-infected cats is the most effective way to prevent the spread of infection.[296,297] FeLV vaccination should not be considered a substitute for testing. The European Advisory Board on Cat Diseases (ABCD) and AAFP have established guidelines for testing cats for FeLV.[297] According to these guidelines, the FeLV status of all cats should be known, because the infection has serious health consequences that influence patient management, both in illness and for wellness care. Failure to identify infected cats can lead to inadvertent exposure and transmission to uninfected cats. Misdiagnosis of infection in uninfected cats can lead to unnecessary changes in lifestyle or even euthanasia.[297] When bringing a new cat into an established household, a follow-up antigen test should be performed at least 90 days after the initial test or after a possible exposure to FeLV because cats could be in the early stage of infection at the time of the first test; and this test should be performed before bringing the cat into the home.[298]

Cats can be tested at any age (Fig. 32.5), because screening tests detect antigen and not antibodies, so neither maternal antibodies nor

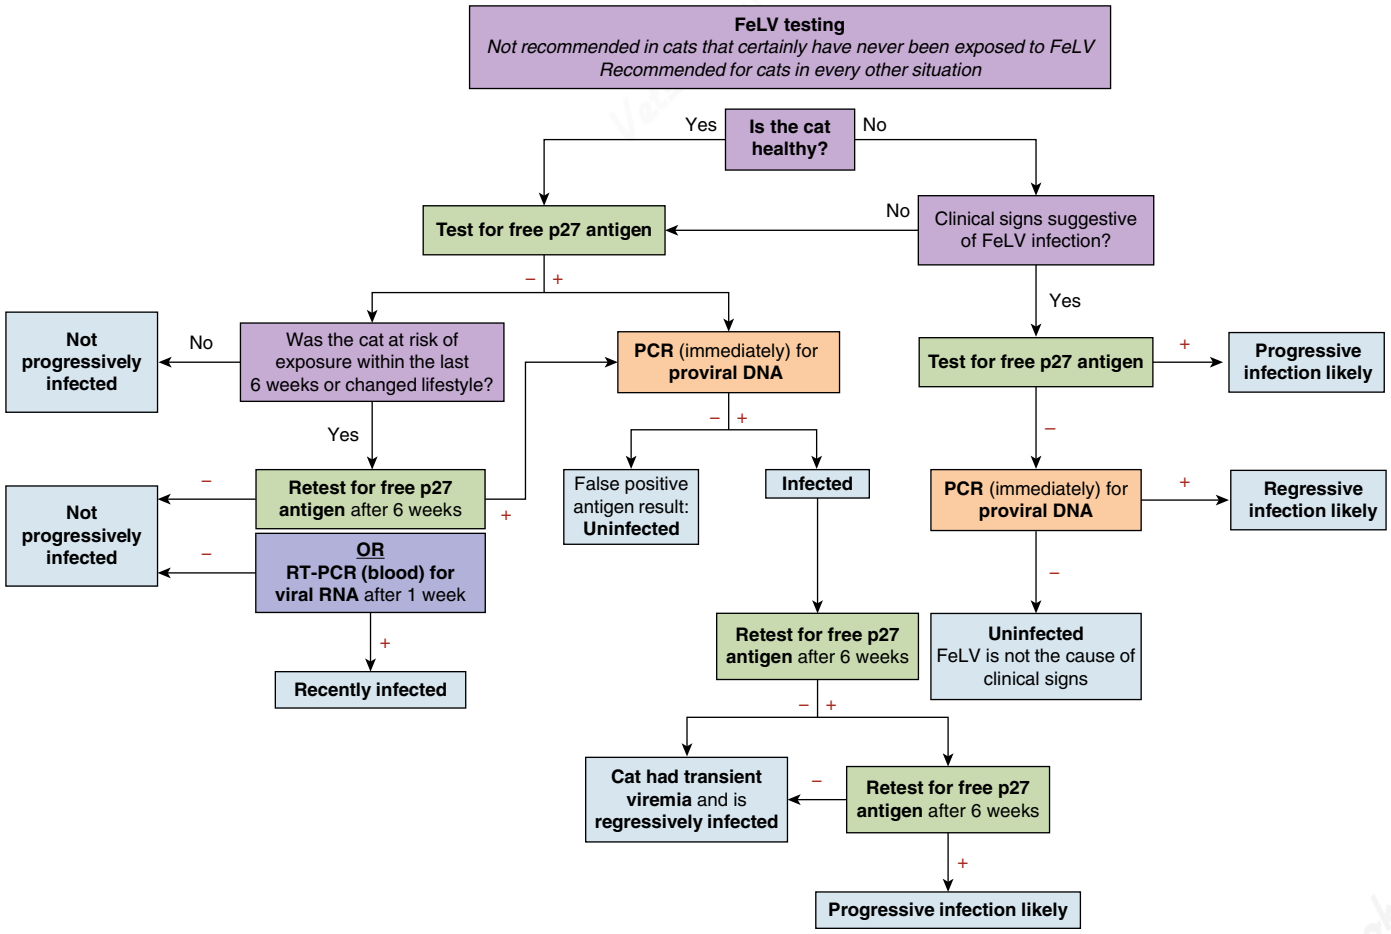

Fig. 32.5 Diagnostic algorithm for FeLV infection. (Redrawn from European Advisory Board on Cat Diseases (ABCD). www.abcdcatsvets.org.)

antibodies from vaccination interfere with testing. However, kittens that are infected as a result of maternal transmission might not test positive for weeks to months after birth.[299] It has been suggested that blood collected immediately after vaccination could contain detectable FeLV antigens from the vaccine itself, so diagnostic samples should be collected before FeLV vaccine administration.[300] It is not known how long this test interference persists. Cats can require retrovirus testing at different times in their lives.[297]

Laboratory Abnormalities

Complete Blood Count

The CBC in progressively FeLV-infected cats can be normal or show regenerative or nonregenerative anemia, neutropenia, lymphopenia, monocytopenia, and/or thrombocytopenia. Evidence of agglutination can be present in cats with IMHA. Moderate to marked leukocytosis due to neutrophilia and bandemia can also be present. Large numbers of circulating blasts, megakaryocytes, or dysplastic cells (such as erythrocytes with giant Howell-Jolly bodies) can be found in cats with leukemia or MDS. When compared to uninfected cats, progressively FeLV-infected cats were nearly fourfold more likely to be anemic, fivefold more likely to be thrombocytopenic, fourfold more likely to be neutropenic, and threefold more likely to have lymphocytosis.[288]

Serum Chemistry Profile

Findings on serum biochemistry analysis and urinalysis are nonspecific and reflect underlying secondary disease processes. Hyperbilirubinemia and bilirubinuria can be present in cats with immune-mediated hemolytic anemia or hemoplasma infection.[288]

Urinalysis

Cats with glomerulonephritis can be proteinuric. Bacteriuria may be identified in cats with urinary tract infections secondary to immunosuppression.

Bone Marrow Cytology and Histopathology

Both bone marrow aspirate and core biopsy specimens should be obtained in cats with pancytopenia or severe nonregenerative anemia. If aspirate results are not diagnostic, a core biopsy should be collected, because bone marrow aspirates from cats with aplastic anemia or myelofibrosis are typically of low cellularity. Bone marrow findings in cats with progressive FeLV infection can include evidence of neoplastic lymphoid, erythroid, or myeloid cells (which circulate in the peripheral blood of cats with leukemia); myelodysplasia; hypoplasia or aplasia of erythroid, myeloid, or megakaryocyte cell lines; erythroid, myeloid, and megakaryocyte hyperplasia despite peripheral cytopenias; and megakaryocyte hypoplasia. Cytochemical stains that identify cells of the myeloid lineage (such as alkaline phosphatase, peroxidase, Sudan black B, and nonspecific esterase), immunocytochemistry, or flow cytometry using antibodies that target cell surface cluster of differentiation (CD) molecules might be needed to definitively identify the cell type involved in some acute undifferentiated leukemias.[295]

Diagnostic Imaging

Plain Radiographs

Imaging findings in cats with FeLV infection can reflect a secondary disease process and are extremely variable. Cats with FeLV-associated thymic lymphoma have a mediastinal mass on thoracic radiography that can be accompanied by mild to severe pleural effusion.

Sonographic Findings

Abdominal sonography in cats with multicentric lymphoma can reveal hypoechoic and enlarged abdominal lymph nodes and enlargement; or hypoechogenicity, or mottling of the spleen, liver, or kidneys. Increased hepatic echogenicity can occur with liver lymphoma. Intestinal masses with loss of normal bowel wall layering can be detected in cases of intestinal lymphoma. Splenomegaly can sometimes be found in cats with immune-mediated cytopenias.

Microbiologic Tests

For diagnosis of FeLV infection, usually direct organism detection assays are preferred (Table 32.4). Routine tests are available that detect free FeLV p27 antigen in blood. Free FeLV antigen can be detected by ELISA or other immunochromatographic assays (ICGAs). Cell-bound antigen can be detected by IFA. Nucleic acid amplification assays can be used to detect FeLV DNA (provirus) or viral RNA, and virus isolation to demonstrate viable virus particles can also be performed in specialized laboratories. Detection of antibodies is necessary for demonstration of abortive infection. The presence of antibodies also can indicate protection against new infection. Table 32.5 shows the results of different diagnostic tests at different stages of FeLV infection.

In practice, diagnosis of FeLV infection is usually based on detection of FeLV p27 antigen. When also obtaining results for proviral DNA, progressively and regressively infected cats are detected, but not cats with abortive infections.

TABLE 32.4 Diagnostic Assays Available for Feline Leukemia Virus Infection

Assay	Specimen Type	Target	Performance
ELISA or immunochromatographic tests for soluble FeLV antigen	Serum, plasma (whole blood)	Free FeLV p27 antigen	Confirmation is recommended in healthy cats with a second test from a different manufacturer or PCR. Positive antigen test results do not signify progressive infection, and the assay must be repeated 6 (and 12) weeks later or an IFA performed. Negative tests can occur in the first month of infection.
Proviral DNA PCR	Bone marrow, tissue, lymph node aspirates	Proviral DNA	Sensitivity and specificity may vary between laboratories. Assays that have demonstrated sensitivity and specificity may be useful to detect cats with regressive infection for elimination from blood donor programs, or to resolve the results of ELISA assays. Quantitative provirus PCR assays can be helpful for prediction of status (regressive vs. progressive) and outcome, although in some cats, repeated testing may be required over time to establish the status of infection.
RT-PCR	Blood, bone marrow	Viral RNA	Sensitivity and specificity may vary between laboratories. Never use in the absence of antigen testing
Virus isolation	Blood, bone marrow	Replication-competent FeLV virus	Difficult, not widely available. Used primarily as a research tool

TABLE 32.5 Characterization of Possible Outcomes of FeLV Infection

Parameter	Progressive Infection	Regressive Infection	Focal Infection (Rare)	Abortive Infection	No Infection
Viremia	Persistently positive	Undetectable or transiently positive	Absent	Absent	Absent
Replicating virus in blood (virus isolation from blood)	Positive	Negative (only positive during transient viremia or after reactivation)	Negative	Negative	Negative
Viral RNA in blood (RT-PCR of blood)	Positive	Blood: positive or negative	Negative	Negative	Negative
Free FeLV p27 antigen in blood (p27 ELISA or immunomigration on blood)	Positive ~ 3–6 weeks after infection	Negative (only positive during transient viremia or after reactivation)	Alternating or low positive	Negative	Negative
Intracellular FeLV p27 antigen in blood (IFA on blood smear)	Positive (~ 3 weeks after free p27 antigen tests)	Negative (only positive during transient viremia or after reactivation)	Negative or alternating	Negative	Negative
Provirus integration into host's genome	Yes	Yes	Yes (localized)	No	No
Proviral FeLV DNA in blood (PCR on whole blood)	Positive	Positive	Negative or low positive	Negative	Negative
Immune response	Poor	Good	Good	Very good	No
Anti-FeLV antibodies serum (different tests on serum/plasma)	Negative (or low titers)	Positive (high titers)	Positive (high titers)	Positive (variable titers)	Negative
Viral shedding	Yes (continuously); major source of FeLV infection	No (only during transient viremia or after reactivation)	Usually no (one report on shedding in milk)	No	No
Viral RNA saliva (RT-PCR on saliva)	Yes	No (only during transient viremia or after reactivation)	No	No	No
Transmission of infection via blood transfusion	Yes	Yes	Potentially	No	No
Reactivation of FeLV infection	No (infection already continuously active)	Possible (seldom; decreasing probability with increasing duration after exposure)	No (infection sequestered continuously active)	No	No
Consequences	FeLV-associated disease common	FeLV-associated disease uncommon (rarely lymphoma or bone marrow suppression), but common after reactivation	Unlikely	None	None
Prognosis	Poor	Good; poor after reactivation	Variable	Good	Good

Former terminology: progressive infection = persistent viremia; regressive infection = latent infection with or without previous transient viremia; abortive infection = regressor cat.

Detection of FeLV Antigen

The mainstay of clinical testing for FeLV are ELISAs and other immunochromatography or rapid immunomigration assays, which are available for use as plate-based ELISAs or rapid POC tests. Plate-based ELISAs are offered by commercial veterinary diagnostic laboratories. IFA testing for viral antigen is still in use in some countries.[301] All of these assays detect free FeLV core protein p27, but POC assays and plate-based ELISAs are more sensitive than IFAs (the latter detects only intracellular antigen, so becomes positive later than ELISA, once the bone marrow has become infected). Cats with a positive POC test or plate-based ELISA and a negative IFA result are more likely to later develop a regressive infection than are cats with positive results on both assays. In general, to distinguish between regressive and progressive infection, cats should be retested for free p27 antigen 6 weeks after the first positive test result. If the result is still positive, the test should be repeated after another 6 weeks. If at this time the cat remains positive, it is most likely progressively infected and will develop FeLV-associated disease. To avoid the need for serial retesting, cats positive for FeLV free p27 antigen can be immediately retested using IFA. More than 90% of cats with positive IFA results have progressive infection.[181,301-304] A small number of cats with persistently positive ELISA and negative IFA results can have focal or atypical infections that are contained by the immune system.[303] A negative ELISA but positive IFA always represents either a false-negative ELISA result (which is rare) or a false-positive IFA result.

Plate-based ELISAs and POC assays. POC tests are the recommended screening tests for FeLV infection. A positive whole

blood, serum, or plasma POC test or plate-based ELISA usually indicates that the cat is viremic. These assays usually become positive within 28 days after exposure, in the first phase of viremia, before the bone marrow is affected. Thus, positive results can reflect transient viremia (in cats becoming regressively infected) or persistent viremia (in progressively infected cats). However, false-positive results are possible, especially when whole blood is used on plate-based ELISAs and some POC tests (that are based on an ELISA principle, such as the SNAP [IDEXX Laboratories]), and particularly when samples are hemolyzed. Thus, plasma or serum should be used with plate-based ELISAs and the SNAP (IDEXX Laboratories). Immunochromatography-based POC tests contain a filtering membrane, so whole blood and serum/plasma do not produce different results.[305] Membrane-based tests eliminate separate washing steps and include positive and negative controls for each test sample. Several comparisons of different POC tests have been performed.[305-310] It is difficult to compare these studies because gold standards differ and tests with similar names can differ among countries or from one time period to the next. However, in general, sensitivities and specificities of different tests have been similar. Positive predictive values of most tests in those comparison studies were between 50% and 80%, whereas negative predictive values were close to 100%.[308] False-positive results are becoming more common because the decreasing prevalence of FeLV infection is leading to lower positive predictive values. Thus, in cat populations with a high prevalence of infection, for example, cats with thymic lymphoma, a positive test result is likely to be accurate, whereas in a lower-risk population, such as a population of indoor cats from single-cat households, a positive test should be viewed with more suspicion, and confirmatory tests should be performed, for example using a POC test from a different manufacturer or a provirus PCR assay.[123] Therefore in general, negative test results are reliable because of the low prevalence of infection in most populations, but positive results have to be interpreted carefully. If a second confirmatory test is positive, this significantly increases the predictive value.[305] POC tests or plate-based ELISAs have been also used on tear and saliva specimens;[311] however, this is not recommended because antigen shedding with saliva and tears is intermittent.

IFA. IFA on smears from blood or bone marrow detect cell-associated p27 antigen within infected blood cells, primarily neutrophils, and platelets. The earliest the test becomes positive after infection of the bone marrow is at about 3 weeks of viremia. IFA is not recommended as a screening test because cats in the first weeks of viremia that are already shedding virus and capable of transmitting infection are not detected. IFA can be used for prognostic reasons or to confirm positive and suspicious ELISA results. IFA requires special processing and fluorescent microscopy and must be performed by a qualified reference laboratory. Generally, two or more blood smears of good quality should be air-dried and mailed, unfixed, to the laboratory. As antigen is present at highest concentrations in neutrophils and platelets, false-negative results can occur when these two cell lines are deficient. False-positive results occur when smears are too thick, background fluorescence is high, or the test is prepared and interpreted by inexperienced personnel. Use of anticoagulated blood rather than fresh blood for preparing smears can also cause errors.[312,313] Variations in quality control among facilities have been reported, and careful attention should be paid to the selection of the reference laboratory.[123]

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR detects proviral DNA (integrated into the cellular genome of the cat), while RT-PCR detects viral RNA (of free replicating virus). PCR and RT-PCR can be performed on blood, saliva, bone marrow, and tissues. When performed under optimal conditions, PCR methods are the most sensitive tests for FeLV diagnosis and can help resolve cases with discordant antigen test results. However, they must be performed by experienced laboratories and should be well validated. Minor alterations in sample handling by laboratory personnel can destroy nucleic acid or introduce contamination, leading to either false-negative or false-positive results, respectively. There are no comparative studies of the diagnostic accuracy of various commercial laboratories offering FeLV PCR. Assays usually target conserved regions of the FeLV genome, but different PCR assays can vary in their analytical sensitivity and specificity. Minor strain variations can prevent binding of the primers, a step necessary to amplify the viral genome. Moreover, primers and probe must be designed to distinguish endogenous FeLV-like sequences from exogenous FeLV infection.

Quantitative real-time PCR and RT-PCR assays can be used to quantify provirus and viral RNA loads, respectively.[15,136,158,314-318] A clinically validated quantitative PCR assay is now available commercially (IDEXX Laboratories) that can help to ascertain whether a cat is progressively or regressively infected.[318]

PCR for detection of FeLV DNA. An important indication for performing proviral PCR on whole blood is to confirm a positive ELISA result, especially in low-prevalence populations. True-positive ELISA results are accompanied by high proviral loads.[136,319] In early infection, provirus PCR is positive earlier than antigen detection. Moreover, provirus PCR is useful to detect regressively infected cats, and prove absence of FeLV in a multicat environment, such as breeding colonies and catteries. Approximately 2% to 10% of cats with negative antigen tests have been positive for FeLV provirus by PCR.[100,136,137] Most of these cats remain antigen-negative, do not shed virus, and are unlikely to ever develop FeLV-associated diseases, but some can reactivate and then shed FeLV and develop FeLV-associated disease.[149] In addition, these cats can transmit infection if they act as blood donors.[144]

RT-PCR for detection of FeLV RNA. Most commercially available PCR assays for FeLV are based on detection of proviral DNA rather than viral RNA. If performed on blood (or serum or plasma), RT-PCR should always be positive when ELISAs are positive, thus indicating progressive infection. Cats with regressive infection are provirus-positive but most do not possess detectable viral RNA in the blood. If performed on blood (or serum or plasma), RT-PCR should always be positive when ELISA tests are positive. However, in some cats, plasma viral RNA can be found in the absence of FeLV antigen. In contrast, detection of viral RNA in saliva generally indicates viremia.[137,138] RT-PCR results from plasma and saliva can also be helpful in the very early phase of infection. Viral RNA can be detected in plasma or saliva by RT-PCR as early as 1 week after FeLV exposure—earlier than antigen testing by ELISA and even earlier than provirus PCR from blood.[139,319] RT-PCR in saliva has also been used to screen multicat households for FeLV shedders. Active salivary shedding as detected using RT-PCR was consistent in antigenemic cats, whereas non-antigenemic cats with a low proviral load did not shed viral nucleic acid in saliva. FeLV RNA is stable for more than 60 days in saliva specimens stored at room temperature, and in naturally infected cats, RT-PCR on saliva had a high sensitivity and specificity when compared to tests for antigen in blood.[100,137,138] If the cost of testing is a limitation in a multicat environment, pooled saliva specimens could be used for RT-PCR, as the assay can be sufficiently sensitive to detect a single infected cat in a pool of up to 30 specimens.[138]

Virus Isolation

Virus isolation is not practical for routine diagnosis because it is difficult and time-consuming to perform and requires special facilities. Where available, it can be used to confirm positive test results or to better understand a cat's infection status if other assays generate conflicting results.

Indirect Detection of Infection

FeLV-infected cats develop antibodies against several viral proteins. Recently, antibodies against the p15E protein have been demonstrated to be valuable predictors of FeLV exposure,[313] and now a new POC test detecting p15E antibodies is available in several European countries, but its usefulness under field conditions still has to be determined. In a study assessing the status of FeLV infection in the cat population of southern Germany, many cats that had never received FeLV vaccines had FeLV antibodies despite negative antigen and PCR test results, and thus were thought to be abortively infected.[100] FeLV low-dose exposure can result in antibody production during an abortive infection, with cats having anti-FeLV antibodies but no detectable FeLV antigen or DNA.[140,157]

Detection of antibodies is the only way to diagnose abortive FeLV infection. Cats with abortive FeLV infection do not get sick and will not shed the virus, and infection will not be reactivated. However, these cats are considered immune against new infection, and thus vaccination might not be necessary. Therefore to avoid overvaccination and injection-site sarcoma formation, tests for FeLV antibodies ultimately might be useful as prevaccination screening tests. The connection between the presence of antibodies and immunity, however, is not absolute, because some vaccinated cats will not develop antibodies,[100] and there will be cats that are protected against FeLV infection despite the absence of detectable antibodies.[319-323]

Pathologic Findings

Most of the pathologic findings in FeLV-infected cats reflect secondary infections or tumors. FeLV itself can sometimes lead to lymph node, CNS, or bone marrow changes.

Gross Pathologic Findings

Gross and histopathologic findings in cats with progressive FeLV infection usually reflect secondary disease processes. Lymphoma and evidence of myelodysplasia or leukemias are the most common findings, but secondary infections also can be detected.

Histopathologic Findings

Reactive lymphoid hyperplasia is a common finding in cats with progressive FeLV infection. Histology of the bone marrow can reveal lymphoma, leukemias, or myelodysplasia. The intestinal tracts of cats with FAE can show crypt cell necrosis and regeneration, lymphoplasmacytic infiltrates, and blunting and fusion of villi.[324] CNS lesions can include loss of axons and dilated myelin sheaths within the spinal cord.[290] Immunohistochemical stains can be applied to tissues, such as bone marrow or tumor tissue, to confirm the presence of FeLV antigen.[161,162,169,325]

TREATMENT

General Management of FeLV-Infected Cats

Disease in cats that test positive for FeLV antigen can be related or unrelated to FeLV infection. Management protocols for FeLV antigen–positive cats must include the housemates of the FeLV-infected cat (Box 32.1).[297,326,327]

BOX 32.1 Management of FeLV Infection in Multicat vs Individual Cat Households*

Multicat households

- FeLV is mainly transmitted through social contact, but also through biting and fighting.
- If a FeLV-infected cat lives in an otherwise negative household, it is likely that the other cats have already been infected and are immune to new infection.
- The risk of progressive infection in adult FeLV-negative cats is approximately 10 to 15% if they have lived together with a viremic cat.
- If owners refuse to separate housemates, uninfected cats should receive FeLV vaccination to enhance immunity. Owners should be informed that vaccination does not provide complete protection in these high-exposure environments.

Individual cat households

- FeLV-infected cats should be kept indoors to avoid transmission of FeLV to other cats and to reduce their risk of acquiring other infectious diseases.
- Vaccinations should be administered to FeLV-infected cats according to guidelines for immunocompromised cats. Progressively FeLV-infected cats might not be able to mount an adequate immune response to vaccines. Therefore more frequent vaccination (e.g., yearly) could be considered.
- FeLV-infected cats should have veterinary wellness visits at least semiannually to promptly detect changes in health status. A CBC, biochemistry profile, and urinalysis should be performed at least annually.
- Intact male and female cats should be neutered.
- Surgery is well tolerated, but perioperative antibiotic administration should be considered, especially if bacterial contamination of normally sterile anatomic sites is likely to occur.
- FeLV-infected cats can be housed in the same ward as other hospitalized patients, but in individual cages. They should not be placed in isolation.
- If FeLV-infected cats become sick, prompt identification of the secondary illness is essential to allow early therapeutic intervention. Most cats with FeLV infection respond as well as uninfected cats to appropriate medications, although a longer and more aggressive course of therapy might be needed.
- In general, the use of glucocorticoids or other immunosuppressive drugs should be avoided unless specifically indicated, e.g., for neoplastic or immune-mediated disease.

* See references[143,297,300]

FeLV-Infected Households

In households with one or more progressively FeLV-infected cats, all cats should be tested for FeLV antigen and provirus so that their status is known. It is likely that all cats in that household have been exposed and are progressively, regressively, or abortively infected. Cats with regressive or abortive infection are likely protected against new FeLV infection. Naïve cats should not be introduced, even if vaccinated. Shedding of virus generally occurs through salivary glands, and cat-to-cat transmission can occur by allogrooming, sharing of food and water bowls and litter boxes, and fighting and biting behavior. Cats within the household that have negative FeLV antigen test results will tend to outlive progressively infected cats. Therefore after months or years, all remaining cats will be antigen-negative and immune to new infection.

Individual FeLV-Infected Cats

FeLV-infected cats should be confined indoors to reduce the likelihood of secondary infections, but also to prevent spread of FeLV to other cats in the neighborhood. Good nutrition and husbandry are essential

to maintain good health. Raw meat, eggs, and unpasteurized milk should be avoided because of the risk of acquiring foodborne bacterial or parasitic infections.[298]

In progressively infected cats, wellness visits to the veterinarian should occur at least semiannually. Visits should include a detailed history, a thorough physical examination including accurate body weight determination, and an ophthalmic examination. In addition, a CBC, biochemistry profile, urinalysis, and centrifugal fecal flotation should be performed at least yearly. Intact males and females should be neutered to reduce stress associated with estrus and mating behavior and to decrease the desire to roam outside. Surgery is generally well tolerated by subclinically infected cats. Perioperative antibiotic administration should be considered during surgeries and dental procedures.[297,298]

Vaccination with core vaccines (against FPV, FHV, and FCV) should be performed regularly and considered even more frequently than in non–FeLV-infected cats due to immunosuppression, even if the cat is kept strictly indoors. One field study could not find a difference in response to vaccination between progressively FeLV-infected and noninfected cats.[328] Ideally, FPV antibodies should be evaluated to confirm protection and to determine necessity to revaccinate in adult cats. If an owner cannot be convinced to keep a FeLV-infected cat inside, rabies vaccinations should be given (in accordance with state and local regulations). FeLV vaccines are not recommended in cats with known progressive or regressive FeLV infections because these vaccines have no effect on viremia, carrier state or elimination, or on development of FeLV-associated disease in an already infected cat and do not prevent reactivation of regressive infection.[329]

Treatment of FeLV-Associated Diseases

In most cases, secondary diseases in progressively FeLV-infected cats are treated as is for uninfected cats, and respond in a similar manner.[330] Prompt and accurate identification of FeLV-associated disease aids early intervention and a more successful outcome (Box 32.2). Nevertheless, the owner should be forewarned that response to treatment can sometimes take longer than expected. FeLV itself does not cause fever, so a search for a concurrent infection must be made in persistently febrile cats.

Glucocorticoids and other immunosuppressive drugs should be avoided whenever possible in FeLV-infected cats, unless clearly indicated. These drugs might compound the risk of secondary infections. Also, cats with regressive FeLV infection should not receive glucocorticoid treatment because it increases the risk of reactivation. Myelosuppressive drugs should also be avoided because they can potentiate the myelosuppressive syndromes caused by FeLV.

Tumors

Although the prognosis is worse for FeLV-associated tumors when compared with the same tumors in cats testing negative for FeLV,[198,206,331,332] some patients greatly benefit from antitumor therapy. Antitumor therapy should be applied with identical protocols used in non–FeLV-infected cats. In an older report of 38 cats with lymphoma treated with a COP (cyclophosphamide, vincristine, and prednisolone) protocol, 75% achieved complete remission with a median remission duration of 150 days and a 1-year remission rate of 20%.[333] The most frequent tumor in these cats was mediastinal lymphoma, and most cats were progressively infected with FeLV. In a later report, cats from the same geographic area were treated with the same protocol and had a complete remission rate of only 47%, with a median remission duration of 86 days.[334] In this group, few cats were progressively FeLV-infected, and the alimentary form of lymphoma was the most frequent.[334] Cats with acute leukemia are difficult to treat because the bone marrow becomes filled with neoplastic blast cells, which must be destroyed before the normal hematopoietic precursors can repopulate. This process can take 3 to 4 weeks. The remission rate in cats with acute lymphocytic leukemia treated initially with vincristine and prednisone is approximately 25%, whereas the rate in cats with AML treated with doxorubicin or cytosine arabinoside is close to zero.[23] A cat with suspected FeLV-associated chronic lymphocytic leukemia was successfully treated with a combination of prednisone, chlorambucil, cyclophosphamide, doxorubicin, and lomustine.[214] Secondary infections are common and must be treated quickly and aggressively, especially if they occur at the time of the granulocyte nadir. Although prophylactic antibiotics are not given routinely in the treatment of leukemia or lymphoma, broad-spectrum bactericidal antibiotics should be given to progressively FeLV-infected cats receiving tumor therapy, especially if fever or other signs of secondary infection occur.

FeSV-induced feline sarcomas should be treated early, with wide and deep surgical excision. If no metastases are present, but microscopic tumors remain after surgery, radiation can be successful in delaying recurrence.

Hematologic Disorders

Although hematologic disorders are sometimes irreversible in progressively FeLV-infected cats, the course can be cyclic and there can be some improvement with time. Treatment with blood transfusions or bone marrow–stimulating cytokines should be considered. Of 29 anemic (HCT < 20%) FeLV-infected cats treated with blood transfusions (over 2 weeks), the HCT returned to the reference range in eight cats. Glucocorticoid treatment can increase the lifespan of erythrocytes if the anemia is immune-mediated, and antibodies are present against erythrocytes or precursors, and some cats with FeLV-associated nonregenerative anemia respond well to high-dose prednisolone. Occasionally, secondary infections (e.g., hemoplasma infections) are responsible for the anemia, and these can be treatable. Even though EPO concentrations are often elevated in cats with FeLV-related anemia, treatment

BOX 32.2 Suggested Management Recommendations for FeLV-infected Cats

If no clinical signs are present

- No treatment
- Cats should be kept strictly indoors

If clinical signs are present

- First assess for and treat underlying diseases, which may or may not be FeLV-related

Treatment of FeLV-infected cats with lymphoma

- Consider chemotherapeutic drug protocols (e.g., COP)
- Prognosis might be more guarded

Treatment of FeLV-infected cats with idiopathic anemia

- Consider transfusion
- Try erythropoietin or darbepoetin if nonregenerative
- If no effect, consider glucocorticoids for possible IMHA

Treatment of FeLV-infected cats with idiopathic neurological signs

- Consider zidovudine (5 mg/kg PO q12h)

Treatment of FeLV-infected cats with recurring bacterial infections

- Treat recurring bacterial infections promptly and using cidal antimicrobial drugs at appropriate doses
- Consider feline interferon omega if available (10^6 IU/kg SC q24h)

COP, cyclophosphamide, vincristine, prednisolone; *IMHA*, immune-mediated hemolytic anemia.

with recombinant human erythropoietin (rHuEPO) or darbepoetin can be helpful. RHuEPO treatment not only increases erythrocyte counts but also can increase platelet and megakaryocyte numbers.[335] In a study in FIV-infected cats, all rHuEPO-treated cats had a gradual increase in erythrocyte counts, hemoglobin concentrations, and HCT and increased white blood cell counts.[336] The recommended dose is 100 IU/kg SC q48 hours until the desired HCT (usually 30%) is reached and then as needed to maintain the HCT at 30%. A response might not be seen for 3 to 4 weeks, and if it does not occur, iron supplementation might be required. Iron should not be given to cats that have received transfusions because whole blood contains 0.5 mg/mL of iron, which increases risk of hepatic hemosiderosis. Anti-EPO antibodies can develop in 25% to 30% of rHuEPO-treated animals after 6 to 12 months. Binding of these antibodies to native EPO can result in bone marrow failure and refractory anemia. However, anti-EPO antibodies dissipate after discontinuation of treatment. Darbepoetin alpha is a synthetic EPO that possesses an additional two N-linked oligosaccharide chains, and seems to be less likely to induce production of anti-EPO antibodies in cats than EPO.

Neutropenia can lead to severe immunosuppression, and antibiotics can be necessary in some neutropenic cats to prevent secondary bacterial translocation and development of sepsis. Treatment with filgrastim (5 µg/kg SC q24h for up to 21 days) has caused transient responses. Potential adverse effects include bone discomfort, splenomegaly, allergic reactions, and fever.[336,337] Short-term increases in neutrophil counts can be followed by neutropenia with continued use of filgrastim because of development of dose-dependent neutralizing antibodies to this heterologous product after 10 days to 7 weeks. Thus, treatment should not be used for more than 3 weeks.[336,337] Another risk is development of persistent antibodies against endogenous feline granulocyte colony-stimulating factor (at higher dosages), with rebound neutropenia. One study suggested that filgrastim is contraindicated in FIV-infected cats because it led to increased viral load.[336] In a pilot study, a small number of naturally FeLV-infected cats were treated with filgrastim; however, treatment did not result in significant changes in neutrophil counts.[338] Other authors reported that filgrastim has been used in FeLV-infected cats with cyclic neutropenia with some success.[123] In some FeLV-infected cats, neutropenia is immune-mediated, and responds to immunosuppressive doses of glucocorticoids. In animals with myeloid hypoplasia and in the absence of myeloid precursors, direct effects of FeLV are suspected, and glucocorticoids should not be used. Thus, bone marrow aspiration and cytology should be performed before glucocorticoids are considered.

Antiviral Chemotherapy and Immunomodulators

Antiviral drugs and immunomodulators are sometimes used to treat FeLV-infected cats (Tables 32.6 to 32.8). Unfortunately, few large controlled studies have been conducted in naturally infected cats, and most of them have shown unclear or no benefit.[339-342] This section will focus on drugs that are currently commercially available. The reader is referred to Chapter 9 for more detailed information on mechanism of action, other uses, study outcomes, and adverse effects.

TABLE 32.6 Antiviral Drug Studies for Treatment of FeLV Infection

Drug Class	Drug	Efficacy *In Vitro*	Controlled Study *In Vivo*	Efficacy *In Vivo*	Comments	EBM Level (I–IV)
Nucleoside Reverse Transcriptase Inhibitors						
	Zidovudine	Yes[406–411]	Yes	No[342,411,412]	Not very effective	I
	Didanosine	Yes[410,411]	No	ND	Possibly effective, but no *in vivo* data available	IV
	Zalcitabine	Yes[411]	Yes	No[413–415]	Not very effective, but relatively toxic	II
	Decitabine	Yes[346]	No	ND	Possibly effective, but no *in vivo* data available	IV
	Gemcitabine	Yes[346]	No	ND	Possibly effective, but no *in vivo* data available	IV
Nucleotide Reverse Transcriptase Inhibitors						
	Adefovir	Yes[416]	Yes	Yes[340,416]	Poorly effective, but relatively toxic	I
	Tenofovir	Yes[346]	No	ND	Possibly effective, but likely also relatively toxic	IV
Non-Nucleoside Reverse Transcriptase Inhibitors						
	Suramin	No	No	ND	Weak efficacy in uncontrolled experimental studies	III
Nucleotide Synthesis Inhibitors						
	Foscarnet	Yes[417]	No	ND	Effective *in vitro*, but too toxic	IV
	Ribavirin	Yes[418]	No	ND	Effective *in vitro*, but too toxic	IV
Integrase Inhibitor						
	Raltegravir	Yes[345,346,419]	Yes	Yes[347]	Mildly effective with reduction of viremia in one experimental study, but viremia relapsed after drug removal	II

ND, Not determined; *EBM,* evidence-based medicine[420]
EBM grade I = This is the best evidence, comprising data obtained from properly designed, randomized controlled clinical trials in the target species (in this context cats).
EBM grade II = Data obtained from properly designed, randomized controlled studies in the target species with spontaneous disease in an experimental setting.
EBM grade III = Data based on nonrandomized clinical trials, multiple case series, other experimental studies, and dramatic results from uncontrolled studies.
EBM grade IV = Expert opinion, case reports, studies in other species, pathophysiological justification.
(Including EBM grades for judgment of the available efficacy data including expert opinion of the authors.)

TABLE 32.7 Immunomodulatory Drug Studies for Treatment of FeLV Infection

Drub Class	Drug	Efficacy *In Vitro*	Controlled Study *In Vivo*	Efficacy *In Vivo*	Comments	EBM Level (I–IV)
Interferons						
	Human interferon-α	Yes[421]	Yes (SC high dose)	No[342]	Ineffective in a placebo-controlled blinded field study	I
			Yes (PO low dose)	No[341]	Ineffective in a placebo-controlled blinded field study, contrary to some effect reported in case series	I
	Feline interferon-ω	Yes[422]	Yes (SC high dose)	Yes[423,424]	Some effect (most likely more on secondary infections)	I
Microorganism-Derived Biologic Response Modifiers						
	Mycobacterium spp.	ND	Yes	No[425]	Not effective in an experimental setting	II
	Staphylococcus spp.	ND	Yes	Yes[341]	Some effect on owners' subjective impression on the health of their cats in a placebo-controlled field study	I
	Cutibacterium acnes	ND	No	ND	Some effect based on anecdotal reports and case series	III
	Serratia marcescens	ND	No	ND	Likely ineffective based on an uncontrolled study	III
	Poxviruses	ND	Yes	No[339]	Ineffective in large placebo-controlled blinded field studies	I
Plant-Derived Biologic Response Modifiers						
	Acemannan	ND	No	ND	Ineffective based on uncontrolled studies	III
Antiparasitics						
	Levamisole	ND	No	ND	Likely not indicated, but controlled studies missing	IV
	Diethylcarbamazine	ND	Yes	No[426]	Ineffective in one experimental study	II

ND, Not determined; *EBM,* evidence-based medicine.[420]

TABLE 32.8 Suggested Medications for Treatment of FeLV Infection

Drug	Dose	Route	Interval (Hours)	Comments
Zidovudine (AZT)	5 mg/kg	PO	12	Monitor CBC weekly during treatment for the first month, then monthly
Feline recombinant interferon-ω	1 million U/kg	SC	q24h for 5 consecutive days starting on days 0, 14, and 60	
Human recombinant interferon-α	1 to 50 U/cat	PO	24	

In general, human antiviral drugs used to treat cats have been less active against FeLV when compared to FIV. Most human antiviral drugs were developed for treatment of HIV infection, which is more closely related to FIV infection. Many drugs developed for humans, such as ribavirin,[343,344] have caused unacceptable toxicity in cats. Drugs that have been used in cats that were experimentally or naturally infected with FeLV include zidovudine (AZT), zalcitabine, adefovir, and suramin. Zidovudine has been administered to FeLV-infected cats with acceptable toxicity, but there has been no clear benefit on clinical outcomes. The same was true for adefovir. Some drugs, such as gemcitabine and tenofovir, have activity against FeLV *in vitro*, but their efficacy *in vivo* and toxicity in cats are so far unknown. The integrase

inhibitor raltegravir was highly active against FeLV *in vitro*.[344,345] Raltegravir was administered at 40 mg q12h PO for 6.5 weeks, and then 80 mg q12h PO for 2.5 weeks. The treatment reduced viremia in each cat, with up to 1 $\log_{10}$ reduction in viral RNA in four of seven cats, and the drug attained therapeutic plasma concentrations at both doses, with no adverse effects noted. However, viremia rebounded in all cats following drug removal.[347]

Immunomodulators used to treat FeLV-infected cats have included human IFN-α, feline IFN-ω, staphylococcal protein A, *Cutibacterium acnes* (formerly *Propionibacterium acnes*), *Serratia marcescens* extract, poxvirus preparations, acemannan, levamisole, and diethylcarbamazine. Benefits of most of these drugs have not been clearly demonstrated (see Chapter 9), and some, such as levamisole, are too toxic for routine use.

Prognosis

Survival times for cats with FeLV infection vary considerably depending on the stage of infection, host immunity, and the strain of FeLV involved. Some older studies suggested that FeLV-infected cats live a maximum of 3 years after diagnosis, but these studies involved group-housed cats in multiple-cat FeLV-endemic environments. With proper care, FeLV-infected cats can live much longer than 3 years and, in fact, die at an older age from causes unrelated to their retroviral infection.[348] Most cats that are progressively infected with FeLV go on to develop FeLV-associated disease within 5 years of diagnosis.[175] A comparison of more than 800 progressively FeLV-infected cats and 8000 controls revealed a median survival time of 2.4 years for progressively FeLV-infected cats versus 6.3 years for controls.[300] Still, many progressively infected cats, especially adult cats, can live for several years with a good quality of life, and so euthanasia is not recommended solely on the basis of a persistently positive FeLV antigen test. Some cats with FeLV-associated lymphoma can have long-term remissions when treated with standard chemotherapy protocols. Proviral DNA load and p27 antigen concentration correlated with survival in one longitudinal study, with cats having both proviral DNA load and p27 antigen concentration above cutoff values of 4×10^5 copies/mL and 37.5 ng/mL, respectively ("high positive" cats) having a median survival time of 1.37 years from time of enrollment; in contrast, over 90% of "low positive" cats were still alive at the end of the 4-year study.[318] In another study, cats with regressive infections also had evidence of a stronger immune response to the FeLV SU glycoprotein compared with cats in other outcome groups, as well as having evidence of virus-neutralizing antibodies.[349] These assays have the potential to be increasingly used in the future to predict outcome in cats that test positive for FeLV.

IMMUNITY

The majority of cats naturally exposed to FeLV will become immune to reinfection. This differs for other retrovirus infections, such as in FIV or HIV infection. As a result, although the mechanism of protection against FeLV and the role of neutralizing antibodies and cell-mediated immunity are still not completely understood, efficacious FeLV vaccines are commercially available.

Antibodies are at least partially protective. Experimentally, susceptible kittens can be protected from FeLV infection after passive immunization with sera containing high antibody concentrations against FeLV.[350] However, once persistent viremia is established, treatment with virus-neutralizing monoclonal antibodies is ineffective.[351] Most cats that overcome viremia exhibit high antibody titers to the virus,[352-354] and cats with regressive infection have higher antibody titers than cats with progressive infection.[136] Antibodies are directed against different components of the virus.[352]

Not all immune cats develop high antibody levels, and thus, cytotoxic T lymphocytes (CTLs) are also important.[352] Use of the recombinant FeLV canarypox vaccine did not induce antibodies to FeLV but cats were nonetheless protected from progressive infection.[319,322] CTLs specific for FeLV appear before virus-neutralizing antibodies, and the virus load in progressively FeLV-infected cats can be lowered after passive transfer of FeLV-specific CTLs stimulated *in vitro*, which suggests an important role of CTLs in FeLV immunity.[353,355]

VACCINATION

Vaccine Development and Efficacy

Cats with abortive and regressive FeLV infection mount an effective immune response and prevent or contain virus replication. This is a unique feature of FeLV infection and supports the idea that immune protection can be achieved through vaccination. Live attenuated vaccines produce a strong humoral immune response[356] but have the potential to establish infection or integrate into the host genome and later result in FeLV antigen–negative lymphomas. Most early inactivated FeLV vaccines were either poor immunogens, ineffective in preventing progressive FeLV infection, or enhanced tumor development. With refinement in cell culture conditions, large amounts of soluble FeLV antigens could be harvested in cell culture supernatants.[357] FeLV envelope antigen preparations alone were shown to provide protection if used in conjunction with potent adjuvants.[358] With such preparations, no viral genes could be introduced into host cells, circumventing the oncogenic potential of FeLV. The first vaccine based on soluble FeLV antigens was licensed in 1985, and then underwent further modifications to improve efficacy.

Although most FeLV vaccines effectively protect cats from progressive infection, there is controversy surrounding the degree of efficacy and which type of vaccine is most efficacious.[323] Few independent studies exist that compare the efficacy of vaccines. Testing protocols vary widely among studies, with differences in time periods assessed between vaccination and challenge, challenge strains, challenge doses, cats, and different methods of virus detection following challenge. Therefore meaningful comparison of studies is difficult if not impossible. To overcome age-related resistance, some studies used glucocorticoids for immunosuppression before intranasal challenge or performed parenteral FeLV exposure. These challenges produce a much higher proportion of infected control cats, reducing the overall number of cats needed for efficacy studies. The comparability of these challenges to natural exposure has been questioned.[147,359-362] However, some FeLV vaccines proved efficacious even under these severe challenge conditions, suggesting that the vaccines could also protect cats against FeLV infection under natural conditions. Some studies involved natural challenge, in which vaccinated and control cats were housed together with FeLV-shedding cats.[362,363] Although more comparable to a field situation, such natural challenge situations often fail to result in a high rate of progressive infection in unvaccinated control cats, leading to a low calculated efficacy of the vaccine and unsuitable data for vaccine approval. For example, for inactivated FeLV vaccines, European licensing authorities require that less than 20% of the vaccinated cats and more than 80% of the unvaccinated controls develop progressive infection.

There are three types of FeLV vaccines licensed: (1) classical inactivated whole virus vaccines; (2) genetically engineered recombinant subunit vaccines based on the FeLV envelope protein p45 (a nonglycosylated form of gp70 produced in bacteria);[364] and (3) infectious recombinant canarypox virus engineered to express the *env* and *gag*/part of *pol* genes of FeLV.[365] The recombinant FeLV p45 subunit vaccine was the first commercial recombinant vaccine for small animals and was

demonstrated to be highly efficacious in protecting cats from progressive FeLV infection. Later, a recombinant canarypox vaccine became available in Europe, which is a different product than that licensed for use in the United States. An independent comparison of FeLV whole virus vaccines available in the United States revealed a very high efficacy for two of four vaccines tested.[366] There was absence of provirus integration and viral RNA in most cats vaccinated with the two whole virus vaccines, thus indicating sterile immunity (complete absence of viral RNA, proviral DNA, antigen, and culturable virus after challenge). These results contradicted with those from an earlier study that showed that neither one of the two whole virus vaccines nor the recombinant canarypox vaccine led to sterilizing immunity.[319] FeLV provirus was found to persist for years even after challenge in vaccinated cats, and recurrence of viremia and disease development was observed in some cats.[150] Thus, vaccination does not appear to consistently protect against development of regressive infection.

While inactivated whole virus and recombinant protein vaccines require adjuvants, the recombinant canarypox vaccine is a replication-defective live virus vaccine that does not require an adjuvant to induce protective immunity.[319,322] Cats protected by the recombinant canarypox vaccine have a higher ratio of FeLV-specific IFN-γ- to IL-10-producing cells than susceptible cats, in accordance with the known importance of CMI induced by this vaccine.[367] An improved version of the recombinant canarypox vaccine was produced by a target mutation within the FeLV envelope protein to delete the immunosuppressive domain p15E; this led to induction of a more pronounced cell-mediated immune response and to slightly increased vaccine efficacy.[367] Two studies that compared the recombinant vaccine to an inactivated vaccine have been the subject of controversial discussion. The first study claimed that an inactivated whole virus vaccine was superior in protecting cats from FeLV challenge (90% protection from progressive infection) compared to the recombinant canarypox vaccine (20% protection from progressive infection).[368] The validity of this study was debated, in part because an intercurrent parvovirus infection was probably introduced by a contaminated challenge virus preparation, which likely created immunosuppression. The challenge and parvovirus infection occurred within 3 weeks after the second vaccination, so likely impacted immunity to vaccination.[369] In the second study, immunosuppression was created using high doses of glucocorticoids during challenge, which occurred 3 months after the second vaccination.[370] Under these circumstances, the whole virus vaccine performed better (preventable fraction 100%) than the recombinant canarypox vaccine (preventable fraction 45%). Concerns were raised in response to this study because the severe immunosuppression during challenge likely specifically impacted CMI, which is critical for responses to recombinant canarypox vaccines.[371] In reaction to this, it was suggested that cats at risk for FeLV infection in the field might also be immunosuppressed.[372]

These debates aside, the administration of FeLV vaccines prolongs the life expectancy of FeLV-exposed cats.[151] FeLV vaccines are considered noncore vaccines, so are recommended for all cats with a potential FeLV exposure risk, such as cats permitted to roam outdoors or cats brought to or living in multicat environments with other cats of uncertain FeLV status. Cats kept strictly indoors are at risk if kept in multicat households in which some cats have outdoor access. In areas with high FeLV prevalence, vaccination of all kittens and juvenile cats up to 1 year of age should be considered, since the environment into which a kitten enters can rarely be predicted with certainty.[373,374] Additionally, kittens also have a particularly high risk of developing progressive infection after FeLV exposure. Recommendations for most vaccines are for two subcutaneous doses 3 to 4 weeks apart for initial protection followed by a vaccination 1 year later. FeLV vaccines should be given in the left pelvic limb as distally as possible.[374] Results of several studies indicate that FeLV vaccine-induced immunity persists for at least 12 months following vaccination, but likely much longer. Some vaccines are licensed for yearly boosters, some for up to 3-year boosters. Recommendations by different expert panels vary concerning the booster intervals of adult cats. In adult cats that have received appropriate initial two-dose immunization and a booster after 1 year, the need for subsequent vaccination and the booster interval is best determined by analysis of risk.[374] At-risk adult cats should continue to be vaccinated for FeLV annually, but cats at low risk of FeLV exposure can be vaccinated every 3 years.[374] In a study that addressed the duration of immunity in cats vaccinated with an adjuvanted inactivated whole virus vaccine, 10 of 12 cats vaccinated 2 years before FeLV exposure were protected from progressive infection, while all 11 controls were unprotected (preventable fraction 83%).[375] In another study using an inactivated whole virus vaccine, cats were exposed 8, 20, and 36 months after vaccination to FeLV. The outcome of the study was hampered by the age-related resistance, which meant that only 10 of the 32 control cats demonstrated progressive infection.[376] Nonetheless, only one of 44 vaccinated cats became progressively infected.

It is not necessary to administer vaccines from the same manufacturer for boosters.[377] Not all cats respond equally to FeLV vaccination, and immunosuppressed cats can fail to develop immunity.[378] In a 5-year field study of a colony of 30 domestic adult cats naturally exposed to FeLV infection, FeLV vaccination was effective in cats not infected with FIV, but failed to protect FIV-infected cats.[98] In contrast, in an experimental study using a recombinant FeLV p45 subunit vaccine, FIV-infected cats were successfully immunized and protected from FeLV challenge exposure in the early phase of infection.[379] No benefit of FeLV vaccination was observed in cats with progressive but subclinical FeLV infection on virus load or life expectancy.[329] Therefore FeLV vaccination is not recommended in progressively FeLV-infected cats. Vaccination of cats with a history of regressive or abortive infections should also not be necessary, since these cats most likely have protective immune response against FeLV. As described in the Diagnosis section, new antibody tests might be useful to detect immune cats, but their validity still has to be evaluated in the field.

FeLV Vaccination and Injection-Site Sarcomas

In early studies, a statistical association was demonstrated between FeLV and rabies vaccinations and later development of feline injection-site sarcomas (FISS) (see Chapter 20). However, in a subsequent multicenter case-control study in the United States and Canada, no single vaccine brand or manufacturer within antigen class could be identified as a risk factor for FISS development.[380] One study compared the subcutaneous tissue response to different FeLV vaccines. Three groups of 15 cats were injected with one of three FeLV multicomponent vaccines, a recombinant canarypox vaccine, a vaccine with a lipid-based adjuvant, and a vaccine adjuvanted with an alum-Quil A mixture. On days 7, 21, and 62 post vaccination, significantly less inflammation was associated with administration of the recombinant canarypox multicomponent vaccine. The inflammation was most severe in cats receiving the multicomponent vaccine containing FeLV p45 and an aluminum-based adjuvant.[381] Not only adjuvanted FeLV and rabies vaccines, but also other vaccines and injections of long-acting drugs, such as glucocorticoids, or injuries, such as through foreign bodies, and microchip implants were associated with the development of FISS in some case reports (see Chapter 20).

Some studies examined a possible role of FeLV and FeSV in the development of FISS, but could not detect either FeLV or FeSV in the tumors.[186] Furthermore, no other viruses, including FIV, FFV, polyomaviruses, or papillomaviruses were detected in tumor tissues.[382-385]

No evidence was found for the replication or expression of endogenous retroviruses in FISS.[383,385] In addition, feline primary cutaneous lymphomas were described in association with vaccination. A total of 17 cutaneous lymphomas with a history of vaccine injection at the site of tumor development were evaluated. Postinjection time of development ranged from 15 days to approximately 9 years in five cats. FeLV gp70 and/or p27 proteins were expressed in 10 of the 17 tumors. It was suggested that persistent inflammation induced by the injection and reactivation of FeLV expression might have contributed to the development of these tumors.[386] Chapter 20 describes recommendations to minimize the risk of FISS. Along these lines, no FeLV vaccinations should be administered to indoor-only cats or already immune cats,[387] and, thus, FeLV prevaccination testing is recommended.

PREVENTION

Preventative methods, including general precautions, testing and removal strategies, and vaccination, have been successful in significantly decreasing the prevalence of FeLV infection.[110]

FeLV is very fragile, surviving only minutes at most outside the host animal. Thus, direct contact among cats and immediate fomite transfer are the major risk factors, but transmission requires prolonged, close contact. Progressively infected cats should be physically separated from other cats in the environment. In a veterinary hospital, FeLV-shedding cats can be housed in the same ward with other hospitalized patients as long as they are housed in separate cages and certain precautionary measures are taken. Simple precautions (e.g., hand washing) and routine cleaning procedures prevent transmission in the hospital setting.

Cats with progressive FeLV infection should be housed in individual cages and confined to them throughout their hospitalization. They should never be placed in isolation with cats that have other infections, such as viral respiratory infections, because FeLV-infected cats may be immunosuppressed. Routine hospital infection-control precautions will prevent transmission of FeLV.

FeLV can be transmitted hematogenously; therefore all feline blood donors should be screened and confirmed to be free of infection before donating blood.[297,298,388] Pre–blood transfusion screening should include not only ELISA to detect FeLV antigen, but also provirus PCR testing because regressively infected cats (antigen-negative, provirus-positive) also transmit the virus, and blood product recipients can become regressively or even progressively FeLV-infected.[144] FeLV was also detected in the corneal tissues of cats by PCR and immunohistochemistry;[389] therefore screening potential corneal donors for FeLV infection is also generally warranted.

In the mid-1970s, test and removal programs were extremely effective for eliminating the virus from catteries. When testing was first implemented, the prevalence of FeLV in purebred catteries was 11%. Within 4 years, the rate was reduced to less than 2%. Today, FeLV infection should be considered an abnormality in a well-run cattery. Many stray-cat shelters also implement testing in their conditioning protocols, thus further reducing the rate of FeLV infection.[123,390]

PUBLIC HEALTH ASPECTS

Although FeLV can replicate in human cell lines,[391] no conclusive evidence of natural human infection with FeLV has been detected. Concerns that relate to the possibility of zoonotic transmission of FeLV infection have arisen from several observations. Firstly, some FeLV strains grow in human cell cultures.[392] Secondly, lymphoma has been induced by injection of large doses of virus into neonates of nonfeline species, such as pups and marmosets.[60] Thirdly, contact of humans with sick cats was linked to development of childhood leukemia, and the degree of contact between FeLV-infected cats and children with leukemia was double that of contact between healthy children and healthy cats.[393,394] Fourth, veterinarians were shown to have a higher death rate from leukemia than a control population of physicians and dentists.[22,359,395-397]

Despite these facts, FeLV does not appear to be a risk to humans. Some investigators have detected antibodies to FeLV in humans with leukemia and owners of progressively FeLV-infected cats.[398-401] On the other hand, studies using more specific radioimmunoassays obtained negative results. No human has ever been found to be viremic with FeLV. PCR was used without success to find FeLV sequences in blood and bone marrow of young and adult humans with leukemia.[402]

One study found that human blood cells are uniquely resistant to infection with FeLV due to the activity of cellular enzymes that mutate the viral genome. A second blockade to infection was identified that appears to suppress viral gene expression after the viral genome has integrated into the host cell genome. As cells derived from other normal human cell types are fully supportive of FeLV replication, innate resistance of blood cells could be critical in protecting against cross-species infection.[403] In conclusion, there is no evidence that FeLV is transmitted from cats to humans. Still, if immunosuppressed people live in close contact with FeLV-infected cats, there is a certain risk, not for FeLV infection but for infection by secondary pathogens that have the potential to be zoonotic.

CASE EXAMPLE

Signalment

"Mausi," a 6-year-old female spayed domestic shorthair from Munich, Germany.

History

Mausi was presented to the Ludwig-Maximilians-Universitaet Munich, Germany, Veterinary Medical Teaching Hospital, for lethargy and anorexia of 3 days' duration. Mausi had not eaten and not defecated during this time. There had been no change in urination.

At a local veterinary clinic on the first day of illness, a physical examination revealed fever (105.1°F or 40.6°C). Treatment with amoxicillin/clavulanic acid did not lead to clinical improvement. Mausi tested positive for FeLV antigen 2 years previously, after which time the cat had been housed exclusively indoors. There were three other cats in the household that were also indoor-only since Mausi was found to be infected with FeLV. A FeLV test had revealed that one other cat was FeLV antigen–positive, the other two cats were FeLV antigen–negative. None of the other three cats were ill. Mausi had not had any known toxin exposure, there were no recent changes in the environment, and the cat was fed a commercial dry cat food.

Current Medications

Amoxicillin/clavulanic acid PO.

Other Medical History

None.

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 6.9 kg

General: Quiet, alert, responsive, well hydrated, T = 104.4°F (40.2°C), HR = 220 beats/min, RR = 36 breaths/min, mucous membranes pink, CRT = 1 s, haircoat unkempt.

Eyes, ears, nose, and throat (including dilated fundoscopic examination): Mild gingivitis.

Musculoskeletal: Body condition score 7/9. Normal ambulation.

Cardiovascular, respiratory, gastrointestinal, genitourinary, and lymph nodes: Mausi resented palpation of her cranial abdomen. No other clinically significant abnormalities were detected.

Laboratory Findings

CBC: HCT 24.6% (30%–50%), MCV 48.4 fL (42–53 fL), reticulocytes 7800 cells/μL, WBC 12,470 cells/μL (4500–14,000 cells/μL), neutrophils 10,438 cells/μL (2000–9000 cells/μL), band neutrophils 1,459 cells/μL (0–1000 cells/μL), lymphocytes 344 cells/μL (1000–7000 cells/μL), monocytes 229 cells/μL (0–1000 cells/μL), platelets 192,000 platelets/μL (180,000–500,000 platelets/μL),

On blood smear, the neutrophils showed mild toxicity.

Serum Chemistry Profile: Sodium 148 mmol/L (151–158 mmol/L), potassium 3.8 mmol/L (3.6–4.9 mmol/L), chloride 119 mmol/L (117–126 mmol/L), bicarbonate 18 mmol/L (15–21 mmol/L), phosphorus 3.9 mg/dL (3.2–6.3 mg/dL), calcium 9.5 mg/dL (9.0–10.9 mg/dL), BUN 19 mg/dL (18–33 mg/dL), creatinine 1.2 mg/dL (1.1–2.2 mg/dL), glucose 169 mg/dL (63–118 mg/dL), total protein 7.0 g/dL (6.6–8.4 g/dL), albumin 2.6 g/dL (2.2–4.6 g/dL), globulin 4.4 g/dL (2.8–5.4 g/dL), ALT 72 U/L (0–101 U/L), ALP 12 U/L (0–71 U/L), cholesterol 104 mg/dL (89–258 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL),

Urinalysis (cystocentesis): SpG 1.020; pH 7.0, 1+ protein, 2+ hemoprotein, 0–1 WBC/HPF, 0–2 RBC/HPF, some rods

Imaging Findings

Plain abdominal radiographs: The intestines were relatively empty. No masses were identified. Abdominal serosal detail appeared normal.

Abdominal sonography: The left kidney measured 4.2 cm in length and showed a mildly enlarged renal pelvis. The remainder of the abdomen was unremarkable.

Microbiologic and Virologic Testing

Aerobic bacterial urine culture: growth of *Escherichia coli* (sensitivity testing revealed that the *E. coli* was sensitive to pradofloxacin, but resistant to amoxicillin/clavulanic acid)

POC ELISA for FeLV antigen and FIV antibodies: positive for FeLV antigen, negative for FIV antibodies

Diagnosis

Progressive FeLV infection and acute pyelonephritis (characterized by fever, bacteriuria, and mild neutrophilia with left shift). Right renal agenesis (likely congenital).

Treatment

Mausi was hospitalized and treated with intravenous fluids, and initially, while awaiting the culture and susceptibility results, treated with amoxicillin/clavulanic acid (20 mg/kg, IV, q12h) and pradofloxacin (oral suspension 5 mg/kg, PO q24h). Rectal temperature normalized within 24 hours, and the cat started eating again. After 48 hours, hematocrit was 27.6%, neutrophil count was 5759 cells/μL with no bands or toxicity, and lymphocyte count was 917 cells/μL. As culture and susceptibility testing revealed an *E. coli* that was resistant to amoxicillin/clavulanic acid, but susceptible to pradofloxacin, amoxicillin/clavulanic acid treatment was discontinued, and Mausi was discharged from the hospital with instructions to continue pradofloxacin treatment for 1 month. Two weeks after the antibiotics had been discontinued, Mausi appeared healthy. A physical examination, CBC, kidney panel, urinalysis, and aerobic bacterial urine culture showed no abnormalities. Her hematocrit was 38.9%, and white blood cell count was 4620 cells/μL. One year later, Mausi remained clinically healthy, and a CBC showed a hematocrit of 38.2%, white blood cell count of 4500 cells/μL, neutrophil count of 3362 cells/μL, and a lymphocyte count of 905 cells/μL. Mausi remained alive and well with a normal CBC 4 years after she was initially seen for the pyelonephritis. Mausi died 2 years later, 7.5 years after first testing positive for progressive FeLV infection.

Comments

Even though this cat was initially seen for moderately severe illness in association with progressive FeLV infection, there was full clinical recovery with treatment and the cat remained alive and well for 6 additional years. Fever, bacteriuria, and neutrophilia with left shift were likely associated with pyelonephritis. The nonregenerative anemia likely represented an anemia of inflammatory disease, and the lymphopenia and the hyperglycemia were likely stress-induced.

The two FeLV antigen–negative cats most likely had been exposed to FeLV and had regressive or abortive FeLV infection, in which case they would be protected against new FeLV infection.

This case clearly demonstrates that other treatable diseases can be present in progressively FeLV-infected cats, long-term survival is possible, and that a search for the underlying cause of clinical signs and adequate treatment is always recommended.

Feline Immunodeficiency Virus Infection

Julia A. Beatty, Jane E. Sykes

KEY POINTS

- Cause: FIV (family *Retroviridae*, subfamily *Orthoretrovirinae*, genus *Lentivirus*).
- First Described: California, 1986;[1] serologic evidence of infection dates back to the 1960s.[2,3]
- Affected Hosts: Domestic and wild cats; hyenas.
- Geographic Distribution: Endemic worldwide.
- Mode of Transmission: Primarily biting. Queen-to-kitten transmission uncommon. Horizontal between housemates rare. Iatrogenic via blood transfusion possible.
- Major Clinical Signs: Most FIV-infected cats are subclinically infected for most or all of their lifetime. Signs include lethargy and fever, stomatitis, chronic GI signs, wasting, neurologic signs, high-grade lymphoma, immune-mediated diseases, and opportunistic infections.
- Differential Diagnoses: Variable depending on clinical signs.
- Human Health Significance: FIV does not infect humans. Immunosuppressed owners should be counseled regarding the risk of opportunistic pathogen exposure from any immunosuppressed pet.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

FIV is an enveloped, RNA virus that belongs to the *Lentivirus* genus of the *Retroviridae*. It infects domestic and wild cats worldwide, as well as hyenas.[4] FIV strains are highly host-specific. Cross-species transmission, even among carnivore hosts, is rare.[5] Like HIV, FIV establishes a chronic, persistent infection that, in some cats, ultimately culminates in immunodeficiency. Because of its similarities to HIV, FIV infection in cats has been used as a research model for HIV infection in the past.[6] Thus, relative to other viral infections of companion animals, much is known about FIV pathogenesis.

Familiarity with retroviral structure and replication assists in understanding diagnostic, treatment, and prevention strategies for these infections. Like other retroviruses, FIV has a three-layered structure that is composed of an innermost genome-nucleocapsid complex with helical symmetry, an icosahedral capsid, and an envelope with glycoprotein spikes (Fig. 33.1). Each virion contains a duplicate, single-stranded RNA genome. The FIV genome contains three major genes: *gag*, which encodes the virion core proteins (capsid [p24], nucleocapsid [p10], and matrix [p15]); *pol*, which encodes the reverse transcriptase, protease, and integrase enzymes; and *env*, which encodes surface (gp120) and transmembrane (gp40) envelope glycoproteins.[7] Several accessory and regulatory genes are also encoded. FIV Env binds to CD134, the primary cell surface receptor, to initiate infection.[8] CD134 is expressed on feline CD4+ T cells, B cells, and activated macrophages. A conformational change in Env exposes the binding site for the co-receptor CXCR4, a chemokine receptor, triggering cell entry.[8] The viral envelope fuses with the cell membrane, and the capsid is released into the cytoplasm where reverse transcription occurs and a double-stranded DNA (dsDNA) copy of the retroviral genome is made. Additional sequences, known as *long terminal repeats* (LTRs), are added to either end of the viral genome. The virus then passes into the nucleus where the dsDNA copy integrates into the host genome; at this point, the integrated dsDNA becomes a *provirus*. Transcription of this proviral DNA, which is controlled by the LTRs, leads to synthesis of new virion components, and virus assembly and budding occur at the cell surface (Fig. 33.2). Depending on the cellular environment, proviral DNA may either be *latent,* whereby transcription does not occur, or be transcriptionally active. Latency is one mechanism by which retroviruses can evade the host immune system. Within an infected cat, FIV mutates frequently to create a pool of variant viruses. Point mutations introduced during reverse transcription and recombination between viruses that co-infect a single cell are the major mechanisms involved. Variable regions in *env* form the basis for the phylogenetic classification of FIV into major subtypes or clades, A to F. Regional variation in the prevalence of subtypes exists with subtypes A, B, and C being most common.[9,10] Classification of FIV subtypes has become complex because sequences used for subtyping do not detect all *env* recombinants. Additionally, recombinant subtypes, such as A/B, B/E, and A/B/C, are now recognized,[11,12] and the existence of additional subtypes likely. The heterogeneity of the virus complicates the design of molecular diagnostic tests and vaccines for FIV. The clinical relevance of subtype classification is not yet clear since subtype does not consistently predict clinical manifestations or vaccine protection.[13,14]

FIV is transmitted by direct inoculation of saliva or blood during fighting.[15,16] Other routes of transmission are of minor epidemiologic significance. Horizontal transmission of FIV between cats in stable households is rare.[17] Queen-to-kitten (prenatal, natal, and postnatal) transmission of FIV is documented infrequently, although primary infection of the queen during pregnancy may increase the risk of transmission.[18] Diagnosis of FIV infection in one kitten does not imply that the whole litter is infected.[19] Natural sexual transmission of FIV is not reported, although experimentally, FIV can be recovered from semen, and intravaginal exposure results in transmission.[20]

Detection of circulating antibodies has been used as a marker of infection in epidemiologic studies because FIV infection is lifelong. Seroprevalence varies from <5% to >20% depending on the region and the population tested (Table 33.1). FIV infection rates are particularly high in Australia and Japan. Two studies in Australia found that 14.6% and 15% of client-owned cats tested at veterinary clinics were seropositive.[21,22] In Japan, the overall seroprevalence was 23.2%, with up to one third of male cats testing positive.[23] Risk factors for FIV

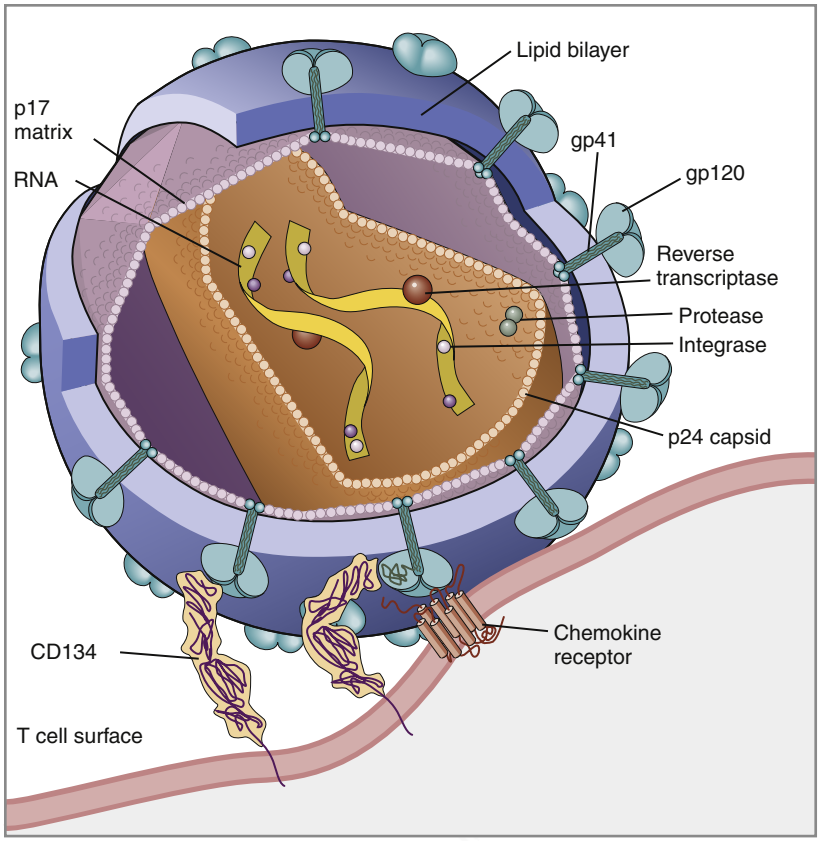

Fig. 33.1 An FIV virion is shown adjacent to the surface of a CD4+ T cell. Lentiviruses contain two identical strands of RNA (the viral genome) and associated enzymes, which include reverse transcriptase, integrase, and protease, packaged into a core composed of the p24 capsid protein with a surrounding p15 protein matrix, all enclosed by a phospholipid membrane envelope that is derived from the host cell. Viral encoded membrane proteins (gp40 and gp120) are bound to the envelope. CD134 (OX40), a member of the tumor necrosis factor receptor superfamily, and CXCR4, a chemokine receptor, on the host cell surface function as primary and co-receptor, respectively, for FIV.

infection are shown in Table 33.2. The mean age at diagnosis is 6 to 8 years, and 80% to 90% of cats are more than 2 years of age.[24] Male cats are up to 4.7 times more likely to be seropositive than female cats.[25] In a North American study, the prevalence of FIV infection in sick, feral cats was 18.2%, whereas that in healthy indoor cats was only 0.7%.[25] Occasionally, co-infections with FeLV occur, and results of some studies suggest that infection with one retrovirus is a risk factor for infection with the other.[26,27]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

FIV infection is characterized by a progressive immune dysfunction which, in some infected cats, results in clinical signs suggestive of immune deficiency or inflammatory, immune-mediated or neoplastic disease.[1,28,29] The immunopathogenesis of FIV infection has been studied extensively in experimental infections of young cats housed in minimal disease environments. The immunologic changes documented in experimentally infected cats are rarely accompanied by clinical signs.[30] An improved understanding of the clinical course of FIV infection in naturally infected cats, which are typically infected in adulthood and exposed to infectious and environmental cofactors, awaits longitudinal field studies of FIV-infected cats and controls.

FIV infection can be broadly considered to progress in three stages: a transient primary stage, a chronic subclinical stage, and an advanced, clinical stage that is eventually terminal (Fig. 33.3). During the primary stage, which lasts for several weeks, the virus replicates rapidly and viremia is detectable by virus isolation and PCR.[31] Immune dysfunction begins soon after FIV infection. CD4+ T-cell numbers decline rapidly during the first weeks of infection. An early rise in an activated subpopulation of lymphocytes that expresses low levels of the CD8 molecule, $CD8^{low}$, exacerbates a reduced CD4:CD8 ratio.[32] Lymphocyte function is negatively impacted, for example, T-cell priming to novel antigens is disrupted within 5 weeks of experimental infection.[33] Dissemination of virus to lymphoid tissues occurs and virus can be detected in saliva within 3 weeks of experimental infection.[34] A strong immune response comprising CD8+, cytotoxic T cells, and antibodies to viral proteins is detectable from 2 to 6 weeks after experimental infection.[35] Virus replication is contained but, crucially, not cleared by the host immune system. Transient clinical signs sometimes accompany the primary stage. These include lethargy, anorexia, waxing and waning fever, neutropenia, and a lymphadenopathy due to reactive lymphoid hyperplasia (Fig. 33.4), which can persist for months.

The subclinical stage lasts for years and, often, for a cat's lifetime. Virus replication proceeds in peripheral lymph nodes,[36] but viremia is almost or completely absent. Hence, antigen testing is not used for FIV diagnosis. CD4+-cell numbers in the periphery rebound initially, then decline progressively.[37,38] Dysregulation of cytokine production contributes to impaired immunity to opportunistic pathogens. For example, primary challenge of clinically normal FIV-infected cats with

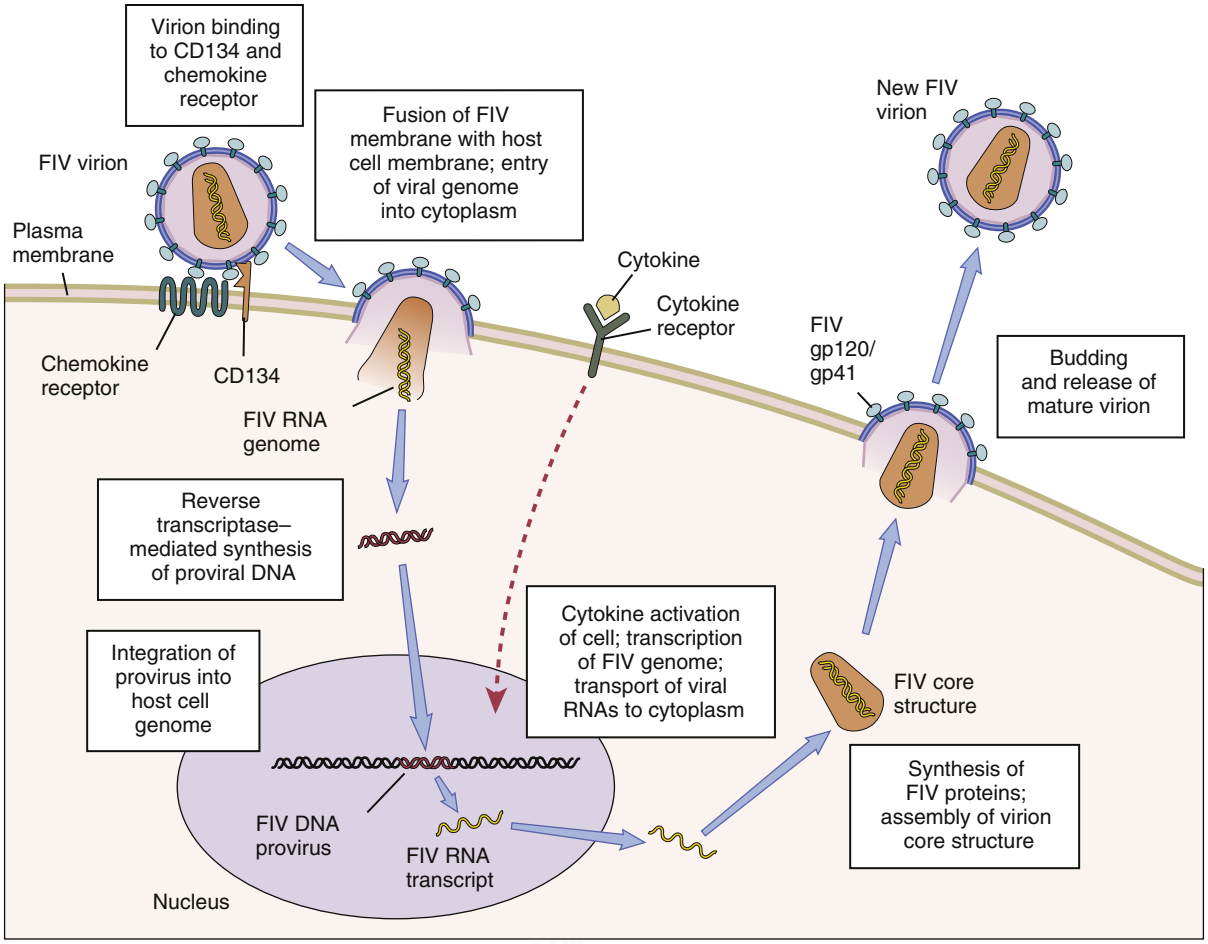

Fig. 33.2 The life cycle of feline immunodeficiency virus (FIV). The sequential steps from initial infection of a host cell to release of a new virus particle are shown. An infected cell produces many virions, each capable of infecting nearby cells, with subsequent spread of the infection.

TABLE 33.1 FIV Seroprevalence Estimates from Selected Regions (2009-)

Country Region	Population	Seroprevalence
United States and Canada	Client-owned and shelter cats	3.6%[124]
Germany	Client-owned cats	3.6%[27]
NW China	Client-owned and shelter cats	9.12%[125]
United Kingdom	Shelter cats	3% and 11.4%[126]
Malaysia	Client-owned cats	10%[127]
Australia	Client-owned cats	14-15%[21,22]
Singapore	Client-owned and shelter cats	16%[128]
Japan	Client-owned cats	23.2%[23]

TABLE 33.2 Risk Factors for FIV Infection

Variable	High Risk	Low Risk
Sex	Male	Female
Neuter Status	Unneutered	Neutered
Breed	Mixed Breed	Pure Breed
Environment	Free Roaming	Confined
Health Status	Sick	Healthy
Age	Adult	Juvenile

Toxoplasma gondii can result in severe, systemic toxoplasmosis compared with only mild, transient signs in FIV-uninfected cats.[39] Cats chronically infected with FIV produce less IL-2 and IL-12, and more IL-10 in response to *T. gondii* infection than control cats.[40] Innate as well as adaptive immunity is affected; defective natural killer (NK)-cell function delayed clearance of *Listeria monocytogenes* in experimental FIV infection.[41] Immune hyperactivation as well as suppression contributes to immune dysfunction in FIV infection. Polyclonal B-cell stimulation results in hypergammaglobulinemia.[42] Chronic antigenemia activates T-cell subpopulations which function as immune suppressors. These include CD4+ and CD8+ cells that express B7 and CTLA4, which contribute to immune anergy and apoptosis in lymph nodes, as well as CD4+CD25+ T-regulatory cells which function as nonspecific suppressors, thereby impacting immunity to FIV and to opportunistic pathogens.[43,44]

In some cats, clinical signs of advanced FIV infection eventually ensue. The advanced stage of FIV infection is characterized by profound lymphoid depletion, escape of virus from immunologic control, and clinical signs including opportunistic infections, neoplastic disease, myelosuppression, and neurologic disease (Table 33.3).[45–48] Immune dysfunction can manifest clinically as atypical and refractory

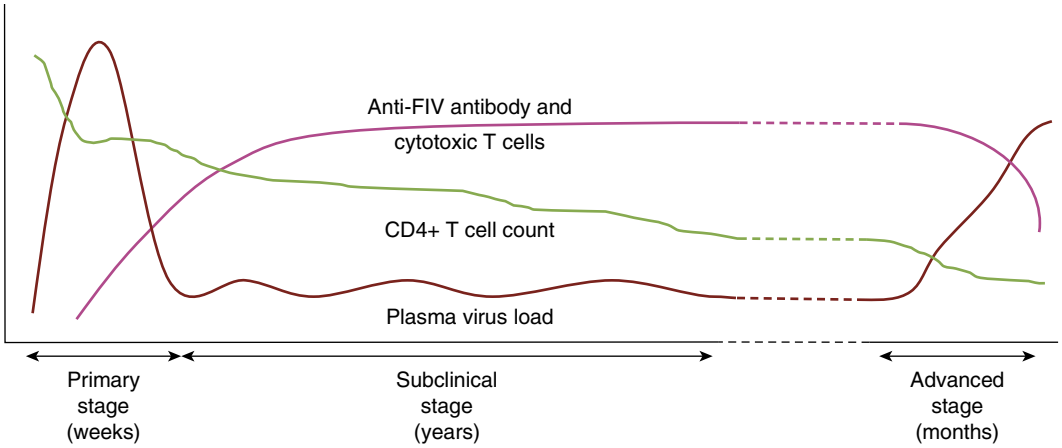

Fig. 33.3 Changes in virus load and CD4+ T-cell numbers over the course of infection with feline immunodeficiency virus (FIV). Viremia is detected early after infection and may be accompanied by systemic signs (primary stage). Plasma viremia then falls to very low levels and remains this way for many years (subclinical stage). Although this period is referred to as "clinical latency," the virus itself is not latent; there is ongoing production of virus and a steady decline in CD4+ T-cell counts. The rate of progression of the subclinical stage depends on factors such as the virus strain, co-infections with other agents that activate virus transcription, and host immunity. Some cats progress to the advanced stage of infection where signs of immunodeficiency develop, and plasma viremia increases. Advanced FIV infection is eventually terminal. Antibody production declines, and antibody tests may be negative in cats with advanced-stage disease, but polymerase chain reaction assays are usually positive.

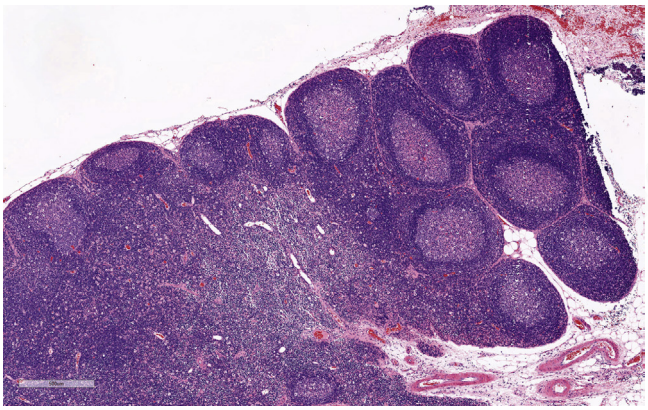

Fig. 33.4 Submandibular lymph node from a young cat in the primary stage of FIV infection with generalized lymphadenomegaly, showing prominent, irregular follicular hyperplasia (H&E staining). (Courtesy of Dr Laura Setyo.)

bacterial, viral, or parasitic infections (Fig. 33.5). Respiratory infections, bacterial pyoderma, generalized demodicosis, mycobacterial infection, disseminated cowpox, pulmonary cryptococcosis, sporotrichosis, and lungworm infections are reported.[28,49–51] Persistent cytopenias, particularly neutropenia or lymphopenia, are described in advanced FIV infection.[21,52] These infections are often more severe and less responsive to treatment than the same infections in immunocompetent cats. FIV infection has been linked to feline chronic gingivostomatitis (FCGS), a painful and debilitating condition that can greatly impact quality of life (Fig. 33.6).[53] The etiology of FCGS is ill-defined, and it is likely to be multifactorial. Epidemiologic evidence identifies FIV as a risk factor in some studies and, while FIV is clearly not causal, a role for the virus in disease manifestation and severity in infected cats seems likely.[54] Immune stimulation triggered by FIV may contribute to chronic oral inflammation, while immune suppression may delay clearance of other pathogens, such as FCV or secondary bacterial invaders. Significant differences in the oral microbiota of FIV-infected cats compared with uninfected cats, including higher relative abundance of fusobacteria and actinobacteria in FIV infection, have been demonstrated. The clinical significance of these findings awaits clarification.[55]

TABLE 33.3 Disease Diagnoses in 127 Cats with FIV Infection[a,b]

Disease	Cats Infected With FIV (n = 127)[c]	Controls (n = 210)[d]	P Value[e]
Intraocular inflammation	16	17	0.18
Stomatitis	21	11	< 0.001
Cardiomyopathy	21	17	0.02
Upper respiratory tract disease	13	9	0.03
Neurologic signs	16	24	0.75
Chronic kidney disease	23	40	0.83
Diabetes mellitus	9	18	0.63
Hyperthyroidism	11	14	0.49
Lymphoma	23	20	0.02
Squamous cell carcinoma (SCC)	12	9	0.057
Fibrosarcoma	2	9	0.17
Carcinomas other than SCC	4	12	0.28

[a]All cats were seen over the same time period at the UC Davis VMTH.
[b]Results should be interpreted with caution because the data were retrospectively collected. Some cats may have had undiagnosed disease, such as subclinical chronic kidney or cardiac disease. The pathogenesis of a disease process in FIV-positive cats might also differ from that found in FIV-negative cats.
[c]All cats were > 6 months of age and none had a history of FIV vaccination.
[d]All control cats were negative for FIV antibody at their visit to UC Davis.
[e]As determined by chi-square (univariate) analysis. The p values < 0.05 were significant.
Modified from Trott KA, Kass PH, Sparger EE, et al. A clinical case control study: clinical presentation of FIV-positive cats. University of California, Davis, STARS in Science Day. 2007; abstr.

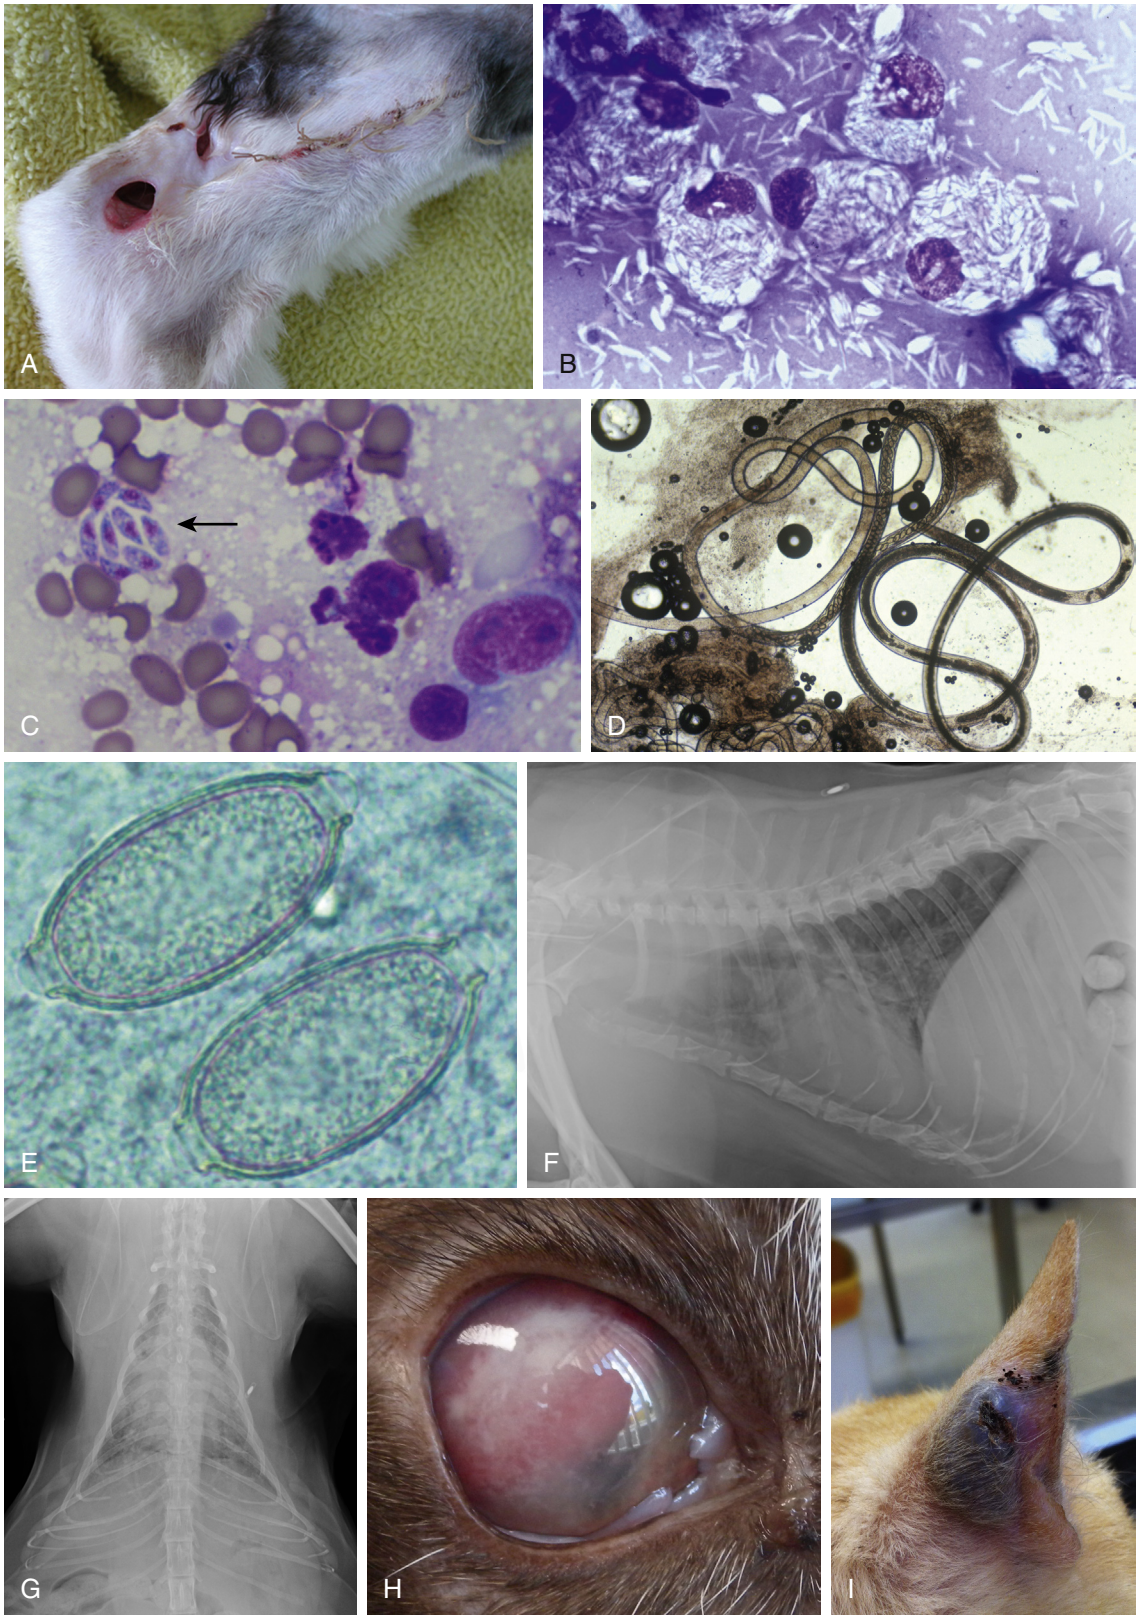

Fig. 33.5 (A) *Mycobacterium lepraemurium* infection causing a nonhealing hock wound in a 12-year-old cat with advanced-stage feline immunodeficiency virus (FIV) infection. (B) Fine-needle aspiration cytology of the lesion shown in A shows numerous negatively staining intracellular bacilli. Modified Wright-Giemsa. (C) Impression cytology of liver biopsy from a 9 year-old male, neutered FIV-infected cat investigated for a hepatopathy. *Toxoplasma gondii* tachyzoites *(arrow)* are surrounded by red blood cells. Modified Wright-Giemsa. (D) Bronchoalveolar lavage (BAL) fluid from an adult cat with advanced FIV infection shows a heavy burden of adult *Eucoleus aerophilus* and (E) characteristic ova. (F) Lateral and (G) ventrodorsal thoracic radiographs from a 9-year-old male, neutered domestic shorthair cat diagnosed with pulmonary cryptococcosis. The cat was investigated for a chronic cough. A generalized mixed, predominantly bronchointerstitial pulmonary pattern is seen on radiographs. *Cryptococcus* was cultured from BAL fluids. No yeasts had been identified on cytology of the BAL. (H) Extranodal (intraocular), high grade, B-cell lymphoma in advanced FIV infection. (I) Focal infection of the pinna of an adult cat with advanced FIV infection. *Cladophialophora carrionii*, a filamentous dematiaceous fungus, was cultured from the lesion and identified on polymerase chain reaction. The cat was on multiagent chemotherapy for nasal lymphoma that had been diagnosed 4 months prior. The phaeohyphomycosis was treated successfully with pinnectomy and oral posaconazole. The cat remained healthy for another 2 years until upper respiratory tract signs recurred and euthanasia was requested. Nasal cryptococcosis was diagnosed at necropsy.

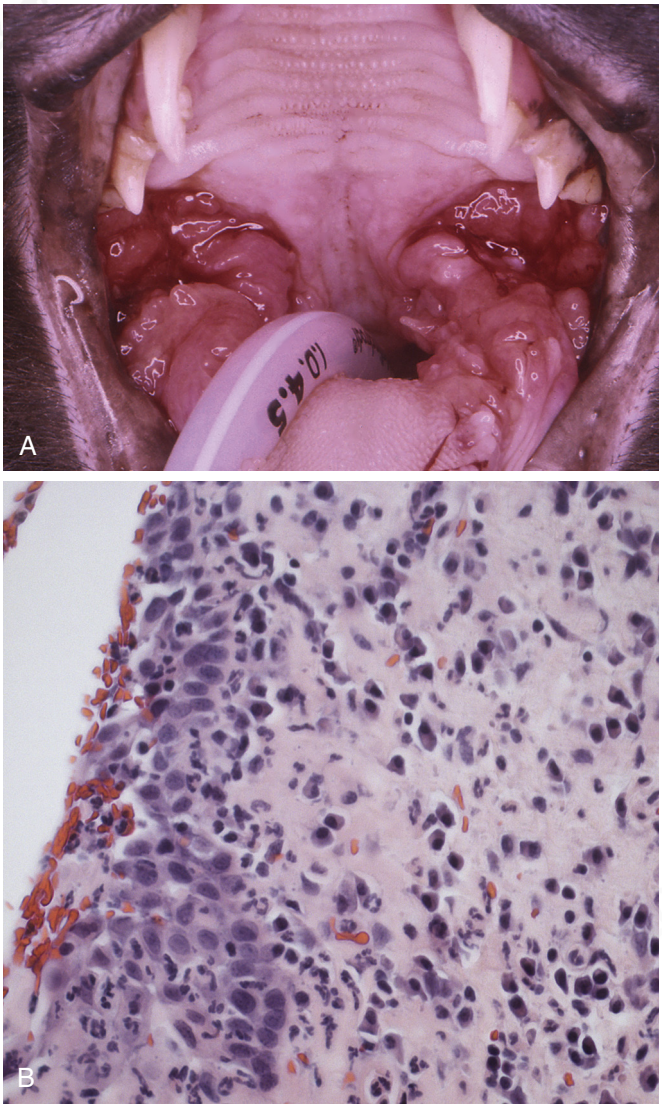

Fig. 33.6 Severe lymphoplasmacytic stomatitis in a cat infected with FIV. (A) There is marked hyperemia, ulceration, and proliferative lesions in the palatoglossal folds. (B) Histopathology of a biopsy from a cat with severe stomatitis associated with FIV infection. (A, From Bonello D, Roy CG, Verstraete FJM. Non-neoplastic proliferative oral lesions. In: Verstraete FJM, Lommer MJ, eds. *Oral and Maxillofacial Surgery in Dogs and Cats*. Philadelphia, PA: Saunders; 2011.)

The risk of lymphoma is increased in FIV-infected cats by fivefold to sixfold.[56] FIV-associated lymphomas are typically high-grade, extranodal, B-cell tumors, similar to HIV-associated diffuse large B-cell lymphoma.[57] Direct oncogenesis by FIV is rare. Integration site mapping demonstrated truncation of a gene on chromosome B3 and downregulation of the unaffected allele, consistent with a loss-of-function mutation, in a single case.[58] FIV-induced immune dysfunction may play a role in lymphomagenesis. Reduced CD4-cell counts, a known risk factor for HIV-associated lymphoma, have been demonstrated in cats developing FIV-associated lymphoma.[59] In HIV-associated lymphomas, co-infecting gammaherpesviruses are causal in 20%–100% of cases depending on the lymphoma subtype.[60] Whether *Felis catus gammaherpesvirus 1*, the lymphotropic gammaherpesvirus of domestic cats, is an infectious co-factor in FIV-associated lymphoma is under investigation.[61] Hyperstimulation of the B-cell compartment in FIV infection might also contribute to oncogenesis, with amplification of normal somatic mutations predisposing to B-cell tumors. Increased numbers of circulating B cells, plasma immunoglobulin, and IL-1 and IL-6, which stimulate B-cell proliferation and differentiation, have been documented in FIV-infected cats that develop lymphoma.[62] Many other neoplasms are described in FIV-infected cats, but the role of FIV, if any, in these cancers is unknown.

Severe unexplained weight loss can occur in advanced FIV infection. This resembles wasting syndrome, an AIDS-defining condition in HIV infection, described as weight loss of 10% or more over 30 days with no identifiable cause other than HIV infection. Wasting syndrome is multifactorial with changes in protein and lipid metabolism, altered energy requirements, anorexia, cytokine derangements, malabsorption, endocrinopathies, and myopathies all contributing. An increased risk for renal diseases in FIV infection is suspected, but a causal association has been difficult to prove. Renal proteinuria but not renal azotemia has been associated with natural FIV infection.[63]

FIV-associated neuropathology has been studied extensively as an experimental model for neurodegenerative diseases in HIV infection. The incidence of neurologic signs that accompany natural FIV infection is unknown. Following experimental infection, FIV provirus can be detected in the CNS from 2 to 4 weeks. The virus targets non-neuronal cells, primarily macrophages and microglia, resulting in a progressive encephalitis.[64] Histopathologic lesions are generally less severe in FIV infection than in HIV infection. This may, in part, be explained by the reduced macrophage tropism exhibited by FIV in comparison with HIV, since macrophages carry virus across the blood-brain and blood-CSF barriers. However, some FIV isolates induce severe neuropathology. Lesions may be clinically silent or induce progressive neurologic deficits including behavioral changes, stereotypic motor behaviors, increased aggression, delayed placing reactions, and reduced pupillary light reflexes.[65] In natural FIV infection, compulsive roaming, changes in sleeping patterns, aggression, seizures, ataxia, tremors, movement disorders, and paraparesis have been reported, but the extent to which other etiologies were excluded is unclear. Some deficits that accompany HIV-associated neurodegeneration (such as reduced concentration, memory or learning, and psychological problems)[66] cannot be routinely assessed in cats.

Perinatal FIV infection, although rare, has been associated with an accelerated disease course, abortion, stillbirth, low birth weights, reduced survival, and T-cell–deficient kittens.[67]

Physical Examination Findings

Cats infected with FIV are often clinically normal or display clinical signs that are unrelated to FIV infection. In the primary stage of FIV infection, cats may be febrile or show generalized peripheral lymphadenopathy. Common physical examination findings in cats with advanced disease include FCGS, chronic upper respiratory tract signs, otitis externa, pyoderma, and abscesses as well as a diverse spectrum of disease manifestations that relate to underlying opportunistic infections or neoplasia. Behavioral abnormalities such as obtundation, aggression, and cognitive impairment have been reported. Other neurologic abnormalities include ataxia, anisocoria, and abnormal segmental reflexes. Ocular abnormalities may result from the FIV infection itself, opportunistic infections, or lymphoma, and include anterior uveitis, hyphema, pars planitis, chorioretinitis, and/or glaucoma.

DIAGNOSIS

FIV-infected cats should be identified to optimize individual healthcare and to prevent infection of other cats. Indications for testing, modified from recommendations by the AAFP, are shown in Box 33.1.[68] Assessment of the clinical significance of FIV infection in a

BOX 33.1 Indications for Serologic Testing for FIV and FeLV

- Sick cats, even if they tested negative in the past
- All newly acquired cats or kittens (2 tests, at least 60 days apart)
- After exposure to a retrovirus-infected cat or a cat with unknown status, and especially after a bite wound (2 tests, at least 60 days apart)
- Cats that live in a household with other retrovirus-infected cats (annual retesting unless isolated)
- Before initial vaccination with FeLV or FIV vaccines
- Before any booster vaccination
- Before use as a blood donor (2 tests, at least 60 days apart)
- On entry to a shelter or before adoption (2 tests, at least 60 days apart); if financial resources are not available for this, cats should be held singly and postadoption testing (2 tests, at least 60 days apart) recommended before mingling with other cats occurs. The status of the other cats in the household should be known before new cats are introduced.
- For group-housed cats, before introduction (2 tests, at least 60 days apart if possible) and on an annual basis
- Testing is considered optional for feral cat trap-neuter-return programs

sick cat is challenging because the virus may, or may not, be contributing to the current clinical signs. Surrogate markers used to stage HIV infection in people, such as CD4+ T-cell counts and viral load, have not been extensively validated for use in cats.[48] It is reasonable to assume that FIV may be playing a role in infected cats with refractory or recurrent infections, infections with intracellular pathogens such as mycobacteria, opportunistic pathogens, and cases of high-grade B-cell lymphoma.

Laboratory Abnormalities

Laboratory abnormalities are not helpful for the diagnosis of FIV infection. If abnormalities are identified, they may be associated with intercurrent disease or may be a consequence of FIV infection itself. Abnormalities that are commonly reported in FIV infection are mild anemia, lymphopenia, neutropenia, and hyperglobulinemia.[52] Such changes should be interpreted cautiously in older sick cats where they are common regardless of FIV status.[21] Mild prolongations in APTT, thrombin time, and fibrinogen concentrations compared with controls have been reported in FIV-infected cats, although PT and platelet function are generally normal.

Microbiologic Tests

Commercial FIV tests detect either anti-FIV antibodies using immunoassays, or viral nucleic acid using PCR. Virus isolation from PBMCs is not commercially available.

Serologic Diagnosis

Serology is the first line for FIV testing. POC tests utilizing lateral-flow ELISA or immunochromatography technologies and diagnostic laboratory-based ELISA assays are in widespread use, have rapid turnaround times, and high sensitivities and specificities for antibody detection.[25,69,70] In cats over 6 months of age that have not been vaccinated against FIV, anti-FIV antibodies are a marker for FIV infection because the virus establishes a persistent infection.

In countries where commercial FIV vaccines are available, or in cats with a history of having been vaccinated for FIV, POC test selection is important. This is because vaccination with inactivated whole virus vaccines induce antibodies to a broad range of FIV proteins, and POC kits vary in their ability to distinguish vaccine-induced from infection-associated anti-FIV antibodies. This means that an uninfected cat that has been vaccinated for FIV can test positive on POC tests in some circumstances. The antigens used in POC kits vary among manufacturers but include p15, p24, and gp40. In a study of FIV-vaccinated (n = 119) and unvaccinated (n = 239) owned cats, two POC assays, Witness FeLV/FIV (Zoetis Animal Health, USA) and Anigen Rapid FIV/FeLV (BioNote, Korea), performed well in their ability to detect antibodies induced by natural FIV infection regardless of the cat's FIV vaccination status (PPV 70% and 100% and NPV 100% and 100%, respectively).[71] The high specificity of these kits for identifying FIV infection (98.1%) was confirmed in an independent study of 104 FIV-uninfected specific pathogen free (SPF) cats that had been vaccinated against FIV.[72] However, prospective studies of FIV-uninfected kittens and young cats vaccinated with the inactivated FIV vaccine have reported that both the Witness and Anigen POC kits may detect transient, vaccine-induced antibodies in up to 66% of vaccinates.[73,74] Some evidence suggests that interference with the results of Witness and Anigen assays by vaccination is more likely in young cats, and within several months of vaccination.[73,74] The SNAP FIV/FeLV Combo POC assay (IDEXX Corporation, Maine, USA) has high (94%–100%) sensitivity and specificity for detection of anti-FIV antibodies but does not distinguish between the antibody response induced by vaccination and that induced by natural infection. Of 119 FIV-vaccinated cats, of which only 5 were infected with FIV, all 119 tested positive using SNAP FIV/FeLV Combo compared with 11 using the Witness assay and 5 (all confirmed as infected using PCR) using the Anigen assay.[71] Clarification of the utility of POC kits from different manufacturers for determination of FIV infection status in cats that may have been vaccinated for FIV is expected. The reliability of a negative serologic test result is unchanged by a history of vaccination.

Other serologic assays, including IFA assays and Western blotting, have limited availability. Both are technically demanding, subject to interoperator variability in interpretation, and Western blotting may be less sensitive than ELISA assays when performed by some laboratories.[75]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Molecular tests target integrated DNA provirus and some also detect viral RNA by qPCR. Variability in performance among laboratories has been demonstrated.[76] Commercial PCR assays have diagnostic sensitivity that is 5%–15% lower than that of serology, and diagnostic specificity that is similar to serology.[77–79] Sequence variability among isolates, low provirus or virus load, poor sample quality, and technical issues may all impact the sensitivity of PCR (see Chapter 6). FIV PCR should not be used to screen for FIV infection. Rather, FIV PCR can be used as an adjunct to serology to determine the true infection status of cats in certain circumstances, including seropositive cats that may have been vaccinated for FIV, seropositive cats less than 6 months of age, seronegative cats that may have been recently exposed to FIV, and seronegative cats where advanced-stage FIV is suspected. After experimental FIV challenge, PCR can detect viral RNA within 1 to 2 weeks and DNA within 3 weeks, but differences in virus strain, dose, and assay sensitivities mean that it is hard to predict how long after natural exposure PCR can be used to detect FIV infection.[31] Positive PCR test results indicate that the cat is almost certainly infected, whereas negative PCR results are inconclusive.

Interpretation and Confirmation of Serologic Test Results

Interpretation of the results of serologic screening requires the integration of clinical findings from the individual cat to guide whether repeat serology or PCR is indicated and what the timing of any repeat testing

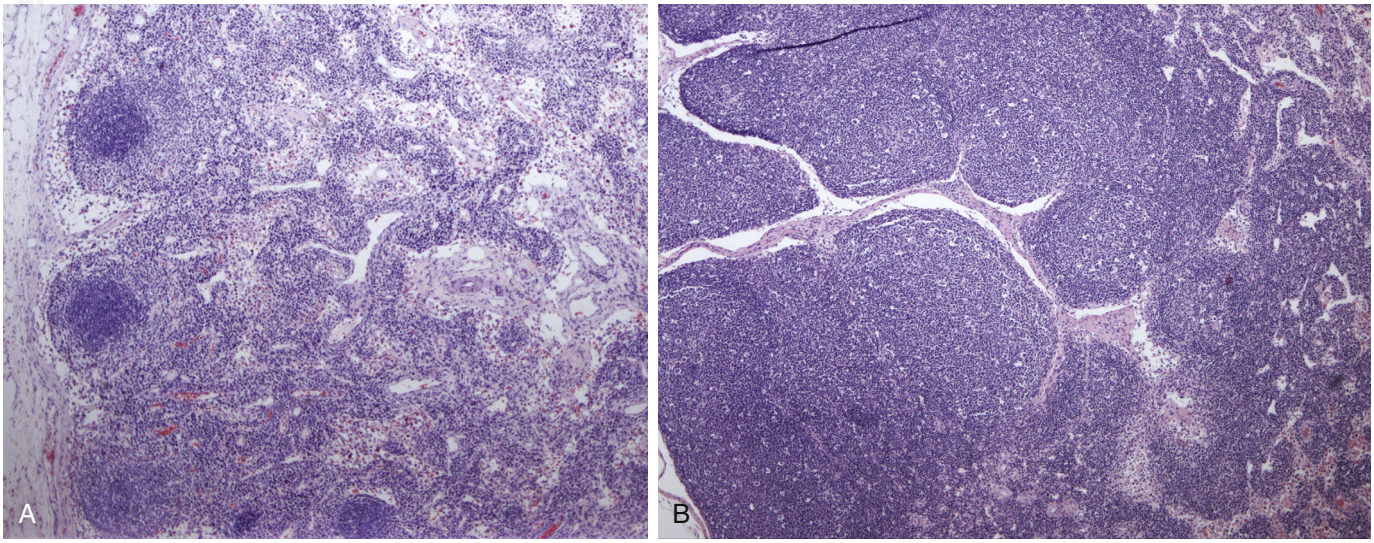

Fig. 33.7 (A) Depletion of paracortical areas in the mesenteric lymph node of an 8-year-old female spayed domestic shorthair with feline immunodeficiency virus infection that was euthanized as a result of the development of progressive neurologic signs. (B) Normal feline lymph node for comparison.

should be.[68] The time to seroconversion following natural infection is variable and can be prolonged.[68] If possible, a seronegative cat that may have been recently exposed should be isolated from FIV-infected cats or cats of unknown FIV status and retested after 60 days. Some cats in the terminal stage of FIV infection have impaired antibody production. These cats often have high plasma viral loads but are seronegative.[80] Thus, if advanced FIV infection is suspected, negative test results should be followed by PCR.

Confirmation of positive serologic test results is recommended. The testing methodology used for confirmation will depend on assessment of the cat's FIV infection risk, test availability, whether previous FIV vaccination can be ruled out, and financial considerations.

The following considerations apply regarding positive serologic test results:

Cats at low risk of infection. Confirmation of a positive serologic test result in cats with a low risk of infection, including healthy cats and indoor cats, is essential because the PPV of serology is low in low-risk groups. The reason for this is that the *prevalence of FIV* in a low-risk population approaches the *expected frequency of false positives*. So for each positive test result obtained in cats at low risk, there is a higher chance that the result is a false positive.

Maternally derived FIV antibodies can result in positive serologic test results in uninfected kittens. Positive serology results in cats under 6 months of age can be confirmed with PCR. Alternatively, serology can be repeated after 6 months of age.[68] Negative serologic test results in kittens are generally reliable.

Cats vaccinated with the inactivated FIV vaccine. As discussed above, where a history of vaccination for FIV is confirmed or cannot be ruled out, the Anigen Rapid FIV/FeLV or Witness FeLV/FIV is currently the preferred POC screening test. A positive result using one of these POC kits can be confirmed using the other kit, or a PCR test.

Pathologic Findings

Cats in the primary stage of FIV infection may have generalized lymphadenomegaly on gross necropsy. Histopathologic changes in lymph nodes, spleen, tonsils, and mucosa-associated lymphoid tissue include hyperplasia, follicular dysplasia, and expansion of B- and T-cell areas (see Fig. 33.4). These changes can persist for months or years. In advanced FIV infection, gross findings may include emaciation, stomatitis, and evidence of lymphoma or opportunistic infections. Advanced FIV infection is associated with lymphoid depletion (Fig. 33.7). Bone marrow pathologies include mild dysplasia, erythroid hypoplasia, and/or myeloid hyperplasia. Inflammatory changes may be seen within skeletal muscle and/or the GI tract. Histopathology of the CNS in cats infected with neurovirulent FIV strains may reveal mild lymphoplasmacytic meningitis, perivascular lymphocytic infiltrates, diffuse gliosis, microglial nodules, and mild neuronal degeneration and apoptosis.[65,81]

TREATMENT AND PROGNOSIS

Many sick FIV-infected cats have treatable diseases. The diagnosis of FIV infection in a sick cat can influence the differential diagnoses to include, for example, unusual opportunistic and parasitic infections. FIV status also guides treatment selection. Where antimicrobial drugs are indicated, selection should ideally be based on the results of susceptibility testing. Clinicians should be vigilant for drug reactions, as these may be more prevalent in FIV-infected cats. For example, severe drug-induced neutropenia following griseofulvin administration has been reported in FIV-infected cats.[82] Glucocorticoids may be indicated to treat intercurrent inflammatory or immune-mediated problems arising in FIV-infected cats. Glucocorticoids should be used judiciously, only where specifically indicated, and with close patient monitoring.

Investigation of chronic gingivostomatitis includes consideration of a range of contributing etiologies including FCV, inflammation associated with dental disease, immune-mediated and neoplastic causes, and eosinophilic granuloma complex.[53] The degree and duration of response to treatments such as dental cleaning, antimicrobial drugs, IFNs, and anti-inflammatory doses of glucocorticoids is variable. Extraction of premolars and molars is reported to improve signs in 60%–80% of cats with severe gingivostomatitis.[83]

In cats with intermediate- or high-grade lymphoma, there is no evidence that FIV infection *per se* is a negative prognostic indicator

for response to multiagent chemotherapy, although data are limited. Close monitoring of the neutrophil count during chemotherapy is warranted. Where neurologic impairment is identified and localized in FIV-infected cats, investigation for potentially treatable causes is indicated. Management of FIV-associated wasting involves investigation for treatable underlying diseases (such as enteropathies and exocrine pancreatic insufficiency), supportive care, nutritional support, and appetite stimulation.

Severe or persistent cytopenias in FIV-infected cats should be investigated for treatable underlying causes since cytopenias are common in sick cats regardless of their FIV status.[21,52] There is currently no suitable supportive treatment for FIV-associated neutropenia. Recombinant human granulocyte colony-stimulating factor (rHuG-CSF) increased neutrophil counts in young cats that were experimentally infected with FIV in the short term, until antibodies to rHuG-CSF developed.[84] Cross-reactivity of induced antibodies to endogenous feline G-CSF risks refractory agranulocytosis. Pegylated feline G-CSF showed promising results with less frequent dosing, but this compound is not commercially available.[85] Anemia occurs with FIV infection, although less commonly than neutropenia. Recombinant human erythropoietin (rhEPO) was effective at increasing PCV in FIV-infected cats without inducing anti-rhEPO antibodies in one small study.[86] Darbepoetin, which is longer acting and less antigenic than rhEPO, is effective in cats,[87] although studies in FIV-infected cats are not reported.

Immune Modulation and Antiviral Therapies

Owners' expectations should be managed before embarking on a treatment trial with immunomodulators or antiviral drugs. FIV infection cannot be cured. The small chance of improving clinical signs should be balanced against the potential risks and costs involved, including monitoring costs. Data to support the use of immunomodulators in FIV infection are very limited (see Chapter 9).[88,89] Nonspecific immune stimulation risks unintended outcomes including increased virus replication and the activation of immune suppressor cells. In a placebo-controlled study using human recombinant interferon-alpha (rHuIFN-α) (50 IU/cat, oral transmucosal, q24h, 7 days on, 7 days off for 6 months) in natural FIV infection, no effect on plasma virus or provirus load was detected although improved clinical signs were reported.[90] Improvements in clinical parameters were also reported using recombinant feline interferon-omega (rFeIFN-ω, Virbagen Omega, Virbac) at 1 MU/kg, SC, q24h for 5 days, repeated on day 14 and 60, or a lower-dose oral protocol (0.1 MU/cat rFeIFN-ω, PO, q24h for 90 days).[91,92]

Antiretroviral therapies have dramatically improved the prognosis for HIV-infected humans. Combinations of drugs that inhibit HIV reverse transcriptase, protease, or integrase avoid the rapid emergence of drug-resistant mutants. Virus load and CD4 count are used to guide the timing of initiation of treatment, and to assess response in asymptomatic HIV-infected patients. In contrast, there are limited data to evaluate antiretrovirals in FIV infection and there are no licensed products. Combination therapy for FIV to avoid the emergence of resistant mutants is hampered by the limited choice of drugs; most inhibitors of HIV protease are not active against FIV, and data on potential inhibitors of FIV integrase are limited to their *in vitro* activity.[93] Several nucleoside analogues inhibit FIV reverse transcriptase, including zidovudine (3'-azido-3'-deoxythymidine), lamivudine (3TC, 2′,3′-dideoxy-3′-thiacytidine) and adefovir (PMEA, 9-(2-phosphonomethoxyethyl)adenine). Improvements in clinical scores, virus load, and CD4 counts are reported in some studies, but adverse effects, including anemia, neutropenia, and GI signs are common and can be severe. The pharmacokinetics of zidovudine has been studied in cats, and this drug was associated with improvement in stomatitis in a blinded, placebo-controlled study.[94,95] Monitoring of the CBC weekly for the first month and then monthly is advised. Treatment is not recommended for cats with myelosuppressive diseases. If HCT drops below 20%, zidovudine should be discontinued, after which anemia usually resolves in a few days.[68] Zidovudine-resistant FIV mutants can develop as early as 6 months from initiation of treatment.[96] Monotherapy with fozivudine (45 mg/kg PO q12h) reduced the viremia in cats with acute FIV infection but had no effect on viral load or immune function in chronic infection.[97] Plerixafor (AMD3100), a selective CXCR4 antagonist, has been evaluated in client-owned, FIV-infected cats.[98] A prospective, placebo-controlled, double-blind trial showed a mild reduction in proviral load, minimal adverse effects, and no emergence of resistance over a 6-week period, but there was no improvement in clinical or immunologic variables. As novel antivirals for potential clinical use in cats become available, their evaluation should include studies of *in vitro* efficacy, safety *in vivo*, pharmacokinetics, and blinded, placebo-controlled clinical trials.

Management of Healthy FIV-Infected Cats

Comprehensive international guidelines for the management of FIV-infected cats are available from the AAFP and the European Advisory Board on Cat Diseases (ABCD), with updates published periodically.[99,100] FIV-infected cats might benefit from small over multicat households because of reduced stress and reduced exposure to infectious agents. Over a 22-month period, clinical immunodeficiency was not detected in FIV-infected cats rehomed from a shelter into households of one or two cats.[101] By comparison, survival of FIV-infected cats in a multicat household of over 60 cats was significantly reduced, with lymphoma reported as the most common cause of death. FIV-infected cats should be prevented from roaming to prevent FIV transmission. The feeding of raw foods and hunting behavior should be avoided to reduce exposure to *T. gondii* and other foodborne pathogens. Cats should be neutered to reduce roaming and aggressive interactions with other cats.

A veterinary examination every 6 to 12 months will facilitate early detection of emerging health problems. Even apparently minor problems in FIV-infected cats should be fully investigated. A CBC, serum biochemistry panel, and urinalysis are recommended annually.[68] Optimal control of ectoparasites, endoparasites, dental prophylaxis, and diet should be discussed with owners. Perioperative antimicrobial drug treatment (i.e., during the procedure) could be considered for cats that undergo invasive surgery or dental treatments, but antimicrobial treatment need not be continued beyond this period.

The use of FHV, FCV, and FPV core vaccines raises several issues for FIV-infected cats: the potential for vaccine failure in the face of immune dysfunction, failure to contain modified live vaccine virus, and enhancement of FIV replication and immune dysfunction from vaccine-induced immunostimulation. Following a review of available evidence by the European ABCD, recommendations for vaccination of FIV-infected and other immunosuppressed cats with core vaccines have been published.[102] In summary, booster vaccinations are *not* recommended for adult FIV-infected cats kept indoors, unless indicated by anti-FPV antibody levels. If exposure to FPV, FHV, or FCV cannot be excluded, then vaccination using an inactivated product is recommended.

Hospitalized cats should not be housed in isolation facilities on the basis of their FIV status alone, since this places potentially immunosuppressed cats at risk of exposure to transmissible infectious diseases.

Prognosis

Controlled studies demonstrate comparable survival time between FIV-infected and uninfected cats.[21,27,103,104] In a study of almost 10,000 retrovirus tested pet cats, including 1,100 seropositive for FIV, the survival rate at 6 years was 65% compared with 90% for uninfected cats.[103] In the same study, if deaths during the first 100 days were excluded, survival of FIV-infected cats was 94% and 80% at 3 and 6 years, respectively, compared with controls. Even though a negative effect of FIV infection on survival is minor or nonexistent when groups of cats are studied, the effect of FIV infection on morbidity may be underestimated. Clinicians should maintain an index of suspicion for subtle consequences of immune dysfunction, even in cats reported as healthy by their owners.

In experimental studies, infection of neonatal cats is associated with more rapid progression and severity of disease than infection of young adult cats.[105,106] Progression to advanced-stage FIV can occur within 2 months in kittens, after which life spans are typically less than 1 year.[107] In the absence of surrogate markers that reliably predict disease progression, the prognosis for an individual FIV-infected cat should be determined regardless of its FIV status.

There is no clinical justification for the euthanasia of healthy cats on the basis of their FIV status. Rehoming of healthy FIV-infected cats to stable households of one or two cats and prevention from roaming is encouraged wherever possible over euthanasia.

IMMUNITY AND VACCINATION

A commercial, inactivated, adjuvanted, whole-virus FIV vaccine is currently marketed in Australia and New Zealand (Fel-O-Vax FIV, Boehringer Ingelheim) and Japan (Ferrovacs FIV, Zoetis JP) having been discontinued in the United States and Canada. The vaccine is licensed for use in healthy cats of at least 8 weeks of age as an aid in the prevention of infection. There has been longstanding controversy regarding the use of the FIV vaccine. One reason for this has been conflicting data from vaccine efficacy studies and the absence, until recently, of data on efficacy in the field. The FIV vaccine, which contains subtypes A (Petaluma) and D (Shizuoka), performs well in most published studies, inducing sterilizing immunity against homologous and heterologous strains such as subtype B viruses.[108,109] In studies performed by the vaccine developers, preventable fractions between 80% and 100% are reported as well as protection from contact challenge and a duration of immunity of 12 months or more.[110–117] In contrast, in an early independent experimental study, Fel-O-Vax FIV provided no protection against challenge with a subtype A isolate (Glasgow-8).[13] A study of 89 FIV-vaccinated cats and 212 unvaccinated cats in the field in Australia reported a protective rate of only 56%.[112] Five vaccine breakthroughs were identified, and all were subtype A, the most common subtype in circulation in Australia.[113,114] A New Zealand study of 185 cats with outdoor access found no protective effect from Fel-O-Vax FIV vaccination.[115] A second area of concern has been that FIV-uninfected cats vaccinated against FIV can test positive on serologic tests for FIV. Commercial PCR testing for FIV was introduced to assist in determining the true infection status of FIV-seropositive cats where prior vaccination was confirmed or could not be excluded. However, FIV POC serology assays from some manufacturers can identify FIV infection regardless of vaccination history in many circumstances (see Diagnosis).[71] FIV vaccination has been reclassified by the Vaccination Guideline Group (VGG) of the WSAVA from "not recommended" to "non-core."[116] The FIV vaccine should only be used for cats at high risk of infection, such as outdoor cats that fight with other cats. The initial vaccination should only be given to cats that test seronegative for FIV. Cat owners should be informed that protection is incomplete and that identification of subsequent infection may not be straightforward. There is also a risk of injection-site sarcoma. The initial vaccine dose is followed by two booster doses at 3- to 4-week intervals, followed by annual boosters so long as the risk persists.

PREVENTION

The most effective way to prevent FIV infection is to confine uninfected cats. Free-roaming cats are at high risk of FIV infection and they represent an important source of new infections. FIV-infected cats should also be confined to prevent new infections. Prevention of roaming reduces infectious disease risk, and also prevents trauma, straying, and hunting. Environmental enrichment is essential for confined cats. Where a cat from a multicat household is diagnosed with FIV infection, all cats in the household should be tested and no new cats introduced, as this may lead to conflict and increased fighting behavior. Isolation of FIV-infected cats in a household should be considered although the spread of FIV among cats in stable, closed households is uncommon.[17,117] In breeding catteries, infection can be prevented by screening all new introductions, preferably with a 2-month quarantine period followed by retesting and removal of all infected cats from the cattery. Transmission in shelters can be reduced by testing on intake, or housing cats singly and testing at, or shortly after, adoption, together with education of adopters regarding the need to retest.

FIV shed in secretions is rapidly inactivated in dry conditions. In veterinary hospitals, routine cleaning and disinfection procedures to prevent the spread of FHV-1, FCV, and FPV effectively eliminate any residual risk of environmental contamination. Standard practices to prevent nosocomial infections transferred in body fluids should be observed. Cats used as blood donors should be free from FIV infection since iatrogenic transmission by this route is almost certain.[118] Ideally, initial FIV serology should be repeated after 60 days and PCR testing is also advised before enrolling a potential blood donor.

PUBLIC HEALTH ASPECTS

Despite its similarities to HIV, FIV does not infect humans. Experimentally, productive infection of human cells *in vitro* and infection of nonhuman primates with FIV can be achieved.[119,120] A serosurvey of veterinary workers with occupational exposure found no evidence of FIV infection, and the human CD134 molecule does not support cellular entry by the virus.[121,122] However, immunosuppressed human patients, such as transplant recipients, should avoid handling any potentially immunosuppressed animal, or observe meticulous hygiene practices to avoid the possibility of exposure to shared, potentially fatal, opportunistic pathogens.[123]

CASE EXAMPLE

Signalment
"Arthur," an 11-year-old male neutered domestic shorthair from northern California.

History
Arthur was initially brought to his veterinarian for a 2-day history of lethargy and decreased appetite. Physical examination was unremarkable. Blood work showed HCT of 28% (reference range, 29%–38%), WBC count of 6,400 cells/μL with a normal differential, clumped platelets, mild hyperbilirubinemia (0.5 mg/dL), mild hypoalbuminemia (2.4 g/dL), and hyperglobulinemia (5.5 g/dL). He was treated with amoxicillin and mirtazapine, but lethargy and inappetence persisted. Serial hemograms performed over the subsequent 3 months showed progressive leukopenia due to a neutropenia and lymphopenia (Table 33.4), during which time Arthur was treated with orbifloxacin, with some improvement in his appetite and attitude. A bone marrow aspirate performed 5 weeks after the onset of illness showed myeloid hyperplasia with a left shift. Serology for FIV and FeLV was performed 11 weeks after onset of illness, and the cat was negative for FeLV antigen and had an equivocal test result for FIV antibody. Serum thyroxine concentration was low (0.7 μg/dL, reference range 1.1–3.3 μg/dL). The cat was referred for further evaluation.

Arthur was an indoor and outdoor cat and had a history of predation (mice and birds) and fighting with other cats in the neighborhood. His diet otherwise consisted of a commercial wet cat food. He was vaccinated regularly for rabies, FeLV, FHV-1, FCV, and FPV infections.

Current Medications
Orbifloxacin, 7 mg/kg PO q12h.

Other Medical History
Routine blood work had been performed 3 years previously, which showed a normal CBC, a globulin of 5 g/dL, a urine SpG of 1.069, and a T4 of 1.3. At that time, Arthur tested negative for FeLV antigen and positive for FIV antibody.

Physical Examination
Body weight: 3.1 kg

General: Quiet, alert, responsive, estimated to be 5% to 7% dehydrated, T = 103.9°F (39.9° C), HR = 144 beats/minute, RR = 50 breaths/minute, mucous membranes pale pink, CRT < 2 seconds. A dry haircoat with moderate amounts of scale was present. There was no evidence of ectoparasites.

Eyes, ears, nose, and throat (with dilated fundoscopic examination): Moderate gingivitis and absent mandibular canine teeth. No other clinically significant abnormalities were detected.

Musculoskeletal: BCS 2/9. Generalized muscle atrophy was noted. Ambulatory in all four limbs.

Cardiovascular: Aside from an intermittent gallop rhythm, no abnormalities were noted.

Respiratory: No abnormalities were detected.

GI and urogenital: Abdomen soft and nonpainful on palpation, mild hepatomegaly. Urinary bladder was small and soft.

Lymph nodes: All lymph nodes less than 1 cm in diameter.

Laboratory Findings
CBC: HCT 22.5% (30%–50%), MCV 47.5 fL (42–53 fL), MCHC 32.9 g/dL (30–33.5 g/dL), reticulocytes 7,400 cells/μL, WBCs 1,100 cells/μL (4,500–14,000 cells/μL), neutrophils 704 cells/μL (2,000–9,000 cells/μL), band neutrophils 99 cells/μL, lymphocytes 220 cells/μL (1,000–7,000 cells/μL), monocytes 77 cells/μL (50–600 cells/μL), platelets 32,000/μL (180,000–500,000/μL). Neutrophils showed moderate toxicity with many Döhle bodies, and there were many macroplatelets.

Serum chemistry profile: Sodium 149 mmol/L (151–158 mmol/L), potassium 3.1 mmol/L (3.6–4.9 mmol/L), chloride 115 mmol/L (117–126 mmol/L), bicarbonate 17 mmol/L (15–21 mmol/L), phosphorus 4.3 mg/dL (3.2–6.3 mg/dL), calcium 8.8 mg/dL (9.0–10.9 mg/dL), BUN 17 mg/dL (18–33 mg/dL), creatinine 1.1 mg/dL (1.1–2.2 mg/dL), glucose 158 mg/dL (63–118 mg/dL), total protein 8.1 g/dL (6.6–8.4 g/dL), albumin 3.0 g/dL (2.2–4.6 g/dL), globulin 5.1 g/dL (2.8–5.4 g/dL), ALT 121 U/L (27–101 U/L), AST 113 U/L (17–58 U/L), ALP 10 U/L (14–71 U/L), creatine kinase 278 U/L (73–260 U/L), GGT <3 U/L (0–4 U/L), cholesterol 204 mg/dL (89–258 mg/dL), total bilirubin 0.8 mg/dL (0–0.2 mg/dL), magnesium 2.4 mg/dL (1.5–2.5 mg/dL).

Antinuclear Antibody Serology
Positive at 1:32

Microbiologic and Virologic Testing
POC ELISA serology for FeLV antigen and FIV antibody: negative

FCoV antibody serology: negative at 1:25

Aerobic and anaerobic blood cultures (three specimens): negative

PCR for FIV proviral DNA: positive (cycle threshold value = 30, values < 40 are positive)

Imaging Findings
Abdominal ultrasound: Hepatomegaly was identified, and the spleen had a mottled echotexture. There was mild enlargement of the ileocecal lymph nodes and mild diffuse thickening of the small intestinal submucosal layer.

Thoracic radiographs: Cardiopulmonary structures were within normal limits.

Cytologic Findings
Liver aspiration cytology: A moderately bloody background contained scattered, variably sized clusters of uniform hepatocytes and low numbers of nucleated cells. The nucleated cells consisted of a mixture of nondegenerate neutrophils, lymphocytes, macrophages, and rare myeloid precursors. Several macrophages were erythrophagic. Interpretation: Possible mild myeloid extramedullary hematopoiesis.

Spleen aspiration cytology: The specimen was highly cellular with a pink background that contained a moderate amount of blood and scattered clumps of hemosiderin. A mixed population of lymphocytes was admixed with variable numbers of hematopoietic precursor cells. Hematopoietic precursors were primarily granulocytic precursors, with many progranulocytes. A few erythroid precursors, including erythroblasts, were noted. Plasma cells were moderately increased in number, and both immature and mature forms were seen. Several binucleated and rare trinucleated plasma cells and scattered immature lymphocytes were noted. Vacuolated macrophages were increased in number and often contained phagocytized erythrocytes or blue-green pigment consistent with hemosiderin. Scattered mitotic figures were noted. Interpretation: Moderate plasmacytosis, extramedullary hematopoiesis, and histiocytic hyperplasia with erythrophagocytosis and increased iron. The large number of immature plasma cells raised the possibility of plasma cell neoplasia; however, reactive plasmacytosis could not be ruled out.

Bone marrow aspiration cytology: Numerous hypercellular unit particles were present. A few mature megakaryocytes were noted. Hematopoietic cells consisted largely of myeloid precursors, with an estimated myeloid-to-erythroid ratio greater than 10. Myeloid cells showed orderly maturation to the band neutrophil stage, with few segmented neutrophils. Few erythroid precursors were noted, which included rare prorubricytes, rubricytes, and metarubricytes. Scattered well-differentiated plasma cells and a small amount of hemosiderin were noted. Interpretation: Marked myeloid hyperplasia, marked erythroid hypoplasia, and moderate megakaryocytic hypoplasia. The myeloid hyperplasia together with persistent neutropenia suggested myelodysplasia.

Continued

CASE EXAMPLE—cont'd

Serum protein electrophoresis: A mild increase in α2 globulins was present (1.34 g/dL, reference range, 0.4–0.9 g/dL) together with a broad-based gamma region. This was consistent with an acute-phase inflammatory response.

Diagnosis

Advanced stage of FIV infection, characterized by pancytopenia secondary to myelodysplasia; hepatopathy (open diagnosis).

Comments

The progression of FIV infection was apparent in this cat, which transitioned from a seropositive to a seronegative, PCR-positive state as a result of progressive decline in immune function and, ultimately, failure to produce antibodies. The cause of the hepatopathy was not identified. Blood cultures were negative, and spleen and liver aspiration cytology failed to reveal evidence of underlying neoplasia. Because of the plasmacytosis in the spleen, serum protein electrophoresis was performed to assist diagnosis of a plasma cell tumor (as supported by a monoclonal gammopathy), but this was not apparent. The cat was treated with clavulanic acid–amoxicillin without clinical improvement. Treatment with glucocorticoids was also offered because of the possibility of undiagnosed round cell neoplasia or immune-mediated neutropenia (in light of the myeloid hyperplasia combined with a positive antinuclear antibody test). The cat died at home 1 month later, and necropsy was not performed.

TABLE 33.4 Laboratory Abnormalities in a Cat with FIV Infection

	DAYS AFTER ONSET OF ILLNESS					
	39	47	56	74	83	Reference Range
Hematocrit (%)	29	29	33	27	22	30–50
White blood cells/μL	2,000	2,100	1,000	1,100	1,100	4,500–14,000
Neutrophils/μL	1,180	1,407	610	572	704	2,000–9,000
Lymphocytes/μL	700	588	340	462	220	1,000–7,000
Platelets/μL	191,000	196,000	Clumped	Clumped	32,000	180,000–500,000
FIV/FeLV serology[a]				Equivocal/negative	Negative/negative	

The cat was an 11-year-old male, neutered domestic shorthair that tested positive for antibodies to FIV 3 years earlier, at which time the CBC was normal.
[a]SNAP FIV/FeLV Combo Test, IDEXX Laboratories.
CBC, complete blood count; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus.

Feline Herpesvirus Infections

Jane E. Sykes, Michael R. Lappin, Sara M. Thomasy, Julia A. Beatty

KEY POINTS

- First Described in Cats: FHV-1, 1958 (United States)[1]; *Felis catus* gammaherpesvirus 1 (FcaGHV1), 2014 (United States).[2]
- Causes: FHV-1, family *Herpesviridae,* an alphaherpesvirus; FcaGHV1, family *Herpesviridae,* genus *Percavirus,* a gammaherpesvirus. Molecular evidence of feline bovine herpesvirus 4 (genus *Rhadinovirus*) infections requires verification.
- Geographic Distribution: FHV-1, worldwide; FcaGHV1, worldwide.
- Mode of Transmission: FHV-1, close contact, fomite spread, to a lesser extent aerosols; FcaGHV1, under investigation, epidemiology supports biting as a plausible route.
- Major Clinical Signs: FHV-1, serous to mucopurulent nasal and ocular discharge, sneezing, stertor, conjunctivitis, keratitis, lingual or facial ulceration, fever, inappetence, tachypnea, cough, rarely death; FcaGHV1, most infections expected to be subclinical.
- Differential Diagnoses: Differential diagnoses for FHV-1 infection are other respiratory viral infections (FCV, influenza viruses), infections with bacteria such as *Bordetella bronchiseptica, Mycoplasma* spp., *Streptococcus* spp., or *Chlamydia felis*; other causes of rhinitis such as cryptococcosis, aspergillosis, neoplasia, foreign bodies, chronic idiopathic feline rhinosinusitis, nasopharyngeal stenosis, or nasopharyngeal polyps; feline chronic airway disease.
- Human Health Significance: Neither FHV-1 nor FcaGHV1 infects humans.

FELINE HERPESVIRUS-1 INFECTION

ETIOLOGY AND EPIDEMIOLOGY

FHV-1 causes ocular disease, URTD, and reproductive failure in domestic cats and wild Felidae. Feline URTD is a widespread and important contributor to morbidity and mortality where large numbers of cats are housed together, especially in overcrowded or stressful conditions.[3] Co-infections with other respiratory viral (especially FCV) and bacterial pathogens (including *Mycoplasma* spp., *Chlamydia felis*, and *Bordetella bronchiseptica*) are common. More information on other viral and bacterial causes of feline URTD can be found in Chapters 25, 35, 49, 50, 55, 57, and 124.

FHV-1 is a large, double-stranded DNA virus with a glycoprotein-lipid envelope that has a worldwide distribution. Most cats are exposed to FHV-1 during their lifetime. FHV-1 is an alphaherpesvirus that is closely related to canine herpesvirus-1, and to a lesser extent, herpes simplex virus (HSV). There is only a single serotype of FHV-1. Isolates are also genetically similar, yet some variation in strain virulence exists.[4] The complete genome sequences of more than 25 FHV-1 strains collected over a 40-year time period have been determined, revealing extremely low genetic diversity (0% to 0.01%).[5,6] In another study of 26 FHV-1 strains from multiple shelters in the United States, the overall interstrain genetic distance was 0.093%.[7]

Using culture, FHV-1 has been detected in 0% to 39% of cats with URTD, although in some catteries and shelters with endemic FHV-1 infection, the prevalence may be higher. When sensitive PCR assays are used to detect FHV-1, the prevalence of infection approaches 100% in some groups of cats with acute URTD.[8,9] The prevalence of shedding by apparently healthy cats has ranged from 0% to 10% but most often is less than 2%.[3,10–17] Virtually all infected cats develop latent infection, which occurs in the trigeminal ganglion, cranial cervical ganglion, and pterygopalatine ganglion.[18] FHV-1 DNA can also be detected in other tissues of the head, such as the cornea and nasal cavity, but this is thought to reflect chronic persistent infection rather than latency. Reactivation of shedding, with or without concurrent clinical signs of URTD, occurs in less than half of latently infected cats 4 to 12 days after stress (Fig. 34.1).[19] Examples of stressors include transportation (such as to a veterinary clinic, boarding or breeding facility, shelter, or cat show), lactation, housing changes, exposure to new cats, concurrent illness, or treatment with immunosuppressive drugs such as glucocorticoids or cyclosporine.[20] The duration of shedding after reactivation ranges from 1 to 13 days (mean, 7 days).[21,22] A refractory period of several months is thought to follow recovery from reactivation whereby cats are less likely to reactivate. Some cats reactivate more frequently than others, and therefore are of greater epidemiologic importance. Shedding that coincides with lactation results in infection of susceptible kittens, but whether or not they develop disease depends on their amount of MDA. On some occasions, kittens with low concentrations of MDA may become subclinically infected and become latent carriers without showing clinical signs.[19] Such a mechanism is obviously ideal for the virus because it can spread to the next generation without harming its host.

FHV-1 survives a maximum of 18 hours at room temperature and is readily inactivated by drying and most disinfectants. Because of this, transmission occurs primarily through close contact, although fomites remain a very important mode of transmission in crowded environments. Aerosol transmission is of lesser importance.[19,23] Aerosols generated by sneezing cats typically travel no further than a distance of 4 to 5 feet, and are not thought to be a major source of infection.

In one study, cats shedding FHV-1 at intake to shelters were at a greater risk of subsequently developing URTD following intake than cats that were not shedding pathogens,[24] whereas this was not the case for cats shedding FCV. Poor hygiene and overcrowding has been associated with an increased risk of URTD due to FHV-1 in shelters. Other risk factors include recent contact with cats outside a household, being of mixed breed, lack of vaccination, and young age.[25,26]

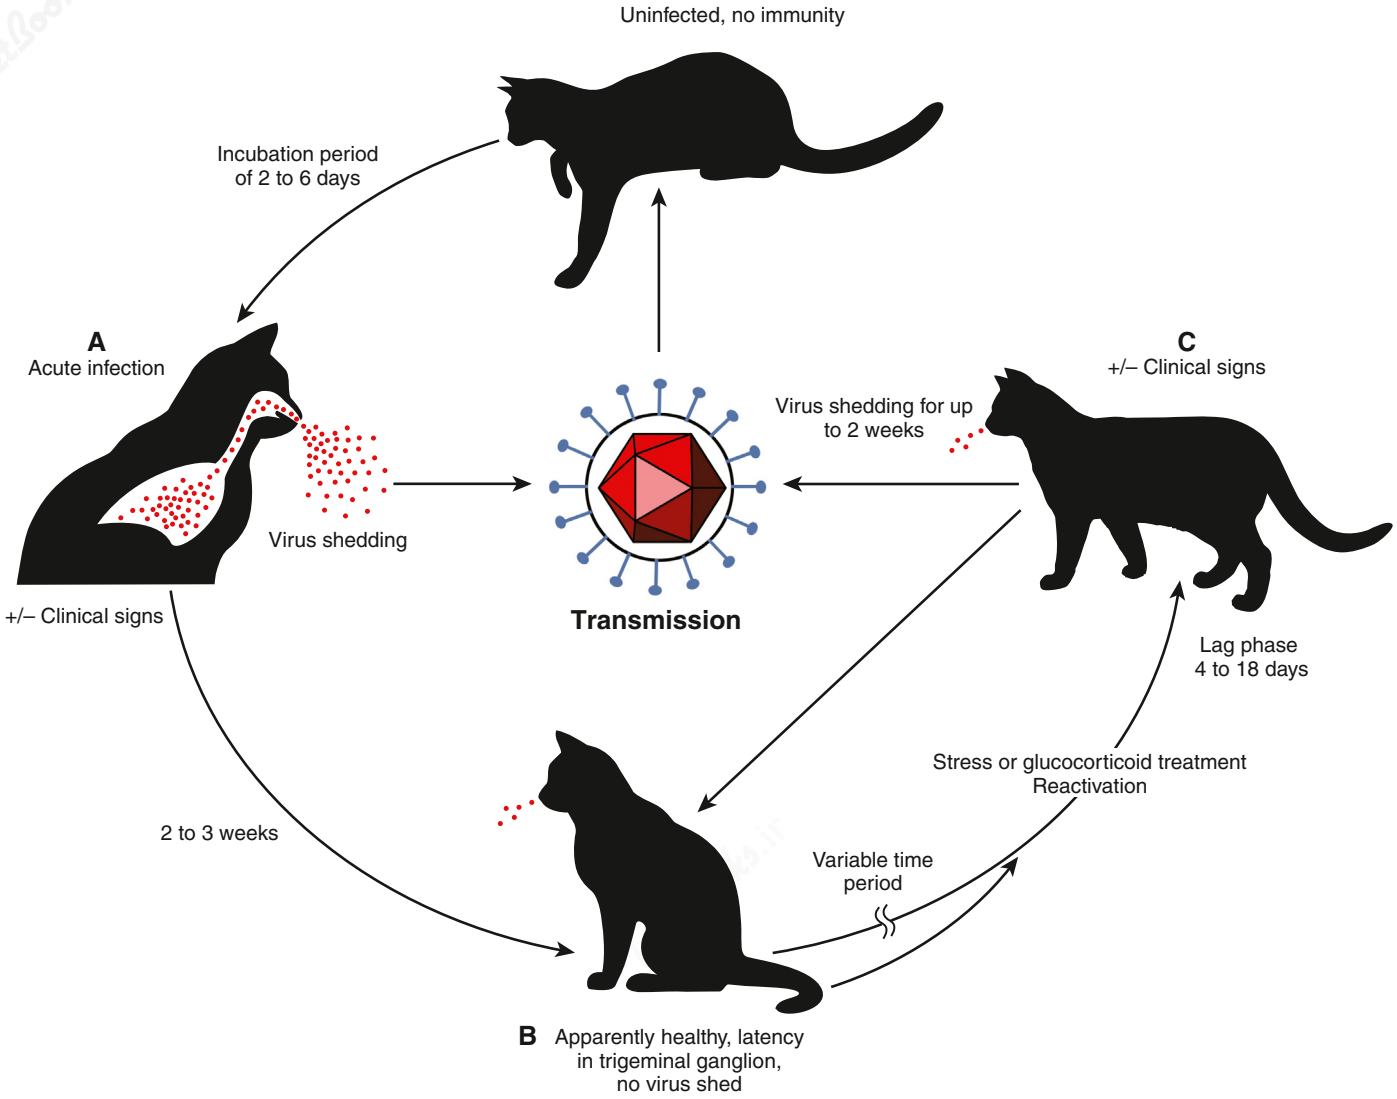

Fig. 34.1 Transmission of feline herpesvirus-1 infection and the carrier state. (A) After initial infection, clinical signs of upper respiratory tract disease (URTD) with virus shedding may occur after an incubation period of 2 to 6 days. Some cats may show no signs of illness. (B) Virtually all cats become latent carriers with persistence of virus latency-associated transcripts (LATs) within neurons of the trigeminal ganglia (see Fig. 34.2). (C) Reactivation of shedding occurs 4 to 18 days after stress, and may or may not be accompanied by clinical signs of URTD. These cats represent a source of infection for other cats.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Following direct or indirect contact with virus in respiratory secretions from the conjunctiva, nasal cavity, and oropharynx, FHV-1 replicates within the lymphoid and epithelial cells in the upper respiratory tract and causes cytolysis. FHV-1 also replicates in corneal epithelial cells.[27] During acute infection, the virus has been isolated from the conjunctiva, cornea, uveal tract, retina, optic nerve, ciliary ganglion, pterygopalatine ganglion, trigeminal ganglion, brainstem, visual cortex, cerebellum, and olfactory bulb.[18] Primary lung involvement may occur but is rare. Systemic infection with viremia occurs in some cats acutely infected with FHV-1 and may be more likely to occur in neonates and debilitated cats. During acute infection, the virus invades sensory nerve endings and is transported to the trigeminal ganglion and cranial cervical ganglion, where it becomes latent. Infection of the trigeminal ganglion can lead to ganglion cell death, increased numbers of glial cells, and lymphoplasmacytic inflammation.[18] In the latent state, the viral genome persists as a circular, histone-associated episome within neuronal cell nuclei, with no production of infectious virus (Fig. 34.2). In this state, production of virus proteins is greatly reduced in order to reduce host immune recognition. However, production of noncoding viral latency-associated transcripts (LATs) and microRNAs occurs at a higher rate. The LATs are thought to be important for maintenance of the latent state, possibly in part through inhibition of cellular apoptosis or other mechanisms of cell death or reduction of expression of lytic genes.[28] There is also evidence in HSV infections that a viral lytic protein, *infected cell polypeptide 0* (ICP0), is functional during latent infection, and important for production of LATs.[28]

Clinical signs of URTD can occur after an incubation period of 2 to 6 days, although longer incubation periods are also possible with lower challenge doses. Viral shedding occurs predominantly in ocular, nasal, and oral secretions as early as 24 hours after infection, and often before the onset of clinical signs. Clinical signs and shedding may also occur following reactivation of latent virus in the ganglia, whereby lytic genes are activated, viral transcription occurs, and there is anterograde

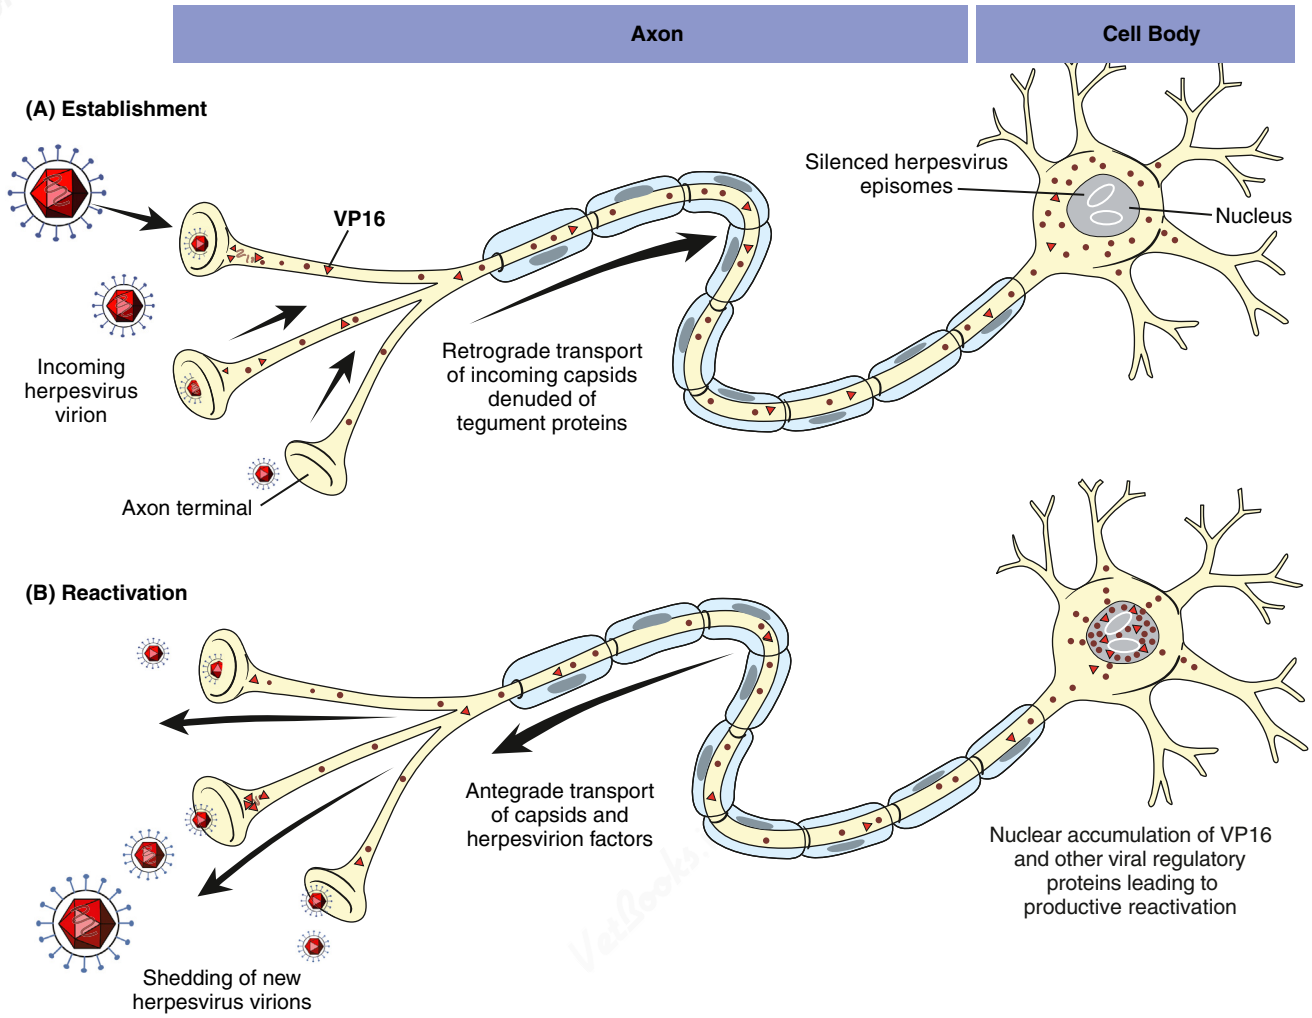

Fig. 34.2 Latency of herpes simplex virus-1 within neurons of the trigeminal ganglia. (A) Virus enters the nervous system via axon terminals of peripheral neurons that innervate the upper respiratory tract. There is retrograde transport of virus capsids to the cell body where the viral genome is delivered to the neuronal cell nucleus. Loss of the viral tegument protein VP16, which is required for virus replication, promotes latency in neurons as a circular (episomal) form. (B) Reactivation, with anterograde transport of new capsids and virions, is associated with accumulation of VP16 and other viral regulatory proteins as a result of increased virus replication secondary to immunosuppression. (Adapted from Wilson AC, Mohr I. A cultured affair: HSV latency and reactivation in neurons. *Trends Microbiol.* 2012;12:604–611.)

transport of virus to initial sites of infection or any region innervated by the ganglia, such as the cornea. Clinical signs range considerably in severity and chronicity, from no signs or mild serous ocular discharge to pneumonia and death. Mild signs of respiratory disease resolve spontaneously within 10 to 20 days. The most severe signs tend to occur in very young or elderly debilitated cats. Concurrent immunosuppressive illness or infection with other respiratory pathogens and opportunistic bacteria also profoundly influences disease severity.

Respiratory Tract Disease

Acute (<10 days' duration) clinical signs of URTD in cats infected with FHV-1 include fever, lethargy, conjunctivitis, blepharitis, and sneezing, which may be followed by development of mucopurulent ocular and nasal discharge, and, less commonly, cough or tachypnea (Fig. 34.3A). Severe sneezing has particularly been associated with FHV-1 infection when compared with infection with other respiratory pathogens. Mucopurulent discharges result from secondary bacterial infections with opportunistic pathogens such as *Streptococcus* spp., *Staphylococcus* spp., *Pasteurella multocida*, and *Escherichia coli*. Ocular and nasal discharges may become crusted, and kittens' eyelids may not open as a result of tenacious exudates. Closed eyelids may bulge as exudate accumulates behind adhered lids, a condition termed *ophthalmia neonatorum*. When severe, this can be followed by extensive corneal damage and rupture of the globe usually due to secondary bacterial keratitis. In neonatal infections caused by FHV-1, damage to upper respiratory epithelium may lead to osteolysis of the nasal turbinates and persistent or recurrent sinusitis and rhinitis. In kittens, concurrent corneal and conjunctival ulceration can result in formation of a symblepharon (adherence between the cornea and conjunctiva or two regions of ulcerated conjunctiva). When severe, symblephara can result in vision compromise or even blindness. FHV-1 infections may also lead to pharyngitis and laryngitis, which can be accompanied by clinical signs of gagging or obstructive respiratory patterns. Pneumomediastinum and subcutaneous emphysema were described in one cat with necrotizing bronchopneumonia and fibrinonecrotic tracheitis due to FHV-1 infection.[29] Although ulcerative glossitis, hypersalivation, and ulceration of the nasal planum, conjunctiva, and skin is more common and severe with FCV infection, it can also be

Fig. 34.3 Chemosis, mucopurulent ocular, and nasal discharge (A) and lingual ulceration (B) in a 6-month-old intact male domestic medium-hair cat with chronic nasal discharge and conjunctivitis. A conjunctival swab specimen tested positive with a PCR assay for feline calicivirus RNA and negative for feline herpesvirus-1, *Chlamydia felis*, and *Mycoplasma* spp. DNA. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

associated with FHV-1 infection (Fig. 34.3B). The role of FHV-1 in chronic rhinosinusitis in adult cats is unclear, but it is possible that repeated viral reactivation and progressive damage to the mucosa may play a role in this syndrome.

Ocular Disease

FHV-1 is an important cause of conjunctivitis, blepharitis, and corneal disease in cats, and has been implicated as a cause of acute and chronic ulcerative (epithelial) keratitis, stromal keratitis, eosinophilic keratitis, corneal sequestra, and uveitis.[30,31] Infection of cats with FHV-1 often results in conjunctivitis and ulcerative keratitis due to viral replication and thus direct cytotoxicity to the conjunctival and corneal epithelium, respectively.[27] While the presence of dendritic corneal ulcers in cats is pathognomonic for FHV-1 infection, these ulcers are less commonly identified as they rapidly enlarge to form superficial geographic ulcers. Cats with FHV-1 infection also exhibit decreases in conjunctival goblet cell density and tear film breakup time, and this resultant tear film instability likely contributes to the ongoing pathology of the conjunctiva and/or cornea.[32,33] Though infrequent, keratoconjunctivitis sicca can occur from damage to the ductules secondary to chronic herpetic blepharoconjunctivitis and/or neurogenic origin.[34] Stromal keratitis consisting of corneal cellular infiltrate and/or vascularization is a relatively uncommon manifestation of FHV-1 infection and occurs presumably as a result of the immune response to viral antigen in the corneal stroma.[30]

While the function that FHV-1 plays in the aforementioned syndromes is relatively clear, its role in the pathogenesis in eosinophilic keratitis, corneal sequestra, and uveitis remains nebulous and requires further study.[35] For example, FHV-1 DNA was detected using PCR in 55% of cats with corneal sequestra and 76% of scrapings from cats with eosinophilic keratitis in comparison with 5.9% of cats with normal corneas.[36] However, for corneal sequestra, brachycephalic cats were significantly less likely to have FHV-1 DNA in the specimens versus domestic shorthair and longhair breeds suggesting that nonviral factors such as corneal sensitivity and exposure likely play a role in its pathogenesis.[37] For eosinophilic keratitis, FHV-1 DNA was more likely to be detected in cats with a history and/or presence of a corneal ulcer at initial presentation.[38] However, it was not possible to discern if the cats with FHV-1 DNA and concurrent eosinophilic keratitis were experiencing primary herpetic disease or reactivation of latent virus in the trigeminal ganglion. Nevertheless, eosinophilic keratitis typically does not respond to antiviral medications, and immunosuppressive medications are often required for treatment. This suggests that this condition may result from an immune response to FHV-1 or another antigenic stimulus.[39] While reflex uveitis secondary to ulcerative herpetic keratitis is common, the role of FHV-1 in the pathogenesis of idiopathic anterior uveitis remains unclear.[38,40]

Studies of chronic HSV infections in rabbits suggest that this may relate to a significant decrease in corneal nerve density that occurs after 4 months of infection, which is associated with severe epithelial and stromal nerve damage with decreased corneal sensitivity, as well as formation of scar tissue in the central cornea.[41] A case report suggests a similar phenomenon exists in cats infected with FHV-1.[34]

Other Clinical Manifestations

FHV-1 can cause severe ulcerative and eosinophilic facial dermatitis, which is most likely to occur on the rostral muzzle and nasal planum, possibly reflecting viral spread to these sites following reactivation from the trigeminal ganglia (Fig. 34.4). A similar syndrome has also been described in cheetahs. Lesions have also been described elsewhere on the body in the absence of facial lesions.[42]

Multifocal necrotizing gastritis was described in one cat with concurrent necrotizing bronchopneumonia and laryngotracheitis in a cat with systemic FHV-1 infection.[43] Rarely, neurologic signs due to meningoencephalitis[44] and reproductive complications such as abortion and fetal resorption have been observed in infected cats, although it is unclear what role FHV-1 itself plays in the pathogenesis of reproductive failure. Abortion may be due to the severe systemic effects of the illness, rather than a direct effect of the virus itself.[19]

Physical Examination Findings

Acute Feline Herpesvirus-1 Infections

Physical examination findings in cats with acute viral URTD vary from mild serous ocular discharge and conjunctivitis to fever, severe mucopurulent ocular and nasal discharges, chemosis, dehydration, thin body condition, stertorous or stridorous respiration, tachypnea, increased breath sounds on thoracic auscultation, hypersalivation, and ulceration of the nasal planum, tongue, and lips. Because ulcerative lesions can occur at the base of the tongue near the larynx, examination of the entire tongue should be performed in cats that are febrile and inappetent, which may require sedation. Punctate or dendritic ulcerative keratitis may be seen in cats with acute FHV-1 infection.

Fig. 34.4 Ulcerative and eosinophilic facial dermatitis secondary to feline herpesvirs-1 (FHV-1) infection. (A) A 3-year-old female spayed domestic shorthair with a 2-month history of a crusted lesion on the right dorsal muzzle. (B) A 14-year-old female spayed domestic shorthair with blepharokeratoconjunctivitis and severe ulcerative facial dermatitis. (C) Same cat as in B after 4 months of treatment with famciclovir. Fluorescein stain is present. Biopsy in both cats showed severe, diffuse, necrotizing, and eosinophilic dermatitis with a few intranuclear inclusions bodies. A PCR assay for FHV-1 DNA on a biopsy from the cat in B was positive. (Courtesy of the University of California, Davis Veterinary Dermatology and Ophthalmology Service.)

Chronic Feline Herpesvirus-1 Infections

Ophthalmic examination findings associated with chronic FHV-1 infection can vary widely and include serous to mucoid ocular discharge, blepharedema, conjunctival hyperemia and/or chemosis, corneal ulceration with edema, corneal vascularization, pigmentation, mineralization, and/or fibrosis, keratoconjunctivitis sicca, and brown or black discoloration to the stroma consistent with corneal sequestra (Fig. 34.5).[27,31,45] Eosinophilic keratitis manifests as superficial, pink to white vascularized proliferative lesions on the cornea and/or conjunctiva; the superotemporal quadrant is the most affected position in the cornea.[38] Herpetic facial dermatitis is manifested as cutaneous ulceration, erythema, exudation, and adherent crusts, most commonly around the nose and eyes but occasionally on the trunk and limbs.[46]

DIAGNOSIS

It is generally not possible to diagnose FHV-1 infection based on clinical signs alone, because other respiratory pathogens can cause similar clinical signs. The presence of corneal ulceration should raise suspicion for FHV-1 infection, but mixed infections occur and complicate diagnosis. A history of exposure to other cats provides support for a diagnosis of viral respiratory disease, but because FHV-1 infections can recrudesce with stress, potential or known exposure to other cats is not essential to implicate respiratory viruses as a cause of disease. Previous vaccination for FHV-1 does not rule out the possibility of FHV-1 infection. All cats with signs of URTD should have known retrovirus infection status because viral URTD is common in retrovirus-infected cats. When signs such as chronic nasal discharge are present, other etiologies should also be considered, such as fungal infections, neoplasia, and foreign bodies. Diagnosis of eosinophilic keratitis and ulcerative facial dermatitis may require corneal scrapings or skin biopsy, respectively.

Laboratory Abnormalities

There are no specific CBC, serum biochemical, or urinalysis abnormalities that aid in a diagnosis of FHV-1 infection. The CBC can be normal or show a mild to moderate neutrophilia, sometimes with band neutrophils or neutrophil toxicity. Lymphopenia may be present in severely affected cats. Serum biochemistry findings are usually unremarkable unless disease is severe or chronic.

Endotracheal lavage specimens from cats with pneumonia may show a suppurative or mixed exudate, sometimes with evidence of secondary bacterial infection. Aerobic bacterial culture and susceptibility testing, and culture for *Mycoplasma* spp. are indicated on wash specimens. Organisms such as *Pasteurella* spp., *Staphylococcus pseudintermedius*, *Streptococcus* spp., *E. coli, Klebsiella pneumoniae*, and some *Mycoplasma* spp. may infect the airways as opportunists. Bacterial culture of nasal swabs is generally not recommended because it often leads to growth of normal flora, which has no clinical relevance. However, resistant *Pseudomonas aeruginosa* infections can develop in some cats with chronic URTD that have been treated repeatedly with antimicrobial drugs.

Herpetic ulcerative keratitis may lead to secondary bacterial and/or fungal infection. Therefore, aerobic bacterial and/or fungal cultures should be considered in cases of feline ulcerative keratitis with stromal loss, malacia, and/or cellular infiltrate. If eosinophilic keratitis is suspected, a corneal scraping should be performed after administration of a topical anesthetic; abundant eosinophils with neutrophils and/or mast cells will typically be present.

Diagnostic Imaging

In uncomplicated FHV-1 infections, plain thoracic radiographs may be unremarkable or show a mild diffuse interstitial to bronchointerstitial pattern. Alveolar patterns or lung lobe consolidation can occur with secondary bacterial pneumonia.

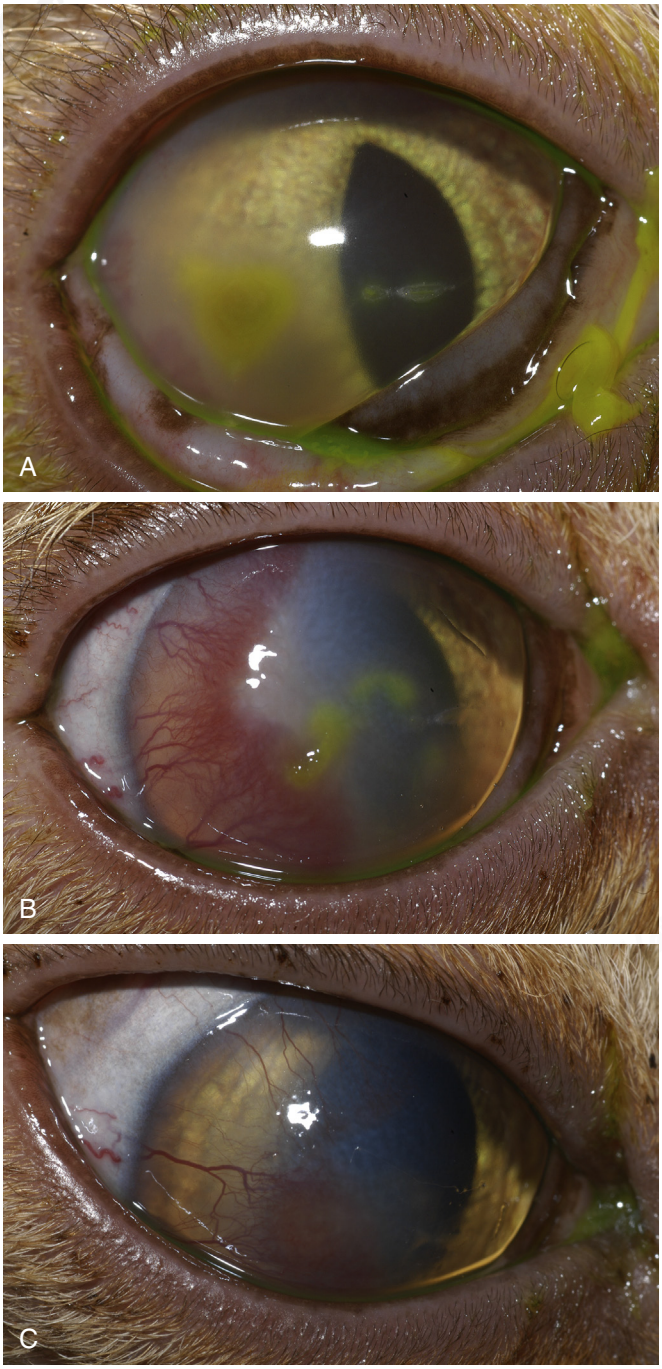

Fig. 34.5 (A) Ulcerative and stromal keratitis in a 2-year-old male neutered Rex cat. Feline herepesvirus-1 infection was suspected. Treatment with famciclovir (375 mg, PO, q8h), L-lysine (500 mg, PO, q12h), and cidofovir (0.5%; one drop, OD, q12h) was associated with clinical improvement over a 1-month period (B and C). The cat had a history of a corneal sequestrum and subsequently developed eosinophilic keratitis. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

Microbiologic Tests

Because many cats experience self-limiting disease, attempts to obtain an etiologic diagnosis of URTD should be made when disease persists for longer than 7 to 10 days or is complicated by pneumonia, with lethargy and inappetence. When outbreaks of respiratory disease occur in shelters or the pattern of endemic respiratory disease changes, attempts to make an etiologic diagnosis are also indicated and strongly encouraged. Because FHV-1 can be detected in apparently healthy cats, it may be difficult to know the significance of a positive test result in a single cat with signs of respiratory disease. In an outbreak situation, collection of multiple specimen types from several cats with and without clinical signs can facilitate diagnosis and allow interpretation of the significance of test results. In shelter situations or outbreaks of severe disease, necropsies can provide valuable information and should be performed by a veterinary pathologist as soon as possible after death or euthanasia. Tissues should be submitted for histopathology (in formalin), bacterial and virus isolation (fresh tissue), and PCR for respiratory viruses and bacteria (fresh or frozen tissue; see Chapter 6).

Assays available to detect FHV-1 include virus isolation, direct immunofluorescence, and PCR assays (Table 34.1). The use of both PCR and culture together offers the greatest sensitivity when it is important to obtain a diagnosis. One study suggested that use of nasal swab specimens results in detection of FHV-1 using PCR in 95% of cats that tested positive using either nasal, oropharyngeal, tongue, or conjunctival swab specimens,[47] but submitting swabs from multiple sites increases the chance of a positive test result, and FCV is more likely to be detected in oropharyngeal swabs.

Virus Isolation

Although not commonly performed for routine diagnosis, FHV-1 is readily isolated in cell culture. Virus isolation is offered to veterinarians by some commercial veterinary diagnostic laboratories that specialize in virology. Suitable specimens for isolation of FHV-1 include conjunctival, nasal, and oropharyngeal swabs, endotracheal or bronchoalveolar lavage specimens, or upper airway tissue or lung obtained at necropsy. If swabs are used for specimen collection, polyester-tipped swabs and specific virus transport media should be used, which are available from commercial testing laboratories. When conjunctival swabs are collected, the use of topical anesthetics should also be avoided because they have the potential to reduce the sensitivity of virus isolation.[48] Isolation may take several days. Sensitivity can be very low in cats with chronic manifestations of infection (more than 10 days after the onset of clinical signs). In cats with mixed FCV and FHV-1 infections, FCV may obscure the presence of FHV-1 because it produces cytopathic effects more rapidly.

Fluorescent Antibody Testing

FA that specifically detects FHV-1 can be applied to conjunctival smears or impression smears from lung tissue collected at necropsy. The effect of vaccination with attenuated live vaccines on direct FA test results has not been reported. The sensitivity of direct FA testing is lower than that of PCR or virus isolation,[49] and inexperienced laboratory personnel may misinterpret nonspecific fluorescence as a positive result.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Panels of real-time PCR assays that detect feline respiratory pathogens are offered by some commercial veterinary diagnostic laboratories and are rapid and relatively inexpensive. These can include assays for FHV-1 and FCV, as well as bacteria such as *Mycoplasma* spp., *B. bronchiseptica*, and *C. felis*. The sensitivity and specificity of PCR assays for FHV-1 vary considerably among laboratories. Swabs of the nasal cavity, conjunctival sac, or caudal pharynx; respiratory lavage specimens; skin biopsies; or upper respiratory tract and lung tissue collected at necropsy are suitable specimens for testing. Topical anesthetics and fluorescein can reduce the sensitivity of PCR assays for human herpesviral infections,[50] and thus should be avoided, although one study showed no inhibitory effect of topical fluorescein or proxymetacaine in cats on FHV-1 PCR results.[51] False-negative PCR results can occur in cats with chronic infections that shed low amounts of virus. An

TABLE 34.1 Diagnostic Assays Available for FHV-1 Infections in Cats

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival, nasal, and caudal pharyngeal swabs, transtracheal and bronchoalveolar lavage specimens, airway and lung specimens collected at necropsy	Virus	Negative results can occur if specimens contain no or low numbers of virus particles. May take several days and requires specialized techniques and expertise.
PCR	See Virus isolation	Viral nucleic acid	Sensitivity and specificity may vary depending on assay design. Sensitivity may be low because of brief shedding or low-level shedding in chronic infections. Testing specimens from multiple different anatomic sites or combining PCR with other diagnostic tests can increase sensitivity. Attenuated live vaccine virus may be detected after vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret.
Serology	Serum	Antibodies against FHV-1 antigens	Interpretation complicated by previous vaccination and exposure.
Histopathology	Necropsy or biopsy specimens	FHV-1 inclusions; immunostaining	Detection of FHV-1 inclusions has low sensitivity, and immunostaining and/or PCR is required to definitively identify the infecting virus.

FHV-1, feline herpesvirus-1.

isothermal PCR assay has been described that permits detection of FHV-1 within 20 minutes.[52]

Positive PCR assay results for FHV-1 should be interpreted with caution because cats with no clinical signs can shed FHV-1. In one shelter, a correlation between the quantity of FHV-1 present in pooled oropharyngeal and conjunctival swabs as determined using quantitative real-time PCR and the severity of histologic lesions within the nasal cavity was detected, with cycle threshold values less than 29 correlating with the most severe histologic lesions.[53] In the future, quantitation of viral nucleic acid within swabs may assist interpretation of the clinical significance of positive PCR results. Also, PCR can detect attenuated live vaccine virus that is shed after routine vaccination. However, this appeared to be an uncommon phenomenon in one study that used PCR to detect FHV-1 in 12 cats previously exposed to the virus over a 3-week period after vaccination with intranasal or parenteral attenuated live FHV-1 vaccines.[12] Additional studies are required to determine the prevalence of positive assay results after vaccination and their relationship to vaccine virus. In outbreak situations, false-positive PCR results have the potential to occur if swabs become contaminated with virus from the environment or the hands of personnel. Clean examination gloves should be worn for each cat, and the swab should touch only the anatomic site to be tested. In one randomized study of shelter cats, results of FHV-1 or *Mycoplasma* spp. PCR assays did not accurately predict response to cidofovir or topical tetracycline ointment, respectively.[54]

Serologic Diagnosis

Serologic assays (such as ELISA or serum neutralization assays) that detect antibodies to FHV-1 are offered on a commercial basis to veterinarians. Unfortunately, serology is not useful for diagnosis because of vaccine titer interference and the high prevalence of subclinical exposure to these viruses in the cat population. Serology has also been used to predict protection from infection, although cats with negative titers can still have some degree of immunity, and cats with positive titers may develop illness after challenge.

Pathologic Findings

Gross lesions in cats with FHV-1 infections include cutaneous and lingual ulcerations, evidence of conjunctivitis and keratitis, and mucopurulent exudate within the nasal cavity and trachea. In cats with pneumonia, the lungs may be edematous with diffuse or multifocal consolidated areas. Histopathology may show rhinitis, tracheitis, and/or alveolitis. Intranuclear viral inclusions may be found within epithelial cells of the upper respiratory tract (Fig. 34.6). Osteolytic changes within the nasal turbinates may also be identified. Virus can be detected in epithelial cells using IHC or FA staining. Skin biopsies from cats with ulcerative herpesviral dermatitis show epidermal hyperplasia, ulceration, and necrosis that extends into the superficial dermis, and infiltration with degenerated neutrophils, eosinophils, and fewer numbers of histiocytes, plasma cells, and lymphocytes. In some skin biopsies, intranuclear viral inclusions are identified.[45,55]

TREATMENT AND PROGNOSIS

Supportive care is the mainstay of treatment for acute FHV-1 infections and includes subcutaneous fluid therapy, antimicrobial drugs for secondary bacterial infections, and enteral nutrition. Antimicrobial therapy should be withheld for cats with acute (<10 days) illness that are otherwise appetent according to ISCAID Antimicrobial Use Guidelines[56] (Table 34.2). When inappetence and mucopurulent discharges are present, empiric treatment with a short course of doxycycline or amoxicillin is recommended for primary or secondary bacterial infections. Use of topical or systemic antiviral drugs is indicated for cats with severe or chronic clinical signs. Appetite stimulants may be useful in some cats, but if inappetence persists for longer than 3 days, feeding tube placement is indicated. Severely affected cats may require hospitalization in isolation and treatment with parenteral fluids, antimicrobial drugs, nebulization, and supplemental oxygen. Acute signs generally resolve within 2 to 3 weeks with supportive care, but some cats experience frequent disease relapses and chronic complications such as keratitis.

The use of antiviral drugs should be considered for cats with severe and recurrent or persistent manifestations of FHV-1 infection such as keratitis, severe conjunctivitis, and ulcerative dermatitis. Antiviral drugs are discussed in more depth in Chapter 9 (see Table 9.5 for dosages). A comprehensive review of antiviral drugs and other compounds with established or purported activity against FHV-1 can be found elsewhere (see Suggested Readings). Acyclovir and its prodrug, valacyclovir, cause unacceptable renal, bone marrow, and hepatic toxicity when administered systemically to cats, and so their

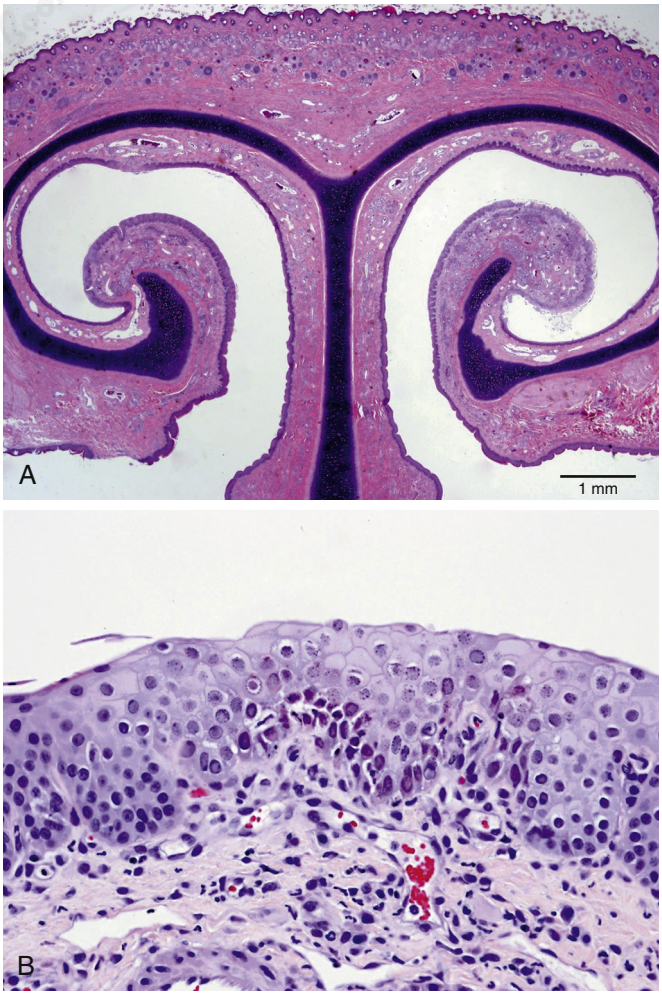

Fig. 34.6 (A) Cross-section of the nares of a shelter cat with rhinitis due to infection by feline herpesvirus-1. Ulceration is most severe on the right side. Hematoxylin and eosin stain. (B) Higher magnification of the nasal epithelium that shows rhinitis and the presence of intraepithelial, intranuclear inclusion bodies. (From Burns RE, Wagner DC, Leutenegger CM, et al. Histologic and molecular correlation in shelter cats with acute upper respiratory infection. *J Clin Microbiol.* 2011;49:2454–2460. Images courtesy Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology Service.)

use is not recommended.[57,58] By contrast, oral famciclovir is generally well tolerated by adult cats and kittens and results in significant clinical improvement and decreased viral shedding in cats with acute and chronic herpetic disease (see Fig. 34.5B and C).[59–61] When administered with other topical and systemic antibacterial drugs, owner-reported clinical response rates in a population of cats seen at a tertiary referral hospital were greater than 80%, with approximately 50% of cats showing marked improvement as assessed by clinicians.[59] Another study of 24 kittens with acute URTD showed no difference in clinical response when famciclovir was compared with doxycycline; however, FHV-1 was only detected using PCR in seven of these cats.[62] No difference in clinical outcome was also reported in a placebo-controlled study of shelter-housed cats with evidence of herpetic disease, although shedding of FHV-1 was reduced in famciclovir-treated cats.[63] Cats in this study were treated for 7 days, and famciclovir was evaluated both for prophylaxis and treatment. The recommended dose based on pharmacokinetic studies of famciclovir and its active metabolite, penciclovir, in plasma and tears is 90 mg/kg q12h.[64] Use of a single dose of famciclovir at intake of cats to shelters was ineffective at reducing shedding and disease.[65] Because viral strains that are resistant to famciclovir have been described,[66] the use of famciclovir should be reserved for severe or refractory infections to minimize further selection for resistance.

The active metabolite of famciclovir, penciclovir, also has potential to be a useful drug for local treatment of feline herpesviral infections since it has poor oral bioavailability.[67] Based on *in vitro* studies using corneal explants as well as a study of experimentally infected cats, the integrase inhibitor raltegravir also shows promise as a treatment for FHV-1 infections.[68,69]

Cidofovir and ganciclovir have shown the greatest promise as topical treatments due to their potency against FHV-1 *in vitro*. Furthermore, topical cidofovir decreases disease severity and viral shedding in experimentally infected cats[70], and has the advantage of requiring only twice-daily administration. Topical ganciclovir (0.15%) had excellent *in vitro* activity and was well tolerated when administered to 4 healthy cats q8h for 7 days.[71] Topical ophthalmic preparations that contain idoxuridine, trifluridine, vidarabine, or acyclovir can be used to treat herpetic keratitis, although the true efficacy of these drugs has not been well studied. Frequent topical application is required (4–6 times daily), and prolonged use may cause corneal and/or conjunctival irritation. Idoxuridine and vidarabine may be better tolerated by cats than trifluridine. In addition to topical and/or systemic antiviral drugs, topical administration of a mucinomimetic such as sodium hyaluronate is beneficial to address the decrease in conjunctival goblet density and concomitant tear film instability caused by FHV-1.[60]

Human recombinant IFN-α and recombinant feline IFN-ω inhibit FHV-1 replication *in vitro* and have been administered parenterally, topically (for keratitis), and orally to cats with FHV-1 infection.[72] Obvious clinical responses to treatment have not been uniformly observed, but controlled clinical trials that involve large numbers of cats are lacking. Topical administration of human recombinant IFN-α or recombinant feline IFN-ω had no benefit over saline in cats with naturally occurring viral keratoconjunctivitis.[73] Clinical improvement was noted when IFN-α was given subcutaneously 2 days before inoculation of cats with FHV-1,[74] and in 8 of 13 naturally infected cats treated with 10,000 U/kg SC for 14 days.[75] Parenteral administration may be followed by the development of neutralizing antibodies beyond 3 weeks of treatment. Use of a combination of low-dose, sequential kinetic activated (SKA) IL-12 and IFN-γ in a randomized, prospective, placebo-controlled study for 6 months was associated with clearance of infection as determined using endpoint (conventional) PCR in 12 of 15 treated cats.[76] Preliminary data suggest that administration of an intranasal FHV-1 and FCV vaccine may result in clinical improvement in cats with chronic URTD that have failed other therapies.[75]

Lysine has shown efficacy for treatment of herpesviral conjunctivitis in cats when administered as tablets[77] and may reduce reactivated shedding by latently infected cats.[78] However, when administered to shelter cats, there was no reduction in URTD, possibly because of the stress of tablet administration.[79] Dietary formulation with lysine has also been ineffective for management of URTD in shelters and in fact may contribute to a worsened outcome.[80] Various concentrations of lysine were not able to inhibit replication of FHV-1 *in vitro*.[81] On the basis of the lack of clear evidence supporting the use of lysine for prevention and treatment of FHV-1 infections in cats and concerns about adverse outcomes, it has been recommended by some that its use be discontinued.[82]

The use of glucocorticoids to treat refractory herpetic keratitis is controversial, because it may reactivate virus and worsen disease. The exception is eosinophilic keratitis which often requires treatment with

TABLE 34.2 Antimicrobials Used To Treat Feline Herpesvirus-1 Infections in Cats

Drug	Dose	Route	Interval	Duration (days)	Comments
Cidofovir	0.5% solution	Topical ophthalmic	q12h	Until resolution	Monitor for ocular irritation. Compounding may be required or a solution can be prepared from commercial 7.5% intravenous solution by dilution in sterile saline. Store diluted solution up to 6 months at 4°C, –20°C, and –80°C.
Idoxuridine	0.1% solution or 0.5% ointment	Topical ophthalmic	4–6 times daily	Until resolution	Monitor for ocular irritation. Compounding is required.
Vidarabine	3% ointment	Topical ophthalmic	4–6 times daily	Until resolution	Monitor for ocular irritation. Compounding is required.
Trifluridine	1% solution	Topical ophthalmic	4–6 times daily	Until resolution	May be poorly tolerated. Monitor for ocular irritation.
Famciclovir	90 mg/kg	PO	q12h	Until resolution	Monitor for inappetence and diarrhea.
Ganciclovir	0.15% gel	Topical ophthalmic	q8h	Until resolution	Monitor for ocular irritation.
Raltegravir	80 mg	PO	q12h	Until resolution	Monitor for adverse events given that safety testing was limited to a 2 week study in healthy cats experimentally infected with FHV-1.
Doxycycline	5 mg/kg q12h OR 10 mg/kg q24h	PO	24	7–10	For secondary bacterial infection. Hyclate suspension should be followed by administration of a bolus of water; compounded suspensions are not stable beyond 7 days.
Amoxicillin	22	PO	12	7–10	For secondary bacterial infection. Not active against mycoplasmas or *Chlamydia*.

topical glucocorticoids. Because the role of FHV-1 in this condition is unclear, topical antiviral medications such as cidofovir are often given concurrently. Topical glucocorticoids are contraindicated when corneal ulceration is present, so it is critical to apply fluorescein stain and carefully examine the corneas for retention of the dye. Cats with ulcerative eosinophilic keratitis may require systemic glucocorticoid treatment until the ulcers heal.

Superficial lamellar keratectomy may be required for chronic corneal ulceration and/or corneal sequestra that are nonresponsive to medical therapy.[83] Other surgical treatments for corneal sequestra include corneoconjunctival transposition, lamellar keratoplasty followed by corneal transplantation, amniotic membrane transplantation, conjunctival graft placement, or placement of acellular matrix.[84–86] For surgical interventions, referral to a veterinary ophthalmologist is recommended.

IMMUNITY AND VACCINATION

Immunity to FHV-1 depends on cell-mediated and systemic and local (mucosal IgA) humoral immune responses. Maternal antibody can persist until 14 weeks of age,[19] although other kittens may be susceptible to infection at 6 weeks of age.

Vaccines for FHV-1 have been available for decades, but these do not provide complete protection, and disease continues to be widespread in the cat population. Infection of kittens before completion of the primary vaccine series contributes to this problem. Both inactivated and attenuated live FHV-1 vaccines are available, and attenuated live vaccines are available for parenteral or intranasal administration. Inactivated vaccines contain adjuvant, and their use should be reserved for immunosuppressed cats (such as retrovirus-infected cats) or pregnant cats, if deemed necessary. A recent study showed that although total clinical score was not significantly different between the groups, clinical signs of respiratory disease in cats vaccinated with a single dose of an inactivated vaccine were significantly reduced when compared with cats vaccinated with an attenuated live vaccine following challenge 7 days later.[87] When infections are a problem in kittens in breeding catteries, vaccination of the queen before mating is preferable to vaccination during pregnancy and may prolong the duration of maternal antibody persistence.[88] Vaccination as early as 4 weeks of age (but not before) could be considered in catteries with high rates of viral URTD. The primary series should consist of vaccines administered every 3 to 4 weeks of age until no earlier than 16 weeks of age.

No FHV-1 vaccine prevents infection, the carrier state, or reactivation, but FHV-1 vaccines can reduce disease severity. Whether a cat contracts feline viral URTD after vaccination depends on factors such as virus strain virulence, the challenge dose, environmental temperature and humidity, and the presence of underlying immunosuppressive disease or other concurrent disease.

Vaccination with FHV-1 vaccines can reduce the duration of shedding, viral infectivity (presumably as a result of complexing of virus by antibody), and the load of latent virus in the trigeminal ganglia.[19,89,90] It is unclear if the frequency of reactivation is reduced, although this is the case for herpesviral vaccines in other species (such as the shingles vaccine for humans). The intranasal FHV-1 vaccine virus can itself become latent, but whether parenteral FHV-1 vaccine virus becomes latent is unknown.

Because FHV-1 strains are antigenically similar, the immune response to one FHV-1 strain cross protects against other FHV-1 strains.

Parenteral vaccines that contain FHV-1 are generally safe. Intranasal vaccines are less well tolerated by cats and can be occasionally followed by mild to moderate postvaccinal signs of URTD. This may be problematic in shelter environments where clinical signs of URTD warrant the need for separate housing. On the other hand, intranasal vaccines

are advantageous in this situation because of rapid onset of immunity, with partial protection after 2 days and significant protection after 4 days.[19] They can also overcome maternal antibody at a young age, although some injectable vaccines may also still be effective at an early age. Concurrent administration of a parenteral and intranasal vaccine to naïve kittens was superior to parenteral vaccination alone in one challenge study.[91] Because vaccine virus is propagated in feline kidney cells, there has been concern that parenteral administration of feline vaccines might lead to chronic renal inflammation when immune responses to vaccine components cross-react with endogenous renal antigens.[92] Further studies are required to determine whether this is clinically important.

Vaccine boosters are recommended by the AAHA/AAFP 6 months after completion of the primary series, and at 3-yearly intervals thereafter in cats with low levels of exposure to respiratory viruses.[93] Titers tend to be low following vaccination and do not predict protection from infection, so they should not be used to decide whether to administer boosters. For cats in contaminated environments such as catteries, cats housed periodically in boarding facilities, or large multicat households with frequent introductions, annual vaccination may be more appropriate. The duration of immunity after vaccination remains incompletely understood. Although partial protection persists for several years after vaccination,[94] the degree of protection does wane with time, at least for cats that receive no natural boostering in the interim (i.e., from exposure to field virus). In one report, relative FHV-1 vaccine efficacy was 95%, when challenge occurred a few weeks after primary vaccination with an inactivated vaccine.[95] This compared with 52% when challenge occurred after 7.5 years.[96] In another study, a 50% reduction in clinical scores occurred after challenge 1 year after administration of an attenuated live FHV-1 vaccine, compared with around 75% after challenge 4 weeks after vaccination.[97] In the field, natural boostering as a result of contact with virus shed by other cats or subclinical reactivation may maintain immunity for longer periods of time.

PREVENTION

In addition to vaccination, reduction of stress and overcrowding is critical for prevention of disease caused by FHV-1. Proper hand washing and disinfection in shelters, boarding facilities, and veterinary hospitals to prevent fomite transmission is also very important, and dedicated food and water bowls should be used. Care of household cats by friends or neighbors should be recommended whenever possible rather than boarding to reduce the chance of infection or reactivation. Veterinarians should remember that all cats, whether apparently healthy or sick, can be a source of FHV-1 infection. Cats should be housed individually (unless they are from the same household and tolerate close proximity to one another). Barriers between cats should be impermeable, and cats with URTD should be separated by at least 4 to 5 feet to prevent aerosol transmission. If possible, cats that enter large multicat environments and shelters should be quarantined for 3 weeks to identify cats that are incubating disease. Use of tactics to reduce stress in shelter environments, such as creating spaces for cats to hide and "gentling" (gentle stroking and vocalizations) multiple times a day[24] can have a tremendous impact on reduction of disease caused by FHV-1 and viral shedding. Fostering in temporary homes can also reduce the prevalence of disease in shelter cats. When all other control measures fail in breeding catteries, early weaning and isolation of kittens from 4 weeks could be considered.

In one randomized trial of experimentally infected cats with chronic, subclinical FHV-1 infection, cats fed a probiotic with immune-modulating effects had less recurrent conjunctivitis than cats fed the control supplement, suggesting a prevention effect.[98]

In a different trial involving a similar model using housing change to induce mild stress, experimentally infected cats with chronic, subclinical FHV-1 infection that were housed in a room with a pheromone diffuser had decreased total stress scores and less sneezing when compared with cats housed is a room with a placebo diffuser.[99]

PUBLIC HEALTH ASPECTS

FHV-1 does not infect humans.

FELINE GAMMAHERPESVIRUS INFECTIONS

FELIS CATUS GAMMAHERPESVIRUS 1

FcaGHV1 infection is believed to be endemic worldwide. Blood samples from 1%–23.6% of cats from the Americas, Australasia, and Europe are positive for DNA using a FcaGHV1-specific qPCR.[2,100–104] Molecular studies do not detect all FcaGHV1 infections. Serology suggests that the true infection rate is at least double that indicated by molecular studies.[105] Age, sex, neuter status, health status, and coinfections have been identified as risk factors for FcaGHV1 infection with some regional variations.[2,100,101,106] Male sex and age over 2 years are important risk factors for FcaGHV1 DNA detection. FIV-infected cats are 5–10 times more likely to be positive for FcaGHV1 DNA than non-FIV–infected controls matched for age and sex,[2,100,103,104,106] and a UK study found that almost all FcaGHV1-infected cats were co-infected with at least one hemoplasma species.[101] Based on epidemiologic data, biting has been suggested as one potential route of FcaGHV1 transmission.[107]

Although generally host specific, some gammaherpesviruses can infect closely related hosts. If the alternate host is nonimmune, rapidly fatal disease can ensue, with malignant catarrhal fever of ruminants being a good example. FcaGHV1 infection of at least one nondomestic felid, the critically endangered Tsushima leopard cat, has been identified in Japan.[108]

Fortunately for a virus that is highly prevalent, it is likely that most FcaGHV1 infections are subclinical. Gammaherpesvirus infections in other species cause persistent infections that are typically clinically latent except in certain circumstances such as when CMI is compromised, when they can cause lymphoproliferative and neoplastic disorders.[109] The existence of a gammaherpesvirus in the domestic cat was first suggested by observations from the FIV cat model of HIV infection in humans. Both FIV and HIV infections increase the patient's risk of developing high-grade B-cell lymphomas.[110,111] Of HIV-associated lymphomas, 30% to 95%, depending on subtype, are causally linked to one or both of the gammaherpesviruses that infect humans, Epstein-Barr virus and Kaposi's sarcoma–associated herpesvirus. Whether FcaGHV1 plays a role in FIV-associated lymphomas is under investigation. Neither a molecular diagnosis of FcaGHV1 nor whole-blood FcaGHV1 load was related to outcome in 122 lymphoma cases compared with 71 controls matched for age and sex.[107] Interestingly, the same study identified shorter survival in FcaGHV1-positive lymphoma cases suggesting that prospective investigation of FcaGHV1 DNA detection as a prognostic marker for lymphoma may be warranted.

Diagnostic tests for FcaGHV1 are only available in a research setting. A qPCR targeting the glycoprotein B gene and serologic assays that detect antibodies recognizing ORF52 and ORF38 proteins have been described.[2,105]

OTHER GAMMAHERPESVIRUSES

Gammaherpesviruses infecting nondomestic Felidae have been identified in the puma (*Puma concolor*, PcoGHV1), African lion (*Panthera leo*, PleoGHV1), bobcat (*Lynx rufus*, LruGHV1 & 2), and ocelot (*Leopardus pardalis*, LpaGHV1).[2,112,113] To date, cross-species infectivity has been identified only for LruGHV1 which was detected in 13% of pumas in a US study.[2]

The bovine gammaherpesvirus, BHV4, has a wide host range and feline infections have been reported, but their prevalence and pathogenic potential remain controversial. Early experimental infections and disease association studies supporting a role for BHV4 in URTD and lower urinary tract disease have not been replicated. Molecular epidemiologic studies using nested or hemi-nested PCR to detect BHV4 DNA in free-ranging domestic cats reported divergent results; 26.9% of 104 blood samples from Michigan were BHV4 positive in one study,[114] whereas none of 101 cats from California, Colorado, and Florida tested PCR positive[115] suggesting that geographic variation in prevalence is likely.

CASE EXAMPLE

Signalment

"Boris," a 7-year-old male neutered Burmese cat from northern California.

History

Boris was brought to the University of California, Davis, VMTH for a 3-day history of inappetence, head shaking, gagging, hypersalivation, coughing, and sneezing. The gagging occurred throughout the day and occasionally was followed by vomiting. The vomit consisted of bile-stained fluid. Boris had not been drinking. He was taken to a local emergency clinic where bilateral serous nasal discharge was noted, and he was treated for 24 hours with IV crystalloid fluids and amoxicillin. Blood work showed hypokalemia (4.0 mEq/L, reference range 4.5–5.3 mEq/L), hyperglycemia (292 mg/dL, reference range 70–150 mg/dL), neutrophilia (12,920 cells/μL, reference range 2,500–12,500) and lymphopenia (136, reference range 1,500–7,000). FeLV and FIV serology was negative. A urinalysis showed a SpG of 1.050, pH of 7, and 1+ proteinuria and glucosuria. Lateral and dorsoventral radiographs of the thorax and abdomen showed moderate to severe gas distention of the proximal esophagus and stomach. Profuse salivation and gagging continued, and he was referred to a specialty clinic because of concerns for a possible GI foreign body. There had been no diarrhea, no history of travel or trauma, and no recent surgical procedures. A new indoor plant was brought into the house 2 days before the onset of clinical signs. He was last immunized for FHV-1, FCV, FPV, and rabies 1 year previously. Boris was housed completely indoors and was exposed to one other cat that only occasionally had access to the outdoors. His diet consisted of a commercial dry cat food.

Physical Examination

Body weight: 4.8 kg.

General: Lethargic, but responsive, 5% to 7% dehydrated. Held head extended and gagged and hypersalivated throughout the examination; seemed unable to swallow. Vomited bile-stained fluid once during the examination. T = 100.8°F (38.2°C), HR > 240 beats/minute, RR = 24 breaths/minute, mucous membranes pink, CRT = 1 second. The cat's haircoat was unkempt.

Eyes, ears, nose, and throat: Bilateral serous nasal discharge was present. A linear ulcer was identified on the right lateral aspect of the tongue.

Musculoskeletal: BCS was 4/9. Ambulatory.

Cardiovascular and respiratory: Other than tachycardia, no other abnormalities were detected.

GI and genitourinary: Mild abdominal distention was present.

Lymph nodes: All lymph nodes were < 1 cm in diameter.

Laboratory Findings

CBC: HCT 34.2% (30%–50%), MCV 51.0 fL (42–53 fL), MCHC 32.5 g/dL (30–33.5 g/dL), WBC 12,600 cells/μL (4,500–14,000 cells/μL), neutrophils 11,844 cells/μL (2,000–9,000 cells/μL), band neutrophils 126 cells/μL, lymphocytes 126 cells/μL (1,000–7,000 cells/μL), monocytes 252 cells/μL (50–600 cells/μL), eosinophils 126 cells/μL (150–1,100 cells/μL), platelets 989,000 platelets/μL (180,000–500,000 platelets/μL). The neutrophils showed slight toxicity, and there were a few Heinz bodies.

Serum chemistry profile: Sodium 141 mmol/L (151–158 mmol/L), potassium 4.0 mmol/L (3.6–4.9 mmol/L), chloride 108 mmol/L (117–126 mmol/L), bicarbonate 27 mmol/L (15–21 mmol/L), phosphorus 4.5 mg/dL (3.2–6.3 mg/dL), calcium 8.1 mg/dL (9.0–10.9 mg/dL), BUN 21 mg/dL (18–33 mg/dL), creatinine 1.1 mg/dL (1.1–2.2 mg/dL), glucose 212 mg/dL (63–118 mg/dL), total protein 5.1 g/dL (6.6–8.4 g/dL), albumin 2.2 g/dL (2.2–4.6 g/dL), globulin 2.9 g/dL (2.8–5.4 g/dL), ALT 83 U/L (27–101 U/L), AST 50 U/L (17–58 U/L), ALP 16 U/L (14–71 U/L), cholesterol 147 mg/dL (89–258 mg/dL), total bilirubin 0 mg/dL (0–0.2 mg/dL).

Imaging Findings

Endoscopy: Boris was anesthetized and an oral examination performed, which showed only mild dorsal pharyngeal lymphoid hyperplasia. Rhinoscopy showed a moderate amount of mucus and mild diffuse erythema of the nasal mucosa. Gastroduodenoscopy revealed focal areas of gastric erosion with hemorrhage.

Treatment

Boris was treated with IV crystalloid fluids (LRS with 20 mEq/L KCl at 20 mL/hour), ampicillin (23 mg/kg, IV, q8h), enrofloxacin (2.6 mg/kg, IV, q24h), sucralfate (0.25 g, PO, q8h), and famotidine (0.25 mg/kg, IV, q12h). He continued to hypersalivate, and he vomited approximately 100 mL of fluid twice daily. After the first day of hospitalization, the owners reported that their other cat had developed signs of URTD, with sneezing and nasal discharge. Enteral or parenteral nutrition was discussed with the owner, but on the evening of the second day of hospitalization, Boris was found gagging and cyanotic. He was taken to the intensive care unit but developed cardiorespiratory arrest. CPR was instituted and tracheal suction revealed yellow fluid consistent with possible aspiration. Although CPR was initially successful, Boris arrested again and died shortly afterward.

Necropsy Examination

Gross necropsy examination showed numerous lingual ulcerations, mostly pinpoint but some coalescing into larger ulcers up to 1 cm long and 0.5 cm wide. Both lungs were diffusely dark red, poorly collapsed, and oozed large amounts of clear fluid on cut surface. There was a small amount of yellow ascites fluid. Histopathology revealed marked, multifocal, acute to subacute necrotizing stomatitis, rhinitis, tracheitis, bronchiolitis, and alveolitis with intranuclear herpesviral inclusions in the bronchiolar epithelium. IFA testing on lung tissue was positive for FHV-1. Virus isolation was negative. Histopathology of GI biopsies collected at endoscopy and tissues collected at necropsy was unremarkable.

Comments

This cat died of a severe and overwhelming FHV-1 infection despite the fact that he was an adult cat that had been vaccinated regularly. Clinical signs of anorexia, gagging, and hypersalivation likely resulted from stomatitis, pharyngitis, and tracheitis. Histopathology with IFA staining confirmed the involvement of FHV-1. The negative virus isolation result may have been because of an insufficient sample size, inactivation of virus by antibody, or lack of viable virus in the specimen. Because FHV-1 survives poorly in the environment, it may deteriorate in clinical specimens during transport to the laboratory.

Feline Calicivirus Infections

Alan Radford, Maria Afonso, Jane E. Sykes

KEY POINTS

- First Described: 1957 (New Zealand, Fastier).[1]
- Causes: FCV, family *Caliciviridae,* genus *Vesivirus.*
- Affected Hosts: Domestic cat and many other Felidae. Similar viruses also isolated occasionally from dogs.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Oronasal, fomite spread.
- Major Clinical Signs: Oral ulceration, oculonasal discharges, lethargy. Less commonly lameness, lower respiratory tract infection, and signs of enteritis. Rare virulent forms may also cause edema, icterus, skin necrosis, and death.
- Differential Diagnosis: Differential diagnoses for FCV infection are other respiratory viral infections (FCV, influenza viruses), infections with bacteria such as *Bordetella bronchiseptica, Mycoplasma* spp., *Streptococcus* spp., or *Chlamydia felis*; other causes of rhinitis such as cryptococcosis, aspergillosis, neoplasia, foreign bodies, chronic idiopathic feline rhinosinusitis, nasopharyngeal stenosis, or nasopharyngeal polyps; feline chronic airway disease. For cats with oral ulcerations, exposure to caustic substances may be suspected.
- Human Health Significance: None known.

ETIOLOGY AND EPIDEMIOLOGY

FCV is a small, unenveloped, single-stranded RNA virus, a member of the *Vesivirus* genus of the *Calicivirus* family (Fig. 35.1 and Table 35.1). Both domestic cats and other members of the Felidae family can be infected.[2–5] Although dogs have their own genetically distinct calicivirus,[6,7] viruses antigenically and genetically related to FCV have also been detected in dogs with diarrhea (see Chapter 29),[8–10] and some epidemiologic evidence suggests a link between the two.[11] The role of FCV strains in canine disease and the significance of dogs as a reservoir of feline infection are not known. Other caliciviruses have been identified in cats, notably feline norovirus, but the role of this virus in disease is unknown.[12]

A large number of different strains of FCV exist, which vary slightly in antigenicity and pathogenicity, although they are all sufficiently cross-reactive to be classified as one serotype.[13] Although in general antigenicity is not associated with pathogenicity, some evidence suggests that FCV isolates collected from chronic stomatitis cases may show minor antigenic differences.[14,15] Genetically, FCV strains appear to represent one large diverse group, with little evidence of within-group clusters.[16–19] However, several studies have identified potential separate genotypes in Asia and Europe using longer genomic sequences which may provide for greater resolution.[20–24] Enteric strains appear to differ genetically from strains that cause respiratory disease, and appear more likely to resist trypsin, and bile treatment.[25,26] Considerable variability may be seen between individual isolates, particularly in immunogenic regions of the viral capsid gene.[22–28] This genetic diversity is useful epidemiologically in that it allows differentiation among FCV strains.[17,29–31]

Most strains of FCV are sufficiently related antigenically to induce some degree of cross-protective immunity, but cats can still be sequentially infected with different strains of virus and show varying degrees of clinical illness. Some isolates appear to be more immunogenic and cross-reactive than others. The most commonly used strains in vaccine products have been F9 and 255, but other strains have also been used, some in bivalent or trivalent FCV vaccines.[32–34] There is continued discussion over the degree of cross-protection afforded by such vaccines, particularly the original monovalent FCV vaccines. Some evidence indicates that they are still cross-reactive against the majority of field isolates, whereas other studies suggest that the percentage of isolates[17,35] neutralized by such vaccine strains may be decreasing, possibly as a result of immune selection pressures from widespread vaccine use.[17,36–38] Direct comparison between studies, however, can be difficult because results may vary according to factors such as the population tested (including perhaps whether sick or healthy cats are sampled), and the methodology used for testing. Nevertheless, structured, routine monitoring of vaccine efficacy against current field isolates would be useful.[17]

The ability to readily grow FCV in cell culture has led to its frequent use as a surrogate for calicivirus inactivation in disinfection studies, as well as more general studies of calicivirus structure and biology. FCV is moderately resistant in the external environment for days to several weeks on dried surfaces at room temperature, and longer in colder wetter conditions.[13] The virus is not as susceptible to the effects of disinfectants as other respiratory viruses such as FHV-1,[39] but useful disinfectants for both viruses are accelerated hydrogen peroxide or household bleach (5.25% sodium hypochlorite) diluted 1 part in 30 in water (1750 ppm) with added detergent.[40] The use of 5% sodium bicarbonate has also been shown to be effective and has been recommended by the ABCD.[41]

FCV infections are fairly widespread in the general cat population, with a generally higher prevalence in multicat households, shelters, and also in younger animals.[11,17,42–44] The virus is mainly shed in ocular, nasal, and oral secretions, and spread is largely by direct contact with an infected cat. Acutely infected animals are clearly one of the most important sources of virus, but infection also commonly occurs from clinically recovered carrier cats.[13] In some situations, particularly within a cattery, indirect transmission may occur. Contaminated secretions may be present on cages, on feeding and cleaning utensils, and on personnel. Some evidence suggests that feces from fleas fed on artificially FCV-infected blood may infect kittens oronasally,[45] but this is unlikely to be a significant source of infection. Aerosols are not thought to be of major importance for the spread of FCV; cats do not appear to be able to produce an infectious aerosol for this virus during normal respiration, although sneezed macrodroplets may transmit infection over a distance of 1 to 2 m (3 to 6 ft).

Despite vaccination, carriers are widespread in the population and are probably the main reason why FCV is so successful. An understanding of the FCV carrier state is important to help determine strategies for control. The carrier state is widespread in the cat population, with approximately 10% of household pets and 25% to 75% of shelter or colony cats testing positive for FCV shedding (Fig. 35.2).[17,43,46–48] As with other pathogens, FCV is likely to be common in situations of cat hoarding.[49] The virus persists in carriers in tonsillar and other oropharyngeal tissues. Although the precise mechanism of persistence is unclear, it is likely to include immune selection pressure driving antigenic variation in the viral capsid protein, which then allows the virus to evade the host immune response.[22,24,28] However other host, viral, and environmental factors also undoubtedly play a role.

In situations such as boarding and rescue facilities, many different FCV strains tend to be present, probably reflecting the relatively rapid turnover of carrier cats bringing in their own strains from different sources.[28,30] In contrast, in colonies of cats where FCV is endemic, in general only one or two distinct strains circulate.[28,30,50] Longitudinal studies of these endemically infected colonies have shown that although many cats appear to be long-term carriers, only a small minority (approximately 10%) are persistently infected, the remainder undergoing cycles of reinfection from within the colony.[50] Those with true persistent infection continuously evolve their own viral strain over time. Unlike FHV-1, there appears to be no latent phase for FCV carriers; FCV carriers shed virus more or less continuously.[51] The remainder of long-term carriers appear to undergo cycles of reinfection, either with a variant of the same strain, or in some cases, a different strain circulating within the colony. Interestingly, some cats within these endemic situations appeared to be resistant to infection, suggesting either age-related or genetically determined resistance.[51] These findings help explain: (1) the lower carriage rate of approximately 10% in household pets, where opportunity for reinfection is less likely to occur; and (2) the inability in some previous experimental studies to induce a carrier state in small groups of cats.

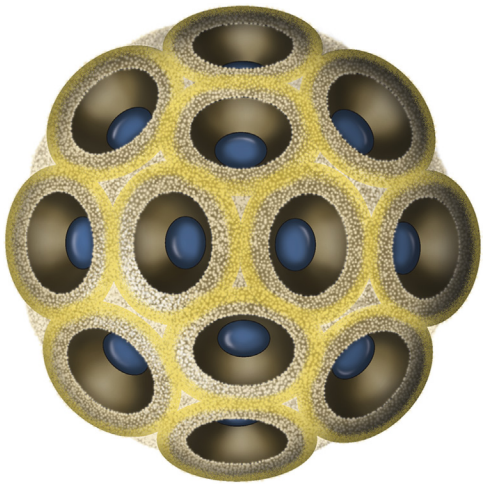

Fig. 35.1 Calicivirus structure.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The natural routes of infection for FCV are nasal, oral, and conjunctival. Viral replication mainly occurs in the oral and respiratory tissues, although some differences between strains can be found. Some strains have a predilection for the lung, and others have been found in synovial fluid macrophages.[52,53] Virus may also be found in visceral tissues, feces, and occasionally in the urine. Oral ulcers are the most prominent pathologic feature of FCV infection.[13] These ulcers begin as vesicles, which subsequently rupture, with necrosis of the overlying epithelium and infiltration of neutrophils at the periphery and the base. Healing takes place over 2 to 3 weeks.

Lower respiratory complications are dominated by multifocal desquamation of activated alveolar macrophages and less frequently occasional type II pneumocytes with fibrin exudation, consistent with diffuse alveolar damage. FCV has also been shown to infect and replicate in alveolar macrophages and, to a lesser extent, type II pneumocytes.[54] Although primary interstitial pneumonia can occur in FCV infection, particularly with more virulent strains, it has probably been overemphasized in the past as a result of experimental studies using aerosol challenge rather than the more natural oronasal routes. More recently it has been suggested that FHV-1 infection may facilitate secondary FCV infection of type II pneumocytes and alveolar macrophages.[54]

Lesions seen in FCV-infected joints consist of an acute synovitis with thickening of the synovial membrane and an increased amount of synovial fluid within the joint. In cases of FCV-associated virulent

TABLE 35.1 Clinically Relevant Caliciviruses

Virus	Host	Reservoirs	Geographic Distribution	Clinical Signs	Human Health Significance	Other
Rabbit hemorrhagic disease virus	Rabbit	May be transmitted by fleas, flies, and mosquitoes	Global	Often acute-onset fever, depression, and death	None	Used as a biological agent to control rabbit populations in Australia
Vesicular exanthema of swine virus	Pig	Sea mammals	West coast USA	Vesicular lesions similar to foot and mouth disease virus	None	Generally considered eradicated in pigs
Norovirus	Mainly human although some affect a range of species including mice, cattle, pigs, cats, and dogs	None known	Global	Human norovirus is generally considered the most common cause of acute gastroenteritis in people	Those noroviruses affecting non-human species are not considered zoonotic	FCV has been used to study calicivirus biology as, unlike most noroviruses, it grows readily in cell culture

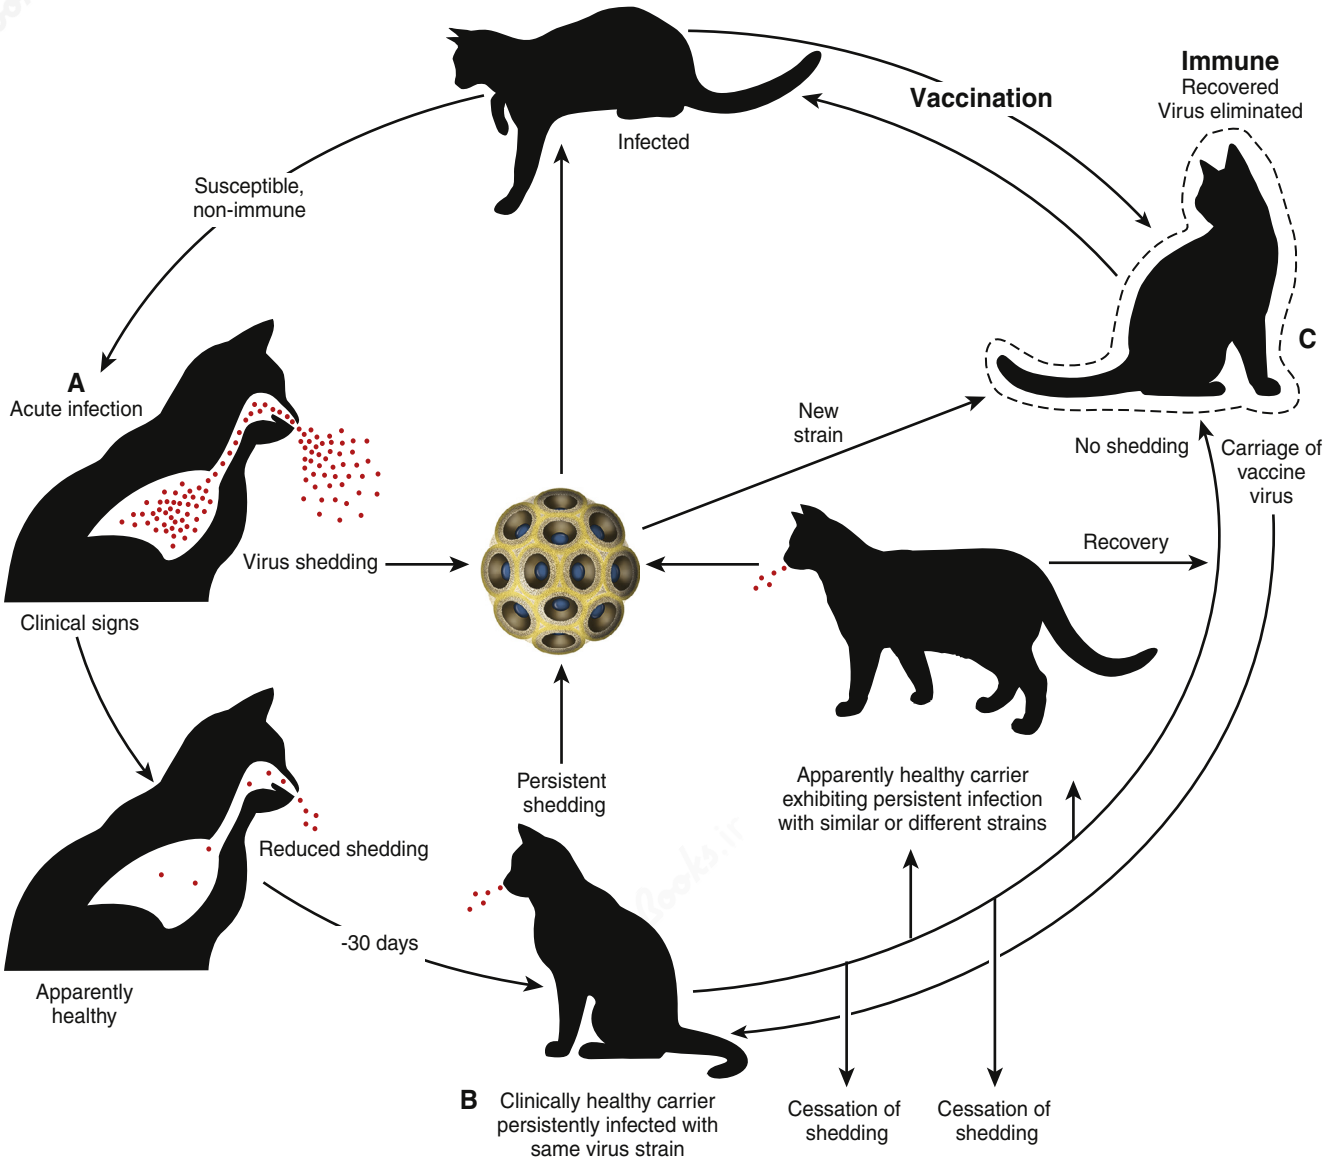

Fig. 35.2 Epidemiology of the FCV carrier state.

systemic disease (VSD), virus gains access to cellular compartments not normally associated with FCV infection.[55] Lesions are widespread and include subcutaneous edema, oral ulceration, and variable levels of cutaneous ulceration, particularly on the pinnae, paw pads, and nares.[51,56–58] Other lesions are more variable and include bronchointerstitial pneumonia and necrosis in the liver, spleen, and pancreas. Viral antigens have been detected in the skin, nasal mucosa, lung, pancreas, liver, and endothelial cells of the dermis associated with necrosis.[51,59]

Strains of FCV can differ in tropism and virulence. Therefore, a wide range of clinical signs may be seen. Most strains induce a fairly characteristic, mild syndrome characterized by pyrexia, oral ulceration, and mild respiratory and conjunctival signs. Signs of enteritis have been associated with some strains.[25,26] Some strains of FCV, however, are nonpathogenic; others are more virulent and may induce more severe systemic disease. Rarely, kittens may develop a fatal pneumonia.[54] Several outbreaks of a severe acute systemic febrile disease with high mortality have been described worldwide caused by particularly virulent strains of FCV (FCV-associated VSD [FCV-VSD]).[57,60,61]

In a typical case of FCV infection, early signs include lethargy and pyrexia. Oral ulceration is the most characteristic feature and may be the only clinical sign present, and it is possible that many cases go unreported (Fig. 35.3). Ulceration is usually on the tongue but can occur elsewhere in the mouth, on the lips, and on the nose. Skin ulceration on other parts of the body occurs rarely. Sneezing, conjunctivitis, and ocular and nasal discharges typically occur but are generally relatively mild.[62,63] Cats with oral ulcers may show hypersalivation. Some strains can cause pneumonia with associated dyspnea, and others have been associated with diarrhea.[25,26]

Other FCV isolates produce a febrile disease with lameness and pyrexia.[64] The lameness may or may not be associated with oral and respiratory signs, and it is likely that considerable overlap exists between the conditions. Affected cats are often dull and anorexic. In most cases, full recovery occurs within 24 to 48 hours. Acute lameness has also been observed after vaccination, and in some of these cases, viruses originating from live vaccines may be involved; this was particularly associated with one vaccine no longer licensed, and lameness following vaccination is now rare.[60]

Fig. 35.3 Lingual ulceration and mucopurulent nasal discharge in a cat infected with FCV.

Many of the described outbreaks of FCV-VSD are nosocomial infections, and each outbreak appears to have been caused by a different FCV strain.[55,57,58,65] Although highly contagious within a group of cats, all outbreaks have been contained, and the disease has not spread into the general population. Possible reasons for the appearance of such strains and for their subsequent disappearance are not understood but have been discussed elsewhere.[13,66] High mortality among affected cats and disease containment may be two important factors that limit spread of these outbreaks, though other factors may play a role.[66]

Cats with FCV-VSD variably show facial and paw edema, pyrexia, classic signs of oral ulceration and upper respiratory infection, icterus, epistaxis and hematochezia, and high mortality. Necropsy findings are again somewhat variable in individual cases but include pneumonia, hepatomegaly, pancreatitis, and pericarditis.[56,57,59,65,67,68] Many affected cats are fully vaccinated, suggesting that, as can occur with more typical strains of FCV, vaccines may not completely protect against these VSD-producing isolates. Although the outbreaks have been relatively well controlled with strict quarantine and isolation, given that FCV is an inherently variable pathogen, clinicians must remain vigilant for further outbreaks of this disease.

The chronic oral disease feline chronic gingivostomatitis complex has also been associated with FCV infection (see also Chapter 125).[69] The prevalence of this condition has been estimated at 0.7% of consultations in first opinion practice in the United Kingdom[70] and can be a particular problem because of the difficulty in treating this condition. In a number of studies, more than 80% of cats with chronic oral disease have been found to shed FCV compared with approximately 20% of controls,[66] but these figures may vary depending on the criteria used to select clinical cases and the diagnostic assays used.[71] Recent work has shown no correlation between FCV load and disease severity or outcome.[72] FCV infection has been associated with acute faucitis,[73] and in one colony of cats, chronic stomatitis developed after the accidental introduction of FCV.[74] However, other agents, in particular FIV, and various host factors are likely to be involved in the condition, and the pathogenesis is not yet fully understood.

Fig. 35.4 Chemosis, mucopurulent ocular and nasal discharge (A); and lingual ulceration (B) in a 6-month-old intact male domestic medium-hair cat with chronic nasal discharge and conjunctivitis. A conjunctival swab specimen tested positive with PCR for FCV RNA and negative for FHV-1, *Chlamydia felis*, and *Mycoplasma* spp. (Courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

Physical Examination Findings

Physical examination findings in cats with FCV infections vary from mild serous ocular discharge and conjunctivitis through to fever, severe mucopurulent ocular and nasal discharges, dehydration, stertorous respiration, tachypnea and/or respiratory difficulty, increased breath sounds on thoracic auscultation, hypersalivation, and ulceration of the nasal planum, tongue, and lips (Fig. 35.4). Because ulcerative lesions can occur at the base of the tongue near the larynx, examination of the entire tongue should be performed in cats that are febrile and inappetent, which may require sedation. Cats with VSD can have edema of the face and lips, icterus, cutaneous ulceration, evidence of petechial hemorrhages, and abdominal pain. Cats with feline chronic gingivostomatitis complex frequently test FCV positive. These animals may have ulceroproliferative caudal stomatitis or buccal/alveolar mucositis and exhibit pain on examination of the oral cavity (Fig. 35.5).

DIAGNOSIS

A range of pathogens other than FCV are associated with upper respiratory tract disease in the cat, notably FHV-1, but also *Bordetella bronchiseptica* and to a lesser extent *Chlamydia felis* (primarily ocular). Generally, FCV remains the most commonly detected pathogen in

Fig. 35.5 Severe lymphoplasmacytic caudal stomatitis in a cat infected with FCV.

diseased cats, either alone or less frequently in mixed infections.[75] While clinical signs can be suggestive of one pathogen over another, they are rarely pathognomonic. Specific diagnostic testing for FCV is not always necessary, particularly in individual cases of relatively mild upper respiratory tract disease. However, identifying a causative agent may be helpful when disease is severe, warranting specific therapy, where multiple cats are involved, and where disease occurs in vaccinated cats.

Laboratory Abnormalities

There are no specific CBC, biochemistry profile, or urinalysis abnormalities that aid in a diagnosis of FCV infection. The CBC may be normal or show a mild to moderate neutrophilia, sometimes with band neutrophils or neutrophil toxicity, and lymphopenia in severely affected cats with secondary bacterial pneumonia. Hematological abnormalities in cats with VSD have included mild to severe anemia, thrombocytopenia, neutrophilia, and lymphopenia. Serum biochemistry findings in cats with viral respiratory disease are usually unremarkable unless disease is severe or chronic. Cats with VSD may have hypoalbuminemia, hyperbilirubinemia, mildly increased serum activities of ALT and AST, and mild to moderately increased serum CK activities. Serum CK activities up to 11,000 U/L can occur.[56] Cats with chronic stomatitis may have hyperglobulinemia due to a polyclonal gammopathy.

Tracheobronchial lavage specimens from cats with pneumonia may show a suppurative or mixed exudate, sometimes with evidence of sepsis. Aerobic bacterial culture with mycoplasma culture if possible is indicated on wash specimens, and antimicrobial susceptibilities should be obtained for any aerobic bacteria isolated. Organisms such as *Pasteurella* spp., *Staphylococcus pseudintermedius*, *Streptococcus* spp., *Escherichia coli*, *Klebsiella pneumoniae*, and some *Mycoplasma* spp. infect the airways as opportunists and are not considered to be primary pathogens. Bacterial culture of nasal swabs is generally not recommended because it often leads to growth of normal flora, which has no clinical relevance.

Diagnostic Imaging

In uncomplicated infections, plain thoracic radiographs may be unremarkable or show a mild diffuse interstitial to bronchointerstitial pattern. Alveolar patterns or lung lobe consolidation may occur with secondary bacterial pneumonia.

TABLE 35.2 Essential Features of Clinical Respiratory Disease Related to the Pathogen Involved

Microbiologic Tests

A presumptive diagnosis may be attempted based on clinical signs alone. For example, predominantly oral ulceration might indicate FCV infection, whereas marked sneezing with more severe respiratory and conjunctival signs might suggest infection by FHV-1 (Table 35.2). With *Chlamydia* infection, the main clinical sign is marked persistent conjunctivitis (see Chapter 49).

Confirmatory diagnosis of FCV is typically made by collection of oropharyngeal swabs for testing, and is generally sufficient (Table 35.3). However, addition of conjunctival or other specimens may modestly increase sensitivity of respiratory pathogen diagnosis.[76] Traditionally, viral isolation in feline cell cultures has been used to detect FCV.[77] Several RT-PCR assays have now been described, using various approaches including targeting different regions of the genome[78–80] and such molecular testing for FCV is now being widely used commercially. PCR and sequencing, particularly of the hypervariable region of the capsid gene, are useful for distinguishing between FCV isolates and have been extensively used to better understand the epidemiology of the disease.[17,66] Serology is generally not helpful in the diagnosis of FCV infection because of the high prevalence of seroreactivity from vaccination.

When an organism is detected in an animal with respiratory disease, it is reasonable to assume that the agent is involved in the disease process. However, especially for FCV and *Bordetella*, a relatively large number of clinically healthy cats will also be shedding the organisms. Therefore interpretation of a positive result may be problematic unless taken in conjunction with other factors, such as the characteristic clinical signs. Similarly for FHV-1, latently infected cats may also shed reactivated virus, and thus a positive result may also be unrelated to the observed clinical signs. In an epidemiologic context, however, a positive result indicates the cat has been infected with FHV-1 and thus has the potential to infect other cats. For FHV-1, quantitative PCR can

TABLE 35.3 Diagnostic Assays Available for FCV in Cats

Assay	Specimen Type	Target	Performance
Virus isolation	Oropharyngeal swabs, transtracheal and bronchoalveolar wash specimens, airway and lung specimens collected at necropsy	Whole virus (viable)	False negatives can occur in specimens that contain no or low numbers of virus particles. May take several days to weeks and requires specialized techniques and expertise
RT-PCR	See above	Conserved regions of the FCV genome	Sensitivity and specificity may vary depending on assay design. Sensitivity may be low because of brief shedding for some viruses or low-level shedding in chronic infections. Assays may not detect all virus strains. Testing specimens from multiple different anatomic sites, or combining PCR with other diagnostic tests can increase sensitivity. Attenuated live vaccine virus may be detected after vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of degradation of viral nucleic acid during specimen transport. Results rapid (1–2 days)
Serology	Serum	Antibodies against FCV capsid antigens	Interpretation complicated by previous vaccination and exposure. May be useful in outbreak situations that involve a novel strain of FCV. May be useful to quantify immune responses and experimentally for estimates of cross-protection
Histopathology	Tissue specimens	Immunostaining for viral capsid antigens	Antigen load can be low even in positive samples. Strain variation again means false negatives may occur depending on the precise antibody used in the test. Particularly useful as an adjunct to the diagnosis of VSD.

VSD, virulent systemic disease.

provide additional information with respect to viral load and stage of infection, especially if consecutive samples are taken. In countries where intranasal vaccines are available, a positive result may be indicative of FHV-1 or FCV vaccine virus rather than wild-type viruses. FCV can be also detected in fecal specimens, although the significance of this is unknown.[2,81]

Pathologic Findings

Gross lesions in cats with FCV infections include cutaneous and lingual ulcerations, submandibular or retropharyngeal lymph node enlargement, mucosal hyperemia, and mucopurulent exudate within the nasal cavity and trachea. The oral ulcers most typical of FCV infection begin as vesicles, which subsequently rupture, with necrosis of the overlying epithelium and infiltration of neutrophils at the periphery and the base. Healing takes place over 2 to 3 weeks. Rarer lower respiratory complications are dominated by multifocal desquamation of activated alveolar macrophages and occasional type II pneumocytes with fibrin exudation, consistent with diffuse alveolar damage; FCV has been shown to infect and replicate in these cell types. Lesions seen in FCV-infected joints consist of an acute synovitis with thickening of the synovial membrane and an increased amount of synovial fluid within the joint; viral antigen in synovial macrophages suggests these cells may be permissive as seen in the lung.

Necropsy findings in cats with VSD have been variable. Gross lesions are widespread and include subcutaneous edema, ulceration of the mouth, and variable levels of ulceration of the skin particularly on the pinnae, pawpads, and nares. Frequently reported findings include individual hepatocellular necrosis and dissociation with minimal inflammation, acute interstitial pneumonia, and free pleural and abdominal fluid.[56,57,65,67] Acute necrotizing vasculitis of subcutaneous and oral submucosal vessels has been reported.[82] Intestinal crypt necrosis and pancreatitis have been reported in experimentally infected cats. Viral antigens have been detected in the skin, nasal mucosa, lung, pancreas, liver, and endothelial cells of the dermis associated with necrosis.

TREATMENT AND PROGNOSIS

Good nursing care is essential in cases of feline respiratory disease, and in milder cases is generally best given at home by the owner. Many cats will not eat because of an impaired sense of smell or oral ulceration, and thus they should be encouraged to eat by offering highly palatable, aromatic foods. Warm, freshly prepared food may have more appealing flavor and odor. Appetite stimulants may be effective in some cats. If eating is painful, baby foods or specialized proprietary or blended food may be helpful. Cats with severe illness may require hospitalization and fluid therapy, and when anorexia is prolonged, placement of a feeding tube may be indicated. Nasal discharges should be wiped away with saline. Mucolytic drugs (e.g., bromhexine hydrochloride) have been suggested to help clear airways in the more chronic phase, but conventional steam inhalation (e.g., placing the cat in a steamy room) or nebulizing saline also may be useful. Administration of pain medications and chlorhexidine mouthwashes may improve appetite for cats with painful oral ulcerations.

In most cases of viral respiratory disease, antibacterial treatment may not be required. Current guidelines suggest that antibacterials are only indicated when clinical signs persist for over 10 days and/or when the cat is systemically unwell; in such cases, doxycycline or amoxicillin/clavulanate are preferred.[83] Because swallowing solid tablets may be painful for cats, antibiotics may need to be given as syrups or long-acting injections, or through a feeding tube.

No specific antiviral drugs are available for treatment of FCV infections. Ribavirin is active in cell culture but was too toxic for *in vivo* use.[84,85] FCV strains show varying susceptibility to IFN *in vitro*.[86] Some authors advocate the use of IFN to treat feline chronic gingivostomatitis complex.[13,87] A synthetic antisense nucleotide sequence, phosphorodiaminate morpholino oligomer, which specifically binds to FCV, was trialed in kittens during natural outbreaks of FCV-VSD. The results suggested an increased survival in treated cats compared to untreated animals.[88] However, this was a small-scale study and such therapies are not commercially available.

IMMUNITY AND VACCINATION

For FCV, immunity has generally been measured by serum virus-neutralizing (VN) antibody levels. Systemic antibodies measured by VN have always been considered the hallmark of immunity for FCV and are certainly important in protection, as studies using mouse-cat chimeric antibodies have also shown.[89,90] However, some cats with no detectable FCV-VN antibody have demonstrated immunity to re-challenge with a heterologous strain, and several types of cell-mediated immune responses have been reported.[91] In a 2021 study, attenuated live vaccination of research cats induced cellular but not humoral cross-protective immune responses, highlighting the importance of non-humoral mechanisms of immunity against FCV.[92] For both FCV and FHV-1, local immune responses are also likely to be important. Nevertheless, for both viruses, a reasonable correlation has been shown with serologic (VN and ELISA) tests to predict resistance or susceptibility to disease after challenge.[32,93] The ultimate test of immunity is, of course, response to challenge.

With FCV infection, homologous VN antibody titers are generally higher than those in FHV-1 and are better correlated to protection,[32] and immunity is also longer lived. However, some variation exists, depending on the viral strain involved and whether homologous or heterologous protection is being considered. Reinfection with a second strain will generally boost responses to both strains. After vaccination against FCV, reasonable protection has been reported to last for at least 3 years, and moderate levels of antibody for at least 4 years.[93–96] However, this will likely depend on vaccine and challenge strain combinations evaluated.

For FCV, in most kittens, MDAs persist for 10 to 14 weeks.[13] However, there is considerable variation for both viruses. In one study, 20% to 26% of kittens had no detectable antibodies at 6 weeks of age.[97] In contrast, in some animals, levels of MDA that interfere with vaccination may persist until 12 to 14 weeks of age.[97–99] Low levels of MDA do not necessarily protect against subclinical infection.

Vaccines for FCV have been available for many years and vaccination has been relatively successful in controlling disease. However, disease can still be a problem, especially when cats are kept grouped together and when kittens lose their MDA before vaccination. FCV is very widespread in the cat population and carriers are common, ensuring plenty of exposure for naïve cats. Prevention and control, therefore, often require a combined approach of vaccination and management.

Three types of FCV vaccines are commercially available: attenuated live virus vaccines administered parenterally or IN, and inactivated virus vaccines given parenterally. The latter are generally adjuvanted, but products are available in some parts of the world where the inactivated FCV component is without adjuvant.

In previously unexposed cats, all vaccines induce reasonable protection against disease. There is increasing evidence that vaccinated animals shed less virus following subsequent challenge.[47,95] However, vaccination does not completely protect against infection or the development of the carrier state, and as a result, vaccinated animals can still act as an important reservoir of FCV infection in the population.

Several FCV strains are used in commercial vaccines, including strains F9 and 255. In addition, bivalent (G1/431) and trivalent vaccines have been developed and in some cases marketed, containing additional strains of FCV including those associated with VSD.[32,34,95,100,101] Most of these strains seem to protect against the majority of FCV isolates.[17,102] A 2021 study showed reduction in viral RNA loads, duration of RNAemia, and severity of clinical signs in cats vaccinated with a single attenuated live FCV strain (F9) and challenged at 46 and 99 weeks with heterologous strains.[103] However, for all vaccines, the antigenic diversity of FCV means that strains will probably vary in the degree of protection offered by different vaccines. Multivalent vaccines may increase the proportion of strains against which the vaccines are effective when compared to the individual antigens that they contain,[32,34,100,101,104,105] but more studies are needed to validate this.

FCV vaccines are only licensed to control acute upper respiratory tract disease. There is no evidence that vaccines affect the onset, development, or course of chronic stomatitis. For VSD, many outbreaks have been reported in vaccinated animals. Evidence for protection against VSD is perhaps conflicting. It is clear that several outbreaks have been reported in vaccinated animals. However, experimental challenge studies for some FCV vaccines have shown protection against individual VSD strains.[32,100] Taken together, it is likely that other potentially virulent strains exist in the field but remain undetected because they happen to be sufficiently neutralized by vaccination. However, all VSD outbreaks have so far been caused by distinct strains, and there is no evidence to suggest the virulent viruses have a unique antigenic profile, distinct from more typical strains.[55,66] Therefore it is likely that no vaccine will protect against all VSD strains. The priority for vaccine efficacy should be to demonstrate broad general cross reactivity against a wide range of strains of varying pathogenicity that remains stable over time.

Parenteral attenuated live vaccines should be administered carefully because clinical signs can be induced if the vaccine virus reaches the oral-respiratory mucosa (i.e., if the cat licks the injection site or if an aerosol is made with the syringe). Vaccine virus should not become systemic; however, replication of FCV vaccine virus after parenteral inoculation may sometimes occur, with the potential for disease in the vaccinated cat and spread to other cats.[13,106] However, genetic typing of FCV isolates from vaccine reactions has shown that the majority are associated with coincidental field virus infection, with vaccine-like viruses only being isolated rarely from either vaccine reactions or the general cat population.[28,29,50,60,107]

Intranasal vaccines induce strong protection, but mild to moderate adverse effects may develop, such as sneezing and oculonasal discharges. Intranasal vaccines, however, are useful for rapid (2 to 4 days) onset of protection.[108–110] Intranasal vaccines used in conjunction with parenteral vaccine on entry have reduced the severity of upper respiratory disease in cats introduced or maintained at contaminated shelters for 3 or more days.[111]

Inactivated adjuvanted FCV vaccines are also effective, and modern adjuvants have led to improvements in immunogenicity. Concerns about an association between adjuvanted vaccines and injection site sarcomas have led to marketing of a nonadjuvanted vaccine containing inactivated FCV antigens in some parts of the world, although the FHV-1 and feline panleukopenia fractions remain attenuated. Vaccination with an inactivated vaccine during pregnancy can help protect kittens by prolonging the duration of MDA. However, product information supplied by the manufacturer should be consulted to determine whether this is approved.

There is a general agreement that FCV vaccination is a core requirement for all cats, such that all cats should benefit from vaccine protection. However, the timing of such vaccines are complicated as local and national guideline groups—including the AAFP, the ABCD, and the WSAVA—seek to balance the desire to reduce injections (and hence sarcoma risk) with the need to ensure high levels of protection in the face of uncertain MDA levels and duration of immunity. In most cases, product data sheets advocate a primary kitten course with parenteral vaccines at approximately 9 and 12 weeks of age. A third vaccination may be considered 3 to 4 weeks later when MDA levels are believed to be high enough to interfere with the first two vaccines.[97–99,112] For example, a third kitten vaccine may be rationally introduced in populations of cats where MDA levels are unknown but where disease has occurred previously in young cats before the first booster (at 6 months or 1 year of age). Similarly, annual booster vaccines would be reserved for those adult cats perceived to be exposed to high-risk situations

(e.g., boarding catteries and rescue shelters), with triennial vaccination being sufficient for cats at low risk (e.g., indoor cats; those living in areas of low cat densities where cat populations are generally stable). Such a tailored approach clearly requires an individual risk-benefit assessment to determine the most appropriate vaccination strategy for a particular cat. The different approaches to vaccination are reflected in practice where it seems a variable approach to vaccination is taken. The reader is referred to Chapter 20 for more information on immunization and the appendix for vaccination interval recommendations.

PREVENTION

Household Cats

After the first booster, pets should be vaccinated regularly against FCV and FHV-1 (1 to 3 years), the frequency depending on the individual cat's perceived risk, and also the specific vaccine being used and its duration of immunity claim. In general, however, for cats at low risk (e.g., indoor cats; those living in areas of low cat densities where cat populations are generally stable), triennial vaccination is likely to be sufficient, whereas cats exposed to high-risk situations (e.g., boarding catteries and rescue shelters) should be vaccinated annually. Ideally, to minimize the possibility of infectious disease, a friend or neighbor should feed the cat while the owner is on vacation, rather than boarding the cat in a cattery. Individual cats should be protected from stress and high-risk social contact as much as possible to avoid exposure.

Boarding Catteries

All cats entering a cattery should have an up-to-date vaccination record for FHV-1 and FCV.[46] In boarding catteries, where animals may be stressed and exposure to carriers is likely, annual boosters may be advisable. When rapid protection is required, the intranasal vaccine may be advisable. Clients should be aware that such vaccines themselves may induce mild clinical signs.

Cattery owners should not rely on vaccination alone for disease control because pathogens will inevitably be present either from the occasional cat incubating disease or from carriers. Thus, measures should be taken to prevent spread of infection and reduce the concentration of infectious agents in the environment (Box 35.1).

Shelter Facilities

In general, the same management measures apply as those with boarding catteries. Although this practice may be more difficult to achieve, molecular typing studies have demonstrated that limiting the spread of individual FCV isolates within a shelter is possible if good hygiene measures are used.[30,50] Because the immune status of cats in a rescue shelter is often unknown, incoming animals should ideally be quarantined from existing residents. Unless animals can be isolated on arrival for 3 to 4 weeks, parenteral vaccines may not have time to become effective.[95] Those with clinical signs should also be isolated. In these circumstances, use of intranasal vaccines may be advisable if available. Stress plays an important role in predisposing to infection and disease for a range of feline pathogens, and it is good practice to reduce stress levels where possible.[113] The reader is referred to Chapter 16 for more information on prevention of infectious diseases in shelter environments.

Breeding Catteries

If any cattery has contact, whether direct or indirect, with other cats, it is safest to assume that most will have some level of FCV infection unless proven otherwise by repeat diagnostic testing. In closed colonies trying to stay virus free, use of inactivated vaccines is preferable. Care should be taken to avoid bringing virus into the colony; any cat with a history of, or contact with, oral or respiratory disease may be a carrier. Vaccinated cats can also be carriers, and kittens can be infected subclinically because of MDA. This, in part, explains the risk of infection from cat shows, where many cats are FCV positive. However, the greatest risk of infection to disease-free households is likely to be from stud cats and new breeding stock when exposure is prolonged; introduction of such animals should ideally be from respiratory disease-free colonies.

Cats entering a disease-free colony should be quarantined for 3 weeks to identify animals incubating the disease. Cats should be tested for virus shedding at least twice a week during this time. This practice increases the probability of detecting FHV-1 (as virus may reactivate after a change of housing) and some FCV carriers that may be shedding only low levels of virus. Even so, the risk still exists of importing a latent FHV-1 carrier or a low-level FCV carrier that may be a source of infection. For most situations, the only reasonable course is to attempt disease control (Box 35.2).

PUBLIC HEALTH ASPECTS

Feline calicivirus is generally considered species-specific and poses no known human health risk. However, FCV has been used as a surrogate virus for the study of human norovirus because of shared biochemical and genomic properties between the two viruses. It was also used to develop a mask decontamination method to assess the ability to reuse N95 masks in the COVID-19 pandemic.[114]

BOX 35.1 Recommendations to Prevent the Spread of the FCV and Other Respiratory Viruses in Boarding Catteries

- Admit only fully vaccinated cats, preferably revaccinated within a year before admission.
- House cats individually with solid partitions between pens, unless cats are from same household.
- Ensure that cage fronts are at least 1 m apart.
- Put known carriers or cats with history of respiratory disease in a separate section, or at least at one end of the cattery, and clean, feed, and provide water to them last.
- Ensure that surfaces of pen can be easily disinfected and that food and litter bowls can be easily removed without entering the pen (i.e., do not handle cats more than necessary).
- Feed cats in same order each day and attend to each pen completely before moving on to the next.
- Either disinfect hands between each pen or have individual rubber gloves for each pen, for use only with that pen.
- Disinfect gloves thoroughly before use with a new boarder. Alternatively, use disposable gloves.
- Wear rubber boots and step into a disinfectant bath if it is necessary to enter a pen.
- Either use disposable food trays or have two sets of food bowls used on alternate days. Soak used set in a 1:30 household bleach (5.25% sodium hypochlorite) solution with detergent for several hours and then rinse and allow to dry until reuse 24 hours later.
- Prepare food in a central area.
- Use similar system to food bowls for litter trays.
- When a cat goes home, thoroughly disinfect cage, allow to dry, and preferably leave empty for 2 days before reusing.
- Reduce concentration of virus in the environment by providing adequate ventilation, low relative humidity, and optimal environmental temperatures.

BOX 35.2 Feline Respiratory Disease Control Program in a Breeding Cattery with Endemic Disease

Provide regular vaccination.

Give booster vaccinations to queens either before mating or during pregnancy (inactivated vaccine only, if licensed for this use).

Keep cats as stress-free as possible, and use good management practices to reduce spread of viruses within the colony.

Avoid breeding queens with a history of oral or respiratory disease in their kittens.

Move queens into isolation at least 3 weeks before term so that the kittens are not exposed to carriers in the colony and that any shedding episode from the queen, as a result of the move, will end before parturition.

Wean kittens into isolation away from the queen as soon as feasible (ideally at 4 to 5 weeks before MDAs wane).

Vaccinate all kittens as soon as MDAs are at a noninterfering level (normally 9 or more weeks), and keep them in strict isolation until a week after the second dose (normally at 12 weeks, but in some cases after a third vaccination 3 to 4 weeks later).

Earlier FHV-1 and FCV vaccination schedules with intranasal (if available) or parenteral vaccines may be used, although these are not always licensed for early use and should be used with care. Parenteral vaccines can be given from 6 weeks of age, at 3-week intervals until 12 weeks, and if indicated, up to 15 to 16 weeks of age. Intranasal vaccination should be carried out 7 to 10 days or so before disease has been occurring and then again at 12 weeks. Some evidence indicates that multiple doses are not necessary, although they were originally advocated.

CASE EXAMPLE 1

Signalment

"Sam," a 1-year-old male neutered domestic shorthair cat from Orangevale, CA.

History

Sam's owner, a veterinary technician, reported a 4-day history of illness that began with ptyalism and progressed to inappetence and difficulty prehending both canned and dry food. The owner also noted that Sam's mouth had a foul odor. There had been no diarrhea, vomiting, coughing, or sneezing. He was an indoor-outdoor cat and was obtained as a kitten, with no previous health problems. There was one other 2-year-old cat in the household that was apparently healthy. Sam was up to date on vaccinations, which included vaccines for FCV, FHV-1, FPV, FeLV, and rabies.

Current Medications

None.

Physical Examination

Body weight: 5.6 kg

General: Quiet, alert, responsive, hydrated. Ambulatory on all four limbs. Temperature = 102.9°F (39.4°C), heart rate = 180 beats/min, respiratory rate = 48 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: A normal haircoat was present and there was no evidence of ectoparasites.

Eyes, ears, nose, and throat: No significant abnormalities of the eyes, nose, or ears were noted. There was moderate ptyalism, and examination of the oral cavity revealed multiple ulcerations along the right lip and a 1-cm ulcer on the rostral aspect of the tongue.

Musculoskeletal: A body condition score of 6/9 was noted. No visible lameness or musculoskeletal abnormalities were noted.

Cardiovascular: Strong femoral pulses were noted. No murmurs or arrhythmias were detected on thoracic auscultation.

Respiratory, gastrointestinal, and genitourinary: No abnormalities detected.

Lymph nodes: There was mild enlargement of the right mandibular lymph node.

Laboratory Findings

Sam was anesthetized and a swab specimen was collected from the oropharynx. The specimen tested strongly positive for FCV using real-time PCR.

Diagnosis

FCV infection.

Treatment

While under anesthesia, an esophagostomy tube for administration of food and water was placed without complication. In addition, Sam was prescribed buprenorphine (1.5 mg PO q12h) for pain and oral sucralfate suspension in an attempt to coat the lingual ulcerations (1 mL PO q8h, at least 1 hour before buprenorphine). The feeding tube was removed 2 weeks later.

Comments

This case was interesting because of the sole finding of lingual ulcerations, without any other evidence of respiratory disease, which was so dramatic that a caustic cause of oral ulceration was suspected by the clinician on the case. The positive PCR test result does not prove that the cause of the oral ulcerations was FCV, because of the carrier state, but the strong positive test result in association with typical clinical signs in a young cat owned by a veterinary technician was strongly suggestive. The cat may have acquired infection from contact with other outdoor cats, or it is possible that the owner introduced the virus on her clothing or other fomites because she was unwittingly in contact with a carrier cat at her workplace. Although she was instructed to do her best to separate this cat from her other cat and disinfect her household with disinfectants that have activity against FCV, it is likely that her other cat had already been exposed. Fortunately, no clinical signs appeared in this cat. This case also illustrates the occurrence of disease in the face of proper vaccination, possibly because of lack of strain cross-protection.

VetBooks.ir

CASE EXAMPLE 2

You provide veterinary care to a breeding colony of some five queens. On the 15th February, four 12-week-old kittens received their second attenuated live core FVRCP vaccine. One week later (22nd February), the four kittens developed lingual ulcers and fever.

The owners were extremely disappointed as they were not aware of previous infections in their colony. Because of the history of recent vaccination, the similarity of the signs to FCV infection, and the fact that an attenuated live vaccine was used, you submit plain oropharyngeal swabs in virus transport medium for diagnostic testing. Four days later, the results confirm that three of the kittens are infected with FCV. Oropharyngeal swabs were also submitted for *Bordetella bronchiseptica* isolation but were negative.

As a result of the positive tests for FCV, you discuss this case with the vaccine manufacturer as a potential adverse event. It is agreed that one of the kitten FCV isolates be typed and compared to the sequence of the virus in the vaccine. This sequence strongly suggested that the FCV infection in the breeding household did not originate from the vaccine, rather that the cats were infected with a distinct field strain of virus.

Several questions should be considered in regard to why the kittens were infected with FCV field viruses so soon after vaccination.

1. *Is FCV causing the disease?* It is possible the disease in the kittens was not caused by FCV. The prevalence of FCV carriers is high and therefore the FCV infection of these cats may have been incidental. However, the clinical signs were quite suggestive of FCV infection, so it seems reasonable to assume that the virus caused the disease.
2. *Why did these kittens develop clinical disease if they have already received vaccines?* The incubation period for FCV is generally approximately 2 to 7 days, although it may be longer in some cases. Therefore it seems likely that the kittens were infected approximately between the 15th and 20th February, 0 to 5 days after their second vaccination on the 13th February. At this stage, the kittens were not completely protected by the anamnestic response of vaccination. Therefore this case cannot be considered a failure of the vaccine to protect. This only becomes a concern when fully vaccinated animals develop clinical disease.
3. *Where did the virus isolated from the kittens come from?* The most likely origin of this field virus is other cats within the breeding household. The prevalence of FCV in households can be very high (up to 90%), unless there is strict isolation of the cats in the colony. Infection can remain clinically silent in fully vaccinated adult cats in such households. Clinical disease may only occur when kittens become infected in the immunity gap between the decline of MDA and onset of vaccine immunity. It can be useful to determine the extent of FCV (and FHV-1) infection in such colonies by testing some of the other cats, especially if clinical disease in kittens is a regular occurrence. Owners are sometimes surprised to learn that their adult cats have FCV (or FHV-1) infection when they have no clinical disease and have been regularly vaccinated. This is because FCV (and FHV-1) vaccines do not protect against the establishment of the carrier state.

Feline Foamy (Syncytium-Forming) Virus Infection

Chrissy Eckstrand

KEY POINTS

- Cause: FFV, family *Retroviridae*, subfamily *Spumaretrovirinae.*
- First Described: 1969, United States.[1]
- Affected Hosts: Domestic cat and many other Felidae.
- Geographic Distribution: Worldwide.
- Route of Transmission: Unknown, but vertical transmission (*in utero* and/or mammary) and salivary transmission through close contact are hypothesized.
- Major Clinical Signs: An association between FFV infection and clinical disease remains unproven, but the virus has been detected in cats with idiopathic polyarthritis.
- Differential Diagnosis: Primary immune-mediated polyarthritis, polyarthritis secondary to other infections such as FeLV, FCV, *Chlamydia felis*, *Mycoplasma* spp. infection.
- Human Health Significance: Although foamy viruses can infect multiple cell lines, no known transmission from cats to humans has been documented.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

FFV, previously known as "feline syncytium-forming virus," is a retrovirus in the family *Retroviridae*, subfamily *Spumaretrovirinae*.[2] Host-specific viruses of this genus have also been isolated from various mammalian species including cattle and nonhuman primates and often have no, or low, pathogenic potential.[3,4] Foamy viruses are atypical retroviruses in that viral particles bud from the endoplasmic reticulum, can contain DNA or RNA, and are highly cell-associated. Additionally, reverse transcription can occur late in the cell infection cycle.[2,5] Proviral DNA is integrated into the host cell chromosome, and persistent infection, with or without viral production, can result. The prevalence of FFV infection is high in both clinically healthy and diseased cats. At least two genotypes and serotypes have been identified, which share broad serologic cross-reactivity even to the serotype-specific ectodomain of the FFV Env-SU glycoprotein.[6–8] Virus has been isolated from primary cultures of tissue and body secretions in up to 90% of a population of cats.[9] More typically, the prevalence of infection in a cat population varies between 25% and 50%, depending on the age, geographic location, and local environment of the cats.[10–16] Furthermore, 50% or more of kittens born to FFV-infected queens are infected at birth,[15] and 15% of cultures from fetal cats are positive for the virus, suggesting that it can be transmitted vertically.[17] *In utero* infection probably occurs by the transfer of infected maternal leukocytes across the placenta, but infection may also be transmitted through milk of lactating animals.[15]

The highest prevalence of FFV infection is in roaming or outdoor cats, suggesting possible transmission through bite wounds (like FIV); however, epidemiologic evidence suggests that FFV is more likely transmitted by intimate social contact (like FeLV).[18] This is also supported by serologic evidence that male and female cats, with or without neutering, have an equal rate of seroreactivity.[14] Some wild cat species (*Felis silvestris, Felis iriomotensis,* and *Felis bengalensis*) also have a relatively high prevalence rate of seroreactivity to FFV; however, extensive surveys are not available.[13,19,20]

FFV is a nuisance to virologists and manufacturers of feline therapeutics like vaccines and mesenchymal stem cells because it often only becomes apparent in feline tissues and cell cultures after multiple passages.[21–23] *In vitro*, FFV is not highly host specific; in addition to cat cells, it infects cells of dogs, chickens, humans, and bats.[20] This is supported by evidence that foamy viruses utilize heparan sulfate, a ubiquitous cellular polysaccharide, as an attachment factor.[24] When FFV is produced, it is enveloped and has long glycoprotein spikes (Fig. 36.1A). Viral particles may accumulate in the host cell cytoplasm within membrane-bound vesicles, giving the cell a foamy appearance. In cell culture, it produces multinucleated syncytia within 1 to 2 weeks of growth in certain rapidly multiplying tissue cultures (Fig. 36.1B). Cell lysis is a late event because large syncytia are not viable. Syncytium formation in cell culture is not unique to FFV; it also has been associated with a variant of FeLV where an insertion into the FeLV envelope glycoprotein gene is responsible for this CPE.[25] FFV can be distinguished from FeLV, which is visualized only as it buds from the cell, whereas FFV often forms recognizable intracytoplasmic inclusions and preassembled nucleocapsids within the cytoplasm before budding (see Fig. 36.1A).

FFV has been considered an attractive retroviral vector for the delivery of feline vaccine antigens and heterologous genes because of its lack of apparent pathogenicity, and its suitability as such has been demonstrated.[26–30] The complete genome of FFV proviral DNA has been cloned, manipulated to be replication-competent or replication-deficient depending on the therapeutic purpose,[31,32] and explored for use in cats.[31–34]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

FFV has never been unambiguously associated with disease. Many cats have been infected naturally and experimentally and had no

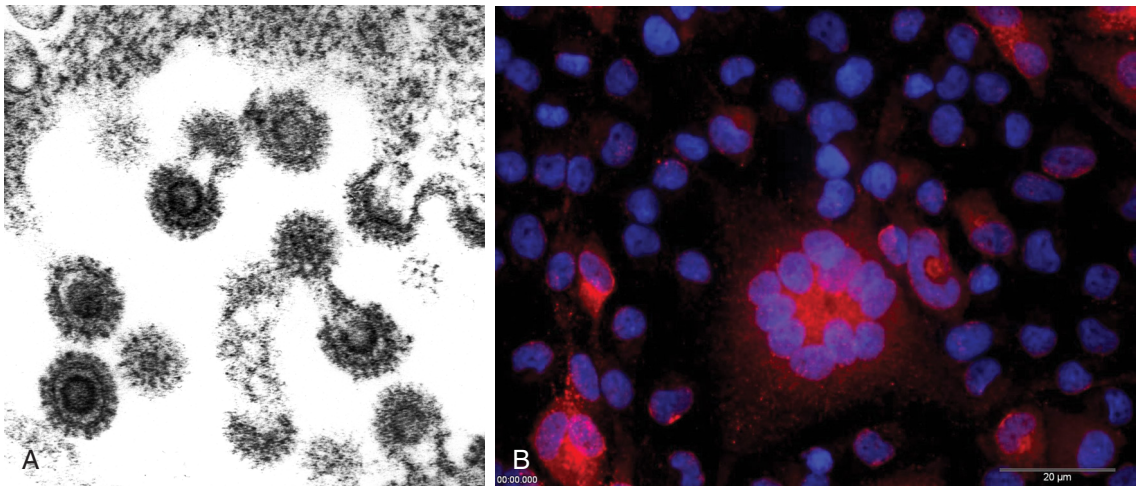

Fig. 36.1 Feline foamy virus (FFV) particles and proteins in productively FFV-infected Crandell-Rees Feline Kidney (CRFK) cells. (A) Thin-section electron microscopy of budding and released FFV particles displaying the regular Env glycoprotein spikes in the membrane surrounding the FFV core. CRFK cells were processed for electron microscopy 5 days after infection (Magnification: ×160,000). (B) Detection of FFV proteins in infected CRFK cells 2 days after infection. Protein antigens staining red are visible in a multinucleated cell. FFV-specific antigens were detected using FFV cat reference serum and a goat anticat IgG *(red)*. Nuclei were counterstained with Hoechst dye *(blue)*. A multinucleated FFV-induced syncytium (cell fusion, center) and cells displaying no cytopathic effects are positive for FFV antigens. (A, Courtesy Birgit Hub, Hanswalter Zentgraf, and Dragana Slavkovic, German Cancer Research Centre, Heidelberg. B, Courtesy Anne Bleiholder, German Cancer Research Centre, Heidelberg.)

clinical illness, a scenario that may reflect a very close virus-host co-adaptation.[35,36] Virus replication in the cat is a complex interplay between host immunity, host antiviral restriction factors such as APOBEC3 proteins, and virus accessory proteins, such as Bet, which counteracts APOBEC3.[37–40]

Reports about FFV pathogenicity are controversial and conflicting. Investigations into the presence of the virus in cats with chronic polyarthritis are quite variable with 100% of cats affected with chronic progressive polyarthritis in one study and 15% in another.[41,42] Concurrent FeLV infection was found in 70% of cats in the former study mentioned. The prevalence of infection with both viruses was 2 to 10 times greater than that in age-matched cats not having chronic progressive polyarthritis. By altering the host immune system, FeLV may potentiate the ability of FFV to produce disease. Combined infections with FFV and FIV are also frequently found.[42,43] However, co-infection with FFV and FIV did not increase the severity of FIV-induced illness in the early stages of the disease.[32] A combined infection is most likely a result of a common mode of transmission rather than a mutual pathogenic mechanism. FFV strains infect lymphoblastoid cells *in vitro*, producing altered replication, syncytia formation, and fragmentation of cellular DNA.[44] These features of apoptosis may be responsible for independent immune alterations in infected cats.

Immune-mediated polyarthritis is hypothesized to result from chronic antigenic stimulation and immune complex deposition. Arthritis that occurs in conjunction with FFV infection is characterized histologically in the acute stage as fibrinopurulent synovitis, and chronically as lymphoplasmacytic synovitis with synovial hyperplasia, loss of articular cartilage, pannus, and periosteal and subchondral bone remodeling.[45] An inherent genetic tendency may explain why certain male cats are more prone to developing disease despite the high prevalence of these viral infections in the general population. It is currently not clear whether FFV or any persisting feline virus contributes to arthritis or related immunopathologic disease of cats. Using PCR, FFV DNA was not detected in tissue from vaccine site-associated sarcomas from cats.[28]

Most FFV-infected cats show no clinical signs. Chronic progressive polyarthritis of cats generally affects naturally infected males between 1½ and 6 years of age.[41,46–49] Two forms of the disease have been described: one with osteoporosis and periarticular periosteal proliferation, the other with periarticular erosions, collapse of the joint space, and joint deformities. Lymphadenomegaly and arthralgias are caused by both types. In experimentally FFV-infected cats that were monitored for a 6-month period PI, histopathologic changes of mild glomerulonephritis and moderate interstitial pneumonia were observed[50]; however, no corresponding co-housed uninfected control cats were evaluated to substantiate the association of the virus infection with these mild lesions.

DIAGNOSIS

Microbiologic Tests

Serologic Diagnosis

FFV infections are associated with the production of virus-specific antibodies by the infected hosts. Therefore, assays based on immunodiffusion methods, IFA, immunoblotting, and ELISA are used to test for virus-specific antibodies.[16,41,42,51,52] Infected kittens can be detected at birth by culturing buffy coat cells from their peripheral blood. Animals are infected for life and develop persistent, nonprotective antibody titers to the virus.[53] For this reason, cats showing a serologic response toward FFV are presumed to be infected. Neonatal kittens born to infected queens lose their maternal antibody by 6 to 8 weeks of age if they are not infected. Serum antibody titers increase after this time if they become infected.[17]

Virus Isolation

In addition to serology, virus cultures to screen cats for infection by the detection of FFV-specific antigens and CPEs (syncytia) can be performed. Virus can be isolated from most tissues but requires one to four passages *in vitro*. IHC has been developed to detect the FFV Bet

protein, and is predominantly present in cells of lymphoid organs such as the lymph nodes, tonsils, thymus, and spleen.[54] Additionally, FFV has been demonstrated in saliva.[53] It appears that FFV replication in peripheral blood leukocytes is suppressed by the host. This latent virus can be reactivated by co-cultivating buffy-coat leukocytes with permissive feline cells.[53]

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR can also be used directly to detect virus in blood leukocytes or cells of body fluids or tissues. There is a 100% correlation between seropositive results in cats and detection of proviral DNA in leukocytes.[52]

TREATMENT AND PREVENTION

FFV infection is lifelong and eradication therapies do not currently exist. Additionally, specific antiviral therapies have not been thoroughly investigated for use as infection is generally considered nonpathogenic. The antiviral drug tenofovir can salvage FFV-infected mesenchymal stem cells from CPEs when cultured *in vitro* for autologous mesenchymal stem cell therapy.[21]

Chronic progressive polyarthritis has no known cure, and the clinical and pathologic changes it causes usually are temporarily responsive for weeks to months to immunosuppressive therapy such as prednisolone (10–15 mg/day per cat) and cyclophosphamide (2.5 mg/day per cat, PO, for 4 days each week). Cats identified as having polyarthritis should be eliminated from research projects and removed from donating stem cells, vaccine production, and SPF colonies because an infectious or contagious etiology cannot be excluded.

PUBLIC HEALTH ASPECTS

All nonhuman primate species harbor distinct host-species specific strains of simian foamy viruses that are genetically different from FFV.[52] No data are available to document the existence of an authentic human foamy virus; however, people who are occupationally exposed to nonhuman primates have the highest rate of exposure and zoonotic infection to the different simian foamy viruses.[55] Other foamy viruses of domestic animals, including FFV, can infect a variety of cell types from different species *in vitro*. No transmission of these other viruses to people has been documented.[3,52] Furthermore, data from studies of seroreactivity among veterinarians and other people occupationally exposed to cats did not support an increased risk of infection.[56]

Paramyxovirus Infections

Hans Lutz, Claire R. Sharp, Jane E. Sykes

KEY POINTS

- Cause: Viruses of the family *Paramyxoviridae*; genera *Morbillivirus* (feline morbillivirus [FeMV], canine distemper virus [CDV]), *Henipavirus* (including Hendra virus [HeV] and Nipah virus], and the newly named *Rubulavirus* (previously paramyxovirus; mumps virus [MuV]).
- First Described: FeMV was first described in China in 2012.[1] CDV was first described in France in 1905.[2] HeV was first isolated in Queensland, Australia in 1994.[3] Nipah virus was first identified in humans in Malaysia in 1999. MuV was first described in 410 BC (Hippocrates).
- Affected Hosts: Domestic cats (FeMV); large wild Felidae, dogs and other Canidae, Procyonidae (raccoons, pandas), Mustelidae (ferrets, mink, skunks, otters), nonhuman primates (CDV); horses, humans, flying foxes (reservoirs), domestic cats (experimental infection only), guinea pigs (experimental), dogs (HeV); pigs, humans, fruit bats (reservoirs), domestic cats, dogs (Nipah virus); humans, dogs, cats (MuV).
- Geographic Distribution: Asia, Europe, North and South America (FeMV); northeastern Australia (HeV); Malaysia, Singapore, Bangladesh, India (Nipah virus); worldwide (MuV).
- Route of Transmission: Oronasal contact with virus in secretions or excretions, droplet nuclei, and large particle aerosol transmission.
- Major Clinical Signs: Paramyxoviruses cause infections of the CNS, and respiratory and urinary tracts. FeMV has been implicated in chronic kidney disease in cats, but its clinical significance remains unclear. Natural infections of dogs with HeV have been rare and subclinical. Natural infections of dogs and cats with Nipah virus are also rare, but death and severe respiratory signs have been described. MuV can cause parotitis with salivary gland enlargement.
- Differential Diagnoses: These include other causes of infectious respiratory disease; parasitic respiratory disease; toxins such as lead and ethylene glycol; other causes of infectious meningoencephalitis. Differential diagnosis for mumps include other causes of parotitis such as immune-mediated disease.
- Human Health Significance: FeMV is not known to infect humans. HeV and Nipah viruses cause serious infections of humans with high mortality. Mumps is a serious infection of humans but largely controlled by vaccination; periodic outbreaks still occur. Dogs and cats do not appear to be important in transmission of these viruses to humans.

INTRODUCTION

The *Paramyxoviridae* family includes, among others, feline morbillivirus (FeMV), canine distemper virus (CDV), *Henipavirus* (including Hendra virus [HeV] and Nipah virus), and *Rubulavirus* (including mumps virus [MuV]). These viruses affect domestic and wild felids, canids, procyonids, mustelids, and many more mammalian species. Transmission is by close contact, droplets, and aerosols. These infections, of which many occur around the world, can cause mild to serious diseases of the CNS, and respiratory and urinary tracts, but many infections are associated with no symptoms. Henipavirus infections in Asia and Australia are zoonotic diseases and can be very serious in humans, but are hardly transmitted to humans by cats and dogs.

Paramyxoviruses have been associated with emerging infectious diseases in a variety of species in recent decades, and as such are important viruses to both human and veterinary medicine.[4] This chapter focuses on paramyxovirus infections in cats, although infections of both dogs and cats with HeV, Nipah virus, and MuV are also described. Diagnostic testing for these latter three virus infections requires coordination with local public health authorities given their significance for human health.

FELINE MORBILLIVIRUS INFECTION

Until recently, the genus *Morbillivirus* was recognized to contain six species: CDV, measles virus, rinderpest virus (now eradicated), peste des petits ruminants virus, phocine distemper virus, and cetacean morbillivirus. Of these, only CDV had been known to affect felids, causing clinical signs in some large exotic felids, but not in domestic cats. In 2012 however, a novel FeMV was isolated from cats in Hong Kong and mainland China.[1]

This virus was officially recognized as the seventh species of the genus *Morbillivirus* in 2016. Early reports of FeMV infection were only in domestic cats, however in 2020 the virus was identified by RT-PCR in urine and homogenized kidney tissue from two black leopards (*Panthera pardus*) in Thailand.[5]

In 2012, FeMV RNA was identified by RT-PCR in 56 of 457 (12.3%) stray cats from Hong Kong.[1] Of the specimen types collected, urine was most commonly PCR positive for FeMV (53/56 cat specimens). Subsequently, many of these cats were shown to have antibodies to the FeMV N protein (54/56 RT-PCR positive cats were antibody positive). Additionally, 78/401 (19.5%) RT-PCR-negative cats were antibody positive, suggesting previous exposure. Concurrently, 1/16 diseased cats from mainland China was RT-PCR positive to FeMV in

oral and rectal swabs.[1] To identify possible disease associations, necropsies were performed in two stray cats that were RT-PCR positive for FeMV.[1] Histology revealed renal tubular degeneration and necrosis in both cats, consistent with tubulointerstitial nephritis (TIN), the histologic correlate of CKD in cats. In a small case-control study of a further 27 stray cats, TIN was documented in 7/12 cats that were positive for FeMV using RT-PCR, but only 2/15 FeMV-negative cats ($P < .05$), suggesting an association between FeMV and TIN.[1] This first report suggesting an association between FeMV and TIN generated significant interest in the field, given the large disease burden of CKD in cats.[6]

Since its discovery, epidemiologic studies have now documented FeMV in domestic cats in Japan,[7–9] Europe,[10–14] the United States,[15] Brazil,[16] Malaysia,[17] and additional cases in China.[18]

To identify infected cats, most investigators have tested urine or kidney tissue specimens, reporting a prevalence of FeMV infection using RT-PCR that has ranged from 3%, in the northeastern United States,[15] to 52.9% (9/17 cats) in a multicat house that had close contact with a stray cat colony in Brazil.[16] While the mode of FeMV transmission is unknown, its higher prevalence in the aforementioned multicat household, as well as in colony cats,[19] suggests that close cat contact may be involved. Male predominance has also been reported in some molecular epidemiologic studies.[17,20]

The seroprevalence of FeMV has also varied widely, although fewer studies report the results of antibody testing. Seroprevalence of anti-FeMV antibodies has ranged from 21.2% in Japan[9,20] to 66.7% in the United Kingdom.[13] However, none of the FeMV serosurveys have employed virus neutralization (VN), the gold standard for diagnostic serology, and thus methodologic limitations may have resulted in inaccuracies in serologic data. Development of VN assays is needed to better understand the epidemiology of, and immune response to, FeMV.

Studies that have reported concurrent molecular and serological data identify four populations of cats: (1) those that have never been exposed to the virus (both RT-PCR and seronegative), (2) those that have been exposed, developed antibodies, and likely cleared the virus from their urine (RT-PCR negative, and seropositive), (3) those likely to be in the early stage of infection but without antibodies (RT-PCR positive but seronegative), and (4) those both RT-PCR and seropositive, suggesting both the presence of active viral shedding and circulating antibodies. At least some cats in the fourth group appear to be chronically infected.[14,15,19]

Several studies have attempted to investigate the role of FeMV infection in CKD in cats. Some have suggested an association,[10,20,21] while others have found no association.[9,13,16,17,19] Undoubtedly FeMV can be identified in cat urine, both by RT-PCR and virus isolation, and will grow after inoculation of CRFK cells. Additionally, some authors have identified FeMV in renal tubular epithelial cells by IHC.[1,13,22] Nonetheless, associations documented in some of these studies do not prove causation, and pathogenesis studies are needed. Of note, other morbilliviruses are not known to cause kidney disease, despite infecting epithelial cells of the urogenital tract.

Given that morbilliviruses are significant pathogens in a variety of host species, it is tempting to hypothesize that FeMV may cause pathology in cats. Morbilliviruses are classically lymphotropic and epitheliotropic, resulting in clinical signs affecting the skin, respiratory tract, GI tract, and CNS. Additionally, morbilliviruses classically result in immunosuppression. Whether or not FeMV results in a similar spectrum of disease in cats remains to be determined. Only two studies specifically evaluating *in vitro* FeMV cell tropism have been published, documenting FeMV replication in cat fibroblasts, lymphoid cells, and glial cells as well as in renal, pulmonary epithelial and primary brain cells. Feline morbillivirus genotype 2 (FeMV-GT2) also replicates readily in several types of lymphocytes.[23,24]

Evidence that FeMV can infect glial cells *in vitro*, in addition to occasional clinical reports of FeMV RT-PCR positivity of cat brain tissue,[19] suggest the potential for the virus to be neurotrophic, as is seen with other morbilliviruses. It remains unknown to what degree FeMV infection may explain historic evidence of a paramyxovirus-like agent in the CNS of stray and pet cats with subclinical focal demyelinating encephalitis.[25,26] Unfortunately at the time, while paramyxovirus-like nucleocapsids were observed using electron microscopy in fixed cat brain and optic nerve tissues, as well as explant cultures of CNS tissue co-cultivated with CRFK cells, the virus could not be definitively identified.[26]

Future FeMV research should focus on acute and chronic pathogenesis studies using experimental infections to understand the route of infection, transmission, viral receptor usage, and cell tropism of FeMV, in addition to the immune response to the virus, and the pathology it causes. Ultimately, if FeMV is identified as a pathogen, there will be a need for commercially available diagnostic tests, the development of effective vaccines, and even investigation of the role of antivirals for the treatment of active infection. Currently, testing for FeMV is being done on a research basis and not offered on a commercial basis, given the unclear role of FeMV in disease.

CANINE DISTEMPER VIRUS INFECTION IN CATS

CDV, which also belongs to the genus *Morbillivirus*, infects a wide variety of terrestrial carnivores. Information on CDV infection in dogs is covered in depth in Chapter 22. Domestic cats can be infected through experimental inoculation, but clinical signs do not develop. Virus-neutralizing antibodies to CDV have been detected in domestic cats housed in close proximity to dogs, but again, clinical illness has not been documented.[27,28] In contrast to domestic cats, large exotic Felidae are more susceptible to infection with CDV. CDV isolates from exotic felids are similar to virulent isolates from other carnivores, and infection likely originates from wildlife and/or domestic dogs in close proximity to exotic cats (Fig. 37.1).[29–39] Noncanid carnivores, such as raccoons and skunks, may also act as vectors of CDV for exotic cats in zoological gardens.[40]

There are several case reports implicating CDV in progressive neurologic disease, with or without respiratory signs, in exotic cats around the world, including an African lioness (*Panthera leo*),[41] Bengal tiger (*Panthera tigris tigris*),[42] both captive and free-ranging adult Siberian tigers (*Panthera tigris altaica*),[38,43] and two snow leopards (*Uncia uncia*).[44] Although isolation of CDV was not performed in many of these cases, the presence of consistent histologic lesions (non-suppurative encephalitis or meningoencephalitis), characteristic intranuclear inclusions, IHC, and serologic documentation of CDV antibodies provide strong support for CDV as the etiologic agent. The aforementioned snow leopards were co-infected with feline panleukopenia virus (FPV),[44] suggesting the possibility of FPV-induced immunosuppression. CDV was also implicated as the cause of death in an Iberian lynx (*Lynx pardinus*) in the Donana National Park in South-Western Andalusia, Spain.[45] The Iberian lynx is at present the most critically endangered felid, and the virus was closely related to that isolated from a stone marten (*Martes foina*) found close by. Thus, CDV represents a constant threat to free-ranging wild felids.

CDV has caused large outbreaks of disease in free-ranging wild felid populations.[46–48] The first such outbreak occurred in 1994, resulting in the death of a considerable proportion of lions in the Serengeti in Tanzania.[46,49–51] Clinical signs were primarily neurologic. Pathologic findings were encephalitis and pneumonia. Inclusion bodies immunologically cross-reacting with CDV proteins were identified in 14/19 lion specimens that were available for examination. A total of 71/83 serum samples were found to be positive for anti-CDV antibodies.[46]

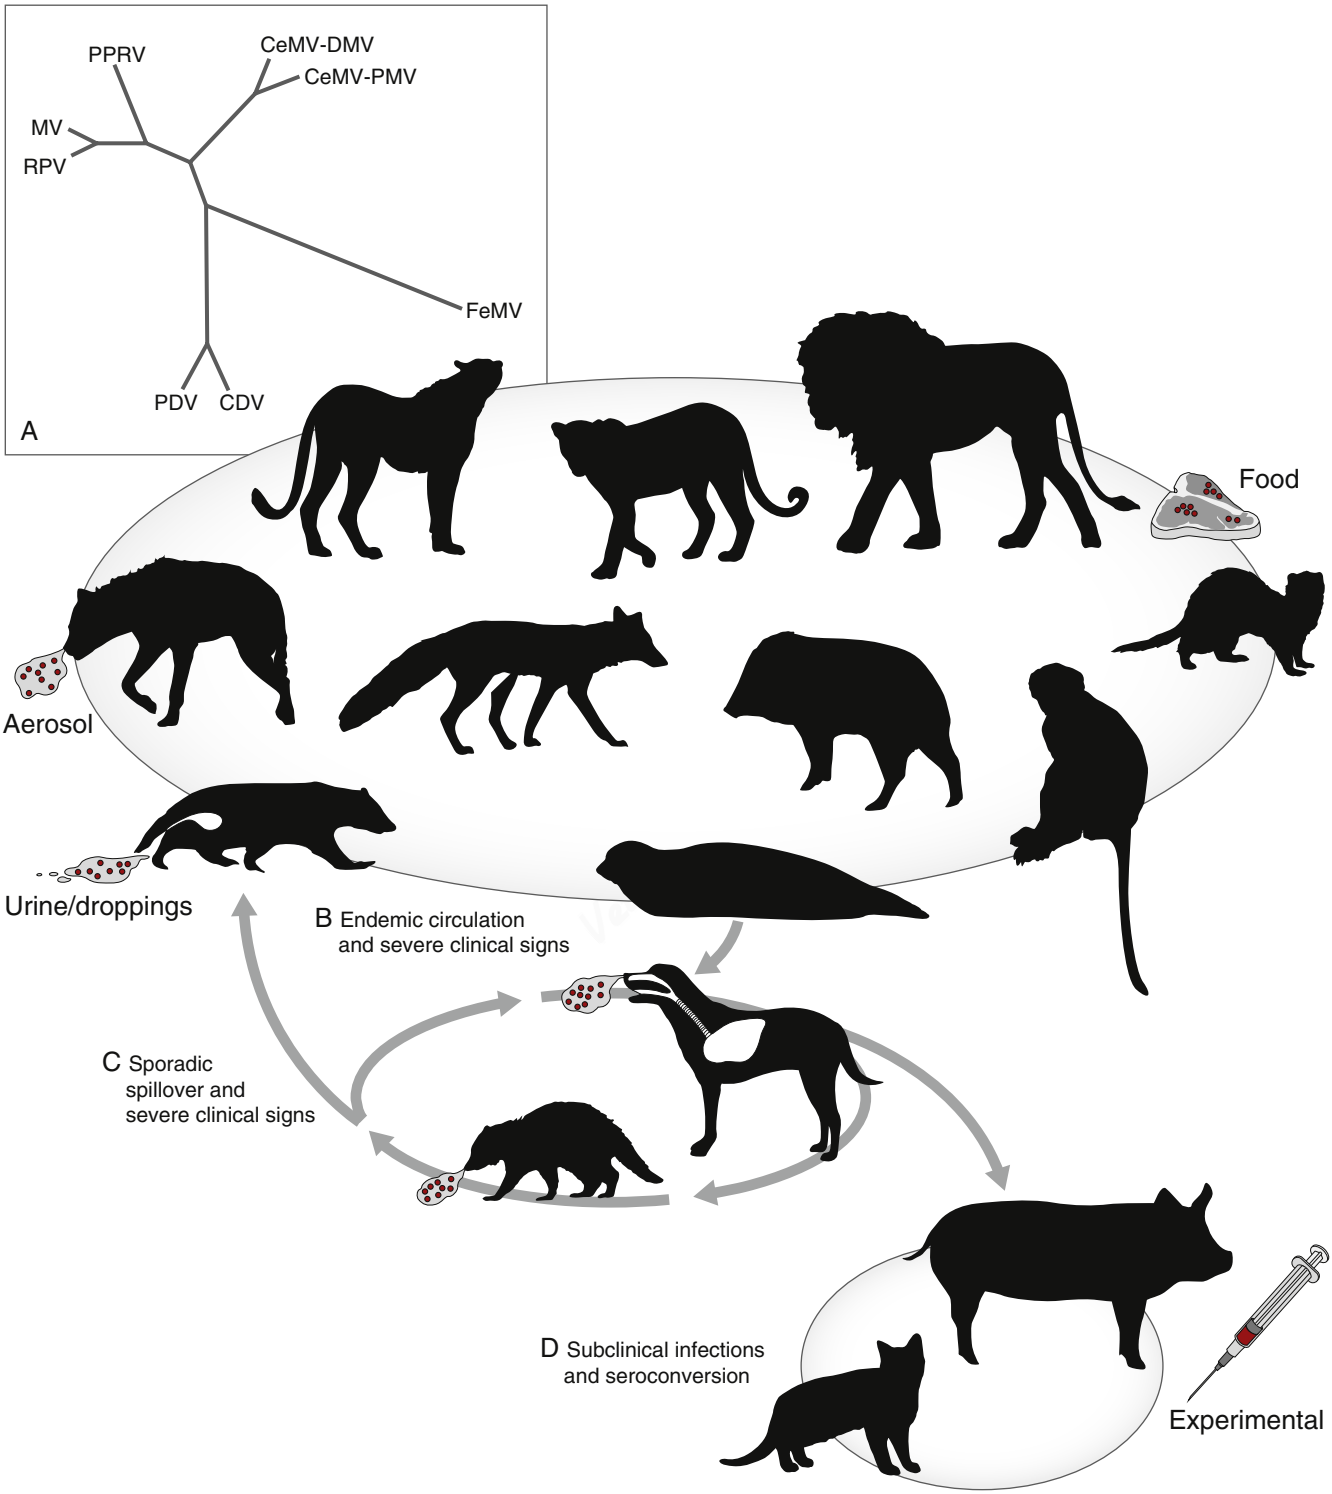

Fig. 37.1 Canine distemper virus (CDV) phylogeny and cross-species transmission. A, Phylogenetic tree based on alignment of morbillivirus H glycoproteins. B–D, Illustration of cross-species transmission of CDV between multiple domestic and wildlife reservoir hosts. B, CDV infection circulates in dogs and raccoons due to population sizes large enough to maintain endemic transmission. C, Spillover and/or limited chains of transmission in a large number of wildlife species including various cat species, e.g., tiger, lynx, leopard, lion, and other Serengeti wildlife; North American wildlife, e.g., gray wolf, coyote, skunk, black-footed ferret, mink; European wildlife, e.g., European badger, fox; seals, and rhesus and cynomolgus macaques. D, Subclinical, self-limiting infection has been reported in experimentally infected cats and pigs. *CeMV-DMV,* cetacean morbillivirus/dolphin morbillivirus, *CeMV-PMV,* cetacean morbillivirus/porpoise morbillivirus, *FeMV,* feline morbillivirus; *MV,* measles virus, *PDV,* phocine distemper virus; *PPRV,* peste des petits ruminants virus; *RPV,* rinderpest virus.

Phylogenetic analysis suggested that the lion CDV isolate was closely related to the Onderstepoort strain of CDV, and may have originated from domestic dogs living around the Serengeti parks.[46] Purported contributors to the epizootic included hyenas transmitting the disease to local domestic dogs and lions, and loss of cross-immunization of lions by consumption of rinderpest-infected buffaloes when the closely related rinderpest virus was eradicated in the 1980s. To reduce the probability of further outbreaks of CDV in lions, a program to vaccinate the domestic dogs living around the parks was initiated.

CDV outbreaks have also occurred in captive lions, tigers, and leopards.[41,52,53] Affected cats developed anorexia, GI and/or respiratory signs, followed by CNS signs of ataxia, myoclonus, seizures, coma, and death. Vaccination has been recommended to protect captive large exotic Felidae, however vaccine efficacy remains incompletely documented.[54,55] A multi-institutional study of 812 captive large felids documented that canarypox-vectored CDV vaccines were used most commonly in tigers, lions, snow leopards, leopards, and jaguars (96.3%) compared with attenuated live CDV vaccines (3.7%). Both vaccine types were associated with low rates of adverse effects (0.5% for the canarypox-vectored vaccine, and 2.9% for the attenuated live vaccine). However, only 66% of animals with serologic data available experienced seroconversion at some point post-vaccination.[54]

HENDRA VIRUS INFECTION

In September 1994, an outbreak of acute respiratory disease in horses occurred in Hendra, a suburb of Brisbane, Queensland, Australia.[3,56,57] The horses developed anorexia, lethargy, pyrexia, tachypnea, and ataxia. Terminally, head pressing and nasal discharge were described. A stable hand and horse trainer became ill with an influenza-like illness. The stable hand was ill for 6 weeks, and the trainer died. A novel virus, HeV (genus *Henipavirus*), that was closely related to a *Morbillivirus* was isolated from the horses and humans. Histologically, the horses had interstitial pneumonia with pneumocyte and capillary degeneration.[58] Virus was detected in endothelial cells using immunofluorescence, as well as in CSF, brain tissue, and serum using PCR.[59] Necrotizing lymphadenitis is also common, and syncytial cells can be found in a variety of different organs. Anti-Nipah virus antibody can be used for IHC due to cross-reactivity (Fig. 37.2).

Since its first isolation, over 90 HeV-associated fatalities in horses and 4 human fatalities have been documented.[60] HeV is transmitted by excretions (saliva, feces, nasal discharge) of pteropid bats (flying foxes)[61] of which some species are now known to be reservoirs. A large number of laboratory animal species, including dogs and cats, were experimentally inoculated subcutaneously with the virus.[3,58] The dogs and cats had been vaccinated for common viral diseases but notably the dogs for CDV. The dogs did not become ill, but the cats developed inappetence and tachypnea by day 5 PI and died 1–2 days later. The cats developed pulmonary edema, hilar lymphadenomegaly, pneumonia, and pleural effusion, but neurologic signs were absent. Histologic lesions of vasculitis resembled those in affected horses. The virus was isolated from the lungs, spleen, kidney, and brain. Of all laboratory species inoculated, cats were most susceptible.

A limited serosurvey of cats in the metropolitan Brisbane area did not reveal detectable antibody to the virus.[3] Subsequent studies in cats have shown that they can be experimentally infected by nonparenteral routes and that the virus can spread naturally among cats.[62] However, no field infections have been described in cats to date. Transmission from bats to another species, such as the horse, may be required for human exposure.

Although the case fatality rate is > 60% in horses and humans, transmission studies have shown that the virus is not highly contagious. Horses in direct contact with experimentally infected cats and infected horses in contact with other horses or cats did not transmit infection.[63] Similarly experimentally infected cats did not transmit the infection to horses. In experimentally infected animals, regardless of species, virus was most prevalent in the kidney and urine, which suggests urinary transmission as the means of spread. Additionally, HeV

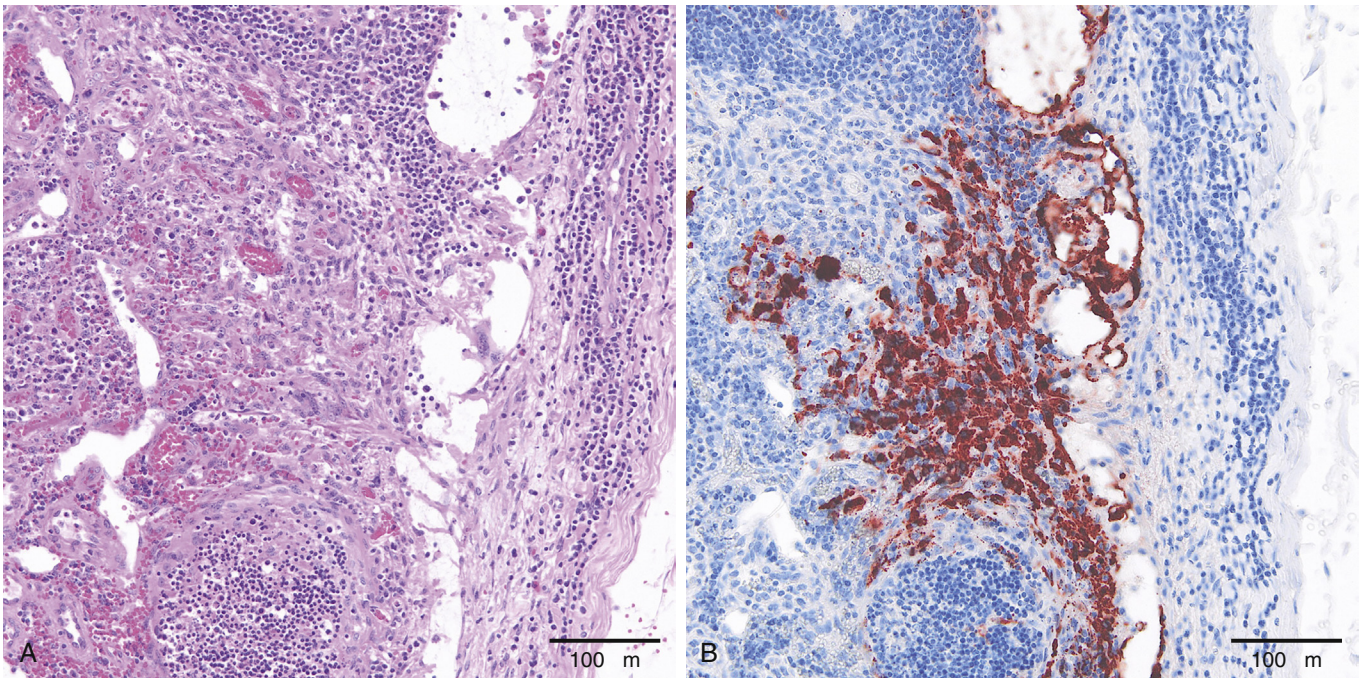

Fig. 37.2 (A) Histologic section of the lymph node from a horse with acute Hendra virus infection showing lymphadenitis with syncytial cell formation (hematoxylin and eosin stain). (B) Hendra virus antigen in a section adjacent to (A). Anti-Nipah N antibody. (From Middleton D. Hendra Virus. *Vet Clin North Am Equine Pract.* 2014;30:579–589.)

was isolated for up to 3 weeks after infection of a horse and 14 months in a human developing infection, suggesting viral persistence and a carrier state.

Natural infections with HeV have been reported in at least two dogs, and additional subclinical infections that were undetected may also have occurred. In 2013, HeV was detected by RT-PCR in the serum of a dog on the same farm as an infected horse in New South Wales, Australia.[64] This dog had been in close contact with the affected horse and was apparently exposed to the horse's blood after the horse was euthanized 14 days prior. The dog was apparently healthy and testing had been done as a surveillance effort. The dog also had virus neutralizing antibodies at a titer of 1:8. Because of concerns surrounding transmission risk, the dog was euthanized 2 days later. At necropsy, necrotizing vasculitis was detected in the dog's kidney, brain, lymph nodes, spleen, liver, intestine, and lungs. Small amounts of viral antigen were detected in the kidney, and many tissues were positive for HeV using RT-PCR; serum collected at necropsy had an antibody titer of 1:128.

The risk of transmission of HeV from dogs to horses or humans remains unknown, but it has been recommended that dogs be kept away from infected horses.[64] Experimentally infected dogs were shown to shed virus in nasal secretions at levels similar to those detected in horses.[65]

NIPAH VIRUS INFECTION

An outbreak of fatal human encephalitis during 1998 and 1999 in Malaysia was attributed to Nipah virus (genus *Henipavirus*), at that time a novel paramyxovirus acquired from swine.[66,67] Pigs, humans (primarily pig farmers), dogs, and cats were infected. As with HeV, fruit bats are reservoirs, which have a worldwide distribution, with spillover to other mammalian hosts. Although illness was reported in the other species, the disease in pigs was self-limiting and, in some cases, subclinical. Human infection was attributed to close contact with pigs. The role of dogs or cats as secondary sources of infection could not be excluded.

Since its emergence, over 700 cases of Nipah virus infection have occurred in humans in South and Southeast Asia, with a mortality rate of 40% to 70%.[66] Only one naturally infected cat has been described.[58] Results of serosurveys of feral cats in endemic areas suggest that transmission among bats and cats may be uncommon.[68] In experimentally infected cats, Nipah virus was similar in its behavior to that of the closely related HeV. Two cats were experimentally infected by the oronasal route with Nipah virus from an outbreak associated with respiratory and neurologic signs in pigs.[69] Respiratory and neurologic disease was observed in the cats, and virus was found in secretions of the oropharynx and excreted in urine. The virus causes widespread systemic vasculitis, especially the respiratory tract and CNS. Pulmonary lesions are giant cell pneumonia, and the secretions and tissues contain large amounts of virus. Transplacental infection also occurs in experimentally infected pregnant cats with resultant infection of kittens.[70,71] Experimental subunit vaccines containing soluble glycoprotein G of either HeV or Nipah virus protected cats against subsequent challenge with virulent Nipah virus.[72,73]

Dogs were suspected of being reservoirs of infection during the initial epidemic in humans.[74] Virus was identified by immunohistochemical staining of tissues in two dogs that died.[58] One of the dogs was found dead, and the other had fever, respiratory distress, conjunctivitis, and mucopurulent ocular and nasal discharge. Interstitial pneumonia, renal tubular necrosis, and nonsuppurative meningitis were described at necropsy.[58] Pigs were readily infected from fruit bats. Dogs were examined because they lived communally with pigs and humans and could have served as secondary reservoir hosts. Despite the high prevalence of seroreactivity among dogs at the time of the initial outbreak,[75] it was very low in dogs outside the immediate disease-endemic area.[76] Thus, infected dogs acted as dead-end hosts; infection did not spread in the absence of the infected pigs that had been depopulated.

MUMPS VIRUS INFECTION

MuV is a paramyxovirus causing parotitis and less frequently deafness, orchitis, and other clinical signs, with a high incidence in children aged between 5 and 9 years.[77] There are rare reports of the transmission of MuV to dogs with signs of lethargy and parotitis[78] and serologic evidence of exposure of cats.[79] After the introduction of vaccines in 1965, and routine vaccination of children, the incidence of disease in humans has decreased by 99%, but periodic outbreaks of disease still occur as a result of lack of vaccination or vaccine failure.[80,81] Dogs and cats do not play a significant role in transmission of MuV to humans.

AVIAN NEWCASTLE DISEASE VIRUS INFECTION

Avian Newcastle disease virus (genus *Paramyxovirus*) has not been reported to naturally infect cats, but has been experimentally inoculated into the CNS of domestic adult cats and kittens, producing disseminated encephalomyelitis.[82,83] Neonatal kittens can also be infected by intraocular or intranasal exposure to large quantities of virus. The incubation period following oculonasal administration of virus was relatively long (11 to 17 days) when compared with that after direct CNS inoculation (3 to 4 days). Clinical signs were seizures, head tilt, myoclonus, and progressive lower motor neuron paralysis. In some affected animals, behavioral alterations were present. A disseminated nonsuppurative meningoencephalitis was found histologically; virus appeared to spread throughout the nervous system along the descending and ascending neuronal pathways.

Feline Poxvirus Infections

Conor O'Halloran

KEY POINTS

- First Described: Feline poxvirus infection was first described in the United Kingdom in 1978.[1–3]
- Causes: Poxviruses (family *Poxviridae*, genus *Orthopoxvirus*). Cowpox virus infection is by far the most frequently reported poxviral infection of both cats and dogs. Other poxvirus infections have also rarely been described in pets.[4,5]
- Affected Hosts: Cats, less often dogs, and a variety of other mammalian host species.
- Geographic Distribution: Cowpox virus is limited to Europe and Asia; infections with other poxviruses have been described in North America.
- Mode of Transmission: Entry through a break in the skin.
- Major Clinical Signs: Single or multiple, papular, and crusted skin lesions with fever, lethargy, hyporexia, and signs of pneumonia can also occur in affected cats.
- Differential Diagnoses: Allergic dermatitis, facial dermatitis caused by FHV-1, nocardiosis, mycobacteriosis, cutaneous lymphoma, autoimmune dermatoses such as pemphigus foliaceus, cutaneous drug reactions.
- Human Health Significance: Many poxviruses, including cowpox and orf viruses, are zoonotic, and owners of affected animals need to be advised of the threat to their health.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Cowpox virus is a member of the *Orthopoxvirus* genus within the family *Poxviridae*, which are large, enveloped, double-stranded DNA viruses. Other orthopoxviruses include smallpox virus (now eradicated), vaccinia virus (the smallpox vaccine virus), monkeypox virus (which is endemic to central Africa but was recently introduced to, and has since been eradicated from, North America), and a range of other mammalian orthopoxviruses.[1,2,4–9] All orthopoxviruses are closely related genetically and antigenically; therefore, vaccinia virus can be used to immunize against all orthopoxvirus infections. Cowpox virus has the largest genome of all the orthopoxviruses. Different strains of cowpox virus exist, as determined by both biologic characteristics and nucleotide sequence.[8,10–12] Whether these relate to geographic variation in the virus (and therefore its main hosts and pathogenicity) or a range of independent virus species is still to be determined. For the purpose of this chapter, they are regarded as a single viral species.

Despite its name and its original isolation from cows, cowpox is rarely described in cattle; rather, cowpox virus circulates primarily in wild rodents.[13,14] Cowpox virus has a wide incidental host range that includes not only rodents, cats, dogs, cattle, and humans but also a variety of captive wildlife mammals.[1,2,4,13,14] The main route of transmission among rodents is not known, although, as for many orthopoxviruses, the respiratory route is probably important.[1,2,4,6,8] In most incidental hosts, which include domestic animals and humans, the most frequent route of infection is through a break in the skin which gives rise to the "primary" lesion. The main reservoirs of cowpox virus are believed to be bank voles (*Myodes glareolus*), field voles (*Microtus agrestis*) and, to a slightly lesser extent, wood mice (*Apodemus sylvaticus*).[1,14] As these rodent species undergo annual population cycles, breeding mainly in the summer and fall months, viral transmission and prevalence has strong seasonality. Therefore, transmission to accidental hosts such as cats, dogs, people, and zoo animals also occurs mainly (but not exclusively) in the late summer, fall, and early winter.[4]

Cats probably become infected directly from rodent hunting, whereas infection in other species is often acquired from an amplifying intermediate host.[1,2] These are incidental hosts in which the virus replicates to higher titers than in the reservoir rodent hosts; thus, they bridge the epidemiologic gap between the reservoir and the host of interest. The main amplifying hosts for human cases of cowpox virus infection are the domestic cat (and, in the past, possibly cattle), followed by peri-domestic rodent species such as rats.[1,2,4,7] Rats can also be a source of infection for captive wildlife species. The virus is very hardy and survives in scabs for weeks or months, including in the environment, where it may be a source of human infection.

Reports of natural orthopoxvirus infection in wild or domestic dogs are rare. A natural orthopoxvirus infection, characterized by ulcerative dermatitis at the site of a suspected rat bite, was identified in a domestic dog in the United Kingdom.[15] This infection was likely caused by cowpox, because this has been the only orthopoxvirus in the United Kingdom since smallpox was eradicated.[8] Specific antibodies were found in 6% to 20% of foxes in Germany.[16,17] Intradermal inoculation of 2×10^5 plaque-forming units of cowpox virus into red foxes (*Vulpes vulpes*) produced mild skin lesions with minimal viral replication, and no lesions were found after oral dose administration of virus.[16,17] Another orthopoxvirus, murine ectromelia, has caused congenital disease in farm-raised silver foxes (*Vulpes* winter coat), blue foxes (*Alopex lagopus* winter coat), and mink (*Mustela vison*) in the Czech Republic.[18] A novel orthopoxvirus was described in 2018 in a 6-month-old cat from Italy with severe and rapidly progressing cutaneous disease that appeared to be more closely related to this virus than to cowpox virus.[5]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The outcome of feline infection is likely to depend on the viral strain, route and site of infection, dose of inoculated virus, and the concurrent presence of systemic immunosuppression, such as infection with exogenous

retrovirus infections (FIV or FeLV) or, critically, the administration of systemic glucocorticoids.[1,2,4,8,19] In many hosts, such as humans, dogs, and cattle, the primary lesion of cowpox virus infection, plus perhaps some limited virus replication in draining lymph nodes, may be as far as disease progresses. In cats and many captive wild mammalian species, however, the virus replicates in monocytes and macrophages and spreads to multiple organs, particularly the lungs and the spleen. Here, the virus replicates further, giving rise to a secondary viremia, which is often associated with pyrexia and mild or occasionally severe systemic signs. In all species, infection most commonly presents externally as focal cutaneous lesions, which heal spontaneously, with no systemic signs. During the viremic period, virus can be isolated from the respiratory tract. Fatal necrotizing pneumonia has been described.[10]

The strain of the virus may also influence the clinical severity of disease.[20] For example, some cats within the United Kingdom were seen with large areas of focal dermal necrosis (eschars) with extensive erythema and edema, which may represent infection with a particularly virulent strain.

In many captive wild Felidae, pneumonia is more common than in domestic cats, and mortality is high.[21–23] Similarly, elephants and rhinoceroses in central European zoos develop severe systemic disease and often die—this can be such a severe disease that elephants are vaccinated in many European zoological parks. Reports of fatal cowpox in captive primates are rare, but high rates of subclinical seroconversion in other primate populations have been reported.[21–23] In wild rodent reservoir hosts, clinical signs are absent or, at least, subtle.[13,14] Population-level studies of naturally infected voles and mice show that infection may be associated with decreased fecundity and decreased survival. When lesions are seen in rodents, they are often in incidental rodent hosts such as rats.

Physical Examination Findings

The skin lesions first develop as papules, which become ulcers up to 1 cm in diameter that crust over and heal over 4 to 6 weeks (Fig. 38.1A and B). This leaves small patches of alopecia until the hair regrows. Lesions are most often found on the head, neck, or forelimbs. In cats such as Siamese breeds, the haircoat may grow back a darker color, and scars are often visible for years in cats if they are clipped. Although unproven, it has been suggested that some strains of cowpox virus may have increased pathogenicity, with infection culminating in large areas of cellulitis, cutaneous ulceration, and/or necrosis (Fig. 38.1C).[10,20]

DIAGNOSIS

Definitive diagnosis of poxvirus infections requires laboratory identification of the causative virus.[13,20,24,25] In Europe, where cowpox virus is endemic, clinical signs combined with identification of an orthopoxvirus frequently suffice to make a diagnosis. Elsewhere, however, more extensive laboratory tests, including sequence analysis, may be required to specifically identify the causative virus. Histopathology of biopsy specimens also yields characteristic findings that can raise strong suspicion for poxvirus infection.[10] Diagnostic test options are summarized in Table 38.1.

Microbiologic Tests

Cell Culture

The best specimens to collect for virus isolation are fresh skin lesions, although virus can be found in crusts from healing lesions for several weeks. No special transport media are required and specimens can be transported in any sterile container at room temperature.[24] The virus replicates in a variety of both feline and non-feline cell lines generating an obvious CPE, usually within 24 to 76 hours. Identification of the virus can then be performed using immunostaining or PCR assay and sequencing.

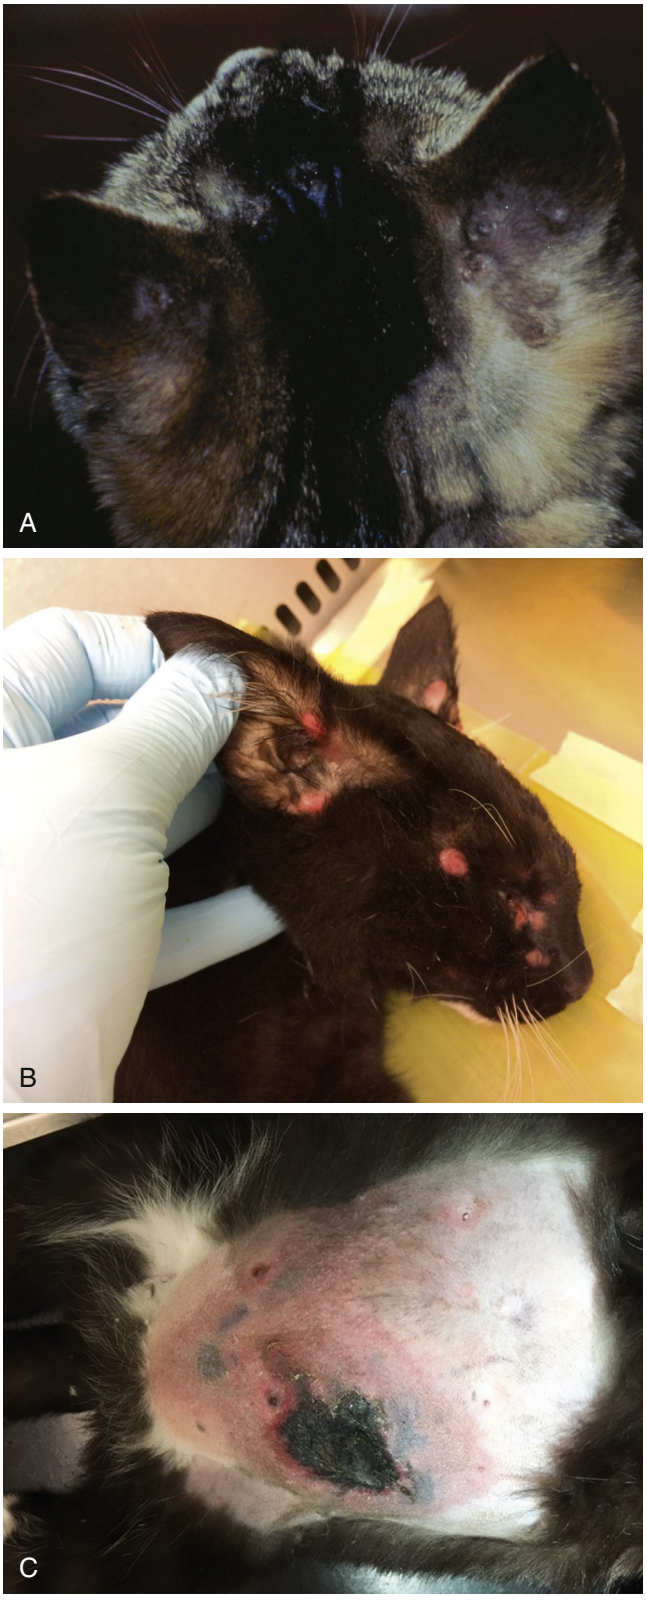

Fig. 38.1 (A and B) Secondary papules and crusted skin lesions in cats with cowpox virus infection. (C) Cat with more severe manifestation of cowpox virus infection, with a large area of cutaneous necrosis.

Electron microscopy can identify virus particles within skin lesions, is a more rapid approach to diagnosis than cell culture and is fairly sensitive (Fig. 38.2).[24] Negative-stained suspensions of skin lesion material allow typical orthopoxvirus particles to be seen in most cases.

TABLE 38.1 Diagnostic Assays Available for Poxvirus Infections

Assay	Specimen Type	Target	Performance
Virus isolation	Skin biopsies, crusts	Poxviruses	May not be widely available in some regions. Sensitive for diagnosis of orthopoxviruses
Polymerase chain reaction (PCR)	Skin biopsies, crusts	Poxvirus DNA	Sensitivity and specificity may vary depending on assay design; may not differentiate between orthopoxviruses. Availability on a commercial basis may be limited in some regions
Histopathology	Skin biopsies, necropsy specimens	Poxvirus inclusions	Confirmation of poxvirus infection requires immunohistochemistry or PCR
Electron microscopy	Skin crusts	Virus particles	May not be widely available, turnaround time can be slow, and may be expensive

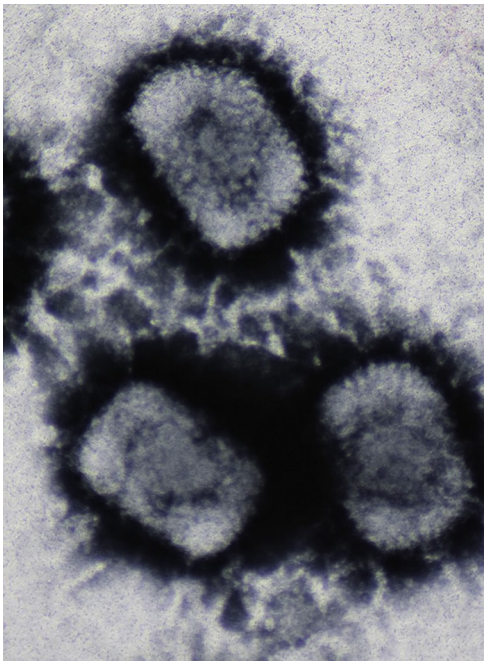

Fig. 38.2 Electron micrograph of a cowpox virus particle. In contrast, parapoxviruses have the appearance of a new ball of yarn, with thread-like surface tubules arranged in a criss-cross fashion.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Some diagnostic laboratories offer PCR assays for diagnosis of poxvirus infection, which can be both sensitive and, if combined with sequencing, specific. Orthopoxviruses are so similar genetically that PCR assays targeted at many orthopoxvirus genes only identify orthopoxviruses to the genus level.[24] PCR assays that differentiate between orthopoxvirus species have been described, but such assays tend to be available through research or other specialist laboratories. Of course, in much of Europe, cowpox virus is the only orthopoxvirus known to infect cats and dogs, so identification to the species level is often not necessary.

Serologic Diagnosis

Serum assays including virus neutralization, HI, complement fixation, and ELISA can detect antibody to orthopoxvirus, but a rising titer is required to prove active infection.[24] However, the prevalence of orthopoxvirus antibodies in domestic cats in Europe is usually only 1% to 2%, so a consistent clinical history combined with an antibody titer is reasonably specific.[8]

Pathologic Findings

Histopathologic Findings

Characteristic histopathologic findings include suppurative dermatitis with evidence of necrosis and ulceration.[10] Epithelial hyperplasia, ballooning degeneration of keratinocytes and large, cytoplasmic eosinophilic viral inclusion bodies within keratinocytes are present (Fig. 38.3). IHC has been used to identify intracellular orthopoxvirus antigen in epidermal and follicular cells.[10]

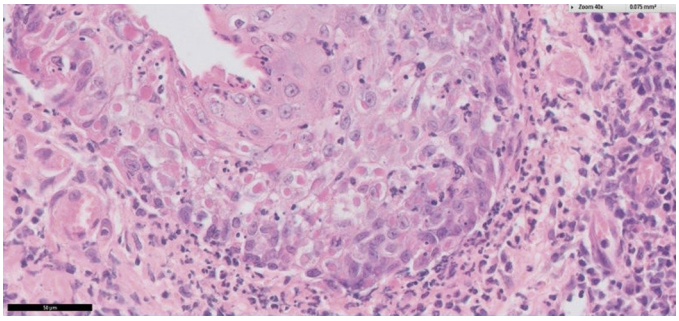

Fig. 38.3 Histopathology of a feline poxvirus lesion that shows epithelial hyperplasia and large numbers of eosinophilic intracytoplasmic inclusion bodies.

TREATMENT

Treatment is generally supportive as there are no antiviral drugs licensed to treat cowpox infections. Broad-spectrum antibacterials are recommended to treat secondary bacterial infections, if identified, and additional nonspecific therapy, including fluids, may be necessary. Glucocorticoids are considered contraindicated because they may exacerbate the condition. There appears to be an association between administration of glucocorticoids and progression of disease from limited skin lesions to pulmonary disease, which may be severe and even fatal.

Historically, most cats with cowpox-induced pneumonia died despite supportive treatment. In a recent case series, recombinant feline interferon-omega (rfIFN–ω, Virbagen Omega, Virbac, France) was used in four cats at a dose of 1 million international units (IU) given either IV or SC for 3 to 5 days (see Chapter 9).[26,27] Two of the cats with severe pneumonia survived. As this drug has been shown to be safe to use in cats, it could be considered for treatment of more severe cases. Other antiviral drugs could also be considered. The most promising antiviral in cats is famciclovir for the treatment of FHV-1 infections, but its efficacy against cowpox virus is unknown.[28] Vidarabine has activity against poxviruses *in vitro*, and cidofovir has broad-spectrum activity against poxviruses in humans, and cowpoxvirus in particular *in vitro* (see Chapter 9).[29,30] Cidofovir was also shown to protect mice from a lethal cowpox challenge. However, more research in cats is needed as this drug has been shown to be nephrotoxic in humans.

PUBLIC HEALTH ASPECTS

Human cowpox is rare (with one or two cases occurring each year in the United Kingdom), but cats are thought to be the source of more than 50% of these cases.[7,9] The risk of cat-to-human transmission is small if basic hygiene precautions are taken, and so this illness does not warrant euthanasia of the cat on public health grounds.

CASE EXAMPLE

Signalment

"Yogi," a 9-year-old entire male domestic shorthaired cat from Lancaster, Lancashire, United Kingdom.

History

Yogi was examined in September following the development of a swollen lateral digit of the left thoracic limb noted by owner over the last 3 days. The cat was in good general health, up to date with all routine parasite prevention and core vaccinations, and was an avid rodent hunter.

Physical Examination

The digit was swollen and erythematous but was not associated with lameness. The associated superficial cervical lymph node was mildly enlarged. Multiple, non-painful, haired crusts were present over the dorsum, but no other clinical abnormalities were detected. The patient was discharged with oral meloxicam for 7 days.

At the week recheck appointment, a number of crusts had fallen away and the alopecic areas oozed a serous to purulent discharge. Histopathology of punch biopsies revealed severe multifocal follicular dermatitis. The inflammatory cells present mainly consisted of neutrophils, macrophages, and fewer lymphocytes and plasma cells. There was multifocal ulceration of the overlying epidermis adjacent to moderately hyperplastic areas. Large eosinophilic intracytoplasmic inclusion bodies were seen in the epidermal and follicular epithelial cells characteristic of poxvirus infection.

Diagnosis

Poxvirus infection.

Treatment

Amoxicillin-clavulanic acid was initially prescribed to treat secondary bacterial pyoderma, but this was switched to cefovecin because the cat could not be medicated orally. IFN-ω (1 million U/kg IV q24h for 3 days) was also administered. The cat was monitored as an outpatient over 6 weeks, during which time there was complete resolution of the clinical signs.

Pseudorabies

Diana Henke, Marc Vandevelde

KEY POINTS

- First Described: 1902 (Hungary, Aujeszky).[1]
- Cause: Suid (porcine) herpesvirus-1 (family *Herpesviridae*, subfamily *Alphaherpesvirinae*, genus *Varicellovirus*).
- Affected Hosts: Domestic and feral swine, cattle, horses, sheep, goats, dogs, cats, bears, raccoons, foxes, hedgehogs, opossums, deer, Florida panther, jackals, coyotes, some nonhuman primates (macaques, marmosets), chickens, pigeons, geese, ducks, buzzards, sparrow hawks, rabbits, guinea pigs, rats and mice.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Fever, lethargy, hypersalivation, muscle stiffness, variable facial pruritis, ataxia, behavioral changes, vomiting, diarrhea, respiratory distress.
- Differential Diagnoses: Rabies, canine distemper, toxicoses (e.g., organophosphates, heavy metals, ethylene glycol, strychnine).
- Human Health Significance: Some cases of pseudorabies virus-induced encephalitis have been reported in humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Pseudorabies virus (PRV), also known as Aujeszky's disease virus or suid (porcine) herpesvirus-1 (SuHV-1), is an enveloped DNA virus, which belongs to the family *Herpesviridae,* subfamily *Alphaherpesviridae*, and genus *Varicellovirus*.[2] As with other herpesviruses, PRV can cause latent infection, with viral DNA being incorporated into the host cell genome. The virus is relatively resistant to environmental factors and can survive outside the host for several months under favorable climatic conditions. Survival of PRV depends on temperature (10 days at 37°C, 40 days at 25°C) and pH (optimum, 7), and it is quickly inactivated by drying and exposure to ultraviolet light.[3] The molecular biology of PRV has been extensively studied because PRV is probably one of the most used viruses in experimental neuroscience.[4]

Pseudorabies, the disease caused by PRV (also known as *Aujeszky's disease*, *mad itch*, and *infectious bulbar paralysis*) occurs in most countries of the world, except Australia, and has been responsible for massive economic losses to the swine industry.[5,6] The name pseudorabies was applied because the clinical signs caused by the virus in rabbits resembled those of rabies. In swine, clinical signs depend on the age at exposure and virus strain. Subclinical infections and shedding occur commonly. When they do develop signs, older pigs typically develop respiratory disease. Encephalitis occurs in adult pigs infected with virulent strains or in piglets; reproductive disease and fetal loss occurs in pregnant sows. Recovered pigs develop latent infection of neuronal tissues with reactivation and shedding of virus in nasal secretions following stress. In the past, clinical disease outbreaks have been reported in several European, South American, and Asian countries. Restricted endemic areas are in the United States, Mexico, Brazil, and China. However, a PRV surveillance scheme is lacking in many countries. Continuous large-scale vaccination, removal of wild-type infected animals, followed by elimination of all PRV antibody-positive animals resulted in the eradication of the disease from domestic pigs in large parts of continental Europe (including Finland, Sweden, Norway, the Netherlands, Denmark, Austria, Switzerland, Germany, Hungary, Slovakia), the United Kingdom, Mexico, Canada, the United States, and New Zealand.[7–10]

Although many mammalian species are susceptible to infection with PRV, it is predominantly a problem in pigs, the main reservoir of the virus.[5,6] However, cattle, goats, sheep, dogs, and cats are sporadically affected.[11–18] It does not appear to affect humans; most reports of possible human infection have been circumstantial and not documented. Infection frequently is subclinical in pigs because they have become well adapted to the virus. The disease is spread by commercial movement of infected pigs or contaminated pork products. Venereal transmission occurs when infected boars shed PRV in semen. Although wild animals such as Iberian lynx, raccoons, panthers,[19–21] and rodents may act as transient reservoirs, they are not important in maintaining the disease in nature. Their role is limited to temporary local spread of virus within enzootic areas. However, in many European countries, the United States, Brazil, and Japan, PRV infection is endemic in wild boars with strongly varying seroprevalences ranging from 0 to 100%, creating a reservoir for the virus.[22–26]

PRV infection in dogs and cats is thought to occur only in areas where the disease is enzootic in pigs. Such interaction has been documented by molecular biologic studies on viral isolates.[27,28] In fact, the occurrence of typical pseudorabies signs in companion animals can be the first indication that the disease is enzootic in the local pig population. Companion animals almost invariably are infected as a result of consuming contaminated raw pork.[12,29] Dogs also have developed pseudorabies after having bitten infected pigs.[30] Direct dog-to-dog spread has not been shown to occur.[31] However, one report described an outbreak in animals without direct contact with swine. Isolated strains of PRV showed considerable differences in DNA patterns to vaccine and isolated strains obtained from pigs in the same region.[11] Feline and canine cases have been reported in Poland, Italy, Austria, Argentina, Germany, Northern Ireland, China, Japan, and the southern United States (Florida, Oklahoma, Arkansas, Alabama).[11,12,14,15,28,30,32–34] These are primarily hunting dogs that contact wild swine,[35–39] which has followed global expansion in wild swine populations; disease in dogs may be more likely to occur in regions that have dense populations of wild swine, such as southern parts of the United States (Fig. 39.1) and regions of Europe such as Germany, France, Spain, Poland, and the Czech Republic.[37] Dogs that reside on swine farms may

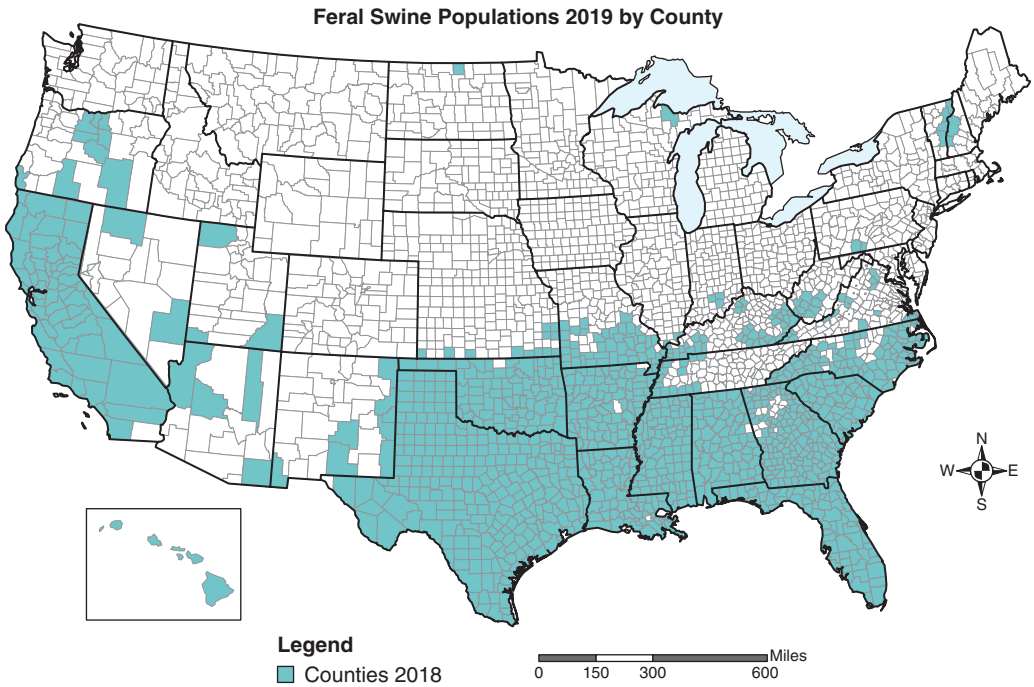

Fig. 39.1 Geographic distribution of wild swine in the United States. (From United States Department of Agriculture Animal and Plant Health Inspection Service; https://www.aphis.usda.gov.)

also become infected.[40] In some reports, packs of dogs have become infected after consumption of uncooked offal from infected pigs or pig carcasses.[41,42] Dogs of any age, sex, and breed can be affected, and dog-to-dog transmission does not occur, presumably because dogs do not shed sufficient virus to infect other hosts. Cats have the potential to be infected after ingestion of pork waste or infected rodents, but reports of naturally occurring Aujeszky's disease are extremely rare.[43] Because subclinical infections and nonspecific signs of disease are common in swine, identification of pseudorabies in dogs may be the first indication that disease is present in a swine herd or wild swine populations.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

SuHV-1 is shed in the saliva and nasal discharges of swine, and transmission can occur by direct contact with these discharges, contact with aerosols from swine, and ingestion of infected swine carcasses or other infected animals, especially wild animals. The virus can survive on fomites and in carcasses for several weeks. Naturally acquired infection in dogs and cats occurs after ingestion of the virus, although a similar sequence of events occurs after parenteral inoculation of virus. PRV enters the nerve endings at the inoculation site and travels in retrograde fashion via the axoplasm of the nerve fibers to the brain, which results in ganglioneuritis and encephalitis. Infection can also lead to ganglioneuritis of the cardiac autonomic plexuses with associated myocardial degeneration[44] and degeneration of intestinal myenteric ganglia.[42] Clinical signs appear rapidly after a short incubation period that typically ranges from 1 to 6 days, but incubation periods up to 10 days have been reported.[41] Experimental studies in orally infected cats have shown that PRV replicates in the tonsils and travels from the oral mucosa via the sensory branches of the 9th and 10th cranial nerves to the nucleus tractus solitarius and area postrema in the medulla oblongata.[45] The 5th cranial nerve has been less frequently involved. Experimental infections in rats have shown that PRV spreads in a highly specific manner through synaptic connections.[46,47] Viral–cellular interactions have been studied in great detail in experimental models.[4]

The majority of dogs and cats that become infected develop severe clinical signs. The onset of clinical illness is hyperacute, and signs progress rapidly until death occurs (possibly as a result of acute myocarditis); the total course rarely lasts longer than 48 hours. With very few exceptions, pseudorabies is always fatal in dogs. Cats may be somewhat more resistant but have rarely recovered from the disease. The initial sign often noted by the owner is a change in behavior, such as inactivity, lethargy, and indifference, although some animals become aggressive or restless. Dyspnea; diarrhea, which may be hemorrhagic (e.g., hematemesis or melena); and vomiting are occasionally seen (Table 39.1). The dyspnea is often caused by severe pulmonary edema. Body temperature may be normal or abnormal, and hypersalivation is common. However, the most characteristic sign is intense pruritus, which usually occurs in the head region and rarely occurs in other areas such as the neck and shoulders. Affected dogs violently scratch their faces and ears and rub their heads against the floor or walls. One side of the head and neck may become swollen. Self-mutilation results in erythema, excoriation, and ulceration of the skin and underlying tissues (Fig. 39.2A and B). The scratching becomes increasingly frantic and may end in generalized seizures. Most of the other neurologic signs observed in PRV infection refer to lesions in the lower brainstem and consist of one or several deficits in cranial nerve function. These deficits are usually unilateral and include anisocoria, mydriasis, lack of direct or consensual pupillary light reflexes, trismus, paresis and paralysis of the facial muscles, head tilt, inability to swallow, and vocal changes.[28] Anisocoria and a hoarse voice are considered to be highly consistent signs in the cat. Less commonly observed neurologic signs include behavioral abnormalities such as aggression, generalized hyperesthesia, head pressing, and generalized seizures. The latter often occur as sequelae to frantic scratching. Paresis and paralysis of the limbs are sometimes noted shortly before death. Although less common, in some cats, death has been preceded predominantly by acute GI signs. Arrhythmias may

occur as a result of myocarditis.[14,48,49] A variety of cardiac arrhythmias have been reported in experimentally infected dogs, which have included ventricular premature complexes, ventricular tachycardia, sinus arrest, atrial tachycardia, atrial fibrillation, wandering pacemaker, second-degree heart block, T- and P-wave abnormalities, and atrioventricular dissociation.

An atypical course of the disease has also been observed in cats that died suddenly without developing neurologic signs.[50] Pruritus has been absent in some cases of spontaneous PRV infection in dogs[15,51] and in experimental oral infection in cats.[45] In one case series, only 18% of dogs exhibited facial pruritis.[52] GI signs have been the predominant feature of some infected dogs.

TABLE 39.1 Clinical Signs Reported in a Retrospective Study of 25 Dogs with Pseudorabies from the United States[53]

Clinical Sign	Percentage Of Affected Dogs
Ptyalism	100
Anorexia	84
Ataxia	76
Wandering	64
Tachypnea	64
Dyspnea	60
Vocalization	56
Pruritis	52
Neck stiffness	48
Vomiting	36
Muscle spasms	36
Aggression	36
Trismus	28
Dysphagia	24
Abnormal pupillary light responses	20
Seizures	16
Mydriasis	12

Physical Examination Findings

Physical examination findings include lethargy, hypersalivation, dehydration, muscle stiffness, tachypnea or respiratory difficulty, and facial pruritis, excoriations, and edema due to self-trauma (see Fig. 39.2). Other neurologic signs that may be detected include ataxia, head tilt, circling, hyperesthesia, behavioral abnormalities, anisocoria, mydriasis, nystagmus, slow or absent pupillary light responses, recumbency, and coma. Fever may be identified early in the course of infection (up to 108°F),[53] but terminally, hypothermia may occur. A variety of cardiac arrhythmias may also be identified on physical examination.

DIAGNOSIS

Diagnosis of pseudorabies in dogs and cats is based on a compatible history (i.e., exposure to domestic or wild swine in regions where the virus is present), suggestive clinical signs, and histopathology and/or virus detection methods such as IFA staining, virus isolation, or PCR on tissues collected at necropsy (Table 39.2). Antemortem diagnosis of pseudorabies in dogs and cats using virus detection methods has not yet been described.

Laboratory Abnormalities

Hematologic or biochemical abnormalities are not found in pseudorabies. Electrocardiographic findings may include cardiac arrhythmias.[54] CSF may show increased protein concentration and mononuclear pleocytosis. This finding is strongly indicative of viral encephalitis but is not specific for pseudorabies.

Microbiologic Tests

Serologic Diagnosis

Virus neutralization, immunodiffusion, latex agglutination test, and ELISA methods commonly are used to detect serum antibody to PRV in pigs. Serologic studies have been valuable in determining the prevalence of disease in pig populations.[22] Serology has not been useful for antemortem diagnosis in dogs and cats. This likely reflects the rapid course of disease and insufficient time for antibody responses to develop.

Fig. 39.2 (A and B) Dogs with pseudorabies and self-mutilation injuries. (A, From Ciarello FP, Moreno A, Miragliotta N, et al. Aujeszky's disease in hunting dogs after the ingestion of wild boar raw meat in Sicily (Italy): clinical, diagnostic and phylogenetic features. *BMC Vet Res* 18, 27 (2022). https://doi.org/10.1186/s12917-022-03138-2; B, From Cramer SD, Campbell GA, Njaa BL, et al. Pseudorabies virus infection in Oklahoma hunting dogs. *J Vet Diagn Invest.* 2011;23:915–923.)

TABLE 39.2 Diagnostic Assays Available for Pseudorabies in Dogs and Cats

Assay	Specimen Type	Target	Performance
Histopathology	Usually necropsy specimens, especially brainstem	Nonsuppurative meningoencephalitis with weakly eosinophilic intranuclear inclusions; SuHV-1 antigen with IHC, IFA, or DNA with *in situ* hybridization	Used for postmortem diagnosis.
Polymerase chain reaction (PCR)	CNS, tonsils, possibly self-traumatized skin biopsies or tonsillar swabs	SuHV-1 DNA	Unknown whether PCR could be used for antemortem diagnosis. Not widely available.
Virus isolation	CNS, tonsils, occasionally other tissues such as skin biopsies or the lung	SuHV-1	Specialized procedure. False negatives occur commonly.

CNS, central nervous system; *IFA,* immunofluorescent antibody; *IHC,* immunohistochemistry; *SuHV-1,* suid herpesvirus-1.

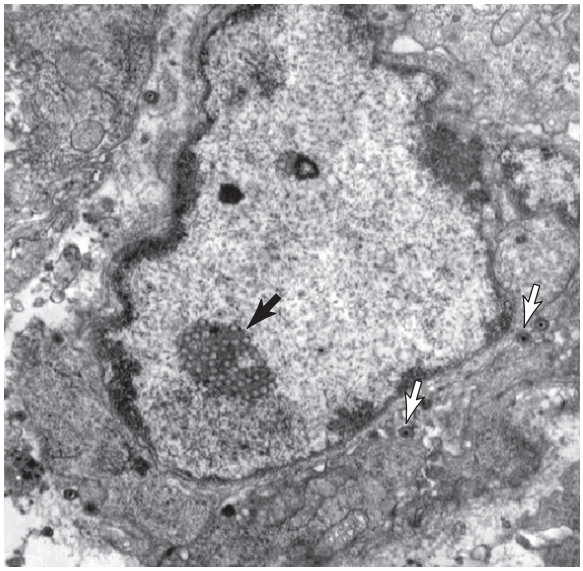

Fig. 39.3 Electron micrograph of pseudorabies virus (PRV)-infected cell culture. Intranuclear *(black arrow)* and cytoplasmic *(white arrows)* PRV viral particles. (Courtesy Dr. R. Maes, Michigan State University, East Lansing, MI.)

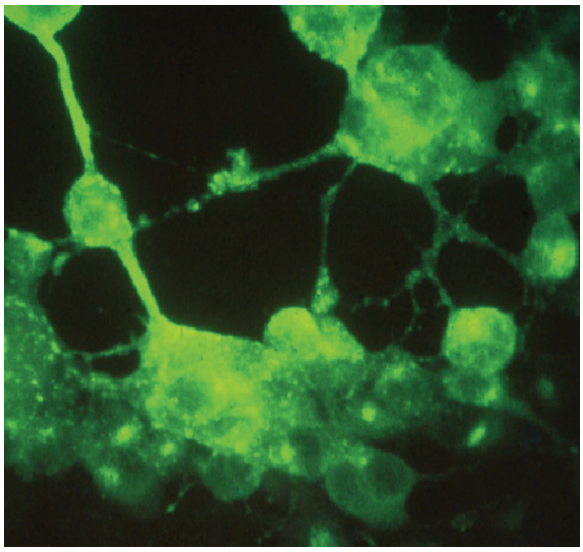

Fig. 39.4 Immunofluorescent antibody staining of cell culture infected with PRV. Note cytopathologic effect as multinucleated syncytia. (Courtesy Dr. R. Maes, Michigan State University, East Lansing, MI.)

Virus Isolation

Virus can be isolated in tissue culture from the lung and spleen and especially from brain and tonsils of animals with pseudorabies (Fig. 39.3). Although many cell lines have been used, most laboratories use pig kidney epithelial cells. A definite CPE consisting of syncytial formation is visible after 12 to 24 hours (Fig. 39.4). Virus isolation is not always easy in dogs, even in well-substantiated cases.[55] Pharyngeal washings, tonsillar swabs, and saliva are unsuitable for viral isolation in dogs.[56] Haired skin from regions of pruritis could be considered for testing.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR for different viral genes is the method of choice to detect the presence of PRV in the porcine population.[57–59] In dogs and cats, besides IHC, rabbit inoculation test, and virus isolation, PCR has been used successfully to detect the virus at necropsy.[14,28] Whether these assays are useful for antemortem diagnosis is not known, but PCR could be attempted on specimens such as biopsies of pruritic regions or tonsillar swabs.

Pathologic Findings

No gross lesions are diagnostic of pseudorabies, with the exception of the skin lesions that result from intense pruritus. Gross pathologic abnormalities include evidence of facial dermatitis, tonsillar enlargement, and GI mucosal hyperemia and ulceration. In some cases, abnormal stomach contents have been noted because of pica. Pulmonary edema and congestion have been consistent findings. Focal myocarditis and ecchymosis have been found in dogs and cats. Histopathology of the tonsils reveals suppurative tonsillar inflammation, sometimes with necrosis. Lesions in the CNS are almost exclusively located in the brainstem and primarily involve cranial nerve nuclei.[14,60] They may be unilateral and consist of perivascular cuffing with mononuclear cells and pronounced proliferation of astrocytes and microglial cells (Fig. 39.5A and B). The areas of focal gliosis often show degeneration (karyorrhexis) in the center and may progress to the formation of microabscesses. Severe changes occur in neurons, with chromatolysis and disintegration of the nucleus (Fig. 39.5C). The most definitive finding is the presence of weak eosinophilic viral inclusion bodies in the nuclei of astrocytes and neurons. Viral-specific antigen or nucleic acid can be demonstrated in formalin-fixed, paraffin-embedded tissues with immunocytochemical methods[14,61] or *in situ* hybridization, respectively.[62,63] Inflammatory changes can also be found in the nerves and ganglia associated with the site of viral entry. Severe inflammation of the myenteric plexus in the alimentary canal of dogs naturally infected with PRV has also been reported.[64] Experimentally infected dogs had ganglioneuritis of autonomic nerves of the heart.[64]

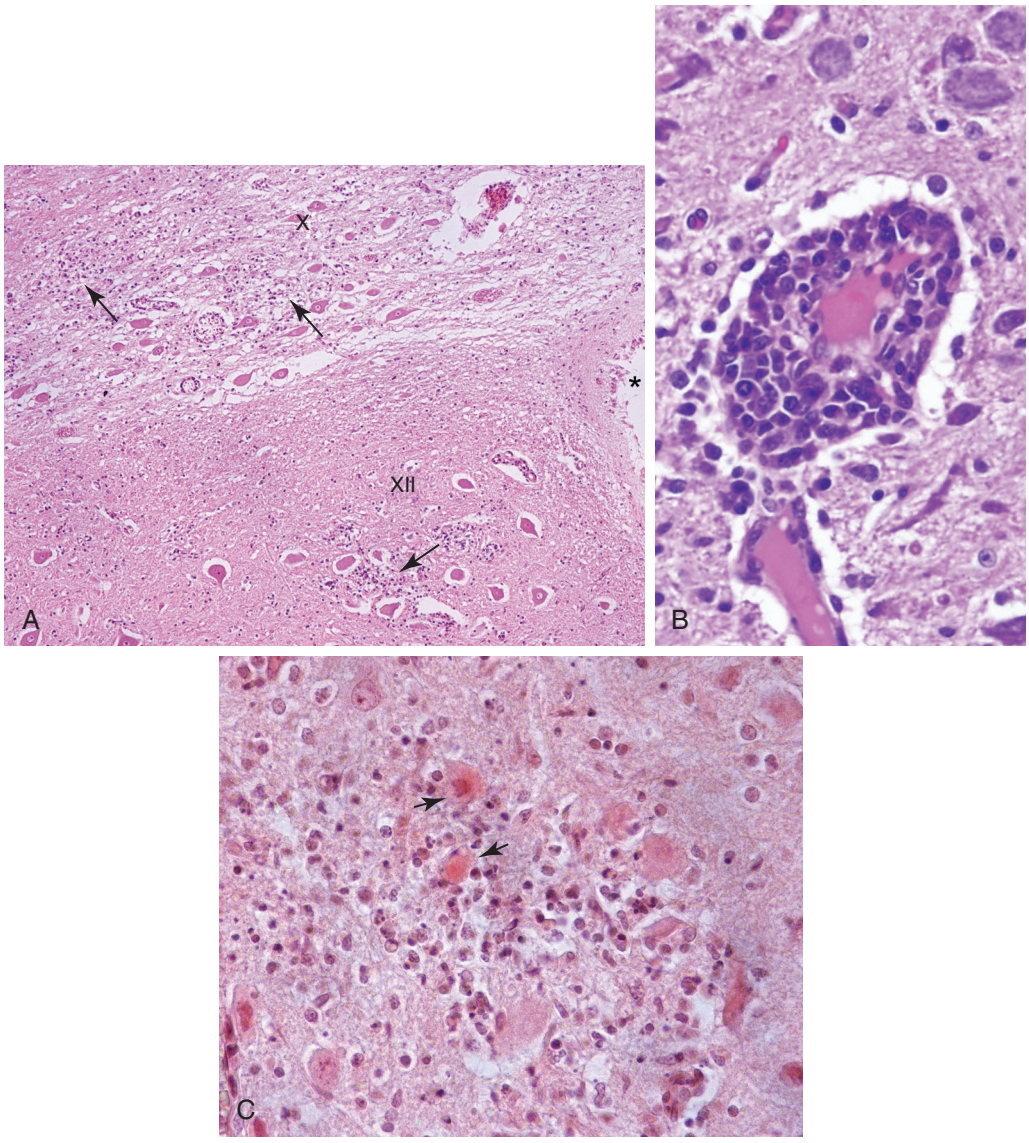

Fig. 39.5 Histologic findings of pseudorabies encephalitis in a dog. (A) Medulla oblongata (*asterisk*, fourth ventricle). Disseminated, inflammatory, mononuclear infiltration *(arrows)* in the nuclei of vagal (*X*) and hypoglossal (*XII*) nerves (H&E stain, ×40). (B) Mononuclear perivascular cuffing and gliosis in the brainstem (H&E stain, ×250). (C) Medulla oblongata, sensory nucleus of the trigeminal nerve. Widespread neuronal degeneration with chromatolysis and some eosinophilic shrunken neurons *(arrows)* associated with severe invasion of inflammatory cells (H&E stain, ×250). *H&E,* hematoxylin and eosin.

Diagnostic methods include IHC, immunofluorescence, or *in situ* hybridization on smears or frozen sections of various tissues. The brain and tonsils are the tissues of choice in such studies.

TREATMENT AND PROGNOSIS

Treatment of pseudorabies is generally futile because the disease is almost always fatal. Heavy sedation and anesthesia may lessen or relieve the itching and convulsions; however, nothing can alter the outcome of the disease. Treatment with anti-PRV serum did not improve the condition of a dog with Aujeszky's disease[51] and is considered to be ineffective in the prevention of infection.[31]

IMMUNITY AND VACCINATION

Although vaccines are used in swine to reduce losses in geographic locations where the disease is enzootic, vaccines are not available for dogs and cats because of the sporadic incidence of the disease. It is possible to vaccinate small animals against PRV, although this would be indicated only in endemic areas where exposure to infected domestic pigs and wild boars may occur. Natural infection with PRV has not been observed in vaccinated dogs and cats.[65] However, experimental vaccination challenge studies showed that it may be difficult to protect dogs with an inactivated vaccine, although most animals develop serum neutralizing antibodies to PRV.[31] Attenuated PRV vaccines may cause postvaccinal reactions that may be as lethal as the natural infection. PRV deletion mutants have been developed for vaccination of pigs.[10] Such "deletion" vaccines are safe and useful for controlling the disease because serologic surveys can distinguish between vaccine-induced and natural anti-PRV antibodies. Deletion vaccines have been tested in raccoons, albeit with limited success.[66] DNA vaccines have also been developed.[45] Human adenoviruses have been used as vectors for experimental immunization of cats against PRV antigens.[67] To the authors' knowledge, none of these modern vaccines have been

systematically tested or applied in dogs and cats. Considerable progress has been made in the eradication of PRV infection in swine in many areas of the world.[10] As a result, Aujeszky's disease has become a very rare condition in dogs and cats, and the development and application of PRV vaccines in small animals have remained insignificant. In view of the extremely low frequency of the disease in dogs and cats, further developments are unlikely.

PREVENTION

Prevention is the most important means of control of PRV infection in dogs and cats. Pseudorabies can be effectively prevented by feeding only cooked food to dogs and cats, control of rodents, and prevention of contact between domestic swine (in regions where the disease is enzootic) and wild swine and dogs.

PUBLIC HEALTH ASPECTS

In general, humans appear to be refractory to infection with SuHV-1. However, cases of PRV-induced encephalitis, as determined by PCR in CSF samples have been discovered in humans working with pigs in China.[68]

Papillomavirus Infections

Jennifer A. Luff, John S. Munday

KEY POINTS

- First Described: The transmissibility of canine papillomaviruses was described in the late 1800s; electron microscopic descriptions occurred in the late 1960s.[1,2] Papillomavirus infections of cats were not recognized until 1990.[3]
- Cause: Papillomaviruses (family *Papillomaviridae*).
- Affected Hosts: With the notable exception of bovine deltapapillomaviruses, papillomaviruses appear to have high species specificity.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Cutaneous or mucosal inoculation, probably through microtrauma.
- Major Clinical Signs: Dogs: oral or cutaneous exophytic or endophytic papillomas, cutaneous pigmented plaques, possibly cutaneous and oral SCCs. Cats: cutaneous viral plaques, cutaneous Bowenoid *in situ* carcinomas, possibly cutaneous SCCs, oral papillomas, and feline sarcoids.
- Human Health Significance: Canine and feline papillomavirus do not infect humans.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Papillomaviruses are small (30 to 60 nm), nonenveloped, icosahedral viruses with a circular double-stranded DNA genome (Fig. 40.1). They lack a lipid envelope, are resistant in the environment, and survive detergents and high temperatures. With rare exceptions, papillomaviruses are strictly host specific and have been identified in most mammalian species.[4]

Papillomaviruses infect keratinocytes at mucosal and cutaneous sites, most likely through microabrasions. Most papillomavirus infections are subclinical.[5] However, due to the ability of papillomaviruses to influence cell growth and regulation, infection by some papillomavirus types can result in marked proliferation of epithelial cells. This proliferation results in thickening and folding of the epidermis and the development of a hyperplastic, self-resolving papilloma (also referred to as a wart).[5] Less commonly, infection by papillomaviruses can influence the development of neoplasia (Box 40.1). In humans, whether infection remains asymptomatic, results in a papilloma, or promotes neoplasia is largely determined by the papillomavirus type[5] and the immune status of the host.[6] It is likely that the same is true for papillomavirus infections of dogs and cats, with both viral and host factors important in determining the manifestation of disease.

Due to the routine use of molecular testing, the number of different papillomavirus types identified in dogs and cats has expanded dramatically in recent years.[4] Papillomaviruses are classified on the basis of the L1 capsid gene nucleotide sequence.[7] At least 23 different types have been identified in dogs so far, with several additional novel types that have not been fully sequenced (Table 40.1).[8–24] These viruses have been classified into three distinct genera: *Lambdapapillomavirus, Taupapillomavirus, and Chipapillomavirus*.[10,25,26] In cats, six *Felis catus* papillomavirus (FcaPV) types have been fully sequenced with FcaPV1 classified within the *Lambdapapillomavirus* genus, FcaPV2 classified within the *Dyothetapapillomavirus* genus, and FcaPV3, 4, 5, and 6 likely to be classified within the *Taupapillomavirus* genus.[27–32] As with dogs, it appears likely that additional FcaPV types will be identified in the future.

The canine lambdapapillomaviruses include *Canis familiaris* papillomavirus (canine papillomavirus, CPV[†]) types 1 and 6.[8,10] CPV1 was the first CPV identified. This virus commonly infects young dogs, often resulting in numerous oral papillomas that spontaneously regress. This CPV has also rarely been associated with cutaneous endophytic (inverted) papillomas and invasive cutaneous SCCs.[33–37] CPV6 was identified from a single cutaneous papilloma that regressed spontaneously.[10] CPV19 was identified from a single oral papilloma.[22]

Taupapillomaviruses that have been identified in dogs include CPV types 2, 7, 13, 17, 21, 22, and 23. CPV2 has been identified within cutaneous papillomas and is only rarely associated with SCC.[18] However, in a research colony of dogs with X-linked severe combined immunodeficiency, CPV2 caused cutaneous papillomas that progressed to invasive and metastatic SCC.[38] CPV7 has thus far only been reported from a single cutaneous papilloma/*in situ* SCC.[10] CPV13 was identified from oral cytobrush specimens from a dog with oral papillomatosis.[9] CPV17 was identified as the likely cause of multiple oral SCCs in a dog.[39,40] CPV21, CPV22, and CPV23 were identified using viral metagenomics from nasal swabs and the association with clinical disease is currently unknown.[24]

Chipapillomaviruses include CPV types 3, 4, 5, 8, 9, 10, 11, 12, 14, 15, and 16. All of these chipapillomaviruses are associated with cutaneous pigmented plaques. CPV3 has been reported in multiple dogs, including a dog that developed numerous pigmented plaques and *in situ* SCC,[16] one dog with pigmented plaques,[41] one dog with pigmented plaques, basal cell carcinomas, SCCs, and trichoblastomas,[42] and one dog with a pigmented viral plaque that progressed to SCC.[36] CPV4 has been most commonly associated with pigmented plaques in pug dogs,[17,43–45] but other dog breeds can be affected.[41] CPV9 has been identified in several dogs with pigmented plaques,[12,19,41,46] including one dog that developed multicentric invasive SCC in association with its persistent pigmented plaques.[47] CPV12 has been identified in two dogs with pigmented plaques[20,41] and two additional related Basenji

[†] For the purposes of this chapter, CPV refers to canine papillomavirus, not canine parvovirus.

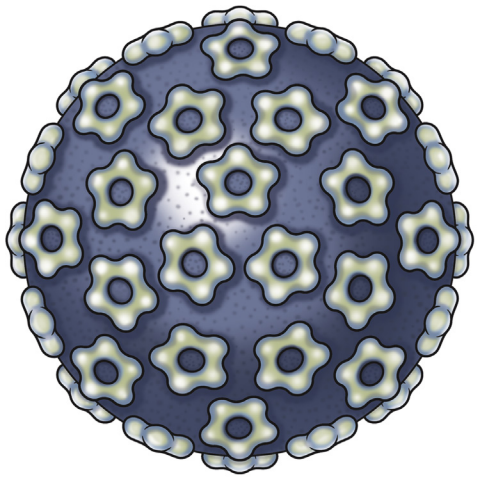

Fig. 40.1 Structure of a papillomavirus. The virus is nonenveloped and has an icosahedral capsid composed of two different capsid proteins (L1 and L2).

BOX 40.1 Spectrum of Clinical Manifestations Associated with Papillomavirus Infections in Dogs and Cats

Dogs
Oral papillomatosis
Cutaneous exophytic papillomas (warts)
Cutaneous endophytic papillomas (inverted warts)
Pigmented cutaneous plaques
Cutaneous *in situ* squamous cell carcinomas (SCCs)
Invasive cutaneous SCCs
Oral SCCs

Cats
Feline viral plaques
Bowenoid *in situ* carcinomas
Invasive cutaneous SCCs
Basal cell carcinomas
Oral papillomas
Feline sarcoids

TABLE 40.1 Spectrum of Papillomavirus Types and Disease Associations in Dogs

Genus	CPV Type	Clinical Manifestation
Lambda	1	Oral papillomas, oral SCC[a], cutaneous papillomas
	6	Cutaneous papillomas (warts)
	19	Oral papilloma
Tau	2	Cutaneous papillomas
	7	Cutaneous papillomas, *in situ* SCC
	13	Oral papillomas
	17	Oral SCC[a]
Chi	3	Cutaneous pigmented plaques, *in situ* SCC
	4, 5, 8, 10, 11, 14, 15, 18	Cutaneous pigmented plaques
	9, 12, 16	Cutaneous pigmented plaques, *in situ* SCC, invasive SCC[a]

CPV, canine papillomavirus; *SCC,* squamous cell carcinoma.
[a]The majority of SCCs in dogs are not associated with papillomavirus infections.

dogs.[15] In one Basenji dog, the lesions progressed to invasive and metastatic SCC. The other Basenji dog developed metastatic SCC associated with pigmented plaques due to CPV16.[13,15] CPV16 has also been identified in two additional dogs with pigmented plaques that progressed to SCC.[36,48] CPV5 and CPV15 have been identified in small numbers of dogs with pigmented plaques,[10,41] while CPV types 8, 10, 11, and 14 have thus far only been identified from single cases of pigmented plaques.[11,12,14,21] CPV18 was originally identified within a pigmented plaque from a pug dog,[23] and has been identified in one additional pug dog with a pigmented plaque and basal cell tumor.[45] CPV20 is most likely a *Chipapillomavirus* based upon its sequence, but there is currently no reported information for this virus.

There have been several reports of pigmented plaques progressing to SCC. The associated CPV type, however, has only rarely been identified; therefore, it remains unknown whether pigmented plaques caused by a particular CPV type are at greater risk of progressing to SCC. Thus far, only CPV3, CPV9, CPV12, and CPV16 have been associated with malignant progression of pigmented plaques to invasive and metastatic SCC.[13,15,47] Overall, these are rare cases and there is currently no evidence to suggest that CPVs are a significant cause of either cutaneous or oral SCCs.[49–51]

Many of these CPV types have been identified in small numbers of dogs, and often from a single lesion or a single animal. Therefore, it is difficult to determine their prevalence, geographic distribution, biologic characteristics, or clinical behavior.

In general, lesions due to papillomavirus infection are more frequently recognized in dogs than in cats. In cats, infections by papillomaviruses are believed to cause feline viral plaques and Bowenoid *in situ* carcinomas (BISCs). As viral plaques can progress into BISCs,[52] these two lesions probably represent a continuum of papillomavirus-induced hyperplasia and dysplasia of the epidermis. BISCs have been previously referred to as multicentric SCCs *in situ.* However, as BISCs can develop as single lesions, and as BISCs contain histologic features not observed in sun-induced *in situ* SCCs, this term is not favored. In cats, papillomaviruses are also recognized to cause feline sarcoids (previously known as fibropapillomas) and oral papillomas. In cats, there is increasing evidence that papillomaviruses may influence the development of a proportion of cutaneous SCCs. While papillomaviral DNA has been occasionally detected in feline oral SCCs,[53–56] there is currently no evidence that feline oral SCCs are caused by papillomaviruses.[57]

Felis catus papillomavirus type 1. This *Lambdapapillomavirus* was initially identified in a feline viral plaque from a cat that was suspected to be immunosuppressed.[30] Subsequent research suggests that FcaPV1 is a rare cause of feline viral plaques. However, this papillomavirus was identified in two feline oral papillomas[58] and, as FcaPV1 is closely related to the papillomaviruses that cause oral papillomas in lions and snow leopards, this virus is the likely cause of oral papillomas in domestic cats.

Felis catus papillomavirus type 2. This *Dyothetapapillomavirus* currently appears to be the most common cause of papillomavirus-induced disease in cats. The majority of feline viral plaques and BISCs appear to be caused by infection with this papillomavirus type.[59] However, as FcaPV2 can be detected on the skin of most cats[60] and yet only a small proportion develop disease, host factors appear to be important for disease development. The importance of host factors is demonstrated by the observation that Devon Rex, and the closely related Sphinx, cats develop an unusually severe manifestation of FcaPV2-induced disease

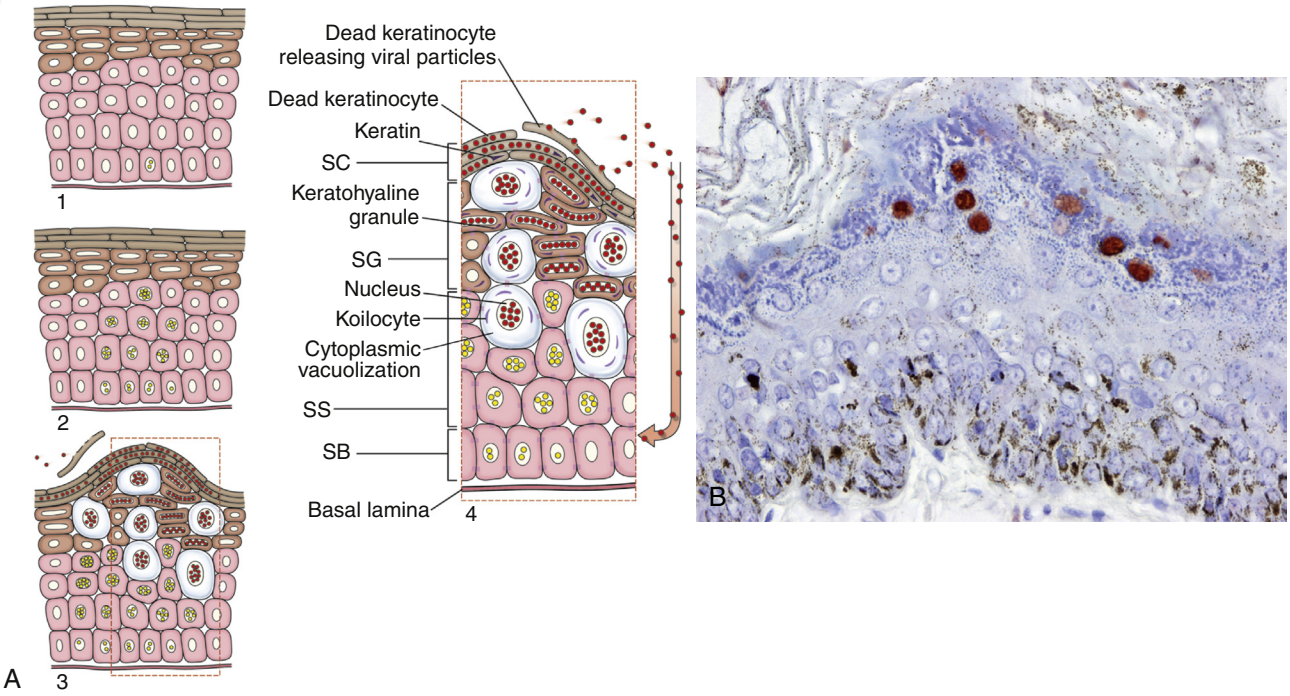

Fig. 40.2 Schematic representation of the events of papillomavirus infection in the epidermis. (A) 1, The primary infection occurs in a cell of the stratum basale *(SB)* after the virus gains entry via a microabrasion. The virus replicates and expresses the early proteins, which leads to increased cellular proliferation. 2, Progeny of the initial infected cells migrate laterally and move upward, where they accumulate in the stratum spinosum *(SS)* and stratum granulosum *(SG)*. 3, Cellular differentiation ultimately occurs, and large numbers of virions are produced in association with papilloma development. Virions are shed with exfoliating keratinocytes of the stratum corneum *(SC)*. 4, Detail from 3. (B) Immunoperoxidase staining of papillomavirus antigen in a cutaneous plaque from a dog. (B, Courtesy of Luff J, University of California, Davis. In: MacLachlan NJ, Dubovi EJ, eds. *Fenner's Veterinary Virology*. 4th ed. Burlington, MA: Academic Press [Elsevier]; 2011.)

early in life.[61,62] The host factors that are important in disease development are currently uncertain. Initial studies suggested immunosuppression predisposed to disease; however, both viral plaques and BISCs can develop without any detectible loss of immune function. This suggests that immunosuppression is not essential for disease development.

In addition to viral plaques and BISCs, there is increasing evidence that FcaPV2 is a significant cause of feline cutaneous SCCs. FcaPV2 DNA has been detected more frequently in SCCs than in non-SCC skin specimens,[59] papillomavirus-induced changes in cell regulatory proteins have been detected in SCCs that contain FcaPV2 DNA,[63] differences in biological behavior have been observed between SCCs with evidence of papillomavirus infection and those without,[64] and FcaPV2 oncogene RNA has been detected within a proportion of feline cutaneous SCCs.[65–67] Overall, FcaPV2 could influence the development of 30%–50% of feline cutaneous SCCs. SCCs from haired skin are most likely to contain evidence of a papillomaviral etiology. However, some evidence also suggests that FcaPV2 can act as a co-factor with sun exposure to promote SCC development.[68]

Felis catus papillomavirus types 3, 4, 5, and 6. These papillomaviruses will probably all be classified within the *Taupapillomavirus* genus. These types have been detected in association with pre-neoplastic or neoplastic skin lesions in cats. However, these seem to be less common causes of feline viral plaques, BISCs, and SCCs than FcaPV2.[27,31,32,69] Currently, it is uncertain whether lesions caused by these four papillomavirus types have a different clinical behavior to lesions caused by FcaPV2. However, these types may be more likely to result in the development of basal cell carcinomas.[70]

Feline sarcoids. Evidence suggests that these mesenchymal neoplasms are caused by cross-species infection with bovine papillomavirus (BPV) type 14.[71] BPV14 is a *Deltapapillomavirus* like BPV1 and BPV2, which are thought to cause equine sarcoids. It is interesting to note that BPV14 has not been detected in an equine sarcoid, and neither BPV1 nor BPV2 has been detected in a feline sarcoid. Evidence of viral replication is not present within feline sarcoids, and these are considered to be dead-end infections.[72] How the papillomavirus is transferred from cow to cat is currently unknown.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Infection with papillomaviruses follows inoculation of the virus through microabrasions in the skin and mucous membranes caused by physical trauma. Initial infection and viral amplification occurs within keratinocytes of the stratum basale.[73] As basal keratinocytes undergo differentiation, early viral proteins (E proteins) are expressed and associate with regulators of the cell cycle to stimulate cell cycle progression.[73] This can lead to enhanced proliferation of cells in the stratum spinosum and stratum granulosum, with accumulation of infected cells and papilloma formation (Fig. 40.2). With the exception of feline sarcoids, which remain as latent (or nonproductive) infections, late viral products, including the virus capsid proteins (L1 and L2), are first expressed in cells of the stratum spinosum. Papillomaviruses are nonlytic viruses, and mature virions are shed with cells that exfoliate from the stratum corneum or the nonkeratinized cells of the mucous membranes. Infected cells develop a characteristic CPE, which consists of cytoplasmic vacuolization. Tens of thousands of virus particles are produced by each infected cell. Papillomaviruses can predispose to the neoplastic transformation of infected cells because

their viral E6 and E7 proteins (also known as oncoproteins) alter normal cell cycle regulation and/or apoptosis.[74] For example, human "high-risk" papillomavirus types produce proteins that degrade p53 and retinoblastoma protein (pRb), which are important tumor suppressors.[75] Accidental integration of the DNA of human "high-risk" papillomavirus types into host cell DNA can result in a marked increase in papillomavirus oncogene expression. The resultant population of rapidly dividing and genetically unstable cells is greatly predisposed to neoplastic transformation.[74]

Canine Oral Papillomatosis

Canine oral papillomas most commonly occur in young dogs and often regress spontaneously over a 4- to 8-week period.[26] They can also occur as a result of immunosuppression, such as after treatment with cyclosporine, less commonly chronic glucocorticoid treatment, or chronic infection with *Ehrlichia canis*. Rarely, papillomas in the caudal oropharynx obstruct respiration. Oral papillomas can occur on the lips, mucocutaneous junctions, tongue, pharynx, eyelids, and infrequently haired skin[26] (Fig. 40.3). They may cause halitosis, ptyalism, and oral discomfort. Early lesions are smooth and raised, but as they enlarge they may become cauliflower-like. They may be pigmented or nonpigmented.

Canine Cutaneous Papillomas

Cutaneous exophytic and endophytic papillomas usually occur as solitary masses.[26] Exophytic papillomas are proliferative nodules, whereas endophytic papillomas are cup-shaped cutaneous nodules that range in size from 2 mm to 2 cm in diameter with a central keratin-filled depression. Cutaneous exophytic papillomas are wart-like projections that appear anywhere on the body, but especially the lower limbs and footpads. Single or multiple lesions can occur anywhere on the body (Fig. 40.4). They have also been described in the interdigital space.[38] Rarely, papillomas can form along sites of previous surgery.[76]

Canine Pigmented Plaques

Pigmented plaques can develop as single or multiple lesions on the skin and have variable degrees of pigmentation. The lesions usually range in size from 1 mm to 1 cm, but can become larger. They appear as dark (although this can be variable), hyperkeratotic flat lesions that are typically present on the ventrum or medial aspects of the limbs[48] (Fig. 40.5). Pugs and miniature schnauzers are considered to be predisposed, but many other breeds can be affected. The lesions can regress spontaneously over the course of a few months, but may persist in some dogs. These are generally not of clinical significance, although rarely they can progress to SCCs.[15,48,77]

Canine Squamous Cell Carcinomas

These neoplasms are often ulcerated, nodular masses that may be found alongside pigmented plaques or cutaneous papillomas when malignant transformation occurs. However, transformation of oral and cutaneous papillomas is rare, and most cases of canine SCCs are not associated with papillomavirus infection.[49–51]

Feline Viral Plaques

Plaques typically develop on older cats and often present as multiple, less than 1 cm in diameter, sessile, hairless, pigmented lesions. They tend to develop most frequently around the face, although they can develop anywhere on the body.

Bowenoid In Situ Carcinoma (BISC)

BISCs also typically develop on older animals, although have been reported in Devon Rex cats as young as 3 years of age.[61] Most cats with

(B) Histology of an inverted papilloma showing typical epithelial hyperplasia that occurs below the level of the surrounding normal skin. (C) Higher magnification of keratinocytes with characteristic blue-gray cytoplasm and prominent intranuclear inclusions *(inset)*. (A, Courtesy of Steven White, University of California at Davis, School of Veterinary Medicine, Dermatology Service.)

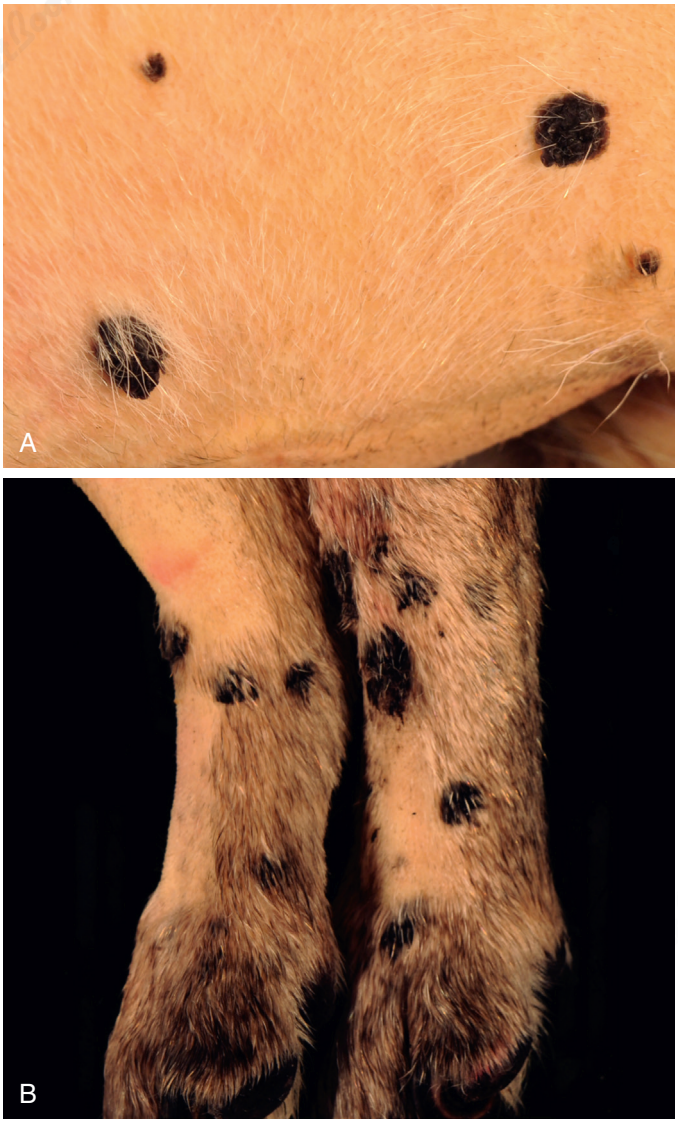

Fig. 40.5 (A and B) Multiple pigmented plaques on the ventral abdomen and limbs of a 10-year-old female, spayed pug dog. (Courtesy of Ashley Talley, North Carolina State University, College of Veterinary Medicine, Anatomic Pathology Service.)

BISCs will develop multiple lesions, although the development of a single lesion does not exclude BISC as a diagnosis.[78] BISCs most commonly involve the head and dorsum of cats (Fig. 40.6). They typically appear as roughly spherical hairless masses that can either be ulcerated or covered by orthokeratosis. They can be pigmented. Differentiation between a feline viral plaque and a BISC may not be possible clinically, but as a general rule, the larger the lesion is, the greater the likelihood of a BISC.

Feline Cutaneous Squamous Cell Carcinomas

These appear as ulcerated masses. Feline cutaneous SCCs can be subdivided into those that are caused by sun exposure and develop as a progression from actinic keratosis and those that are caused by papillomavirus infection and develop as a progression from a BISC. As sunlight appears to be the most common cause of feline cutaneous SCCs, these neoplasms most often occur in lightly pigmented and lightly haired areas of the body. SCCs that develop on the pinnae are the least likely to contain evidence of papillomavirus infection, while SCCs from haired, pigmented skin are most likely to have a putative papillomaviral etiology.

Feline Oral Papillomas

These lesions are rarely reported in middle-aged to older cats. However, as the papillomas do not cause clinical signs and are only discovered as an incidental finding, the true prevalence of oral papillomas in cats is unknown. Oral papillomas appear as multiple < 5-mm diameter pale raised lesions on the ventral surface of the tongue.[58]

Feline Sarcoids

Feline sarcoids have been described in cats from North America, New Zealand, the United Kingdom, Sweden, and Australia. They are thought to be caused by BPV14, and contact with cattle appears necessary for disease development. Affected cats are often young (<5 years), male, outdoor cats from rural environments.[79] Sarcoids typically appear as hairless, solitary, firm, exophytic masses. Although they most commonly develop around the mouth and nose, especially the nasal philtrum (Fig. 40.7), they have also been reported at other locations such as in digits, tail tip, eyelids, and pinnae.[79,80]

DIAGNOSIS

The history and gross appearance of oral papillomas in dogs is generally sufficient for diagnosis. For other papillomas and plaques, the diagnosis can be confirmed with biopsy and histopathology. A full-thickness biopsy that includes adjacent normal skin should be collected. The presence of papillomaviruses can be investigated using PCR, IHC, *in situ* hybridization, or electron microscopy, although these techniques are primarily used on a research basis. Caution should be used when interpreting the results of PCR assays because papillomaviruses can be detected on normal skin,[60,81] so results should be interpreted in association with clinical signs. While DNA *in situ* hybridization is considered less sensitive than PCR, this technique can confirm the location of papillomavirus DNA within the lesion. However, the presence of DNA within a lesion does not necessarily prove causality. Assays to detect papillomaviral oncogene RNA in a lesion have been used to further investigate whether the papillomavirus is likely to be influencing cell behavior or simply present within the lesion as an "innocent bystander."[15,65]

IHC and electron microscopy can be used to detect viral antigen and viral particles, respectively. These techniques can only detect papillomaviruses in lesions that contain viral replication. Typically, little or no viral replication is present in SCCs and sarcoids, which makes these techniques of reduced value to investigate a papillomavirus etiology of these lesions. In the authors' experience, few papillomavirus-induced lesions contain antipapillomavirus immunostaining in the absence of histologically detectible papillomavirus-induced cell changes. Canine and feline papillomavirus-specific reagents are not widely available, and care has to be taken to ensure cross-reactivity between the available antipapillomavirus antibodies and canine and feline papillomaviruses.

IHC to detect $p16^{CDKN2A}$ protein (p16) can also be used to investigate a possible papillomaviral etiology of a lesion. Papillomaviruses consistently alter normal cell regulation by degrading pRb. Loss of normal pRb function in a cell increases p16. Therefore, the detection of intense nuclear and cytoplasmic p16 immunostaining in a human oral SCC is considered consistent with a papillomaviral etiology.[82] Similarly, intense p16 immunostaining has been observed in association with loss of pRb in feline viral plaques, BISCs, and papillomavirus-associated SCCs.[75] Additionally, increased p16 immunostaining was observed in a feline oral papilloma and in a canine oral SCC that was associated with CPV17 infection.[40,58] The advantage of p16 immunostaining over papillomavirus immunostaining is that p16

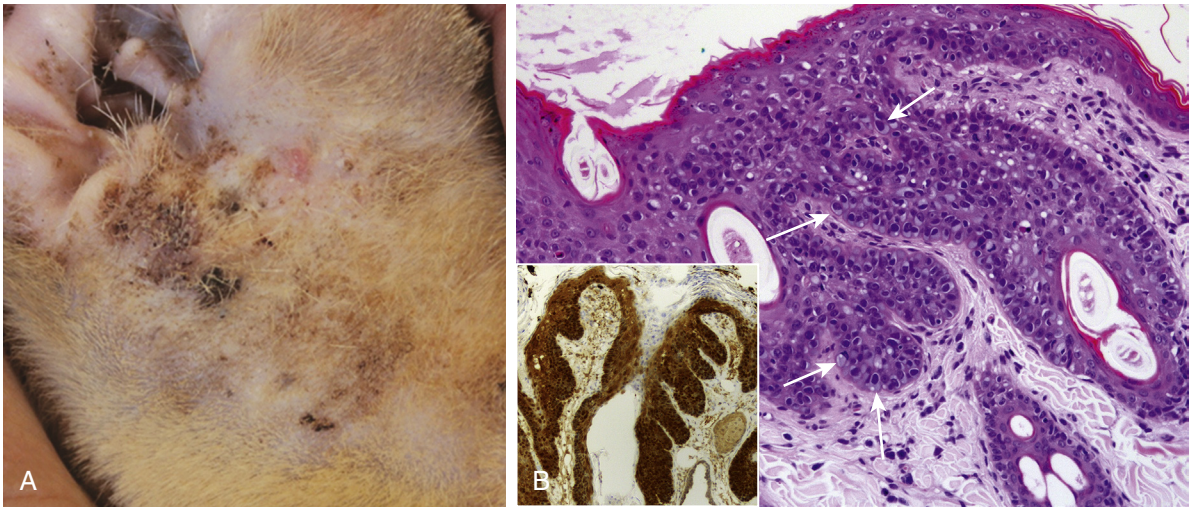

Fig. 40.6 (A) Bowenoid *in situ* carcinoma (BISC). These masses appear as single or multiple scaly or ulcerated plaques that are most common on the head and dorsum. (B) Histopathology of a BISC reveals hyperplasia and dysplasia involving the full thickness of the epidermis and extending into follicular infundibula. While this lesion contains prominent papillomavirus-induced cell changes *(arrows)*, such changes tend to be rare in advanced BISC lesions. The dysplastic cells contain a marked increase in p16CDKN2A *(inset)* suggesting that the papillomavirus has influenced cell cycle regulation by interfering with normal retinoblastoma protein function.

Fig. 40.7 Sarcoid of the nasal philtrum of a cat. The sarcoid recurred after repeated attempts at surgical excision. The sarcoid eventually began to interfere with eating and the cat was euthanized. (Courtesy of Dr. William Miller, Cornell University College of Veterinary Medicine and Dr Cameron Knight, University of Calgary.)

immunostaining is not dependent on active viral replication. In addition, the presence of increased p16 within a lesion that contains papillomavirus DNA provides evidence that the papillomavirus was altering cell regulation rather than being present as an incidental infection. However, a disadvantage of p16 immunostaining is that any cause of reduced pRb function will increase cell p16 and the specificity of this test for the detection of a papillomavirus etiology in dogs and cats has not been determined.

Microbiologic Tests

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays can be used to detect papillomaviruses within biopsy or cytobrush specimens from dogs and cats. Consensus primers are available to detect multiple different papillomavirus types. If unfixed tissue is available, either rolling circle amplification or next generation sequencing can be used to amplify whole circular genomic DNA.[26,29]

Pathologic Findings

Productive infection of an epithelial cell by a papillomavirus can result in papillomavirus-induced cell changes. Recognition of these changes is good evidence that the lesion was caused by papillomavirus infection. Furthermore, each papillomavirus genus appears to result in subtly different cell changes and so detection of these changes can be valuable to suggest the likely etiologic agent.[69] Papillomavirus infection can result in *koilocytosis*—cells with a dark shrunken nucleus surrounded by a clear cytoplasmic halo. Papillomavirus infection can also result in the development of large cells that have increased quantities of blue-gray fibrillar cytoplasm (see Fig. 40.4C). Less frequently, papillomaviruses can result in the development of prominent intracytoplasmic bodies, likely due to aggregates of keratin. Papillomaviruses can also be visible as amphophilic to basophilic intranuclear inclusions in the upper layers of the epidermis, although these inclusions tend to be transient and can sometimes be hard to differentiate from nucleoli (see Fig. 40.4C).

Histopathology of canine exophytic papillomas generally reveals exophytic projections of epidermal hyperplasia (acanthosis) with extensive hyperkeratosis and clumped keratohyalin granules in the stratum spinosum (see Fig. 40.3C). Endophytic papillomas are cup-shaped masses of epithelial hyperplasia that occur below the level of the surrounding normal skin (see Fig. 40.4B). Koilocytosis and intranuclear inclusions are often prominent (see Fig. 40.4C).

Histopathology of canine pigmented plaques reveals locally extensive epidermal hyperplasia, hyperkeratosis, hyperpigmentation, and clumped keratohyalin granules; koilocytes and viral inclusions are generally not observed.[26]

Feline viral plaques appear as focal well-demarcated areas of epidermal thickening. They frequently contain koilocytes and often contain cells that have increased quantities of blue-gray fibrillar cytoplasm.

BISCs also appear as well-demarcated foci of epidermal thickening; however, in contrast to a viral plaque, the thickened epidermis contains evidence of dysplasia (see Fig. 40.6). The cells within the basal

cell layers typically become crowded and groups of cells can develop dorsoventrally aligned nuclei resulting in a "windblown" appearance. Papillomavirus-induced cell changes can be present within BISCs; however, they tend to be less frequent in advanced lesions. The presence of invasion of cells through the basement membrane prompts a classification of SCC.

SCCs that are associated with papillomavirus infection rarely have evidence of papillomavirus infection and histology cannot be used to predict which SCCs contain papillomaviral DNA.

Feline oral papillomas appear as a focus of thickened epithelium that is arranged as exophytic folds supported by a fibrovascular stalk. Papillomavirus-induced cell changes are present including the presence of prominent eosinophilic cytoplasmic bodies.[58]

Feline sarcoids appear as dermal fibroplastic proliferations. The overlying epidermis is mildly hyperplastic and includes long, thin rete ridges that extend into the tumor.[79] The characteristic epidermal changes allow differentiation from a fibrosarcoma. Papillomaviral replication does not occur in feline sarcoids, and these lesions do not contain papillomavirus-induced cell changes.

TREATMENT AND PROGNOSIS

The outcome of a papillomavirus infection depends on the papillomavirus type and as more information becomes available, certain papillomavirus types may be found to be more likely to result in neoplastic transformation, which may aid prognostication. The prognosis also appears to be influenced by host factors. The overwhelming majority of oral and cutaneous papillomas in young dogs regress spontaneously 4 to 16 weeks after onset of clinical signs. However, they may persist in older dogs, or when there is underlying immune compromise, and occasionally progress to malignancy.[36,37] If possible, underlying immunosuppression should be treated (for example, through removal or tapering of immunosuppressive drug treatment).

Lesions can be removed surgically if they cause physical obstruction or for cosmetic reasons, but surgical treatment may be followed by recurrence. As in human medicine, cryotherapy appears to be a useful technique to treat canine papillomas that persist. As seen in humans with warts, repeated treatments may be required for some canine papillomas.[83] Numerous other treatments have been proposed to accelerate resolution of a papilloma. However, because a high proportion of papillomas eventually spontaneously regress, definitively proving that a treatment influences resolution is difficult. Treatment with azithromycin (10 mg/kg PO q24h for 10 days) appeared to be effective in a prospective, randomized, double-blinded placebo-controlled clinical trial that included 12 dogs with oral papillomatosis and 5 dogs with cutaneous papillomatosis.[84] However, azithromycin has been subsequently reported to have been used without showing beneficial clinical effects. The use of topical or intralesional immunomodulators (such as imiquimod cream) and antiviral drugs (such as cidofovir) has shown promise for treatment of persistent papillomas in humans, but these treatments have not been evaluated for papillomas in dogs. Papilloma regression is dependent on CMI and there is no evidence that stimulating a humoral antibody response by autogenous vaccination influences resolution of a papilloma.

Canine pigmented plaques can persist, but transformation to invasive SCC is rare.[15,47] There are single case reports demonstrating successful treatment of extensive cutaneous pigmented plaques with carbon dioxide laser treatments[85] and the antineoplastic agent tigilanol tiglate.[86]

The behavior of feline viral plaques and BISCs is poorly understood. It appears that spontaneous regression is possible, although some lesions remain stable over a long period of time, and others progress to SCC.[87] Progression to SCC appears to be especially frequent and rapid in Devon Rex and Sphinx cats with subsequent metastases reported.[61,62] In a study of 12 cats with BISCs that were treated using topical imiquimod cream, partial resolution of a treated lesion was noted in all cats with 5 cats reported to have complete remission of at least one BISC lesion.[78] However, five cats developed erythema at the site of treatment and two cats showed signs of systemic toxicity. While this study showed some promise, no untreated cats with BISCs were included and whether or not imiquimod significantly alters the disease course in cats with BISCs remains unknown. It should also be noted that imiquimod does not have any specific action against papillomaviruses. Due to the surface location of BISCs, it appears likely that cryotherapy may be a potential treatment option, although there are no published studies using this as a treatment for BISCs in cats. As in humans, papillomavirus-associated feline cutaneous SCCs appear to have a more favorable prognosis than nonpapillomavirus-associated SCCs.[64]

Most feline oral papillomas probably spontaneously resolve and there is no evidence that they progress to oral SCCs in cats.[50,58]

Feline sarcoids often recur locally after surgical removal, but metastasis does not occur. Topical imiquimod cream did not appear to slow the disease progression in a cat with a feline sarcoid.[71]

IMMUNITY AND VACCINATION

Regression of a papilloma is associated with papillomavirus type-specific resistance to reinfection. Immunity to papillomaviruses comprises: (1) the host immune response to the virus and (2) a cell-mediated immune response to the tumor, which is ultimately responsible for tumor regression. This explains why new tumors may not occur, but old tumors persist and continue to grow in the face of an immune response to the virus, and immunization with the virus does not induce tumor regression. Papillomaviruses can evade the host immune response because infection is limited to the skin, and the immunogenic capsid protein is not expressed until the virus reaches the terminally differentiated outer layer. A variety of other mechanisms of immune evasion have been identified in human papillomavirus infections, including downregulation of the antiviral interferon response by papillomavirus proteins.[88]

PREVENTION

No vaccines are available for prevention of papillomavirus-induced disease in dogs and cats. While vaccination against CPV1 would be expected to prevent oral papillomas and a proportion of cutaneous papillomas, it appears unlikely that clients would pay for a vaccine to prevent a benign disease that almost always spontaneously resolves. An experimental vaccine against FcaPV2 was recently developed and shown to induce antibodies against this virus. However, the vaccine did not decrease the viral load on the skin of cats.[89] This suggests that any vaccine has to be given prior to first infection by the virus. As cats seem to be infected immediately after birth,[90] it appears to be hard to use vaccines to prevent FcaPV2-induced BISCs or SCCs in cats. Prevention of immunosuppressive conditions, such as retrovirus infections in cats, and cautious use of potent immunosuppressive drugs, such as cyclosporine, may reduce the chance of papillomavirus-induced disease.

PUBLIC HEALTH ASPECTS

More than 250 papillomavirus types infect humans. Papillomaviruses are relatively species specific, and there is no evidence that either CPV or feline papillomavirus infect humans.

CASE EXAMPLE

Signalment

"Oscar," an adult male neutered Rottweiler mix (Fig. 40.8).

History

Oscar was brought to the University of California-Davis, Veterinary Medical Teaching Hospital for examination after adoption by a veterinary student as a stray from an American Indian reservation in Arizona. The student was concerned about the possibility of malnourishment, a painful mouth, and pruritic skin disease. Since his rescue 5 days previously, the student had been feeding him four times daily with maintenance commercial wet and dry dog foods. His appetite had been ravenous and tapeworm segments had been observed in his feces. He had been isolated from other pets in the household.

Physical Examination

Body weight: 25.5 kg.

General: Bright and alert with normal mentation, nervous. T = 100.8°F (38.2°C), HR = 90 beats/minute, RR = 18 breaths/minute, mucous membranes pink, CRT = 1 second.

Fig. 40.8 (A) Adult male neutered Rottweiler with a high antibody titer to *Ehrlichia canis*, malnutrition, gastrointestinal parasitism, and sarcoptic mange. (B) Oral papillomatosis was present on oral examination and involved the hard and soft palates, buccal mucosa, and lips.

Integument: A dull haircoat was present. Patchy generalized alopecia with severe scaling, crusting, hyperpigmentation, ulceration, and lichenification was present on the face, pinnae and pinnal margins, shoulders, trunk, and extremities.

Eyes, ears, nose, and throat: Moderate mucoid discharge was present from both eyes. The incisor teeth were severely worn. Oral examination also revealed pain on opening the mouth and multiple pink to gray pedunculated masses that ranged from a few millimeters to over 1 cm in diameter on the buccal mucosa and gingiva, lateral aspect of the tongue, and on the hard and soft palates (see Fig. 40.8B). These were consistent with oral papillomatosis.

Musculoskeletal: BCS 1/9. Normal gait. No other musculoskeletal abnormalities were noted.

Cardiovascular and respiratory: No clinically significant abnormalities were detected.

GI and genitourinary: Abdominal palpation was within normal limits. Intact male with soft, symmetrical testes. Soft feces were noted on rectal examination.

Lymph nodes: Mandibular and superficial cervical nodes were enlarged (approximately 3 cm); the popliteal nodes were sized within normal limits.

Laboratory Findings

CBC: HCT 32.3% (40%–55%), MCV 64.3 fL (65–75 fL), MCHC 36.2 g/dL (33–36 g/dL), WBC 10,390 cells/μL (6,000–13,000 cells/μL), neutrophils 5,995 cells/μL (3,000–10,500 cells/μL), lymphocytes 1,891 cells/μL (1,000–4,000 cells/μL), monocytes 758 cells/μL (150–1,200 cells/μL), eosinophils 1,704 cells/μL (0–1,500 cells/μL), platelets 322,000 platelets/μL (150,000–400,000 platelets/μL), rare macroplatelets observed.

Serum chemistry profile: Sodium 144 mmol/L (145–154 mmol/L), potassium 4.8 mmol/L (3.6–5.3 mmol/L), chloride 108 mmol/L (108–118 mmol/L), bicarbonate 26 mmol/L (16–26 mmol/L), phosphorus 5.1 mg/dL (3.0–6.2 mg/dL), calcium 10.1 mg/dL (9.7–11.5 mg/dL), BUN 26 mg/dL (5–21 mg/dL), creatinine 0.7 mg/dL (0.3–1.2 mg/dL), glucose 108 mg/dL (64–123 mg/dL), total protein 7.7 g/dL (5.4–7.6 g/dL), albumin 2.9 g/dL (3.0–4.4 g/dL), globulin 4.8 g/dL (1.8–3.9 g/dL), ALT 48 U/L (19–67 U/L), AST 30 U/L (19–42 U/L), ALP 117 U/L (21–170 U/L), GGT < 3 U/L (0–6 U/L), cholesterol 210 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.048; pH 5.0, negative protein (SSA), 1+ bilirubin; no hemoprotein, ketones or glucose; 1–2 WBC/HPF, rare RBC/HPF, rare bilirubin crystals, moderate sperm.

Cytology of superficial and deep skin scrapings: *Sarcoptes* mites were seen.

Imaging Findings

Lateral and dorsoventral thoracic radiographs were unremarkable. Abdominal ultrasonography revealed a small, 1-cm hypoechoic nodule in the body of the spleen. The remainder of the abdominal structures was within normal limits.

Microbiologic Testing

Lateral flow ELISA assay for antibodies to *E. canis, Anaplasma phagocytophilum,* and *Borrelia burgdorferi* and *Dirofilaria immitis* antigen (SNAP 4Dx Plus, IDEXX Laboratories, ME, USA): Positive for antibodies to *Ehrlichia* spp.

Vector-borne disease serology panel (*Babesia canis, A. phagocytophilum, E. canis, Rickettsia* spp. IFA): Positive for antibodies to *E. canis* (1:655,360) and *Rickettsia* spp. (1:40,960).

Fecal flotation: *Giardia* spp. cysts (<1 per 40× field), *Sarcoptes* mites (1 to 10 per 10× field).

Diagnosis

Canine oral papillomatosis; malnutrition; sarcoptic mange; suspected chronic canine monocytic ehrlichiosis; previous exposure to SFG rickettsias; giardiasis; cestodiasis.

CASE EXAMPLE—cont'd

Treatment

Oscar was treated with doxycycline (5 mg/kg PO q12h for 6 weeks) for ehrlichiosis, topical selamectin (every 2 weeks for a total of 6 weeks) for sarcoptic mange, praziquantel (5 mg/kg, once) for cestodiasis, cephalexin (22 mg/kg q12h for 4 weeks) for secondary bacterial pyoderma, and fenbendazole (50 mg/kg PO q24h for 3 days) for giardiasis. The owner was instructed to bathe him with an oatmeal shampoo twice weekly. At a recheck appointment 4 weeks later, Oscar weighed 31.5 kg. The skin lesions had improved, and new hair growth was noted. Pruritus was still present. More oral papillomas were present, and the owner described worsened halitosis. Mandibular lymph nodes remained enlarged. Treatment with cephalexin and doxycycline was continued for an additional 3 weeks. After 3 weeks, Oscar's bodyweight was 33.4 kg, the oral papillomas and mandibular lymphadenomegaly had resolved, and Oscar was vaccinated with CDV, canine parvovirus, CAdV, CPIV, and rabies virus vaccines and neutered.

Comments

The gross appearance of the oral lesions in this dog was sufficient to make a diagnosis of oral papillomatosis. Papillomatosis has been reported in other dogs with chronic *E. canis* infection, but the extent to which ehrlichiosis contributed to papillomatosis in this dog is unknown. The immunosuppression associated with malnutrition may also have played a role. Resolution of lesions occurred within 7 weeks after treatment of the immunosuppressive disorders, but papillomatosis can also resolve spontaneously over the same time period.

Arthropod-Borne Viral Infections

Jane E. Sykes, Andrea Tipold

KEY POINTS

- First Described: Eastern equine encephalitis, 1831 (horses, Massachusetts)[1]; West Nile virus infection, 1937 (human, Uganda)[2]; tick-borne encephalitis virus, 1931 (humans, Austria);[3] African horse sickness virus, 1569 (horses, Africa).[4]
- Causes: RNA viruses that belong to the families *Togaviridae* (genus *Alphavirus*), such as eastern equine encephalitis virus; *Bunyaviridae,* such as La Crosse virus; *Reoviridae,* such as African horse sickness virus, and *Flaviviridae,* such as West Nile virus and tick-borne encephalitis virus.
- Affected Hosts: A variety of animal species including horses, humans, and dogs.
- Geographic Distribution: Follows that of the vector host. Eastern equine encephalitis virus is found in the eastern and southeastern United States, as well as Central and South America; West Nile virus is found in Africa, Asia, Middle East, Europe, and the United States; African horse sickness virus is found in Africa and the Middle East; tick-borne encephalitis virus is found in continental Europe and Asia.
- Mode of Transmission: Primarily mosquitoes, and for tick-borne encephalitis virus, *Ixodes* ticks. Dogs can be infected with African horse sickness virus by ingestion of horse meat, but *Culicoides* midges in addition to mosquitoes may also be involved in transmission of the virus to dogs.
- Major Clinical Signs: Fever (sometimes >105°F [40.6°C]), lethargy, neurologic signs, and sometimes systemic signs such as anorexia and diarrhea. African horse sickness virus also causes respiratory signs due to pulmonary edema.
- Differential Diagnoses: Rabies, distemper, pseudorabies; bacterial, protozoal, or fungal meningitis; meningoencephalitis of unknown origin (MUO); hemic neoplasia with CNS involvement. Differential diagnosis for African horse sickness virus infection also includes severe viral or bacterial respiratory tract diseases (e.g., influenza virus infection or *Streptococcus equi* subsp. *zooepidemicus* infection).
- Human Health Significance: Humans are susceptible to disease caused by many arboviruses. Dogs and cats are dead-end hosts and do not serve as reservoirs for human infection. Blood and tissues of affected dogs and cats should be handled with caution.

ETIOLOGY, EPIDEMIOLOGY, AND CLINICAL FEATURES

A large number of viruses that are spread by arthropod vectors (sometimes referred to as *arboviruses*, for *ar*thropod-*bo*rne *viruses*) can infect dogs and cats, often causing encephalitis (Box 41.1 and Table 41.1). These viruses are enveloped RNA viruses that are unstable in the environment and readily inactivated with routine disinfectants. Disease is sporadic, and for many arboviruses, only subclinical infections have been documented in dogs and cats. Arboviruses are maintained in vectors and often small rodent and/or avian reservoir hosts, and some of these reservoir hosts can develop illness in association with infection. The geographic distribution is dependent on that of the vectors and reservoir hosts. Dogs and cats, as well as other domestic animal and human hosts, are generally considered "dead-end" hosts that do not maintain sufficient viremia to infect arthropods (Fig. 41.1). Arboviruses replicate within the arthropod vector and are transmitted to vertebrate hosts when the vector feeds; this is followed by viremia and, in some cases, viral spread to the CNS and neuroinvasion, with subsequent neuronal necrosis and inflammation. When neurologic disease occurs, it has important public health significance, because the clinical signs can mimic those of rabies. Because humans have the potential to be infected with these viruses, serologic evidence of infection of dogs and cats in a region where disease in humans is not widely recognized can also have public health significance.

BOX 41.1 General Features of Arbovirus Infections as They Relate to Dogs and Cats

Vector-borne RNA viruses
Often mosquito borne
Maintained among small wild vertebrate reservoir hosts, especially birds and/or rodents
Geographic distribution follows that of vector host
Seasonal distribution that reflects activity of the vector host
May cause disease in humans and other domestic animals, especially horses
Infection of dogs and cats is most often subclinical
Dogs and cats are "dead-end" hosts
Infection more prevalent in dogs than in cats
Sporadic reports of disease, especially in young animals (<6 months)
Neurologic signs accompanied by fever and sometimes other systemic signs (e.g., diarrhea)
Histopathology shows neuronal necrosis, gliosis, and perivascular cuffing within the brain, which is predominantly nonsuppurative. Occasionally hepatitis and myocarditis are described

Alphavirus Infections (Family *Togaviridae*)

Alphaviruses are enveloped, single-stranded RNA mosquito-borne viruses that belong to the family *Togaviridae*. Members of this group that are of importance to human and animal health include Eastern,

TABLE 41.1 Arthropod-Borne Viral Infections of Dogs and Cats

Classification	Virus	Vector	Reservoir Hosts	Affected Hosts	Geographic Distribution
Family *Togaviridae*, genus *Alphavirus*	Eastern equine encephalitis virus (EEEV)	Mosquitoes (*Culiseta melanura, Coquillettidia* spp., *Aedes* spp., *Culex* spp.)	Birds	Humans (North American strains), horses, dogs, other domestic farm animal species and farmed and captive birds	Primarily southeastern (especially Georgia and Florida), eastern, and Great Lakes regions of the United States and the Caribbean Islands (North American EEEV strains); also Central America, Brazil, Guyana, Argentina (South American EEEV strains).
	Venezuelan equine encephalitis virus	Mosquitoes (*Psorophora confinnis, Aedes spp., Culex* spp.)	Rodents	Horses, humans, possibly dogs	Southern United States (Florida), Central and South America (especially Colombia, Venezuela, Trinidad, Peru, Ecuador, Mexico)
	Ross River and Barmah Forest virus	Mosquitoes (*Ochlerotatus vigilax*)	Wallabies, kangaroos	Humans, dogs, cats	Australia, from Tasmania to Queensland
Family *Bunyaviridae*, genus *Orthobunyavirus*	La Crosse virus	Mosquitoes	Small mammals (chipmunks)	Humans, dogs	Eastern and Midwestern United States
Family *Bunyaviridae*, genus *Orthobunyavirus*	Tensaw virus	Mosquitoes (*Anopheles* spp.)	Rodents	Dogs, cattle	Southeastern United States
Family *Bunyaviridae*, genus *Phlebovirus*	Rift Valley fever virus	Mosquitoes (*Culex theileri, Aedes caballus*)	Ungulates (sheep)	Humans, dogs, cats	East Africa
Family *Flaviviridae*	West Nile virus	Mosquitoes	Birds	Horses, humans, birds, dogs	North, Central, and South America; Africa, the Middle East, Europe, Asia, Australia
	Tick-borne encephalitis virus	*Ixodes* ticks	Rodents, birds	Humans, horses, dogs; domestic animals are frequently infected subclinically	Europe, Asia
	St. Louis encephalitis virus	Mosquitoes (*Culex* spp.)	Birds	Humans, dogs, cats	United States, Canada, Central America, Caribbean Islands, Colombia, Brazil, Argentina
	Japanese encephalitis virus	Mosquitoes (*Culex* spp.)	Birds	Humans, dogs, cats, pigs, horses	Siberia, Japan, China, many far-east countries
	Powassan virus	Ticks (*Ixodes cookei, Ixodes marxi*)	Rodents	Sheep, humans, dogs	United States, Canada
	Louping-ill virus	Ticks (*Ixodes ricinus*)	Red grouse	Sheep, cattle, humans, dogs	Scotland, Ireland
	Wesselsbron virus	Mosquitoes (*Aedes* spp.)	Ungulates, sheep	Sheep, dogs	South Africa
	Yellow fever virus	Mosquitoes (*Aedes* spp.)	Nonhuman primates, humans	Humans, cats	South America, Africa
Family *Reoviridae*	African horse sickness virus	Midges (*Culicoides* spp.), mosquitoes	Zebra	Horses, dogs	Africa, Middle East, Mediterranean
	Bluetongue virus	Midges (*Culicoides* spp.)	Sheep	Sheep, dogs	Worldwide

Western, and Venezuelan encephalitis viruses, which cause disease in humans and horses in the Americas; and Ross River virus, which causes disease in humans in Australia and the Pacific islands. Venezuelan equine encephalitis virus (VEEV) primarily causes outbreaks of disease in horses and humans in Central and the northern parts of South America, although an outbreak occurred in Texas in 1971, and there is the potential for additional outbreaks in the United States.[5] Experimental infection of dogs with VEEV resulted in fever, leukopenia, and neurologic signs.[6] Although there is one possible report of encephalitis in a puppy due to a VEEV,[7] only eastern equine encephalitis virus (EEEV) is a significant cause of naturally occurring disease in dogs. Dogs have been used as sentinels for the presence of VEEV variants (such as Everglades virus) in epidemiologic serosurveys.[8] Western equine encephalitis virus causes encephalitis in dogs after experimental parenteral or intracerebral inoculation, but naturally occurring disease has not been described.[9]

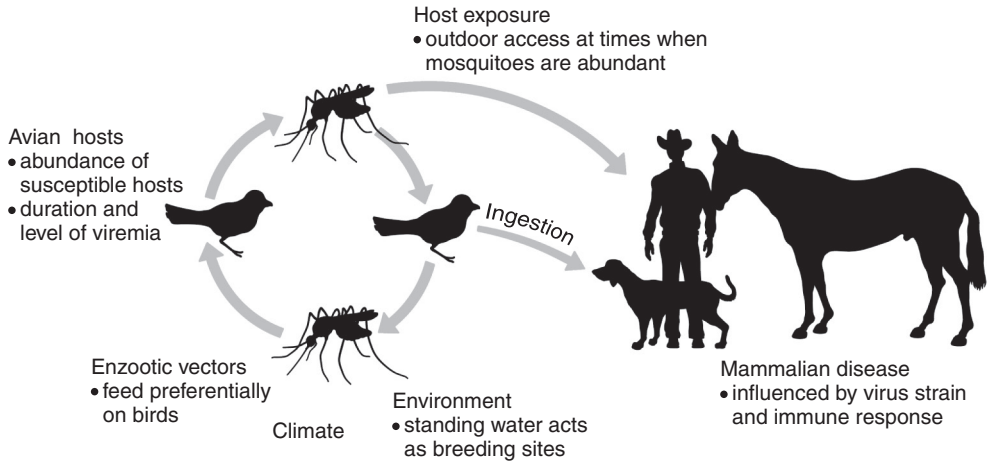

Fig. 41.1 West Nile virus transmission cycle and factors that influence arbovirus epidemiology. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Other alphaviruses cause subclinical seroconversion when they infect dogs under natural conditions. Ross River and Barmah Forest viruses are endemic in Australia, affecting kangaroos and wallabies as major mammalian reservoirs. Serum neutralizing antibodies are widespread in human and mammalian populations, and have been detected in dogs and cats. Dogs and cats that were experimentally fed infected mosquitoes were relatively resistant to both viral infections.[10] A few animals seroconverted, but none developed viremia or clinical signs. Therefore they are unlikely to be important reservoirs of these viruses.

EEEV is endemic in swampy areas of the southeastern United States,[11] where it is maintained in a variety of avian reservoir hosts. It causes disease in humans, horses, dogs, and other domestic animal species. Different viral lineages vary in pathogenicity for humans and horses. Human cases occur in the southeastern, eastern, and Great Lakes regions of the United States, but especially Florida, Georgia, Massachusetts, and New Jersey; there has been most recent expansion of the virus' geographic range in the New England region (Fig. 41.2A).[12–15] Most affected dogs have been reported from Georgia; dogs from New York state and Michigan have also been affected, as well as captive wolf pups in Michigan in 2019.[13,16,17] Dogs with signs of encephalitis have always been young (<7 months of age). Disease usually occurs in late spring or summer. Clinical signs include fever, lethargy, inappetence, and diarrhea, with rapid progression (within 1 to 2 days) to recumbency, tachypnea, miosis, nystagmus, tremors, seizures, and death.[11,16]

Bunyavirus Infections

Like togaviruses, bunyaviruses are enveloped, single-stranded RNA viruses. Clinically important bunyaviruses for animal and human health are the mosquito-borne viruses Rift Valley fever (genus *Phlebovirus*) and La Crosse (genus *Bunyavirus*) viruses; the tick-borne virus Crimean-Congo hemorrhagic fever virus (genus *Nairovirus*); and members of the genus *Hantavirus*, which are not transmitted by vectors and cause hemorrhagic febrile and respiratory illness in humans (see Chapter 43, Emerging and Miscellaneous Viral Infections). Serologic evidence of infection with some vector-borne bunyaviruses has been documented in dogs and cats.

Tensaw Virus

Tensaw virus is a bunyavirus found in the southeastern United States. It infects a variety of mammalian species, and although not considered a significant disease threat to humans, there is widespread human exposure to the virus, and it has rarely caused human encephalitis.[18] When inoculated into dogs and cats, it produced subclinical viremia, and mosquito-mediated transmission from infected dogs was demonstrated.[19]

Rift Valley Fever Virus

Rift Valley fever virus (genus *Phlebovirus*, family *Bunyaviridae*) causes widespread outbreaks of abortion and death in livestock in parts of Africa and the Arabian peninsula, often after heavy rainfall, which facilitates emergence of infected mosquitoes. Humans can also be infected, either as a result of mosquito-borne transmission, or contact with infected livestock tissues, fluids, or aborted material.[20] Disease in humans tends to be self-limiting, but 1% to 2% of infected humans can develop clinically significant hepatitis, retinitis, delayed-onset encephalitis, or hemorrhagic disease, the latter with high mortality. Because it threatens both livestock and human health, Rift Valley fever virus is of significant public health concern.

When experimentally inoculated subcutaneously into newborn puppies and kittens, Rift Valley fever virus can cause viremia with fever then neurologic signs (ataxia and seizures), terminal hypothermia, and death.[21–24] In contrast, older puppies and adult dogs show no clinical signs, but the virus can cause abortions and stillbirths in experimentally infected pregnant bitches.[21] Puppies were shown to transmit the virus to their mother and to other puppies, raising concern for the possible role of dogs in transmission of the virus to livestock or humans. Under natural conditions, it has been suggested that dogs might become infected through inhalation or ingestion of the virus from infected carcasses. Given that only neonatal puppies and kittens are capable of transmitting infection following experimental infection, the role of dogs and cats in the epidemiology of this disease seems to be of limited significance.

La Crosse Virus

La Crosse virus rarely causes naturally occurring disease in dogs.[25,26] La Crosse virus was named after La Crosse in Wisconsin, where it was first identified as a human pathogen, and is mostly found in the eastern and midwestern United States (Fig. 41.2B). The virus is maintained in rodents, especially Eastern gray squirrels

and chipmunks. Vector infection can be lifelong, with transovarial transmission to subsequent generations of mosquitoes. La Crosse virus is a major cause of human pediatric encephalitis in North America, although mortality is low. Affected dogs have included an adult dog from Florida and three puppies from southern Georgia.[25,26] Mild fever, lethargy, ataxia, vestibular signs, and ultimately seizures occurred in the adult dog, and sudden death was reported in the puppies.

Reovirus Infections

Reoviruses are icosahedral, nonenveloped viruses. The major reovirus of significance to dogs and cats is African horse sickness virus (genus *Orbivirus*). As its name implies, African horse sickness virus causes outbreaks of disease in horses in Africa with high (90%) mortality. Infection occurs throughout sub-Saharan Africa, extending from Senegal to Somalia and South Africa. The disease also occurs sporadically in the Middle East, India, and Pakistan, and spread to Spain in 1966 and again in 1987, which resulted in significant equine mortality.[27] It is spread by biting *Culicoides imicola* midges; other biting insects may play a lesser role in transmission.[27] In horses, disease results from damage to the respiratory and cardiovascular systems, and has been divided into a mild febrile form; a peracute pulmonary form, with rapid death due to pulmonary edema; a subacute cardiac form characterized by fever and subcutaneous edema; and a mixed cardiopulmonary form.[4] Dogs are the only other animals capable of developing the severe form of disease. Dogs can be naturally infected, most commonly when they ingest infected horse meat, but there have also been reports of infection of dogs from South Africa without this history, suggesting the possibility of vector-borne transmission.[27,28] In further support of vector-borne transmission, most of these cases were seen during peak seasonal *Culicoides* midge activity (late summer). Many dogs show no clinical signs, but severe disease can occur. The incubation period is 1 to 2 weeks, followed by variable fever, lethargy, inappetence, and signs of pulmonary edema, including tachypnea, cough, and foamy nasal discharge. This can be followed by diarrhea and seizures, with high mortality.[27–29]

A reovirus with historical significance for dogs is bluetongue virus, which causes disease in sheep and to a lesser extent in cattle in Australia, the United States, Africa, the Middle East, Asia, and Europe. Natural disease caused by this virus in dogs is unlikely based on the observed low prevalence of seropositivity in dogs in endemic areas.[30] Abortion in pregnant bitches and their subsequent death occurred 7 to 9 days after vaccination with a bluetongue virus-contaminated, attenuated live virus combination canine vaccine in the early 1990s.[31,32] Lesions in

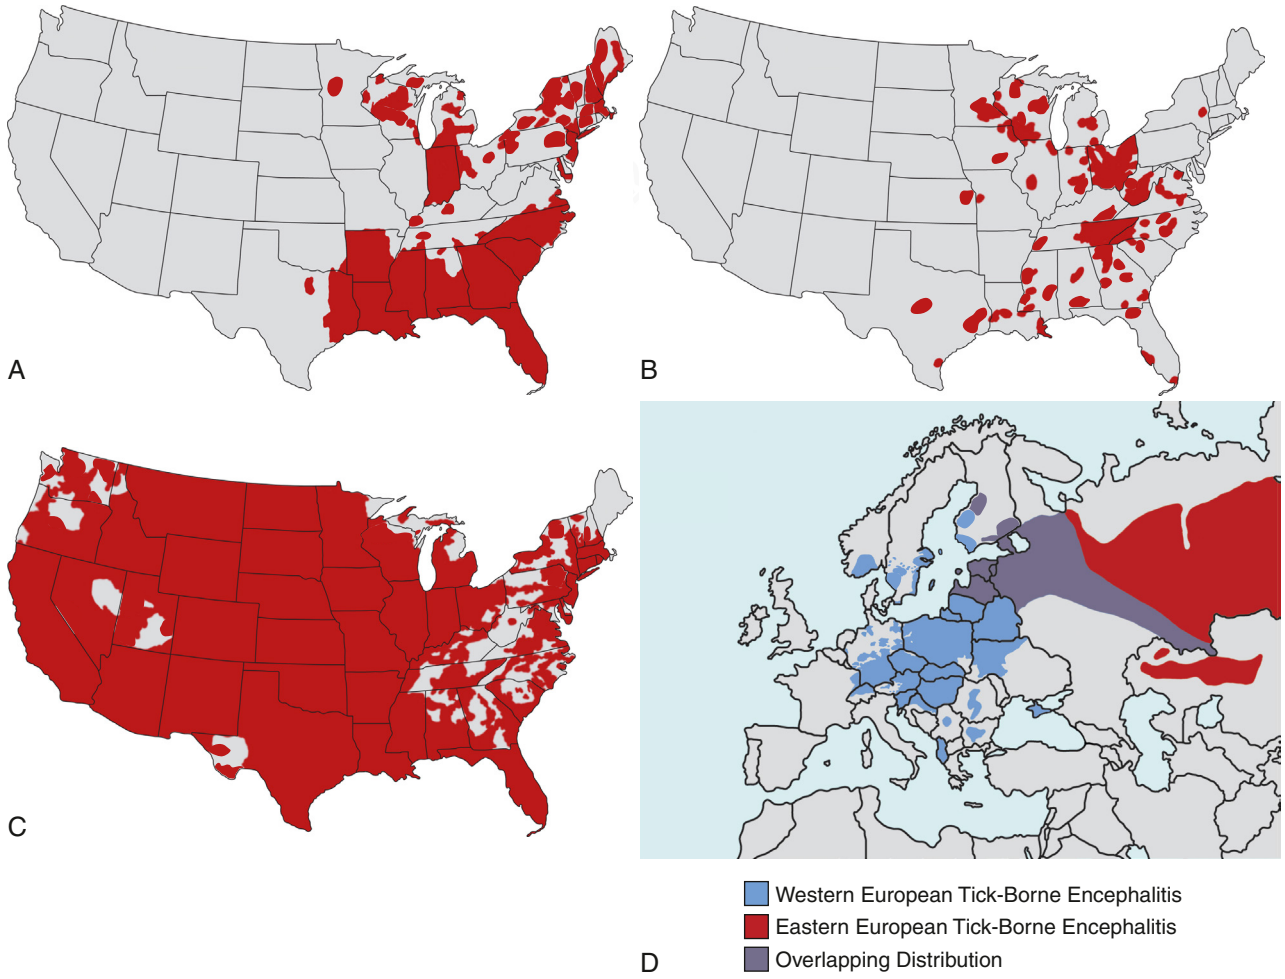

Fig. 41.2 Geographic distribution of some arboviruses that can cause disease in dogs and cats. (A) Regions in the USA with eastern equine encephalitis virus transmission. (B) Regions in the USA with La Crosse virus transmission. (C) Regions in the USA Regions with West Nile virus transmission. (D) Regions with tick-borne encephalitis virus transmission. (A–D, Modified from Sykes JE. *Canine and Feline Infectious Diseases.* Elsevier; 2014.)

the dam consisted of interstitial pneumonia, myocardial degeneration, hepatic vasculitis, and renal glomerulitis.[32]

Flavivirus Infections

Flaviviruses are small, icosahedral, enveloped viruses with a single-stranded RNA genome. Vector-borne flaviviruses (*flavi* = "yellow," Latin) of importance to human and animal health are the mosquito-borne viruses Japanese encephalitis virus, yellow fever virus, Murray Valley encephalitis virus, St. Louis encephalitis virus, Wesselsbron virus, Dengue viruses, and West Nile virus (WNV), as well as the tick-borne viruses inducing tick-borne encephalitis (TBE) virus, Louping-ill virus, and Powassan virus. Japanese encephalitis virus, Murray Valley encephalitis virus, and St. Louis encephalitis virus all belong to the *Japanese encephalitis complex*. Antibodies to some of these viruses have been detected in dogs and to a lesser extent, cats in serosurveys,[33–37] but serologic cross-reactivity among flaviviruses can occur. Although uncommon, WNV in the United States and TBE virus in Europe have been reported to cause disease in dogs on more than one occasion. One dog from Africa with fatal encephalitis was initially thought to be infected with Wesselsbron disease virus,[38] but the isolate was later confirmed to be WNV.[39]

West Nile Virus Infection

WNV was first isolated in 1937 from a woman in the West Nile region of Uganda.[2] In the 1950s, the virus was recognized in Israel as a cause of human neurologic disease in the elderly,[40] and subsequently was identified in other parts of Europe and South Africa. In 1999, it appeared in New York state, possibly by transport of infected humans, birds, or mosquitoes.[41] WNV then spread explosively westward across the United States, and by 2003, disease was detected across the United States to California (Fig. 41.2C). WNV also spread into Canada, Mexico, the Caribbean, and Central and South America, and is now one of the most broadly distributed arboviruses.[41,42] Several different variants of the virus exist, which differ in virulence. Strains circulating within the Western hemisphere, Europe, the Middle East, India, Africa, and Australia belong to WNV lineage 1; lineage 2 strains circulate in South Africa, Madagascar, and, now also Europe. Other lineages have also been reported, but these are not associated with outbreaks of human disease.

Although most of the natural transmission of WNV in the United States has been associated with three *Culex* subspecies (*pipiens*, *quinquefasciatus*, and *tarsalis*), WNV has been isolated from at least 65 mosquito species.[43–72] Transmission of WNV by mosquitoes increases in the warmer months, with peak activity in the northern hemisphere between July and October. Birds (especially passerines such as crows, jays, brown sparrows, and the American robin; shorebirds; owls; and hawks) are important reservoir hosts (see Fig. 41.1). Some avian species, such as brown sparrows, maintain high viremia in the absence of clinical signs, whereas crows develop high viremias and near-uniform mortality. Other modes of transmission include ingestion through predation of infected birds or rodents, blood transfusion, needle-stick injuries, and transplacental transmission. Increased ambient temperature is associated with increased efficiency of transmission from mosquitoes to birds. Disease primarily occurs in birds, humans, and horses, but disease has been reported in several other vertebrate species, including farmed alligators.[44] Most mammalian species develop a viremia of insufficient magnitude to infect feeding mosquitoes, but some exceptions occur, including among some rodent and lagomorph species.[45] Dogs develop low-titer viremia and are considered incompetent as amplifying hosts, but treatment of dogs with glucocorticoids before infection resulted in levels of viremia roughly 50 times that in untreated dogs.[46]

After inoculation, the virus replicates in keratinocytes, dendritic cells, and Langerhans cells. This is followed by spread to draining lymph nodes, further replication in lymph node macrophages, cell-associated viremia, and dissemination to peripheral organs.[43] The vast majority of infected humans experience no clinical signs. When signs occur in humans they follow an incubation period of 2 to as long as 21 days (usually 2 to 6 days). They are often mild and self-limiting and include fever, headache, myalgia, fatigue, GI symptoms, and a transient rash.[43,47] Rarely, hepatitis, pancreatitis, myocarditis, rhabdomyolysis, orchitis, uveitis, and chorioretinitis can occur. Severe neuroinvasive disease occurs in fewer than 1% of cases, is most common in the elderly, those with advanced immunosuppression, or people with chronic medical conditions. Severe disease is characterized by high fever, cervical rigidity, muscle weakness, seizures, and flaccid paralysis, and neurological signs may persist for over a year in those that recover. Fatality rates in humans with encephalitis are reported to be 3% to 19%.[45] Neurologic signs result from viral invasion of neurons in the brainstem, deep nuclei, and anterior horns within the spinal cord. Neuroinvasion appears to occur by both anterograde and retrograde axonal transport.[43,48] The innate immune system plays a critical role in control of WNV replication. Cellular immunity, mediated by CD4+ and CD8+ T cells, is essential for clearance of virus from the CNS, but in some cases, cellular immune responses appear to contribute to immunopathogenetic lesions in the CNS.[49]

Clinical signs in horses result from polioencephalomyelitis and include fever and neurologic signs such as ataxia, weakness, and muscle tremors.[50] Approximately two-thirds of horses recover. Infected wild birds can exhibit neurologic disease but are usually found dead. Myocarditis and meningoencephalitis are common necropsy findings in these birds.[51]

In dogs, there is widespread serologic evidence of infection, but disease is rare. Dogs have been widely used as sentinels for evidence of WNV in different geographic locations. Serologic surveys have revealed prevalences of 27% in Senegal in 2014, 62% in working dogs in Morocco in 2012,[52] 28% in Saskatchewan, Canada in 2008–2010,[53] 5% in New York City in 1999, 4.6% in China in 2011,[54] 18% in Harris County, Texas in 2005,[55] and 56% in Louisiana after Hurricane Katrina.[56] Cats also can become infected and seroconvert, but illness has not been described. Dogs that were experimentally infected with WNV using mosquitoes developed viremia of low magnitude and short duration, and failed to show clinical manifestations of illness, except for transient pyrexia in one dog.[57] Cats infected experimentally by feeding them infected mice remained healthy, and cats infected using mosquitoes developed transient fever, inappetence, and lethargy, with viremia that was more sustained than that in dogs.

Five clinically affected dogs have been described following natural infection. All, apart from a dog from Africa, resided in various parts of the United States (Missouri, Mississippi, California, and Illinois).[58–61] All of the dogs showed signs of fever and progressive neurologic disease. Neurologic signs included generalized tremors, ataxia, a head tilt, bobbing movements, altered mentation, cervical pain, abnormal placing reactions, and tetraparesis. Diarrhea, serous oculonasal discharge, conjunctivitis, abdominal pain, cardiac arrhythmias due to myocarditis, tachypnea, tachycardia, and a stiff gait associated with mild neutrophilic polyarthritis have been reported (Fig. 41.3). For all dogs, diagnosis was made at necropsy. In Europe, WNV infection was suspected at necropsy of dogs with encephalitis of unknown origin after detection of immunohistological precipitates using virus-specific antibodies; however, the infection was not confirmed using other techniques.[62]

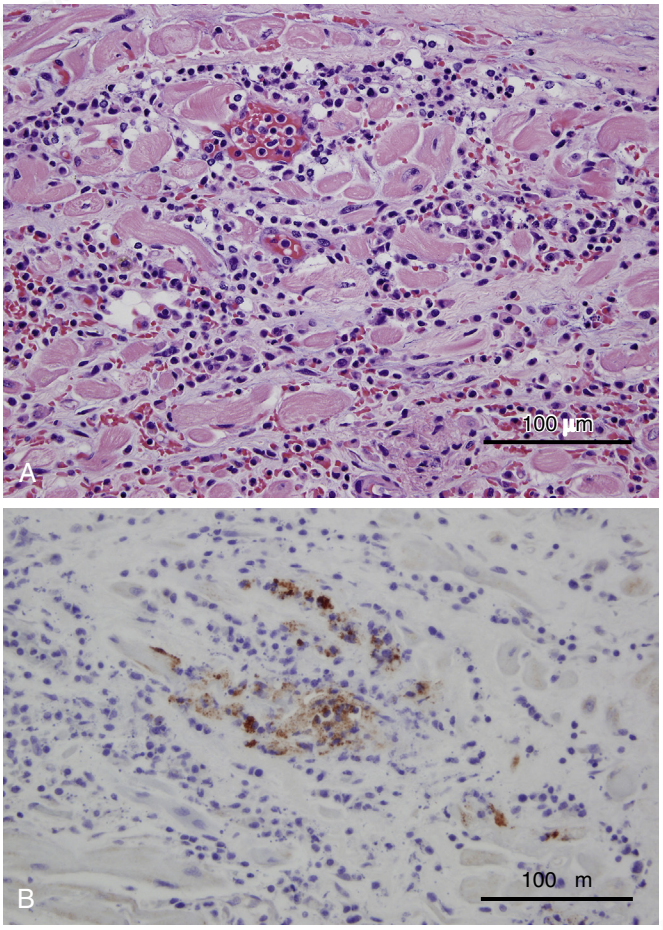

Fig. 41.3 Severe lymphocytic and neutrophilic myocarditis and vasculitis due to West Nile virus (WNV) infection with focally extensive hemorrhage and myonecrosis. (A) Hematoxylin and eosin stain. (B) Immunohistochemical stain showing WNV immunoreactivity within neutrophils and histiocytes *(brown)*. (From Cannon AB, Luff J, Brault C, et al. Acute encephalitis, polyarthritis and myocarditis associated with West Nile virus infection in a dog. *J Vet Intern Med.* 2006;20:1219–1223.)

Tick-Borne Encephalitis Virus

TBE virus is a notifiable disease that causes potentially fatal neurologic disease in humans in Europe and Asia, where it is the most important tick-borne viral disease of humans.[63] The virus is transmitted transstadially and to a lesser extent transovarially within infected ticks, and ticks can transmit the disease to each other while co-feeding, independent of systemic viremia in vertebrate hosts.[64] The primary reservoirs for the virus are small rodents such as mice and voles. Consumption of raw milk from infected ruminants (especially goats) is a lesser mode of transmission to humans (Fig. 41.4). TBE has been reported not only in humans, but also in dogs, horses, monkeys, and wild ruminants, but not in cats.

At least three subtypes of TBE virus exist, which vary in virulence and geographic distribution. The three predominant subtypes are designated the European, Siberian, and far-eastern subtypes,[65,66] although as of 2019 two additional subtypes have been proposed—the Baikalian and Himalayan subtypes.[66] The far-eastern subtype occurs in far-eastern Russia, Japan, Korea, and China and is the most virulent subtype, with mortality rates in humans that may exceed 20%. In much of Europe, *Ixodes ricinus* ticks spread the European subtype (Western and Central European TBE). *Ixodes persulcatus* ticks transmit the other viral subtypes in northeastern Europe, Russia, and far-east Asia (Eastern European TBE) (Fig. 41.2D).[67] Both Siberian and European subtypes may be found in eastern Europe. The disease was originally detected in 1937 in Austria (Central European TBE), but its geographic distribution has expanded rapidly so that the European subtype now occurs throughout Europe as far west as France and now possibly Belgium, the Netherlands, Northern Germany, and the United Kingdom.[37,66,68,69] Until very recently, TBE had not been reported in the United Kingdom and Ireland, but a related tick-borne flavivirus, Louping-ill virus, was known to be present. However, a recent surveillance effort in the United Kingdom detected TBE virus in ticks from the Norfolk/Suffolk (Thetford Forest) area, where the seroprevalence of flavivirus infection was highest.[66] No human or canine cases of TBE have yet been reported in the United Kingdom. An astonishing finding suggests that a specific adaptation of the tick populations to their respective TBE virus isolates occurs.[70]

In Europe, some of the highest incidence rates have occurred in central European countries, especially the Czech Republic.[71] Disease seasonality correlates with the activity of the tick in various parts of Europe.

In humans, signs of TBE occur in approximately one-third of infected individuals 4 to 28 days (and usually 7 to 14 days) after a tick bite and are usually biphasic.[66] In the first, viremic phase, fever, malaise, headache, myalgia, and vomiting occur, which resolve within 1 week. In some individuals, after an asymptomatic period that lasts 2 to 10 days, clinical signs return and are accompanied by signs of meningitis, meningoencephalitis, meningoencephalomyelitis, or meningoencephaloradiculitis. About 4 to 14% of cases are fatal, most often in the elderly,[72] but neurologic signs can persist for months or longer than a year. Co-infections with *Borrelia* (*Borreliella*) *burgdorferi* can occur. Vaccines are currently recommended for prevention of TBE in humans, and national vaccination programs have greatly reduced the incidence of disease.[73]

Subclinical infection of dogs with TBE virus is widespread, and so dogs have been important sentinels for the presence of the virus in new regions of Europe. Rarely, illness that resembles that in humans can occur in dogs. Affected dogs have been described from Sweden, Norway, Greece, Switzerland, Austria, Germany, the Czech Republic, and Italy.[63,74–77] Several reports have described disease in rottweilers, but it is not clear whether this represents a true breed predisposition. Signs in dogs include high fever (over 39°C [102.5°F]), lethargy, anorexia, and neurologic signs such as decreased mentation, behavioral changes such as aggression, delayed placing reactions, ataxia, flaccid paralysis, reduced segmental reflexes, neck pain, vestibular signs, tremors, tetraparesis, miosis, anisocoria, and generalized seizures.[63,67] These signs progress rapidly over several days to a week, sometimes culminating in death or euthanasia. In a 2021 long-term follow-up study of 54 dogs with TBE, the disease was clinically biphasic, with initial non-specific clinical signs followed by onset of neurologic deficits. The case fatality rate in that study was 33%.[77] Of the dogs that died, all died within 4 months, and of those that survived, 17% had residual neurologic signs. Neurologic sequelae were more often detected in older dogs and dogs with seizures at the time of initial evaluation. Because of the rapid progression of neurologic signs, the disease is sometimes mistaken for rabies. Recovery has been described rarely.

Louping-Ill Virus

Louping-ill virus is transmitted by *I. ricinus* ticks, which are the most abundant ticks in the United Kingdom, and mainly causes neurologic disease in sheep (especially weaned lambs) and red grouse, an economically important gamebird. This is in contrast to TBE virus,

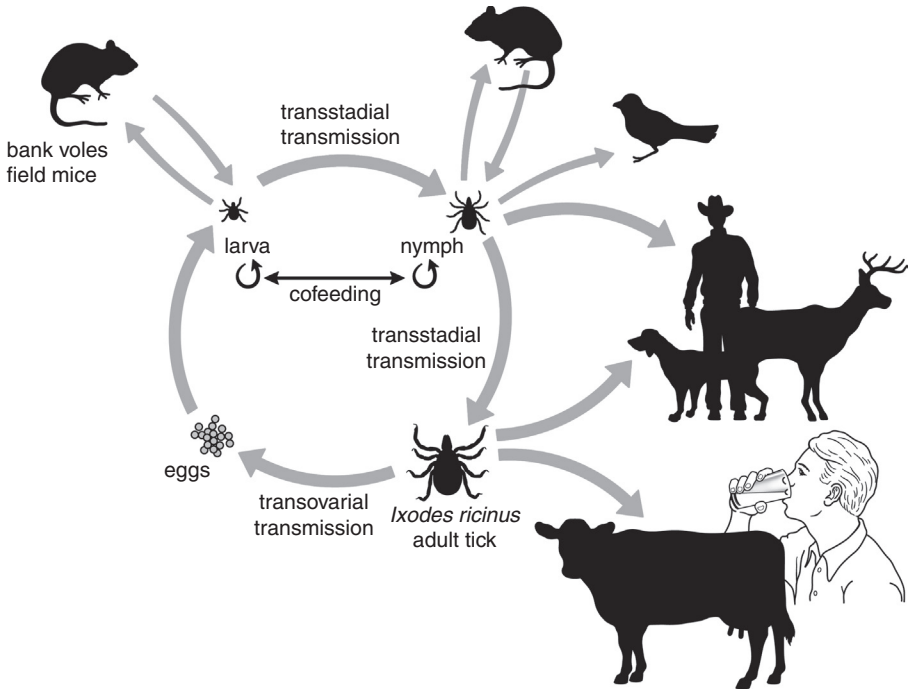

Fig. 41.4 Transmission cycle for tick-borne encephalitis virus. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

which does not cause disease in sheep. Several different molecular types of the virus have been described that circulate in distinct geographic regions, and although the virus has been detected in Europe, disease predominantly occurs in rough pastures and upland heather moorland of Scotland, Cumbria, Wales, Devon, North Yorkshire, and Ireland (Fig. 41.5).[78,79] Red grouse and sheep, together with mountain hares, are considered to be important reservoir hosts, another important difference from TBE virus, which is maintained in small rodents. Red grouse are most often infected as a result of ingestion of infected ticks. The virus rarely causes encephalitis in other species, such as cattle, humans, horses, pigs, goats, farm-raised deer, and dogs.[79–82] Fewer than 50 cases have been reported in humans, but when disease caused by Louping-ill virus occurs in people it is typically a febrile illness that may be followed by neurological signs, and most often occurs in abattoir workers, farm workers, and laboratory staff.[79] Disease in cats has not been described. In sheep, mixed infections with *Anaplasma phagocytophilum* and Louping-ill virus can be associated with high mortality. Much of the efforts to prevent the disease have been to protect red grouse for hunting.[78]

Working sheepdogs and gun dogs are at increased risk of exposure. A virus that was genetically very similar to sheep-derived Louping-ill virus strains was identified in one infected dog.[82] The risk of infection is also highest in the spring and fall, when tick activity is greatest. Most dogs are probably subclinically infected. When clinical signs develop, initial signs are primarily caused by cerebellar dysfunction and include mild paresis, ataxia, and tremors. Within 24 hours, severe incoordination, tetraplegia, and opisthotonos may develop. In surviving dogs, recovery has been slow, and neurological signs may persist for months to years.

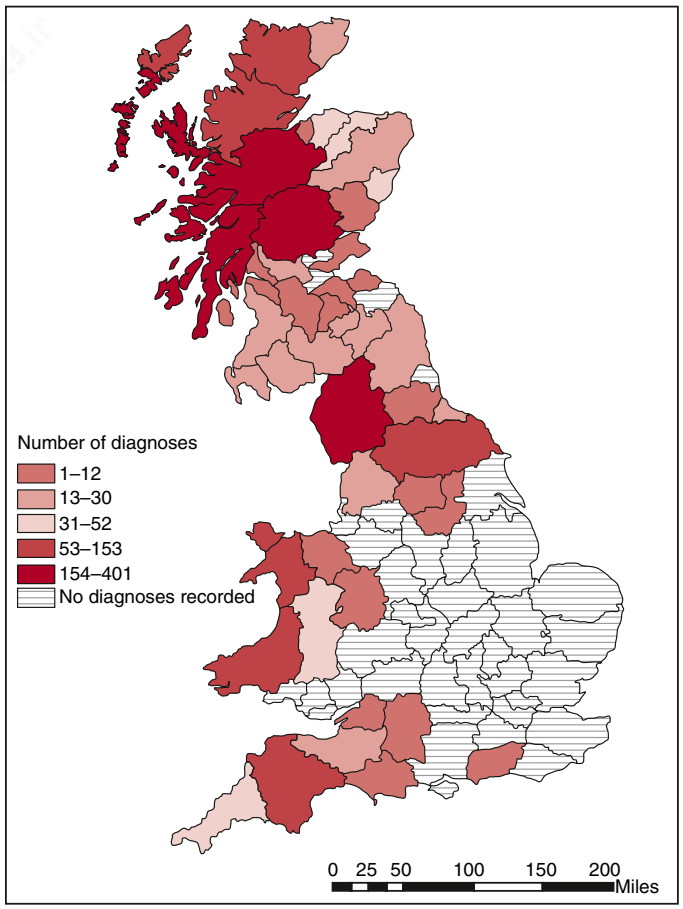

Fig. 41.5 Regions of the United Kingdom with Louping-ill virus transmission. (Modified from Jeffries CL, Mansfield KL, Phipps LP, et al. Louping ill virus: an endemic tick-borne disease of Great Britain. *J Gen Virol*. 2014;95:1005–1014.)

DIAGNOSIS

Laboratory Abnormalities and Diagnostic Imaging

Laboratory abnormalities in dogs with vector-borne viral encephalitis are nonspecific. No or minimal abnormalities may be detected in

some dogs. Mild anemia, leukopenia, lymphopenia, or leukocytosis due to a neutrophilia (sometimes with a left shift) may occur. The CSF may also be unremarkable, or there may be increased protein concentration and mononuclear pleocytosis. MRI findings described in a puppy with EEEV infection consisted of changes consistent with multifocal meningoencephalitis with transtentorial and foramen magnum herniation.[83]

Microbiologic Tests

Serologic Diagnosis

Serologic assays such as serum neutralization or ELISAs are available for detection of antibodies to arboviruses through specialized veterinary diagnostic or research laboratories, and have primarily been used for epidemiologic serosurveys of dogs and cats. Serologic assays have, in general, not been very useful for diagnosis of acute viral encephalitis in dogs and cats. First, because disease is rare, arbovirus infections are often not suspected before death or euthanasia, and euthanasia is often performed early because of suspicion for rabies. Second, incubation periods are often short and disease in dogs progresses rapidly with a high mortality rate, so there is usually insufficient time for an antibody response to develop. The possibility of previous exposure confounds interpretation of single titers. Serologic assays have mainly been used to detect IgG and IgM in serum and CSF of dogs with TBE from Europe.[34] Demonstration of serum antiviral IgM is the standard diagnostic test for equine WNV disease, and in any species, a fourfold or greater rise in neutralization titer is evidence of an infection.

Virus Isolation

Arboviruses can be isolated in a variety of cell lines, and virus isolation has been used to detect WNV, TBE virus, La Crosse virus, and African horse sickness virus in naturally infected dogs.[25,59,84,85] Fresh or fresh-frozen brain or spinal cord homogenates from dogs with encephalitis are suitable specimens. Because viremia occurs, blood, CSF, lung, spleen, and liver might also be useful specimens for isolation.[59,63] Immunofluorescent antibody staining and RT-PCR assays can be used to confirm the presence of the virus in cell cultures.[11,59] Because many of these viruses can infect humans, specialized biosafety level 3 facilities are generally required. This limits the availability and practicality of virus isolation for routine diagnostic purposes.

Molecular Diagnosis Using Nucleic Acid–Based Testing

End point (conventional) and real-time RT-PCR assays have been described for many different arboviral pathogens. Specialized veterinary diagnostic and research laboratories generally perform these assays. In dogs, RT-PCR assays have been used to detect EEEV, African horse sickness virus, TBE (CSF), and WNV in clinical specimens.[11,27,28,59,83]

Pathologic Findings

In general, histopathology of the CNS in dogs with vector-borne viral infections reveals nonsuppurative meningoencephalitis or meningoencephalomyelitis, with multifocal mild to moderate gliosis, neuronal necrosis, and perivascular cuffing with lymphocytes, histiocytes, and plasma cells within Virchow-Robin spaces.[25,59,63] Neutrophils predominate within the meninges of dogs infected with EEEV.[11] Within brain tissue, inflammatory infiltrates in dogs infected with EEEV have been most prominent in the gray matter of the cerebral cortices and midbrains. Gray matter has also been preferentially infected in dogs with WNV encephalitis.[59] Pathologic changes in dogs with TBE are most severe in the gray matter of the brainstem and the cerebellum;[86–88] meningitis and spinal cord involvement have also been described.[63] In animals with Louping-ill virus infection, lesions have been concentrated in the spinal cord and cerebellum. Immunohistochemical reagents are available for detection of most arboviruses that can infect dogs, and have been used to detect antigen of WNV, La Crosse virus, African horse sickness virus, and TBE virus in CNS and other tissues of dogs.[26,27,59,73,88] In dogs with advanced TBE virus infection, viral antigen is not easily found, suggesting rapid clearance of the virus occurs early in the course of infection.

Extraneural lesions have mainly been reported in dogs infected with WNV and young puppies that were experimentally infected with Rift Valley fever virus, although foci of myocardial degeneration have been noted in dogs with naturally occurring EEEV. Dogs with African horse sickness virus infection had acute interstitial pneumonia and pleuritis (Fig. 41.6).[27] Multifocal to diffuse hepatocellular necrosis has been the most consistent finding in neonatal puppies and kittens infected with Rift Valley fever virus. Lesions in experimentally infected puppies and kittens showed poorly defined intrahepatic eosinophilic intranuclear

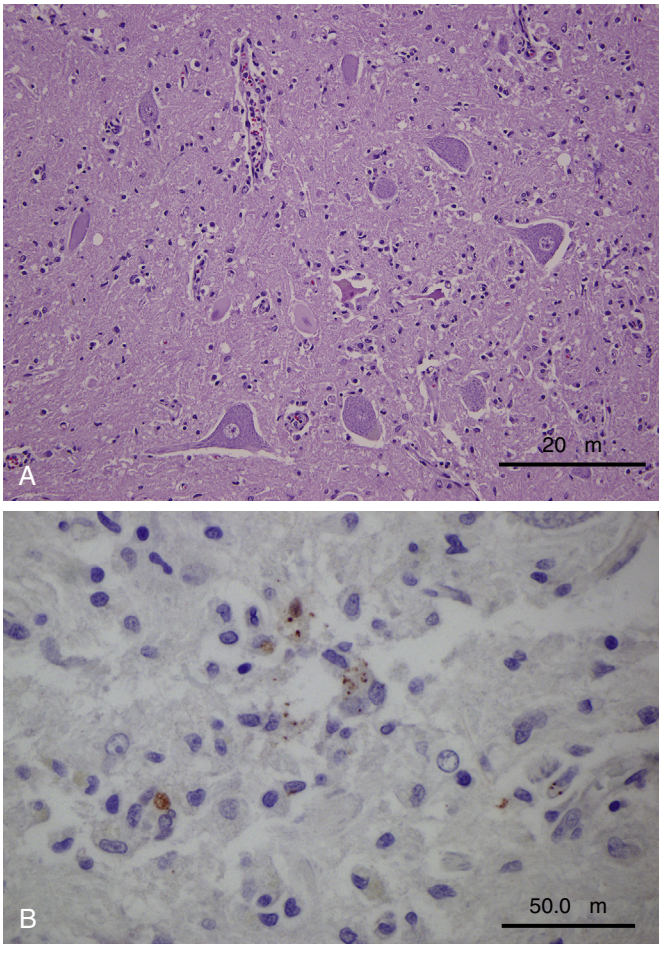

Fig. 41.6 Spinal cord segment of a dog with West Nile virus (WNV) encephalitis that shows gliosis and multiple degenerate neurons. (A) Hematoxylin and eosin stain. (B) Immunohistochemical stain showing WNV immunoreactivity *(brown)*. (From Cannon AB, Luff J, Brault C, et al. Acute encephalitis, polyarthritis and myocarditis associated with West Nile virus infection in a dog. *J Vet Intern Med.* 2006;20:1219–1223.)

inclusions and Councilmanlike bodies, which are more prominent in other hosts.[24] Lymphocytic and necrotizing myocarditis was present in some puppies and a kitten experimentally infected with Rift Valley fever virus, and several dogs naturally infected with WNV (Fig. 41.7). Other findings in dogs with WNV infection have included evidence of hepatic and renal tubular epithelial cell necrosis, adrenal gland cortical necrosis and lymphoid aggregates, neutrophilic pancreatitis, and mild plasmacytic synovitis.[58–61]

TREATMENT AND PROGNOSIS

Treatment of dogs with vector-borne viral encephalitis is supportive only. The prognosis appears to be poor, but because only a handful of infected dogs have been reported, the true prognosis is poorly understood. In virtually all dogs with neurologic signs, diagnosis has been made at necropsy. Some dogs with TBE recover with supportive care.[34] In the 2021 study of 54 dogs from Switzerland, the case fatality rate was 33%, and long-term neurological deficits occurred in 17% of the dogs.[77] Glucocorticoids have been used to treat some dogs and cats with viral encephalitides, but their use is controversial because of immunosuppression, and controlled studies are not available.

IMMUNITY AND VACCINATION

Exposure to vector-borne viruses appears to confer immunity to future infections with the same virus. Vaccines are not available for dogs because disease is uncommon to rare. However, vaccines are available and used widely in endemic areas to prevent flavivirus infections in humans (such as TBE, yellow fever, and Japanese encephalitis); WNV encephalitis in horses; and Louping-ill virus infection in sheep, cattle, and goats. Human vaccines have been used to prevent TBE in dogs, but there is limited evidence of the efficacy of these vaccines in dogs. Use of inactivated Louping-ill virus vaccines for sheep in dogs has resulted in fluid-filled swellings at the site of injection that may require surgical drainage, and dogs appear to require at least two injections to elicit a detectable serum antibody response.[89]

PREVENTION

The risk of arboviral infections in dogs and cats can be reduced through control of mosquito and tick vectors. Keeping pets indoors, especially at dawn and dusk when mosquitoes are most active, can also reduce exposure, provided mosquitoes are excluded through the use of proper screens and windows. For WNV, prevention of predation on dead birds or rodents may also reduce the risk of infection, and for African horse sickness, dogs should be prevented from consuming carcasses from dead horses in endemic areas. Drainage of standing water and removal of containers (tin cans, old tires, flower pots, clogged gutters, bunched tarpaulins) that act as breeding sites are important for mosquito control. Water in birdbaths should be changed at least weekly. Weeds and brush should be reduced. Human mosquito repellents that contain DEET (N,N-Diethyl-meta-toluamide) are not recommended for pets, because they can be toxic.[53] Some products labeled for tick prevention in dogs and cats may help to repel mosquitoes but are not likely to completely protect against mosquito bites. More information on tick prevention can be found in Chapter 13. Only products specifically labeled for cats should be used on cats or on dogs that are in contact with cats, because of the sensitivity of cats to permethrin toxicosis.[54]

PUBLIC HEALTH ASPECTS

Many arboviruses that cause disease in humans also infect dogs and cats. Dogs and cats are generally not considered reservoirs for transmission of virus to humans because they do not develop high-level or sustained viremia. As noted previously, dogs have been used as sentinels for the presence of these viruses in epidemiologic studies.

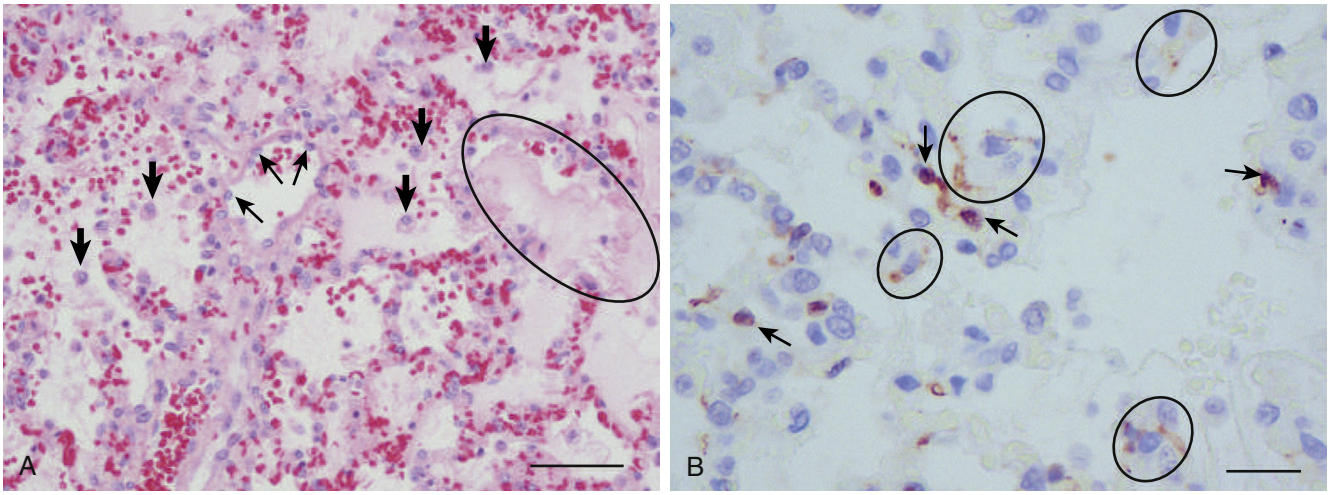

Fig. 41.7 Interstitial pneumonia with alveolar macrophage proliferation in a dog infected with African horse sickness virus. (A) Hematoxylin and eosin, 200× magnification. Clinical presentation and pathology of suspected vector transmitted African horse sickness in South African domestic dogs from 2006 to 2017. *Vet Rec.* 2018;182:715.)

CASE EXAMPLE

Signalment
"Paloma," a 13-year-old female spayed golden retriever–Irish setter mix from Vacaville in northern California.

History
Paloma was evaluated at the University of California, Davis, VMTH in September for a 3-day history of inappetence and lethargy. Two days before, physical examination by the referring veterinarian had revealed tachycardia (96 beats/min) and pyrexia (103.1°F or 39.5°C). Results of routine CBC, biochemistry tests, and a urinalysis did not reveal clinically significant abnormalities. The dog was treated with amoxicillin (20 mg/kg PO q12h) and enrofloxacin (10 mg/kg PO q12h), without improvement.

Physical Examination
Body weight: 28.6 kg.

General: Obtunded, 5% dehydrated. T = 106°F (41.1°C), HR = 140 beats/min, RR = 92 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: No clinically significant abnormalities.

Eyes, ears, nose, and throat: Bilateral enophthalmos, mild serous ocular discharge, conjunctivitis, and nuclear sclerosis were present. Moderate to severe dental disease was present. Examination of the ocular fundus showed no abnormalities.

Musculoskeletal: Body condition score 4/9. Ambulatory on all four limbs, but generalized weakness was noted. Moderate atrophy of the temporalis, quadriceps, and gastrocnemius muscles was present.

Cardiovascular, respiratory, GI, urogenital, and lymphoid systems: Tachypnea and tachycardia were identified. There was mild cranial abdominal discomfort on palpation. All peripheral lymph nodes were normal sized.

Neurologic examination: Decreased placing reactions were noted in all four limbs, and there was pain on manipulation of the neck.

Laboratory Findings
CBC: HCT 37.5% (40%–55%), MCV 67.3 fL (65–75 fL), MCHC 34.4 g/dL (33–36 g/dL), WBC 6050 cells/μL (6000–13,000 cells/μL), neutrophils 5627 cells/μL (3000–10,500 cells/μL), lymphocytes 363 cells/μL (1000–4000 cells/μL), monocytes 61 cells/μL (150–1200 cells/μL), adequate platelet numbers (clumped on smear).

Serum chemistry profile: Sodium 144 mmol/L (145–154 mmol/L), potassium 4.0 mmol/L (3.6–5.3 mmol/L), chloride 110 mmol/L (108–118 mmol/L), bicarbonate 16 mmol/L (16–26 mmol/L), phosphorus 3.1 mg/dL (3.0–6.2 mg/dL), calcium 9.1 mg/dL (9.7–11.5 mg/dL), BUN 8 mg/dL (5–21 mg/dL), creatinine 0.6 mg/dL (0.3–1.2 mg/dL), glucose 86 mg/dL (64–123 mg/dL), total protein 5.7 g/dL (5.4–7.6 g/dL), albumin 2.3 g/dL (3.0–4.4 g/dL), globulin 3.4 g/dL (1.8–3.9 g/dL), ALT 25 U/L (19–67 U/L), AST 34 U/L (19–42 U/L), ALP 53 U/L (21–170 U/L), GGT 3 U/L (0–6 U/L), cholesterol 236 mg/dL (135–361 mg/dL), total bilirubin 0.3 mg/dL (0–0.2 mg/dL).

Imaging Findings
Thoracic, abdominal, spinal, and joint radiographs: No significant abnormalities were noted.

Abdominal ultrasound: Mild mesenteric and moderate sublumbar lymphadenomegaly was identified. The dog exhibited pain on ultrasound of the right cranial abdomen, but no abnormalities in this region were identified. Impressions: mesenteric and sublumbar lymphadenomegaly.

Microbiologic Testing
Aerobic and anaerobic blood cultures (five sequentially collected specimens): negative.

Serology for *Ehrlichia canis, Anaplasma phagocytophilum*, and *Borrelia burgdorferi* antibodies (POC assay, IDEXX Laboratories, ME, USA): negative.

Treatment
Paloma was treated with lactated Ringer's solution (3 mL/kg/h IV) with potassium chloride supplementation (20 mEq/L), amoxicillin (22 mg/kg PO q8h), enrofloxacin (10 mg/kg PO q24h), and doxycycline (5 mg/kg PO q12h). Physical examination on day 2 revealed persistent pyrexia (105.6°F), tachycardia (108 beats/min), and a stiff gait, but there was no evidence of joint pain or swelling on palpation. Cytologic analysis of synovial fluid collected from both carpal and tibiotarsal joints using arthrocentesis revealed mild suppurative and mononuclear inflammation.

On day 3, the dog became tetraparetic and was unable to stand for longer than a few seconds. Pyrexia (104.5°F) persisted, and treatment with dexamethasone sodium phosphate (0.2 mg/kg IV once) and hydromorphone (0.05 mg/kg IV once) was initiated. Neurologic examination disclosed mental dullness, decreased placing reactions in all four limbs, and normal segmental reflexes. Further evaluation for neurologic disease, such as imaging of the brain, CSF analysis, or both, was offered, but declined by the owner because of financial limitations. On day 4, the dog was normothermic, and sternally recumbent. Prednisone (1 mg/kg PO q12h) and metronidazole (10 mg/kg PO q8h) were added to the treatment regimen. Despite this treatment, by day 5, Paloma was laterally recumbent and obtunded. The owner elected euthanasia.

Necropsy Findings
Histopathologic findings at necropsy consisted of severe acute multifocal necrotizing perivascular and random neutrophilic pancreatitis; severe lymphocytic and neutrophilic myocarditis and vasculitis with myonecrosis; and mild, multifocal gliosis and perivascular to random lymphoplasmacytic and neutrophilic polioencephalomyelitis. The cervical spinal cord was the most severely affected. Mild perivascular plasmacytic synovitis was also present. Aerobic and anaerobic cultures of the liver, spleen, lung, and synovial fluid were negative. West Nile virus (WNV) antigen was detected with immunohistochemical stains within foci of encephalomyelitis and myocarditis. The virus was isolated from fresh-frozen lung tissue, and WNV RNA was detected using RT-PCR in the synovium, synovial fluid, spinal cord, heart, and kidney tissue.[59]

Diagnosis
Encephalitis, myocarditis, and polyarthritis associated with WNV infection.

Comments
This was a rare case of encephalitis and myocarditis associated with WNV infection in a dog. Disease occurred in September, the time of peak activity for virus transmission by mosquitoes (July to October).

Bornavirus Infection

Jonas Johansson Wensman, Mikael Berg, Karin Hultin Jäderlund

KEY POINTS

- First Described: Staggering disease was first described in the 1970s in Sweden (Kronevi et al., 1974). It was linked to BoDV infection in 1995 in Sweden (Lundgren et al., 1995).
- Causes: Borna disease virus (BoDV) (species *Mammalian 1 orthobornavirus*), family *Bornaviridae.*
- Affected Hosts: *Mammalian 1 orthobornavirus* mainly affects horses and sheep, but also cats, dogs, other equids, and ungulates.
- Geographic Distribution: Europe (endemic in horses and sheep in Central Europe; in cats mainly reported in Sweden), worldwide serologic evidence of exposure in various species.
- Primary Mode of Transmission: Not entirely known. Reservoirs (small mammals) have been suggested.
- Major Clinical Signs: Gait disturbances and behavioral changes.
- Differential Diagnoses: Other feline encephalitides and neoplastic diseases affecting the CNS.
- Human Health Significance: A variant bornavirus has been associated with three cases of fatal encephalitis in breeders of variegated squirrels. Also, at least eight cases of BoDV-1 in humans have been described further emphasizing the zoonotic potential for BoDV-1, especially in endemic regions. The suggested association of BoDV and neuropsychiatric disorders in humans is however still highly controversial.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Naturally occurring clinical feline bornavirus infection, characterized by behavioral and motor dysfunction ("staggering disease"), was first described in Sweden.[1] Although BoDV infection has been reported in cats with ataxia and other neurologic signs in the United Kingdom, Japan, and Belgium,[2] a direct etiologic role of BoDV has not been established in these cases. One case of feline Borna disease (BD), verified by IHC, was reported from Switzerland.[3] Two dogs have been reported with BD, one from Austria[4] and the other from Japan.[5] BoDV has been detected in dogs in China, associated with importation of infected sheep from Germany.[6] A wild cat (*Lynx lynx*) in Sweden was also diagnosed with classic BD.[7] Feline BoDV isolates have however only been rarely reported.

BoDV is an enveloped, nonsegmented, negative-stranded RNA virus of the family *Bornaviridae* in the order *Mononegavirales.*[8] The genus *Orthobornavirus* consists of a number of new species such as *Mammalian 1 orthobornavirus*, *Elapid 1 orthobornavirus*, *Passeriform 1* and *2 orthobornavirus*, *Psittaciform 1* and *2 orthobornavirus*, and *Waterbird 1 orthobornavirus*. This chapter will only deal with *Mammalian 1 orthobornavirus* viruses. These viruses seem to be rather stable genetically, whereas the genetic variation within other virus species is considerably greater.

BoDV persistently resides within the CNS after natural and experimental infection of various animal species, ranging from birds to primates.[9] Historically, BoDV infected military horses in the endemic area around the city of Borna in Germany.[10] Cases of "classic BoDV encephalomyelitis", or "BD," in horses, sheep, and cattle seem to be restricted to endemic regions in Germany, Switzerland, and Austria. However, numerous other species may also be infected naturally, possibly including humans. Special concern was raised after fatal transmission of a bornavirus variant to three humans who were breeding variegated squirrels (*Sciurus variegatoides*),[11] indicating that some bornaviruses may be zoonotic.

Specific BoDV antibodies have been detected in horses and cats in various regions of the world. The disease in horses may be largely subclinical because the prevalence of antibodies in sera is much greater than the prevalence of clinical illness.[12] Based on serologic and nucleic acid screening, many feline infections are also subclinical. Serologic studies indicate that in addition to Europe, cats have been subclinically exposed in the Philippines, Indonesia, Turkey, Japan, and Australia.[13] BoDV antibodies have also been detected in cats with a wide variety of clinical signs. Although the clinical manifestations may not be directly caused by BoDV, it is possible that the virus is an opportunistic pathogen. Serologic results from two studies suggest that cats infected with FIV are more prone to BoDV infection.[14,15]

Disease associated with BoDV occurs most frequently in spring and summer,[13] and thus arthropod transmission has been suspected. A definitive reservoir host has not been documented, but rodents, insectivores, and birds are suspected. There are a number of recent reports of BoDV in various small mammals such as white-toothed shrews[16] and bank voles,[17] which indicate that different hosts exist in various geographical regions.

Viral RNA has been detected in feces and urine of naturally infected cats,[18] and in salivary, nasal, and conjunctival secretions of horses and sheep[12,19]; animals may become infected by direct contact with these secretions or with fomites, such as contaminated food or water. Infection does not appear to spread readily among cats. Epidemiologic studies suggest that risk factors for infection in cats are highest for intact males that hunt mice in rural woodland environments.[20]

CLINICAL FEATURES

Pathogenesis

BoDV is highly neurotropic and probably gains access to the CNS by transmucosal entry into nerve endings terminating in the olfactory, oropharyngeal, or GI mucosae.[21] Similar to the spread of rabies virus,

BoDV spreads into and throughout the CNS by intra-axonal transport and from there spreads centrifugally into the peripheral nerves.[22] Unlike rabies virus, the replication rate of BoDV is slow. The immune response to viral antigens is not protective but incites an immunopathologic response.[23] Neutralizing antibodies appear in the serum and CSF. This response fails to clear the infection; the inflammation subsides, and BoDV persists at low levels in the CNS of the host. In the CNS, BoDV infects neurons, astrocytes, oligodendrocytes, and ependymal cells. Experimental infection of feline astrocytes has been shown to impair their glutamate uptake function, a proposed mechanism for additional neuronal injury.[24] Interactions between BoDV and host proteins likely contribute to the development of clinical signs.[21,25,26]

In experimentally infected rats, acute-phase immunity is cellular, with T cells as the predominant cell infiltrate. With chronic infection, plasma cell infiltrates and antibody titers increase and may magnify the inflammatory reaction.[27] These findings are similar to those found with naturally infected cats with staggering disease, in which T cells predominate in the CNS and peripheral circulation,[28] with an intense IFN-γ gene expression in the CNS.[29] Cytotoxic CD8+ T cells are thought to induce this immune response against the virus. Antibody titers increase with persistent infection of the CNS.

Experimentally and naturally infected cats develop humoral immune responses to the BoDV proteins p24 and p40.[30] Serum antibodies to another BoDV protein, p10, have also been found in cats with ataxia.[31] In addition to the systemic humoral response, BoDV-specific antibodies are produced intracerebrally in naturally and experimentally infected cats.[30] Intracerebral inoculation of BoDV produces high antibody titers against the immunodominant proteins in CSF; however, natural infections induce a weak humoral immune response in cats, primarily directed against BoDV p24.[30]

Clinical signs

Affected cats are typically presented with a history of gait disturbances mixed with behavioral changes.[18,32] The gait is most often described as unsteady, predominantly in the pelvic limbs, with stiff and slow movements, as well as falling. At the same time, affected cats often become more social and affectionate, vocalize more frequently, with absent-minded behavior. Besides these overt neurological signs, > 40% of the cats are inappetent and approximately every fourth case exhibits constipation.[18,32] Otherwise, affected cats are apparently healthy.

Physical Examination Findings

On physical examination, almost half of affected cats are febrile (≥39.3°C).[18,32] About as many have an inability to retract the claws, predominantly of the pelvic limbs, and show signs of lumbosacral pain on palpation.[18,32] On neurologic examination, affected cats display varying degrees of proprioceptive ataxia with a stiff, stilted gait, sometimes with an abnormally stiff tail. As a rule, postural reactions and menace responses are absent or decreased. A majority of the affected cats is mildly obtunded and a similar proportion of cats exhibit increased vocalization throughout the whole examination.[18,32] In one study, 86% of affected cats behaved abnormally during a nociception test; their pupils dilated and their muscles flexed in response to a perceived painful stimulus, but they showed a reduced inclination to physically retreat from the painful stimulus.[18] Spinal reflexes are normal to exaggerated. Neurological deficits are bilateral and mainly symmetrical. Some clinical signs previously associated with other feline neurologic diseases, such as epileptic seizures, compulsive walking, lateralized vestibular syndrome, or facial paresis, are seldom included in the plethora of neurologic signs in cats with staggering disease.[18]

DIAGNOSIS

Laboratory abnormalities

Complete Blood Count and Serum Chemistry Profiles

Leukopenia, or a WBC count in the low-normal range, has been the only hematologic abnormality present in affected cats. Approximately 50% of the affected cats have had WBC counts below the reference range. Both neutrophil and lymphocyte counts have been at the lower end of the reference range. A few affected cats have had a slight increase in the activity of serum ALT.[18,32]

Cerebrospinal Fluid Analysis

On CSF analysis, a mononuclear pleocytosis is found in about one third of cats with staggering disease. The CSF protein content is increased (> 0.36 g/L) in approximately 50% of affected cats.[18,32] In a few cases, there has been evidence of previous intrathecal hemorrhage in the form of xanthochromia.

Microbiologic Tests

Because BoDV causes a persistent infection of the CNS, associating infection with clinical disease can be challenging. Therefore, positive test results using serologic and molecular methods support staggering disease as a tentative diagnosis when other explanations for clinical signs have been ruled out. Antibodies are most often detected using indirect IFA testing.[17] This method is considered to be specific, but insensitive. In one study, antibodies were found in 81% of cats with staggering disease compared with 16% in a control group.[18] Nested RT-PCR has been frequently used in research settings to detect BoDV RNA in peripheral blood monocytes or brain tissue.[33,34] This method is highly sensitive, but because of its inherent high risk of laboratory contamination, the results have been questioned.[35] To overcome this drawback, real-time RT-PCR assays have been developed and used to detect BoDV RNA in brain tissue, though its use as an antemortem clinical diagnostic tool has not yet been demonstrated.[36,37] Virus RNA has been detected mainly in blood in a few clinical cases in cats.[18]

Detection in the CNS of BoDV antigen by IHC, of BoDV RNA by *in situ* hybridization, or both in combination with neurohistopathologic alterations is considered the most reliable method of confirming active CNS disease. BoDV can be isolated from CNS tissue by inoculation of cell cultures or rats.[38]

Although lesions of feline BD resemble those of feline poliomyelitis, no evidence suggests that these disorders are related. The histologic and clinical features of BD should be contrasted with feline poliomyelitis, which predominantly affects the spinal cord, causing progressive lower motor neuron dysfunction with milder brainstem involvement (see Chapter 129).

Pathologic Findings

The inflammatory reaction in the CNS is characterized by a lymphohistiocytic or lymphoplasmacytic meningoencephalitis in the gray matter of the olfactory bulb, cerebral cortex, hippocampus, basal ganglia, and brainstem.[18,32] The spinal cord is affected to a lesser degree. Perivascular mononuclear cell infiltrates mainly consist of lymphocytes. The surrounding brain parenchyma is also affected, sometimes with neuronophagia and neuronal degeneration (Fig. 42.1). Inflammation of intra-abdominal ganglions may also be observed.

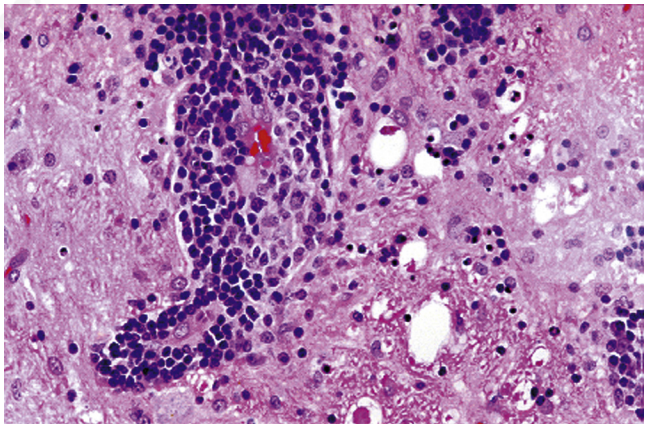

Fig. 42.1 Histopathologic findings showing characteristic nonsuppurative perivascular cuffs in gray matter of the CNS (Hematoxylin and eosin stain, ×200). (Courtesy Anna-Lena Berg, Medical Products Agency, Uppsala, Sweden.)

BoDV antigen and nucleic acid persist in brain tissue of cats, particularly within astrocytes, causing chronic inflammatory lesions (Fig. 42.2). In one cat, large amounts of virus but no inflammation were found within neurons, presumably from viral persistence by infection at an early age.[39]

BD in dogs has been characterized by a rapid onset of progressive intracranial CNS deficits that are similar to those in canine distemper.[4,5] Histopathologic lesions, which predominated in the forebrain and midbrain, have been characterized by a nonsuppurative meningoencephalitis with perivascular cuffing and diffuse mononuclear cell infiltrates of adjacent neuropil. Inflammatory cells in the cuffs largely comprise CD3+ T cells. Viral antigen and RNA can be detected in neurons using IHC and *in situ* hybridization.

TREATMENT AND PROGNOSIS

In the initial stage of staggering disease, supportive care such as IV fluids should be considered. In addition, antibacterial drugs, glucocorticoids, and/or the antiviral drug amantadine hydrochloride have been used in many cats. In a retrospective study of 54 affected cats, broad-spectrum antimicrobial drugs and glucocorticoids, as well as combinations of such medications, had a beneficial effect on survival time. Treatment with amantadine hydrochloride did not significantly increase survival time.[40] Treatment with glucocorticoids, especially at an early stage of disease, also has shown promise.[41] However, in the absence of controlled treatment trials, the effect of any therapy is anecdotal. Clinical signs progress within 1 to 4 weeks until the clinical condition either deteriorates, resulting in euthanasia,[18] or stabilizes and might improve slightly with time, still leaving most cats permanently afflicted with motor dysfunction, personality changes, or both (Fig. 42.3). In surviving cats, neurologic signs often eventually relapse. However, survival times for up to 7 years have been described.[40]

IMMUNITY AND VACCINATION

There is currently no available vaccine for BoDV infection.

PREVENTION

Because the mechanism of BoDV transmission is currently not completely understood, it is difficult to provide adequate advice on preventive measures. BoDV is inactivated by common decontamination methods, such as heat, detergents, and chlorine.

PUBLIC HEALTH ASPECTS

BoDV has been studied as a cause of human neuropsychiatric illnesses.[42,43] Antibodies to the virus have been detected in sera of patients with psychiatric disorders in various countries. The prevalence of BoDV-specific antibodies is fourfold higher in patients with HIV infection than in control patients.[44]

As in animals, controversy surrounds the significance of BoDV infection in humans.[45–47] The most definitive evidence of a link between infection and disease has been the detection of BDV-specific antigen and RNA in the brains of humans with hippocampal sclerosis and schizophrenia.[48–50] Also, a number of human fatal cases of encephalitis were described in association to BoDV-1 infection.[51] Thus, BoDV shall be considered to be a potential lethal zoonotic virus for both immunocompromised as well as fully healthy individuals. However, it is unclear how these patients were infected in the first place.

A variant bornavirus was associated with fatal encephalitis in breeders of variegated squirrels. In one squirrel, the same virus as detected in affected humans was found, suggesting direct transmission from apparently healthy squirrels to humans.[11]

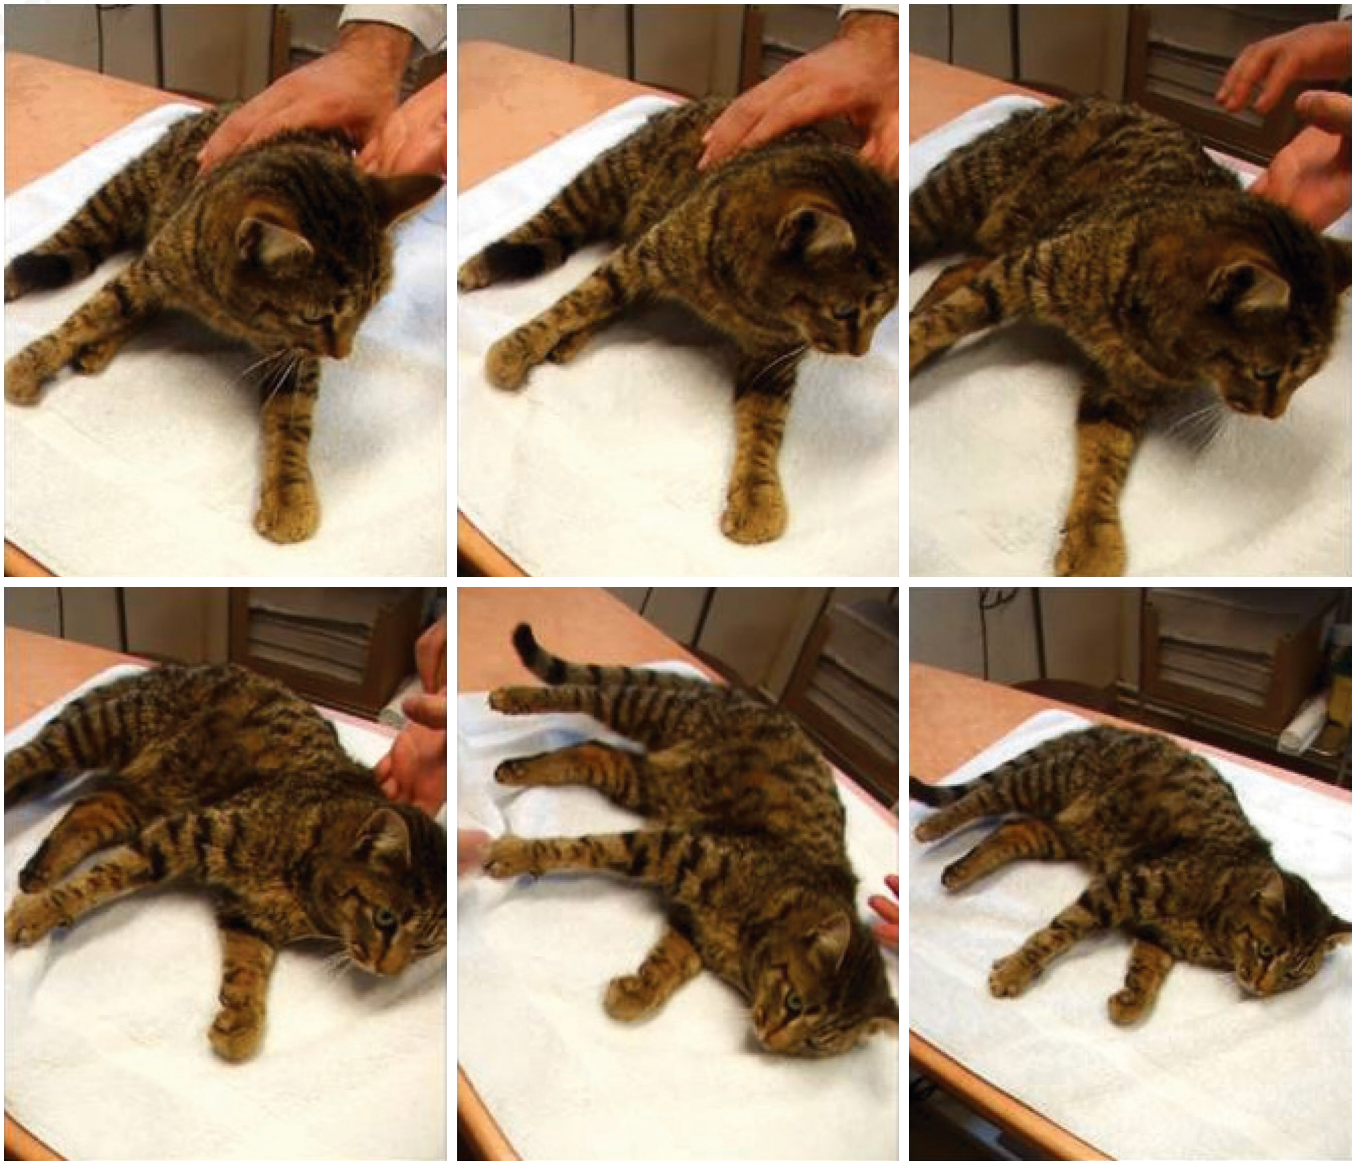

Fig. 42.3 A 2.5-year-old pregnant female cat with clinical signs of Borna disease virus infection. The series of photos show how the cat falls to the left (from upper left to lower right). The cat displayed a severe general proprioceptive ataxia with an absent menace response and decreased postural reactions in the thoracic and pelvic limbs.

CASE EXAMPLE

Signalment

"Teddy," a 4-year-old male, neutered, European shorthair cat from Alunda in the Uppsala area, Sweden.

History

Teddy was described to be ataxic 4 weeks before initial examination. Treatment with oral prednisolone and amoxicillin was initiated for a tentative diagnosis of staggering disease. Teddy improved somewhat initially, but ataxia then worsened. Over the 2 weeks leading up to initial examination, pelvic limb ataxia, "knuckling" of the thoracic limbs, and changes in behavior (abnormal degree of affection and increased vocalization) were noted. Although his appetite was unaffected, a 1-kg weight loss over the last month had occurred. He was up to date on vaccinations. Teddy was an outdoor cat from rural surroundings. There were three other cats in the household, and all were healthy.

Current Medications

Prednisolone 2.5 mg q24h PO.

Physical Examination

Body temperature = 38.5°C; body weight = 3.5 kg; BCS = 3/9; HR = 130 beats/minute; mucous membranes moist and pink. No significant abnormalities were noted during examination of lymph nodes, integument, eyes, ears, nose and throat, cardiovascular, respiratory, GI, or genitourinary organs.

Neurologic Examination

Mental status: Slightly obtunded. Behavior: Affectionate and meowing. Posture: Stiff limbs. Extension of the claws were noted in both thoracic and pelvic limbs. Gait: Teddy was ambulatory, with paraparesis and a severe ataxia, more pronounced in the pelvic limbs. The gait was stiff and stilted. Cranial nerves: Menace reactions were reduced, otherwise no abnormalities were noted. Postural reactions: The postural reactions in all four limbs were reduced. Spinal reflexes: A crossed extensor reflex was present in all four limbs, the other spinal reflexes were normal. Nociception: Teddy showed an abnormal response to toe stimulation, in that he vocalized but did not attempt to escape the nociceptive stimulus.

CASE EXAMPLE—cont'd

Laboratory Findings

CBC: Hemoglobin 162 g/L (80–150 g/L), WBC 4,200 cells/μL (5,500–9,500 cells/μL), neutrophils 2,900 cells/μL (2,500–12,500 cells/μL), eosinophils 0 cells/μL (0–1,500 cells/μL), lymphocytes 1,100 cells/μL (1,500–7,000 cells/μL), monocytes 100 cells/μL (100–1,000 cells/μL).

Serum chemistry profile: ALT <72 U/L (<60–120 U/L), ALP 24 U/L (<300 U/L), creatinine 1.1 mg/dL (0.7–1.9 mg/dL), albumin 4.6 g/dL (3.2–4.6 g/dL)

Serum protein electrophoresis: globulin 2.5 g/dL, α1-globulins 2 g/L (2–3 g/L), α2-globulins 9 g/L (11–17 g/L), β1-globulins 3 g/L (3–6 g/L), β2-globulins 2 g/L (1–3 g/L), γ-globulins 9 g/L (8–18 g/L).

Total T4: 26 mmol/L (7–35 mmol/L).

CSF analysis from the cerebellomedullary cistern: Clear and colorless. Mononuclear pleocytosis; erythrocytes 105/μL, leucocytes 58/μL, 100% mononuclear cells. Protein 0.75 g/L.

Serology: BoDV IFA in serum ≥ 1:160, BoDV IFA in CSF 1:5. Serology for *Toxoplasma* antibodies, CoV antibodies, FeLV antigen, and FIV antibodies negative in serum.

Real-time PCR for BoDV RNA in blood, urine, and CSF: Negative.

Diagnosis

Staggering disease. Teddy was euthanized a few days later due to further progression of signs.

Necropsy findings: Meningoencephalomyelitis, especially in the grey matter.

Comments

In this case, a diagnosis of staggering disease was strongly suspected based on the typical clinical signs and the positive serology, as well as ruling out other possible causes of disease.

Emerging and Miscellaneous Viral Infections

Jane E. Sykes

KEY POINTS

- The infectious diseases described in this chapter are either: (1) diseases of humans or other animals generally transmitted through contact with the secretions or excretions of rodents (hantaviruses, arenaviruses, and encephalomyocarditis virus), swine (hepatitis E virus), monkeys (Ebola virus), or bats (systemic coronaviruses); (2) common diseases of humans where the role of companion animals in transmission has been investigated (enteroviruses, SARS-CoV-2); (3) diseases of significant importance to the agricultural industry (foot-and-mouth disease virus, vesicular exanthema, encephalomyocarditis virus); or (4) significant diseases of potential prey of dogs and cats (rabbit hemorrhagic disease virus).
- Clinical illness has not always been confirmed in dogs and cats with these infections, but evidence of seroconversion to these viruses exists.
- In some cases, concern has been raised in the possible role of dogs and cats in zoonotic transmission; this has been heightened by the COVID-19 pandemic.
- In general, research suggests that dogs and cats do not play a major role in transmission of these viruses, but the potential exists should new viral variants emerge.

HANTAVIRUS INFECTION

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Hantaviruses are enveloped RNA viruses that belong to the family *Bunyaviridae*, which contains four other genera (*Nairovirus, Orthobunyavirus, Phlebovirus,* and *Tospovirus*), and are named after the Hantan River area in South Korea where the disease was first observed. Hantaviruses are the only members of the *Bunyaviridae* that are not transmitted by arthropod vectors (for comparison, see *Bunyaviridae* in Chapter 41, Arthropod-Borne Viral Infections). Each hantavirus strain of is uniquely adapted to a subclinically infected rodent, shrew, or bat reservoir, and humans usually become infected through contact with rodent feces, urine, or saliva. Direct physical contact with the rodents is not required, so aerosolized virus is the likely means of spread of infection between rodents and humans. Rodent bites have also been documented as a means of transmission.[1] Although humans are generally considered dead-end hosts, some strains (Andes virus in South America) can be directly transmitted between humans. Species differences exist among rodents as to the length of salivary excretion, with times ranging up to 1 year. Infected rodents are thought to harbor the virus in their lungs and kidneys for life.

Over 50 different hantavirus strains have been identified worldwide. Those that are pathogenic for humans cause two clinically distinct syndromes. *Hantavirus hemorrhagic fever with renal syndrome (HFRS)* is the vastly more common syndrome, and is caused by Hantan River, Seoul, Dobrava-Belgrade, and Saaremaa viruses in Europe, Asia, and Africa. *Hantavirus pulmonary syndrome* (*HPS*; also known as hantavirus cardiopulmonary syndrome), a pulmonary disease with 40%–50% mortality, occurs in North, Central, and South America. It is primarily caused by Sin Nombre virus in North America, which is carried by deer mice. In the United States, most human infections have occurred in the Four Corners states (Arizona, Colorado, New Mexico, and Utah), although only a few dozen cases are reported in North America annually (Fig. 43.1).[2] Monongahela, New York, Bayou, and Black Creek Canal viruses also cause HPS in North America and are found in eastern Canada and the eastern and southeastern regions of the United States. In South and Central America, a number of other viruses can cause HPS, including Andes virus in Argentina, Brazil, and Chile; Laguna Negra virus in Bolivia and Paraguay; and Choclo virus in Panama.[3]

The disease is more prevalent during seasons and years when population densities of rodents are highest. The greatest incidence of infection in humans occurs when their work or recreational activities expose them to rodents. Infections occur on farms, in suburbs, and in residential areas. In laboratory rats in the United States, infection by the Seoul virus has been controlled by serologic testing and by producing rodents from cesarean-derived stock maintained under strict barrier conditions.

Although human infections receive the most attention, dogs and cats have the potential to become infected following contact with rodents and rodent excreta. The possibility of hantavirus infection in cats was initially raised in a study from China that indicated that cat ownership was a risk factor for hantavirus infection in humans.[4] Several studies conducted worldwide have identified hantavirus antibodies in domestic cats, with seroprevalences of 5% in Austria,[5] 9.6% in Great Britain,[6] 16.9% in Belgium,[7] 2.9% in rural cats from the southwestern Canadian prairie,[8] and 2.8% in New Mexico and northeastern Arizona.[9] Cats that are allowed to roam or hunt outdoors have the highest seroprevalence, and in the Belgian study, cats and dogs living in forested areas had higher seroprevalence.[7] Hantavirus antigen was detected in the lungs of 2 of 100 cats that had a history of rodent hunting at necropsy.[10] The seroprevalence in dogs has been low, 4.9% in Belgium,[7] 0% in the Canadian prairie,[8] and 3.5% in New Mexico and Arizona.[9] At this time, it seems that neither coyotes nor dogs or cats appear to play a major role in the maintenance and transmission of Sin Nombre virus.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In cats and dogs, clinical hantavirus infection has never been documented, and so most or all infections are probably subclinical. Both

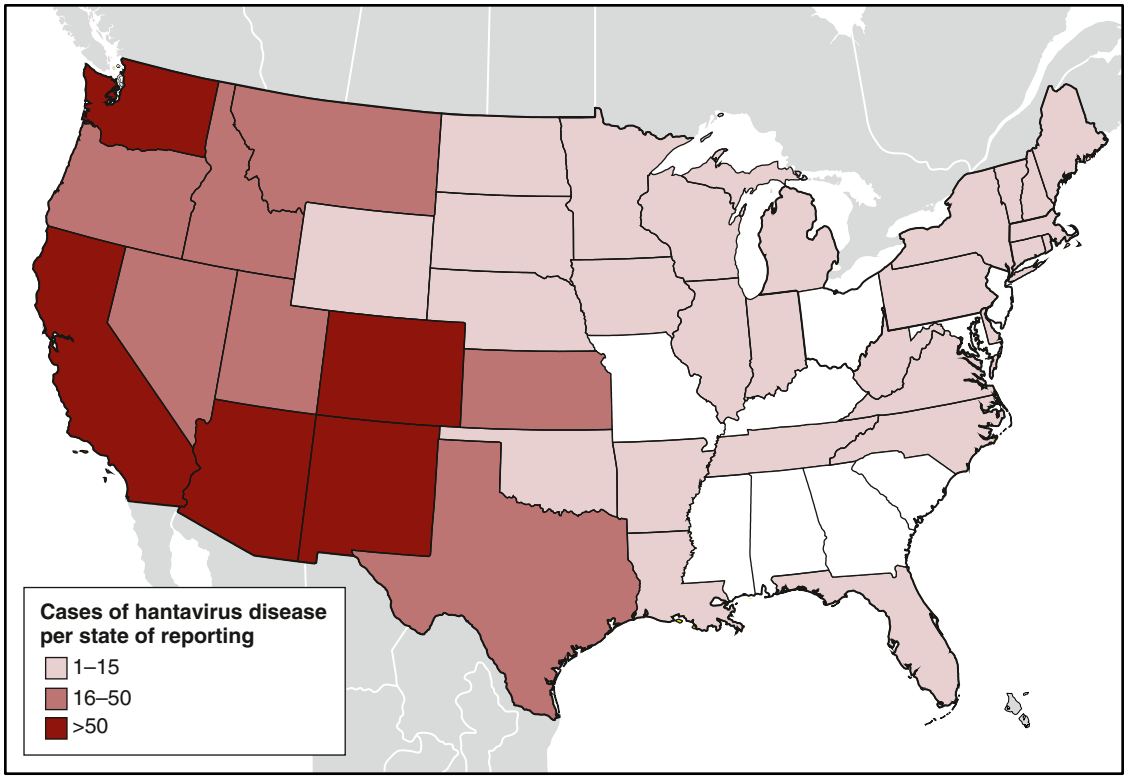

Fig. 43.1 Geographic distribution of cumulative reported hantavirus pulmonary syndrome cases in the United States. States that are not shaded had no cases reported. (Modified from the CDC; http://www.cdc.gov/hantavirus/surveillance/reporting-state.html. 2019.)

hantaviral syndromes result from vascular leakage, although the pathogenesis of this remains unclear.[1] In humans, hantavirus infection resembles leptospirosis, which is an important differential diagnosis.[11] The clinical manifestations depend on viral strain, but in general, HFRS is associated with fever, headache, abdominal pain, signs of renal dysfunction, thrombocytopenia, hemorrhagic diathesis, and sometimes neurologic signs. HPS is characterized by fever, myalgia, vomiting, abdominal pain, respiratory signs resulting from acute pulmonary edema, and circulatory collapse.[12] Some humans also develop renal insufficiency, although this is less common when compared with HFRS. Radiographs reveal acute bilateral pulmonary interstitial infiltrates. Most deaths associated with HPS are related to cardiogenic shock rather than pulmonary failure; therefore, the term "hantavirus cardiopulmonary syndrome" is more appropriate than "hantaviral pulmonary syndrome."[3]

DIAGNOSIS

The diagnosis of hantavirus infection in humans is made using serologic and molecular methods. Early in the course of illness, virus can be detected using RT-PCR in whole blood.[12] A serologic diagnosis can be made using a variety of serologic methods (most commonly ELISA) through detection of serum IgM, a fourfold increase in serum IgG, or detection of IgG or IgM against the N protein.

TREATMENT

In human patients, treatment includes cautious IV crystalloid fluid administration, colloids, electrolyte replacement, oxygen supplementation, blood pressure support, and dialysis.[12] Intravenous ribavirin has also been effective in the treatment of HFRS when used early in the course of illness. Excessive fluid administration must be avoided because it may increase the severity of pulmonary edema.

PUBLIC HEALTH ASPECTS

Avoidance of contact with rodents and their excreta is the most effective way to reduce the prevalence of disease. Masks, and in some cases respirators, should always be worn by people cleaning rodent-infested buildings. Areas to be cleaned should be thoroughly soaked with disinfectants such as dilute sodium hypochlorite before they are mopped. Vacuuming and sweeping should be avoided to minimize aerosolization.

ARENAVIRUS INFECTION

The arenaviruses are enveloped, single-stranded RNA viruses that generally infect rodents (genus *Mammarenavirus*, family *Arenaviridae*). At least eight different arenaviruses cause disease in humans, which range in severity. Each arenavirus species is usually associated with a particular rodent reservoir host. One of the most significant arenaviruses is lymphocytic choriomeningitis virus (LCV), an arenavirus of house mice (*Mus musculus*) that is found worldwide. Hamsters are also competent reservoirs. LCV is transmitted *in utero* or at birth and persists for the life of the rodent in high concentrations in tissues. Humans can become infected as a result of contact of mucous membranes or abraded skin with aerosols from infected rodents. Immunocompromised people are most susceptible; postnatal infections cause acute aseptic meningoencephalitis, whereas congenital infections produce CNS and ocular malformations.[13] Outbreaks in humans resulted from contact with pet or laboratory hamsters, including

accidental transmission of the infection in organ recipients.[14–16] Other arenaviruses have more restricted geographic distributions (e.g., Lassa virus in West Africa and Whitewater Arroyo virus in the southwestern United States) and cause febrile or febrile hemorrhagic diseases in humans.

Outbreaks of rodent lymphocytic choriomeningitis infections have raised concern that domestic dogs or cats might serve as reservoirs or vectors of the virus for human exposure. Although puppies did not develop clinical illness after parenteral or cerebral inoculation,[17] they developed neutralizing antibody titers to the virus, and infection was transmitted from infected to noninfected puppies. Except for intranuclear inclusions in the adrenal cortex, pathologic changes were not observed. It is unlikely that dogs or cats become infected or spread the virus by natural exposure, because most human infections result from direct contact with rodents.

ENCEPHALOMYOCARDITIS VIRUS INFECTION

Encephalomyocarditis virus (also known as Cardiovirus A) is a small, nonenveloped RNA virus that belongs to the genus *Cardiovirus* in the family *Picornaviridae*. It infects a variety of domestic and wild animals worldwide, with rodents as subclinically infected reservoir hosts. Humans may also be infected. Most human infections are thought to be subclinical.[18] Rodents shed virus for up to 29 days after infection. Transmission is by the fecal-oral route, and infections typically occur through ingestion of contaminated food, water, or carcasses. Pigs are most susceptible and can develop myocarditis or transplacental infection with fetal death at various time periods of gestation. Disease in humans is rarely described, and can range from a mild febrile illness to meningoencephalitis.[18]

The extent to which encephalomyocarditis virus can cause disease in dogs and cats is unclear. In Austria, 0.5% of 200 cats were seropositive to encephalomyocarditis virus.[19] Encephalomyocarditis virus antigen was found in the brains of four dogs and four cats with nonsuppurative meningoencephalitis.[20] In China, an encephalomyocarditis virus (EMCV-C15) was detected in 4 of 69 serum specimens from dogs with fever and variable GI and respiratory signs using real-time PCR.[21] These four dogs were co-infected with canine parvovirus. The virus was subsequently propagated in cell culture, and experimental infection of 4-week-old puppies with the isolate was followed by development of pulmonary edema, myocarditis, pelvic limb paralysis and encephalitis. The virus was then detected in a variety of tissues, but especially the heart and brain, using RT-PCR. However, whether the experimentally infected dogs were tested for CPV infection was not reported.

ENTEROVIRUS INFECTIONS

Enteroviruses are tiny, nonenveloped, single-stranded RNA viruses that belong to the genus *Enterovirus* (family *Picornaviridae*). Viruses in this genus commonly infect humans worldwide and were previously separated into polioviruses, coxsackieviruses (types A and B), echoviruses, and as yet unclassified enteric viruses. However, because of recognized overlap in these viral groups, newer members of the genus are called enteroviruses (EVs), which are designated by a sequential numbering system (e.g., EV70). The genus also includes the human rhinoviruses (which cause the common cold) and poliovirus. EVs are environmentally resistant and infect humans primarily via the fecal-oral route, but are also shed in respiratory secretions and can contaminate fomites. After replication in submucosal lymphoid tissues, the viruses can spread systemically to various other tissues.

Dogs have been tested to determine whether they harbor a variety of human EVs because of the possible zoonotic potential (Table 43.1).[22–27] Similar information is not available for cats. Dogs are exposed to and can shed human EVs. Although dogs appear to become infected with these viruses, clinical signs have not been apparent. The viruses

TABLE 43.1 Human Enteroviruses Recovered From Apparently Healthy Dogs

Virus	Specimen	Geographic Location
Poliovirus 1	Feces	West Bengal[22]
	Feces	Costa Rica[23]
Echovirus 6	Feces	California[24]
	Nasopharynx, feces	New Mexico[24–26]
Echovirus 7	Feces	West Bengal[22]
Coxsackievirus A9, A20	Feces	Costa Rica[23]
Coxsackievirus B1	Nasopharynx, feces	Texas, New Mexico[24,25]
Coxsackievirus B3	Nasopharynx, feces	New Mexico[25]
Coxsackievirus B5	Nasopharynx, feces	New Mexico[25]
Unclassified enteroviruses	Feces	Philippines[27]

can be found in canine feces for a period of months, but whether the extended shedding results from persistence or reinfection is uncertain. EVs recovered from nasopharyngeal or fecal cultures of dogs have been grown in tissue culture and cause cytopathogenic effects, primarily in monkey kidney but not canine cell lines, supporting the fact that they are human viruses. Neutralization tests have shown them to be closely related to human isolates.[28,29] In some instances, EVs in canine feces were believed to be simply passing through the GI tract of dogs, rather than causing infection. Alternatively, they may be canine EVs antigenically related to human EVs, such as the recently discovered canine picornavirus.[30] Newer techniques to determine viral homogeneity by genetic analysis should shed light on this in the future.

Oral inoculation of dogs with echovirus 6 or coxsackievirus B1 produced minimal signs of enteric disease. Although virus could be isolated from the feces, seroconversion did not occur.[31,32] Although dogs shed these viruses in low amounts, viral spread to susceptible dogs has resulted in infection.[32] Whether infected dogs can be a source of human infection is uncertain. In one study, dog and cat ownership had a protective effect on EV infection in infants.[33]

EBOLA VIRUS INFECTION

Ebola virus is a filamentous, enveloped, single-stranded RNA virus that belongs to the genus *Ebolavirus* and family *Filoviridae* (Fig. 43.2). The virus causes vascular injury, leading to a fulminant hemorrhagic fever in human and nonhuman primates with a 40% to 80% mortality rate. Clinical signs in humans include fever, fatigue, abdominal pain, severe headache, vomiting, diarrhea, myalgia, arthralgia, weakness, and hemorrhages.[34] Death generally results from hypovolemic shock and multiorgan dysfunction. The first recorded description of the disease was in 1976 in Zaire (now the Democratic Republic of Congo), and the virus is named after the Ebola River where the first outbreak occurred. Various species of fruit bats act as reservoir hosts.[35] Humans become infected by contact with body fluids of other infected humans, or contact with other infected animals, especially bats. Infections have occurred as a result of handling meat of bats, nonhuman primates, or duikers (a species of antelope) (Fig. 43.3).[35] Healthcare workers have also been infected. Transmission is more likely later in the course of infection than in the first few days of clinical signs, and the incubation period is 2 to 21 days (average 8 to 10 days). Diagnosis of infection in humans is based on cell culture, serologic detection of antibodies or antigen, and/or detection of viral RNA with real-time RT-PCR assays.[36] Treatment is with aggressive supportive care, as no antiviral

TABLE 43.2 Comparison of Features of the Four Major Hepatitis E Virus Genotypes of Significance to Human Health

Characteristics	Genotype 1	Genotype 2	Genotype 3	Genotype 4
Geographic location	Africa and Asia	Mexico, West Africa	Developed countries	China, Taiwan, Japan
Risk groups	Young adults	Young adults	Older adults (>40 years), males, and immunocompromised individuals	Young adults
Zoonotic transmission	No	No	Yes	Yes
Chronic infection	No	No	Yes	No
Outbreak occurrence	Common	Smaller scale	Uncommon	Uncommon

(Modified from the Centers for Disease Control and Prevention; https://www.cdc.gov/hepatitis/hev/hevfaq.htm. 2020.)

drugs have yet proven to be effective.[34] The virus can persist weeks to months in some recovered humans, and chronic infection of semen has led to sexual transmission. The possibility of development of an effective vaccine holds promise.[37]

The most significant outbreak began in Guinea in December 2013 and spread rapidly throughout West Africa. The outbreak continued to early 2016, affecting approximately 30,000 people and resulting in over 11,000 deaths.[34,38] During the outbreak, the virus underwent mutation that increased its tropism for human cells, and decreased its tropism for bat cells, which was thought to contribute to the size of the outbreak.[39] In August 2014, the WHO declared the outbreak was an international public health emergency. Human-to-human transmission occurred outside Africa in Madrid, Spain, and Dallas, Texas. In Spain, a nurse was infected when she cared for a patient with Ebola virus infection that was transferred from West Africa to Spain. She subsequently recovered. In Texas, a man contracted the disease after flying from Liberia to Dallas. Subsequently, two nurses that cared for him became infected. The man died, but the nurses recovered with supportive care.

Antibodies to Ebola virus have been detected in the serum of dogs,[38,40] raising concerns about the role of feral and domestic dogs in the transmission of Ebola virus. During the 2001-2002 outbreak of Ebola virus in Gabon, Africa, dogs were observed feeding on animal carcasses. The seroprevalence in dogs in the virus-epidemic area (25.2%) was higher than the seroprevalence in nonepidemic areas of Gabon (15.2%) or France (2%).[40] In another study that aimed to investigate the role of dogs as sentinels for human exposure to filoviruses, 47 (73%) of 64 dog serum specimens had evidence of exposure to filoviruses, and up to 100% of dog serum specimens from some regions where Ebola had occurred in humans had evidence of possible exposure to Ebola virus.[38] Neither Ebola virus antigens nor nucleotide sequences or cultivated virus were detected in any seropositive or seronegative dog blood specimens. Clinical signs have not been observed in exposed dogs, and whether they can serve as a source of infection for people remains uncertain. In 2014, the Spanish government ordered the pet dog of the nurse in Spain, "Excalibur," to be euthanized, and "Bentley," a Cavalier King Charles spaniel owned by one of the nurses in Dallas was quarantined under BSL-4 precautions for 3 weeks. Such precautions require considerable resources, including people trained in how to use and remove appropriate personal protective equipment (PPE). Suitable quarantine facilities were not available in Spain.[41] Although Excalibur was not tested for Ebola virus infection, no evidence of Ebola virus infection was detected in Bentley despite repeated testing over the course of the quarantine period. As a result of concerns about the role of companion animals in transmission of Ebola virus infection, the AVMA and CDC issued guidance statements for public health officials on pets of Ebola virus disease contacts and on quarantine of dogs and cats after exposure to a human with confirmed Ebola virus disease.[42] Quarantine is required for a minimum of 3 weeks after the pet was last exposed to a person with Ebola. In order to avoid quarantine, it is recommended that animals in contact with a person being monitored for development of symptoms be moved to another household, so that in the event symptoms do occur, those animals are not exposed.

HEPATITIS E VIRUS INFECTION

Hepatitis E virus (HEV) generally causes an acute self-limiting hepatitis in humans. Although previously considered a disease primarily occurring in developing tropical and subtropical countries, it has recently emerged as the most common cause of acute hepatitis in the United Kingdom.[43] Chronic infections that can culminate in cirrhosis can occur in immunosuppressed individuals such as transplant recipients.[44] The virus is icosahedral and nonenveloped, with a single-stranded positive-sense RNA genome, and belongs to the family *Hepeviridae*, genus *Orthohepevirus*. Strains that infect humans are classified into four genotypes; genotypes 1 and 2 exclusively infect humans, but genotypes 3 and 4 infect humans and other animal species, with pigs considered the predominant reservoir (Table 43.2).[44–46] Additional strains of HEV have been detected in other animal species, including chickens, rats, ferrets, and moose, but these are genetically distinct from those that infect humans.[45] All genotypes are shed in feces with fecal-oral contact as the means of transmission. Genotype 1 infection is the most common form of acute hepatitis in people in Asia, with most infections resulting from ingestion of water that has been contaminated with feces. Outbreaks of genotype 1 infection occur in developing countries in southeast and central Asia, the Middle East, and North Africa, especially after heavy rainfall and monsoons. Sporadic outbreaks caused by genotype 2 occur in Mexico and West Africa. Genotype 3 causes disease in developed countries and genotype 4 in China, Taiwan, and Japan. Foodborne transmission through consumption of undercooked pork, deer, and boar meat predominates for genotypes 3 and 4, and outbreaks are uncommon. Genotype 3 strains have also been detected in wild and farmed rabbits.[45] Contamination of water with pig feces can result in contamination of other foodstuffs, including shellfish and fruit.

Antibodies to HEV have been detected in cats and dogs worldwide, and an epidemiologic connection between pet ownership and human HEV infection has been implied because of the number of infected humans that have reported dog or cat contact.[47–49] Seroprevalences have been reported of approximately 20% in dogs and 6% in cats from China,[50,51] 0% in dogs and 8% in cats from Korea,[52] 28% of 287 dogs from South Korea,[38] 0.9% of 212 dogs in the United States,[53] 0.8% in dogs from the United Kingdom,[54] less than 1% in dogs and 2% in cats from Japan,[55,56] 7% in dogs from Brazil,[57] and 23% of 44 dogs from

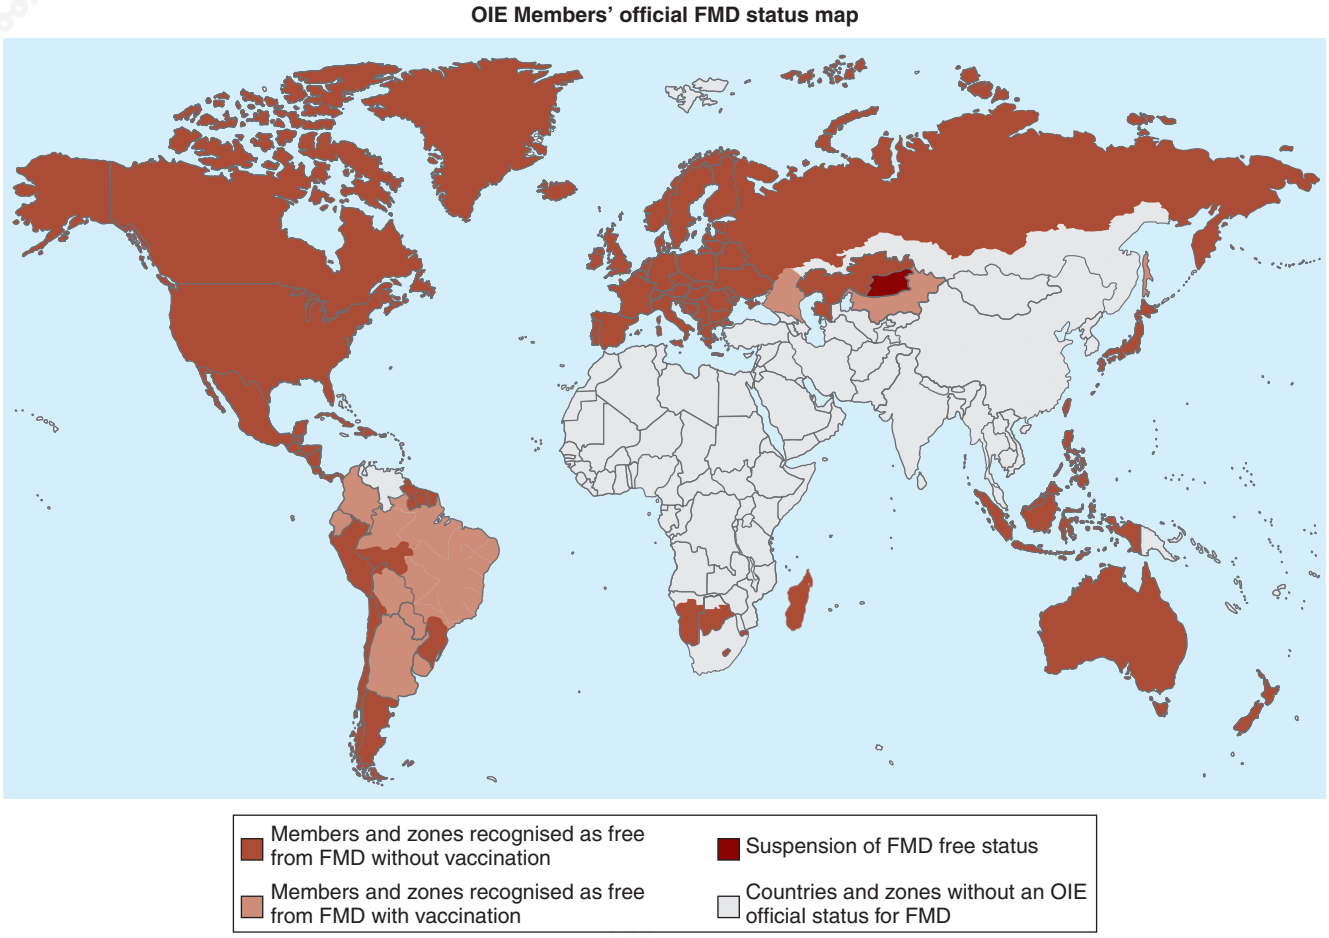

Fig. 43.4 World Health Organization Member Countries' foot-and-mouth disease (FMD) status. (From World Organization for Animal Health. Foot and Mouth Disease [FMD]. http://www.oie.int/en/disease/foot-and-mouth-disease/#ui-id-2. 2022. ©OIE 2022.)

India.[58] In China, dogs and cats were more likely to be seropositive if they shared kitchen scraps with humans, as opposed to being fed a commercial pet food.[51] However, attempts to detect HEV RNA in serum, liver, and feces from dogs and cats have consistently yielded negative results.[54,55,59,60] This included one attempt that used broadly reactive primers expected to detect strains divergent from those that infect humans.[54] Furthermore, pet veterinarians attending a conference in Portugal were not found to have an increased risk of seropositivity when compared with the general population,[61] whereas in the United States, swine veterinarians were much more likely to be seropositive than those who did not have contact with swine.[62] Currently, the evidence suggests that dogs and cats do not play an important role in transmission of HEVs to humans. Prevention of HEV infection involves general sanitation.

FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease (FMD) is a highly contagious febrile vesicular disease of wild and domestic cloven-hoofed animals. It is caused by various strains of FMD virus, a nonenveloped RNA virus (genus *Aphthovirus*, family *Picornaviridae*). It occurs worldwide and has significant economic impact on the agricultural industry. Seven serotypes are recognized, named following their recognition in France, Germany, South Africa, and Pakistan (O, A, C, SAT1, SAT2, SAT3, Asia-1). Eradication has been variably successful in Australia, New Zealand, Japan, Europe, and North America, with the last outbreak in the United States occurring in 1929.[63] Many countries in South America are considered disease-free (Fig. 43.4).[64] The disease continues to be a problem in the Middle East, Africa, and parts of Asia, and reappearance of the disease in places it has been eradicated, usually as a result of accidental importation of contaminated meat (or pigs fed contaminated meat products) from countries where FMD persists, results in major economic losses. For example, the 2001 outbreak in the United Kingdom was estimated to cost US $12.3 to 13.8 billion.[63] Culling, restriction of movement, disinfection, monitoring, and vaccination are used to control the disease. Vaccines do not cross-protect among different strains, so they must be designed to target a particular outbreak strain.

Dogs and cats are resistant to infection and do not play a major role in spreading or harboring the disease under conditions of natural exposure. Dogs and cats can be experimentally infected,[65] but naturally occurring disease has not been recognized. Carnivores have the potential to become incidentally infected during outbreaks in herbivores by contacting these animals or their offal, but are only considered to play a role in transmission by acting as fomites. Dogs can also contribute to the spread of FMD by carrying remains of animals from one location to another.

Guidelines have been established for dog owners in areas known to have infected animals. Dogs in areas with infected animals must be leashed or enclosed to a confined space at all times. Dogs must not

be walked across farmland and contact with livestock and wild animals should be prevented. Certain sporting activities involving dogs should not be allowed in quarantined areas. In the United Kingdom, concerns about the spread of FMD during the 2001 outbreak resulted in postponement of the Crufts Dog Show. Similarly, cats should be kept indoors as much as possible. Disinfectants suitable for inactivating the virus are 4% sodium carbonate, 0.5% citric acid, 4%–5% acetic acid, 1% potassium peroxymonosulfate, 3% sodium hypochlorite (2:3 ratio of gallons of household bleach to 3 gallons of water), or 2% sodium hydroxide.[66] Phenolic disinfectants, quaternary ammonium compounds, and biguanides are not effective. Halogens such as sodium hypochlorite or iodine are less effective because of inactivation by organic matter.

VESICULAR EXANTHEMA AND OTHER CALICIVIRUSES

Vesicular exanthema of swine is caused by a calicivirus that causes lesions on the mouth, lips, snout, and feet of pigs. It has only been reported in the United States, and not since 1959, but is of historic importance because it can be confused with FMD. Dogs have developed clinical signs of illness characterized by vesicular eruptions when outbreaks of vesicular exanthema virus infection have occurred in swine.[67] Virus was not definitely isolated in these cases. Experimentally infected dogs developed fever within 24 hours after inoculation and vesicular eruptions on their tongues and in their oral cavities.[67] These lesions healed within a few days. Virus was isolated from the spleen of a dog that became febrile after inoculation.

In 2018, several additional caliciviruses were isolated from military working dogs in the United States.[68] These were closely related to canine calicivirus. Further work will be required to determine their pathogenicity. A calicivirus (canine vesivirus) was isolated from dogs that died in 2015 during a focal outbreak of hemorrhagic gastroenteritis in a pet housing facility in Virginia, USA. Virus nucleic acid was found in association with areas of necrosis and hemorrhage in the intestinal tract, but also in the brain of a dog that had nonsuppurative meningoencephalitis.[69]

RABBIT HEMORRHAGIC DISEASE

Rabbit hemorrhagic disease (RHD), also known as *rabbit calicivirus disease*, is an acute, highly contagious, and often fatal disease of rabbits caused by rabbit hemorrhagic disease virus (RHDV, genus *Lagovirus*, family *Caliciviridae*). Transmission of the virus is by direct contact with secretions from infected rabbits or with infected fomites. The disease was first identified in China in 1984, spread rapidly to Europe, where it killed millions of domesticated rabbits in less than a year, and has now also been reported in other parts of Asia, Africa, Australia, New Zealand, and the Americas. In 2010, a new variant of the virus, RHDV2, emerged in France. The virus was introduced into Australia and held under quarantine to investigate its utility to control rabbit overpopulation, but escaped quarantine in 1995 and killed over 10 million rabbits within a 2-month period. Subsequently, it was deliberately and illegally introduced into New Zealand. In 2019 and 2020, it appeared in wild and domestic lagamorphs in the northwestern and southwestern United States, respectively.[70,71] By March of 2022, the virus had been identified in lagomorphs from 19 different US states.[72] Affected rabbits develop a febrile hemorrhagic disease, sometimes accompanied by icterus, neurologic signs, and cutaneous ulceration.

Only rabbits are susceptible to disease caused by RHDV. Feral cats in New Zealand have antibodies to RHDV, and the virus was detected using nested RT-PCR in the liver of one seropositive cat.[73] Cats fed rabbit livers infected with RHDV developed serologic titers to the virus, and RHDV RNA was detected in the tonsils, mesenteric lymph nodes, spleen, and liver. Even though large amounts of virus were found, clinical disease was not observed. Active replication of RHDV was not demonstrated.

SEVERE ACUTE RESPIRATORY CORONAVIRUS INFECTIONS

Severe acute respiratory syndrome coronaviruses are betacoronaviruses most closely related to betacoronaviruses isolated from bats. Other betacoronaviruses include OC43 and HKU1, the cause of common colds in humans; Middle Eastern Respiratory Syndrome (MERS) virus; canine respiratory coronavirus (CRCoV); and bovine coronavirus (BoCV) (Table 43.3). While also a betacoronavirus, CRCoV is more closely related to BoCV and OC43 than SARS-CoVs (Fig. 43.5).[74] The original SARS-CoV, which caused disease in humans from 2002 to 2004, was thought to be transmitted to farmed civets after recombination in bats.[75] When Himalayan palm civets were transported to Guangdong market in China, the virus spread among market civets; spillover to humans likely occurred in 2002, with spread of the virus that extended over the course of 2003. Civet cats are not true cats but small mammals that resemble weasels; they are more closely related to mongoose. The virus was also found in raccoon dogs at street markets. However, civets seemed like a more likely conduit than raccoon dogs because the virus was able to persist in infected animals for up to 2 weeks, and many infections were associated with restaurants where civet meat was prepared and served. Extensive culling of palm civets followed. SARS-CoV-1 causes respiratory illness in humans with pneumonia and lymphopenia after an incubation period of 2 to 10 days, with a case fatality rate of 9.6%.[76] The SARS outbreak ended by 2004, with no more cases resulting from person-to-person transmission since then. In total, there were about 8,000 cases in 30 countries,

TABLE 43.3 Major Coronaviruses of Humans and Animals That Belong to the Alpha- and Betacoronavirus Genera

Alphacoronavirus	Betacoronavirus
Human 229E (common cold)	Human OC43 (common cold)
Human NL63 (common cold)	Human HKU1 (common cold)
Feline coronavirus (FECV and FIPV) (serotypes I and II)	MERS-CoV (Middle Eastern respiratory syndrome) (systemic)
Canine coronavirus (serotypes I and II [a, b, c])	SARS-CoV (severe acute respiratory syndrome) coronavirus (systemic)
Transmissible gastroenteric virus of swine (TGEV)	SARS-CoV-2
Porcine epidemic diarrhea virus (PEDV)	Bovine coronavirus
	Canine respiratory coronavirus Equine coronavirus Murine hepatitis virus Porcine hemagglutinating encephalomyelitis virus

Deltacoronaviruses (such as wild avian coronaviruses, porcine deltacoronavirus) and gammacoronaviruses (such as avian infectious bronchitis virus) primarily infect birds.

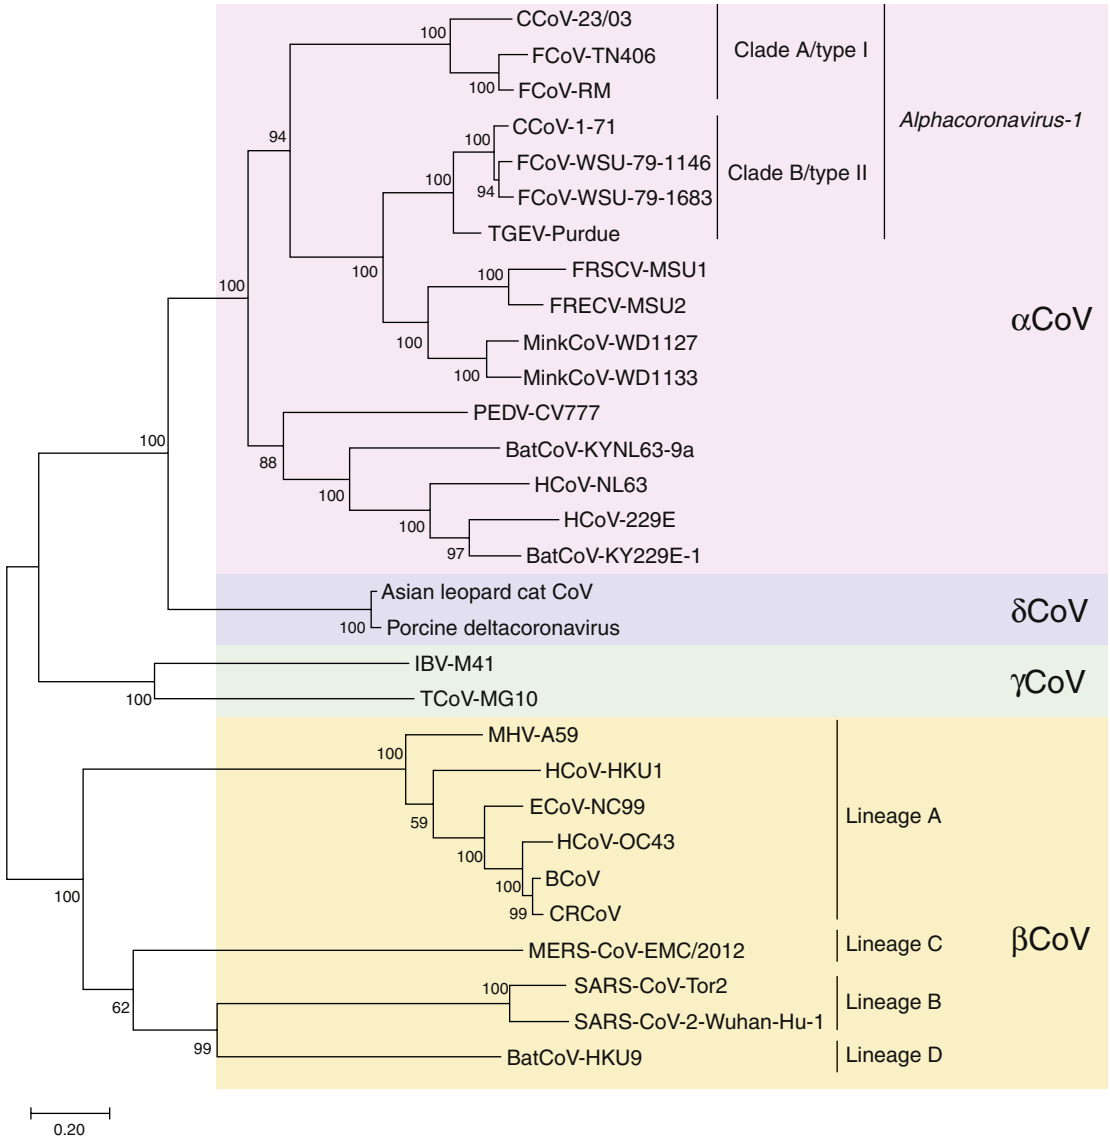

Fig. 43.5 Phylogenetic tree of selected coronaviruses based on spike protein sequences. The tree is drawn to scale, with branch lengths measured in the number of nucleotide substitutions per site. *BatCoV,* bat coronavirus; *BCoV,* bovine coronavirus; *CCoV,* canine coronavirus; *CRCoV,* canine respiratory coronavirus; *ECoV,* equine coronavirus; *FCoV,* feline coronavirus; *FRECV,* ferret enteric coronavirus; *FRSCV,* ferret systemic coronavirus; *HCoV,* human coronavirus; *IBV,* infectious bronchitis virus; *MERS-CoV,* Middle East respiratory syndrome coronavirus; *MHV,* murine hepatitis virus; *PEDV,* porcine epidemic coronavirus; *SARS-CoV,* severe acute respiratory syndrome coronavirus; *TCoV,* turkey coronavirus; *TGEV,* transmissible gastroenteritis virus. (Reprinted from Stout AE, Andre NM, Jaimes JA, et al. Coronaviruses in cats and other companion animals: Where does SARS-CoV-2/COVID-19 fit? *Vet Microbiol.* 2020;247:108777.)

including North America, South America, Europe, and Asia.[77] It was the search for other human coronaviruses at this time that led to the discovery of the common cold coronaviruses NL63 and HKU1.[78] It is generally believed that civets and raccoon dogs do not represent ongoing reservoirs of SARS-CoV-1. A small number of pet cats tested positive and seroconverted in a large outbreak of SARS that occurred in an apartment complex in Hong Kong.[79] In that outbreak, which involved over 300 people, there was evidence that airborne transmission of the virus was occurring as a result of hydraulic action of sewerage drainage pipes, so the situation was unusual.[80] Experimental infection of six ferrets and six cats was also accomplished.[79] None of the cats in that study had clinical signs, whereas several ferrets developed lethargy and one died. Infection was transmitted to a limited number of in-contact animals, and only ferrets developed clinical illness. However, pulmonary pathology was detected in the cats that was similar to that in humans.

MERS-CoV was first isolated from the lungs of a 60-year-old person who died from severe respiratory illness in Saudi Arabia in 2012.[81] Clinical manifestations range from none to severe pneumonia, acute renal failure, and septic shock. Since then, 2,984 confirmed cases have been reported with 858 deaths in 27 countries.[82] Three-quarters of patients had co-morbidities. All human cases have been associated with travel to the Arabian Peninsula. Only two infected humans have been reported in the United States.[83] Dromedary camels have been implicated as amplifying hosts based on the detection of antibodies in these camels as well as sequences resembling MERS-CoV in camels

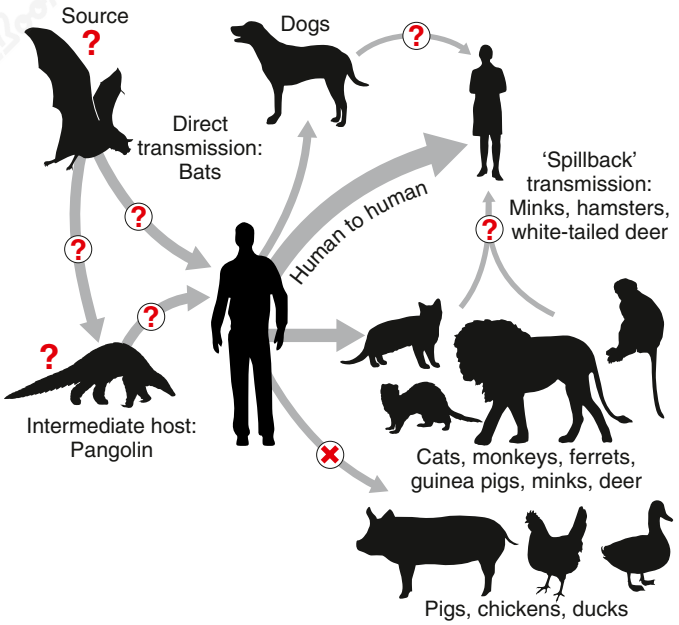

Fig. 43.6 Diagram representing our understanding of zoonotic and reverse zoonotic transmission of SARS-CoV-2 at the time of writing.

from the Arabian Peninsula. In addition, most people with the disease have a history of interactions with dromedary camels. However, the precise role that dromedaries play in the transmission of MERS remains unknown.[84] No sustained human-to-human transmission has been documented anywhere in the world.

SARS-CoV-2 infection emerged in late 2019 in Wuhan, China, as the cause of COVID-19, a highly contagious systemic viral disease that at the time of writing has infected nearly 500 million people worldwide and contributed to the death of over 6.1 million people.[85] COVID-19 occurs after an incubation period of 2 to 14 days, and consists of fever, myalgia and fatigue, respiratory signs (primarily cough and shortness of breath), GI signs, and anosmia and ageusia (loss of taste). Less frequently, stroke-like neurologic signs, cardiac arrhythmias due to myocarditis, and acute kidney injury have been described. Severe outcomes and death are more likely in older people and those with chronic conditions such as diabetes mellitus, chronic lung disease, and cardiovascular disease. Early in the pandemic, a case fatality rate of 10%–27% was reported in people over 85 years of age, 3% to 11% in those aged 65–84 years, 1% to 3% in those aged 55–64 years, <1% in those aged 20–54 years, and 0% in those aged less than 19 years.[86]

The precise origin of SARS-CoV-2 is not known (Fig. 43.6). The overwhelming majority of CoVs have been identified only in bats, and so bats are considered the major natural CoV reservoirs. However, two of the human common cold CoVs likely originated in rodents. Importantly, domestic animals are important intermediate hosts for transmission of CoVs to humans, and camelids, cattle, civet cats, dromedary camels, and pigs have all been implicated in this role.[87] Pangolins have been most closely studied as a possible amplifying host for SARS-CoV-2, because they have been shown to harbor genetically very similar CoV strains (albeit more different than those found in bats), coronavirus strains capable of infecting human cells, and are sold in Chinese food markets.[88] Considered the world's most trafficked mammal, pangolins have been trafficked for their scales, which are used in traditional Chinese medicine, and they are also a luxury food item. It has been suggested that the African swine fever outbreak in China may have contributed to emergence of SARS-CoV-2 because shortage of pork products drove an increased trade of farmed susceptible animals and wildlife as a source of food.[89] Accidental or deliberate release of an engineered virus from a laboratory (the "lab-leak theory") has also been suggested as a possible origin of the virus, but has been disputed on the basis of epidemiological studies or studies of the composition of the virus.[90,91]

The host receptor for SARS-CoV and SARS-CoV-2 is the angiotensin-converting enzyme 2 (ACE2) receptor, whereas MERS binds to the dipeptidyl peptidase 4 receptor. A receptor-binding domain (RBD) on the viral spike (S) protein interacts with the ACE2 receptor, which is followed by viral entry into host cells. The S protein must be activated before the virus can enter cells. This requires the synergistic action of host furin enzymes, which cleave the S protein into S1 and S2 components, and a cell surface serine protease enzyme known as serine 2 (TMPRSS2).[92] Although the amino acid sequence of the ACE2 receptor can influence whether a host species can be infected, other factors, such as the distribution and density of ACE2 receptor expression in tissues, host and virus factors influencing spike protein cleavage, the use of co-receptors (such as neuropilin 1), and the host immune response to infection, also influence species susceptibility and expression of clinical disease.[93]

Experimental infection studies have shown that cats and ferrets are capable of transmitting SARS-CoV-2 infection to other cats and ferrets, whereas dogs did not transmit infection to a small number of in-contact dogs.[94–97] Hamsters, rabbits, deer, American minks, raccoon dogs, deer mice, fruit bats, otters, and nonhuman primates are also susceptible to experimental infection.[98] At the time of writing, more than 200 pet dogs and cats worldwide have tested positive for SARS-CoV-2, with reports documented by the OIE and the USDA.[99,100] Most dogs and cats have been subclinically infected, or if signs are present, it has not been possible to determine whether they are associated with infection or due to an unrelated comorbidity.[100,101,102,103] A small number of animals died shortly after they tested positive, but co-morbidities explained the reason for death. However, one 4-month-old kitten from the United Kingdom was euthanized and viral pneumonia was confirmed at necropsy, with FA showing intralesional SARS-CoV-2 antigen.[104] Of 10 dogs and cats that tested positive for SARS-CoV-2 and then died or were euthanized in the United States, it was concluded that infection was an incidental finding in 8 animals, but was the cause of disease in one dog and one cat.[105] In a necropsy surveillance study of 5 animals in contact with infected humans, infection was confirmed in 3 cats and a tiger, but infection was not thought to be the cause of death in any of the cases. The remaining animal was a dog that died of bronchopneumonia, but this dog tested negative for SARS-CoV-2.[106]

A small number of infected dogs and cats have been reported to have cardiac disease at the time of death,[103,105] including the first dog reported to be infected with SARS-CoV-2. Suspected myocarditis was described in association with natural infection in 8 cats and 3 dogs in the United Kingdom.[107] However, cardiac disease and exposure to SARS-CoV-2 in pet dogs and cats is likely widespread, and no convincing evidence for an association between these and disease exists at the time of writing. The possibility remains that new variants of SARS-CoV-2 could arise that are more virulent in dogs and cats or more transmissible, so ongoing monitoring is critical.

Animals with positive test results have typically been in contact with infected owners. Evidence of transmission of infection from dogs or cats back to owners has not been documented, but remains theoretically possible. Mink on mink farms appear to be the most susceptible to infection and disease, with fatal infections reported. There has been evidence of mink-to-mink, mink-to-human, and mink-to-dog and cat transmission on mink farms worldwide. In addition, an outbreak of the delta variant of SARS-CoV-2 in Syrian hamsters in a pet shop in Hong Kong was followed by zoonotic transmission and then human-to-human transmission.[98] Extensive culling efforts associated

TABLE 43.4 Selected Studies Reporting the Prevalence of Antibodies to SARS-CoV-2 and Shedding of SARS-CoV-2 in Dogs

Location (Number of Dogs)	Dates	Population	Seroprevalence (%)	Virus Detection By PCR (Specimen Type)

with these zoonotic transmission events have drawn considerable media attention. Recently, likely transmission from white-tailed deer to humans was described.[108] Concern has been raised that evolution of the virus in wildlife with subsequent "spillback" to humans could lead to additional pandemic waves, potentially with higher mortality. One study provided evidence that the highly transmissible Omicron variant may have evolved in mice, with subsequent spillback to humans,[109,110] although the true origin of the Omicron variant at the time of writing remains unknown.

In early April of 2020, a report was released of an infected tiger at the Bronx zoo in New York.[111] The tiger was tested because it developed a cough and inappetence and was in contact with a caregiver that was subclinically shedding SARS-CoV-2. In addition, the tiger's sister, two Siberian tigers, and three lions at the zoo were reported to also have clinical signs of respiratory illness. It was later published that there were two separate transmission events that involved the tigers and the lions, with the lions being infected with a slightly different variant than the tigers. Infected animals shed infectious virus in their respiratory secretions and feces.[112] Since then, there have been reports of other clinical infections in captive wild felids worldwide (puma, snow leopards, lions, and tigers)[113,114] Widespread vaccination of captive wildlife species and mink has been introduced to reduce morbidity and mortality in these species. The vaccine being used for this purpose in the United States at the time of writing is an experimental recombinant subunit vaccine (Zoetis, NJ, USA).[115]

Since the start of the pandemic, evidence has been accumulating in regard to the extent of infection of pet dogs and cats. One commercial veterinary diagnostic laboratory (IDEXX Laboratories, ME, USA) reported no positive PCR tests in 4,617 dogs and cats from Asia, Europe, and North America for which specimens were submitted for respiratory viral PCR testing from mid-February 2020 to mid-April 2020.[116] Instead, assays were positive for common respiratory pathogens such as FCV, *Bordetella bronchiseptica*, and *Mycoplasma cynos*. The seroprevalence has ranged from 0% to 40% in dogs and 0% to 44% in cats (Tables 43.4 and 43.5). The prevalence of positive PCR results has ranged from 0% to 13% in dogs and 0% to 25% in cats. Virus has been more often detected in respiratory swab specimens than in rectal swabs or feces, and shedding in cats has been documented in respiratory secretions for up to 25 days.[117] In many cases, full-length SARS-CoV-2 genome sequence has been obtained using next-generation sequencing platforms, and shown to match that of the animal's owner.[117–119] In a Texas study, SARS-CoV-2 infection was identified using PCR and sequencing in 3 of 17 (17.6%) cats and 1 of 59 (10.3%) dogs from 4 of 39 separate households. All PCR-positive animals were subclinically infected. In a study from Idaho and Washington, USA, signs of illness that could be consistent with COVID-19 were reported in 20% of dogs and 39% of cats that had been in contact with people with COVID-19.[120] Differences in prevalence may reflect variations in assay performance, the time of year, as well as the degree of contact between positive owners and sampled animals. Behaviors that promote close contact between humans and pets, such as sharing of food dishes and beds may increase risk of transmission.[120,121]

In general, the results of studies to date suggest that subclinical infection of dogs and cats with SARS-CoV-2 occurs commonly, although shedding of virus is relatively uncommon. Cats appear to be more susceptible to infection than dogs and may be able to show signs of respiratory illness and shed virus for over a week. Although domestic cats can transmit infection to other cats following experimental infection, the extent to which this occurs in the field remains unknown. However, veterinarians working in small animal practice have not been identified as at increased risk of infection and contact

TABLE 43.5 Selected Studies Reporting the Prevalence of Antibodies to SARS-CoV-2 and Shedding of SARS-CoV-2 in Cats

Location (Number of Cats)	Dates	Population	Seroprevalence (%)	Virus Detection By PCR (Specimen Type)
Wuhan, China (102)[134]	Jan–Mar 2020	Random source, some shelter cats	15/102 (14.7) (ELISA) 11/102 (10.7) (VN)	0/102 (NP, R)
United States, Asia, Europe (2466)[116]	Feb–Apr 2020	Cats with respiratory disease (being tested for other respiratory pathogens)		0/2466 (PR)
France (9)[127]	Feb–Mar 2020	In close contact with veterinary students, some of which tested positive for SARS-CoV-2	0/9 (LIPS)[128]	
Hong Kong (50)[119]	Feb–Aug 2020	In contact with humans with COVID-19		6/50 (12) (N, O, R)[a]
Wuhan, China (10)[130]	Mar 2020	In contact with humans with COVID-19	2/10 (ELISA, VN)	0/10 (O, R)
Northern Italy (316)[131]	Mar–May 2020	High-prevalence regions, some living with infected humans, some with respiratory signs	11/191 (5.8) (VN)	0/173 (OP) 0/78 (N) 0/30 (R)
United Kingdom (387)[104]	Mar–Jul 2020	Cats with respiratory disease (being tested for other respiratory pathogens)		1/387 (0.3) (OP)[a]
France (22)[101]	April 2020	In contact with humans with or suspected to have COVID-19		1/22 (4.5) (NP, R)[a]
Spain (8)[132]	Apr–May 2020	In contact with humans with COVID-19		1/8 (OP, R)
Germany (920)[135]	Apr–Sep 2020	Visiting veterinary hospitals with hematology testing	6/920 (0.7%) (ELISA, IFA)	
Chile[118]	May–Sep 2020	In contact with humans with COVID-19	1/12 (ELISA)	3/12 (25) (N, F)[a]
Texas, USA (17)[117]	Jun–Jul 2020	In contact with humans with COVID-19	7/16 (43.8) (VN)	3/17 (17.6)[a] (PR, R, B)
United States (WA and ID) (47)[120]	Apr 2020-Sep 2021	In contact with humans with COVID-19	13/32 (ELISA)	3/39 (N/OP)
Brazil (Rio de Janeiro) (29)[121]	May 2020-Oct 2020	In contact with humans with COVID-19	2/10 (VN)	4/10 (N/OP)

[a]Virus sequence obtained.

B, body; *ELISA,* enzyme-linked immunosorbent assay; *F,* feces; *LIPS,* luciferase immunoprecipitation system; *N,* nasal; *NP,* nasopharyngeal; *O,* oral; *OP,* oropharyngeal; *PR,* pooled respiratory; *R,* rectal; *VN,* virus neutralization.

with other humans continues to represent the main risk factor for human infection. Over time, it is possible that the virus could develop a greater propensity to cause illness in, or be shed by dogs and cats through further mutation, a situation that requires close monitoring. If this should occur, SARS-CoV-2 vaccines for companion animals may be needed. According to CDC recommendations, humans that test positive for SARS-CoV-2 should quarantine themselves with their pets, and limit contact with their pets in the household until the quarantine period is over (including distancing, wearing a mask in the house, hand washing, and if possible separating the pets and having others perform activities that require contact).[3] If their pet becomes sick, someone else in the household should take the pet to the veterinarian, and if possible, an initial telemedicine consultation should be organized. Veterinary clinics should question people that plan to bring animals in for care about potential infection by, or exposure to, SARS-CoV-2, as is done in human healthcare institutions. Updated guidance for veterinarians on appropriate prevention practices for different exposure situations is provided by the CDC, together with a variety of other resources.[122] Testing for SARS-CoV-2 may need to be done in conjunction with local public health authorities.[123]

Should a pet test positive for the virus, owners should interact with them as if there were a positive human in the household (although the pet should not be made to wear a mask). Owners can be referred to guidance from the CDC[3] and the AVMA[124] on SARS-CoV-2 and animals. The virus is readily susceptible to disinfectants, and temperatures that exceed 55°F can inactivate the virus in well under an hour.[125] At the time of writing, the risk of fomite transmission is considered low, generally less than 1 in 10,000 (see Suggested Readings), so the primary mode by which people are infected with SARS-CoV-2 is through respiratory droplet exposure.[126]

SECTION 2

Bacterial Diseases

Jane E. Sykes

This section covers a number of important vector-borne and zoonotic diseases including ehrlichiosis, anaplasmosis, and rickettsioses; Q fever; leptospirosis and borreliosis; bartonellosis; brucellosis; plague; and tularemia. Although previously thought to be transmitted by fleas, evidence has accumulated that feline hemotropic mycoplasmas are most likely transmitted primarily through aggressive interactions among cats and that vectors are not involved (Chapter 58). With the increasing use of more potent immunosuppressive drugs, especially in dogs, there is also more recognition of atypical bacterial diseases such as nocardiosis and mycobacteriosis; these are covered in Chapters 60 and 61.

The modern era of antimicrobial therapy began with the discovery of sulfonamides in 1936. This was followed in the 1940s by the discovery of the therapeutic value of penicillin and streptomycin, and by 1950, the "golden age" of antimicrobial therapy was underway, and well-intentioned academic leaders predicted the demise of bacterial infections. But after only a few decades, antimicrobials are now facing an uncertain future. By the late 1980s, methicillin-resistant staphylococci were widespread, and gram-negative rods emerged as important nosocomial pathogens in hospitals. Veterinarians face major challenges with the increasing prevalence of multidrug-resistant pathogens, such as methicillin-resistant *Staphylococcus pseudintermedius* (Chapter 51), *Bordetella bronchiseptica* (Chapter 55), and other gram-negative bacteria (Chapter 53), and few new drugs in the antibiotic pipeline. Some strains of drug-resistant bacteria that have the potential to cause disease in humans have been identified with increasing prevalence in dogs and cats, such as *Clostridioides difficile* (Chapter 64) and pathogenic *Escherichia coli* (Chapter 63). It is critical that we model good antibacterial stewardship if we are to preserve critical weapons against life-threatening bacterial infections.

Ehrlichiosis

Shimon Harrus, Trevor Waner, Mathios E. Mylonakis, Jane E. Sykes, Barbara Qurollo

KEY POINTS

- First Described: *Ehrlichia canis* was first described in 1935 (Algeria).[1] *Ehrlichia ewingii* was described in 1992 (United States).[2] *Ehrlichia chaffeensis* was described in 1991 (United States).[3] The first report of naturally occurring ehrlichiosis in a cat occurred in France in 1986.[4]
- Cause: The most important species causing disease in dogs are *E. canis* (canine monocytic ehrlichiosis) and *E. ewingii* (canine granulocytic ehrlichiosis).
- Affected Hosts: *Ehrlichia canis* causes disease in dogs, humans, and cats. *Ehrlichia ewingii* causes disease in dogs, humans, and goats and has been detected in a clinically ill cat. *Ehrlichia chaffeensis* causes disease in humans, possibly dogs and goats, and has been detected in a clinically healthy cat. *Ehrlichia muris* subsp. *eauclairensis* causes disease in humans and possibly dogs. Panola Mountain *Ehrlichia* causes disease in dogs, goats, and humans in the United States.
- Geographic Distribution: *Ehrlichia canis* is distributed worldwide, but is more prevalent in tropical and subtropical regions. *Ehrlichia ewingii* is primarily found in the south-central and southeastern United States. Most reports of *E. chaffeensis* infection are from the southern and south-central United States, but it has also been identified in Africa. *Ehrlichia muris* subsp. *eauclairensis* has been found in the Upper Midwest of the USA. Panola Mountain *Ehrlichia* has been found in the southeastern United States.
- Mode of Transmission: *Rhipicephalus sanguineus* ticks (*E. canis*); *Amblyomma americanum* ticks (*E. ewingii* and *E. chaffeensis*), *Ixodes scapularis* ticks (*E. muris* subsp. *eauclairensis*), and *A. americanum* and *Amblyomma maculatum* ticks (Panola Mountain *Ehrlichia*).
- Major Clinical Signs: Dogs—typical clinical signs of *E. canis* infection are fever, lethargy, inappetence, weight loss, cutaneous and mucosal petechial and/or ecchymotic hemorrhages, lymphadenomegaly, splenomegaly, and uveitis. *Ehrlichia ewingii* primarily causes fever, lethargy, inappetence, and signs of polyarthritis. Cats—typical clinical signs of *Ehrlichia canis* infection are fever, lethargy, inappetence, weight loss, hyperesthesia, and joint pain. *E. ewingii* was detected in a clinically ill cat with thrombocytopenia and anemia.
- Differential Diagnoses: Other tick-borne diseases (e.g., granulocytic anaplasmosis, Lyme borreliosis, babesiosis, and cytauxzoonosis [cats]), bartonellosis, hemotropic mycoplasmosis, leptospirosis, and other systemic non-vector-borne diseases such as lymphoma, multiple myeloma, and systemic primary immune-mediated disease.
- Public Health Aspects: All four *Ehrlichia* species can infect and cause disease in humans. The most virulent human pathogen is *E. chaffeensis* and results in the highest percentage of hospitalizations and death compared with the other North American *Ehrlichia* species.

Ehrlichioses are a group of tick-transmitted diseases caused by intracellular, gram-negative bacteria that include *Ehrlichia canis, Ehrlichia ewingii,* and *Ehrlichia chaffeensis*. An organism related to *Ehrlichia ruminantium,* the cause of heartwater disease in cattle, has also been detected in ill dogs from South Africa.[5] *Ehrlichia muris eauclairensis* has been detected in an ill dog and humans from Upper Midwest of the United States (formerly *E. muris*-like).[6] Panola Mountain *Ehrlichia* was detected in a dog with atypical lymphocytosis and clonal T-cell expansion.[7] These organisms form morulae (Latin for "mulberry"), clusters of bacteria, within phagosomes of circulating leukocytes. *E. canis* infects monocytes, macrophages, and less frequently lymphocytes (Fig. 44.1A–C), and causes canine monocytic ehrlichiosis (CME), one of the most important infectious diseases of domestic dogs that are exposed to ticks, worldwide. *Ehrlichia ewingii* infects granulocytes and causes canine granulocytic ehrlichiosis; the organism is very difficult to culture and only short-term maintenance in cultured cells has been documented to date.[8] *Ehrlichia chaffeensis* causes human monocytic ehrlichiosis (HME); dogs are a proposed reservoir for this organism. The geographic distribution of each pathogen is generally restricted to that of their vectors and mammalian reservoir hosts. According to one large study, the prevalence of exposure to *Ehrlichia* spp. in the United States in dogs has been increasing in both endemic and nonendemic areas.[9]

Organisms in the genus *Ehrlichia* are grouped within the family Anaplasmataceae. Also within this family are the bacteria *Anaplasma platys* and *Anaplasma phagocytophilum,* which cause canine thrombocytic and granulocytic anaplasmosis, respectively (see Chapter 45); and organisms belonging to the genera *Neorickettsia* (see Chapter 47). *Rickettsia rickettsii,* the cause of Rocky Mountain Spotted Fever (RMSF), and other spotted fever group rickettsiae belong to a separate family, the Rickettsiaceae (see Chapter 46). The families Rickettsiaceae and Anaplasmataceae are phylogenetically related through the order Rickettsiales (Table 44.1).

The severity of clinical signs in animals with ehrlichial infections depends on factors such as the organism species and strain, inoculum size, host immunity, and genetic factors. Because of shared arthropod vectors and/or concurrent exposure to multiple tick species, coinfections with more than one rickettsial pathogen, as well as other arthropod-borne pathogens (such as *Babesia* and *Bartonella* spp.) occur and may obscure the clinical picture.

EHRLICHIA CANIS

Shimon Harrus, Trevor Waner, Mathios E. Mylonakis

ETIOLOGY AND EPIDEMIOLOGY

Ehrlichia canis is transmitted primarily by the brown dog tick, *Rhipicephalus sanguineus* sensu lato (Fig. 44.2), one of the most widely

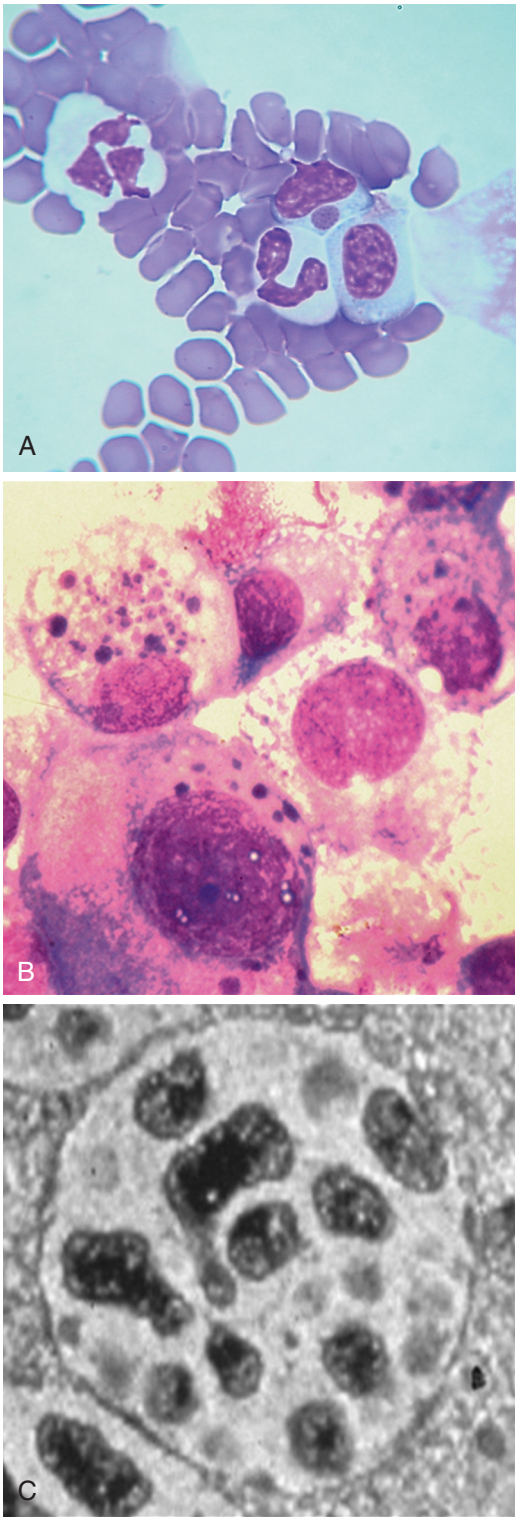

Fig. 44.1 (A) *Ehrlichia canis* morula in a peripheral blood mononuclear cell in a dog with experimental *E. canis* infection (buffy coat, Giemsa, originally photographed at ×1000). (B) Morulae within DH82 culture cells, as seen by light microscopy (originally photographed at ×400). (C) Morula within DH82 culture cell as seen by transmission electron microscopy (originally photographed at ×20,000). Note the multiple number of organisms within the morula. It can be seen that two of the organisms are undergoing binary fission.

distributed tick species, worldwide. In a transmission study, when *E. canis*-infected ticks were placed on naïve dogs, *E. canis* DNA could be detected in the dogs as early as 3 hours postexposure to the ticks.[10] Infection has been reported in dogs from Asia, Africa, Europe, the Americas, and most recently in Australia.[11] New Zealand appears to be free of *E. canis* infection. The DNA of *E. canis* has been detected in other tick species, which include other *Rhipicephalus* species (e.g., *Rhipicephalus turanicus* and *Rhipicephalus bursa*),[12,13] *Ixodes ricinus*,[14] and *Haemaphysalis*[15] and *Dermacentor* spp.[15,16] In one study, experimental transmission was accomplished with *Dermacentor variabilis* ticks.[17] Different strains of *E. canis* exist in different geographic regions and may vary in virulence. Although *Rh. sanguineus* is found throughout the United States (Fig. 44.3), it prefers warm climates, and so CME is diagnosed most frequently in dogs living in the southeastern and southwestern states. In Europe, *Rh. sanguineus* is primarily found in the Mediterranean basin, but its distribution appears to be moving northward, and CME has been reported in dogs that lack travel history as far north as the Netherlands.[18] Dogs can be persistent subclinical carriers for years.[19] Such dogs may be transported to nonendemic regions and subsequently develop the disease months or years later. Tick larvae or nymphs acquire infection when they feed on infected dogs and transmit the disease as nymphs or adults when feeding on naïve dogs. Jackals, foxes, and possibly coyotes may also act as reservoir hosts. *Ehrlichia canis* is transmitted transstadially (i.e., from larva to nymph to the adult tick) (Fig. 44.4).[20,21] Male ticks can also transmit the pathogen intrastadially.[22] No clear age or sex predilection for CME exists, but German shepherd dogs are reportedly more susceptible, and prognosis may be poorer in this breed. Cross-bred dogs may be less likely to develop CME.[23]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Ehrlichia canis multiplies by binary fission within vacuoles of mononuclear phagocytes (see Fig. 44.1A–C); rupture of infected host cells leads to infection of additional cells. Immune-mediated mechanisms are important in the pathogenesis of the disease, and the presence of the spleen appears to contribute to disease severity.[24]

Stages in the invasion and pathogenesis of *Ehrlichia* include adhesion, internalization, proliferation, and spreading. Outer membrane glycoproteins (e.g., gp19, gp36, and gp140kDa) are associated with adhesion and internalization.[25] The movement of *E. canis* through cells is dependent on polymerization of actin cytoskeleton and lysosomal evasion, and requires influx of iron and calcium ions.[26] The course of CME has been divided into acute, subclinical, and chronic phases. Clinical signs occur 8 to 20 days after infection. The clinical manifestations vary considerably among dogs, which may reflect factors such as *E. canis* strain variation, host immune response, stage of disease, and concurrent infections. Lethargy, inappetence, fever, and weight loss are the most common signs of the acute disease. Replication of the organism in reticuloendothelial tissues is associated with generalized lymphadenomegaly and splenomegaly. Ocular and nasal discharge and uveitis are common findings and are associated with lymphocytic-plasmacytic inflammation in these tissues. Retinal detachment may occur in rare cases due to serum hyperviscosity and subretinal hemorrhage. Bleeding tendencies occur in some dogs and may result from thrombocytopenia and platelet dysfunction.[24] Platelet dysfunction may at least in part be the result of immune-mediated platelet damage.[27] Experimentally infected dogs developed low platelet counts, activated platelets, and

TABLE 44.1 Members of the Order Rickettsiales of Clinical Importance in Dogs and Cats[a]

Family Anaplasmataceae			Family Rickettsiaceae

Ehrlichia chaffeensis	*Anaplasma platys*	*Neorickettsia risticii*	
Ehrlichia ewingii			

[a]Other species of *Ehrlichia* and *Rickettsia* may also cause disease in dogs, but their clinical significance is unclear.

Fig. 44.2 The brown dog tick, *Rhipicephalus sanguineus* being removed from the ear of an infested dog.

antiplatelet antibodies.[28,29] The results of thromboelastography in one study revealed evidence of a hypercoagulable, hypofibrinolytic state.[28]

Neurologic signs may result from meningeal inflammation or hemorrhage. Dogs can recover spontaneously from the acute phase within 2 to 4 weeks, after which time they may eliminate the infection or remain subclinically infected. Sequestration of organisms within the spleen or other tissues may occur, and the organisms may evade the host immune system through modulation of the host immune response and by decreasing its antiehrlichial activities (i.e., decreased presentation by downregulation of MHC class II receptors, evasion of phagosome-lysosome fusion, decreased host cell apoptosis, recombination, and antigenic variation).[25,26] The subclinical phase of CME may persist for months to years.[19]

Chronic CME develops in only some infected dogs. Factors that influence the development of the chronic disease are unclear, but the pathogen, the host genetics, and the interrelations between them probably play their role. The presence of severe pancytopenia characterizes the severe chronic form of ehrlichiosis, and results from hypoplasia of all bone marrow cell lines.[30] Clinical signs at this stage are usually severe and include lethargy, inappetence, bleeding tendencies, mucosal pallor, fever or hypothermia, weight loss, lymphadenomegaly, splenomegaly, dyspnea, anterior uveitis, retinal hemorrhage, and edema.[23,31–33] Secondary opportunistic infections such as protozoal infections, viral papillomatosis, and bacterial UTIs can also develop. Marked granular lymphocytosis and bone marrow plasmacytosis may occur in all phases, sometimes accompanied by a monoclonal gammopathy, which may lead to misdiagnosis of lymphocytic leukemia or multiple myeloma. This has led to the recommendation that all dogs with well-differentiated lymphocytosis or otherwise unexplained monoclonal gammopathy be tested for *E. canis* infection.[34]

Common physical examination findings in dogs with CME include lethargy, fever, generalized peripheral lymphadenomegaly, and splenomegaly. Ocular and nasal discharge, cutaneous and mucosal petechial hemorrhages (Fig. 44.5A–C), peripheral edema, and/or neurologic signs may be evident. Ocular abnormalities include anterior uveitis, hyphema, scleral, conjunctival or retinal hemorrhage, retinal detachment, and optic neuritis, with anterior uveitis being most commonly reported (Fig. 44.6A and B).[32,33] Neurologic signs include twitching, ataxia, seizures, vestibular signs, hyperesthesia, and cranial nerve deficits. Dogs with chronic ehrlichiosis may have thin body condition or diffuse muscle atrophy and mucosal pallor in addition to the aforementioned signs.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia is the most common hematologic abnormality of CME, occurring 1 to 4 weeks following infection with *E. canis*, in more than 90% of acutely infected dogs. Occasionally, mild leukopenia due to neutropenia, monocytopenia, and lymphopenia may occur, together with a mild left shift.[35] Nonregenerative anemia is usually present. During the subsequent subclinical phase, mild thrombocytopenia, with increased mean platelet volume, may persist.[36] Typically, dogs in the severe chronic phase of CME are profoundly pancytopenic.[30] Moderate to marked granular lymphocytosis may also occur in subclinically or chronically infected dogs.

In some acutely infected dogs, morulae are visualized within the circulating monocytes and less frequently in lymphocytes (see Fig. 44.1A). Examination of buffy coat smears, or lymph node or splenic aspirates increases the sensitivity for detection of morulae.[37] Cytology is notoriously insensitive for the detection of morulae in the subclinical and especially chronic infection, and it does not distinguish between *E. canis* and *E. chaffeensis* infection. In one study, morulae were found in only 2 of 19 dogs with chronic CME after careful screening.[30] Dogs with acute CME may have evidence of reactive lymphocytes, activated monocytes, mild left shift, erythrophagocytosis, metarubricytosis, thrombophagocytosis, phagocytosis of nuclear material, and megaplatelets in their blood smears.[12,35]

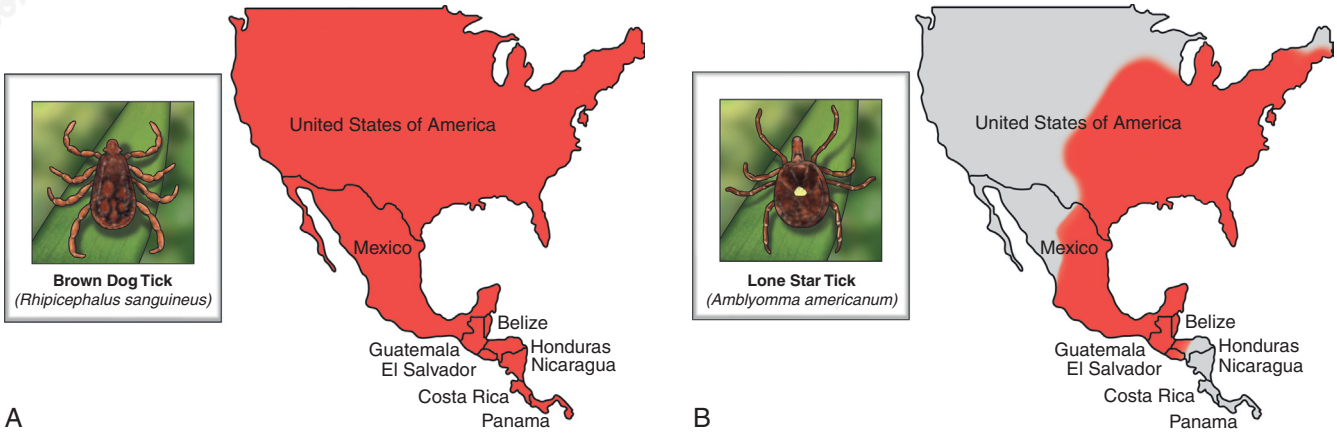

Fig. 44.3 (A) Distribution of *Rhipicephalus sanguineus*, which transmits *Ehrlichia canis*, in the United States and Central America. (B) Distribution of *Amblyomma americanum* in the United States and Central America. which transmits *Ehrlichia ewingii* and *Ehrlichia chaffeensis*. The distribution of *E. ewingii* infections in dogs more closely matches that of *A. americanum* than the distribution of *E. canis* matches that of *Rh. sanguineus* (highest prevalence in the southern states). This is because of chronic *E. canis* infections that occur in dogs with travel histories to southern states, where the climate is warmer and *Rh. sanguineus* is more prevalent.

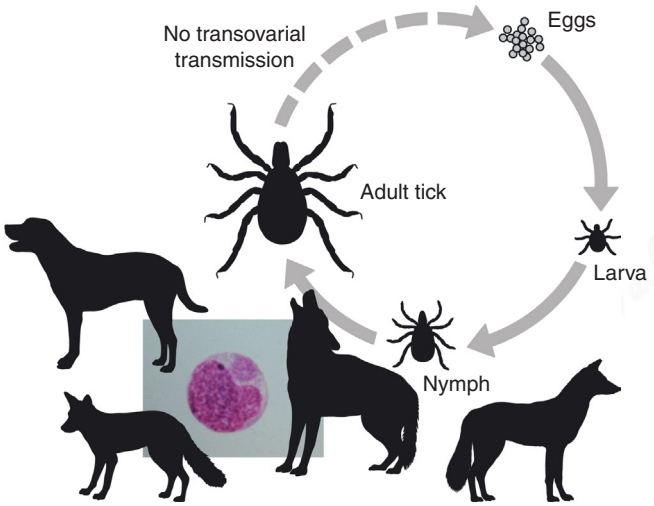

Fig. 44.4 Life cycle of *Ehrlichia canis*. The organism is transmitted only transstadially (from larva to nymph to adult) within the tick. Jackals, foxes, and possibly coyotes also act as reservoir hosts. A morula is shown within the cytoplasm of a monocyte as seen on a blood smear.

Serum Biochemical Tests

Serum chemistry abnormalities are seen during the acute and chronic phases and include hypoalbuminemia, hyperglobulinemia, hypergammaglobulinemia and elevated activities of serum ALT and ALP. Most often, hyperglobulinemia is due to polyclonal gammopathy.[23] Monoclonal gammopathy can also develop but is uncommon. Less frequently, increases in serum urea nitrogen and creatinine concentrations are present.[29]

Urinalysis

Transient proteinuria has been reported in dogs with acute CME.[38] Dogs with chronic CME may also have evidence of proteinuria.

Coagulation Profile

In addition to thrombocytopenia, coagulation abnormalities in dogs with CME include prolongation of the buccal mucosal bleeding time (BMBT), decreased platelet aggregation (thrombocytopathy), and prolongation of APTT.[29,39] Thromboelastography may reveal evidence of hypercoagulability and hypofibrinolysis.[28]

Cerebrospinal Fluid Analysis

Dogs with CNS involvement may have increased CSF protein concentrations and lymphocytic pleocytosis. Although rarely found, morulae may be detected in cells within the CSF.[40–42]

Bone Marrow Analysis

Bone marrow is commonly hypercellular in the acute phase but with chronic disease becomes hypoplastic and pale, which is the result of fatty infiltration, decrease of all bone marrow elements, decreased iron stores, and marrow plasmacytosis (Fig. 44.7). Bone marrow mastocytosis has also been described.[43] Myelofibrosis does not typically develop in chronic CME.[44]

Diagnostic Imaging

Sonographic Findings

Findings on abdominal ultrasonography in dogs with CME include splenomegaly, alterations in splenic echotexture, enlargement and hypoechogenicity of the abdominal lymph nodes, and scant peritoneal effusion.

Microbiologic Tests

Available diagnostic assays for ehrlichiosis in dogs are listed in Table 44.2.

Serologic Diagnosis

Most often, the diagnosis of CME is made using serology, which may be performed either by IFA testing, ELISA, or Western immunoblotting.[45] Using IFA testing, which is considered the gold standard serologic test, antibodies can be detected between 7 and 28 days after initial infection. Dogs with acute ehrlichiosis may have false-negative test results if sufficient time has not elapsed for antibody production to occur. PCR assays may be helpful for diagnosis in this situation. Use of a combination of serology with PCR is highly recommended as it allows better interpretation of the results and the animal health status. A positive initial serum antibody titer may reflect previous exposure and not necessarily active infection. Retesting should be performed 2 to 3 weeks later to demonstrate seroconversion and/or the possibility of an increase in the *E. canis* antibody titer. Serologic test results

Fig. 44.5 (A) Ventral abdominal skin petechiation due to thrombocytopenia in a bitch infected with *Ehrlichia canis*. (B) Mucosal petechiae due to *E. canis* infection. (C) Numerous petechiae and ecchymoses in the penile mucosa of a dog with acute canine monocytic ehrlichiosis. (A,B courtesy Dr. Pedro Paulo Diniz, Western University of Health Sciences, Pomona, CA.)

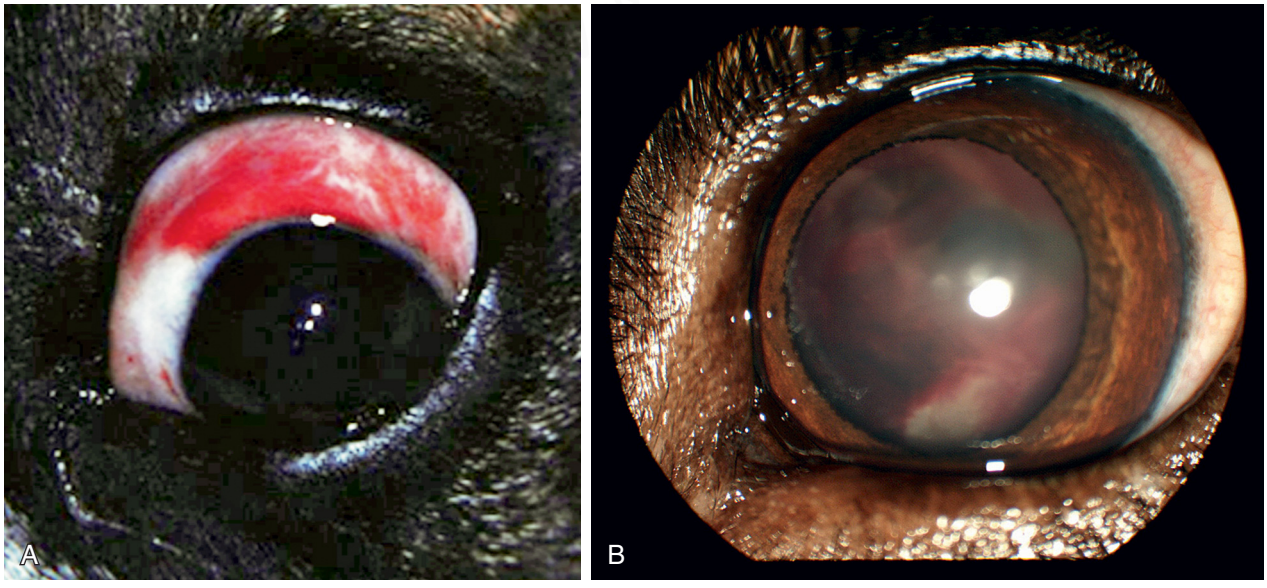

Fig. 44.6 (A) Scleral hemorrhage in a dog due to *Ehrlichia canis* infection. (B) Retinal hemorrhage and detachment in a 4-year-old female spayed Rhodesian ridgeback mix with canine monocytic ehrlichiosis. The dog also had thrombocytopenia (26,000 platelets/μL). Systolic blood pressure was within normal limits. (A, Courtesy Dr. Pedro Paulo Diniz, Western University of Health Sciences, Pomona, CA. B, Courtesy of University of California, Davis Veterinary Ophthalmology Service.)

should be interpreted in light of a dog's clinical signs and the results of testing for other potential causes of the dog's illness. Dogs with subclinical and chronic *E. canis* infection frequently have very high IFA titers (≥1:3,200), and these antibodies may persist in the face of treatment, suggesting persistence of the organism.[19] Antibody titers may decline in some dogs with treatment. High titers do not correlate with the severity of hyperglobulinemia, severity of disease, or duration of illness. A titer of 1:100 or greater is suggestive of exposure. Serologic cross-reactivity with other *Ehrlichia* species can occur, which includes *E. chaffeensis* and, less frequently, *E. ewingii*.[46] Variable cross-reactivity

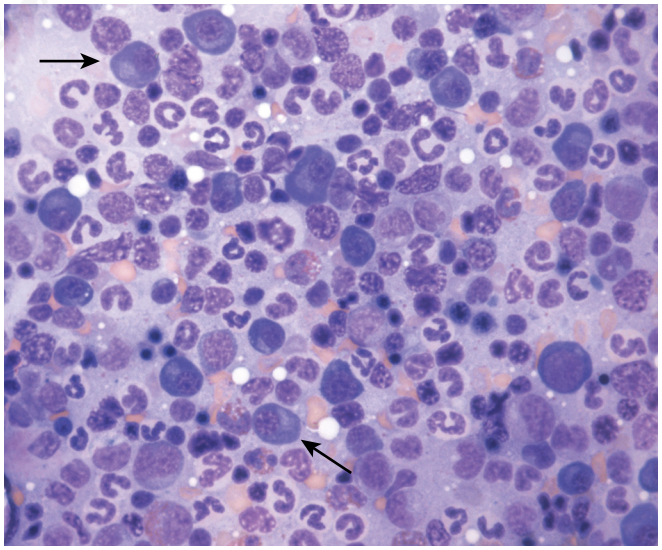

Fig. 44.7 Bone marrow plasmacytosis in an 8-year-old female spayed Labrador retriever with canine monocytic ehrlichiosis. Serum globulin was 12.1 g/dL (reference range, 2.3–4.4 g/dL), and serum protein electrophoresis revealed a polyclonal gammopathy. Plasma cells have a clock-faced nucleus, a clear area adjacent to the nucleus and a dark blue cytoplasm; two of the plasma cells in this figure are identified with black arrows. Mild to moderate megakaryocyte hyperplasia, mild erythroid hypoplasia, and mild mature granular lymphocytosis were also present. Romanowsky stain.

to *A. phagocytophilum* antigens can also occur.[45] In areas where other rickettsial agents are endemic, Western immunoblotting can be used to confirm that positive IFA antibody titers are truly reactive to *E. canis* antigens. However, Western blotting is laborious to perform and interpret, and not routinely available. As a result, Western immunoblotting has predominantly been used on a research basis. When *E. canis* antigens are used as target antigens, it may be difficult to distinguish between *E. canis* and *E. chaffeensis* infections.[47] Species-specific peptides in microtiter plate-based ELISA assays are highly specific for the detection of antibodies specific to *E. canis, E. ewingii,* and *E. chaffeensis* in experimentally and naturally infected dogs.[48,49]

In-clinic lateral-flow immunoassays, containing single or multiple antigens, have become popular rapid assays for detection of anti-*Ehrlichia* antibodies (e.g., SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME, USA; Immunocomb, Biogal, Galed, Israel; Fastest, Megacor Diagnostik, Hoerbranz, Austria; FLEX4 Rapid Test, Abaxis, Union City, CA, USA). Some laboratories also offer ELISA-based assays that report the presence of antibodies to multiple vector-borne pathogens (e.g., Accuplex, Antech, USA). The results obtained from these assays are mostly qualitative, and semiquantitative in some. These tests can be sensitive and specific when compared with IFA, especially when the IFA titers are greater than 1:320.[50] However, variation in performance exists among assays; one study showed a low sensitivity of the FLEX4 Rapid test when compared with the SNAP test for detection of antibodies to *Borrelia burgdorferi*, and *Ehrlichia* and *Anaplasma* spp.[51] Practitioners should be aware that a positive result on these tests could reflect active infection or previous exposure, as is the case with IFA assays. If a positive result is obtained, determination of a quantitative titer using IFA may be helpful; high titers (e.g., greater than 1:800) may support chronic CME, and a fourfold rise in titer may support recent infection.

Molecular Diagnosis

Whole-blood PCR assays for detection of *E. canis* DNA are more sensitive than IFA or ELISA for early diagnosis of CME. PCR assays, targeting different genetic loci (16S rRNA, p28, p30, disulfide oxidoreductase, gp19, gp36, gp140), are widely available for routine diagnosis of *E. canis* infection.[12] Several laboratories offer panels that include real-time PCR assays for a variety of different vector-borne pathogens. The results of these assays should be interpreted in light of a dog's anamnesis (e.g., presence of ticks, trip to an endemic area), clinical signs, and the results of appropriate serologic assays; the latter should be performed to support the results of PCR testing. PCR assays for *E. canis* may be performed on blood, splenic aspirates, lymph nodes, or bone marrow specimens. IFA or ELISA testing is more sensitive than PCR assays for diagnosis of chronic CME.[30,52,53] The sensitivity of PCR assays for diagnosis of CME when performed on bone marrow in dogs with chronic ehrlichiosis has ranged from 25% to 68%, depending on the laboratory.[30] The use of PCR assays in the absence of serology is currently not suitable for screening potential blood donors for infection because of the lack of sensitivity of PCR. PCR assays may be useful to confirm infection in the first week of illness, when serologic assays are often negative. Real-time PCR assays are widely available which can distinguish *E. canis* from other *Ehrlichia* species. Clinicians should consult their diagnostic laboratory to ensure this is the case, especially in regions where multiple *Ehrlichia* species are present.

LAMP assays also have been developed for detection of *E. canis*.[54] These assays allow amplification under constant temperature (60°C to 65°C), allowing them to be performed in the clinic setting, as well as in a commercial diagnostic laboratory (see Chapter 6). LAMP assays are highly specific, efficient, and rapid (result available in less than an hour). In one study, the results of a LAMP-based POC assay for *Ehrlichia* spp. (PCRun, Biogal, Galed Laboratories, Israel) were equivalent to that of a TaqMan assay.[55] The study included 33 samples from dogs in the United Kingdom and 100 samples from dogs in Israel with a prevalence of infection as determined using TaqMan of 42% and 21%, respectively. The PCRun assay was shown to detect multiple species of *Ehrlichia* as well as *A. phagocytophilum* and *A. platys* without being able to distinguish among them, so more specific assays are required for an accurate diagnosis of CME.

Isolation in Culture

Ehrlichia canis can be cultured (e.g., from blood samples) in certain cell lines, such as DH82 and J774.A1 cells. Isolation is time-consuming and generally performed only on a research basis.[12]

Pathologic Findings

Gross pathologic findings in CME include widespread petechial and ecchymotic hemorrhages, generalized pallor, edema, lymphadenomegaly, and splenomegaly.[56,57] On histopathology, lymphoid and plasma cell hyperplasia and lymphoplasmacytic infiltrates may be present in numerous organs, such as the brain, eyes, spinal cord, spleen, liver, kidneys, lymph nodes, bone marrow, and lungs. Histiocytic infiltrates may be found in the lymph nodes. With chronicity, the proportion of plasma cells increases. Nonsuppurative meningitis and perivascular cuffing within the CNS can also occur.[56,57] Glomerulonephritis is rare in dogs with CME.[57] Interstitial renal plasmacytosis may occur in dogs with ehrlichiosis and may account for the proteinuria in some cases. Minimal histologic changes were noticed in the kidneys of dogs experimentally infected with *E. canis*. Ultrastructural examination showed fusion of podocyte processes that coincided with the development of proteinuria.[38]

TREATMENT AND PROGNOSIS

Antimicrobial Treatment

The treatment of choice for CME consists of antibacterial agents and supportive care (Table 44.3). Generally, the earlier the treatment of

TABLE 44.2 Diagnostic Assays Available for Ehrlichiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Ehrlichia canis*; *Ehrlichia ewingii* currently cannot be readily cultured	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation and special laboratory facilities.
Morula detection	Blood smears, buffy coat smears, body fluids, tissue aspirates	*E. canis* or *E. ewingii* morulae	Low sensitivity (especially for chronic *E. canis* infection). *E. canis* morulae cannot be distinguished from those of *Ehrlichia chaffeensis*. *E. ewingii* morulae cannot be differentiated from those of *Anaplasma phagocytophilum*. Morulae may be confused with platelets, cytoplasmic granules, phagocytized nuclear material, and lymphoglandular bodies.
IFA serology	Serum	Antibodies to *E. canis*	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease, and positive results can reflect previous exposure rather than active infection. Cross-reactivity occurs to other *Ehrlichia* species and occasionally to *A. phagocytophilum*.
ELISA serology	Serum	Antibodies to *E. canis* or *E. ewingii* antigens	Rapid, inexpensive, can be performed as an in-practice, POC test. Similar limitations as for IFA. Lack of quantitation in most commercial kits limits the ability to document seroconversion.
Western immunoblotting	Serum	Antibodies to specific *E. canis* or *E. ewingii* antigens	Technically difficult; primarily used on a research basis to identify serologic responses to specific ehrlichial antigens. May be difficult to distinguish antibody responses to *E. canis* and *E. ewingii*.
PCR	Whole blood; spleen, lymph node or bone marrow aspirates	*E. canis*, *E. chaffeensis*, *Ehrlichia muris* subsp. *eauclairensis*, or *E. ewingii* DNA	Positive result confirms active infection. Negative results does not indicate absence of *Ehrlichia* spp. DNA. Sensitivity and specificity may vary depending on assay design and specimen type. Sensitivity for diagnosis of chronic CME may be low. The clinical significance of positive test results may be unclear as chronic subclinical infections occur (and whether *E. chaffeensis* causes disease in dogs is unclear). Assays that specifically detect *Ehrlichia muris* are not widely available on a commercial basis.

CME, Canine monocytic ehrlichiosis; *ELISA*, enzyme-linked immunosorbent assay; *IFA*, immunofluorescent antibody.

TABLE 44.3 Antimicrobial Drug Doses Used for Treatment of Ehrlichiosis in Dogs and Cats

Drug	Species	Dose (mg/kg)	Route (Alternative)	Interval (Hours)	Duration (Days)
Doxycycline	D, C	10	PO (IV)	24	21–28
	D, C	5	PO (IV)	12	21–28
Minocycline	D	10	PO	12	28
Oxytetracycline	D, C	7.5–10	IV	8	Until gastrointestinal signs abate, and then change to oral doxycycline as above

D, dogs; *C,* cats; *IV,* intravenous; *PO,* oral.

acutely infected dogs is initiated, the more favorable the prognosis and outcome. Dogs in the chronic phase that have severe myelosuppressive disease may be unresponsive to treatment.[58] Doxycycline (see Chapter 10) is considered the drug of choice for CME. It is readily absorbed to produce high blood, tissue, and intracellular concentrations. Given that *Ehrlichia* spp. can persist intracellularly, drug penetration into the cell is essential in eliminating infection. Doxycycline has the added advantages of a longer half-life and a higher CNS penetration when compared with other tetracyclines. A consensus statement of the ACVIM Infectious Disease Study Group suggested that dogs with CME should be treated with doxycycline (10 mg/kg daily) for a minimum of 28 days.[34] However, several studies have shown that shorter periods may be sufficient.[58] One study found that doxycycline (5 mg/kg twice daily) used for 14 days completely eliminated experimentally induced *E. canis* infection, as detected by PCR or blood cultures, from eight acutely infected dogs.[59] Other studies have shown that either 16 to 23 days or 21 to 28 days of treatment with doxycycline was sufficient to clear the organisms from all infected dogs.[28,60,61] However, in another study, a 6-week course of doxycycline (10 mg/kg, PO, daily) was not sufficient to clear *E. canis* bacteria from all subclinically experimentally infected dogs.[62] It is therefore currently recommended to treat

acutely infected dogs with doxycycline (10 mg/kg, PO, daily) for 21 to 28 days.[58] Minocycline (10 mg/kg, PO, q12h) was also shown to clear infection as determined using whole-blood PCR in five naturally infected dogs, although the time to clearance (28 days) was longer than that for five dogs treated with doxycycline (10 mg/kg, PO, q24h) (21 days), with all dogs remaining PCR negative 7 days after discontinuing treatment.[63]

The efficacy of the "consensus doxycycline regimen" was investigated following experimental *E. canis* infection in the dog.[64] Despite clinical and hematologic recovery of the dogs and negative blood PCR results, *Rh. sanguineus* ticks fed on the dogs after doxycycline treatment became PCR positive for *E. canis* DNA, regardless of the phase during which the treatment was initiated. These results may imply that a very low level of infection, not detectable in whole blood using PCR, may persist in some cases following doxycycline treatment. Overall, noteworthy clinical improvement generally occurs within 24 to 48 hours after initiation of doxycycline therapy in dogs with acute-phase disease, as well as many dogs with mild chronic disease. The platelet count correspondingly begins to increase during this time and is usually in the reference range by 10 to 14 days after treatment initiation. Administration of glucocorticoids at standard immunosuppressive doses to a small number of dogs that had been experimentally infected with *E. canis* and treated with doxycycline was not found to be associated with recrudescence of infection.[65]

Rifampicin, an inhibitor of the B subunit of DNA-dependent RNA polymerase, has been assessed as a potential alternative drug to doxycycline for treatment of CME. In a recent experimental study, rifampicin (10 mg/kg, PO, q24h, for 21 days) hastened hematologic recovery in *E. canis* acutely infected dogs compared with untreated dogs, but achieved *E. canis* clearance in only two out of five dogs.[66]

Recovery is not equated with permanent immunity, and dogs can be reinfected with *E. canis* after a previously effective treatment. Moreover, experimental reinfection with heterologous strains has caused more severe disease manifestations than those with homologous strains.[59]

There is currently limited evidence-based justification for using other tetracyclines (e.g., tetracycline, oxytetracycline), or other drugs such as chloramphenicol, enrofloxacin, or imidocarb dipropionate in the treatment of CME. *Ehrlichia canis* appears to have intrinsic gyrase-mediated resistance to fluoroquinolones,[67] so although their use may be associated with clinical improvement,[68] they are not recommended. Imidocarb dipropionate, an antiprotozoal drug, has been used in the past in treating *E. canis* infections. *In vitro* and *in vivo* studies have shown that imidocarb (6.6 mg/kg, IM, two injections given 2 weeks apart) was not effective in clearing *E. canis* infection in dogs.[69] Because co-infection with *Babesia canis* and/or *Hepatozoon canis* (organisms transmitted by the same vector as for *E. canis*) may occur, imidocarb dipropionate may be used in conjunction with doxycycline when co-infections are identified.

Risk factors for mortality from CME in one study were severe leukopenia (WBC < 930 cells/μL), severe anemia (HCT < 11.5%), hypokalemia (<3.7 mmol/L), and prolonged APTT (>18.25 second).[70] After treatment, titers can decline and become negative in 6 to 9 months. Some dogs retain high titers for several years. Treatment for these dogs should be based on resolution of thrombocytopenia and improvement of hyperglobulinemia, although hyperglobulinemia may resolve over several months after treatment is discontinued. The use of PCR assays on splenic and/or bone marrow aspirates could be considered to determine if persistent infection is present in these dogs, but whether ongoing treatment with doxycycline changes the outcome for these dogs is unknown. Platelet counts should be reassessed 1 and 3 months after discontinuation of therapy, because of the potential for relapse or reinfection.[58]

Supportive Care

For dogs with CME that are dehydrated or anemic, intravenous fluids or blood products, respectively, may be required. In a nonseverely pancytopenic dog, if thrombocytopenia fails to resolve with doxycycline administration, a short course of therapy with immunosuppressive doses of glucocorticoids could be considered in addition to doxycycline. In one case report, use of high-dose filgrastim (50 μg/kg, SC, q48h for 4 days) together with glucocorticoids was followed by bone marrow recovery.[71]

IMMUNITY AND VACCINATION

A commercial vaccine for *E. canis* infection is currently not available, but in one study vaccination of dogs with an attenuated strain extensively reduced disease manifestations in dogs challenged with a virulent strain of *E. canis*.[72] The immune response to *E. canis* infection is not well understood. Because *E. canis* is an intracellular pathogen, cell-mediated immune response is required for pathogen elimination. In one study, dogs with acute infection developed CD8+ lymphocytosis that subsided after several weeks, despite organism persistence.[73] Cytokine studies suggest that the immune response may vary according to the strain of *E. canis* involved.[74,75] Genetic factors of the host are also likely to be important determinants of the immune response and outcome of infection.

PREVENTION

Avoidance of tick-infested areas and routine inspection of dogs for ticks after outdoor activities, especially in endemic areas, can help to prevent ehrlichiosis. Clients should be instructed to remove ticks properly and avoid handling ticks with bare hands or crushing them, to prevent exposure to infected hemolymph. A variety of devices are available to assist tick removal, which are placed around the area where the mouthparts enter the skin to avoid crushing or squeezing the tick and leaving the mouthparts behind (see Fig. 44.2). Fine-tipped tweezers can be used to grasp the tick as close to the skin as possible, followed by steady retraction to remove the tick. The bite wound should then be thoroughly cleaned with a suitable antiseptic solution (such as iodine or chlorhexidine-based antiseptics) or soap and water. Ticks can be disposed of in alcohol or tested for vector-borne pathogens using PCR assays.

The use of topical ectoparasiticides with activity against ticks also prevent tick-borne infectious diseases (see Chapter 13). Examples of effective canine products include those that contain amitraz, fipronil, pyrethroids (permethrin, etofenprox, pyrethrin, deltamethrin, flumethrin), sarolaner, afoxolaner, lotilaner, and fluralaner. Products that contain pyrethroids and amitraz have the most potent activity against ticks. In one field study, the use of monthly imidacloprid 10% and permethrin 50% effectively prevented infection with *E. canis* in kennel dogs.[76] In another study, the use of monthly (days 0, 28, and 56) topical imidacloprid 10% and permethrin 50% prevented tick transmission of *E. canis* to experimentally infected dogs, whereas use of monthly afoxolaner or a single dose of fluralaner did not completely prevent infection.[77] It was suggested that failure of isoxazolines to prevent transmission resulted from the slower speed of kill for these products, which was significantly lower than that for the imidacloprid/permethrin combination. Amitraz, a monoamine oxidase inhibitor, should not be used in dogs treated with selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, and pet owners

who are receiving SSRIs should also use alternative preventatives for their dogs. Prophylactics should be applied consistently at the recommended interval for optimum activity. No preventatives completely protect dogs or cats from tick attachment, especially where tick infestation rates are high. Unfortunately, acaricide-resistant strains of *Rh. sanguineus* have been reported following the indiscriminate use of these drugs.[76]

Low-dose doxycycline (6.6 mg/kg, PO, q24h) has also been used to prevent infection in working dogs or those residing in kennels in which *E. canis* infection is a substantial problem. Resistance to doxycycline remains a theoretical concern in this situation.

Because of the potential persistent subclinical carrier state, blood donor dogs should be screened with serology and PCR for evidence of *E. canis* exposure or infection. All seropositive/PCR-positive dogs should be excluded as donors. Transport of persistent carrier dogs to nonendemic regions has the potential to introduce the infection or new strains of *E. canis* to these regions if the appropriate tick vectors are present.

PUBLIC HEALTH ASPECTS

Ehrlichia canis DNA has been detected in some human patients from Venezuela with clinical signs compatible with HME,[78] and in samples from blood bank donors in Costa Rica,[79,80] suggesting that strains closely related to *E. canis* might be a cause of monocytic ehrlichiosis in people in Central and South America. Appropriate precautions should be taken to prevent transmission when handling engorged ticks as well as blood and tissue specimens from infected dogs, and care should be taken to prevent needle-stick injuries.

EHRLICHIA CHAFFEENSIS

Shimon Harrus, Trevor Waner, Mathios E. Mylonakis

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Ehrlichia chaffeensis, the cause of HME, can naturally infect dogs, based on molecular detection of the organism in southeastern Virginia, Oklahoma, North Carolina, Venezuela, and South Korea.[81–87] White-tailed deer (*Odocoileus virginianus*) serve as the principal reservoir host that sustains the enzootic cycle of *Ehrlichia chaffeensis* in North America.[88] *E. chaffeensis* is transstadially transmitted primarily by the lone star tick, *Amblyomma americanum*, but can also be transmitted by the gulf coast tick, *Amblyomma maculatum*. *Dermacentor variabilis* and possibly *Rh. sanguineus* and other tick species may also play a minor role in the transmission of this agent.[88–90]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Experimentally infected dogs develop mild and inconsistent clinical and clinicopathologic abnormalities, including fever, thrombocytopenia, and leukopenia.[82,91–94] Overall, the intensity of thrombocytopenia and histopathologic lesions in several organs tended to be less severe in dogs experimentally infected with *E. chaffeensis* compared with dogs inoculated at the same time with *E. canis*.[82,91] *Ehrlichia chaffeensis* DNA could be PCR amplified and antibody titers detected for up to 117 days and 180 days postinoculation, respectively,[93] while ticks could acquire the infection for up to 566 days following intradermal inoculation of a dog.[92] *Ehrlichia chaffeensis* infection in dogs may lead to a persistent carrier state, with localization in several tissues (e.g., bone marrow, spleen, liver, lymph nodes, lungs, kidneys, and brain).[91,92]

Physical Examination Findings

In naturally infected dogs, *E. chaffeensis* infection has been associated with lymphadenomegaly, anterior uveitis, and epistaxis,[82] but the clinical implications of this infection in dogs are still unclear.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count and Serum Chemistry Profile

Anemia, thrombocytopenia, moderate pancytopenia, hyperproteinemia, and hypoalbuminemia have been reported in a limited number of naturally infected dogs.[81,86,87] However, as coinfections are common in naturally infected dogs, these findings should be interpreted with caution.

Microbiologic Tests

Cytologic Diagnosis

The diagnostic sensitivity of cytology for the confirmation of the *E. chaffeensis* infection has yet to be evaluated and to the best of the authors' knowledge, no microscopic visualization of *E. chaffeensis* morulae has been reported in experimentally or naturally infected dogs. Of note, the cytologic differentiation between *E. canis* and *E. chaffeensis* morulae in host cells is not possible.[95]

Serologic Diagnosis

Dogs experimentally infected with *E. chaffeensis* develop IgG antibody titres 7 to 23 days postinoculation, which remain detectable for at least 6 months postinoculation.[81,91,93] In the clinical setting, serologic diagnosis is complicated by strong cross-reactivity of *E. chaffeensis* antibodies with antigens of other *Ehrlichia* species.[12,81,83,84,96] Recently, species-specific peptides in microtiter plate-based ELISA assays have been shown to demonstrate very high specificity in the detection of antibodies specific to *E. ewingii*, *E. canis*, and *E. chaffeensis* in experimentally and naturally infected dogs.[46,49,81,83,84,96]

Molecular Detection Using Nucleic Acid–Based Testing

Real-time PCR assays for detection of *E. chaffeensis* have been applied mostly to whole blood and occasionally other tissues specimens.[85,91–93] Some commercial veterinary diagnostic laboratories offer vector-borne PCR panels that include an assay that specifically detects *E. chaffeensis*, with separate assays for *E. canis* and *E. ewingii*. The *16S rRNA* gene has been the major molecular target, but other genes including the *p28*, *gp120*, *homp*, and disulfide oxidoreductase have also been targeted.[81,83,85,92,93]

TREATMENT

In vitro susceptibility testing has indicated that doxycycline and rifampicin are the most active drugs against *E. chaffeensis* infection, but clinical trials are lacking for both antibiotic agents.[97]

PREVENTION

In endemic areas, the risk of acquiring *E. chaffeensis* infection can be lowered by implementing strict tick control programmes for dogs and premises. No vaccines are currently available for the protection of dogs against *E. chaffeensis* infection. However, vaccination with a live, attenuated *E. chaffeensis* mutant (Ech_0660) may have induced a pathogen-specific humoral and cellular immunity

conferring protection in vaccinated dogs against tick-transmitted *E. chaffeensis* infection but not against a heterologous challenge with *E. canis*.[94]

PUBLIC HEALTH ASPECTS

In south-central and southeastern United States, *E. chaffeensis* is considered the major causative agent for HME, which is exhibited as an acute influenza-like illness characterized by fever, headache, malaise, and occasionally death in severely affected humans.[98] Dogs may be carriers of *E. chaffeensis* in endemic geographic regions and may be involved in transporting infected ticks to humans.

EHRLICHIA RUMINANTIUM

Shimon Harrus, Trevor Waner, Mathios E. Mylonakis

Ehrlichia ruminantium, the cause of heartwater in cattle, has been detected using PCR in the blood of dogs presenting with clinical signs suggestive of ehrlichiosis and also in clinically healthy dogs from countries in sub-Saharan Africa, including South Africa, Kenya, Uganda, Ethiopia, Nigeria, and Mali.[5,99] The organism has not been isolated from the blood of dogs in culture or tested for its infectivity to dogs; therefore, its virulence, potential vectors, and definitive classification are uncertain. Whether the clinical signs, which were similar to those of *E. canis* infection, were caused by or were incidental to the infection with this organism is uncertain.

EHRLICHIA MURIS SUBSPECIES *EAUCLAIRENSIS*

Shimon Harrus, Trevor Waner, Mathios E. Mylonakis, Jane E. Sykes

Ehrlichia muris was originally isolated from a wild mouse in Japan,[100] and later PCR amplified and sequenced.[101] *Ehrlichia muris* or a closely related organism was detected using molecular techniques in a febrile person in Russia,[102] and then in four people with febrile disease from Minnesota and Wisconsin.[103] The people from Minnesota and Wisconsin had clinical signs and laboratory abnormalities resembling those of human ehrlichiosis or granulocytic anaplasmosis, but no morulae were visualized in blood smears. They were seronegative to *A. phagocytophilum* and showed variable seroreactivity to *E. chaffeensis*.[103] The DNA of this organism was also detected in *Peromyscus leucopus* mice as well as *Ixodes scapularis* ticks from Minnesota and Wisconsin.[104] Subsequently, additional human cases were identified in the United States (at the time of writing, more than 100 cases according to the CDC), and multilocus sequence analysis led to the proposal that the organism from the United States be classified as a novel species, *E. muris* subsp. *eauclairensis*.[105]

Dogs experimentally infected with *E. muris* did not show clinical or hematologic abnormalities, did not seroconvert, and their PCR was negative for the duration of the follow-up period.[101] In 2012, the DNA of *E. muris* subsp. *eauclairensis* was identified in an ill dog from northern Minnesota that was seronegative for *E. canis* and seroreactive to *Anaplasma* spp., although the extent to which this organism contributed to the dog's clinical signs was unclear.[6] The extent to which *E. muris* subsp. *eauclairensis* can cause disease in dogs requires further investigation.

PANOLA MOUNTAIN *EHRLICHIA*

Jane E. Sykes

Panola Mountain *Ehrlichia* is a novel species of *Ehrlichia* that was identified in a goat in Georgia in the USA in 2006[106] and subsequently detected in a human from Atlanta with doxycycline-responsive neck pain. The person had been hiking 3 weeks previously in the Panola Mountain State Park in Georgia and had removed an *A. americanum* nymphal tick from his upper arm.[107] The organism is closely related to *E. ruminantium* and was subsequently detected in *A. americanum* ticks from all over the southeastern United States,[108] as well as *A. maculatum* ticks in the United States and *Amblyomma variegatum* ticks from the Caribbean and Africa.[109] Infections have been detected in white-tailed deer, which were also shown to be susceptible to experimental infection using infected *Amblyomma* ticks and may be reservoirs for the organism.[110] Panola Mountain *Ehrlichia* was also detected in a dog from Raleigh, North Carolina, with reactive lymphocytosis and clonal expansion of T cells, which appeared to respond to treatment with doxycycline.[7] The extent to which this organism causes disease in dogs and humans requires further study.

EHRLICHIA EWINGII

Barbara Qurollo

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Ehrlichia ewingii, a gram-negative, obligate intracellular bacterium is the causative agent of canine and human granulocytic ehrlichiosis. To date, the organism has only been transiently cultured *in vitro*. *Ehrlichia ewingii* has been detected in dogs from North America, Cameroon, and Brazil.[2,79,111] In the south-central and southeastern states of the United States, *E. ewingii* may be the primary agent of canine ehrlichiosis. Of mostly healthy dogs from Oklahoma and Arkansas, 45% were seropositive for *E. ewingii*.[112] Furthermore, in two large-scale studies addressing healthy and sick dogs, the overall seroprevalence was 14.5% in the central states (Oklahoma, Arkansas, Missouri, and Kansas) and 5.9% in the southeastern states,[113] while seroprevalences of 5.7%, 5.2%, 3.4%, 1.2%, and 0.4% were reported in mid-Atlantic, south, northeast, midwest, and west, respectively.[49] The PCR-based prevalence of *Ehrlichia ewingii* infection ranges from 6% to 30% in ill or apparently healthy dogs.[83,84,112,114] The median age of 41 infected dogs in one study was 9 years, with most cases occurring in summer (39%), fall (27%), and winter (24%).[115] *E. ewingii* is transmitted transstadially by the lone star tick, *A. americanum*, which is the only proven vector, but the DNA of *E. ewingii* has also been detected in *D. variabilis*, *Rh. sanguineus*, and rarely *A. maculatum* ticks.[84,88,116] Infection and associated disease was identified for the first time in Texas in 2019, suggesting the presence of infected *Amblyomma* ticks in this region, and possibly an under-recognized disease.[117]

The white-tailed deer and possibly dogs are the major reservoir hosts of *E. ewingii* in nature.[114,118] One case report described evidence of vertical transmission of *Mycoplasma haemocanis* but not *E. ewingii* from an infected pregnant beagle.[119]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Dogs experimentally or naturally infected with *E. ewingii* can maintain the infection for at least 5 months or 2 years, respectively, possibly serving as reservoir hosts.[118,120–122] Like *A. phagocytophilum*, *E. ewingii* replicates in neutrophils and delays neutrophil apoptosis thus prolonging the life span of the host cells.[123] The course of infection is usually subclinical, or after an incubation period of 2–3 weeks may culminate in an acute disease with intermittent fever, lethargy, anorexia, lameness due to neutrophilic polyarthritis, and possibly neurologic manifestations.[122,124]

Physical Examination Findings

The most common clinical findings include fever and musculoskeletal signs. In dogs that are naturally infected with *E. ewingii*, physical examination may indicate a thin body condition, fever, lethargy, peripheral lymphadenopathy, splenomegaly or hepatomegaly, reluctance to move, lameness or stilted gait, joint swelling or pain on palpation, peripheral edema, and occasionally vomiting or diarrhea.[115,125] Joint pain was the most commonly reported sign in one study of 41 naturally infected dogs, and was present in over one third of the dogs.[115] Dogs that tested PCR positive for other vector-borne pathogens were excluded from this study, but other concurrent disorders were present in many of the dogs tested. Reported neurologic signs include proprioceptive deficits, paraparesis, ataxia, neck pain, anisocoria, tremors, and head tilt.[124] Importantly, an unknown proportion of dogs with spontaneous infection do not develop any clinical manifestations.[115,118]

DIAGNOSIS

Laboratory Abnormalities

Morulae may be cytologically detected in the peripheral blood, synovial fluid, or bone marrow in 1%–7% of granulocytes, but are morphologically indistinguishable from those of *A. phagocytophilum*.[115,125] In experimental infections, morulae have been seen in the peripheral blood of some dogs about 2 to 3 weeks PI, before the onset of clinical signs or seroconversion.[121,122] In the study of 41 infected dogs, morulae were reported in 6 (16%) of 37 dogs where CBC findings were available.[115]

Common hematologic abnormalities in dogs naturally infected with *E. ewingii* include thrombocytopenia (43% of dogs in one study), anemia, and mild to moderate neutrophilic leukocytosis with a left shift or rarely leukopenia.[111,115,124,125] Reactive lymphocytosis and mild neutrophil toxic changes may also occur.[115,124] Serum biochemistry may be unremarkable or show mild abnormalities such as hypoalbuminemia, hyperglobulinemia, and mildly elevated activities of serum ALP and ALT.[115,124,125] Increased serum urea nitrogen and symmetric dimethylarginine (SDMA) concentrations were detected in approximately one third of 41 infected dogs, and significant proteinuria in the face of inactive urine sediments was also frequently detected, suggesting the possibility of glomerulonephritis.[115] Synovial fluid analysis reveals neutrophilic polyarthritis (nucleated cell counts may range 16,000–125,000/μL).

Microbiologic Tests

Serologic Diagnosis

In experimentally infected dogs, antibodies appear approximately 1 month PI.[122] Serologic diagnosis of *E. ewingii* infection is currently limited to a POC ELISA assay that detects the presence of antibodies to a specific peptide of *E. ewingii* (SNAP 4Dx Plus, IDEXX Laboratories, Westbrook, ME, USA). Because this peptide is combined on a spot with a peptide that detects antibodies to *E. canis*, the antibody response to these pathogens cannot be distinguished from one another. Cross-reactions may also occur to other *Ehrlichia* species such as *E. chaffeensis*. Recently, species-specific peptides in microtiter plate-based ELISA assays have been shown to demonstrate very high specificity for the detection of antibodies specific to *E. ewingii*, *E. canis,* and *E. chaffeensis* in experimentally and naturally infected dogs.[46,48,49,112,113,118] Dogs with acute illness may initially test negative with serologic assays, and positive test results may reflect the presence of antibodies from previous exposure or subclinical infection.[48,122] A total of 83% of 41 infected dogs had antibodies to *Ehrlichia* species antigens using the SNAP 4Dx Plus assay.[115] Seroconversion from a negative to a positive result over a 2- to 4-week time period in paired serum samples may support a diagnosis of current active *E. ewingii* infection in endemic areas.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Whole-blood PCR assays with variable sensitivities have been developed for the specific detection of *E. ewingii* DNA.[115,118,124,125] Taking into account the low specificity of serologic tests, *E. ewingii*-specific PCR assays are currently the only means to confirm active infection with this pathogen and to differentiate it from *A. phagocytophilum* infection. In experimental studies, PCR was shown to become positive as early as 4 days after inoculation.[122]

TREATMENT

Treatment with doxycycline results in rapid clinical improvement within 24 to 48 hours.[85,124] Subclinically infected dogs may spontaneously clear the infection within weeks to months.[118,121]

PREVENTION

In the endemic areas, the risk of acquiring *E. ewingii* infection can be lowered by implementing strict tick control programs for dogs and premises. Potential blood donor dogs should be screened for infection with *E. ewingii*-specific ELISA and PCR assays.

PUBLIC HEALTH ASPECTS

Human infection with *E. ewingii* has been rarely described in endemic regions of the United States.[85,126,127] In one study of 4,177 human patients that were tested using real-time PCR for *Ehrlichia* across 41 US states, 10 (9.2%) of 109 *Ehrlichia* infections were *E. ewingii*, with 2 patients from New Jersey and Indiana, where cases had previously not been described.[128] The remaining infections were caused by *E. chaffeensis* (99 cases) and none tested positive for *E. muris* subsp. *eauclairensis.* Affected humans show headache, nausea, fever, myalgia, and thrombocytopenia, with or without leukopenia, and respond to doxycycline treatment. Both immunocompetent and immunocompromised humans have reportedly been affected.[126] Although direct dog-to-human transmission does not occur, blood from affected dogs should be handled with caution.

FELINE EHRLICHIOSES

ETIOLOGIC AGENT AND EPIDEMIOLOGY

The species of *Ehrlichia* that infect cats after natural exposure have not been fully determined. Reports of *Ehrlichia*-like bodies or morulae have been detected in peripheral lymphocytes or monocytes of naturally exposed cats in the United States[129] (Fig. 44.8), Kenya,[130,131] France,[4,132–136] Brazil,[137] and Thailand.[138] Electron microscopic assessment of an isolate from feline mononuclear cells revealed organisms from 0.54 to 1.3 μm, intermediate in size between *E. canis* and *Neorickettsia sennetsu*.[130] Confirmation of feline ehrlichiosis on a molecular basis using PCR has improved our understanding of which species of *Ehrlichia* infect cats. Many recent studies in cats document PCR-amplified DNA from *Ehrlichia* spp. with similar, and in some cases identical, DNA sequence from those *Ehrlichia* spp. commonly detected in dogs.[139,139–151] In one North American report,[143] DNA most consistent with *E. canis* was documented in the blood of three clinically ill cats, and a second retrospective study[146] described *Ehrlichia* DNA in 6 of 331 (1.8%) feline whole blood samples that had been submitted for vector-borne disease testing. Of those six cats, sequence analysis identified one cat with *E. canis*, two cats with *E. chaffeensis* and three cats with *E. ewingii* infections. Prevalence studies of vector-borne pathogens in cats in Brazil have often yielded positive PCR results for *Ehrlichia*, whereas many studies from North America and Europe have been negative for *Ehrlichia* DNA, instead amplifying the DNA of *Anaplasma* or *Bartonella species,* or hemoplasmas. *Ehrlichia canis* DNA segments amplified from three cats in Brazil were 99% identical with each other and 100% identical with reported sequences from dogs in the area, suggesting that the same strain was infecting dogs and cats.[144] Furthermore, molecular studies from Brazil described amplified regions of the 16S rDNA and *dsb* gene from infected cats as 100% identical to *E. canis*.[139–141,149,151] In a Brazilian study of cats from Rio de Janeiro, investigators amplified 16S rRNA gene sequences with 100% identity to *E. canis*, but obtained negative *dsb* gene PCR results.[150] However, another study from Brazil identified 16S rDNA from *Ehrlichia* spp. that was 98% identical to *E. canis* in one cat and 97% identical to *E. chaffeensis* in another cat indicating the potential for a different species of *Ehrlichia* that infect cats.[142] In a French report,[132] the 16S rDNA *Ehrlichia* sequences obtained from two cats were 100% identical to those obtained from North American cats, and in two recent reports from Europe, *Ehrlichia* spp. DNA was amplified from 14 (5.4%) of 260 cats in Italy[148] and 35 (5.4%) of 649 domestic and stray cats in Portugal.[147] Sequence analysis was reported for one of the Portugal cats, which confirmed the presence of *E. canis* DNA. *Ehrlichia canis* DNA was amplified from blood of one cat in Trinidad, West Indies.[145] These reports support a conclusion that cats can be infected with the same or similar species of *Ehrlichia* commonly diagnosed in dogs and that veterinarians should consider molecular testing modalities in cats with clinical signs of ehrlichiosis. Most cats for which signalment was reported were domestic short-haired cats and 1 year or older. Both male and female cats were affected.

To the knowledge of the authors, only one experimental inoculation study of cats with *E. canis* has been conducted.[152] When cats were inoculated subcutaneously with an *E. canis* strain (North Carolina State University canine isolate) maintained in cell culture, *E. canis* DNA or antibodies that reacted to *E. canis* morulae were not detected in an 8-week follow-up period.[152] It is possible that: (1) subcutaneous inoculation is not an effective method for infecting cats with *E. canis*; (2) natural transmission via a tick species is necessary for infection; (3) the *E. canis* strain maintained after many passages through cell culture lost its natural virulence in a host animal; or (4) *Ehrlichia* species that replicate in cats are not identical to those infecting dogs.[143] Additional experimental infection studies in cats using different *Ehrlichia* spp. and transmission methods are warranted. In addition, whether *E. muris* can be transmitted to cats that ingest infected rodents requires further study.[100,101]

Sera from cats have been assessed for *Ehrlichia* spp. antibodies using IFA, ELISA, or Western immunoblot. By the use of IFA, serum antibodies that react with *E. canis* morulae have been detected in cats from multiple states of the United States,[129,146,153] France,[135,136] Italy,[154,155] Spain,[156–160] Kenya,[161] and Brazil.[140–142,150,162] In a neighborhood in Colorado from which a cat infected with a monocytic *Ehrlichia* was identified, 14 of 17 cats (82.4%) and 9 of 17 cats (52.9%) had serum antibodies detected by IFA against *E. canis* and *Neorickettsia risticii*, respectively.[129] Cats with antibodies against both species generally had higher titers to *E. canis* antigens. A recent serologic survey of 715 archived feline serum samples from client-owned cats in North America documented a low *Ehrlichia* seroprevalence.[146] The samples were screened with a qualitative ELISA with *Ehrlichia*-genus and species-specific peptides, and a subset of those were further analyzed by whole cell *E. canis* and *E. chaffeensis* IFA. *Ehrlichia* spp. antibodies to peptides were detected in 12 of 715 cats (0.14%), with species-specific seroreactivity to *E. canis*, *E. chaffeensis*, and *E. ewingii* documented in 5, 1, and 2 cats, respectively. Of the 59 cats screened by IFA, 5 cats had serum antibodies to *E. chaffeensis*, 1 of which was also seroreactive to *E. canis*, and 2 cats were seroreactive to *E. canis*.[146] Serosurveys performed in other countries using *E. canis* IFA documented *E. canis* antibodies in 67 of 680 client-owned and stray cats (9.9%) from Spain, 57 of 216 client-owned cats (26.4%) from Brazil, and 88 of 212 client-owned and stray cats (41.5%) from Brazil.[140,150,157] Recent serosurveys using *E. canis* or *Ehrlichia* spp. peptide ELISAs measured *Ehrlichia* antibodies in 73 of 624 (11.7%) client-owned cats from Germany and 2 of 100 (2%) stray cats from Bulgaria.[163,164] Overall, seroprevalence of *Ehrlichia* spp. in client-owned cats in North America was low, with potential epizootic areas such as the area in Colorado, while feline *Ehrlichia* seroprevalence was higher in Europe and South America. The differences in prevalence may be due to serologic testing modalities, lifestyle of the cats tested, and prevalence of *Ehrlichia* spp.

Many healthy cats have serum antibodies from exposure to other pathogens (e.g., *Bartonella henselae*)[160] that may cross-react with *E. canis* antigens, as observed for dogs.[153] Additionally, variable serologic cross-reactivity occurs among *Ehrlichia*, *Neorickettsia*, and *Anaplasma* spp.; therefore, seroreactivity to a specific test antigen does not definitely document exposure to the *Ehrlichia* spp. morulae or peptides used for testing.[34,152,165,166] Serologic cross-reactivity has been suspected in epidemiologic investigations in domestic or exotic cats, which likely overestimates infection prevalence.[146,156,159,160,162,167–169] For example, one study documented a cat with *A. phagocytophilum* DNA in blood that had serum antibodies to *E. chaffeensis* by IFA, and another cat with *E. chaffeensis* DNA in blood that did not have serum antibodies to *E. chaffeensis* by IFA but had antibodies to *E. canis* by IFA.[146] Standardization of *Ehrlichia* spp. serologic methodologies between laboratories has not been performed, and the most appropriate cutoff values have not been determined. Results of serologic tests performed by different laboratories have not shown 100% concordance.[143] Thus, results of antibody-based surveys should be interpreted with caution until such time as laboratories can better correlate serologic results with feline *Ehrlichia* spp. isolates or PCR assay findings.

The way in which the clinically ill, naturally exposed cats with ehrlichiosis described in the literature were infected remains unknown. Documentation of arthropod exposure in proven cases has been variable. A study in Brazil documented *Rh. sanguineus* sensu

lato ticks parasitizing three cats infected with *E. canis*, where one of the attached ticks was also PCR positive for *E. canis*.[151] *Haemaphysalis leachi* was found on each of four cats with clinical ehrlichiosis in Kenya.[130,131] *Amblyomma aureolatum* was found on an infected cat in Brazil.[149] *Ctenocephalides felis* taken from cats in the United States and Australia were negative for *Ehrlichia* and *Anaplasma* spp. DNA.[170,171]

CLINICAL FEATURES

Pathogenesis, Clinical Signs and Physical Examination Findings

The pathogenesis of disease associated with ehrlichiosis in cats is unknown. Based on clinical, laboratory, and radiographic findings, pathogenesis of disease may be similar to that for *Ehrlichia* infection of dogs. In the three cats with *E. canis*-like DNA in blood, antinuclear antibodies were detected along with cytopenias, similar to results reported for infected dogs.[143] In one cat infected with *E. ewingii*, clinical signs were also similar to those seen in infected dogs, and consisted of anemia and thrombocytopenia.[146] Additional studies monitoring cats naturally or experimentally infected with *Ehrlichia* spp. are needed to better understand the pathogenesis of feline ehrlichiosis.

Clinical manifestations of ehrlichiosis have been described in 22 cats with suspected morulae in mononuclear cells,[4,129–131,134,135,137,172] and in 4 cats with *Ehrlichia* spp. DNA in blood (see Table 44.1).[143,146] Ehrlichiosis has also been suspected in 34 reported feline cases in which the diagnosis was presumptively based on the combination of positive *E. canis* or *N. risticii* serology results, clinical or laboratory findings consistent with ehrlichial infection, and response to known antiehrlichial drugs.[129,135,136,172–175] Furthermore, several studies that evaluated clinical signs in cats that were seropositive and/or PCR positive for *Ehrlichia* documented abnormalities consistent with ehrlichiosis, but results of treatment were not reported.[141,148,158] Some cats that tested positive for *Ehrlichia* using PCR have been apparently healthy. In other cats, co-morbidities such as lymphoma or concurrent infection with *Mycoplasma haemofelis, Cryptococcus neoformans*, FeLV, or FIV infections were detected.

When clinical signs are present, fever and nonspecific signs of lethargy, inappetence, and weight loss are common manifestations. Hyperesthesia, joint pain, dyspnea, vomiting, and diarrhea have also been described. Reported physical examination abnormalities include splenomegaly, lymphadenomegaly, dyspnea, petechiae, retinal detachments, vitreous hemorrhages, epistaxis, and pale mucous membranes.

DIAGNOSIS

Diagnostic tests used to detect *Ehrlichia* infections in cats are similar to those used in dogs (see Table 44.2). Assessment of regional and tick exposure, clinical signs, and characteristic laboratory abnormalities should prompt clinicians to proceed with diagnostic modalities such as PCR, IFA, ELISA, and cytologic examination of blood smears. Use of a combination of molecular and serologic modalities can improve evidence of infection or exposure to *Ehrlichia* spp.[176] Cytologic examination of blood, joint fluid, CSF, and tissue aspirates can identify active infections but is generally less sensitive than molecular techniques.

Laboratory Abnormalities

Anemia is most commonly nonregenerative and has been noted in cats with chronic disease histories. One cat with regenerative anemia was co-infected with a hemotropic *Mycoplasma* species.[4] Leukopenia, leukocytosis, neutrophilia, neutropenia, lymphopenia, lymphocytosis, monocytosis, and thrombocytopenia occur in some cats, alone or in combination. A Brazilian study documented thrombocytopenia and lymphopenia as the most common CBC abnormalities in eight cats with *E. canis* DNA in their blood[141]; the same study evaluated 42 cats seropositive to *E. canis* by IFA and documented anemia, leukocytosis, leukopenia, thrombocytopenia, lymphopenia, and monocytosis. A recent study of 57 cats from Brazil, either seropositive or PCR positive for *E. canis* reported anemia, thrombocytopenia, leukocytosis, left-shift neutrophilia, and hyperproteinemia as the most common abnormalites.[150] In contrast, 14 cats from Italy with *Ehrlichia* spp. in their blood,[148] 3 cats with *E. canis* in their blood,[151] and 1 cat in the southern United States with *E. chaffeensis* DNA in its blood had no CBC abnormalities.[146] Bone marrow evaluation of cats with cytopenias has revealed primarily hypoplasia of the affected cell line. However, one cat had bone marrow cytologic characteristics consistent with myeloid leukemia.[143] In regions where ticks are abundant, ehrlichiosis should be considered on the differential list for cats with unexplained leukocytosis or cytopenias.

Biochemical abnormalities have been infrequently reported in cats with suspected clinical ehrlichiosis and are nonspecific. Hyperproteinemia was the most consistent abnormality and polyclonal gammopathy was detected in five of the cats assayed by protein electrophoresis.[133,143,150,172] In a separate study, an epidemiologic association was made between monoclonal gammopathy and cats seropositive for *E. canis* antibodies.[153] Based on these results, in tick endemic regions, ehrlichiosis should be on the differential list for cats with hyperglobulinemia.

Cytologic Examination

Microscopic examination of stained blood smears may reveal *Ehrlichia* morulae in mononuclear cells or granulocytes. However, this method of diagnosis is not sensitive and cannot identify the *Ehrlichia* spp. present.

Organism Cultivation

Infection by *Ehrlichia* spp. can be confirmed by cell culture, but this is not routinely used in a clinical setting. Furthermore, not all *Ehrlichia* spp. can be grown in cell culture. Attempts to culture an *Ehrlichia* spp. from cats seropositive to *E. canis* were unsuccessful.[158] An *Ehrlichia*-like organism was isolated from whole blood from domestic cats on monocyte cultures[130] but not from a lioness from Kenya.[131] Although results of PCR assays will likely be used to help further define feline ehrlichiosis, clinicians should assist research laboratories in efforts to obtain feline *Ehrlichia* spp. isolates for comparative microbiologic studies.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays have been used to successfully diagnose *Ehrlichia* infections in cats through the amplification of a variety of gene targets and comparison of DNA sequences with known *Ehrlichia* species.[132,139–149] The same assays used for dogs can be applied to cat blood and tissue specimens.

Serologic Testing

When antibodies are present, most cats with morulae in mononuclear cells have had antibodies in sera to *E. canis*, as detected using IFA. However, some cats with ehrlichiosis have been seronegative, and thus clinicians may have to obtain convalescent samples to document seroconversion. There has been poor correlation between the detection of *E. canis* DNA and seroreactivity. Of three cats with *E. canis*-like DNA in blood in one study, none had detectable antibodies to *E. canis* by IFA in two different laboratories,

even though chronic disease existed.[143] Subsequent studies have examined the combination of serologic and molecular test results for detection of *Ehrlichia* spp. infection in cats.[140–142,146,156] Of eight cats from Brazil that were PCR positive for *E. canis*, six had serum antibodies to *E. canis* by IFA.[141] In another study, 12 of 20 cats that were PCR positive for *E. canis* had antibodies.[140] These results suggest that not all cats seroconvert when infected with *Ehrlichia* spp., that another *E. canis*-like organism that does not induce cross-reacting antibodies is present, or the sensitivity of currently available serologic assays is poor. In another study, five cats with presumed ehrlichiosis had serum antibodies that reacted with *N. risticii* but not to *E. canis*.[175] POC ELISAs designed to detect antibodies reactive to specific *Ehrlichia* spp. peptides are available for testing dog sera. Because these tests do not apply host species-specific conjugate, use of feline sera has been repo rted.[146,163,177] However, cats' immunologic reactivity to diagnostic peptides may differ from that of dogs. For example, one study reported that five cats seroreactive to the *E. canis* p16 peptide were not seroreactive to *E. canis* p30/p31-1 peptides or whole cell antigen from *E. chaffeensis* or *E. canis*.[146] Hence, a diagnosis of feline ehrlichiosis should never be based on positive serologic test results alone. Clinicians should always exclude other potential causes of the clinical syndrome.

Other Testing

Antinuclear antibody test results are positive in some cats with *Ehrlichia* spp. infection.[143] Coombs' test results have generally been negative. Neutrophilic polyarthritis and increased CSF protein concentrations were present in one cat.[143] Lymph node aspirates, when performed, show lymphoid or plasma cell hyperplasia.

Diagnostic Imaging

Of cats with ehrlichiosis that had historical or physical examination findings consistent with respiratory disease, interstitial lung patterns were the only abnormalities reported. Cardiomegaly was reported in two cats with *E. canis*-like DNA in their blood; however, most thoracic and abdominal radiographs were within normal limits.

Pathologic Findings

Before treatment, pyogranulomatous lymphadenitis was detected in a mesenteric lymph node from a cat from Colorado with antibodies against *E. canis* and *N. risticii*.[129] Perivascular plasma cell and lymphocyte infiltrates were detected in the lungs, kidneys, and liver of an untreated lioness in Kenya.[131] After doxycycline treatment in one cat, ARDS developed that was followed by death.[143] Neutrophilic and histiocytic myocarditis and pneumonia, multifocal lymphoplasmacytic nephritis, and multifocal lymphoplasmacytic pancreatitis were the predominant findings. However, *Ehrlichia* spp. or other infectious causes were not identified after death.

TREATMENT AND PROGNOSIS

Treatment of cats with monocytic ehrlichiosis is as recommended for dogs (see Table 44.3). Resolution of illness was seen in three cats following administration of doxycycline at 5 mg/kg, q12hr for 21 days and in one cat after treatment at 10 mg/kg, q24hr for 21 days.[129,173] One cat was seropositive 180 days after discharge but seronegative 1365 days after discharge, and another cat was seronegative 180 days after completing doxycycline therapy. Serologic follow-up was available for multiple presumptive cases in France,[135,136] where most cats became seronegative with time. However, increasing or persistently positive titers can occur as reported for the dog.[178] Imidocarb dipropionate administered at 5 mg/kg, intramuscularly, and repeated in 14 days was followed by resolution of disease in two cats in Kenya.[130] Although not effective in clearing *E. canis*, imidocarb diproprionate has been used for the treatment of infected dogs[161] and has been shown to be safe when administered to cats.[179] Enrofloxacin was used to treat two cats with suspected mononuclear ehrlichiosis[136]; however, this drug is considered to be inferior to tetracyclines for the treatment of ehrlichiosis in dogs.[34,69] The Infectious Disease Study Group of the ACVIM currently recommends treating cats with suspected clinical ehrlichiosis with doxycycline at 10 mg/kg, PO, q24h for a minimum of 28 days.[34] Whether the treatment protocols used to date eliminate the organism is currently unknown.[180,181]

Two cats with morulae in mononuclear cells were euthanized because of treatment failures with tetracycline[4] or doxycycline,[134] and death occurred in another.[143] Thrombocytopenia did not resolve until 7 months after doxycycline treatment in a cat infected with *E. ewingii*.[146]

IMMUNITY AND VACCINATION

Epidemiologic studies of tick-borne diseases in cats document a lower prevalence of *Ehrlichia* infections in cats than in dogs, and fewer tick-borne diseases are diagnosed in cats than in dogs. This may be due to environmental factors (many cats are strictly indoors), shorter periods of tick attachment in cats due to fastidious grooming, decreased testing of cats for vector-borne pathogens by veterinarians, and/or potential differences in canine and feline immune function.[184] Vaccines for feline ehrlichiosis are not available.

PREVENTION

Because routes of transmission for naturally infected cats are unknown, definitive statements concerning prevention cannot be made. Exposure of cats to potential arthropod vectors and ingestion of rodents should be avoided. Several topical ectoparasiticides with activity against ticks are available for cats. However, those with permethrin, deltamethrin, and amitraz cannot generally be used in cats (see Chapter 13), and use of these products should also be avoided on dogs that co-habitate with cats. Isoxazolines have been developed as oral ectoparasiticides and some formulations have been approved for use in cats.[185] *Ehrlichia* spp. can be transmitted by blood transfer, so cats used as blood donors that are in tick-endemic areas should be screened using both serology and PCR and excluded if positive.[184–186]

PUBLIC HEALTH ASPECTS

Human infection with *E. canis* has never been reported in association with cat contact. If cats are housed indoors and arthropod control is maintained, the risk to humans should be minimal. Appropriate precautions should be taken to prevent transmission when handling engorged ticks as well as blood and tissue specimens from infected cats.

CASE EXAMPLES

CANINE EHRLICHIOSIS

Signalment

"Dubi," a 7-year old, male, mixed breed dog from Tel Aviv, Israel.

History

Dubi was brought to the Koret School Veterinary Teaching Hospital, The Hebrew University, because of a 10-day history of lethargy and inappetence. Dubi had been drinking well and there was no history of vomiting or diarrhea. There was a history of exposure to ticks, and no history of trauma. Dubi's diet consisted of a commercial adult dry dog food.

Physical Examination

Body weight: 15.0 kg.

General: Quiet, depressed. T = 103.3°F/39.6°C, HR = 140 beats/minute, panting, mucous membranes pale pink with multiple mucosal petechiae, CRT < 2 seconds. Approximately 5% to 7% dehydrated.

Integument: No clinically significant abnormalities were noted. No ectoparasites were detected.

Musculoskeletal: BCS was 6/9.

Cardiovascular and respiratory systems: No clinically significant findings were present.

GI and urogenital systems: Cranial organomegaly was noted on abdominal palpation. Rectal examination revealed no significant abnormalities.

Lymph nodes: All peripheral lymph nodes were slightly enlarged.

Laboratory Findings

CBC: RBC 5.0 (5.5–8.7 × 10^6 cells/μL), HCT 32.0% (40%–55%), MCV 72 fL (65–75 fL), MCHC 34 g/dL (33–36 g/dL), WBC 9,400 cells/μL (6,000–13,000 cells/μL), neutrophils 6,400 cells/μL (3,000–10,500 cells/μL), lymphocytes 1,100 cells/μL (1,000–4,000 cells/μL), monocytes 1,680 cells/μL (150–1,200 cells/μL), eosinophils 220 cells/μL (0–1,500 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 65,000 platelets/μL (150,000–400,000 platelets/μL), MPV 16.5 fL (7–13 fL).

Serum chemistry profile: Sodium 151 mmol/L (145–154 mmol/L), potassium 4.5 mmol/L (3.6–5.3 mmol/L), chloride 110 mmol/L (108–118 mmol/L), bicarbonate 18 mmol/L (16–26 mmol/L), phosphorus 5.7 mg/dL (3.0–6.2 mg/dL), calcium 10.6 mg/dL (9.7–11.5 mg/dL), BUN 49 mg/dL (5–21 mg/dL), creatinine 1.3 mg/dL (0.3–1.2 mg/dL), glucose 85 mg/dL (64–123 mg/dL), total protein 7.7 g/dL (5.4–7.6 g/dL), albumin 2.4 g/dL (3.0–4.4 g/dL), globulin 4.2 g/dL (1.8–3.9 g/dL), ALT 53 U/L (19–67 U/L), AST 39 U/L (19–42 U/L), ALP 102 U/L (21–170 U/L), creatine kinase 355 U/L (51–399 U/L), GGT 5 U/L (0–6 U/L), cholesterol 255 mg/dL (135–361 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL), magnesium 2.4 mg/dL (1.5–2.6 mg/dL).

Urinalysis: SpG 1.022; pH 7.0; no RBC; no WBC.

Imaging Findings

Abdominal ultrasound: The spleen was enlarged with rounded edges and a heterogeneous, hypoechoic parenchyma. Abdominal lymph nodes were slightly enlarged. The liver had normal parenchymal architecture.

Microbiologic Testing

4Dx SNAP test serology (IDEXX Laboratories, ME, USA): Positive for antibodies to *E. canis*. Negative for antibodies to *Anaplasma* spp. and *B. burgdorferi* and negative for *Dirofilaria immitis* antigen.

Vector-borne disease serology (IFA): Positive for antibodies to *E. canis* at 1:1,280.

Vector-borne real-time PCR panel (whole blood): Positive for *E. canis* DNA. Negative for *A. phagocytophilum, A. platys, Bartonella* spp., *Rickettsia* spp., and *B. burgdorferi* DNA.

Diagnosis

CME, characterized by thrombocytopenia, hypoalbuminemia, hyperglobulinemia, generalized lymphadenopathy, splenomegaly, and mucosal petechiae.

Treatment

Dubi was initially treated with IV crystalloids (lactated Ringer's solution) and doxycycline (10 mg/kg, q24h). The dog was released home with instructions to continue the antibiotic treatment and report to the clinician on Dubi's condition after 72 hours, and to return for a recheck, CBC, and biochemistry panel after 21 days.

Three days later, the owners reported that the dog's attitude and appetite improved. After 21 days, the owners reported that Dubi was bright, alert, responsive, eating, and drinking well. On physical examination, no abnormalities were noted. CBC revealed no hematologic and biochemistry abnormalities. The spleen had returned to a sonographically normal appearance, and the abdominal lymph nodes were markedly reduced in size. Additional serology or follow-up PCR was not performed. He was subsequently lost to follow-up.

FELINE EHRLICHIOSIS[129]

Signalment

"Squirrel," a 10-year old female spayed domestic short-hair cat from Colorado.

History

"Squirrel" was brought to the College of Veterinary Medicine at Colorado State University because of a 2-week history of intermittent fever, anorexia, lethargy, and pain in the lumbar area. The referring veterinarian completed a CBC and serum biochemical analysis and reported abnormalities which included hyperproteinemia (8.9 g/dL; reference range, 5.4–8.4 g/dL), hyperglobulinemia (5.9 g/dL; reference range, 2.9–4.4 g/dL) and hypercholesteremia (263 mg/dL; reference range, 53–217 mg/dL). Serum antibodies for FeLV, FIV, *Toxoplasma gondii,* and FCoV were undetectable. The cat was treated with oral amoxicillin for 7 days with no improvement and then amoxicillin-clavulanic acid and subcutaneous fluids prior to presentation.

Physical Examination

Body weight: 3.1 kg.

General: Listless. T = 102°F (38.9°C), HR = 195 beats/minute, RR = 46 breaths/minute. Approximately 7% dehydrated.

Integument: No clinically significant findings.

Eyes, ears, nose, and throat: No clinically significant findings.

Musculoskeletal: Signs of pain upon palpation of the lumbar area.

Neurologic examination: No clinically significant findings.

Cardiovascular and respiratory systems: No clinically significant findings.

GI and urogenital systems: No clinically significant findings.

Lymph nodes: All peripheral lymph nodes were of normal size.

Laboratory Findings

CBC abnormalities: Normocytic, normochromic nonregenerative anemia: PCV 25%, MCV 43 fL, MCHC 32 g/dL. Neutrophilic leukocytosis: 23,700 nucleated cells/μL and 21,330 neutrophils/μL.

Serum chemistry profile: Hyperglobulinemia 4.6 g/dL (reference range, 2.9–4.4 g/dL)

Serum protein electrophoresis: Increased in β_1 fraction 0.9 g/dL (reference range, 0.23–0.84 g/dL)

Urinalysis: No clinically significant findings.

Cytologic Findings

Paracentesis was performed based on previous findings of fever and nonspecific hyperesthesia and showed a small amount of fluid with a large number of nondegenerate neutrophils, moderate numbers of large mononuclear cells, few eosinophils, and rare small mononuclear cells and basophils.

CASE EXAMPLES—cont'd

Exploratory Laparotomy

Exploratory laparotomy was performed because of concern for peritonitis. A 2- to 4-cm, irregular, raised mass was identified at the ileocecal junction. The liver was a mottled yellow, nutmeg color.

Postsurgical Histology and Cytology

Histopathology of the excised ileocecal mass was reported as inflammatory cell infiltration of a lymph node. The cells were primarily neutrophils and macrophages and a diagnosis of severe pyogranulomatous lymphadenitis was assigned. Liver tissue showed mild multifocal infiltration of bile ducts by neutrophils and lymphocytes and a diagnosis of mild cholangitis was assigned. Impression smears of mesenteric lymph nodes revealed clumps of intracellular gram-negative organisms in mononuclear cells, morphologically similar to *E. canis*.

Microbiologic Testing

All specimens were negative for routine aerobic bacterial culture.

No antibodies to *Chlamydia* spp. were detected (see Chapter 49).

Vector-borne disease serology (IFA): Positive for antibodies to *E. canis* at 1:80 and 1:160, 180 days following discharge. Positive for antibodies to *N. risticii* at 1:40, 180 days following discharge.

Diagnostic Imaging

Abdominal and thoracic radiographs were within normal limits.

Diagnosis

Suspected feline monocytic ehrlichiosis.

Treatment

At the referral hospital, Squirrel was initially treated with with cefoxitin (22 mg/kg, IV, q8h), crystalloids (lactated Ringer's solution), cat food puree administered via a gastrostomy tube. The antibiotic was changed to amoxicillin (22 mg/kg, PO, q12h) 4 days after surgery, upon release to the owner. At reexamination 4 days after release, Squirrel was lethargic and febrile (rectal temperature of 103.6°F). Doxycycline (5 mg/kg, PO, q12h) was administered via the gastrostomy tube. Two days later, the cat's attitude improved and fever was absent; treatment was continued for 21 days. The gastrotomy tube was removed 14 days following discharge and at that time the cat was clinically normal. *E. canis* and *N. risticii* antibody titers were negative 1,365 days after discharge.

Comments

In this cat, while organisms cytologically similar to *E. canis* were visualized and antibodies to *E. canis* detected by IFA, active infection with *E. canis* was not confirmed through culture or molecular testing. Where the cat became infected was unclear, but vector-borne disease testing performed on 17 cats living within a 2 mile radius of the infected cats identified 14 and 9 cats with antibodies to *E. canis* and *N. risticii*, respectively. The rationales for paracentesis and exploratory laparotomy were not completely clear. Two of the seropositive cats had a 2- to 4-month history of malaise and one cat lost weight during this time. All cats were apparently healthy at the time of blood collection and no abnormalities were detected by CBC, serum biochemistry panel, buffy coat films, urinalysis, or serology testing for other infectious agents. The two cats with malaise were treated with doxycycline (5 mg/kg, PO, q24h for 21 days) which was followed by resolution of illness within days after initiation of treatment.

Anaplasmosis

Jennifer Granick, Michael R. Lappin, Trevor Waner, Shimon Harrus, Mathios E. Mylonakis

KEY POINTS

- Cause: *Anaplasma phagocytophilum* (granulocytic anaplasmosis), *Anaplasma platys* (thrombocytotropic anaplasmosis).
- First Described: First reports of *A. phagocytophilum* infection came from sheep in 1951 (Scotland).[1–3] Canine infection was first reported in the United States (California) in 1982[4] and in domestic cats in 1999.[5] *Anaplasma platys* was first reported in the United States in dogs (Florida) in 1978[6] and in cats in Brazil in 2010.[7]
- Affected Hosts: *Anaplasma phagocytophilum* causes disease in dogs, cats, humans, ruminants (European strains), horses, and camelids. *Anaplasma platys* causes thrombocytopenia in dogs and cats.
- Geographic Distribution: In the United States, *A. phagocytophilum* is most prevalent in the upper midwestern, northeastern, and western states. Infection also occurs throughout continental Europe and the United Kingdom, Asia, and Russia. The organism has been detected in dogs from Africa and South America. *Anaplasma platys* occurs throughout the Americas, Europe, Asia, Australia, the Middle East, and Africa.
- Mode of Transmission: Tick vectors, primarily *Ixodes ricinus-persulcatus* complex ticks transmit *A. phagocytophilum. Rhipicephalus sanguineus* is suspected to be the major vector of *A. platys,* though this remains unconfirmed.
- Major Clinical Signs: The major clinical signs of *A. phagocytophilum* infection are fever, lethargy, inappetence, and lameness due to polyarthritis. Vomiting, diarrhea, cough, and neck pain may occur. Infection by *A. platys* is usually associated with no signs, but fever and lethargy are possible.
- Differential Diagnoses: Major differential diagnoses include other tick-borne diseases (such as ehrlichioses, rickettsioses, Lyme borreliosis, and babesiosis), bartonellosis, leptospirosis, primary immune-mediated disease, and lymphoma.
- Human Health Significance: *Anaplasma phagocytophilum* causes human granulocytic anaplasmosis. Dogs act as sentinels for human infection and may carry unfed ticks to humans on their coats.

ANAPLASMA PHAGOCYTOPHILUM INFECTION

Jennifer Granick, Michael Lappin

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Canine and feline granulocytic anaplasmosis are caused by *Anaplasma phagocytophilum*, a tick-borne, obligately intracellular bacterium belonging to the family Anaplasmataceae. Based on DNA sequencing, the causative agent formerly called *Ehrlichia equi*, *Ehrlichia phagocytophila*, and, in humans, the human granulocytic ehrlichiosis (HGE) agent, was removed from the genus *Ehrlichia* in 2001 and placed into the genus *Anaplasma*.[8] *Anaplasma phagocytophilum* is tropic for granulocytes, primarily infecting neutrophils, where it forms host membrane-enclosed morulae. Ticks that belong to the *Ixodes ricinus-persulcatus* complex are the major vectors for *A. phagocytophilum*.

Rickettsiae of the family Anaplasmataceae are gram-negative, nonmotile, pleomorphic bacteria. They are obligate aerobes and obligate intracellular parasites.[9] All species in the genus *Anaplasma* inhabit cell membrane–derived vacuoles in immature or mature hematopoietic cells of mammalian hosts.[8] *Anaplasma phagocytophilum* preferentially infects cells of the myeloid lineage, predominantly neutrophils and rarely eosinophils.[8] Unlike other gram-negative bacteria, members of the family Anaplasmataceae lack a cell wall, and the absence of a peptidoglycan layer or LPS makes them dependent upon host cholesterol for survival but allows them to closely associate inside cellular inclusions.[9] Replication inside vacuoles results in the formation of morulae, which are basophilic structures detectable by light microscopy typically 1.5 to 2.5 µm (but up to 6 µm) in diameter, within the cytoplasm of granulocytes (Fig. 45.1).[10]

Anaplasma phagocytophilum causes granulocytic anaplasmosis in dogs, humans, horses, and, in Europe, domestic ruminants that include sheep, cattle, goats, and deer. Cats and camelids may also be affected. A variety of wild animal species, which include rodents and deer, act as reservoir hosts. For the midwestern and eastern United States, white-footed mice, the woodland deer mouse, and eastern chipmunks may act as reservoirs. Seroreactivity to *A. phagocytophilum* in white-footed mice in endemic areas of North America ranges from 10.1% to 85%.[11–14] In the western states, dusky-footed woodrats, gray squirrels, and chipmunks have all been implicated as reservoirs, but the dusky-footed woodrat is one of the most extensively exposed species (seroprevalence ranging from 17% to 80%),[15,16] followed by the western gray squirrel (70.7% seroprevalence and 12.1% PCR prevalence).[17] In Europe, bank voles, wood mice, yellow-necked mice, shrews, and roe and red deer are likely reservoirs.[18,19] In addition to mammals, birds likely play a role in the spread of infected ticks. Migratory birds in Europe and North America can be infected with *A. phagocytophilum* and evidence suggests that, in addition to spreading infection, they also can act as reservoirs by transmitting infection to tick larvae that co-feed with infected nymphs.[20,21] Dogs, cats, and humans are accidental hosts and are not important in the transmission of infection to other host species.

The geographic distribution of granulocytic anaplasmosis follows that of the *Ixodes* tick vectors and is expanding as vector ranges change, likely due to climate change (Fig. 45.2). Because *Ixodes* ticks are three-host ticks, and tick-to-tick transmission of *A. phagocytophilum* only occurs transstadially, nymph and adult stages are potential vectors.[8] In

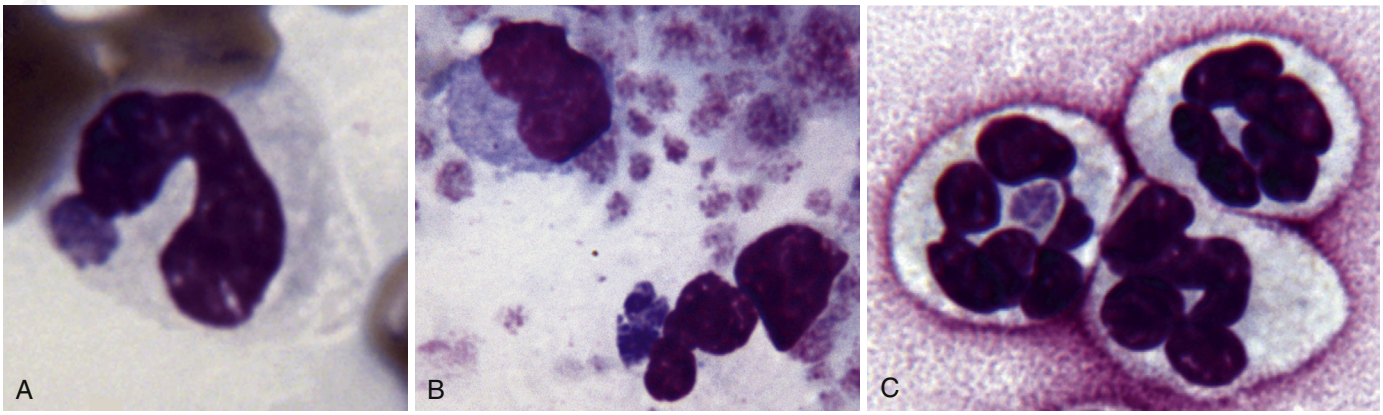

Fig. 45.1 *Anaplasma phagocytophilum* morulae in canine neutrophils. (A) Peripheral blood from a dog. A circular, stippled, deeply basophilic morula is present intracellularly within a band neutrophil. A few erythrocytes are densely clumped in the background (Wright Giemsa, ×100). (B) Buffy coat from a dog. Two abutting, large, circular, stippled, deeply basophilic morulae with irregular borders are present intracellularly within a neutrophil *(lower right).* A lymphocyte and a monocyte are also present. A large number of platelets are seen in the background, which is expected in buffy coat direct smear preparations (Wright Giemsa, ×100). (C) Synovial fluid from a dog with inflammatory polyarthritis. A circular, stippled, basophilic morula is present intracellularly within a neutrophil *(left).* Three neutrophils are present on a granular eosinophilic background, which reflects the mucin content of synovial fluid and is expected in such direct smear preparations (Wright Giemsa, ×100). (Courtesy Heather L. Wamsley, University of Florida, Gainesville, FL.)

the northeastern and upper midwestern United States, the tick vector of *A. phagocytophilum* is *Ixodes scapularis*, though recent extension into Ontario, Canada, has been reported.[22] Dispersal of *I. scapularis* ticks by ovenbirds and wood thrushes are responsible for the expanding range of these ticks both west and south.[23] *Ixodes pacificus* is the vector in the western United States. In Europe, the primary vector is *I. ricinus*, and the disease has been described in dogs throughout continental Europe and in the United Kingdom. *Ixodes persulcatus* and *Dermacentor silvarum* ticks transmit the organism in Asia and Russia. Other *Ixodes* spp. ticks have also been implicated in transmission. *Ixodes inopinatus* has been shown to carry *A. phagocytophilum* in Germany, though transmission has not been verified.[24] Evidence of *A. phagocytophilum* infection has been found in dogs from Brazil and Tunisia, and a closely related organism was found in dogs from South Africa.[25–27]

Many strains of *A. phagocytophilum* exist that differ in DNA sequence, geographic distribution, pathogenicity, and host tropism. For example, strains that infect domestic ruminants in Europe and white-tailed deer in the United States appear to be distinct from those that infect horses, humans, and dogs. Phylogenetic analyses have grouped strains into North American and European lineages,[28] though there is heterogeneity among lineages. Further analyses have separated the North American lineage into two clades, upper Midwest and Northeast,[29,30] and the European lineage into three other clades.[25,29] These differences likely have clinical implications. In the Netherlands and Belgium alone, four distinct and geographically separated ecotypes were identified, and only one of these was linked to human disease.[31] Higher morbidity and mortality rates in humans seem to be associated with American strains of *A. phagocytophilum* compared with those in Europe.[2,3] Conversely, in ruminants, *A. phagocytophilum* causes significant mortality in Europe but is considerably less pathogenic in North America.[32–35] There is a significant mismatch at the spatial scale between clinical cases in humans, dogs, and horses in the western United States and infection in the supposed reservoirs.[36] Similarly, the prevalence of strains causing disease in domestic animals and humans is decreased in eastern European locales in which roe deer are present versus those in which red deer predominate.[37] Taken together, these data suggest that multiple distinct *A. phagocytophilum* strains, which differentially infect various mammalian species, could circulate in endemic ecosystems.

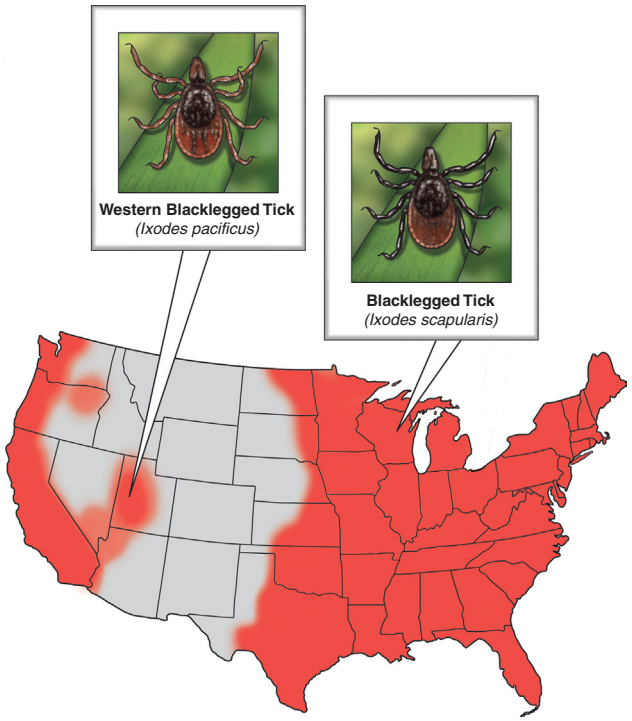

Fig. 45.2 Distribution of *Ixodes scapularis* and *Ixodes pacificus*, the vectors of *Anaplasma phagocytophilum*, in the United States. The distribution of granulocytic anaplasmosis follows that of the tick vectors.

Many seroprevalence studies of dogs and cats have been reported worldwide.[38,39] The seroprevalence varies with geographic location and whether the animals studied were clinically ill or healthy. The prevalence of positive antibody titers in dogs from some regions of Europe and North America exceeds 50%. A study that used a commercially

available ELISA assay to determine the prevalence of seroreactivity to *A. phagocytophilum* in more than 400,000 dogs from the United States revealed wide variation in seroprevalence rates, with some counties in the upper midwestern and northeastern United States having seroprevalence rates that exceeded 40%.[40] A 2014 study found that the overall seroprevalence in these regions were 7.1% and 3.9%, respectively.[41] Interestingly, prevalence of seroreactivity to *A. phagocytophilum* in dogs appears to be increasing in some states and decreasing in others, which may reflect changes in ecosystems, testing, or tick prevention.[42] Less data exists for cats, though one study found that 3.7% of healthy cats and 21.7% of clinically ill cats presenting to one practice in Maine were seropositive for *A. phagocytophilum*.[43] In feral cats in the northeastern United States, *A. phagocytophilum* serum antibodies were detected in 17 of 175 cats (9.7%) and specific DNA was amplified from blood of 12 of 175 cats (6.9%).[44] Serologic cross-reactivity with *A. platys* may also influence these data in both dogs and cats, particularly in areas where *Rhipicephalus sanguineus* is endemic.

The seasonal pattern of disease reflects times of peak nymphal and adult tick activities, as well as periods when humans and their dogs are active outdoors. In the western United States, *A. phagocytophilum* infection occurs most frequently in dogs between April and July, when nymphal ticks are abundant. Some infections occur in October, during early questing of adult ticks. In Minnesota and Wisconsin, most cases are diagnosed in late spring (May, June) and fall (October, November).[45–47] In a study from Berlin, most cases occurred between May and September.[48] The median age of clinically affected dogs is 6 to 8 years (range, 6 months to 14 years).[46,47,49,50] In the upper Midwest of the United States, a bimodal age distribution has been recognized, with 25% of dogs 1 year of age or less, and 50% of dogs at least 8 years of age.[46] Affected cats in the northeastern United States have ranged from 4 months to 13 years of age (mean, 3.7 years).[51] Although no breed predispositions are recognized, in one study, golden retrievers comprised almost half of affected dogs; this may reflect the popularity of these dogs for outdoor activities.[52] Infection with other tick-borne pathogens is a risk factor for *A. phagocytophilum* infection. Evidence for co-infection with *Borrelia burgdorferi* is common because *B. burgdorferi* is transmitted by the same *Ixodes* tick species.[40,45,46] When a population of 731 naturally exposed dogs from one veterinary practice in Minnesota was evaluated, seroreactivity to both *A. phagocytophilum* and *B. burgdorferi* was detected more frequently in dogs with clinical signs compatible with tick-borne illness than in healthy dogs.[45] In northern California, dogs seroreactive to *A. phagocytophilum* were 18 times more likely to be seropositive for *Bartonella vinsonii* subsp. *berkhoffii* than dogs that were seronegative.[53] In cats, seroreactivity to both *A. phagocytophilum* and *B. burgdorferi* is also common.[43,44]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Anaplasma phagocytophilum is transmitted transstadially within the tick (i.e., from larva to nymph to adult), and not transovarially (from adult to egg). Dogs and cats thus become infected after exposure to infected nymphs or adult ticks, which acquire infection when they feed on wild animal reservoir hosts as larvae or nymphs (Fig. 45.3). Ticks must attach for 24 to 48 hours for transmission to occur.[54] Transmission could potentially occur more quickly, as *A. phagocytophilum* can reside in the salivary glands of unfed *Ixodes* spp. ticks.[55] Though the mechanisms of *A. phagocytophilum* entry into the bloodstream are unclear, *in vitro* infection of endothelial cells results in upregulation of cell adhesion molecules and inflammatory mediators

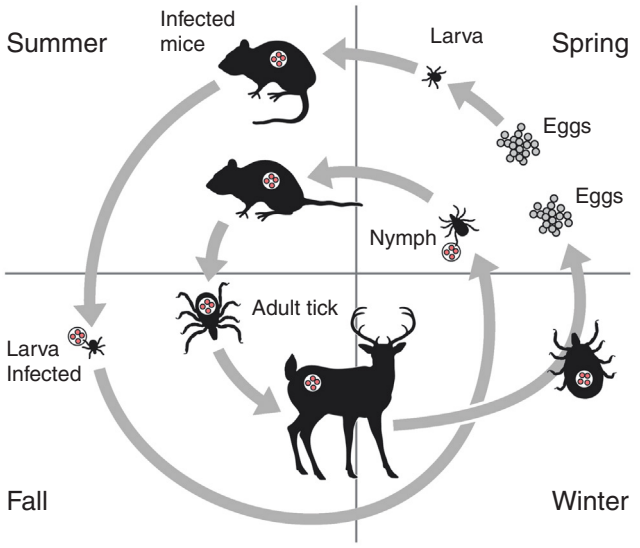

Fig. 45.3 Life cycle of *Ixodes scapularis* ticks and *Anaplasma phagocytophilum* infection. Uninfected larvae (top right) hatch in the late spring and acquire infection from small rodents in the summer. They then overwinter (often in protected mouse burrows) and then molt into nymphs the following spring. The nymphs feed in the late spring or early summer on a variety of animal species including rodents, humans, deer, and dogs. Nymphs molt into adults in the late summer to fall, which subsequently feed on large mammals such as deer, where they mate and drop off. The females then lay eggs and die. Dogs, cats, and humans become infected by nymphs or adult ticks.

that recruit and promote adhesion of neutrophils to the endothelial surface.[56] This may serve as a way for the bacteria to disseminate into the bloodstream. Furthermore, endothelial cells may serve as a reservoir for persistent infection, though this is controversial and may be strain dependent.

Once *A. phagocytophilum* enters the bloodstream, it attaches to the sialylated ligands on the surface of neutrophils, such as P-selectin glycoprotein ligand-1.[38] The organism then enters the neutrophil through caveolae-mediated endocytosis. *Anaplasma phagocytophilum* survives in the harsh neutrophil environment through dysregulation of neutrophil function and by bypassing phagolysosomal pathways. It inhibits neutrophil superoxide production and can reduce neutrophil motility and phagocytosis. *Anaplasma phagocytophilum* also reduces the adherence of infected neutrophils to endothelium and inhibits neutrophil transmigration into tissues, possibly through downregulation of selectin molecule expression.[38] This may promote its survival in peripheral blood. Normally, neutrophils circulate for 10 to 12 hours before they enter tissues and undergo death through apoptosis. *Anaplasma phagocytophilum* delays neutrophil apoptosis, which allows it to survive longer periods of time within the neutrophil.[38] *Anaplasma phagocytophilum* may also infect other cell types, such as bone marrow cells, endothelial cells, and megakaryocytes, although the importance of these cells in the pathogenesis of infection is not clear.

The clinical signs and laboratory abnormalities that occur in dogs and cats with granulocytic anaplasmosis probably vary somewhat in different geographic locations as a result of local strain variation. The vast majority of dogs and cats infected with *A. phagocytophilum* show no clinical signs. Some dogs and cats develop a self-limiting febrile illness, which in dogs occurs after an incubation period of 1 to 2 weeks. Lethargy occurs in almost all clinically affected cats and dogs. Fever and inappetence are also common findings. Lameness, reluctance to move, polydipsia, vomiting, diarrhea, and a soft cough can also occur. Generalized lymphadenopathy and splenomegaly

develop as a result of reactive lymphoid hyperplasia and, in the spleen, concurrent extramedullary hematopoiesis.[57] Uncommonly, hemorrhage, manifested as mucosal petechiae, melena, or epistaxis, has been reported in naturally infected dogs, but co-infections with other tick-borne pathogens may contribute to these signs in some dogs.[47,49,50,58] Neurologic signs such as seizures, circling, cervical pain, and decreased placing reactions have been described in a few dogs from the upper Midwest with granulocytic anaplasmosis, but one dog with seizures had a history of idiopathic epilepsy.[47,58] Neurologic signs and detection of the organism in the CSF have been uncommonly reported in humans.[59,60]

Infection with *A. phagocytophilum* results in mild to moderate, and occasionally severe, thrombocytopenia, although other cytopenias may also occur (Table 45.1). The mechanism(s) of these hematologic abnormalities remain unclear. Though *A. phagocytophilum* are able to infect megakaryocytes, platelet production is not affected.[61] Antiplatelet antibodies occur in serum from humans and dogs with granulocytic anaplasmosis,[49,62] suggesting the possibility of immune-mediated mechanisms of thrombocytopenia. However, thrombocytopenia occurs in acute disease, before antibodies are noted, so other mechanisms may be important. Platelet destruction or consumption might be involved in the observed thrombocytopenia, as the bone marrow of infected dogs shows megakaryocyte hyperplasia.

Impaired neutrophil function as a result of *A. phagocytophilum* infection may predispose to development of secondary opportunistic infections or influence the outcome of co-infections with other tick-borne pathogens such as *B. burgdorferi*. Although uncommon, opportunistic infections have been occasionally documented in humans and dogs with granulocytic anaplasmosis and are well recognized in small ruminants.[63]

Infection with *A. phagocytophilum* appears to be self-limiting in many infected dogs and cats, with minimal fatality. Whether persistence of infection and chronic disease manifestations exist is controversial and may be dependent on the infecting strain and host immune response to infection. In one study, prednisolone treatment of three dogs that were experimentally inoculated with a Swedish strain of *A. phagocytophilum,* up to 6 months after infection was followed by the development of positive PCR results for the organism and, in some dogs, thrombocytopenia and reappearance of morulae on blood smears.[64] None of these dogs were treated with doxycycline. In another study, six dogs were inoculated with *A. phagocytophilum* via ticks harvested in the northeastern United States.[65] Prednisolone administration did not result in reactivation of infection regardless of whether or not the dogs were treated with doxycycline prior to immunosuppression. However, one dog's blood was positive for *A. phagocytophilum* via PCR 24 weeks after inoculation. Persistent infection is not recognized in humans,[66] and there is little evidence for persistent infection in naturally infected dogs; thus, the clinical significance of these experimental findings remains unclear.

Physical Examination Findings

The most common findings on physical examination in dogs include lethargy, fever (up to 106.7°F [41.5°C]), dehydration, tachypnea, mild peripheral lymphadenopathy, and splenomegaly.[38,61] Scleral injection in dogs and conjunctivitis in cats may be noted. Lameness, reluctance to move, swollen joints, and pain on joint manipulation may also be detected in some dogs. Increased lung sounds, abdominal pain, diarrhea, epistaxis, petechial hemorrhages, and neurologic signs such as circling, cervical pain, and decreased placing reactions occur uncommonly.

Physical examination findings reported in cats have been similar to those described in dogs, and include fever, lethargy, tachypnea, increased lung sounds, mild abdominal pain, hepatomegaly, splenomegaly, vomiting, ataxia, hyperesthesia, muscle and joint pain, lameness, conjunctivitis, and ocular discharge.[39,51,67–69]

DIAGNOSIS

Laboratory Abnormalities

Granulocytic anaplasmosis should be suspected in dogs and cats with acute febrile illness and thrombocytopenia that reside in endemic areas, regardless of tick exposure history. Diagnosis relies on detection of morulae within granulocytes, results of acute and convalescent serology, or molecular testing using PCR assays. The diagnostic criteria for confirmed human granulocytic anaplasmosis are clinical signs and laboratory findings suggestive of granulocytic anaplasmosis together with: (1) a fourfold rise in antibody titer to *A. phagocytophilum*; (2) presence of *A. phagocytophilum* antigen in tissue via immunofluorescence; (3) a positive PCR test result using specific *A. phagocytophilum* primers; or (4) isolation of *A. phagocytophilum* from blood.[66] Consistent clinical signs along with either detection of morulae in the blood or a single positive antibody titer of ≥ 640 is considered supportive of, but not diagnostic for, infection.[66] These criteria could also be applied to dogs. The use of multiple diagnostic modalities may be needed to confirm the diagnosis of granulocytic anaplasmosis in some dogs and cats.

TABLE 45.1 Hematologic Abnormalities in 10 Dogs with Granulocytic Anaplasmosis in Minnesota[a]

Test	Reference Range	Median	Range	Number Below Reference Range	Number Within Reference Range	Number Above Reference Range
Hematocrit (%)	37.5–60.3	39.8	34.7–48.9	3	7	0
Neutrophils (cells/μL)	2,100–11,200	6,180	2,870–7,540	0	10	0
Band neutrophils (cells/μL)	0–130	40	0–160	0	9	1
Monocytes (cells/μL)	0–1,200	150	0–490	0	10	0
Lymphocytes (cells/μL)	780–3,360	370	190–910	9	1	0
Eosinophils (cells/μL)	0–1,200	0	0	0	10	1
Platelets (cells/μL)	129,000–395,000	73,000	35,000–166,000	9	1	0

[a]Diagnosis was based on compatible clinical signs and morulae within circulating neutrophils.

Complete Blood Count

Thrombocytopenia occurs in approximately 90% of dogs with granulocytic anaplasmosis.[46,47,49,50,70] The platelet count in thrombocytopenic dogs is often mild to moderately decreased, though can occasionally be as low as 5,000 platelets/μL (see Table 45.1).[46,47,49,50,70] In one study of 54 thrombocytopenic dogs with PCR-confirmed granulocytic anaplasmosis, 39% had severe thrombocytopenia, with platelet counts below 30,000/μL.[70] The majority of affected dogs are lymphopenic, but lymphocytosis can occur.[47,49,50] Circulating reactive lymphocytes may be present. Anemia is common and typically mild and nonregenerative. In one study, a direct Coombs test was positive in 17% of dogs tested, suggesting a possible immune-mediated component to anemia in some dogs.[70] Both neutrophilia and neutropenia occur, but most dogs have neutrophil counts that lie in the lower half of the reference range. Low numbers of band neutrophils, as well as mild neutrophil toxicity, are often present. Monocytopenia or monocytosis can occur.[47,49,50] Cytologic examination of blood smears often reveals morulae within granulocytes (Fig. 45.4). Morulae were detected in neutrophils from 36%, 56%, 67%, and 100% of dogs in four respective case series.[47,49,50,52] Morulae appear as early as 4 days after experimental inoculation of dogs, well before seroconversion, and persist for 4 to 8 days.[57] The morulae are indistinguishable from those of *Ehrlichia ewingii*, so serology or PCR assays are needed to confirm *A. phagocytophilum* infection.

Presence of thrombocytopenia in cats with PCR-confirmed granulocytic anaplasmosis is variable and moderate in severity when it occurs. In two reports from the northeastern United States, 2 of 5 cats and 7 of 16 cats had thrombocytopenia at the time *A. phagocytophilum* DNA was amplified from blood.[69,71] In cats infected with *A. phagocytophilum* and *B. burgdorferi* after infestation with *I. scapularis* wild caught ticks from Rhode Island, lymphopenia was the only significant CBC finding. In one study of 16 cats, lymphopenia was detected in 7 of 11 cats with CBC results available for review.[71] In the same 11 cats, morulae were detected in neutrophils of three cats.

Serum Biochemical Tests

The most frequent serum biochemistry finding in dogs with granulocytic anaplasmosis is mild to moderate hypoalbuminemia (Table 45.2). Mild hyperglobulinemia, mild electrolyte abnormalities (hypokalemia, hyponatremia, and metabolic acidosis), and a mild increase in the activities of serum ALP and to a lesser extent ALT may occur.[47,50,52,61,70] Abnormalities in serum biochemical panel results from experimentally or naturally infected cats are uncommon.[39,69,71,72]

Urinalysis

Urinalysis in dogs with granulocytic anaplasmosis may reveal isosthenuria, hyposthenuria, and proteinuria. Increased urine protein-to-creatinine ratios were reported in two affected dogs from the United States (1.5 and 2.2),[61] but there is no evidence that *A. phagocytophilum* infection causes severe glomerulonephritis in dogs. Proteinuria was detected by dipstick in 2 of the 4 naturally infected cats tested in one report of 16 cases.[71]

Synovial Fluid Analysis

Dogs with granulocytic anaplasmosis can develop neutrophilic polyarthritis. In one study, 13 of 63 dogs had clinical signs and physical examination findings of lameness and 3 had synovial fluid cytologic findings consistent with immune-mediated polyarthritis.[70] Cytologic examination of synovial fluid in these dogs revealed increased numbers of nondegenerate neutrophils. In some affected dogs, morulae are found within these cells and the synovial fluid can be PCR positive (Fig. 45.4C).[70]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs are usually normal in dogs with granulocytic anaplasmosis but may show a mild interstitial infiltrate. Focal alveolar infiltrates occur as well.[73]

Sonographic Findings

Abdominal ultrasound may reveal splenomegaly, with a hypoechoic spleen, or mild abdominal lymphadenomegaly.

Microbiologic Tests

Diagnostic assays available for anaplasmosis in dogs and cats are shown in Table 45.3.

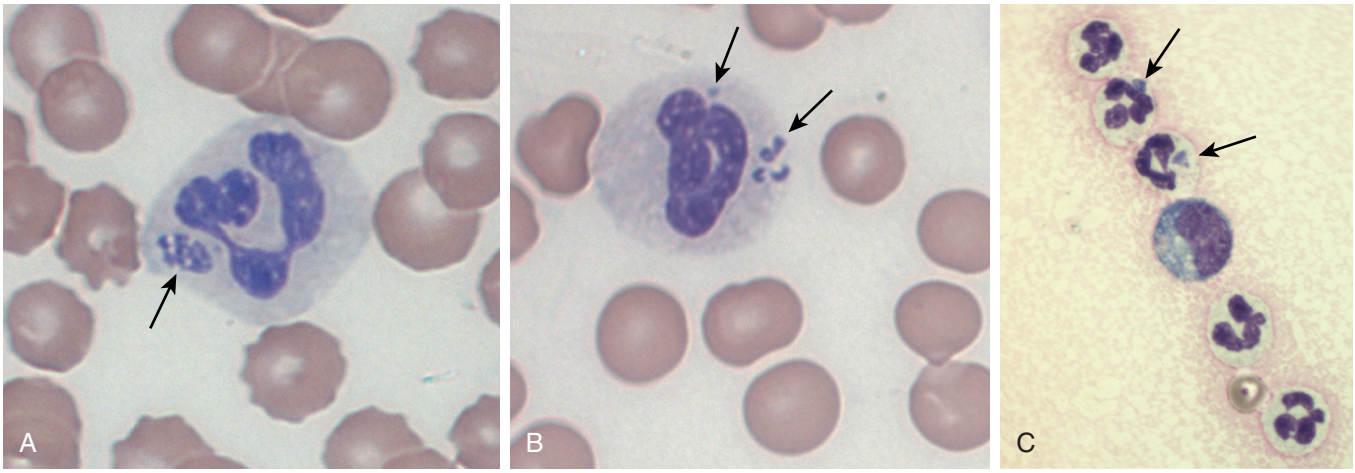

Fig. 45.4 (A) Intracytoplasmic morula and (B) cocci of *Anaplasma phagocytophilum (arrows)* within the neutrophils of an 8-year-old male neutered golden retriever with granulocytic anaplasmosis. (C) Morulae (*arrows*) are present in neutrophils within the synovial fluid of a 5-year-old curly-coated retriever that had polyarthritis.

TABLE 45.2 Findings on Serum Biochemistry Analysis in 10 Dogs with Granulocytic Anaplasmosis in Minnesota[a]

Test	Reference Range	Median	Range	Number Below Reference Range	Number Within Reference Range	Number Above Reference Range
Sodium (mmol/L)	145–153	144	137–147	8	2	0
Potassium (mmol/L)	3.6–5.3	4.0	3.7–4.4	0	10	1

[a]Diagnosis was based on compatible clinical signs and morulae within circulating neutrophils.

Serologic Diagnosis

Diagnosis of granulocytic anaplasmosis can be accomplished with acute and convalescent serology. Many veterinary laboratories perform serologic testing using IFA techniques. IgG antibodies are first detectable approximately 8 days after exposure, 2 to 5 days after morulae appear. As a result, early in the course of illness, antibodies may be undetectable. PCR assays may be more useful for diagnosis of acute infection in the absence of detectable morulae. Because positive titers can reflect previous exposure, demonstration of a fourfold rise in titer is required. Antibody titers may persist for many months.[52,64] In some human patients, antibody titers have persisted as long as 3 years.[63] In the United States, a silicon disc-based ELISA assay is available commercially for detection of antibodies to *A. phagocytophilum* (Accuplex 4, Antech Diagnostics, Irvine, CA, USA). The performance of this assay when compared with IFA requires further study. An in-clinic lateral-flow ELISA device (SNAP 4Dx Plus, IDEXX Laboratories, ME, USA), which uses a recombinant Msp2/p44 protein, is also available for the detection of antibodies to *Anaplasma* species in dog serum. Positive results obtained with these ELISA assays do not imply that *A. phagocytophilum* is the cause of illness, and as with IFA testing, negative results can occur in dogs with acute illness due to the lag in antibody production relative to the onset of clinical signs.

Serologic cross-reactivity between *Anaplasma* species occurs. Dogs infected with *A. platys* also seroreact to *A. phagocytophilum* antigen; this includes the recombinant Msp2 assay.[40] Serologic cross-reactivity between *A. phagocytophilum* and *Ehrlichia canis* also occurs, but is relatively uncommon and minor.[50,73,74] Dogs diagnosed with granulocytic anaplasmosis that have antibodies to *A. phagocytophilum* generally lack antibodies to *E. canis* using IFA testing.[38,40]

While not approved by the USDA for use with feline serum, one commercially available device (SNAP 4Dx Plus, IDEXX Laboratories, ME, USA) has been shown to detect *A. phagocytophilum* and *B. burgdorferi* antibodies in sera from naturally exposed and experimentally infected cats.[43,72] Antibodies against *A. phagocytophilum* in feline sera can also be detected by IFA.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Several endpoint and real-time PCR assays for *A. phagocytophilum* exist for detection of *A. phagocytophilum* DNA in peripheral blood, buffy coat, bone marrow, or splenic tissue. These can be useful for early diagnosis of granulocytic anaplasmosis in dogs and cats. The sensitivity and specificity of PCR assays may vary depending on the assay design and the laboratory used. Most, but not all, assays detect either the 16S rRNA gene or the outer surface protein gene *msp2* (p44). Assays that detect the *msp2* gene are usually specific for *A. phagocytophilum*, whereas assays that detect the 16S rRNA gene may detect other *Anaplasma* species, and even other bacteria. *Anaplasma phagocytophilum* DNA has occasionally been amplified from healthy dogs, so results must be interpreted in light of the clinical signs.[45] In experimentally infected dogs, whole-blood PCR becomes positive several days before and after morulae appear on blood smears.[57,64]

In cats that are experimentally infected with *A. phagocytophilum* and *B. burgdorferi* following *I. scapularis* infestation, DNA can be amplified from blood up to 2 weeks before detection of antibodies.[72] This has also been documented in some field cases.[69]

Culture

Anaplasma phagocytophilum can be isolated in human promyelocytic leukemia cell lines (HL-60) and tick embryo cell lines. Culture is highly sensitive for diagnosis of acute infection in human patients,[75] but it is not routinely used in dogs for diagnostic purposes because it requires special facilities, technical expertise, and prolonged incubation.

Pathologic Findings

Little information is available regarding the pathology of granulocytic anaplasmosis in dogs or cats. Tissue injury appears to result from the host inflammatory response, rather than the bacterial infection itself.[76] In humans, splenic lymphoid depletion, macrophage aggregates and apoptosis within the liver, paracortical lymphoid hyperplasia, and hemophagocytic cells within reticuloendothelial tissues have been described.[77]

TREATMENT AND PROGNOSIS

The treatment of choice for granulocytic anaplasmosis in dogs and cats is doxycycline (5 mg/kg, PO, q12h).[39,78] In 16 naturally infected dogs, doxycycline therapy for 28 days resulted in clinical resolution in all dogs, and all dogs were negative by molecular testing of blood 1 and 2 months after initiation of therapy.[78] The optimum duration of

TABLE 45.3 Diagnostic Assays Available for Anaplasmosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Whole blood	*Anaplasma phagocytophilum*; *Anaplasma platys* cannot be cultured	Not widely offered or utilized for routine diagnostic purposes. Requires several weeks' incubation.
Cytology	Whole blood, buffy coat smears, body fluids, tissue aspirates	*A. phagocytophilum* or *A. platys* morulae	Low sensitivity (especially for *A. platys* infection). Morulae of *A. phagocytophilum* cannot be distinguished from those of *Ehrlichia ewingii*. Morulae may be confused with cytoplasmic granules or stain precipitate.
IFA serology	Serum	Antibodies to *Anaplasma* spp.	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative in dogs with acute disease and positive results may reflect previous exposure rather than active infection. Cross-reactivity occurs between *Anaplasma* spp.
ELISA serology	Serum	Antibodies to *Anaplasma* spp. antigens	Rapid, inexpensive, can be performed as an in-practice test. Similar limitations as IFA. Lack of quantitation limits ability to document seroconversion.
PCR	Whole blood, splenic or lymph node aspirates, bone marrow aspirates, buffy coat specimens, tissue specimens	*A. phagocytophilum* or *A. platys* DNA	Confirms active infection. Sensitivity and specificity may vary depending on assay design and specimen type. Because healthy animals may be PCR positive, positive PCR results must be interpreted in light of the clinical signs.

ELISA, enzyme-linked immunosorbent assay; *IFA,* immunofluorescent antibody; *PCR,* polymerase chain reaction.

therapy is unknown, but 2 weeks appears to be sufficient. The prognosis is excellent. Most dogs show clinical improvement within 24 to 48 hours of treatment, although some dogs require more than 1 week of treatment before clinical signs resolve.[46,50,78] Platelet counts often normalize 2 to 14 days after treatment is initiated, though in one study 4/16 dogs remained thrombocytopenic after a 4-week course of doxycycline.[46,78] In one study, 30% of 23 owners reported that their dog returned to normal activities in 1 to 2 days after treatment was initiated, 30% reported this took 3 to 5 days, 21% reported this took 1 to 3 weeks, and 17% reported that it took 1 month or longer for their dogs to return to normal activity.[46] Death due to granulocytic anaplasmosis has not been described in dogs or cats. Intravenous crystalloid fluids and antiemetics may be required for supportive care until clinical signs improve.

IMMUNITY AND PREVENTION

The immune response to *A. phagocytophilum* infection is not fully characterized. Both humoral and cell-mediated immune responses appear to be important in clearance of infection. Host cytokines such as IFN-γ may play a role in the initial control of *A. phagocytophilum* infection[79,80] but may also contribute to the inflammatory process associated with disease.[81] In lambs, *A. phagocytophilum* evades the host immune response through differential expression of MSP2, an outer surface protein involved in immune recognition.[82] Variation in MSP2 also occurs in chronically infected woodrats.[83] Further research is required to document whether persistence occurs through similar mechanisms in other host species. It is possible that recovery from natural infection confers long-term protection against development of disease. Reinfection has not been reported in dogs, but was described in one human patient.[84]

A vaccine for granulocytic anaplasmosis is not available for companion animals. There is one study of cats experimentally infested with *A. phagocytophilum* and *B. burgdorferi* containing ticks from Rhode Island, twice, 6 months apart.[85] In that study, repeated infection was documented in one of the four cats with primary *A. phagocytophilum* infection, suggesting that immunity against the agent was not permanent.

Infection may be prevented by avoidance of tick exposure, prompt tick removal, and use of topical ectoparasiticides (see Chapter 13). Although not a guaranteed protection, combinations of topical imidacloprid and permethrin; or fipronil, amitraz, and (*S*)-methoprene; and imidacloprid and flumetrin prevent transmission of *A. phagocytophilum* to dogs from infected ticks.[86–88]

PUBLIC HEALTH ASPECTS

Anaplasma phagocytophilum infection was first recognized in humans in the upper Midwest of the United States in the early 1990s and has since been increasingly recognized in humans from the United States, Europe, and Asia. Men are affected slightly more frequently than women. In Europe, the disease is most commonly reported in Sweden and Slovenia, where it was first reported in 1997, and those involved in forestry, hunting, farming, and veterinary care are at most risk.[89,90] Morulae are observed less often in humans with granulocytic anaplasmosis in Europe, and the disease may be milder than that described in humans from the United States.

Human granulocytic anaplasmosis closely resembles the disease in dogs, which has been described as an "influenza-like illness after a tick bite."[91] The most common clinical signs reported in human patients are myalgia, headache (which is often severe), malaise, and chills. Anorexia, nausea, arthralgias, and cough may also occur.[66,91,92] The disease typically resolves within 2 months in the absence of appropriate antibiotic treatment. Occasionally, more severe disease may occur. In one study, up to 17% of affected humans required admission to an intensive care unit.[91] Death occurs in 1% or fewer clinically affected humans, usually as a result of complications such as a septic or toxic shock–like syndrome, respiratory insufficiency, opportunistic fungal or viral infections, rhabdomyolysis, acute renal failure, hemorrhage, or neurologic disease.[66] Severe illness tends to occur in humans of advanced age or with concurrent immunosuppressive illness or drug

therapy. Peripheral blood neutrophils containing morulae are present in 80% of cases, though only a low number of neutrophils may be infected.[91] Laboratory testing of peripheral blood typically reveals normal or slightly decreased white blood cell and platelet counts, sometimes with a neutrophilic left shift, and mild to moderate elevation of hepatic transaminase activities. In the United States, the disease is reportable to the CDC. Dogs act as sentinels for human exposure and may be a source of infection through mechanical carriage of infected ticks to humans.[93,94] Blood from affected dogs should be handled with caution, needle-stick injuries should be avoided, and precautions should always be taken when performing necropsies on an animal with suspected *A. phagocytophilum* infection.

ANAPLASMA PLATYS INFECTION

Trevor Waner, Shimon Harrus, Mathios Mylonakis

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Anaplasma platys (previously *Ehrlichia platys*), is the cause of infectious canine cyclic thrombocytopenia (ICCT). The disease was first described by Harvey *et al.* in the United States in 1978[6] and since then it has been reported worldwide.[95] *Anaplasma platys* is an obligatory intracellular rickettsial organism which has a tropism for platelets (Figs. 45.5 and 45.6). To date, the organism has not been cultivated *in vitro*. The reclassification of the organism in 2001 as *Anaplasma* was based on nucleotide sequences of the heat shock protein gene (*groEL*), the heat shock operon (*groESL*), and the citrate synthase gene (*gltA*).[8]

Based on the identification of *A. platys* DNA in *Rh. sanguineus* (the brown dog tick) from different regions of the world, and the molecular evidence for transstadial transmission by *Rh. sanguineus* sensu lato, it is most likely that *A. platys* is transmitted by this tick species.[96,97] One study from Thailand identified *A. platys* DNA in *Dermacentor auratus* ticks from dogs.[98] Notwithstanding, no evidence was present that this tick species could potentially transmit the organism to dogs. The possibility that *D. auratus* ticks may have passively ingested *A. platys* while feeding on infected dogs is more likely.

Recent studies have suggested that vertical transmission of *A. platys* from pregnant bitches to their offspring (maternal transmission), during the first half of gestation, might occur.[99,100]

Although the disease has been identified as a disease of dogs, there is growing evidence that *A. platys* can infect a number of other animal species. Molecular evidence has identified the possibility of infection of cats with *A. platys*.[7,101] In both reports, the cats were thrombocytopenic. One of the cats had anorexia and inclusion bodies were observed in platelets.[7] In Portugal, *A. platys* has been reported in dogs, ticks, and red foxes, and recently in red deer and wild boars.[102] Other animals reported to be infected with *A. platys* include Bactrian camels in Xinjiang, China[103]; Arabian camels (*Camelus dromedarius*) in Tunisia[104]; and cattle in Algeria.[105] The ability of *A. platys* to cause disease in these host species has not been established. The importance of these findings lies in the possibility that these animals may serve as a reservoir for *A. platys*.

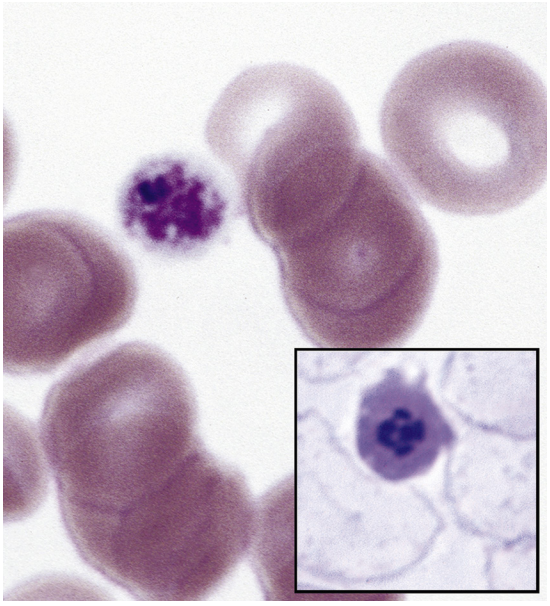

Fig. 45.5 *Anaplasma platys* in a platelet from a dog with infectious cyclic thrombocytopenia (Giemsa stain, ×2500). *Insert*, platelet containing morula of *A. platys* (new methylene blue, ×2300).

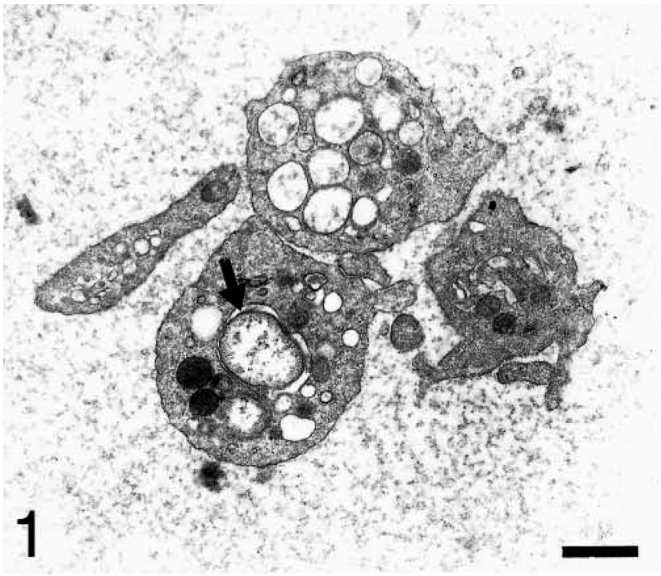

Fig. 45.6 Transmission electron micrograph of a platelet containing *Anaplasma platys* (arrow). The specimen examined was a peripheral blood platelet concentrate collected from a dog on day 18 after experimental infection. Bar = 1 µm. (From Arraga-Alvarado C, Palmar M, Parra O, Salas P. Ehrlichia platys (Anaplasma platys) in Dogs from Maracaibo, Venezuela: An Ultrastructural Study of Experimental and Natural Infections. *Veterinary Pathology*. 2003;40(2):149–156.)

CLINICAL FEATURES

Pathogenesis and Clinical Signs

There is some evidence that a variation in the virulence and pathogenesis of different *A. platys* strains exists between the United States and Australia compared with countries bordering the Mediterranean basin, suggesting that *A. platys* strains from the latter geographic locations are more pathogenic.[106] Co-infection with other vector-borne pathogens, which can modify or even exacerbate clinical signs, may also influence disease severity.[107] Increased intraoperative hemorrhage was described in dogs co-infected with *A. platys* and *E. canis*,[107] but this more likely reflects the influence of *E. canis*, which is the more pathogenic rickettsial species.

Dogs with milder forms of infection may show minimal clinical signs such as fever and hematochezia; rarely more severe clinical signs have been recognized.[108] These include anorexia, fever, cutaneous petechiae, ecchymoses, hyphema, hematuria, hematochezia, and epistaxis. Cutaneous signs including hyperkeratosis, alopecia, and erythema have been described in a study of 32 naturally infected dogs from the Mediterranean basin region.[109] However, the authors noted that although the prevalence of cutaneous signs was high (31.3% of dogs), the results should be interpreted carefully as other vector-borne diseases that cause cutaneous lesions are endemic in the area. Lethargy and musculoskeletal disorders were observed less often, and splenomegaly, ocular lesions, and dehydration were infrequently observed.[109]

DIAGNOSIS

Laboratory Abnormalities

Thrombocytopenia is the hallmark of *A. platys* infection. Mild nonregenerative anemia may also occur. Blood smear evaluation may reveal reactive lymphocytes and monocytes.[109] Morulae in the platelets have been documented to be present in dogs artificially infected IV with *A. platys* after 7 to 19 days.[110] Cycles of thrombocytopenia may occur at intervals of 1 to 2 weeks.[95]

Microscopic Detection in Blood Smears

Diagnosis can be made when the morulae are observed within platelets on blood smears (see Fig. 45.5); however, this is insensitive. The cyclic nature of the thrombocytopenia severely limits this diagnostic technique due to the low levels of bacteremia during thrombocytopenic episodes (Fig. 45.7); therefore, additional tests are recommended in order to confirm a diagnosis. Moreover, platelet inclusions such as dense bodies and alpha granules can be mistaken for morulae.

Serologic Testing

Serologic cross-reactivity exists between *A. platys* and *A. phagocytophilum*[111]; however, cross-reactivity between *A. platys* and *E. canis* is negligible.[112] Seroconversion of experimentally infected dogs occurs shortly after the first episode of bacteremia.[113] An immunoblot analysis based on recombinant *A. platys* major outer membrane proteins, P44 and Omp-1X, has been developed as a simple tool for the detection of antibodies against *A. platys*.[114] However, such assays require laboratory expertise.

Point-of-care (POC) ELISA test kits that detect *Anaplasma* antibodies are available commercially (e.g., SNAP 4Dx Plus Test, IDEXX Laboratories, Westbrook, ME, USA).[115,116] Due to the cross-reaction between *A. platys* and *A. phagocytophilum* antibodies, it is not possible to distinguish between the two, which can be problematic when both agents exist in the same geographic region. A positive result indicates exposure to either or both of the agents. It should also be taken into account that antibodies to *A. platys* only develop 1 to 2 weeks after infection; therefore, a recently infected dog might be seronegative to *A. platys*. A continuingly rising titer (paired titers) would indicate an active infection with either agent.

Molecular Detection

Considering the limitations of microscopy and serology in the diagnosis of *A. platys* infection, molecular detection is considered the most sensitive and specific diagnostic test. A number of PCR-based assays have been developed to detect *A. platys* in infected dogs and are offered by commercial veterinary diagnostic laboratories, often as part of vector-borne pathogen panels. A POC loop-mediated isothermal amplification (LAMP)-based assay has been developed.[117] Such assays may assist in rapid diagnosis, although further assessment of their clinical performance is required.

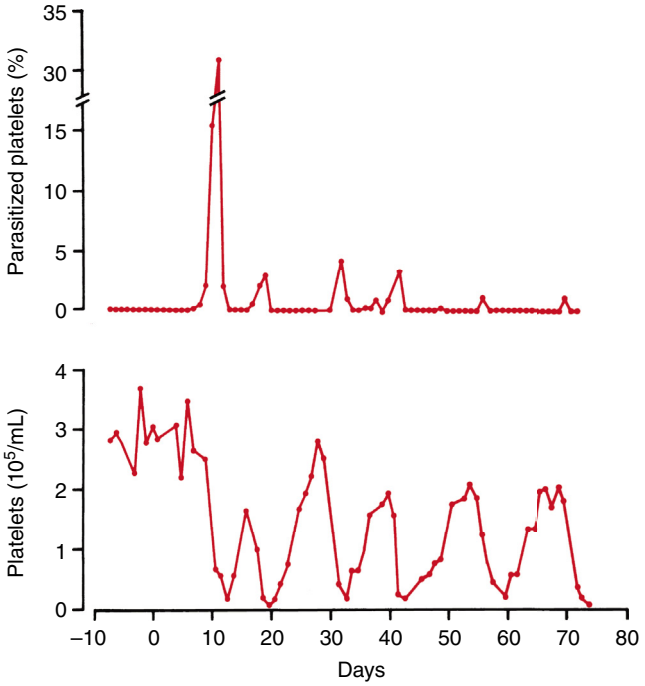

Fig. 45.7 Percentage of infected platelets and platelet counts from a dog inoculated intravenously with *Anaplasma platys*; 0 on the abscissa represents the day of inoculation. (From Harvey JW, Simpson CF, Gaskin JM. Cyclic thrombocytopenia induced by a *Rickettsia*-like agent in dogs. *J Infect Dis* 137:182–188. Reprinted with permission from the University of Chicago.)

TREATMENT AND PROGNOSIS

Although the optimal doxycycline dose and period of treatment of dogs with ICCT is unknown, a similar treatment protocol as recommended for *E. canis* (10 mg/kg doxycycline, PO, q24h) for 21 days is currently recommended.[118,119] However, some dogs with the more severe Mediterranean form of ICCT may not respond to 28 days of doxycycline at this dose.[109]

Infection with *A. platys* has also been documented to be a potential causative agent of secondary IMHA.[120] This should be considered in the course of the treatment and may affect the prognosis and the outcome of treatment.

As ticks are responsible for the natural transmission of *A. platys*, vector control prophylaxis is recommended to prevent the spread of ICCT (see Chapters 13 and 109).

PUBLIC HEALTH ASPECTS

Infection with *A. platys* was documented in two women from Venezuela.[121] In one case, *A. platys* morulae were identified ultrastructurally and in the second case *A. platys* DNA was amplified. In another report, a veterinarian with extensive animal and vector exposure in Grenada, Ireland, and South Africa was diagnosed with a coinfection of *A. platys, Bartonella henselae,* and a *Mycoplasma* species.[122] Furthermore, emphasizing the zoonotic potential of *A. platys,* sequential PCR testing has provided molecular evidence supporting intravascular persistence of *A. platys* and *Ehrlichia* spp. in two humans and their dog.[123]

CASE EXAMPLE

Signalment
"Loki," a 2-year-old male neutered Siberian Husky dog from Minneapolis, MN.

History
Loki's owner reported a 3-day history of inappetence and lethargy and a 2-day history of vomiting. Diarrhea was not observed. Loki continued to drink normally. Loki's owner also noted that he had been displaying some reluctance to lie down. The owner removed a tick from Loki about 1 week before presentation. He was up to date on core vaccines. Loki had no travel history outside of Minnesota.

Physical Examination
Body weight: 29.0 kg.
General: Quiet, alert, and responsive. Temperature = 104.3°F (40.2°C), HR = 130 beats/minute, RR = 32 breaths/minute, mucous membranes pink, CRT = 1 second.
Integument: Healthy haircoat was present. No ectoparasites observed. No evidence of petechiation or ecchymoses.
Eyes, ears, nose, and throat: No significant abnormalities were noted. Mild dental plaque and calculus of canine teeth, maxillary fourth premolars, and mandibular first molars. Mild amount of ceruminous debris was present within both ear canals.
Musculoskeletal: Normal gait and range of motion of joints in all limbs. Repeatedly painful on palpation of thoracolumbar spine. No pain on palpation of hips, stifles, tarsi, elbows, or carpi. No joint effusion detected.
Cardiovascular: Normal heart rhythm. Femoral pulses strong and synchronous. No murmurs detected.
Respiratory: Normal rate and effort. Normal bronchovesicular sounds. No crackles or wheezes on auscultation.
GI and genitourinary: Painful on palpation of mid to caudal abdomen (possibly referred back pain). No obvious masses, organomegaly, or fluid waves detected.
Lymph nodes: Peripheral lymph nodes small and symmetrical.

Laboratory Findings
CBC: HCT 37.0% (37.5%–60.3%), MCV 68.1 fL (63–75.3 fL), MCHC 34.7 g/dL (33.6–37.4 g/dL), WBC 6920 cells/μL (3,880–14,570 cells/μL), neutrophils 6,570 cells/μL (2,100–11,200 cells/μL), lymphocytes 280 cells/μL (780–3,360 cells/μL), monocytes 70 cells/μL (0–1200 cells/μL), platelets 65,000 platelets/μL (129,000–395,000 platelets/μL).
Blood smear findings: 1+ echinocytes, 1+ reactive lymphocytes, 1+ large platelets, few morulae present within neutrophils.
Serum chemistry profile: Sodium 137 mmol/L (145–153 mmol/L), potassium 4.1 mmol/L (3.6–5.3 mmol/L), chloride 105 mmol/L (109–118 mmol/L), bicarbonate 17.4 mmol/L (15–25 mmol/L), phosphorus 3.8 mg/dL (3.3–6.8 mg/dL), calcium 10.1 mg/dL (9.3–11.5 mg/dL), BUN 8 mg/dL (9–31 mg/dL), creatinine 0.9 mg/dL (0.6–1.6 mg/dL), glucose 107 mg/dL (75–117 mg/dL), total protein 6.6 g/dL (5.0–6.9 g/dL), albumin 3.0 g/dL (2.7–3.7 g/dL), globulin 3.6 g/dL (1.7–3.5 g/dL), ALT 48 U/L (22–92 U/L), AST 39 U/L (16–44 U/L), ALP 132 U/L (8–139 U/L), creatine kinase 115 U/L (36–348 U/L), GGT 3 U/L (0–6 U/L), cholesterol 440 mg/dL (143–373 mg/dL), total bilirubin 0.3 mg/dL (0–0.3 mg/dL), magnesium 2.2 mg/dL (1.7–2.4 mg/dL).
Urinalysis: SPG 1.007; pH 7.5, no protein (SSA), no bilirubin, no hemoprotein, no glucose, 0–1 WBC/HPF, occasional RBC/HPF, no crystals, 5–20 lipid droplets/HPF.

Imaging Findings
Abdominal radiographs: Serosal margin detail was good throughout the abdomen. The stomach was mildly distended with gas. Small intestinal size was diffusely normal, and the gas content of the small intestine was appropriate. No fecal material was identified in the colon, but there was no colonic distention. The liver, spleen, and kidneys appeared normal. The urinary bladder was moderately to markedly distended with fluid. Fluid was persistently present in the caudal portion of the intrathoracic esophagus. The caudal vena cava was mildly small. No musculoskeletal abnormalities were seen.

Serology
Negative for heartworm antigen, negative for antibodies to *Anaplasma, Ehrlichia,* and *Borrelia* (SNAP 4Dx Plus Assay, IDEXX Laboratories, ME, USA).

Diagnosis
Canine granulocytic anaplasmosis.

Treatment
Doxycycline, 5 mg/kg PO q12h for 14 days; maropitant 2 mg/kg PO q24hr for 3 days; carprofen 1.9 mg/kg PO q12hr for 5 days. Fever resolved and appetite improved within 24 hours after initiation of treatment. Loki was back to normal within 3 days.

Comments
This dog was diagnosed with granulocytic anaplasmosis based on the presence of characteristic cytologic findings of morulae within neutrophils on blood smear evaluation. The morulae were presumed to be due to *A. phagocytophilum* and not *E. ewingii,* which can have an identical cytologic appearance, due to the restricted geography of these infections. The thoracolumbar pain present in this dog was unusual, but could have been associated with polyarthritis, despite no obvious effusion of limb joints. The timing of clinical signs approximately 1 week after tick exposure is consistent with the acute nature of this infection. Loki was seronegative using the SNAP 4Dx Plus test (IDEXX Laboratories) as it was too early in the course of disease for seroconversion. This highlights the need for additional testing for diagnosis. In this case, morulae were present within granulocytes on blood smear evaluation, though this is not always the case. Additional testing could have included PCR of whole blood.

Spotted Fever Rickettsioses, Flea-Borne Rickettsioses, and Typhus

Linda Kidd, Edward B. Breitschwerdt

KEY POINTS

- First Described: *Rickettsia rickettsii* was first described in Montana, United States, 1909[1] (Ricketts).
- Cause: *Rickettsia rickettsii*, a gram-negative, obligately intracellular bacteria. Other spotted fever group (SFG) *Rickettsia* spp., typhus group (TG) *Rickettsia* spp., and *Rickettsia felis* (a separate lineage designated ancestral group) are important causes of emerging infectious disease in people. *Rickettsia conorii*, a SFG *Rickettsia* spp., causes Mediterranean spotted fever (MSF) in people and a doxycycline-responsive disease in dogs that is similar to Rocky Mountain Spotted Fever (RMSF). A novel *Rickettsia* species causing a febrile illness similar to *R. rickettsii* and *R. conorii* has been more recently reported in dogs in the United States.
- Affected Hosts: Humans and dogs (*R. rickettsii*).
- Geographic Distribution: North, Central, and South America.
- Primary Mode of Transmission: Ticks (*Dermacentor* spp., *Rhipicephalus sanguineus, Amblyomma* spp.). Most affected dogs lack a history of a tick bite. *Rickettsia conorii* is transmitted by *Rh. sanguineus* in the Mediterranean basin.
- Major Clinical Signs: RMSF is generally an acute, febrile illness. Clinical signs are consistent with a vasculitis because *R. rickettsii* infects endothelial cells. Major clinical signs include fever, vomiting, ocular signs (retinal hemorrhage, uveitis, episcleral injection), lymphadenomegaly, splenomegaly, peripheral edema, cutaneous hyperemia and necrosis, polyarthritis, and neurologic signs. Signs may be complicated by prior or simultaneous infection with other tick-borne pathogens. The degree to which other SFG *Rickettsia*, TG *Rickettsia,* and *R. felis* cause illness in dogs and cats is being investigated.
- Differential Diagnoses: Infection with other tick-borne agents such as *Anaplasma phagocytophilum, Ehrlichia* spp., *Bartonella* spp., *Babesia* spp., and *Borrelia burgdorferi* should be considered. Other causes of severe systemic decompensation and vasculitis such as sepsis and SIRS due to other causes may mimic RMSF. Leptospirosis and other causes of vasculitis and thrombocytopenia may also mimic RMSF. Other differential diagnoses for the neurologic signs seen in RMSF must also be considered. Appropriate antimicrobial treatment with doxycycline must begin before the diagnosis is confirmed by laboratory testing. Misdiagnosis and delayed or inappropriate antimicrobial drug therapy increase morbidity and mortality.
- Human Health Significance: Owners and their physicians should be contacted whenever RMSF is diagnosed in any canine patient, because illness in dogs can coincide with or precede illness in humans. Dogs also are sentinels for MSF in people. Control of flea and tick vectors on dogs and cats is important to prevent rickettsioses in people.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Rickettsial diseases are important causes of morbidity and mortality in dogs and humans worldwide. The terms "rickettsial disease," "rickettsioses," and even the term "*Rickettsia*" have been used to refer to several obligately intracellular organisms including *Rickettsia, Bartonella, Ehrlichia, Anaplasma, Coxiella,* and *Neorickettsia*. Previously, all of these organisms belonged to the order Rickettsiales and most were in the family Rickettsiaceae, based on their fastidious or intracellular nature and other characteristics. Therefore, members of these diverse genera were collectively referred to as "rickettsial organisms."[2,3] Advances in molecular biologic techniques have resulted in the reclassification of several of these organisms. Many have been moved out of the family Rickettsiaceae, and others have been moved out of the order Rickettsiales. Currently the order Rickettsiales includes only two families, the family Anaplasmataceae, which contains the genera *Anaplasma, Ehrlichia, Neoehrlichia, Wolbachia,* and *Neorickettsia*; and the family Rickettsiaceae, which includes the genera *Rickettsia* and *Orientia*.[3–6] The term "rickettsial" refers to diseases caused by organisms in the order Rickettsiales, "rickettsioses" refers to diseases caused by organisms in the family Rickettsiaceae (*Rickettsia* and *Orientia*), and "*Rickettsia*" refers specifically to members of the genus *Rickettsia*.[2,3,5]

The genus *Rickettsia* is divided into the SFG and the typhus group (TG) and an ancestral group based on phenotypic and, more recently, genotypic characteristics.[3,5–7] There is some evidence that *Rickettsia felis* and *Rickettsia akari* (currently classified as SFG *Rickettsia*) may have separate lineages.[6,8] Phenotypic characteristics that have historically been used to group the organisms into TG or SFG include the types of vectors that transmit them, their pathophysiologic manifestations of the disease, and serologic differences. Therefore, the division of *Rickettsia* into SFG and TG has clinical relevance.

SFG rickettsia species are transmitted by arthropod (primarily tick) vectors and infect endothelial cells in mammalian hosts.[3,6,7] The two most pathogenic and well-studied SFG rickettsiae that cause disease in humans and dogs are *Rickettsia rickettsii,* the cause of Rocky Mountain Spotted Fever (RMSF) in North, Central, and South America, and *Rickettsia conorii,* the cause of Mediterranean spotted fever (MSF) in Europe, Africa, Asia, and the Middle East. The first human case of RMSF was described in the late 1800s, and the first case of MSF was

described in the 1920s.[9] Therefore, these organisms and their associated diseases are the most well characterized among the SFG rickettsiae.[5] Currently, there more than 20 species of tick-borne rickettsiae.[5,7] Some species appear to be nonpathogenic endosymbionts of ticks.[7] However, some SFG rickettsiae previously thought to be nonpathogenic, such as *Rickettsia parkeri* and *Rickettsia massiliae,* have more recently been associated with disease in humans.[10–12] Previously thought to have rather limited geographic boundaries, many SFG rickettsiae have also been detected in expanding geographic locales around the world.[7] Increasing travel and the effects of climate change on tick populations and habitat are thought to be partly responsible for this phenomenon.[13,14]

Dogs are sentinels for SFG rickettsioses in humans. Both *R. rickettsii* and *R. conorii* infect and cause disease in dogs.[15–21] *Rickettsia rickettsii* infection in dogs can occur before, or coincide with, outbreaks of RMSF in people in the same household or community.[22–26] Similarly, several serosurveys in endemic areas have shown an increased risk of MSF in people who live near dogs that are seropositive for SFG rickettsiae.[27–29] Other SFG rickettsial species infect dogs, but the extent to which they cause clinical disease has not yet been definitively established. Species implicated in natural infection in dogs include *R. massiliae, R. parkeri, R. felis, R. akari, Rickettsia amblyommii, Rickettsia montanensis, Rickettsia japonica,* and *Rickettsia australis*.[30–37] These rickettsial infections along with flea-borne rickettsioses are discussed further below. The DNA from SFG rickettsiae *R. massiliae* and *R. conorii* has been amplified from naturally infected cats, and cats in regions endemic to pathogenic and nonpathogenic SFG *Rickettsia* are seropositive to SFG rickettsiae.[38–41] The degree to which SFG rickettsiae cause illness in cats has yet to be defined.[38,39] Typhus group rickettsiae are a phenotypically and genotypically distinct group of rickettsiae that are described at the end of this chapter.

ROCKY MOUNTAIN SPOTTED FEVER

Young and purebred dogs are overrepresented in some but not other studies of RMSF in dogs.[18,19] Although some studies suggest that male dogs are at increased risk, no sex predilection has been definitively documented.[18,19,42] Severe disease has been reported in English springer spaniels with phosphofructokinase (PFK) deficiency and in German shepherd dogs.[19,42] Dogs that live outdoors, particularly those with access to shrubs and high grass, are at increased risk for RMSF.[18]

Rickettsia rickettsii is transmitted by several hard (ixodid) ticks including *Dermacentor variabilis* (the American dog tick) (Fig. 46.1A), *Dermacentor andersoni* (the Rocky Mountain wood tick) (Fig. 46.1B), *Amblyomma americanum* (the lone star tick), *Amblyomma cajennense sensu lato* (the Cayenne tick), *Amblyomma aureolatum* (the yellow dog tick), and *Rhipicephalus sanguineus* (the brown dog tick).[7,43–47] The primary vectors for *R. rickettsii* in the south-central and southeastern United States are *Dermacentor* ticks, whereas *Rh. sanguineus* is the primary vector in the southwest United States and Mexico. Tick species other than *D. variabilis, D. andersoni,* and *Rh. sanguineus* are also associated with *R. rickettsii* in the United States. For example, *A. americanum* transmitted RMSF to a person in North Carolina, and the organism has been isolated from *Dermacentor occidentalis* in California.[45,48] *Amblyomma cajennense sensu lato* species and to a lesser extent, *A. aureolatum* transmit this rickettsia in Brazil.[49]

Ticks that transmit *R. rickettsii* feed once during each life stage (Fig. 46.2). Both transstadial and transovarial transmission occurs in *Dermacentor* spp. infected with *R. rickettsii,* making them a reservoir as well as a vector of infection.[50,51] *Dermacentor* spp. and *Amblyomma* spp. are three-host ticks. Infection is transmitted among mammalian hosts and ticks when the tick feeds on different hosts during each stage

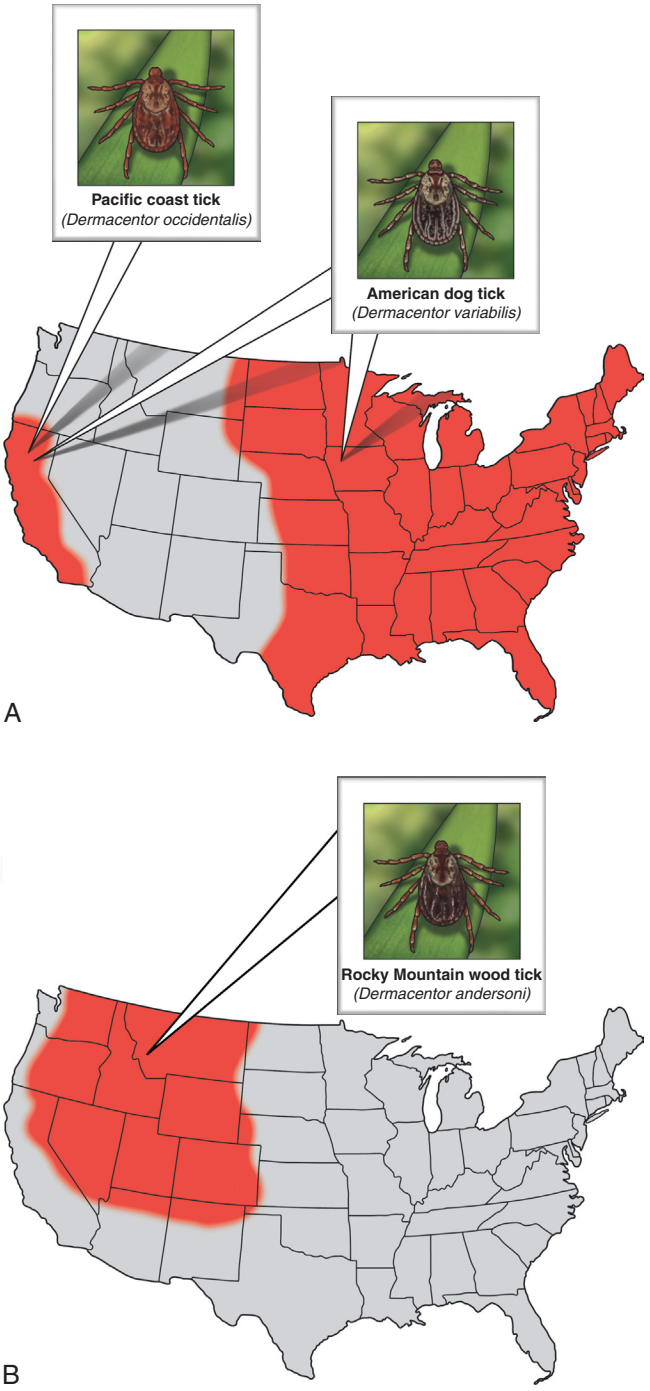

Fig. 46.1 (A) Distribution of *Dermacentor variabilis* and *Dermacentor occidentalis* ticks in the United States. (B) Distribution of *Dermacentor andersoni* ticks in the United States.

of molting. The sylvatic cycle for *Dermacentor* ticks involves small mammals, such as chipmunks, pine voles, mice, and ground squirrels. After organisms are ingested by the tick, SFG rickettsiae initially replicate in the epithelial cells of the tick midgut, enter the hemolymph and hemocytes, and then multiply in tissues.[51] Once in the salivary glands, the organism is transmitted to a naïve mammalian host on feeding. Transmission can occur within hours of attachment. However, transmission may be prolonged (up to 48 hours) when changes in virulence occur under conditions such as starvation of the tick. These "dormant" rickettsiae undergo a process called reactivation after the tick begins

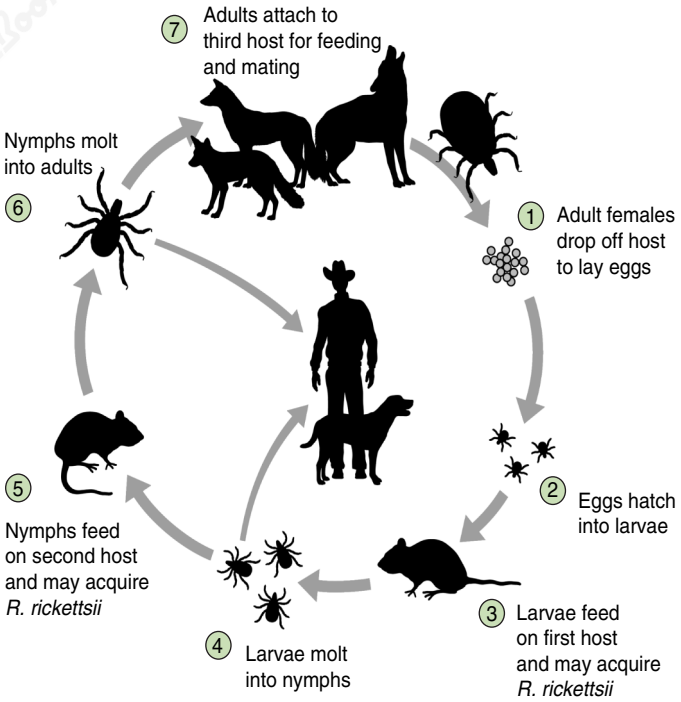

Fig. 46.2 Transmission cycle of *Rickettsia rickettsii* in tick populations, humans, and dogs. After adult female ticks lay eggs and they hatch *(1 and 2)*, *Dermacentor* spp. ticks acquire *R. rickettsii* upon feeding as larvae or nymphs on rodents *(3)*; they then transmit during subsequent feeding as nymphs or adults *(4 to 6)*. Adult ticks feed on a variety of canid species, such as foxes and possibly wolves and coyotes. In addition, *R. rickettsii* infection can be maintained transovarially in *Dermacentor* ticks, so some larvae that hatch from the egg mass already harbor an infection. (Redrawn from Nicholson WL, Allen KE, McQuiston JH, et al. The increasing recognition of rickettsial pathogens in dogs and people. *Trends Parasitol.* 2010;26:205–212.)

feeding.[52] Therefore, rapid tick removal can decrease the risk of transmission in many, but not all, circumstances.

Rhipicephalus sanguineus is a one-host tick, with dogs being the preferred host.[53] It can adapt to hot environments and commonly resides in walls of housing structures in close proximity to humans.[53] Increases in global temperature have been implicated in association with increased feeding on humans.[13,53] The role of this tick as a reservoir for *R. rickettsii* in nature has yet to be elucidated.

The role of dogs as a natural reservoir of infection for *R. rickettsii* is also unknown. Dogs are thought to act as incidental hosts when *Dermacentor* ticks are the vectors, because ticks rarely acquire the organism from rickettsemic dogs.[54] In contrast, all stages of *Rh. sanguineus* acquired infection at a high rate from experimentally infected dogs in one study, but this may have been related to the virulence of the rickettsial strain used.[47] A relatively high infection rate with SFG rickettsiae in naturally infected *Rh. sanguineus* has also been described.[7,46,48] Therefore, dogs may play a role in maintenance of a reservoir of *R. rickettsii* infection in endemic foci where *Rh. sanguineus* is the primary vector.

Direct transmission of *R. rickettsii* to humans has been described in laboratory settings through aerosolization. Direct transmission from tick blood or other contaminated biologic products also has the potential to occur. For example, in Portugal, a SFG rickettsia was directly transmitted to a human through conjunctival inoculation after a *Rh. sanguineus* tick removed from a dog was crushed.[55] Therefore, care should be taken when handling laboratory specimens and removing ticks.

RMSF occurs in North, Central, and South America (where it is known as Brazilian spotted fever). In North America, most cases of RMSF occur in the southeastern and south-central states. North Carolina, Oklahoma, Arkansas, Tennessee, and Missouri consistently have the highest reported number of human cases in the United States (Fig. 46.3). Disease distribution in the United States primarily follows the distribution of *D. variabilis*, the primary vector in this region; however, over the last decade the importance of *D. variabilis* as vectors in endemic areas has been questioned.[56] Although disease can occur at any time of the year, most cases of canine and human RMSF in the United States are reported from April through October, months of peak *Dermacentor* tick activity.[18,57–59] Interestingly, in contrast to the southern regions of the United States, a 2016 study showed no seasonality for the occurrence of human SFG rickettsioses in the western United States. The authors speculated that moderate temperatures and year-round activity of *Rh. sanguineus,* the vector for *R. rickettsii* in the southwest, might explain this finding.[58]

This tick also helps explain why the geographic distribution of RMSF in people in the United States has expanded beyond the distribution of *D. variabilis* and *D. andersoni*. Novel vectors, including *Rh. sanguineus*, have played a role in this phenomenon. This tick was associated with an outbreak of fatal human RMSF in a previously nonendemic area of Arizona.[24,60] Infection existed in the dog population before the fatal outbreak in people.[25,26] *Rhipicephalus sanguineus* is found throughout the United States, southern Canada, Mexico, and South America. Notably, *Rh. sanguineus* is the main vector for *R. rickettsii* in some parts of the Western Hemisphere.[7] Over the last decade, an outbreak in Mexicali, Mexico, just across the border from California and Arizona, was also attributed to *R. rickettsii* transmitted by *Rh. sanguineus* ticks associated with dogs.[61] This prompted ongoing surveillance efforts in ticks, dogs, and humans in southern California, a nonendemic area for RMSF. *Rickettsia rickettsii* was not found in *Rh. sanguineus* ticks removed from dogs residing in animal shelters located just across the United States border from the Mexican outbreak.[62,63] In addition, a 2020 study found increased exposure to SFG rickettsiae in dogs living in a California county that borders Mexico that had a history of traveling into Mexico, compared with dogs living in the same region that had not crossed the border.[64] These regional discrepancies in exposure risk may be due to subtle differences in microenvironment or other factors that affect regional infection rates in ticks and further emphasize the need for ongoing vigilance and surveillance for RMSF.[65]

Over the last decade, the incidence of SFG rickettsioses in people in the United States has increased.[58] There was a significant increase in the number of confirmed or suspected cases of SFG rickettsioses reported to the CDC in 2010–2014 as compared with 2005–2009 (Wilcoxon matched pairs signed-rank test $P = .0058$;) (Fig. 46.4). Some of the increase may be due to disease caused by species of SFG rickettsiae other than *R. rickettsii*.[58,66,67] Because the case definition of human spotted fever rickettsioses (SFR) can be based exclusively on serologic testing, which does not differentiate among species of SFG *Rickettsia*, the Council for State and Territorial Epidemiology changed the name RMSF to SFR for surveillance purposes in 2009. It is thought that up to one third of cases of SFG rickettsioses in the United States may actually have been caused by *R. parkeri* rather than *R. rickettsii*.[67] As is the case for humans, some dogs with positive titers to *R. rickettsii* may have been caused by exposure to other species of pathogenic or nonpathogenic SFG rickettsiae.

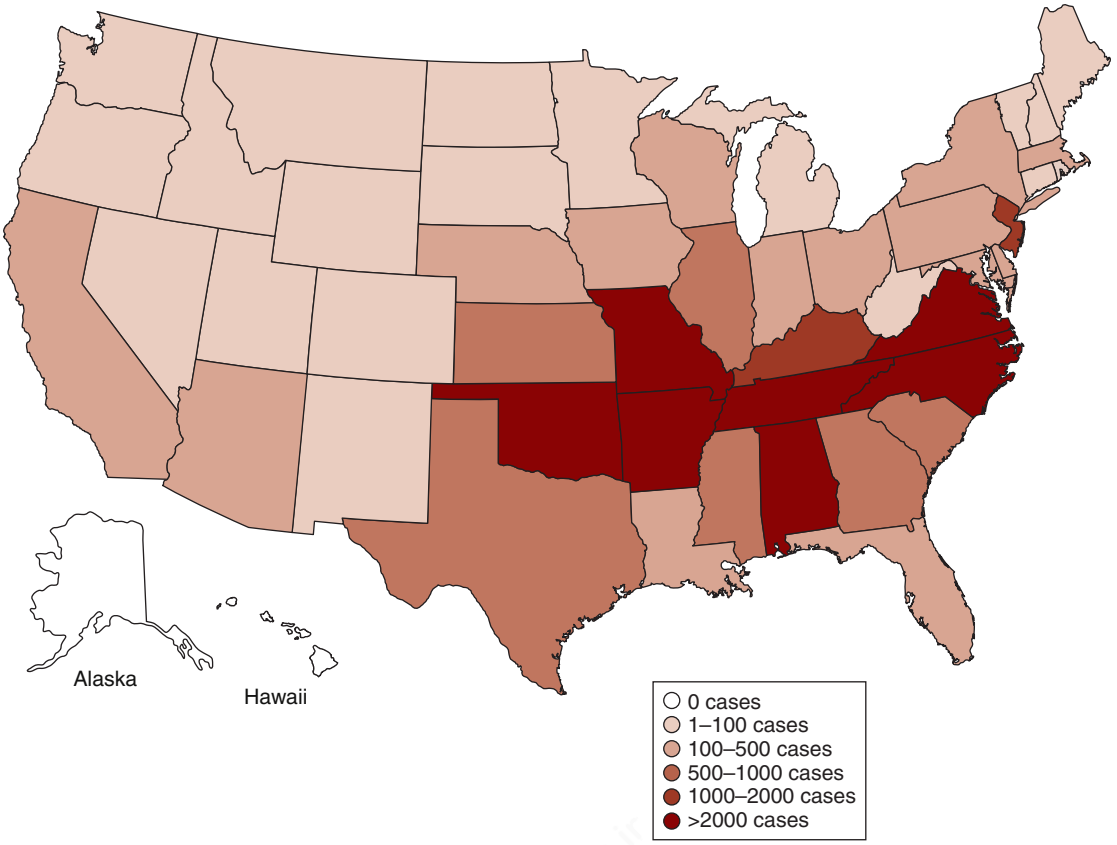

Fig. 46.3 Geographic distribution of the incidence of spotted fever group rickettsioses in people in the United States, 2010–2019. (Compiled from data from the Centers for Disease Control and Prevention, Morbidity and Mortality Weekly Reports: https://www.cdc.gov/mmwr/mmwr_nd/index.html.)

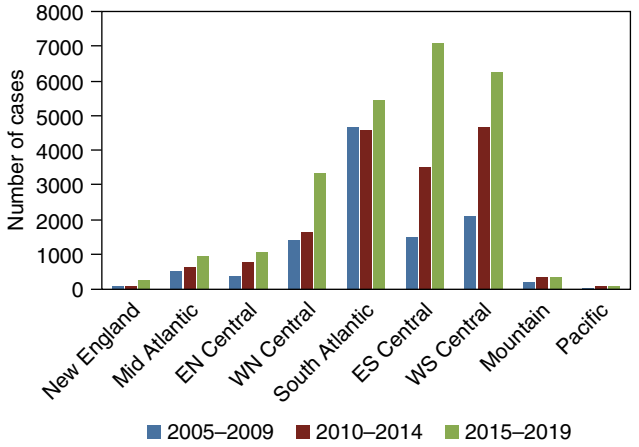

Fig. 46.4 Comparison of the incidence of confirmed and probable spotted fever rickettsioses in people in the United States during 2005–2009, 2010–2014, and 2015–2019. (Compiled from data from the Centers for Disease Control and Prevention, Morbidity and Mortality Weekly Reports (https://www.cdc.gov/mmwr/mmwr_nd/index.html). As defined by the CDC, NE = North-east States and includes CT, ME, MA, NH, RI, VT; Mid-Atlantic includes NJ, NY, PA; EN Central = East North-central states and includes IL, IN, MI, OH, and WI; WN Central = West North-central states and includes IA, KS, MN, MO, NE, ND, SD; WS Central = West South-central states and includes AR, LA, OK, TX; South-Atlantic includes DE, DC, FL, GA, MD, NC, SC, VA, WV; ES Central = East South-central and includes AL, KY, MS, TN; Mountain includes AZ, CO, ID, MT, NV, NM, UT and WY; and Pacific includes AK, CA, HI, OR and WA.)

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The endotheliotropism of *Rickettsia* spp. infection results in the characteristic clinical sign of infection, which is disseminated vasculitis. In humans, cutaneous macules, papules, and petechiation that occur in association with vasculitis form a rash that looks like "spots," hence the name "spotted fever."[9] The clinical signs, time course of illness, and response to therapy for RMSF in dogs are very similar, if not identical, to those associated with RMSF in humans.[18–21] However, cutaneous lesions are not always present in dogs or humans ("RMSF"). In humans, SFR caused by organisms other than *R. rickettsii* are often associated with an eschar (an area of cutaneous necrosis) formation.[4,7,14] Clinicians should keep in mind that dogs from nonendemic areas that have classic signs of RMSF, or those that develop atypical clinical signs, may be infected with *R. rickettsii* or other SFG rickettsial species.

Once the organism is inoculated, it spreads through lymphatics or directly into the bloodstream to the small capillaries. *Rickettsia rickettsii* primarily infects endothelial cells, although smooth muscles and monocytes may also be infected.[4,68] The bacterial autotransporter outer membrane protein A (OmpA) and outer membrane protein B (OmpB), are important for attachment, adhesion, and virulence.[69–71] These proteins also account for differences in serotype, and antibodies to OmpB and OmpA contribute to immunity to reinfection. Other autotransporter proteins such as Sca1 and Sca2 are important for adhesion.[72] Phagocytosis is likely triggered by adhesion proteins interacting with host cell receptors.[72] Enzymes such as phospholipase

D and hemolysin C facilitate the release of the organisms into the host cell cytoplasm.[70,71] SFG *Rickettsia* live in both the cytoplasm and the nucleus, deriving nutrients and energy from the host cell.[4,6,69] They spread from cell to cell by inducing actin to polymerize, which transports the bacteria directly into adjacent cells.[70,73] This helps the bacteria to evade the immune response and to disseminate without rupturing the cell. They are also released into circulation when they exit the luminal surface of the cell membrane or when endothelial cell death or detachment occurs.[70] SFG rickettsiae activate the transcription factor NF-κB, which inhibits apoptosis, fosters further growth of the organism, and promotes inflammation.[69,70]

Damage to endothelial cells leads to vasculitis and an increase in microvascular permeability. Mechanisms of cellular damage include oxidative injury through the production of reactive oxygen species, cellular necrosis, and induction of endothelial apoptosis by CD8+ T cells.[68–70,72,74] Activation of PFK may be important in maintaining vascular integrity and energy metabolism in endothelial cells under hypoxic or oxidative stress,[75,76] which may explain the predisposition of English springer spaniels with PFK deficiency to severe disease. Vasculitis associated with *R. rickettsii* infection manifests as disordered primary hemostasis, tissue edema, hypovolemia, and microthrombosis.

Increased vascular permeability and the associated edema and hypovolemia results from disruption of adherens junctions, endothelial cell death, expression of inflammatory cytokines, such as IL1-β, IFN-γ, and TNF-α, and induction of COX-2 with subsequent prostaglandin production.[68,72] Microthrombosis results from altered platelet adherence to endothelium, increased tissue factor expression, increased plasminogen activator inhibitor, and thrombomodulin expression and the release of von Willebrand's factor.[68,72]

Low numbers of organisms circulate in blood for approximately 13 days after infection, which includes the time that clinical signs are observed.[20,77,78] Organisms are free and also contained within circulating endothelial cells, which are thought to be released from the vessels because of decreased adhesion after rickettsial invasion.[70] Thus, RMSF is primarily an *acute* disease. However, a 2014 study demonstrated a recurrence of clinical signs 44 days and circulating rickettsial organisms 60 days after experimental infection via *D. variabilis* ticks in a beagle.[79] Chronic infection has not been documented in naturally infected dogs or humans. Co-infection with other vector-borne agents is common. A 2014 serological survey involving dogs in the United States showed *R. rickettsii* and *Ehrlichia* spp. co-exposure to be the most common among vector-borne disease agents nationally.[59] Co-infection should be considered if the clinical signs are atypical, if there is an incomplete response to doxycycline therapy, or if clinical signs have been present chronically.[18,80]

Because of variation in the extent and severity of vascular injury among dogs, a range of signs can occur, and importantly, disease manifestations are initially mild and nonspecific.[16,18,19] Often, there is no known history of a tick bite. Therefore, the clinician (physician or veterinarian) must have a high index of suspicion in order to correctly diagnose and treat this disease. A delay in diagnosis and appropriate antimicrobial therapy dramatically increases morbidity and mortality in humans and dogs.[18,57] Lethargy and anorexia are common and may be the only clinical signs. Vomiting and diarrhea occur frequently in dogs and humans with RMSF. Melena may be observed, as may a variety of CNS abnormalities including vestibular disease and seizures.[18,19,21] Dramatic and rapid weight loss has been described.[21]

Physical Examination Findings

Fever is present in approximately 80% of naturally infected dogs. Ocular signs are also frequently observed and may include a mucopurulent discharge, scleral and conjunctival injection and hemorrhage, conjunctivitis, uveitis, retinal hemorrhage, and retinitis (Fig. 46.5). Lymphadenomegaly and splenomegaly also occur. Respiratory abnormalities include nasal discharge, epistaxis, and tachypnea. Mucocutaneous and cutaneous abnormalities include petechiae, ecchymosis, peripheral edema (which can be localized over a joint, the prepuce, or the mammary chain), hyperemia, and necrosis. Gangrenous necrosis can be so severe as to require reconstructive surgery after successful treatment of the acute febrile illness.[16–19,21,42,81] Orchitis and scrotal edema, hyperemia, and epididymal pain are common in intact male dogs and should prompt consideration of RMSF when present. Generalized myalgia and arthralgia can be observed. Arrhythmias may also be detected. CNS abnormalities can be focal or generalized and include paraparesis, tetraparesis, ataxia, hyperesthesia, ataxia, central or peripheral vestibular signs, stupor, seizures, and/or coma. Neurologic signs are more common in dogs with a high *R. rickettsii* antibody titer, which suggests a longer duration of illness or a delay in diagnosis.[18] Residual neurologic deficits may occur after infection in severely affected individuals. Microvascular hemorrhage, thrombosis, hypotension, oliguric renal failure, cardiovascular collapse, and coma can occur terminally.

DIAGNOSIS

Application of a combination of diagnostic tests is often necessary to confirm infection by SFG rickettsiae. Active infection is confirmed in a patient with compatible acute clinical signs and demonstration of the organism using PCR assays or IHC, or documentation of seroconversion (Fig. 46.6). Importantly, a high index of suspicion based on

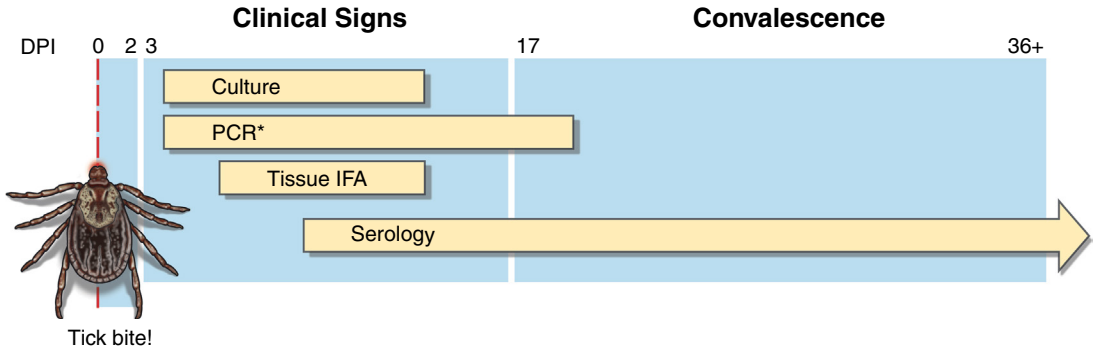

Fig. 46.6 Timing in relation to day postinfection *(DPI)* that clinical signs and diagnostic tests for *Rickettsia rickettsii* may be positive in an infected dog.[16,77–79,86,95] *Further studies are needed to determine exactly how DNA can be detected in peripheral blood after infection. *IFA,* immunofluorescent antibody; *PCR,* polymerase chain reaction.

clinical signs is necessary because treatment must be instituted before the results of diagnostic tests (including rapid PCR assays) confirm infection.[18,21] Co-infection with other vector-borne disease agents or alternate causes of illness should be considered in patients who fail to respond rapidly to treatment (within the first 24 to 48 hours after initiation of doxycycline treatment).[80] Because direct inoculation into blood or aerosolization can cause infection, all specimens should be handled with care and marked clearly as biohazards. Needle-stick injuries, contact with cuts in the skin, and aerosolization of rickettsemic blood should be avoided.

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia is common in RMSF and occurs due to vasculitis and immune-mediated platelet destruction.[82] However, thrombocytopenia does not occur in all dogs with RMSF.[18,21] The white blood cell count may initially decrease and then tends to increase with duration of illness.[19–21] Neutrophils may have toxic change.[18] Despite the acute nature of this severe illness, a nonregenerative anemia may be present and persist until the dog is treated appropriately and begins to recover.[16,18,21]

Serum Biochemical Tests

Serum biochemical abnormalities can include hypoalbuminemia (due to vasculitis or protein-losing nephropathy), increased serum ALP activity, hyponatremia, and mild hyperbilirubinemia.[16,18,21,83] Hyponatremia is thought to occur secondary to antidiuretic hormone secretion in response to hypovolemia in people with RMSF.[57]

Urinalysis

Urinalysis results in dogs with RMSF are variable and may include proteinuria, hematuria and bilirubinuria, and pyuria. Granular casts can be observed.[18,19]

Coagulation Profile

Coagulation abnormalities include prolonged APTT and increased serum fibrinogen concentration. Less commonly, prolonged PT and increased fibrin degradation products are observed. Although a prothrombotic state can occur during fulminant disease, disseminated intravascular coagulation is uncommon.[16,18]

Cytologic Examination of Tissue Aspirates and Body Fluids

Cytologic examination of aspirates from enlarged lymph nodes in dogs with RMSF is consistent with reactive lymphoid hyperplasia.[18,19] Arthrocentesis may reveal neutrophilic polyarthritis.[18,19] CSF analysis in dogs with neurologic signs may reveal a mixed cellular, neutrophilic, or lymphocytic pleocytosis.[18,19,21,84]

Diagnostic Imaging

Thoracic radiographs in dogs with RMSF may show an unstructured interstitial pattern.[19,85] Testicular ultrasound findings may be consistent with orchitis in intact males.[81]

Microbiologic Tests

Diagnostic assays available for RMSF in dogs are shown in Table 46.1. Because of the pathogenesis of the infection, laboratory diagnostics (including serology and PCR assays) may not indicate that infection is present at the time that clinical signs manifest (see Fig. 46.6). In addition, most diagnostic tests do not differentiate among species of SFG rickettsiae.

Culture

Because of the obligately intracellular and extremely pathogenic nature of *R. rickettsii,* cell culture is difficult to perform and processing of specimens for isolation is limited to BSL-3 facilities (see Table 46.1). Therefore, culture is not commonly used for routine diagnosis.

Serologic Diagnosis

Indirect microimmunofluorescence (MIF) assays that detect IgM and IgG antibodies are most commonly used to document seroconversion in dogs infected with *R. rickettsii*.[18] Because of a lack of specificity, assays that detect IgM alone cannot be used to accurately diagnose acute RMSF.[86] There is extensive serologic cross-reactivity among SFG rickettsiae, and thus a positive titer only indicates exposure to SFG rickettsial species. In general, the infecting species is presumed based on geographic locale, so RMSF is the presumptive diagnosis in dogs that seroconvert in the southeastern United States. However, other species of SFG rickettsiae may also be present and potentially induce disease.[30,87] Seropositivity that indicates exposure to SFG *Rickettsia* is common in dogs in the United States. Exposure to nonpathogenic SFG rickettsiae, some of which are common endosymbionts in ticks, may be a common cause of positive titers, particularly low and persistent titers, to *R. rickettsii* in healthy people and dogs.[67,88] Serologic cross-reactivity with SFG rickettsiae does not appear to occur in dogs infected with *Bartonella* spp.[89–91] In addition, previous infection with *R. rickettsii* may result in persistent antibody titers.[86] Thus, infection with *R. rickettsii* cannot be definitively diagnosed based on a single positive titer. However, a single high titer in the context of acute and

TABLE 46.1 Diagnostic Assays Available for Rocky Mountain Spotted Fever in Dogs

Assay	Specimen Type	Target	Performance
Indirect microimmunofluorescence assay (MIF)	Serum	IgM and IgG antibodies against *R. rickettsii*	Demonstration of a fourfold change in titer (seroconversion) is very sensitive. False-negative results are common during the acute phase of infection. A positive antibody response may reflect prior exposure to a nonpathogenic SFG rickettsia, or long-lived circulating antibody from previous infection with SFG rickettsiae. Cross-reactivity to other SFG rickettsiae occurs.
PCR	Whole blood	Gene target varies with testing laboratories	*In vitro* sensitivity may approach 100%; however, absolute (clinical) sensitivity is lower, approximately 60%, because organisms circulate in blood in low numbers and transiently during the acute phase of infection. Sensitivity is further reduced by antimicrobial drug treatment. Specificity approaches 100%, particularly if the laboratory sequences all PCR amplicons. PCR testing for other tick-borne organisms that cause similar clinical signs is available as PCR panels from some testing laboratories. Only a few PCR assays differentiate among *Rickettsia* species. Negative PCR assay results do not rule out infection.
Histopathology with direct IFA or Gimenez staining	Cutaneous biopsy (inguinal or flank targeting areas with lesions) or necropsy specimens	Characteristic perivascular inflammation and vasculitis with necrosis and presence of the organism	Direct IFA sensitivity is approximately 80% during acute infection. Biopsy of a petechial or ecchymotic lesion may increase sensitivity. False negatives occur if organisms are absent from the lesion because of random chance, timing of specimen collection, or prior antimicrobial treatment. Does not differentiate among species of SFG rickettsiae.

IFA, immunofluorescent antibody; *PCR,* polymerase chain reaction; *SFG,* spotted fever group.

compatible clinical signs and an appropriate response to therapy suggests infection.[18] Titers are commonly negative early in the course of infection, because clinical signs often occur before seroconversion in naturally and experimentally infected dogs.[21,86,92] Thus, acute and convalescent serology (run in the same laboratory and ideally in the same batch) and documentation of a fourfold change in titer is necessary to confirm acute SFG rickettsiae infection. The convalescent serum specimen should be drawn 2 to 3 weeks after the acute specimen.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR testing of whole blood can be used to confirm infection in seronegative dogs during the acute phase of disease.[77,78,92] A sensitive PCR assay that detects and differentiates among SFG rickettsiae that infect dog blood has been described, and a variety of PCR assays are available through commercial veterinary diagnostic laboratories.[92] However, because *R. rickettsii* circulates in blood in low numbers and only transiently, the sensitivity of any diagnostic assay to detect infection in the bloodstream is limited. One real-time PCR assay, which could detect as few as five copies of organism DNA, had a sensitivity of only 53% for detection of *R. rickettsii* in acute samples from naturally infected dogs with signs of RMSF.[92] The sensitivity of another *R. rickettsii* PCR assay for detection of *R. rickettsii* in experimentally infected dogs ranged from 33% to 100% depending on the day of sample collection.[78] Furthermore, false negatives can occur after initiation of appropriate antimicrobial treatment. Therefore, although a positive PCR assay result confirms infection, a negative result does not exclude the diagnosis. Some PCR assays can differentiate among infecting *Rickettsia* species, whereas others only amplify conserved rickettsial DNA targets.[77,92] Clinicians should consult with laboratories to determine the *in vitro* (analytical) and *in vivo* (clinical) sensitivity of a PCR assay and its ability to differentiate among infecting *Rickettsia* species. Whenever possible, it is important for veterinary and human clinicians to submit specimens to laboratories that use PCR assays that differentiate among *Rickettsia* species.[58] Samples should be obtained before antirickettsial antibiotic therapy is administered. Combining PCR with serologic testing, repeating PCR assays on samples taken before treatment, and serologic testing of convalescent samples facilitates diagnosis.[92]

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with RMSF are consistent with vasculitis and may include edema, particularly of the ears, muzzle, and scrotum; and ecchymosis, petechiae, and/or focal hemorrhages of the skin, mucous membranes, and viscera (including the brain). Lymphadenomegaly and splenomegaly are also common findings.[16,17,21,23]

Histopathologic Findings

Microscopically, the predominant lesion is vasculitis. Neutrophils, monocytes, and/or lymphoreticular cells predominate in the inflammatory lesions. Inflammatory cells may surround and invade large-, small-, and medium-size vessels of multiple organs and tissues and this is frequently accompanied by focal necrosis and hemorrhage. Meningoencephalitis, splenitis, myocardial necrosis, glomerulonephritis, and renal vasculitis have been described.[16,21,23]

Direct IFA can be used to detect organisms in skin and other organs. Identification of abundant SFG rickettsiae within and around small- to medium-size vessels and vascular endothelial cells can confirm infection.[21] In experimentally infected dogs, the sensitivity of IHC was 78.3%, and organisms could be visualized between days 7 and 12 of infection (days 3 to 8 of fever).[93] In that study, specimens collected from areas other than the central focus of vasculitis were negative. However, in naturally infected dogs, the sensitivity was 80% for skin specimens collected from the inguinal region. Half of those specimens lacked gross lesions.[19] Thus, the diagnostic sensitivity of IHC is most likely enhanced by obtaining lesional biopsies, but may not be decreased when a lesion is not biopsied. The sensitivity of direct IHC is decreased by antibiotic therapy. IHC does not differentiate between SFG rickettsial species. Gimenez stain can also be used to visualize rickettsial organisms

TABLE 46.2 Antimicrobials Used to Treat Rocky Mountain Spotted Fever in Dogs

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)
Doxycycline	5	PO, IV	12	7–14
Chloramphenicol[a]	30	PO, IV	8	7–14
Enrofloxacin	3[b] to 5	PO, IV	12	7–14

[a]May cause aplastic anemia in humans (wear gloves); may be less effective than doxycycline.
[b]Dose used in experimentally infected dogs.[95] Caution required in young animals (see Chapter 10).
IV, intravenous; *PO,* oral.

in tissues or tissue culture isolation attempts, but this stain is not rickettsia specific and does not allow for differentiation among species.

TREATMENT

Antimicrobial Treatment

Appropriate antibiotic therapy must be immediately instituted based on clinical suspicion for SFG rickettsiosis, and before diagnostic tests confirm infection. Inappropriate or delayed antibiotic therapy may increase morbidity and mortality.[18,57] Some antimicrobial drugs such as trimethoprim-sulfonamides may worsen disease progression of RMSF in human patients.[57] Doxycycline is the treatment of choice (Table 46.2). It effectively eliminates infection with *R. rickettsii* and also has activity against *A. phagocytophilum, Ehrlichia* spp., and *B. burgdorferi,* which may be present in co-infections or cause disease that resembles RMSF. In most cases, 7 days of treatment is adequate for RMSF. Treatment for a few days beyond defervescence is recommended. A longer course of treatment is recommended for dogs that are co-infected with *Ehrlichia* spp. or *B. burgdorferi* (see Chapters 44 and 69). Tooth discoloration and enamel hypoplasia, which are permanent adverse effects of tetracycline use in pediatric patients, has not been observed with short-term (7–10 days), low-dose (approximately 2.2 mg/kg q12h) doxycycline therapy in children less than 8 years of age.[57,94] Therefore, as is the case for adults, doxycycline is the treatment of choice for RMSF in children.[57] Chloramphenicol was effective for RMSF in experimentally infected dogs.[95] However, it may be less effective than doxycycline for treating RMSF in humans and has less activity *in vitro* against *Ehrlichia chaffeensis* and *A. phagocytophilum*.[57,96] Enrofloxacin was effective for treatment of RMSF in experimentally infected dogs.[95] However, enrofloxacin is not effective for treatment of *Ehrlichia canis* infections.[97] Use of parenteral antimicrobial drugs may be necessary in severely debilitated or vomiting patients.

Supportive Care

Many dogs with RMSF require hospitalization.[21] Aggressive supportive care for complications such as thrombosis, CNS deficits, and GI signs may be necessary. Because of the loss of vascular integrity, fluids should be administered with caution, and colloids may be warranted in some cases. The clinician should avoid exacerbation of interstitial edema, which can contribute to cerebral edema and death. The use of glucocorticoids in dogs with RMSF is controversial. Treatment with anti-inflammatory and immunosuppressive doses of glucocorticoids did not affect overall outcome in experimentally infected dogs, but rickettsemia was prolonged in dogs concurrently treated with immunosuppressive doses of glucocorticoids and doxycycline.[98] Anti-inflammatory doses of glucocorticoids have been used in dogs with severe CNS manifestations and may be necessary topically or systemically for treatment of ocular abnormalities.[84,99]

PROGNOSIS

The response to appropriate antibiotic therapy in dogs with RMSF is rapid (24 to 48 hours). Co-infection with *B. burgdorferi, Ehrlichia* spp., *Babesia* spp., and *Bartonella* spp. should be considered in dogs with severe or prolonged clinical signs or dogs that fail to respond to doxycycline. Residual CNS and other deficits may occur in severely affected patients.[18] The prognosis is good to excellent if the disease is diagnosed and treated with appropriate antibiotics and supportive care early in the course of illness.[18,84] Due to the potential clinical severity of RMSF, reactivation of occult *Bartonella* spp. infection is possible.[89] In contrast to most other canine vector-borne infections, doxycycline is not recommended as a sole treatment for bartonellosis.[100]

IMMUNITY AND VACCINATION

Innate and adaptive (primarily CMI) immunity are important in the clearance of SFG *Rickettsia* infections. Dendritic cells (DCs) serve as a bridge between innate and adaptive immunity. Binding of rickettsial LPS to DC TLR-4 causes DC activation and production of inflammatory cytokines; recruitment, activation, and expansion of NK cells and NK IFN-γ production; and DC-mediated induction of T-helper 1 and T-helper 17 adaptive immune responses.[72] CD4+ and CD8+ cells, along with macrophages and DCs, are believed to be sources of inflammatory cytokines such as IFN-γ, TNF-α, IL-1β, and RANTES (CCL5). These cytokines increase the production of nitric oxide synthetase and hydrogen peroxide by the endothelial cell, which helps to eliminate the organisms.[69,70] The endothelial cells themselves also produce cytokines such as IL-6, IL-8, and MCP-1 (CCL2) that recruit immune cells and combat infection. It is thought that endothelial cells present antigen to CD8+ T cells in the context of MHC I.[72] CD8+ cells appear to be particularly important in clearance of rickettsiae from the endothelium.[101] Antibodies are not thought to be important initially for clearance of infection because they form after the fulminant stages of disease.[70,72] However, antibodies are long-lived and together with CMI may prevent subsequent infection. Immunity to reinfection is thought to be lifelong in people, and experimentally infected dogs did not develop illness following rechallenge at 6 months and 3 years after the initial infection. Vaccination is not available for dogs or humans currently, but may be in the future.[102,103]

PREVENTION

The use of acaricides, avoidance of tick-infested areas, and routine inspection of dogs for ticks after outdoor activities can help to prevent RMSF. The reader is referred to Chapters 13 and 109 for information on tick prevention and safe tick removal. Safe tick removal is especially critical when exposure to *R. rickettsii* is a possibility. In cases where *Rh. sanguineus* is the vector, environmental control of ticks is particularly important.[104]

PUBLIC HEALTH ASPECTS

A "One Health" approach to the management of canine and human RMSF is important. It has been well established that people living near dogs and with dogs in endemic areas are at increased risk for

acquiring RMSF. This results from increased human contact with ticks through interaction with tick-infested dogs. Interestingly, one 2019 study of personnel working in veterinary clinics showed that exposure risk was highest in groomers.[105] Dogs and humans can also independently acquire the infection from different ticks questing in the same environment, particularly as *R. rickettsii* is transmitted transovarially to offspring. Because dogs have higher exposure to ticks than their human counterparts, they serve as excellent environmental sentinels for RMSF.[22,23,25,87] In the United States, the diagnosis of SFG rickettsioses in humans is notifiable to public health authorities. Some counties in certain states also require reporting for dogs, particularly during suspected outbreaks.[106] From a public health standpoint, it is important for veterinarians to confirm a diagnosis of RMSF in a dog whenever possible, and to warn the family of the increased risk of acquiring a *R. rickettsii*–infected tick in the same location as the dog acquired the disease. Veterinarians must communicate with owners and physicians that infection in a dog may precede tick-transmitted infection to owners or neighbors. Clients should be instructed to remove ticks properly. Education of owners with regard to the importance of tick control and prevention for both people and pets and the environment is critical. Novel and well-characterized species of SFG rickettsiae are important causes of emerging infectious disease in humans. Because dogs are sentinels for infection, veterinarians play an important role in detection, definition, and prevention of illness in their canine patients and their human companions.

MEDITERRANEAN SPOTTED FEVER

Rickettsia conorii subsp. *conorii* is the cause of an endemic tick-borne rickettsial illness of people in the Mediterranean basin and Africa known as MSF (or boutonneuse spotted fever). Several other subspecies of *R. conorii* (*indica*, *caspia*, and *israelensis*) are responsible for clinical or subclinical infections in people in India, Eastern Europe, and the Middle East, respectively.[7] In humans, the clinical appearance of MSF is similar to RMSF, except that the presence of an eschar at the site of tick bite is common.

MSF is transmitted by *Rh. sanguineus.* It is suspected that this tick serves as a reservoir for the disease.[7] Whether dogs or other vertebrate hosts are also reservoirs is uncertain, but experimentally, dogs are able to transmit the organism to *Rh. sanguineus* ticks.[7,107] Serologic studies indicate a high rate of exposure among clinically healthy dogs[29,108] and cats in endemic areas.[108] However, seroconversion was associated with fever in a 2015 study of ill dogs in Italy.[35] Host immunity is likely important in determining if clinical illness develops in dogs with MSF. Like RMSF, dogs serve as sentinels for MSF in humans.[7] Interestingly, one study found that *R. conorii* survived 35 days in stored canine whole blood, suggesting that iatrogenic infection from transfused blood products is potentially possible.[109]

Male Yorkshire terriers were the only affected breed in the first clinical report of naturally occurring MSF in dogs.[15] This breed also had the highest rate of infection with *R. conorii* in another study testing for SFG rickettsemia in large numbers of dogs in Italy.[110] An inherent susceptibility to MSF in Yorkshire terriers is suspected, but uncertain.

Findings of clinical and pathologic studies in experimentally and naturally infected dogs with MSF are analogous to those described in RMSF. Clinical signs include lethargy and, less commonly, vomiting and diarrhea.[35] Physical examination abnormalities include elevated rectal temperature (generally 40.1°C to 41°C [104.2°F to 105.8°F]), hyperesthesia, peripheral edema, orchitis, erythema, stiff gait, lymphadenomegaly, splenomegaly, tachycardia, lameness, conjunctival swelling, and dehydration.[15,35,111]

Laboratory abnormalities associated with MSF in dogs include neutrophilic leukocytosis with a variable left shift, thrombocytopenia, hypoproteinemia and concurrent hypoalbuminemia, hyperglobulinemia, and increased serum urea nitrogen concentration, C-reactive protein (CRP) concentration, and hepatic aminotransferase activities. Although α-hyperglobulinemia is observed in RMSF in dogs as an acute-phase reaction, the additional observation of increased β- and γ-globulins in natural cases of MSF would suggest a longer-standing infection with *R. conorii* before the onset of clinical illness or co-infection with other vector-borne pathogens.

Diagnosis is made either by demonstrating seroconversion, or a positive PCR test, and a corresponding clinical improvement after antirickettsial therapy. Serologic cross-reactivity with other SFG *Rickettsia* preclude definitive speciation if diagnosis is based on serologic testing. Because of the high seroprevalance in dogs in endemic areas, a single positive titer does not confirm active infection.

Antimicrobial treatment is the same as for RMSF, and response to doxycycline appears to be rapid.[15] The public health risk of tick-infested dogs infected with *R. conorii* would be presumably high because *Rh. sanguineus* can become domiciled indoors in homes or kennels. This been demonstrated with *Rh. sanguineus*-associated RMSF in the United States and Mexico.[46,112] A higher association of MSF in people with dog ownership supports this contention.[113] Inadvertent tick bites and direct inoculation and subsequent infection sustained during removal of ticks from dogs have been associated with transmission to humans.[55,114] Tick control in dogs and the environment would have a likely beneficial effect of reducing the prevalence of this disease in both humans and dogs. Interestingly, a 2016 serosurvey showed a decrease of exposure to *R. conorii* in humans in an endemic area. It was suggested that widespread tick control in dogs contributed to the decline in human exposure.[115]

OTHER TICK-BORNE SPOTTED FEVER GROUP RICKETTSIAE

Although RMSF and MSF are the most well-characterized SFR in the world, serologically, genetically, and pathogenically distinct SFG rickettsiae have also been described as important disease-causing agents in humans.[7] Many closely related SFG rickettsial species of unknown pathogenicity have been detected in or isolated from ticks in the United States. Other than *R. rickettsii*, SFG species isolated from ticks associated with dogs in the United States include *R. parkeri, R. amblyommii, R. montanensis* (formerly *R. montana*), *Rickettsia rhipicephali*, *Rickettsia bellii*, *Rickettsia andeanae*, and *R. massiliae.*[30,83,116]

Rickettsia parkeri was previously considered to be a nonpathogenic SFG rickettsia. Its vector is *Amblyomma maculatum* (the Gulf Coast tick). *Rickettsia parkeri* has now been shown to cause clinical illness in humans in the United States.[117] It is suspected that many cases of human RMSF that are diagnosed in areas where *A. maculatum* is endemic are caused by *R. parkeri* rather than *R. rickettsii.*[58] *Rickettsia parkeri* also was associated with a spotted fever type of illness in hikers in Arizona. *Amblyomma triste* was the suspected vector.[118] Human disease associated with *R. parkeri* infection appears to be milder and is characterized by the presence of eschar and lymphadenomegaly, signs not commonly seen with RMSF.[14] In 2011, *R. parkeri* was amplified using PCR from overtly healthy shelter dogs in Louisiana.[34]

Rickettsia amblyommii, *R. montanensis*, *R. rhipicephali*, and *R. bellii* are thought to be of low pathogenicity or nonpathogenic in

humans.[7] However, like *R. parkeri*, evidence suggests that *R. amblyommii* and *R. montanensis* may cause illness in people in the United States, and account for some of the reported SFR in areas endemic for RMSF.[119,120] In the last decade, DNA from *R. amblyommii* and *R. montanensis* has been amplified from the blood of naturally exposed, apparently healthy dogs.[37] The rickettsemia was short-lived. *Rickettsia rhipicephali*, *R. bellii*, and *R. andeanae* have not been shown to cause disease in dogs or humans to date.

Rickettsia massiliae has been characterized as a human pathogen in Europe, and was implicated as a cause of febrile illness in dogs and people living in a *Rh. sanguineus*-infested home in Los Angeles.[30,121] *Rickettsia massiliae* DNA has also been amplified from the blood of naturally infected cats and from the blood of a naturally infected dog.[38,122] *Rickettsia phillipii* (SFG *Rickettsia* strain 364D) is the cause of an emerging tick-borne disease known as Pacific Coast Fever. Pacific Coast Fever is transmitted by *D. occidentalis* ticks.[123] Although cases have been reported in California, cases could occur within the entire geographic range of this tick, which includes Oregon to Baja California, Mexico. Whether it causes disease in dogs has not been determined.

In a 2020 report, a novel, genetically well-characterized rickettsia species with 95% homology to both *R. massiliae* and *Rickettsia heilongjiangensis* was amplified from the blood of three different dogs in three different regions of the United States.[124] Clinical signs resembled RMSF and the dogs were seroreactive to *R. rickettsii*.

Diseases similar to MSF have also been described in people in the Eastern Hemisphere. Queensland tick typhus (*R. australis*), Flinders Island spotted fever (*Rickettsia honei*), Australian spotted fever (*Rickettsia marmionii*), African tick bite fever (*Rickettsia africae*), Astrakhan fever (*R. conorii* sub sp. *caspia*), Japanese spotted fever (*R. japonica*), Far Eastern spotted fever (*R. heilongjiangensis*), North Asian tick typhus (*Rickettsia sibirica*), and European tick-borne lymphadenopathy (*Rickettsia helvetica*, "*Rickettsia sibirica* sub sp. *mongolotimonae*," *Rickettsia slovaca*, *Rickettsia aeschlimannii*, *R. massiliae*) are analogous diseases of humans caused by other SFG rickettsiae and transmitted by arthropods in geographically distinct regions.[7] *Rickettsia helvetica* is found in *Ixodes* spp. ticks and has a wide distribution in Europe and the Far East. *Rickettsia helvetica* DNA, along with that from *R. japonica*, has been identified by PCR in ticks removed from dogs and cats in Japan.[125] Dogs and cats have had positive serologic reactions to this *Rickettsia*, indicating exposure, and DNA of *R. japonica* has been amplified from dog blood.[126,127] *Rickettsia japonica* causes transient clinical signs including fever, anorexia, and depression in immunosuppressed but not healthy experimentally infected dogs.[33] Antibodies to *R. australis* have been documented in dogs in southeastern Australia. Antibodies to SFG rickettsiae have been detected in the blood of dogs and cats in the Tasmanian region of Australia; however, there was no correlation between seroreactivity and the animal's health.[128] Experimental infection in dogs was subclinical, and although seroconversion occurred, *R. australis* could not be reisolated.[31] Taken together, these studies suggest that SFG rickettsiae other than *R. rickettsii* may cause milder disease in dogs, as is the case in humans, and that novel rickettsiosis should be considered in dogs with atypical clinical signs or those presenting in endemic or nonendemic areas. Some PCR assays and other molecular biological techniques may be used to differentiate among species in clinical cases. Whenever possible, it is important for veterinary and human clinicians to submit to laboratories that use PCR that can differentiate among SFG species.[58] Among other examples, determination of the infecting species resulted in the recognition of the novel *Rickettsia* sp. in dogs in the United States.[124] Antibodies to SFG rickettsiae that are nonpathogenic (or of low pathogenicity) cross-react with pathogenic SFG rickettsiae and therefore may make determining the meaning of a positive titer in an ill patient challenging.

RICKETTSIALPOX

Rickettsialpox is a nonfatal febrile zoonotic illness caused by *R. akari*, a SFG rickettsia that predominantly affects people in urban areas. Serum antibodies to *R. akari* were found in dogs examined during routine veterinary care in New York City.[129] The only possible source of exposure for a person in North Carolina who developed rickettsialpox was captured mice brought in by a pet cat.[130] An 8-month-old dog from Mexico was infected with *R. akari* and had hyporexia, fever, vomiting, and melena.[131] Physical examination abnormalities were weight loss, abdominal discomfort, suspected myalgia, and hepatosplenomegaly. Hematologic and biochemical abnormalities included neutrophilic leukocytosis, anemia, thrombocytopenia, increased hepatic aminotransferase activity, hypoalbuminemia, and hypoglobulinemia. Treatment was instituted with oral doxycycline for 7 days, and remission occurred in 48 hours. The organism was also detected by PCR in two *Rh. sanguineus* ticks found on the dog. The maintenance of *R. akari* involves horizontal transmission between the house mouse *(Mus musculus)* and its mite *(Liponyssoides sanguineus)*. Transovarial and transstadial transmission occurs in the mite. Seropositivity in dogs indicates that an alternative form of this transmission cycle might exist. It is presumed that mites feed on dogs; however, a tick such as *Rh. sanguineus*, or another tick vector as-yet unknown may be responsible for exposing dogs.

FLEA-BORNE SPOTTED FEVER (*RICKETTSIA FELIS* INFECTION)

A flea-borne typhus-like illness caused by *R. felis* has been reported in people from many countries worldwide.[132] *Rickettsia felis* shares some phenotypic characteristics with the TG *Rickettsia*. For example, *R. felis* is primarily flea-borne rather than tick-borne, and it is ultrastructurally indistinguishable from, and has extensive serologic cross-reactivity with, *Rickettsia typhi*. However, genotypic studies show that it is more closely related to SFG *Rickettsia*, or may be a part of a separate phylogenetic lineage.[8,133]

The cat flea *(Ctenocephalides felis)* is the primary vector for *R. felis*, although *R. felis* has been detected in other arthropod vectors including other flea species, ticks, and mites.[132] More than 90% of fleas purchased commercially for research purposes are infected, whereas the percentage in naturally infected fleas is much lower and depends on the geographic area. In the United States, the disease is endemic in southern Texas and California and overlaps that of human murine typhus caused by *R. typhi.*[134] Opossums and fleas have been found to be co-infected with both rickettsiae, and cat flea infection with *R. felis* is more common than with *R. typhi* in these regions.[134–139] Given the presence of both agents in fleas, some reports of murine typhus based on serology may have been caused by *R. felis.*[132] Indeed, PCR and restriction fragment length polymorphism identified *R. typhi* in four of five people from Texas who had typhus, and *R. felis* was found in the remaining person.[138] However, the importance of *R. felis* as a predominant cause of typhus-like illness in southern California has been questioned.[140] An infection cycle in people with *R. felis* and *C. felis* has been found in France, Germany, and Brazil.[141,142] The infection probably exists worldwide in areas where cat fleas are prevalent. In Africa, there is some evidence that additional vectors may play a role in human cases.[132]

Rickettsia felis is transmitted vertically through transovarial transmission and possibly through consumption of infected feces by larvae

to successive generations of *C. felis*.[132,143,144] Infection can be maintained in cat fleas for up to 12 generations without the fleas having fed on an infected host. Therefore, it is also likely serves as a reservoir.[132] Horizontal transmission from vector to vector by a shared meal occurs, but whether mammalian blood or tissues serve as a source of infection for fleas has been questioned.[132] Infection with *R. felis* has been transmitted among cats by infected fleas, and cats are seropositive to *R. typhi* antigen in endemic areas.[137,145,146] Experimental infection of cats with *R. felis* produced subclinical infection with seroconversion between 2 and 4 months.[145] Fever was not associated with natural exposure to *R. felis* in one study.[39] Another study suggested that lymphadenopathy and polycythemia may be associated with infection.[147] In one study, neither the organism nor its nucleic acid was identified from blood of cats naturally infested with infected *C. felis*.[148] However, a 2018 study described amplification of *R. felis* DNA from the blood of a community cat in southern California.[135] Two additional cats in the California study had circulating DNA from the *R. felis*-like agent "*Candidatus* Rickettsia senegalensis." Out of 64 flea pools collected from community cats in that study, 12 were PCR positive for *R. felis*, 5 were PCR positive for "*Candidatus* R. senegalensis," and none were PCR positive for *R. typhi*.

Rickettsia felis was detected using PCR from dogs sampled in northern Cambodia and Queensland, Australia, and dogs have been shown to be seropositive in endemic areas in some but not other studies.[137,146,149–151] A recent study using PCR and cell culture demonstrated sustained *R. felis* rickettsemia in experimentally infected 14-week-old puppies.[152] Transmission of *R. felis* between infected and uninfected *C. felis* fleas also occurred. No changes in RBC or platelet count were documented in infected puppies, although some puppies developed transient leukocytosis, self-limiting diarrhea, and decreased appetite. One puppy demonstrated petechial hemorrhages. Whether clinical disease may occur in naturally infected puppies or adult dogs with or without co-morbidities is not known.

In the United States, *R. felis* has been detected in cat fleas taken from cats or dogs from states where sampling has been done.[135,144,148,153] Cats, dogs, and opossums may be likely hosts that transport infected fleas into human habitats.[154] Infection in humans is transferred by flea bites; however, flea feces contain viable organisms that might be inoculated into cutaneous bites or scratches similar to the suspected transmission of *Bartonella henselae*.[132] Clinical signs in humans include fever, headache, and rash. Fatigue, myalgia, photophobia, conjunctivitis, abdominal discomfort, vomiting, and diarrhea are also observed.[155] Doxycycline is the preferred treatment in humans, but many of the other drugs used to treat SFG rickettsial infections are also effective. Clearing of infection in cats or dogs by use of antimicrobials has not been determined. Flea control is essential to reduce the public health risk in endemic areas.

TYPHUS GROUP RICKETTSIAE

Typhus refers to diseases caused by TG rickettsiae. The TG *Rickettsia* spp. include *Rickettsia prowazekii* and *R. typhi*. TG rickettsiae are phenotypically and genotypically different than SFG rickettsiae. For example, they are serologically distinct, they reside in cytoplasm and not the nucleus, and they do not spread between cells through actin polymerization, but instead replicate until the cell bursts.[6,72] Humans are the primary reservoirs of *louse-borne typhus*, or *epidemic typhus*, a sporadic illness caused by *R. prowazekii*. It occurs when events favor proliferation and spread of the human body louse, such as unsanitary conditions and natural disasters. The organism infects the louse's alimentary tract and is excreted in its feces. Irritation from biting lice causes the person to scratch, thereby contaminating the abraded site with infected louse feces. Infection can also occur after rubbing contaminated hands on mucosal surfaces. Lice infected by *R. prowazekii* die within 1 to 3 weeks after ingestion of infected blood. Lice do not transmit the infection transovarially to their progeny. Another reservoir for this infection in humans in the United States appears to be the southern flying squirrel. The disease is referred to as "sylvatic epidemic typhus." The clinical signs in humans are generally similar to those of RMSF. Interestingly, in apparent contrast to infection with *R. rickettsii*, *R. prowazekii* can recrudesce years after initial infection in the same person.[156] This is referred to as "Brill-Zinsser disease" or recrudescent typhus. Antibody reactivity to TG rickettsiae has been observed in the sera of dogs suspected of having rickettsial disease.[157] *Rickettsia prowazekii* caused no illness or sustained infection in experimentally inoculated immunocompetent dogs.[157] No information clarifies whether this organism infects dogs or cats in nature.

Murine typhus, or *endemic typhus*, has a more worldwide distribution than louse-borne typhus. It is caused by *R. typhi*, which is transmitted by fleas. It is most prevalent in the temperate and subtropical climates where the reservoir rodent hosts and their fleas are found. The disease is transmitted by scratching of infected flea feces into a pruritic bite wound. Some transovarial transmission occurs, so direct bites from fleas can also produce illness in people. The clinical signs in people are very similar to those of RMSF. In the continental United States, murine typhus is endemic in southern California and South Texas. In this region, the natural host and vector system is the opossum and cat flea. It has also been isolated from cat fleas infesting dogs in Oklahoma.[153] In one study, dog and cat owners were no more likely to be seropositive than nonowners.[158] However, in another study, owning a dog was a significant risk factor for human exposure.[159] Because it is flea-transmitted, flea control on pets is important to help prevent human infection. *Rickettsia typhi* has been amplified from the blood of dogs[160] and from *Rh. sanguineus* ticks,[161] suggesting other vectors may play a role in transmission.

Scrub typhus is a rickettsial disease of humans caused by *Orientia* (previously *Rickettsia*) *tsutsugamushi* in southeastern Asia, the South Pacific, and Australia. It is transmitted by the chigger mite, and wild rodents and birds are reservoir hosts. Clinical signs are similar to those of RMSF. However, dogs have been experimentally infected with *O. tsutsugamushi* without signs of clinical illness. *Orentia tsutsugamushi* was amplified from the blood of a dog in Japan with clinical signs of rickettsial disease that responded to minocycline. Blood samples taken from 10 dogs fed in the same area as the ill dog were also PCR positive.[162] An *O. tsutsugamushi*-like organism has also been amplified from the blood of a naturally infected dog in South Africa.[163] The role of this organism as a disease-causing agent in dogs and cats requires further study.

CASE EXAMPLES

ROCKY MOUNTAIN SPOTTED FEVER IN A DOG

Signalment

A 5-year-old MC Australian shepherd from North Carolina.

History

The dog was examined by the North Carolina State University veterinary emergency service on April 11 because of recent onset of lethargy, fever, tachypnea, and a stiff gait when walking. Historically the dog had been healthy, had received routine vaccinations, heartworm preventative, and a flea preventative, and ran approximately 3 miles each evening with the owner, who was a veterinarian. On the day of examination and several hours after the evening run, the dog became lethargic, refused to eat dog food or treats, and seemed painful upon manipulation. The owner noticed that the dog's HR, which was normally 50 to 60 beats/minute, was 120 beats/minute at rest. Rectal temperature at home just prior to presentation was 104.4°F (40.2°C). Three days before the dog was evaluated, the owner had removed a nonengorged tick from the dog.

Physical Examination

Physical examination findings included a body weight of 21.3 kg, 3%–5% dehydration, pain score of 1 out of 4, rectal temperature of 103.7°F (39.8°C), HR 130 beats/minute, tachypnea (42 breaths/minute), and a normal CRT. The BCS was 5/9. The dog stood in a hunched position and had a stiff gait, but localizing pain was not elicited on palpation of the spine, joints, or long bones. There was no nasal or ocular discharge, no petechiae or rash, and no obvious swelling or joint effusion. Popliteal lymph nodes were prominent, but there were no other abnormalities noted on physical examination. Systolic blood pressure was 153 mmHg, and diastolic and mean blood pressures were 93 and 111 mmHg, respectively.

Laboratory Findings

The hematocrit was 42%, total plasma protein was 6.2 mg/dL, and the platelet count was 120,000/μL. A serum biochemical profile showed only hypoglobulinemia (1.7 g/dL).

Microbiologic Testing

A SNAP 4Dx Plus (IDEXX Laboratories, Portland, ME, USA) in-house ELISA assay was negative. Indirect IFA assays for *Babesia canis, B. henselae, Bartonella vinsonii* subsp. *berkhoffii,* and *E. canis* were negative (no detectable antibodies at a 1:16 screening dilution). The dog was seroreactive to *R. rickettsii* at a titer of 1:64. A PCR panel capable of detecting *Anaplasma* spp., *Babesia* spp., *Ehrlichia* spp., and *Rickettsia* spp. was negative on whole blood. A convalescent *R. rickettsii* antibody titer was 1:256, which supported a diagnosis of SFG rickettsiosis, most likely RMSF.

Treatment

Because of the acute onset of lethargy and fever, the history of recent tick attachment, the documentation of thrombocytopenia, and the relatively high frequency of RMSF in dogs and people in North Carolina, doxycycline (4.8 mg/kg, PO, q12h) was prescribed for 3 weeks before the results of microbiologic testing became available. The dog responded rapidly after doxycycline treatment, with appetite and behavior normalizing within 24 to 48 hours after the first dose.

Comment

Although the clinical signs in this dog were relatively nonspecific, the clinical presentation was very typical of RMSF. Because *R. rickettsii* causes generalized vascular injury resulting in increased vascular permeability, fluid and protein leakage out of the intravascular space, and an acute neutrophilic inflammatory response throughout tissue sites within the body, pain that appears to shift in location (back pain, joint pain, abdominal pain, and neck pain) is a typical disease manifestation. Also, the hunched appearance reported in this dog is commonly observed in dogs with RMSF. As this dog was owned by veterinarian and a tick had been removed a few days earlier, a clinical diagnosis and appropriate treatment were initiated earlier in the course of illness than is typical of most dogs with RMSF. The rapid initiation of doxycycline may have blunted the humoral antibody response and decreased the convalescent antibody titer to a level that is lower than expected in most cases of RMSF in dogs. It is important to note that PCR assay is insensitive in the early stages of RMSF, as there are often inadequate numbers of organisms in the blood to achieve successful amplification of rickettsial DNA. A very rapid response to doxycycline is expected, unless there has been a delay in diagnosis, accompanied by the onset of neurologic abnormalities. Dogs that develop neurologic complications experience a more prolonged recovery and can have residual neurologic deficits.

ROCKY MOUNTAIN SPOTTED FEVER IN A HUMAN PATIENT

On May 9, a 61-year-old man, who resided on a farm in Wake County, North Carolina, removed an embedded tick from the hairy portion of his right armpit. Although the duration of attachment was unknown, it was likely that the tick was acquired 2 to 3 days earlier while pulling weeds from a hay field. Using a tick identification key, an experienced research technician classified the tick as a male *A. americanum* and stored the tick in a vial containing alcohol. On May 16, while working on the farm, the patient experienced mild nausea after drinking water and became transiently dizzy. The next morning chills developed, and by the mid-afternoon the patient became febrile (101.2°F [38.4°C]), developed muscle pain, a mild headache, and remained in bed until the next morning. These symptoms became progressively more severe during the day and the tick attachment site had developed into an erythematous, circular lesion with induration and a necrotic center, consistent with a rickettsial eschar. Due to the history of tick attachment and fever (maximum temperature 102.9°F [39.4°C]), a SFR, such as RMSF, or neutrophilic or monocytic ehrlichiosis, caused by *Ehrlichia ewingii* or *E. chaffeensis*, respectively, was suspected. Neutropenia (2,553 cells/μL) was accompanied by a left shift (5% band neutrophils) and thrombocytopenia (148,000/μL). Doxycycline was dispensed with instructions to take 100 mg q12h for 7 days. That evening, after sleeping for 6 hours, the patient ate a small quantity of food, after which he became severely nauseated and fainted, and impact with the floor was associated with a severe blow to the back of the head. The next day (May 19) a maculopapular rash appeared that predominantly involved the inferior portions of the arms and legs. Throughout the day the distribution of the rash spread and the severity progressed from barely visible to obvious over most of the body. At no time did the rash involve the palms or plantar surface of the feet. Fever resolved within 36 hours after the initiation of doxycycline, and the rash began to fade gradually after 48 hours of treatment. Within a week after starting doxycycline, the patient was experiencing no symptoms and had no sequelae as a result of the infection or the fall. A repeat CBC (May 25) identified a normal neutrophil count (4,378 cells/μL), no band neutrophils, and a normal platelet count (320,000/μL). Acute-phase serum was collected and stored until the convalescent sample was obtained. *Rickettsia* and *Ehrlichia* spp. PCR was performed immediately. PCR amplicons, obtained from the patient's blood and from the tick, were sequenced, confirming the presence of *R. rickettsii* DNA. PCR for *Ehrlichia* spp. DNA was negative from both the tick and the patient. Subsequently, seroconversion to *R. rickettsii* antigens was identified (1:64 acute titer, convalescent titer 1:512 after 4 weeks). The patient did not seroconvert to *Ehrlichia* spp. antigens.

Comment

Historically, transmission of *R. rickettsii* in North America was attributed solely to *D. variabilis* in the eastern United States and to *D. andersoni* in the western United States. However, between 2002 and 2004, researchers at the CDC documented *Rh. sanguineus* transmission of *R. rickettsii* to people residing in Arizona. Although this is most likely an infrequent occurrence, this patient was infected with *R. rickettsii* by *A. americanum*. It is important to note the similarities between the historical, physical examination, and laboratory findings for the dog discussed previously and the human patient. In several published case reports, dogs develop RMSF before a family member contracts the infection from a tick. Thus, it is important for veterinarians to recognize and confirm a diagnosis of RMSF in dogs and to educate the client as to the risk of tick exposure within their local environment.

Jane E. Sykes

KEY POINTS

- Cause: *Neorickettsia helminthoeca*, the *Stellantchasmus falcatus* (SF) agent/Elokomin fluke fever (EFF) agent (salmon poisoning disease [SPD]) and *Neorickettsia risticii.* All are gram-negative, obligately intracellular bacteria that belong to the family Anaplasmataceae. A related organism, *Neorickettsia sennetsu*, causes febrile illness in humans who ingest raw fish in Asia (Sennetsu fever).
- First Described: The first reports of SPD were from northwestern Oregon, United States, in 1814 (Astoria).[1] Reports of natural infection of dogs with *N. risticii* first appeared from the United States in 1994.[2]
- Affected Hosts: *Neorickettsia helminthoeca* infects dogs, foxes, coyotes, raccoons, and captive bears. The SF agent infects dogs. *Neorickettsia risticii* infects horses (causing Potomac horse fever or equine neorickettsiosis), bats, and dogs. In addition, experimental transmission to dogs and cats has resulted in disease.
- Intermediate Hosts: The intermediate hosts for *N. helminthoeca* and probably the SF agent are aquatic snails (*Oxytrema silicula*) and fish (especially salmonids). For *N. risticii*, they are aquatic snails (*Juga* and *Elimia* spp.) and aquatic insects (caddisflies and mayflies).
- Geographic Distribution: The distribution of SPD is limited to the coastal areas of Washington, Oregon, northern California, British Columbia, and Brazil (2004). Infections with *N. risticii* have been documented in horses from the United States, Canada, and South America, including Uruguay and Brazil.
- Route of Transmission: SPD is transmitted to dogs by ingestion of the infected trematode vector *Nanophyetus salmincola*, most often in salmonid fish. *Neorickettsia risticii* is transmitted to horses by ingestion of the trematode vector *Acanthatrium oregonense* within aquatic insects. The mode of transmission of *N. risticii* to dogs is unknown, but they also may become infected through ingestion of infected aquatic snails or insects.
- Major Clinical Signs: SPD is often associated with fever, lethargy, anorexia, vomiting, diarrhea, and lymphadenomegaly. In the rare reports of *N. risticii* infection, dogs and cats have shown signs of lethargy, vomiting, hematemesis, petechial hemorrhages, fever, and polyarthritis.
- Differential Diagnoses: These include lymphoma, CPV infection, CDV infection, granulocytic anaplasmosis, ehrlichiosis, leptospirosis, septic shock, disseminated fungal disease (especially cryptococcosis), hemorrhagic gastroenteritis, dietary indiscretion, GI foreign body, pancreatitis, hypoadrenocorticism, and inflammatory bowel disease. For SPD, appropriate antimicrobial treatment with doxycycline must begin before the diagnosis is confirmed by laboratory testing. Misdiagnosis and delayed or inappropriate antimicrobial drug therapy increase morbidity and mortality.
- Human Health Significance: *Nanophyetus salmincola* can cause GI disturbances and eosinophilia in humans, but *N. helminthoeca* does not cause human disease. Similarly, *N. risticii* has not been reported to cause human disease. *Neorickettsia sennetsu* is a related pathogen that causes febrile illness in humans consuming raw fish in Asia.

SALMON POISONING DISEASE

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Salmon poisoning disease (SPD) is primarily caused by the gram-negative, obligately intracellular rickettsial pathogen *Neorickettsia helminthoeca*, which, like other *Neorickettsia* spp., resides within a trematode (fluke) vector for the course of the trematode's life cycle from egg to adult. The complete genome of *N. helminthoeca* has been sequenced.[3]

The trematode vector of *N. helminthoeca* is *Nanophyetus salmincola*, thought to be the most common trematode species endemic to the United States. The disease occurs in dogs, foxes, and coyotes. In addition, two captive polar bears receiving long-term glucocorticoid therapy for skin conditions succumbed to an SPD-like disease after eating inadequately frozen salmon,[4] an SPD-like disease was also reported in two captive Malayan sun bears after they were fed live trout from a northern California reservoir,[5] and SPD was confirmed using molecular methods in a captive African lion (*Panthera leo krugeri*) from Oregon after it was fed raw salmon.[6] Domestic cats are not susceptible to SPD, but trematodes develop when infected fish are ingested.[7]

SPD is geographically restricted to coastal regions of northern California, Oregon, and Washington in the United States, and southern British Columbia in Canada. This reflects the distribution of an aquatic snail, *Oxytrema silicula* (also known as *Juga silicula*), which is an intermediate host of the trematode (Fig. 47.1). The snail is prevalent in coastal streams. A similar disease has been described in dogs from southern Brazil,[8–10] and infection with *N. helminthoeca* was detected in several dead coatis (*Nasua nasua*) from a wildlife sanctuary in Foz do Iguaçu (southern Brazil).[11] It was not clear whether the infection in the coatis was clinical or subclinical; two of the coatis had died as a result of vehicle trauma. The trematode host and intermediate hosts involved in southern Brazil remain unclear.[8]

Another related, yet antigenically distinct organism is capable of causing SPD in dogs, the Elokomin fluke fever (EFF) agent.[12–16] Discovered during attempts to understand the role of black bears as reservoirs for SPD, it was initially thought to be a less pathogenic strain of *N. helminthoeca*, because experimental infection of dogs with the agent resulted in only mild disease.[14] The EFF agent has never been sequenced. In 2020, an organism known as the *Stellantchasmus falcatus* (SF) agent was detected in three dogs from the Pacific Northwest with severe clinical signs of SPD.[17] This organism is so named because it was first detected in the metacercariae of the trematode SF in grey mullet fish in Japan.[18,19] Inoculation of the SF agent into a dog resulted in mild disease.[19] The 16S rRNA gene sequence of the SF agent was published in 1996,[20] and in

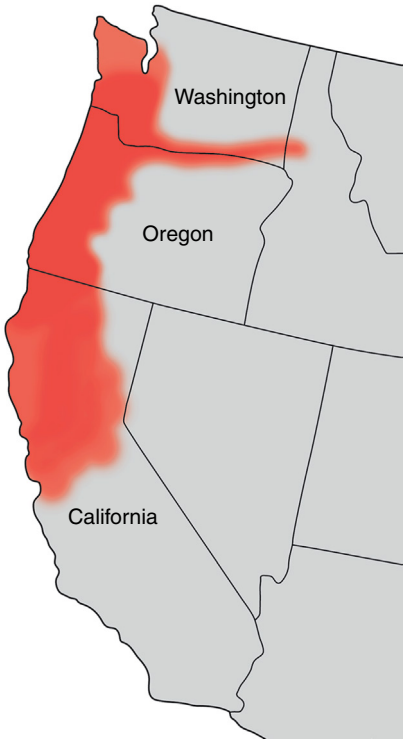

Fig. 47.1 Geographic distribution of salmon poisoning disease in dogs from the United States. The distribution also extends into the southern portion of British Columbia.

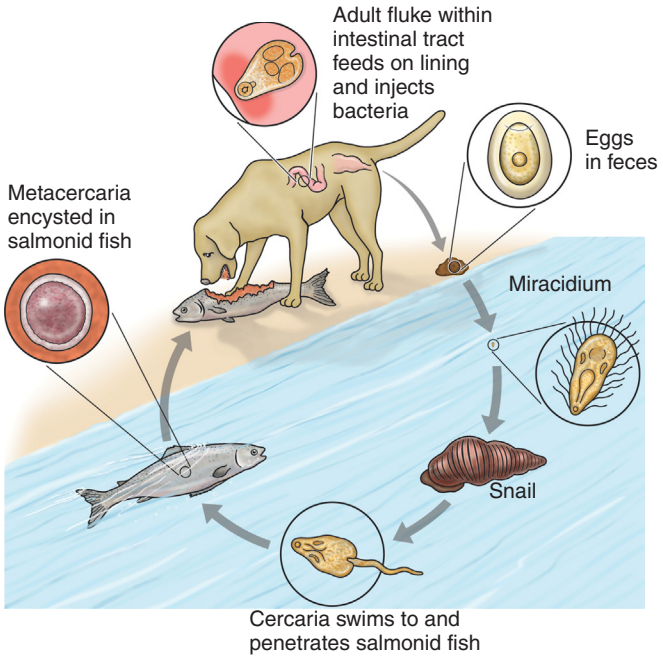

Fig. 47.2 Life cycle of *Nanophyetus salmincola,* the trematode vector of salmon poisoning disease. The fluke harbors the rickettsial organism throughout its lifecycle.

2016, an organism with the same 16S rRNA gene sequence was detected in *N. salmincola* metacercariae in Chinook salmon in the Willamette valley in Oregon.[21] It was then suggested that the EFF agent and the SF agent might be the same organism. The SF agent has also been detected in an adult fluke (*Metagonimoides oregonensis*) in Florida,[22] so there is the possibility that as-yet unrecognized disease occurs in dogs in Florida. The intermediate hosts for this fluke on the east coast are thought to be aquatic snails (*Pleurocerca* spp.) and the salamander (rather than salmonid fish), and so disease may be unrecognized on the east coast because intermediate hosts are infrequently consumed by domestic dogs. Raccoons are the primary definitive host for the fluke.

Dogs usually become infected with *N. helminthoeca* when they ingest encysted trematode metacercariae within uncooked or undercooked freshwater fish, most commonly salmonid fish. The Pacific giant salamander is also a competent second intermediate host. Ingestion of encysted metacercariae is followed by maturation of the trematode over a 6-day period, which feeds on the intestinal mucosa and inoculates the rickettsia into the host. The fluke has an oral sucker and a ventral sucker, which are used to grasp host intestinal tissue, although the fluke itself does not cause extensive damage to the intestinal wall.[23] Infected trematode ova are shed in the stool for 60 to 250 days.[24] After several months, miracidia develop within the eggs, hatch, swim away, and penetrate the snail. They then develop into rediae, each of which give rise to many free-swimming cercariae. Thousands of cercariae are released intermittently from the snail. These rapidly penetrate the skin of a fish (or are ingested by the fish), and encyst throughout the fish as metacercariae (Figs. 47.2 and 47.3). The metacercariae usually localize in the kidneys of fish, but can be found in any tissue, as well as slime on the skin of fish. Infected fish may contain more than 1,000 metacercariae. Infected fish may have visible damage to their skin, and the infection may also interfere with their swimming activity.[25] Fish are infected in freshwater and retain the trematode and the rickettsial infection throughout their ocean migration before

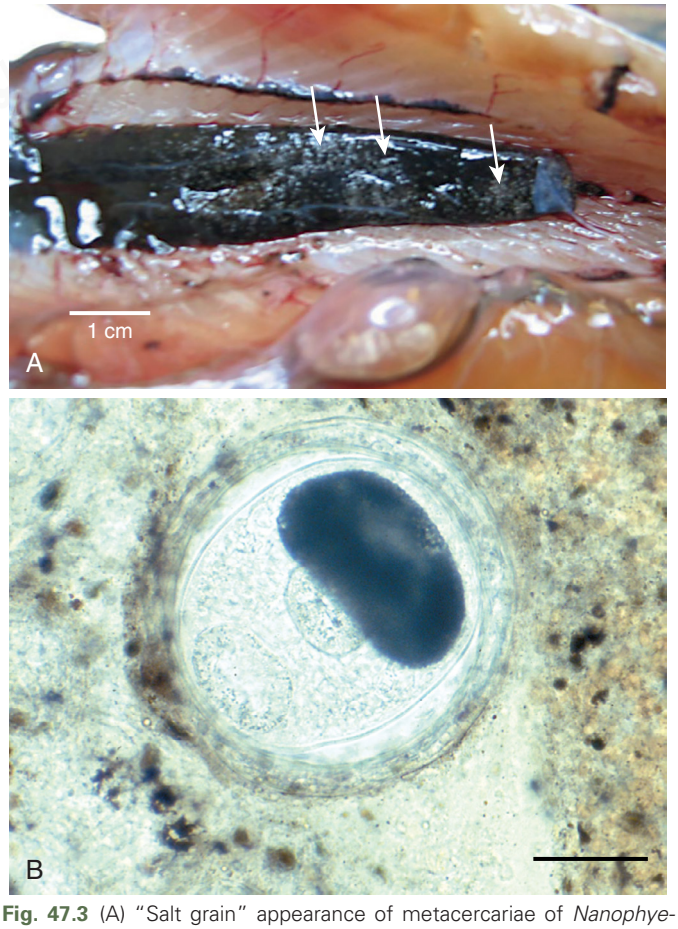

Fig. 47.3 (A) "Salt grain" appearance of metacercariae of *Nanophyetus salmincola (arrows)* in the kidneys of a Chinook salmon. (B) Wet mount squash of fresh kidney material from a Chinook salmon showing a metacercaria of *N. salmincola*. Bar = 100 μm. (A, Courtesy Craig Banner, Oregon Department of Fish and Wildlife. B,Courtesy Dr. Ronald Hedrick, University of California, Davis.)

returning to fresh water up to 3 years later.[26] Dog-to-dog transmission of *N. helminthoeca* has been demonstrated experimentally by mechanical aerosolization or rectal administration of lymph node suspensions or homogenates of rectal mucosa.[27] SPD also has been transmitted by parenteral injection of infected blood, spleen and lymph suspensions, adult flukes, helminth-infected snail livers, and helminth eggs. Partial transmission success was obtained by allowing ticks (*Haemaphysalis leachi* and *Rhipicephalus sanguineus*) that had fed on infected dogs to subsequently feed on susceptible dogs and by parenteral injection of suspensions of *Rh. sanguineus* into dogs.[28]

Intact male dogs and Labrador retrievers appear to be overrepresented among dogs with SPD,[29] possibly because they are popular with individuals engaged in fishing activities, although dogs of any sex and breed can be affected. Dogs of any age are affected; the median age in one study was 3 years.[29] Dogs develop SPD at any time of year. Occasionally, dogs from areas not endemic for SPD develop disease after they ingest fish that is exported from endemic areas.[30]

Most but not all infected dogs have a history of access to or consumption of raw or improperly cooked fish.[29,31] Consumption of any part of the fish, including the entrails and skin, may result in SPD. Supermarket-bought salmon may also be infected.[29] Infection has also been reported after swimming activity, without apparent exposure to fish.[29]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Neorickettsia helminthoeca replicates within macrophages. Rickettsiae enter the blood early in the course of the disease and spread to the lymph nodes, spleen, tonsils, thymus, liver, lungs, and brain.[32] This results in a granulomatous inflammatory response that is most profound in the stomach, intestines, lymph nodes, and spleen. Granulomatous meningitis has also been detected in dogs with SPD.[33,34] Affected dogs in southern Brazil have also had evidence of chronic interstitial pneumonia and choroid plexitis.[8]

The incubation period ranges from 2 to 14 days (median, 7 days), but may be as long as 33 days.[35] The severity of illness varies considerably (Box 47.1). Dogs with peracute infection may be found dead.[29] A marked febrile response is commonly detected (>70% of cases) (Box 47.2) and may reach 42°C (107.6°F).[29] A median rectal temperature of 40.6°C (105°F) was reported in one series of naturally infected dogs.[29] Rectal temperature gradually decreases to normal or below normal over the subsequent 4 to 8 days. Terminally ill dogs may be hypothermic. Some animals show only a mild increase in temperature or a brief period of fever; they may still die if left untreated. Virtually all dogs develop inappetence or anorexia, and lethargy is also common. Vomiting occurs in more than 80% of dogs, and rarely, hematemesis.[29] Diarrhea is also common (>70% of dogs) and may be semiformed to liquid in consistency, sometimes containing frank blood, melena, and, less commonly, mucus. Occasionally, a history of diarrhea and vomiting is absent. Other signs include serous nasal discharge, weight loss, and increased thirst and urination. Neurologic signs including mental obtundation, myoclonic twitching, seizures, and apparent neck pain have been reported in fewer than 20% of affected dogs, a primary differential diagnosis being CDV infection.[29] Dogs from southern Brazil have also shown neurologic signs and evidence of respiratory distress.[8]

Physical Examination Findings

Dehydration is frequently noted on physical examination and may be severe. More than 70% of dogs have peripheral lymphadenomegaly, which may be generalized or involve only some peripheral lymph nodes (see Box 47.2). Lymph nodes may be up to 4 cm in diameter and firm on palpation. Lack of lymphadenomegaly may be present occasionally, sometimes as a result of lymph node necrosis. Abdominal palpation may reveal pain, and splenomegaly may also be detected. Other abnormalities include tachypnea or labored respirations, tachycardia, scleral or conjunctival injection, serous nasal discharge, and edema that involves the limbs, face, or cervical region.[29] Mucosal pallor, tachycardia, and weak pulses may be present in dogs with hypovolemic shock. Cardiac arrhythmias such as ventricular premature contractions have also been noted, and signs of hemorrhage such as epistaxis and hyphema may also be present. Rectal examination may indicate the presence of liquid stool, sometimes accompanied by fresh blood or melena.

BOX 47.1 Signs in the Clinical History of 29 Dogs with Salmon Poisoning Disease from the United States

Inappetence or anorexia: 100%
Lethargy: 86%
Vomiting: 86%
Diarrhea: 72%
Hematochezia: 38%
Weight loss: 28%
Melena: 21%
Polyuria and polydipsia: 3%

BOX 47.2 Physical Examination Findings in 29 Dogs with Salmon Poisoning Disease from the United States

Peripheral lymphadenomegaly: 74%
Fever: 73%
Dehydration: 65%
Abdominal pain: 28%
Tachypnea or labored respirations: 24%
Tachycardia: 24%
Neurologic signs: 17%
Weak pulses: 17%
Splenomegaly: 14%
Scleral injection: 14%
Mucosal pallor: 10%
Hypothermia: 5%

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

Thrombocytopenia is present in 90% of affected dogs. Anemia is present in up to 40% of dogs with SPD and generally occurs as a result of GI hemorrhage. More commonly, the CBC shows evidence of lymphopenia, thrombocytopenia, and neutrophilia, frequently with bandemia (Table 47.1). Uncommonly, neutropenia occurs.[29] Toxic changes may be present within neutrophils, and immature monocytes may occasionally be found in the peripheral blood. Despite the association with helminthiasis, eosinophilia is often not present.

Serum Chemistry Profile

Hyponatremia and hypokalemia are the most common electrolyte abnormalities in dogs with SPD and result from GI losses that occur with vomiting and diarrhea (Table 47.2). Low concentrations of ionized calcium may be detected in some dogs, possibly as a result of

TABLE 47.1 Hematologic Findings in 29 Dogs with Salmon Poisoning Disease from the United States

Test	Reference Range	Percent Below Reference Range	Percent Within Reference Range	Percent Above Reference Range	Range For Dogs With Salmon Poisoning Disease	Number of Dogs

ALP, alkaline phosphatase; *ALT,* alanine aminotransferase; *BUN,* blood urea nitrogen.

decreased intestinal absorption. Hypoalbuminemia is present in most (>80%) dogs. Hypoglobulinemia and hypocholesterolemia occur in fewer than 25% of dogs with SPD. Abnormal liver enzyme activities may be present, the most common of which is increased ALP activity,[29,34] but increases in the activity of ALT and AST may also occur, and hyperbilirubinemia is present in fewer than 20% of dogs. Azotemia can be evident in dogs with severe dehydration.

Urinalysis

Bilirubinuria and proteinuria are frequently detected on urinalysis in dogs with SPD.[29] Uncommonly, cylindruria and glucosuria are present, perhaps as a result of renal injury secondary to impaired renal perfusion. Microscopic hematuria occurs in some dogs, possibly reflecting underlying coagulopathies that can occur in dogs with SPD.

Clotting Function

Evaluation of clotting function in some dogs may show evidence of DIC. Abnormalities include increased PT or APTT, increased fibrin degradation products, and decreased antithrombin activity.[29]

Diagnostic Imaging

Plain Radiography

Abdominal radiographs may be unremarkable or reveal fluid-filled small intestines; focal areas of decreased serosal detail; and less frequently, hepatomegaly or splenomegaly. Thoracic radiographs are typically unremarkable or show reduction in size of the intrathoracic vasculature, consistent with hypovolemia.

Sonographic Findings

Abdominal ultrasound examination of dogs with SPD often shows mild or moderate generalized abdominal or mesenteric lymphadenomegaly, as well as splenomegaly with a mottled splenic echotexture. Some dogs that lack peripheral lymphadenomegaly have abdominal lymphadenomegaly on ultrasound examination,[29] and ultrasound-guided aspiration of enlarged abdominal lymph nodes can be helpful for diagnosis in dogs that lack peripheral lymphadenomegaly. Lymph nodes develop a rounded appearance with a hypoechoic or hypoechoic mottled echogenicity (Fig. 47.4). Fluid-distended intestinal loops, sometimes with wall thickening, corrugation, hypermotility, or hypomotility, may be documented. Uncommonly, hepatomegaly or a small amount of free peritoneal fluid is identified.

Microbiologic Tests (Table 47.3)

Diagnosis Using Fecal Examination

SPD can be confirmed when operculated trematode eggs are found in fecal samples of dogs with consistent clinical signs, which appear within 5 to 8 days after the ingestion of infected fish. The light brown eggs are approximately 87 to 97 µm long and 35 to 55 µm wide, with a small, blunt point on the end opposite the indistinct operculum (Fig. 47.5). Although the sensitivity of centrifugal zinc sulfate fecal flotation for detection of *N. salmincola* ova in dogs with SPD is similar to that of fecal sedimentation, some dogs that test negative by one method test positive using the other, so the sensitivity of fecal examination for diagnosis is maximized by performing both centrifugal zinc sulfate fecal flotations and fecal sedimentation together. In one study, 93% of dogs with SPD tested positive for *N. salmincola* ova using a combination of fecal flotation and fecal sedimentation.[29] False negatives may occur when the duration of illness is shorter than the prepatent period of *N. salmincola* or when light fluke burdens are present. The finding of fluke ova on fecal examination may not be diagnostic of SPD, because dogs may be infected with trematodes that do not harbor the rickettsia, and ova may be shed for months after recovery. Nevertheless, *N. salmincola* ova were detected in only 0.2% of more than 1,800 fecal flotations in dogs seen at a teaching hospital in an endemic area, and all positive test results were in dogs suspected to have SPD. Thus, the specificity of fecal examination for a diagnosis of SPD appears to be extremely high.[29]

Centrifugal zinc sulfate fecal flotation may reveal co-infections with other GI parasites, which can complicate the clinical picture. Co-infections with *Dipylidium caninum* and *Trichuris vulpis* have been reported in dogs with SPD.[29]

Fig. 47.4 Enlarged and hypoechoic abdominal (medial iliac) lymph nodes as detected using abdominal sonographic examination in a 9-year-old male German shepherd dog with salmon poisoning disease.

Cytologic Diagnosis

In addition to fecal examination for trematode ova, SPD can be diagnosed following cytologic examination of peripheral lymph node aspirates, or ultrasound-guided aspirates of abdominal lymph nodes or the spleen. Cytologic findings consist of histiocytic hyperplasia and lymphoid reactivity. Rickettsial organisms are 0.3-µm cocci or coccobacilli and may be seen in large numbers within the cytoplasm of macrophages. Pleomorphic rods up to 2 µm long, sometimes forming

Fig. 47.5 Egg of *Nanophyetus salmincola* (×480).

TABLE 47.3 Diagnostic Assays Available for Salmon Poisoning Disease in Dogs

Assay	Specimen Type	Target	Performance
Fecal sedimentation combined with zinc sulfate centrifugal fecal flotation	Feces	*Nanophyetus salmincola* ova	Specificity nears 100% when performed by a parasitologist. Sensitivity probably > 90%. Eggs are light brown, ovoid, operculate at one end and measure 0.087–0.097 mm × 0.038–0.055 mm.
Cytology	Lymph node or splenic aspirates	Detection of *Neorickettsia* spp. within macrophages	Sensitivity > 70% when performed by a veterinary clinical pathologist. Sensitivity may be improved by examination of aspirates from multiple lymph node. Organisms within macrophages may be confused with debris or hemosiderin. Other changes include lymphocytic reactivity and histiocytic hyperplasia.
Histopathology	Biopsy or necropsy specimens, especially lymph nodes, spleen, gastrointestinal tissues	*Neorickettsia* spp. within macrophages	Organisms may be stained with Giemsa. Antimicrobial therapy can lead to false-negative results.
PCR	Blood, lymph node or splenic aspirates, tissue samples, feces	*Neorickettsia helminthoeca* DNA	Some assays may also detect other *Neorickettsia* spp., including the SF agent. Clinicians should consult with the laboratory. The optimum sample type is unknown. Antimicrobial therapy may lead to negative PCR results.

PCR, polyermase chain reaction; *SF, Stellantchasmus falcatus.*

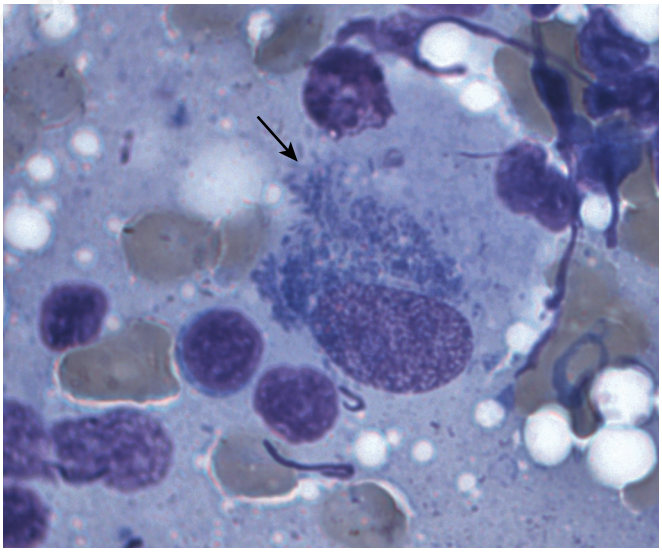

Fig. 47.6 Lymph node aspirate from a dog with salmon poisoning disease. Note the large histiocyte that contains granular coccoid organisms consistent with *Neorickettsia helminthoeca* (arrow).

rings or crescents, have also been observed. The organisms resemble granular to amorphous material of a uniform blue color using Wright stain, occasionally forming loose clusters of organisms (morulae) (Fig. 47.6).[29,35,36] Similar findings were described in dogs infected with the SF agent.[17] Extracellular organisms are not easily separated from artifacts and should not be considered diagnostic for SPD. In as many as one quarter to one third of dogs, rickettsial organisms are not identified. The presence of histiocytic hyperplasia should alert the clinician to the possibility of SPD. Organisms may also be absent in dogs with a recent history of antimicrobial therapy.

Serologic Diagnosis

Serologic tests for *N. helminthoeca* antibodies or antigen are not available on a commercial basis for veterinary practitioners. Antibodies to *N. helminthoeca* can cross-react serologically with those of *Ehrlichia* spp., so it is possible that dogs with SPD might test positive using serologic tests for *Ehrlichia* spp. (provided enough time had elapsed for antibody formation to occur).[37] In one study, most dogs with SPD that were tested for antibodies against other rickettsial pathogens did not seroreact to *Ehrlichia canis* or *Anaplasma phagocytophilum*.[29] Serologic cross-reactivity occurs among *N. helminthoeca*, the SF agent, *Neorickettsia risticii*, and *Neorickettsia sennetsu*.[38]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays have been used to detect the DNA of *N. helminthoeca* in clinical specimens from affected dogs.[29] Real-time PCR assays for *N. helminthoeca* are available from some veterinary molecular diagnostic laboratories and can be performed on blood, lymph node or splenic aspirates, and possibly fecal samples from dogs with SPD in order to confirm the diagnosis. More research is required to understand the sensitivity and specificity of PCR assays for diagnosing SPD in dogs, including the optimum specimen type for testing. A broad-spectrum *Neorickettsia* spp. PCR assay was used to detect the SF agent in dogs.[17] Some real-time PCR assays designed to detect *N. helminthoeca* have the potential to also detect the SF agent and other *Neorickettsia* spp.[29] However, genetic differences between the SF agent and *N. helminthoeca* have been identified that would allow development of species-specific assays.[38] Clinicians should contact their laboratory to determine the specificity of the PCR assays offered.

Cell Culture

Neorickettsia helminthoeca has been grown in canine monocytes,[16] canine leukocytes and sarcoma cells, mouse lymphoblasts, and a macrophage cell line.[39,40] However, cell culture is not used for routine diagnosis.

Pathologic Findings

Gross Pathologic Findings

Gross necropsy findings in dogs with SPD consist of enlargement of lymphoid tissues, including the tonsils, thymus, lymph nodes, and spleen. Lymph nodes may be yellowish and edematous and may contain white foci that represent foci of granulomatous inflammation. Petechial hemorrhages may be noted on the lymph nodes, GI tract, pancreas, gallbladder, and urinary bladder. The GI tract may be thickened and contain white foci. The lumen of the intestinal tract may contain free blood (Fig. 47.7A). Intestinal intussusception has also been described in association with SPD.[4] Flukes are only 0.8 to 1.1 mm long and 0.3 to 0.5 mm wide[41] and may not always be visible grossly.

Histopathologic Findings

Lymphoid tissues show marked depletion of lymphoid follicles, and subcapsular and medullary sinuses are filled with histiocytes, the cytoplasm of which can contain numerous rickettsial organisms, which occasionally form clusters within vacuoles. Organisms are readily appreciated using Giemsa stain (Fig. 47.7C). Lymph node and splenic necrosis may also be present.[4,29] Inflammatory nodules that contain lymphocytes, plasma cells, and infected histiocytes expand the lamina propria of the GI tract and extend into the submucosa. Parasites consistent with *N. salmincola* may be found embedded in the mucosa, primarily within the duodenum (Fig. 47.7B).[27,33] Nevertheless, flukes are not always found using histopathology in dogs that die from SPD, even in the absence of anthelmintic therapy.

One dog that died of SPD had widespread and multiple thromboses involving numerous organs with associated tissue infarction. Granulomatous meningitis has been described at necropsy in dogs that were experimentally infected with *N. helminthoeca*.[34] In addition to having characteristic GI and lymphoid lesions described in dogs from the United States, dogs from southern Brazil have had evidence of choroid plexitis as well as chronic interstitial pneumonia, with marked accumulations of alveolar macrophages and thickening of alveolar septa due to hyperplasia of type II pneumocytes.[8] IHC was used to demonstrate intralesional *Neorickettsia* antigen within affected tissues.

TREATMENT AND PROGNOSIS

The treatment of choice for SPD is doxycycline, tetracycline, or oxytetracycline, which should be given for a minimum of 7 days. Administration of tetracyclines is generally associated with clinical improvement within 24 hours, and signs resolve within 1 to 4 days.[29] Dogs that are vomiting may require treatment with parenteral tetracyclines. Clinical improvement has also been reported following treatment with enrofloxacin and parenteral trimethoprim-sulfamethoxazole. Antimicrobials that do not appear to be effective include first-generation cephalosporins, penicillins, aminoglycosides, chloramphenicol, and metronidazole.[29] Although complete clinical recovery may occur without anthelmintic treatment, the fluke infection should be treated with praziquantel after initial recovery from SPD (Table 47.4).[42] Elimination of *N. salmincola* from infected animals minimizes the diarrhea associated with fluke infections alone and minimizes or eliminates fluke eggs from feces. Dogs should also be treated and evaluated for concurrent parasite infections of the GI tract.

Dogs with mild signs or infrequent vomiting may respond well to treatment with oral tetracyclines alone, whereas those with more severe disease often require hospitalization for IV antimicrobial and crystalloid fluid therapy (Table 47.4). Oral antimicrobial therapy can be continued once

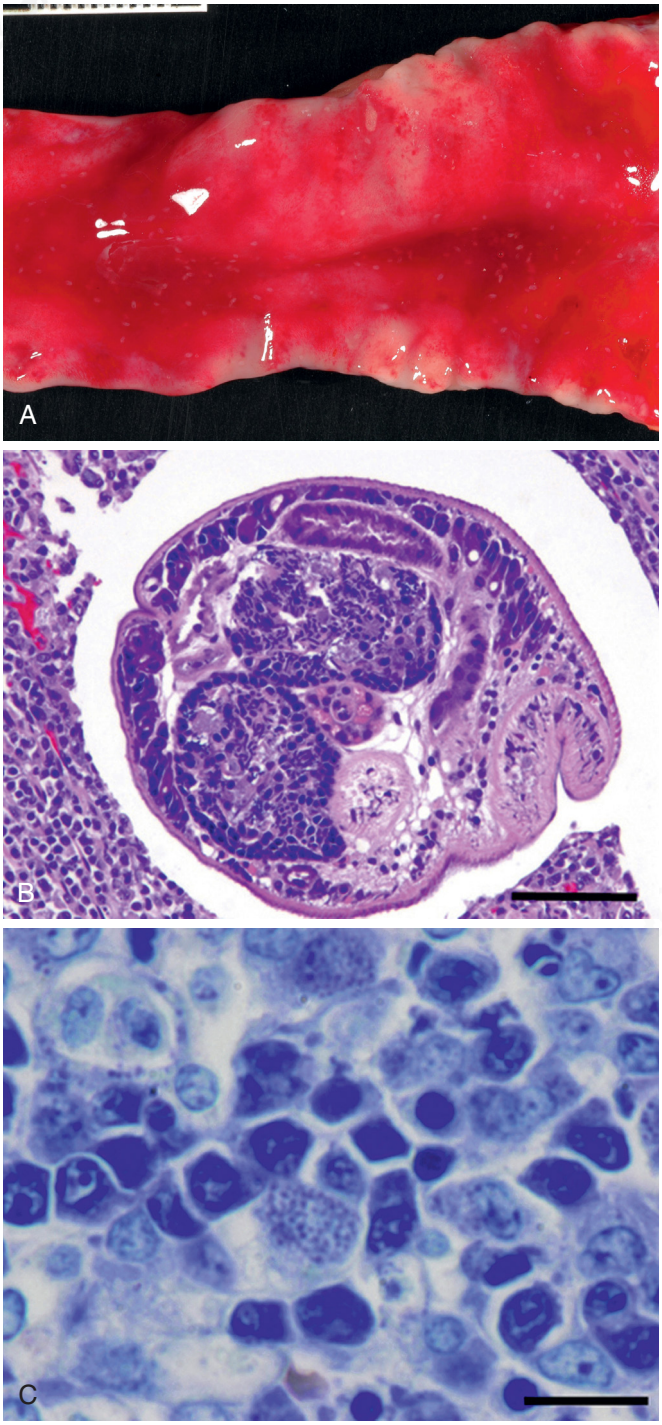

Fig. 47.7 (A) Intestinal mucosa of an 8-month-old female spayed Maltese mix dog that died of salmon poisoning disease. The intestinal wall was thickened and the contents were dark red and mucoid. (B) Duodenum. A transverse section of an adult *Nanophyetus* fluke is embedded within the intestinal villi. H&E stain. Bar = 200 μm. (C) Lymph node, medullary sinus from a dog with salmon poisoning disease. Many histiocytes have intracytoplasmic clusters of coccobacilli less than 1 μm in diameter. Giemsa stain. Bar = 5 μm. (A, Courtesy University of California, Davis Veterinary Anatomic Pathology Service. B and C, From Sykes JE, Marks SL, Mapes S, et al. Salmon poisoning disease in dogs: 29 cases. *J Vet Intern Med.* 2010;24:504–513.)

vomiting ceases. The presence of severe hypovolemia or hypoalbuminemia may necessitate treatment with colloids such as fresh frozen plasma, dextrans, or hetastarch. Packed RBCs or whole blood may be required for dogs with severe anemia. Treatment with central or partial parenteral nutrition may also be required if vomiting is persistent and does not respond to antiemetics such as metoclopramide, maropitant, or ondansetron. Close monitoring of HCT, albumin, electrolytes, acid-base status, renal parameters, and coagulation parameters may be required in some severely affected dogs. Blood cultures should be considered in dogs with severe hemorrhagic diarrhea and abnormal perfusion parameters, after which treatment with broad-spectrum parenteral antimicrobial drugs should be commenced.

Prolonged hospitalization may be required for dogs that develop complications such as cardiac arrhythmias, intussusceptions, adverse reactions to tetracyclines, DIC, or bacteremia.[29,31] In a study of dogs evaluated at a tertiary referral hospital, death or euthanasia occurred in 14% of 29 dogs with SPD.[29] The mortality rate may be lower in dogs seen in primary care practice, so long as appropriate treatment can be administered. In general, early treatment is associated with an excellent prognosis. Without treatment, death can occur within 5 to 10 days. The exact cause of death in SPD is unknown. Bacterial sepsis may result from translocation of bacteria across the damaged intestinal wall. Severe hypoalbuminemia and anemia secondary to GI hemorrhage and fluid losses may contribute.

IMMUNITY AND VACCINATION

Animals that recover from SPD are immune to reinfection with the same strain of *N. helminthoeca*,[4,43,44] but challenge with an alternate strain (then the EFF agent) results in disease, and antibodies fail to cross-react with the alternate strain. Reinfection with the EFF/SF agent may explain why SPD has been reported to occur more than once in some dogs.[4,21,29] In an unpublished survey of 331 practitioners in endemic areas, 35% reported that they had diagnosed SPD in dogs that had been treated previously for SPD.[4] No vaccine is available.

PREVENTION

Nanophyetus salmincola metacercariae are effectively destroyed by proper cooking or freezing of infected fish at –20°C for 24 hours.[30] Ingestion of raw fish by dogs in endemic areas should be discouraged, and dog owners in endemic areas should be educated about the disease. Dogs that have eaten raw fish from an endemic area, or those swimming in rivers or lakes in these areas, should be watched carefully for signs of lethargy, vomiting, or decreased appetite that occur within 2 weeks of exposure. If multiple dogs are simultaneously exposed to a source of *N. helminthoeca*, and one dog develops SPD, treatment of the other dogs in the group with 7 days of doxycycline should be considered. Medical equipment used in the treatment of dogs with SPD should not be reused on other patients without proper sterilization.

PUBLIC HEALTH ASPECTS

Human infection with *N. helminthoeca* has not been reported. However, humans may become infected with the fluke, *N. salmincola*, after consumption of poorly cooked fish. Most humans are subclinically infected, although abdominal discomfort, diarrhea, vomiting, weight loss, nausea, and peripheral eosinophilia may occur.[45] The SF agent was discovered during a search for the cause of "Hyuga" fever, which was thought to be caused by *N. sennetsu*. However, only the SF agent, and not *N. sennetsu*, was discovered in metacercariae from grey mullet fish ingested raw by most people that developed the disease.[19] Therefore, it is possible that the SF agent may be able to cause febrile disease in people, but this requires further study.

TABLE 47.4 Antimicrobials Used to Treat Salmon Poisoning Disease in Dogs

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)
Doxycycline	5	PO, IV	12	7–14
Tetracycline	22[a] 7	PO IV	8 8	7 7
Oxytetracycline	7–10[a]	PO, IV	8	7
Praziquantel[b]	10–30	PO	24	1–2

[a]Reduce dose in renal failure; may cause teeth discoloration in young animals.
[b]For treatment of fluke infection.
IV, intravenous; *PO,* oral.

NEORICKETTSIA RISTICII INFECTION

Rarely, dogs have been reported to develop disease in association with infection by *N. risticii*, the cause of equine neorickettsiosis ("Potomac horse fever"), or a closely related organism.[2] The life cycle of this organism involves a trematode vector, which in the eastern United States is *Acanthatrium oregonense*.[46] The fluke miracidia infect aquatic snails (*Elimia virginica* and likely other species) and metacercariae can be found in aquatic insects (caddisflies and mayflies).[47] Adult trematodes also lay eggs in the intestinal tract of insectivorous bats.[46] Potomac horse fever has been reported from the United States, eastern Canada, and South America, with reports from Uruguay and southern Brazil.[48]

Horses are often infected in summer following ingestion of infected aquatic insects and develop a severe systemic illness with fever, lethargy, anorexia, dehydration, diarrhea, laminitis, or abortion. In one report, *N. risticii* or a closely related organism was detected using culture and PCR in a small number of dogs from the western and southwestern United States with signs of fever, lethargy, vomiting, hematemesis, petechial hemorrhages, edema, or polyarthritis.[2] These dogs were seroreactive to *N. risticii* antigens using IFA. Serologic evidence of exposure to *Neorickettsia* spp. has also been documented in dogs from Thailand and Spain.[49,50] Experimental infection of dogs did not result in development of clinical signs.[51] There is some evidence that *N. risticii* can cause disease in cats. Clinical signs reported in a study of experimentally infected cats included lethargy, fever, anorexia, diarrhea, and lethargy, and infected cats seroconverted between 10 and 23 days after infection.[52] There were no clearly defined hematologic abnormalities associated with the infection. To date, *N. risticii* has not been detected in naturally infected cats using culture or molecular methods, but serologic evidence of *Neorickettsia* spp. infection has been reported in cat populations from the United States[53] and Spain[54,55] and in a small number of cats with signs of anorexia, lethargy, fever, vomiting, diarrhea, polyarthritis, and ocular discharge.[56] Laboratory findings in these cats included anemia, leukopenia, and thrombocytopenia. Because of the possibility of serologic cross-reactivity with other organisms, further studies are required to determine the significance of this organism in dogs and also in cats. In the meantime, screening of blood donors using PCR assays for *N. risticii* has been recommended given the potential for transmission by blood transfusion.[57]

Should infection by *N. risticii* be strongly suspected or confirmed in dogs or cats, treatment with doxycycline (5 mg/kg, PO, q12h for 2–3 weeks) is recommended.

CASE EXAMPLE

Signalment
"Herman," 9-year-old male German shepherd dog from Sacramento, CA (Fig. 47.8).

History
Herman's owner reported a 2-day history of inappetence, lethargy, and one episode of vomiting. The dog had been drinking normally. There had been no diarrhea, coughing, sneezing, or increased thirst and urination. The owner also reported that Herman ate turkey and chicken that contained bones 3 days before the onset of illness. He was normally fed a strict diet of rabbit- and potato-based prescription dog food and grilled salmon because of atopic dermatitis. Herman was sometimes fed salmon scraps from the local supermarket, which the owner grilled briefly. He had not traveled out of his local area. He was up to date on vaccinations, which included vaccines for distemper, hepatitis, parvovirus, and rabies.

Current Medications
Lincomycin 29 mg/kg PO q12h; trimeprazine tartrate 0.2 mg/kg PO q48h; and prednisolone 0.1 mg/kg q48h for atopic dermatitis.

Other Medical History
Herman had been diagnosed with hip osteoarthritis using pelvic radiography 8 months earlier. Controlled weight loss was the recommended treatment. He was cryptorchid, and the abdominal testicle had been removed when he was a young dog. The descended testicle was still present.

Physical Examination
Body weight: 51.5 kg.

Fig. 47.8 "Herman," a 9-year-old male German shepherd dog with salmon poisoning disease.

CASE EXAMPLE—cont'd

General: Quiet, alert and responsive. Ambulatory on all four limbs. Temperature = 104.3°F (40.2°C), HR = 108 beats/minute, RR = 60 breaths/minute, mucous membranes pink, CRT = 1 second.

Integument: A full, shiny haircoat was present and there was no evidence of ectoparasites.

Eyes, ears, nose, and throat: No significant abnormalities were noted. A mild amount of brown waxy debris was present within both ear canals.

Musculoskeletal: A BCS of 6/9 with symmetrical muscling was noted. Mild to moderate pelvic limb weakness was identified.

Cardiovascular: Strong femoral pulses were noted. No murmurs or arrhythmias were detected on thoracic auscultation.

Respiratory: An increased RR with increased abdominal effort was present.

GI and genitourinary: Abdominal palpation revealed a tense abdomen, with abdominal splinting, and splenomegaly. There was one descended testicle, which was smooth with no masses. No abnormalities were detected on rectal examination. Soft feces were present in the rectum, and the prostate was palpable and symmetrical.

Lymph nodes: Marked peripheral lymphadenopathy was present. Mandibular, superficial cervical, and popliteal lymph nodes were all 3–4 cm in diameter and firm.

Laboratory Findings

CBC: HCT 40.4% (40%–55%), MCV 65 fL (65–75 fL), MCHC 36.6 g/dL (33–36 g/dL), WBC 4,240 cells/μL (6,000–13,000 cells/μL), neutrophils 3,689 cells/μL (3,000–10,500 cells/μL), lymphocytes 466 cells/μL (1,000–4,000 cells/μL), monocytes 42 cells/μL (150–1,200 cells/μL), platelets 74,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 141 mmol/L (145–154 mmol/L), potassium 4.0 mmol/L (3.6–5.3 mmol/L), chloride 112 mmol/L (108–118 mmol/L), bicarbonate 13 mmol/L (16–26 mmol/L), phosphorus 2.8 mg/dL (3.0–6.2 mg/dL), calcium 9.9 mg/dL (9.7–11.5 mg/dL), BUN 15 mg/dL (5–21 mg/dL), creatinine 1.1 mg/dL (0.3–1.2 mg/dL), glucose 86 mg/dL (64–123 mg/dL), total protein 6.9 g/dL (5.4–7.6 g/dL), albumin 3.6 g/dL (3.0–4.4 g/dL), globulin 3.3 g/dL (1.8–3.9 g/dL), ALT 108 U/L (19–67 U/L), AST 109 U/L (19–42 U/L), ALP 105 U/L (21–170 U/L), creatine kinase 381 U/L (51–399 U/L), GGT < 3 U/L (0–6 U/L), cholesterol 296 mg/dL (135–361 mg/dL), total bilirubin 0.4 mg/dL (0–0.2 mg/dL), magnesium 1.7 mg/dL (1.5–2.6 mg/dL).

Urinalysis: SpG 1.048; pH 6.0, 2+ protein (SSA), 1+ bilirubin, 1+ hemoprotein, no glucose, 0–1 WBC/HPF, 20–30 RBC/HPF, rare ammonium biurate crystals, many lipid droplets.

Imaging Findings

Thoracic radiographs: The cardiovascular and pulmonary structures appeared within normal limits. A mild diffuse bronchial pattern throughout all lung fields was considered consistent with the age of the patient. Marked spondylosis deformans was present throughout the thoracic spine.

Abdominal ultrasound: The liver had a diffuse, coarse echotexture. The spleen was markedly, diffusely enlarged and had a diffuse hypoechoic, mottled echotexture. The prostate gland was enlarged and had multiple small anechoic cysts within its parenchyma. One testicle was present in the scrotum and had a striated, heterogenous echotexture. A second inguinal or intra-abdominal testis was not observed. Multiple enlarged, hypoechoic inguinal lymph nodes were present (see Fig. 47.4). A large (2.5 cm), round, hypoechoic mass with a focal area of mineralization was present in the cranial abdomen caudal to the liver and most likely represented a lymph node. Multiple enlarged, hypoechoic sublumbar lymph nodes were observed. The splenic lymph nodes were enlarged and mildly hypoechoic.

Cytology Findings

Cytology of ultrasound-guided splenic aspirate: splenic stromal clumps contained increased numbers of plump histiocytes and many large clumps of hemosiderin. Histiocytes were also present in moderate numbers throughout the smear, often in clumps, and often mildly vacuolated. They were occasionally erythrophagocytic and often contained hemosiderin. Interpretation: moderate to marked histiocytic inflammation.

Cytology of popliteal lymph node aspirate (see Fig. 47.6): moderate reactive lymphoid hyperplasia with pyogranulomatous inflammation was identified. Rare histiocytes were present that contained intracellular small coccoid purple-blue structures that were organized individually and in clusters. These were consistent with *N. helminthoeca* organisms.

Fecal Examination

Fecal flotation: Negative for parasites.

Fecal sedimentation: *N. salmincola* ova, <1 per 10× field.

Diagnosis

SPD

Treatment

Doxycycline, 5 mg/kg PO q12h for 14 days. This was associated with resolution of fever and inappetence within 24 hours of starting treatment. By 7 days after diagnosis, Herman's owner reported that Herman was completely back to his normal self.

Comments

This dog was diagnosed with SPD based on the presence of characteristic cytologic findings on examination of a lymph node aspirate, together with the detection of *N. salmincola* ova in the stool. The case was unusual because the dog was infected after ingestion of incompletely cooked supermarket-bought salmon, which the dog had been fed for years without developing illness. Although the splenic aspirate contained inflammatory cells typical of those seen in SPD, organisms could not be convincingly documented.

Coxiellosis and Q Fever

Jane E. Sykes, Jacqueline M. Norris

KEY POINTS

- First Described: Mid 1930s, Queensland, Australia, in slaughterhouse workers (Derrick).[1]
- Cause: *Coxiella burnetii,* an obligately intracellular gram-negative bacterial species that belongs to the family Coxiellaceae.
- Affected Hosts: Humans are most susceptible; reproductive disease can occur in farm animal species such as sheep, goats, and cattle, but the evidence for disease in cats and dogs is inconclusive.
- Geographic Distribution: Worldwide, with the exception of New Zealand and Antarctica.
- Major Clinical Signs: Dogs and cats are usually subclinically infected. Abortion, premature birth, and stillbirth have been reported in infected cats or dogs at the center of Q fever outbreaks in humans, but the role of *C. burnetii* in disease in cats and dogs is uncertain.
- Differential Diagnoses: Other infectious causes of reproductive disorders or pregnancy loss such as brucellosis, herpesviral infections, leptospirosis, neosporosis, CDV, and CPV infection. Noninfectious causes of pregnancy loss, such as endocrinopathies, genetic disorders, and nutritional deficiency, should also be considered.
- Human Health Significance: Q fever in humans results primarily from contact with infected sheep, goats, and cattle, or indirect contact with surfaces contaminated with secretions or excretions of these animals. However, contact with infected periparturient companion animals can also lead to transmission. Q fever in humans is most commonly an acute febrile illness, but pneumonia and chronic complications such as endocarditis, granulomatous hepatitis, and chronic fatigue can occur.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Coxiella burnetii is a gram-negative, obligately intracellular, small, pleomorphic rod that causes Q fever in humans, a significant zoonosis worldwide. Sheep, cattle, and goats are the most commonly reported reservoirs for the organism, but infected cats and less commonly dogs have also been implicated in transmission to humans.[2–7] Animals other than humans are often subclinically infected, although reproductive complications such as premature birth, abortion, and stillbirth may occur. In avian species, systemic illness has been associated with infection by other *Coxiella*-like organisms.[8–10] Reservoir hosts shed organisms in vaginal secretions and the products of parturition due to recrudescence of infection during pregnancy, with shedding in the urine, feces, saliva, and/or milk in some species. The placentas of infected animals are heavily infected (up to 10^9 organisms per gram of tissue). At parturition, aerosols are created, which are subsequently inhaled by other animals and humans (Fig. 48.1). Ingestion of unpasteurized contaminated milk is a less common and more controversial mode of transmission.[11,12] The term *Q fever* stands for *query* fever, the name it was given when it first emerged in Queensland, Australia, before the underlying cause had been identified. In humans, acute Q fever is characterized by a febrile "flu-like" illness, with headaches and profound fatigue, and sometimes pulmonary and hepatic involvement. However, infection is initially asymptomatic in 60% of those infected.[13] Persistent focal Q fever (previously known as chronic Q fever) can follow acute Q fever or asymptomatic infection and can be characterized by cardiac disease (endocarditis, pericarditis, myocarditis), fatigue syndromes, skin rash, and neurologic, pulmonary, and hepatic disease.

Unlike other obligate intracellular pathogens, *C. burnetii* survives prolonged periods in the environment, where it resists high temperature, a variety of disinfectants, and ultraviolet light. The organism exists in two forms: a small cell variant, which is a nonreplicating form that survives in the environment, and a large cell variant, which replicates within mononuclear phagocytes, especially alveolar macrophages (lung) and Kupffer cells (liver). Survival of the organism for up to 10 months on wool at 15°C to 20°C (59°F to 68°F) has been reported, and it can also survive in tissues that have been stored in formalin for several months. It is inactivated by 1% Lysol or 5% hydrogen peroxide.[14] Although originally classified within the order Rickettsiales, the availability of sequence information led to its reclassification as a gammaproteobacterium in the order Legionellales, which also includes *Legionella* species. *Coxiella burnetii* undergoes phase variation, which is associated with alterations in its cell wall components. The variants have nominally been called phase I and phase II.[15] The changes in cell surface antigens and the creation of phase variants have clinical implications for serologic testing in humans due to the production of phase I and phase II antibodies to the bacterium at different stages of natural infection (see Diagnosis, later). The whole genome of *C. burnetii* has been sequenced.[16]

Coxiella burnetii is extremely contagious, and only small numbers of organisms are required to cause disease in humans. The epidemiology of Q fever varies geographically. Because of its predilection for domestic ruminant species, Q fever is most commonly reported from rural areas although the potential role of wildlife continues to be explored. *Coxiella burnetii* has been detected within a huge variety of different tick and other arthropod species. Within ticks, it replicates in the midgut and it is shed in large quantities in tick feces. Although ticks have the potential to transmit the organism to domestic animal species, the most significant role of ticks appears to be in transmission to wildlife,[17] and molecular investigations question whether *C. burnetii* or other *Coxiella* spp. are involved.[18] Nevertheless, transstadial transmission of *C. burnetii* in *Ixodes ricinis* ticks has been accomplished under experimental conditions, supporting the role of *I. ricinus* as a vector.[19] *Coxiella burnetii* has been identified in fish, wild birds,

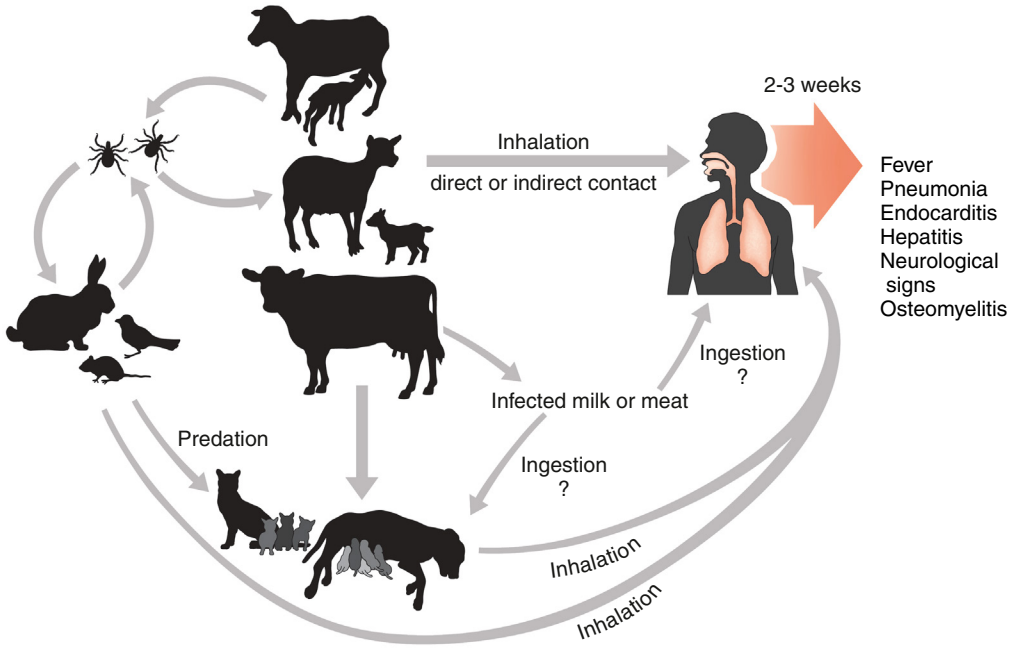

Fig. 48.1 Transmission of *Coxiella burnetii.* The organism is most often transmitted to humans when animals give birth. People become infected by inhalation when they directly contact the products of parturition or as a result of indirect contact with organisms that survive in the environment. Sheep, cattle, and goats are the most common reservoirs of the organism for human infection, but infected cats and less commonly dogs can also transmit the infection to humans. Although not a major mode of transmission, ticks can also harbor the organism and are thought to maintain transmission to wildlife species, especially rodents (such as small mice) and rabbits, and also birds. Dogs, cats, and humans can also become infected when they contact (or ingest) wildlife species. Ingestion of infected milk also may be a lesser mode of transmission.

rodents, marsupials, horses, swine, camels, marine mammals, ducks, turkeys, geese, cats, dogs, and rabbits. Although the mechanism is not clearly defined or established, cats and dogs could potentially become infected through exposure to infected sheep, cattle, and goats—possibly through ingestion of products from these species—and through contact with, or ingestion of, infected wildlife reservoir hosts such as rodents, birds, macropods, and rabbits.

Exposure to stillborn kittens or apparently healthy newborn kittens has been a risk factor for human infection in Africa, Japan, Korea, Canada, Australia, and the United States. In a study of intact female cats from Colorado, *C. burnetii* DNA was not detected in vaginal swab specimens or uterine biopsies from 50 shelter cats using a PCR assay, but 4 of 47 uterine biopsies from client-owned cats were positive.[20] Further molecular studies of uterine tissues of 26 normal cats and 11 cats with histopathologic evidence of uterine disease or other reproductive abnormalities identified three positive samples, two of which were from cats with normal reproductive systems.[21] In the Netherlands, following the largest Q fever outbreak in humans ever documented (2007 to 2010, approximately 4,000 cases), *C. burnetii* DNA was not detected in the placentas from 15 cats but was found in 4 of 54 (7%) dog placentas from veterinary clinical practices that focus their expertise on breeding animals. Some seroprevalence studies suggest that infection is more common in stray cats and dogs than in client-owned animals, while others suggest an increased prevalence in breeding cats or dogs from remote communities.[22–24] Further research is required to determine risk factors for exposure in dogs and cats including the role of ingestion of raw meat.[25–27] In one study from Australia, *C. burnetii* DNA was detected in 43% of 58 raw meat packages sold for companion animal consumption.[25] All of the positive samples contained meat of kangaroo origin amongst other things, whereas all the negative samples contained no kangaroo. No association has been found between prevalence of Q fever in humans and cat or dog ownership.[28] Laboratory-acquired infections have been described in humans, and infection can occur as a result of exposure to straw, manure, or dust, such as that from contaminated farm vehicles and contaminated clothing. Q fever has emerged as a disease of United States combat arms military personnel deployed to Iraq.[29] Studies of a large, 2-year outbreak in the Netherlands showed that dust-accumulating surfaces contained higher levels of *C. burnetii* DNA than vaginal swabs from sheep and goats.[30] The organism can travel for miles as a result of windborne transmission.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After inhalation (and to a lesser extent, ingestion), *C. burnetii* enters mononuclear phagocytes and survives within the harsh environment of the phagolysosome.[31] Remarkably, the acidic conditions of the lysosome appear to be a requirement for the metabolic functions of *C. burnetii.* Replication is prolonged, and minimal CPEs occur in infected cells. The organism appears to modulate apoptosis in order to inhibit cell death and promote its own replication.[31,32] Subsequently, infected cells enter the bloodstream. After experimental infection, bacteremia may be prolonged (up to 1 month) in cats.[33] The organism can persist in a variety of tissues, and in human patients, this contributes to chronic disease manifestations, such as prolonged fever, endocarditis, vasculitis, chronic fatigue, and immune-mediated consequences such as demyelinating polyradiculoneuritis.[34] Appropriate diagnosis and treatment at the acute stage of clinical illness is important in reducing the risk of postacute Q fever sequelae and development of chronic disease. Reactivation of shedding has been described during pregnancy in humans.[14] Infected cats and dogs usually show no clinical signs of infection, but stillbirth, abortion, and prolonged vaginal bleeding for 3 weeks before delivery have

TABLE 48.1 Diagnostic Assays Available for Q Fever

Assay	Specimen type	Target	Performance
Cell culture	Placental materials, vaginal swabs, blood, urine, feces, milk	*Coxiella burnetii*	Not widely offered or utilized for routine diagnostic purposes. Requires special facilities.
Histopathology	Placental materials	*C. burnetii*	Organisms may be seen when present in large numbers and stain with Gimenez stain. Immunohistochemistry and fluorescence *in situ* hybridization can be used to identify the organisms as *C. burnetii.*
Serology	Serum	Antibodies to phase I or phase II *C. burnetii*	Acute and convalescent serology is required for diagnosis of acute infection. At least 1 to 2 months may be required for seroconversion. Cross-reactivity may occur to related bacteria. IFA is considered the serologic test of choice in human patients. CFT is the OIE standard in animals but is less sensitive. IFA method has now been optimized for cats and dogs.
PCR	Whole blood, tissue specimens, vaginal swabs, milk, feces	*C. burnetii* DNA	Confirms active infection. Sensitivity and specificity may vary depending on stage of infection, assay design, and specimen type. PCR is most sensitive in acute infections (in the first 2 weeks of illness in humans), but is usually negative in humans with chronic infections. Subclinical shedding in animals is variable but is greatest during parturition.

CFT, complement fixation test; *IFA,* immunofluorescent antibody; *OIE,* World Organization for Animal Health; PCR, polymerase chain reaction.

been reported in cats.[7,35] The organism replicates in trophoblasts, and in experimentally infected goats, massive bacterial replication occurs in the placenta just before abortion.[36] An infected rabbit hound dog that transmitted *C. burnetii* to a family in Nova Scotia gave birth to four puppies, all of which died within 24 hours of birth.[2] The importance of *C. burnetii* in reproductive tract disease and chronic disease manifestations such as endocarditis in cats and dogs requires further investigation.

DIAGNOSIS

Microbiologic Tests

Diagnostic assays available for Q fever are listed in Table 48.1. In humans, a combination of serologic testing and molecular testing using PCR is recommended, especially in acute infections when serologic test results are often negative.[37]

Culture

Coxiella burnetii can be isolated in a variety of different cell lines. It has also been isolated in a cell-free medium that mimics the phagolysosome environment.[38] Because it is highly infectious to humans, most laboratories do not have the special facilities required to isolate *C. burnetii*. Thus, diagnosis of infection is usually performed using serology, PCR, or IHC.

Serologic Diagnosis

The World Organization for Animal Health (OIE) reference test for serologic diagnosis of *C. burnetii* infection in animals is ELISA.[39] A variety of serologic assays have been used to detect antibodies to phase I or phase II *C. burnetii* antigens in humans and other animals, including IFA assays, ELISA, and CFT. CFT is considered the least sensitive and specific method, but is still used for diagnosis.[40] In human patients, anti–phase II antibodies (IgG and IgM) are present in acute Q fever, whereas anti–phase I IgG antibodies predominate in chronic infection.[17,41] In humans, the use of IFA assays has been recommended for diagnosis of Q fever.[14,37,42] Acute and convalescent serology is required for diagnosis of acute Q fever in humans. It can take at least a month before seroconversion occurs; titers peak around 8 weeks after infection.[17] Diagnosis of focal persistent Q fever in humans is based on detection of an increased phase I IgG antibody titer (≥1:1024) and an identifiable persistent clinical manifestation, such as endocarditis.[37] Because infection is usually not clinically detected in dogs and cats, serologic assays have primarily been used in dogs and cats for epidemiologic studies or as part of import requirements to Q fever–free countries such as New Zealand. An IFA assay has been optimized for use in feline and canine serum and species-specific cutoff values have now been established that replace the less sensitive CFT used previously.[23,24]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Both conventional and real-time PCR assays have been described for detection of *C. burnetii* DNA. PCR assays are the diagnostic test of choice for organism detection and have revolutionized knowledge of the epidemiology of *C. burnetii* infections. In animals, PCR assays have primarily been used on a research basis. In humans, PCR is typically performed on whole blood (acute infections) or heart valve tissue (endocarditis), and is almost always positive in acute infections before antibodies develop.[37] Negative results can occur with PCR assays in chronic infections or even as early as 2 weeks after onset of acute illness in humans, because of undetectable levels of the infection or absence of bacteremia. Because *C. burnetii* is highly infectious to humans, special handling (BSL-3) conditions are required for fresh specimens that are submitted for *C. burnetii* PCR assays. When infection by *C. burnetii* is suspected (such as in placentas or aborted material), the laboratory should be contacted in advance, and specimens should be labeled and transported appropriately.

Pathologic Findings

Little information is available about the pathology of *C. burnetii* infection in dogs and cats. In affected livestock, *C. burnetii* causes a necrotizing placentitis with mixed inflammatory cell infiltrate and nonsuppurative vasculitis. In some cases, small, basophilic intracytoplasmic organisms can be seen (Fig. 48.2). The organisms stain with Gimenez, Giemsa, and modified acid-fast stains, but not Gram, silver, or periodic acid–Schiff stains.[43] IHC and FISH[44] can be used to identify *C. burnetii* antigen within lesions.

TREATMENT

Many acute infections in humans are self-limiting (or even subclinical), and symptoms respond to nonspecific therapy such as antipyretics and rehydration. However, because of concerns related to the development of focal persistent Q fever, specific antimicrobial therapy is recommended regardless of the severity of acute Q fever. When antimicrobial

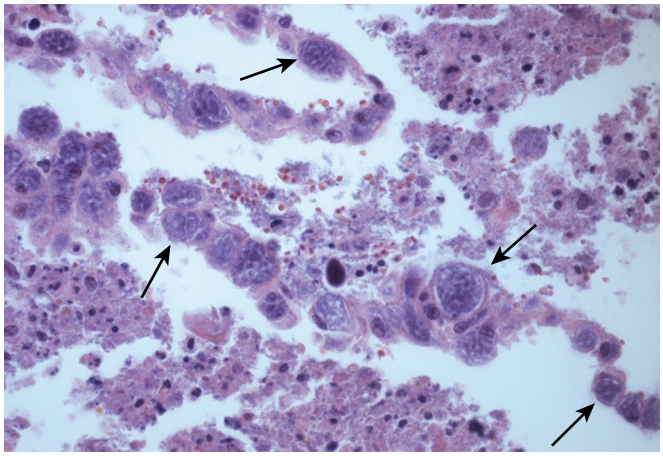

Fig. 48.2 Histopathology showing severe, acute necrotizing placentitis in the placenta of a goat from which dead fetuses were removed by caesarian section. Trophoblasts are distended with abundant basophilic bacterial organisms *(arrows)*. The organisms were subsequently identified as *Coxiella burnetii* with immunohistochemistry.

agents are required, doxycycline for at least 14 days or quinolones have been used successfully to treat pneumonia and hepatitis in human patients with *C. burnetii* infection. Combination therapy, such as doxycycline and hydroxychloroquine (which alkalinizes phagolysosomes) (as recommended by the CDC)[37] or doxycycline, ciprofloxacin, and rifampin for prolonged periods (e.g., 2 years), has been required for treatment of Q fever endocarditis, and valve replacement is frequently needed.[14,17] Antibody titers decrease with successful treatment. Q fever during pregnancy, which may result in abortion when infection occurs in the first trimester, is treated with trimethoprim-sulfamethoxazole for the duration of the pregnancy.[45] Treatment of an infected sheep herd with oxytetracycline on days 100 and 120 of gestation did not prevent shedding of *C. burnetii* in milk, vaginal swabs, or feces as assessed with PCR, nor did it affect the duration of shedding.[46]

PUBLIC HEALTH ASPECTS

In humans, asymptomatic infections with *C. burnetii* are probably widespread. When it occurs, Q fever is most often a systemic febrile illness. Because it mimics a variety of other illnesses, and confirmatory diagnostic tests require a specific index of suspicion by the medical clinician, Q fever is most likely under recognized. Veterinarians involved in mixed or farm animal practice, slaughterhouse workers, and workers in the livestock industry (farmers, shearers, transporters of animals) are most likely to develop Q fever as a result of direct contact with infected livestock. Person-to-person spread of Q fever is rarely reported, but humans can shed organisms during parturition, and infection of an obstetrician during delivery has been described.[47] Infection during pregnancy may also be associated with reproductive complications such as fetal death.[48,49] Transmission during necropsy examinations has also been reported. Between 2014 and 2017, approximately 160 to 190 cases of Q fever were reported to the CDC each year.[50] Approximately 80% of cases were acute and 20% were chronic, and more than one third of cases were from three states—California, Iowa, and Texas (Fig. 48.3). Peak months are in the spring and early summer, which correlates with the peak of the birthing season for cattle, sheep, and goats. In Australia where the disease

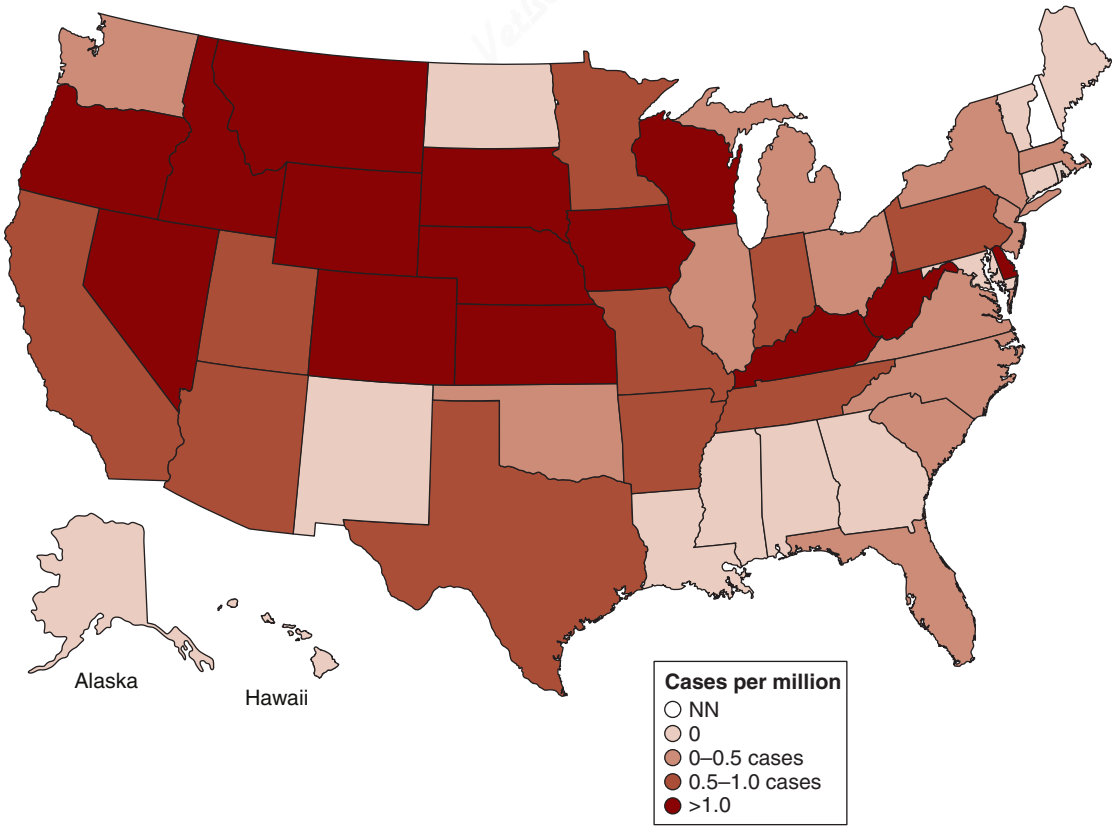

Fig. 48.3 Annual reported incidence (per million persons) for Q fever in the United States in 2017. Cases are most frequently reported from western and plains states where ranching and rearing of livestock are common. (From CDC, https://www.cdc.gov/qfever/stats/index.html)

is also notifiable, 300 to 500 cases are reported annually with most cases occurring in two states—Queensland and New South Wales.[51]

In humans, acute Q fever occurs after an incubation period that ranges from 9 to 39 days, although shorter incubation periods are possible with exposure to high doses of the agent.[14] The incubation period after exposure to an infected cat has ranged from 9 days to 4 weeks.[4,14] Males are predisposed, which relates to an increased likelihood of exposure to ruminants, the more common mode of exposure, and older men are more susceptible to disease.[37] Patients who develop pneumonia may also develop severe headache, as well as sweats, chills, fatigue, and myalgia. Other signs include cough, chest pain, nausea and vomiting, sore throat, diarrhea, a rash, and abdominal pain and hematuria.[14] Myocarditis and pericarditis can occur rarely. Blood work often shows a normal white cell count, and thrombocytopenia or marked thrombocytosis can occur. Serum biochemistry testing reveals mild to moderate increases in the activity of hepatic transaminases in almost all patients.[14] Pulmonary infiltrates are present on thoracic radiographs (Fig. 48.4), and in some cases, pleural effusion.[14,17] Q fever pneumonia is rarely fatal. Focal persistent Q fever may manifest as endocarditis, optic neuritis, osteomyelitis, granulomatous hepatitis, interstitial pulmonary fibrosis, and prolonged fever. In addition, a chronic fatigue syndrome, has been described in up to 10–15% of patients who develop acute infection with *C. burnetii*.[52] This syndrome appears to be due to cytokine dysregulation and may be characterized by incapacitating fatigue, nausea, headache, night sweats, myalgia, muscle fasciculations, lymphadenomegaly, disturbed sleep, irrational anger, and inability to concentrate. Endocarditis follows acute Q fever in fewer than 1% of cases,[41] and it may not become apparent for several years after acute illness. Approximately 3% to 5% of human endocarditis cases have been attributed to *C. burnetii*. Host factors seem to be important in whether chronic manifestations of Q fever occur. Cellular immunity and the production of IFN-γ appear to be required for resolution of infection.[41]

Because treatment with tetracyclines does not seem to reduce shedding by reservoir hosts, an emphasis has been placed on the development of effective vaccines for public health purposes. A phase I inactivated vaccine (Coxevac, Ceva, France) is commercially available in some parts of Europe to prevent shedding by reservoir livestock species, such as sheep and goats. Vaccination of sheep flocks led to a reduced number of abortions and decreased shedding, but did not completely prevent infection.[41] Vaccination was ineffective in previously infected cattle or naïve pregnant cattle.[53] Another phase I whole cell vaccine (Q-VAX, Commonwealth Serum Laboratories, Parkville, Australia) has also been used to protect naïve but at-risk humans, such as livestock workers (farmers, shearers, slaughterhouse workers, animal transporters), veterinarians, veterinary nurses, cat and dog breeders, wildlife carers, and laboratory workers, from infection. A Q-VAX skin test as well as serologic assays are performed as a prescreening of potential vaccine recipients for prior sensitization to Q fever antigens to minimize adverse vaccine reactions; humans with previous exposure to *C. burnetii* should never be vaccinated. It has been recommended that humans should not drink raw milk from infected farms. Aborted material and placentas can be buried with lime or incinerated.[41]

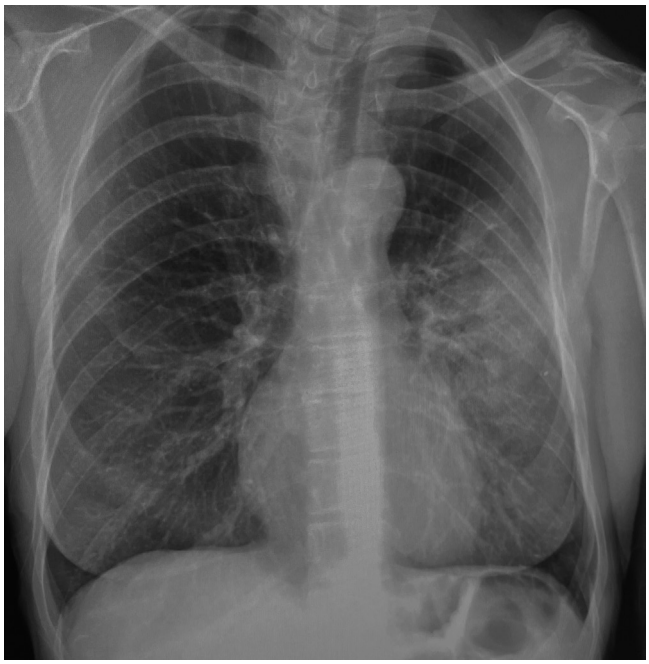

Fig. 48.4 Thoracic radiograph from a 49-year old female veterinarian with probable acute Q fever pneumonia. Left lobar consolidation is present. Cough, fever, myalgia and headache developed 2 weeks after running through a barn where lambing ewes with endemic coxiellosis were present. There was no response to amoxicillin and azithromycin, but treatment with 3 weeks of doxycycline led to gradual resolution of clinical signs. Phase I and Phase II acute titers were 1:256. Convalescent titers are pending at the time of writing.

Q fever has occurred in people exposed to periparturient cats. An outbreak in an Australian small animal veterinary hospital was linked to a cesarean section in a pregnant queen; nine veterinary personnel and the queen's owner had evidence of recent infection (see case example).[3] The most severely affected individuals had assisted in the surgery and performed mouth-to-mouth resuscitation on the newborn kittens. Small animal practices should incorporate measures into their infection control protocols to limit exposure to *C. burnetii,* including wearing appropriate PPE when around birth products and avoiding mouth-to-mouth and mouth-to-nose resuscitation of neonates. In mixed or large animal practices where veterinarians are exposed to periparturient sheep and goats, the use of proper PPE, including protective clothing (boots, coveralls) and eye protection and N95 masks, is recommended.[50]

CASE EXAMPLE

Signalment

A 50-year-old female veterinarian and a 23-year-old female veterinary technician from southeastern Australia.

History

A 3-year-old female British short-hair cat with dystocia was brought to a veterinary clinic by the breeder/owner at 8 o'clock in the morning. One kitten was stillborn in the home environment overnight. Safe delivery of the two remaining kittens required a cesarean section. Surgery was performed immediately, and the kittens were delivered and revived by vigorous rubbing with dry towels. The kittens were discolored by yellow-green placental material and were slow to revive. They were able to successfully suckle once the queen had recovered from general anesthesia. The queen and kittens were returned to the breeder's cattery the same afternoon.

CASE EXAMPLE—cont'd

Two weeks after the surgery, the veterinarian and the veterinary technician who had been involved in the cesarean section developed fever, severe headache, neck pain, chills, night sweats, myalgia, and stiffness. The veterinarian sought medical attention. Psittacosis was considered the most likely diagnosis by the attending physician, because psittacine birds were frequently treated in the clinic. A serologic test for chlamydiosis was negative, but nevertheless treatment with doxycycline was commenced. The veterinary technician's clinical signs were more severe and included cough, chest pain, nausea, and vomiting. As a result, she was hospitalized for 3 weeks for further diagnostic testing, treatment, and convalescence. When the technician tested positive by PCR assay for *C. burnetii* DNA on day 10 after the onset of illness, serial diagnostic tests for Q fever were also performed on the veterinarian. However, the veterinarian did not test positive until over a month after the day of the cesarean (Table 48.2).

Comments

Determination of the date of onset of illness is essential in any diagnostic investigation of Q fever in people for correct interpretation of diagnostic test results. In the first 8 to 10 days after the onset of illness, patients are frequently (80%) bacteremic (and therefore PCR positive) but still antibody negative. IgM class antibody to phase II antigens, as measured via IFA or ELISA assays, appear as early as 10 to 12 days after the onset of illness, but this may also be delayed, as occurred in the veterinarian in this example. IgM class antibody to phase I and IgG class antibody to phase II antigens often appear on day 15 to 20, but again this can be delayed. Small animal veterinarians and veterinary technicians or nurses who are exposed to kittens and placental secretions and subsequently develop illness should inform their practitioner of the possibility of exposure to *C. burnetii* because diagnosis requires a high index of suspicion and specific diagnostic assays. Fatigue often persists in patients for months after the onset of illness (as was the case for the veterinary technician in this example) and does not necessarily mean that focal persistent Q fever has developed.

TABLE 48.2 Results of Diagnostic Assays for Q fever in a Veterinarian and Veterinary Technician after Exposure to an Infected Cat's Reproductive Secretions

Days After Illness Onsent	REAL-TIME PCR ON WHOLE BLOOD		SEROLOGY FOR IgM AND IgG TO PHASE I AND PHASE II ANTIGENS[a]	
	Veterinarian	Technician	Veterinarian	Technician
10	ND	Positive	ND	Negative for IgG and IgM to phase II antigen
14	Negative	ND	Negative	ND
20	Negative	Negative	Negative	Positive for IgM to phase I and phase II antigens, positive for IgG to phase II antigen. Positive CFT for antibodies to phase II antigen
35	ND	ND	Positive for IgM and IgG to phase II antigen. Positive CFT for antibodies to phase II antigens	ND

[a]Performed by immunofluorescent antibody unless otherwise specified.
CFT, complement fixation test; *ND,* not determined.

Chlamydial Infections

Jane E. Sykes

KEY POINTS

- First Described in Cats: In 1944, United States.[1]
- Causes: *Chlamydia felis* (and possibly other chlamydiae such as *Chlamydia pneumoniae*) causes ocular disease in cats; *Chlamydia psittaci* and *Chlamydia abortus* have both rarely been detected in association with ocular and respiratory disease in cats and dogs.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Direct contact with respiratory secretions and possibly also vaginal secretions and feces.
- Major Clinical Signs (Cats): Acute and chronic conjunctivitis, chemosis, serous to mucopurulent ocular discharge, blepharospasm, with or without sneezing and nasal discharge.
- Differential Diagnoses (Cats): FHV-1, FCV, *Mycoplasma* spp., *Bordetella bronchiseptica* infections.
- Human Health Significance: *Chlamydia felis* has rarely been documented as a cause of human conjunctivitis. The importance of cats and dogs as a source of other human chlamydial infections requires further investigation. *Chlamydia psittaci* is generally acquired from avian species and not from dogs and cats.

ETIOLOGY AGENT AND EPIDEMIOLOGY

Chlamydiae are obligately intracellular bacteria that belong to the order Chlamydiales and primarily cause conjunctivitis in cats, but may also play a role in other systemic and reproductive disorders in dogs and cats that remain poorly characterized. Most knowledge of chlamydial infections results from research on human chlamydial infections, such as *Chlamydia trachomatis*, *Chlamydia pneumoniae* and *Chlamydia psittaci*, which have significant clinical and public health importance (see Public Health Significance). Chlamydiae structurally resemble gram-negative bacteria, lack peptidoglycan, and have extremely small genomes; they depend on the host cell for many amino acids and nucleotides. They exist in two forms: an infectious elementary body (EB), which is 0.2 to 0.6 μm in diameter and exists outside the cell, and the reticulate body (RB), which is larger (0.5 to 1.5 μm), noninfectious, and replicates within the cytoplasm of host cells, before it matures and forms EBs (Fig. 49.1). The EBs survive only a few days in the environment at room temperature and are readily inactivated by most disinfectants. Transmission occurs via direct contact or, to a lesser extent, aerosols. Fomites are also likely to be an important means of transmission among group-housed cats in heavily contaminated environments. In one study of stray and pet cats from Switzerland, rectal shedding was documented using real-time PCR in 25% of infected cats; 22% of infected cats had both positive conjunctival and rectal swabs. Therefore, rectal shedding may also contribute to environmental contamination.[2] Although the chlamydiae at one time separated into two genera, *Chlamydia* and *Chlamydophila*, based on sequence analysis of the 16S rRNA and 23S rRNA genes, there has been disagreement in the field regarding this classification, and reversion to the single genus *Chlamydia* has since been recommended based on the availability of complete genome sequence information.[3,4]

Chlamydiae persistently infect epithelial cells of the ocular, respiratory, GI, and genitourinary systems; chlamydial infections of the synovium have also been reported in a number of different host species. Different chlamydial species tend to cause disease in certain hosts, although evidence has accumulated that some chlamydial species may be capable of causing disease in more than one host species (Table 49.1). Some disease manifestations in a single host species may be caused by more than one chlamydial species. For example, whilst the human ocular disease trachoma is caused primarily by *C. trachomatis*, it has now also been associated with infection by *C. pneumoniae* and *C. psittaci*.[5] *Chlamydia felis* is an important cause of conjunctivitis and possibly reproductive disease in domestic cats, but recently DNA that resembles that of the human pathogen *C. pneumoniae* has now also been detected in ocular swabs from cats with conjunctivitis from Europe.[6] *Chlamydia abortus* DNA was also detected in 4.3% of 69 Chlamydiaceae-infected cats from Switzerland[2] and was detected in histopathology specimens from 1 of 13 cats with arteriosclerosis.[7] There are rare reports of chlamydial infections in dogs, in association with ocular and respiratory disease, polyarthritis, and atherosclerosis.[8–13] However, chlamydiae were not detected with PCR in canine atherosclerotic lesions from 16 dogs in one study.[7] Respiratory disease associated with *C. psittaci* infection has been reported most frequently among dogs.

The most significant pathogen of cats is *C. felis*, which causes acute and chronic conjunctivitis in cats worldwide. Conjunctivitis due to *C. felis* infection has also been reported in a free-ranging Eurasian lynx (*Lynx lynx*).[14] Based on sequence information from outer membrane protein genes, all feline isolates appear to be genetically similar. However, the results of serologic methods and random amplification of polymorphic DNA (RAPD) fingerprinting suggest that more than one strain of *C. felis* might exist. The prevalence of infection varies from one group of cats to another, geographic location, age of the cat population sampled, and presence or absence of clinical illness. Infection is most commonly detected in multiple cat households, especially breeding catteries. *Chlamydia felis* DNA is uncommonly detected in conjunctival swabs from healthy cats. For example, in household cats, clinically healthy cats, those with a history of past conjunctivitis, and those with active conjunctivitis, positive PCR results were 0%, 4.6% and 7.3%, respectively.[15] Isolation rates of up to 30% of household cats have been reported.[16] In shelter cats, the prevalence of *C. felis* infection has ranged from 0% to 15%.[17–20] In cats from 218 European rescue shelters,

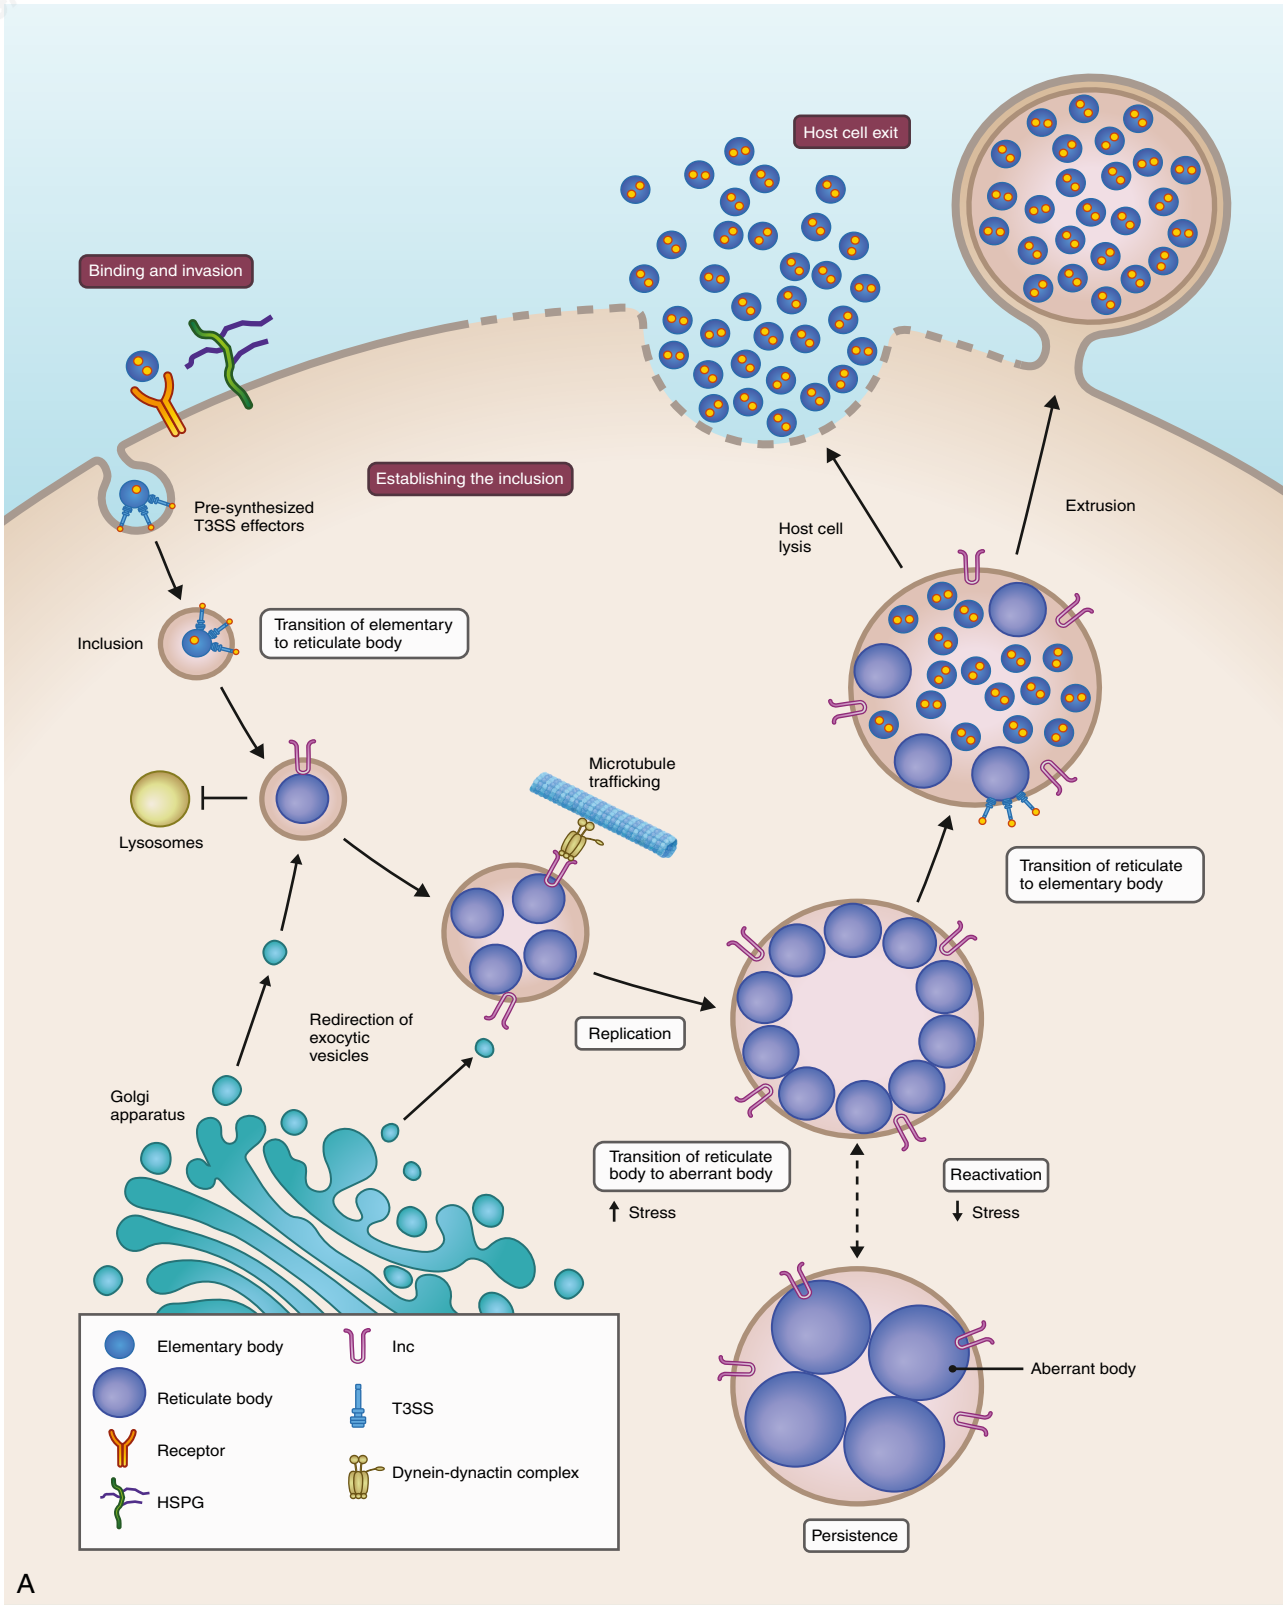

Fig. 49.1 (A) The binding of elementary bodies (EBs) to host cells is initiated by the formation of a trimolecular bridge between bacterial adhesins, host receptors, and host heparan sulfate proteoglycans (HSPGs). Next, pre-synthesized type III secretion system (T3SS) effectors are injected into the host cell, some of which initiate cytoskeletal rearrangements to facilitate internalization and creation of an anti-apoptotic state. The EB is endocytosed into a membrane-bound compartment (inclusion), which dissociates from the endolysosomal pathway. EBs convert to reticulate bodies (RBs) and newly secreted inclusion membrane proteins (Incs) promote nutrient acquisition by redirecting exocytic vesicles that are in transit from the Golgi apparatus to the plasma membrane. The RBs then replicate exponentially and secrete effectors that modulate processes in the host cell. Under stress, RBs enter a persistent state and transition to enlarged aberrant bodies. The bacteria can be reactivated upon removal of the stress. In late stages of infection, RBs synthesize EB-specific effectors before differentiating back to EBs. The EBs exit the host through lysis or extrusion. (Modified from Elwell C, Mirrashidi K, Engel J. *Chlamydia* cell biology and pathogenesis. *Nat Rev Microbiol.* 2016;14:385–400.)

Continued

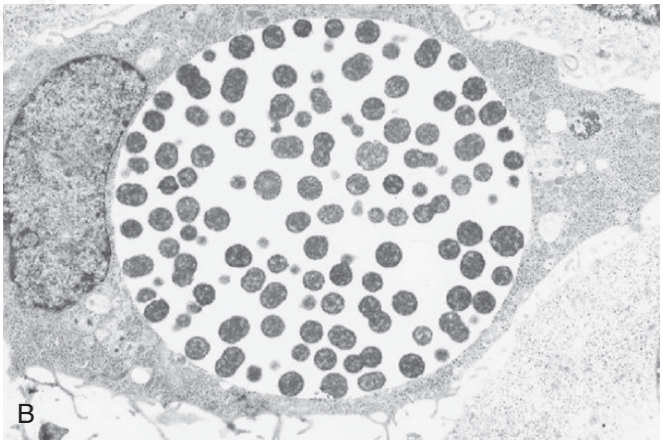

Fig. 49.1 cont'd. (B) Electron micrograph of chlamydial organisms growing in an inclusion in tissue culture. The larger RBs have more diffuse chromatin. One of the RBs appears to be dividing. The smaller dense bodies are EBs. (From Mandell GL, Bennett JE, Dolin R. *Principles and Practice of Infectious Diseases.* 7th ed. Philadelphia, PA: Elsevier: 2012;2:2440.)

breeding establishments, and private households, the prevalence of infection in cats without respiratory disease was 3% versus 10% in those with evidence of respiratory disease.[21] In this study, infection with *C. felis* was associated with suboptimal hygiene. Infection with *C. felis* is more commonly detected in young cats, especially those aged 2 to 12 months; kittens less than 2 months of age may be protected by maternal antibody, although neonatal infections have been described. Cats older than 5 years of age are very unlikely to be infected with *C. felis.* Co-infections with other respiratory pathogens, such as FHV-1 and FCV, are common and may contribute to increased severity of clinical signs.

The DNA of organisms that belong to the family Parachlamydiaceae has also been detected in cats with ocular disease. These organisms are *Chlamydia*-like organisms that reside symbiotically within amoebae. Parachlamydial species include *Neochlamydia*, *Parachlamydia*, *Protochlamydia*, *Rhabdochlamydia, Criblamydia, Simkania,* and *Waddlia*. DNA that closely resembles that of *Neochlamydia hartmanellae* has been detected in feline conjunctival specimens.[22] This organism is an endosymbiont of the amoeba *Hartmannella vermiformis*, which has been identified as a cause of ocular surface infection in humans and may play some role in feline ocular infections. The DNA of *Parachlamydia acanthamoebae* has also been detected with PCR in cats with keratitis and conjunctivitis.[23] As yet, amoebic co-infections have not been detected in cats. Further studies are required to determine the prevalence and clinical significance of these organisms.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Chlamydia felis infection is acquired by cats primarily through close contact, fomite, or, to a lesser extent, aerosol transmission. Kittens may be infected from the mother at birth. Whether venereal transmission occurs, as reported for other chlamydial species, is unknown, but in some infected cats, the organism is shed in vaginal discharges and from the rectum as well as in ocular discharges. After uptake of EBs, the EB transitions into the RB, which replicates by binary fission in a membrane-enclosed vacuole called an inclusion, and avoids lysosomal fusion. The RBs then transition back to the EB form, which is released into the extracellular milieu after cell lysis occurs and subsequently infect other host cells. The entire replication cycle takes about 2 days to complete (see Fig. 49.1).[24]

Chlamydiae primarily infect columnar epithelial cells, but they can also infect a variety of other cell types including endothelial cells, smooth muscle cells, lymphocytes, monocytes, and macrophages. *Chlamydia felis* replicates in the cytoplasm of conjunctival epithelial cells, and also spreads via the bloodstream to a variety of other tissues, such as the tonsil, lung, liver, spleen, GI tract, and kidney. Infection is typically followed 2 to 5 days later by the development of acute, chronic, or recurrent conjunctivitis, with or without signs of rhinitis, such as nasal discharge and sneezing. Most cats remain otherwise well and appetent. Lower respiratory tract signs such as cough and dyspnea rarely, if ever, occur. Corneal disease such as keratitis or corneal ulceration is rare, and if present, is likely caused by other or co-infecting pathogens such as FHV-1 or bacteria. Experimental inoculations have also been associated with fever, lethargy, lameness and joint pain (possibly due to polyarthritis), and weight loss.[25] There are also rare reports of gastritis and peritonitis in association with the detection of *Chlamydia*-like organisms in cats.[26,27]

After the initial episode of acute conjunctivitis, infection may persist for many months, and this may be accompanied by mild signs of conjunctivitis, or in some cases, no clinical signs of disease. Organisms have been isolated from the conjunctiva for up to 215 days after experimental infection.[28,29] Whether chronic disease is the result of repeated reinfection or the presence of persistent chlamydiae is unclear. Co-infections with other agents such as FCV, FHV-1, *Bordetella*, or *Mycoplasma* may increase the clinical severity of infection and duration of shedding. Other bacteria, including those that normally colonize the healthy conjunctival sac, can also act as secondary invaders and worsen the disease.

Whether *C. felis* can cause reproductive disease in cats remains unclear. The stage of pregnancy at which infection occurs, co-infection with other organisms such as FHV-1, concurrent immunosuppression, route of infection, and the strain involved may be important in

TABLE 49.1 Chlamydial Species That Infect Animals and Humans

Species	Major Host(s)[a]	Major Clinical Manifestations
Chlamydia trachomatis	Humans	Conjunctivitis (serovars A–C); urethritis, cervicitis, proctitis (serovars D–K); lymphogranuloma venereum (serovars L1, L2, and L3)
Chlamydia pneumoniae	Humans	Upper respiratory infection, community-acquired pneumonia, possibly atherosclerosis and asthma
Chlamydia psittaci	Humans, a variety of bird species (e.g., parrots, finches, poultry, pigeons, pheasants, seagulls, egrets, puffins)	Pneumonia, systemic infection
Chlamydia felis	Cats	Conjunctivitis, upper respiratory infection, arthritis, reproductive disease
Chlamydia abortus	Sheep, cows, goats, cats, other mammals	Reproductive disease
Chlamydia pecorum	Cattle and sheep	Encephalomyelitis, pneumonia, reproductive tract disease, conjunctivitis, polyarthritis
Chlamydia caviae	Guinea pigs	Keratoconjunctivitis

[a]Infection may occasionally extend to other host species.

determining the ability of *C. felis* to cause reproductive dysfunction, if this indeed occurs in cats.

Chlamydial infections are infrequently described in dogs. *Chlamydia psittaci* has been detected in dogs with respiratory disease, such as pneumonia and pleural effusion, and/or keratoconjunctivitis.[8–10] One group of bitches that had ocular and lower respiratory signs as well as stillbirths and low litter signs had nasal, conjunctival, and pharyngeal swab specimens that tested positive for *C. psittaci* infection with a nested PCR assay.[8] *Chlamydia abortus* was detected in a dog with keratoconjunctivitis.[11] The DNA of *C. pneumoniae* was detected in atherosclerotic lesions from dogs in Japan,[12] and *Chlamydia*-like organisms were found in a dog from South Africa with polyarthritis.[13]

Physical Examination Findings

Physical examination findings in cats with chlamydiosis include conjunctivitis, chemosis, serous to mucopurulent ocular discharge, and blepharospasm (Fig. 49.2). Signs of nasal involvement, such as stertorous respiration, serous or mucopurulent nasal discharge, and sneezing, may accompany conjunctivitis. Mucopurulent vaginal discharge has been reported in some cats that were experimentally infected by ocular inoculation.

Physical examination findings described in dogs with chlamydiosis have included fever, tachypnea, keratoconjunctivitis with mucopurulent ocular discharge, shifting leg lameness, and lymphadenopathy.[8–11,13]

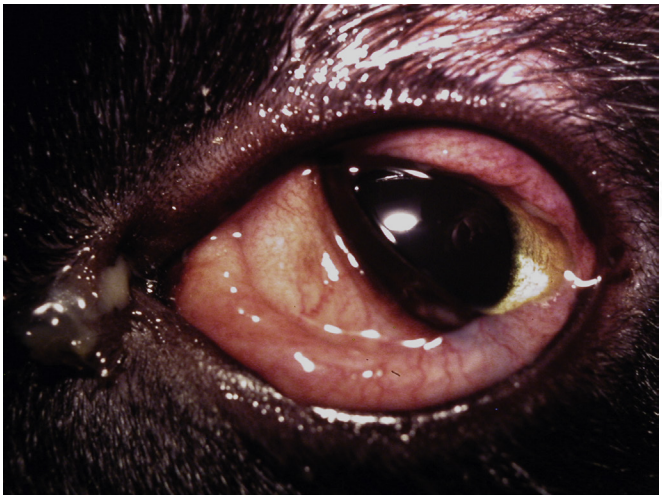

Fig. 49.2 Cat with acute chlamydial conjunctivitis. Note the intense hyperemia and chemosis.

DIAGNOSIS

There are no clinically significant laboratory abnormalities in cats with chlamydiosis, and there is insufficient information on laboratory abnormalities that might occur in affected dogs. Diagnosis of chlamydiosis is most often based on the results of molecular testing using PCR. For all diagnostic tests that detect chlamydial organisms, an attempt to collect sufficient numbers of infected epithelial cells should be made. This generally involves vigorous swabbing of infected mucosal sites such as the conjunctiva using a cotton swab (Table 49.2).

Microbiologic Tests

Cytologic Examination for Inclusions

Using light microscopy, chlamydial intracytoplasmic inclusions may be seen in epithelial cells that are present in smears of conjunctival scrapings. Inclusions comprise clusters of coccoid bacteria, and are usually 10 μm in diameter and stain basophilic (Fig. 49.3). Large inclusions adjacent to the nucleus can have a "cloak-like" appearance (hence the name *Chlamydia* which is derived from the Greek word meaning "cloak"). Giemsa is the preferred staining method. Inclusions are generally visible only early, if at all, during the course of infection, so this method is insensitive. Also, melanin granules in the cytoplasm of conjunctival epithelial cells can yield false-positive results. The use of direct FA staining or immunocytochemistry with antibodies directed to chlamydial antigens increases sensitivity and specificity.

ELISA Antigen Detection

A variety of commercial antigen detection enzyme immunoassay kits have been developed and marketed for diagnosis of human chlamydial infections in the past (e.g., Chlamydiazyme, Abbott Labs, Chicago, IL, USA). Nucleic acid amplification tests have now largely replaced the use of these assays for diagnosis of human infections. Reagents in ELISA used to detect the antigen of human chlamydial pathogens in swab specimens (such as conjunctival swabs) cross-react with *C. felis* antigen, so have also been used for diagnosis of feline chlamydiosis. Unfortunately, the kits vary considerably in their sensitivity and specificity. In general, ELISA methods that detect chlamydial antigen have lower sensitivity and specificity than cell culture, direct FA methods, and PCR for detecting feline infections.

Cell Culture

Culture of chlamydiae has traditionally been considered the gold standard for chlamydial diagnosis, but is now mostly performed on a research basis. Isolations from cats are usually highest from

TABLE 49.2 Diagnostic Assays Available for Chlamydiosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cell culture	Conjunctival swabs	*Chlamydia* spp.	Not widely offered or utilized for routine diagnostic purposes. Requires special chlamydial transport media. False negatives may occur when organisms lose viability during transport or in chronic infections, when organism numbers are very low.
Cytology	Conjunctival smears	Chlamydial inclusions	Low sensitivity. Inclusions are most likely to be seen early in infection. False positives can occur when cytoplasmic granules are mistaken for inclusions. Fluorescent or immunoperoxidase antibody techniques may increase sensitivity and specificity.
Serology	Serum	Antibodies to *Chlamydia* spp.	Acute and convalescent serology is required for diagnosis of acute infection. Vaccination may interfere with interpretation of results. Not widely available worldwide.
Polymerase chain reaction (PCR)	Conjunctival swabs, scrapings or biopsies	*Chlamydia felis* DNA or *Chlamydia* spp. DNA	Confirms active infection. Assays may be genus- or species-specific. Sensitivity and specificity may vary depending on assay design and specimen type. Because healthy animals may be PCR-positive, positive PCR results must be interpreted in light of the clinical signs. Vaccination with modified live chlamydial vaccines has the potential to interfere with results.

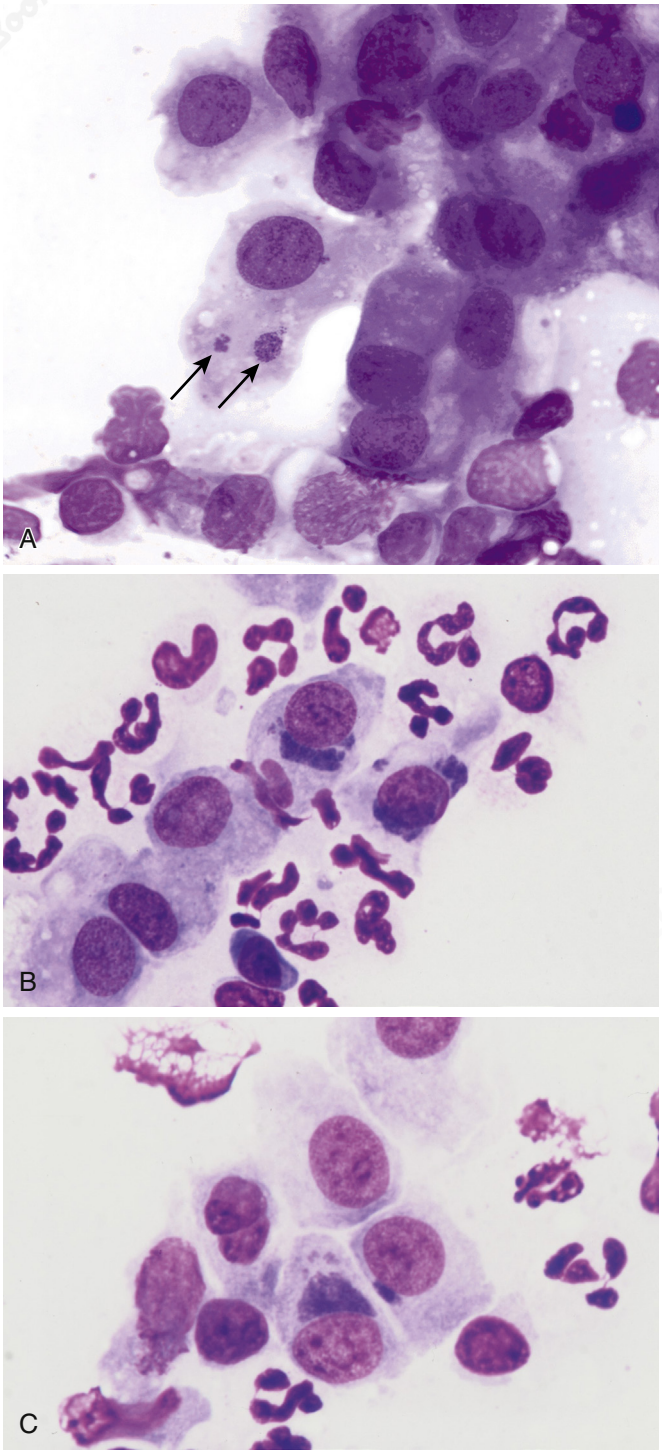

Fig. 49.3 Conjunctival scrapings from cats with chlamydial conjunctivitis. (A) Inclusions of *Chlamydia felis* are found in an epithelial cell *(arrows)* (Wright stain, original magnification 1000×). (B and C) Cloak-like inclusions adjacent to the nucleus of a conjunctival epithelial cell. (B and C, Courtesy of Dr. William Vernau, University of California, Davis.)

conjunctival swabs, although nasal and pharyngeal swab specimens may also contain infectious organisms. To enhance organism survival, swabs can be placed immediately in a chlamydial transport medium such as 2SP (0.2 M sucrose and 0.02 M phosphate). Routine viral transport medium contains antibiotics which will inactivate the organisms. The sample should be refrigerated (4°C) if it is not immediately

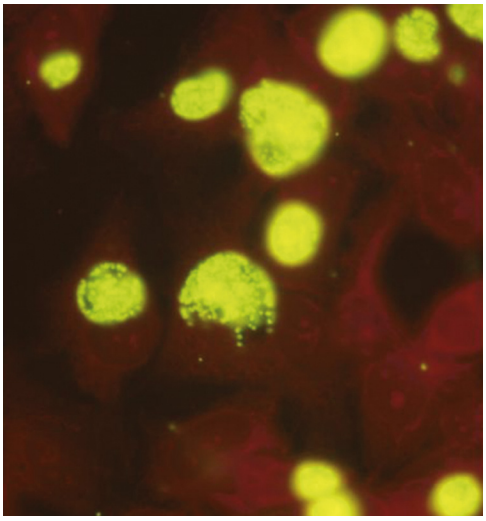

Fig. 49.4 Chlamydial inclusions stained with fluorescent antibody in a McCoy cell monolayer.

sent to the laboratory and ideally should reach the laboratory within 24 hours of specimen collection. In the laboratory, organisms can readily be grown in the yolk sac of embryonating eggs or in cell lines such as McCoy or HeLa cells. Incubation times are in the order of 2 to 3 days. Chlamydial inclusions within the infected cell culture are then identified using FA (Fig. 49.4).

Molecular Diagnosis Using Nucleic Acid–Based Testing

The use of molecular assays such as PCR has revolutionized the diagnosis of chlamydial infections in animals and humans, because these assays are rapid, sensitive, specific, and do not require special transport conditions. Sequence analysis of PCR products can be used to differentiate among species of chlamydiaceae. Both endpoint (conventional) and real-time PCR assays have been used to detect *C. felis* in conjunctival swab specimens from cats,[30–32] and real-time PCR assays that detect *C. felis* are offered by several commercial veterinary diagnostic laboratories worldwide. Unfortunately, considerable interlaboratory variation in assay performance can exist.[33] In addition, PCR assays for *C. felis* may not detect other chlamydial species, such as *C. pneumoniae*. Genus- or family-specific chlamydial PCR assays must be used to detect these organisms. The use of a DNA microarray assay for detection and identification of chlamydiae in cats was also reported.[7] The microarray assay consists of a chip that carries species- and genus-specific probes for identification purposes. DNA within the specimen is first amplified and biotin labeled with PCR, then reacted with the microarray probes.[34]

PCR assays for *C. felis* are usually more sensitive than culture in which comparisons have been made in naturally infected cats (see Table 49.2).[30] During antimicrobial treatment of infected cats, PCR results may continue to be positive for several days.[30,31] In one study, topical ophthalmic solutions such as proxymetacaine and fluorescein did not interfere with the ability of real-time PCR to detect *C. felis*, although there was a slight inhibitory effect when fusidic acid was used.[35] Because cats without signs of conjunctivitis have occasionally tested PCR positive for *C. felis*, the results of PCR must be interpreted in light of the history, clinical signs present, and response to appropriate treatment.

Serologic Testing

Serologic tests are not widely available for routine diagnosis of chlamydial infections. Assays for serum antibodies to chlamydiae, such

TABLE 49.3 Suggested Medications for Treatment of Cats with Ocular Chlamydiosis

Drug	Dose	Route	Interval (Hours)	Duration
Doxycycline[a]	10 mg/kg	PO	24	At least 4 weeks or 2 weeks after resolution of clinical signs
Amoxicillin-clavulanate	12.5	PO	12	4 weeks
Enrofloxacin	5	PO	24	3 weeks
Pradofloxacin	5	PO	24	6 weeks

[a]Doxycycline is the treatment of choice. For cats that fail to tolerate doxycycline, amoxicillin-clavulanate should be used. The fluoroquinolones enrofloxacin and pradofloxacin are an option for cats that do not tolerate either doxycycline or amoxicillin-clavulanate.

as IFA or ELISA, have been of limited benefit for detection of active infection because the IgG antibody titer increase is variable or prolonged, and IgM antibody titers are inconsistently increased. However, very high antibody titers (≥ 1:512) have been associated with clinical illness and/or chlamydial shedding, and high antibody titers among group-housed cats with conjunctivitis can suggest a role for *C. felis* in disease.[16,36,37] Chlamydial infections persist in the presence of high serum antibody levels, so serologic testing cannot be used to evaluate vaccine-induced protection. Serial titers may be needed to document active infections, and recent vaccination may interfere with interpretation of positive titer results. An ELISA that discriminates between the antibody response from vaccination and that from natural infection has been described.[38]

TREATMENT AND PROGNOSIS

Chlamydial infections are generally treated with tetracycline antibiotics. Oral administration of doxycycline at 5 to 10 mg/kg q12h, for 3 to 4 weeks results in clinical resolution in most cats. A dose of 10 mg/kg q24h can also be used.[37] Clinical improvement occurs within 24 to 48 hours after treatment is initiated. Treatment of all cats in a colony for 4 weeks is recommended, because in one study that used real-time PCR to detect infection, a 3-week course of treatment was insufficient to clear infection in some cats, but treatment for 28 days subsequently cleared infection in all cats.[31] Treatment may have to be continued for up to 6 to 8 weeks to ensure that all cats have been successfully treated. Regardless, treatment should continue for at least 2 weeks after the resolution of clinical signs.

Failure to respond completely may reflect the concurrent presence of viral causes of feline URTD. Because doxycycline hyclate administration can result in esophagitis and esophageal stricture formation, the administration of tablets should be followed by a bolus of water or food (see Chapter 10 for additional information on doxycycline). Ocular infections may initially respond to tetracycline eye ointment applied two or three times daily,[39] but recurrent infections have been documented,[40] possibly because systemic infection with chlamydiae can occur in cats with conjunctivitis.

For cats that do not tolerate doxycycline, 4 weeks of amoxicillin-clavulanate is a suitable alternative.[41] In experimentally infected cats, the efficacy of enrofloxacin (5 mg/kg, PO, q24h, for 14 days) was similar to that of doxycycline as determined with direct FA on conjunctival swabs, although a few cats in both the doxycycline and enrofloxacin groups had evidence of persistent infection at the end of the treatment period.[42] Doxycycline is the preferred antimicrobial drug because of concerns that relate to the possibility of retinal toxicity in cats treated with enrofloxacin. Doxycycline was more efficacious than pradofloxacin in experimentally infected cats that were monitored with PCR.[43] Sulfonamides or chloramphenicol are ineffective, and *in vitro*, penicillin is only inhibitory at higher doses. Treatment with azithromycin is also incompletely effective when compared with doxycycline (Table 49.3).[44]

IMMUNITY AND VACCINATION

Kittens acquire maternal antibodies to *C. felis* that usually protect them from infection until 7 to 9 weeks of age. Both humoral and cell-mediated mechanisms are important for protective immunity in chlamydial infections of other host species. Natural infection seems to confer little protection against reinfection, and this protection appears to be short-lived. However, given the low prevalence of chlamydiosis in older cats, an age-related resistance to chlamydiosis appears to exist in cats. Both inactivated and attenuated live vaccines are available to protect cats from chlamydial respiratory disease. These vaccines do not entirely prevent infection and shedding of chlamydiae after challenge, but they minimize the replication of the organism and hence reduce the severity of clinical signs. Transient fever, anorexia, lethargy, and lameness have been described 1 to 3 weeks after use of combined vaccines containing attenuated live *C. felis* in a low percentage of cats. Chlamydial vaccines are noncore vaccines that are recommended for cats with a high risk of acquiring infection, such as those introduced to or that reside in catteries with documented endemic chlamydiosis. These cats should be vaccinated after treatment of all cats with appropriate antimicrobial drugs.

PREVENTION

Given that chlamydiae survive poorly in the environment and the major route of transmission is close contact, transmission can be minimized by good hygiene, quarantine, single housing, and disinfection practices in cattery situations. Chlamydiae are readily inactivated by detergent solutions and common disinfectants.

PUBLIC HEALTH ASPECTS

The most significant chlamydial pathogens of humans are *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*. *Chlamydia trachomatis* causes trachoma, the leading cause of infectious blindness worldwide, and it also is the most common bacterial cause of sexually transmitted diseases in humans. *Chlamydia pneumoniae* is extremely widespread, may infect nearly all humans, and is an important cause of community-acquired pneumonia worldwide. It has also been implicated in atherosclerotic cardiovascular disease, although its role in this condition remains unclear. *Chlamydia psittaci* is the cause of psittacosis in birds and humans, a potentially life-threatening zoonosis.

Chlamydia felis has long been suspected as a cause of conjunctivitis in humans. However, many of the reports of human infection

with *C. felis* before the advent of genetic detection methods remain unconfirmed, because diagnosis was either based on culture without identification to the species level, or on serologic testing, which has the potential to cross-react with other chlamydiae and organisms such as *Bartonella*. Molecular assays have since been used to confirm the diagnosis of *C. felis* infection in humans. *Chlamydia felis* has rarely been detected in the conjunctiva of humans with conjunctivitis.[45,46] In these reports, the organism found in the humans was genetically indistinguishable from isolates recovered from the patients' cats. Although these associations have been difficult to document, routine precautions should be taken when handling cats with conjunctivitis, especially young cats with chronic conjunctivitis. Proper handwashing and routine cleaning and disinfection are likely to be sufficient to prevent transmission.

The identification of *C. psittaci* in dogs with respiratory disease and *C. pneumoniae* in cats with ocular disease suggests that dogs and cats may have the potential to be a source of these pathogens for humans, although avian species and other infected humans, respectively, are likely to be much more significant sources of infection.

CASE EXAMPLE

Signalment

"Sam," a 3-year-old male neutered domestic shorthair cat from Davis, CA.

History

Sam was brought to the University of California, Davis, by a veterinary student for evaluation of fever, right thoracic limb lameness, and bilateral conjunctivitis with mucopurulent ocular discharge of 2 days' duration. There had been no cough, sneezing, vomiting, diarrhea, or abnormal thirst or urination noted. Sam lived indoors with five other cats, three of which also had severe conjunctivitis, ocular discharge, fever, lethargy, and lameness for the last week. These three cats ranged in age from 8 months to 2.5 years. All of the cats had been vaccinated regularly for FHV-1, FCV, and FPV and tested negative for FeLV and FIV as kittens. They were all fed a commercial dry cat food.

Physical Examination

Body weight: 6.7 kg.

General: Bright, alert, responsive, and hydrated. T = 103.6°F, HR = 240 beats/minute, RR = 66 breaths/minute, mucous membranes pink, CRT = 1 second.

Eyes, ears, nose, and throat: No evidence of ocular discharge, mild conjunctival hyperemia; nasal planum clean and moist with no discharge; no oral erosions or ulcerations.

Musculoskeletal: BCS 7/9, decreased weight bearing on left thoracic limb, sometimes holds left thoracic limb up when sitting; possible mild effusion in the left elbow; resents flexion of the left carpus and left and right elbows.

Cardiovascular: No clinically significant abnormalities detected.

Respiratory: No clinically significant abnormalities.

GI and genitourinary: Nonpainful abdomen, no masses palpated, small-sized bladder.

Lymph nodes: No clinically significant abnormalities detected.

Laboratory Findings

CBC: HCT 46.3% (30%–50%), MCV 46.9 fL (42–53 fL), MCHC 30.7 g/dL (30–33.5 g/dL), WBC 10,500 cells/μL (4,500–14,000 cells/μL), neutrophils 7,455 cells/μL (2,000–9,000 cells/μL), lymphocytes 2,310 cells/μL (1,000–7,000 cells/μL), monocytes 525 cells/μL (50–600 cells/μL), eosinophils 210 cells/μL (150–1,100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 174,000/μL (180,000–500,000 platelets/μL), with moderate macroplatelets.

Serum chemistry profile: Sodium 152 mmol/L (151–158 mmol/L), potassium 4.4 mmol/L (3.6–4.9 mmol/L), chloride 117 mmol/L (117–126 mmol/L), bicarbonate 18 mmol/L (15–21 mmol/L), phosphorus 4.0 mg/dL (3.2–6.3 mg/dL), calcium 9.5 mg/dL (9.0–10.9 mg/dL), BUN 21 mg/dL (18–33 mg/dL), creatinine 1.6 mg/dL (1.1–2.2 mg/dL), glucose 151 mg/dL (63–118 mg/dL), total protein 7.1 g/dL (6.6–8.4 g/dL), albumin 3.1 g/dL (2.2–4.6 g/dL), globulin 4.0 g/dL (2.8–5.4 g/dL), ALT 48 U/L (27–101 U/L), AST 8 U/L (17–58 U/L), ALP 31 U/L (14–71 U/L), GGT 0 U/L (0–4 U/L), cholesterol 154 mg/dL (89–258 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.055; pH 6.5, trace protein, no hemoprotein, glucose, ketones, or bilirubin, 0–1 WBC/HPF, 0–2 RBC/HPF, few lipid droplets.

Synovial fluid cytology: Synovial fluid from the right stifle, right carpus, left carpus, and right tarsus was examined. All specimens apart from that from the left carpus were markedly blood contaminated and so could not be properly evaluated. The cell counts in these specimens ranged from 2,000 to 4,000 nucleated cells/μL, and consisted predominantly of neutrophils (66%–80%) and small mononuclear cells (7%–18%). The specimen from the left carpus had 2,000 nucleated cells/μL, of which 14% were neutrophils, 85% large mononuclear cells, and 1% small mononuclear cells. There were moderate numbers of erythrocytes and blood-associated leukocytes, as well as low numbers of large mononuclear cells of normal morphology, which was consistent with mild blood contamination and otherwise no cytologic abnormalities.

Conjunctival smear cytology: Chlamydial inclusions visualized within several epithelial cells.

Imaging Findings

Radiographs of the left radius and ulna, including carpus and elbow joints: No radiographic abnormalities.

Microbiologic Testing

FeLV antigen and FIV antibody serology: Negative

PCR for FCV (oropharyngeal swab specimens): Negative

Mycoplasma culture (conjunctival swab specimen): Negative

Diagnosis

A tentative diagnosis of chlamydial conjunctivitis and arthritis was made.

Treatment and Outcome

Treatment of all cats in the household with doxycycline (10 mg/kg, PO, q24h) was initiated. This was associated with rapid resolution of fever, ocular signs, and lameness.

Comments

The cats in this household may have had conjunctivitis and arthritis related to a chlamydial infection. The major differential diagnosis was FCV infection, which is more widespread than chlamydiosis and for which an association between lameness and infection has been widely documented. Infection with *Mycoplasma* spp. has also been associated with conjunctivitis as well as synovitis in cats (see Chapter 57). Infection with *C. felis* has been associated with development of lameness in experimentally infected cats, but there are no reports of lameness in association with natural infection. The negative PCR and culture results for FCV and *Mycoplasma* spp., respectively, could not definitively rule out infection with these agents. The presence of chlamydial inclusions in the conjunctival smear supported a diagnosis of chlamydiosis, but false positives can occur and unfortunately PCR was not performed to confirm the presence of a chlamydial agent. Nevertheless, the rapid response to doxycycline supported the possibility of a bacterial cause of the arthritis.

Streptococcal and Enterococcal Infections

John F. Prescott, Jane E. Sykes, Joshua B. Daniels

KEY POINTS

- First Described: Streptococci were first described in Germany in 1868 by Billroth.[1] Enterococci were separated from the genus *Streptococcus* in 1984.[2]
- Major Causes: In dogs and cats, the most common causes are *Streptococcus canis*, *Streptococcus equi* subsp. *zooepidemicus, Enterococcus faecium,* and *Enterococcus faecalis,* which are gram-positive coccoid bacteria.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Direct contact usually; hospital environments can become contaminated with resistant enterococci. Organisms are usually commensals that invade opportunistically.
- Major Clinical Signs: Clinically highly variable opportunistic infection; includes arthritis, bacteremia and endocarditis, bronchopneumonia, cervical lymphadenitis, cholangiohepatitis, discospondylitis, keratitis, mastitis, meningoencephalitis, necrotizing fasciitis and toxic shock syndrome (primarily *S. canis*), neonatal bacteremia, osteomyelitis, otitis externa, peritonitis, pharyngitis, postoperative incision or wound infections, pyometra or metritis, pyothorax, rhinitis and necrotizing sinusitis, and UTIs. Inflammation associated with these infections tends to be very pyogenic. In the lungs, these organisms are frequent components of polymicrobial aspiration pneumonia.
- Differential Diagnoses: Primarily other gram-positive and gram-negative bacterial infections.
- Human Health Significance: The role of dogs and cats in the transmission of *Streptococcus pyogenes*, a major human pathogen, (Lancefield group A) is commonly exaggerated. Streptococcal species that infect dogs and cats occasionally infect human patients. Dogs and cats, or their contaminated environments, may also have the potential to serve as sources of MDR enterococcal infections for humans.

ETIOLOGY, EPIDEMIOLOGY, AND CLINICAL FEATURES

Streptococci are catalase-negative, gram-positive, nonmotile cocci that divide along a single axis, forming pairs and chains of organisms (Figs. 50.1 and 50.2). They are facultative-to-strict aerobes that require complex media for growth, preferably supplemented with blood for the β-hemolytic types. They cause localized to widespread pyogenic infections in animals and humans. Although numerous species are pathogenic, many are commensal microflora of the oral cavity, nasopharynx, skin, and genital and GI tracts. More than 115 species of streptococci have been described. Species of streptococci vary in host tropism and virulence properties, and so are discussed separately. There has been conflicting literature as to whether one of the most important streptococcal pathogens of humans, *Streptococcus pyogenes*, which causes human streptococcal pharyngitis ("strep throat"), can infect dogs and cats. Reports in the medical literature that pets may be a reservoir of infection for humans have frequently been based on erroneous identification studies (see Public Health Aspects). However, interspecies transmission has been reported for some pathogenic streptococci such as *Streptococcus pneumoniae, Streptococcus canis,* and *Streptococcus equi* subsp. *zooepidemicus*. As is the case in humans, streptococci that infect dogs and cats range from commensals of low virulence to highly virulent organisms that can cause severe disease manifestations and death.

Several classification systems exist for streptococci based on cultural characteristics, antigenic composition, and biochemical features. Streptococci have been classified based on their *in vitro* hemolytic properties as: β-hemolytic streptococci, which cause complete hemolysis when they grow on blood agar; α-hemolytic streptococci, which reduce hemoglobin to cause a greenish discoloration of the agar around bacterial colonies; and, rather strangely, "γ-hemolytic," which are actually nonhemolytic streptococci. The β-hemolytic strains tend to be most pathogenic. Organisms in the α-hemolytic and nonhemolytic (γ-hemolytic) categories are found on mucous membranes and skin of clinically healthy animals. If present in an infectious process, they are usually regarded as contaminants or unimportant invaders. When they do cause illness, it may take the form of valvular endocarditis or embolic abscess. The precise species classification of streptococci in numerous disease processes described next is in doubt, especially in the older literature. The lack of harmonization of methods used to speciate streptococci among veterinary diagnostic laboratories unfortunately perpetuates this uncertainty.

Streptococci are also classified from A through W based on their surface antigens (Lancefield classification system) and further classified based on phenotypic characteristics. The Lancefield classification system tends to correlate with pathogenicity. Lancefield groups A, B, C, E, G, L, and M are usually β-hemolytic. Major pathogenic streptococci of dogs and cats belong to Lancefield groups B, C, D, or G (Table 50.1). "Pyogenic streptococci" are β-hemolytic streptococci that belong to Lancefield groups A *(S. pyogenes)*, B *(Streptococcus agalactiae)*, C (includes *Streptococcus dysgalactiae* and *S. equi* subsp. *zooepidemicus*), and G (includes *S. canis*). "Viridans streptococci" is an archaic term for catalase-negative gram-positive aerobic cocci that are either nonhemolytic or α-hemolytic (*viridis* = Latin for green) that tend to be commensals, have low virulence, and rarely invade tissues opportunistically. Many of these streptococci, which are also Lancefield group D, have now been classified as enterococci. Molecular typing schemes have revealed that hemolytic reactions, Lancefield antigens, and phenotypic characteristics do not necessarily predict genetic relatedness among streptococcal strains. Although these traditional classification

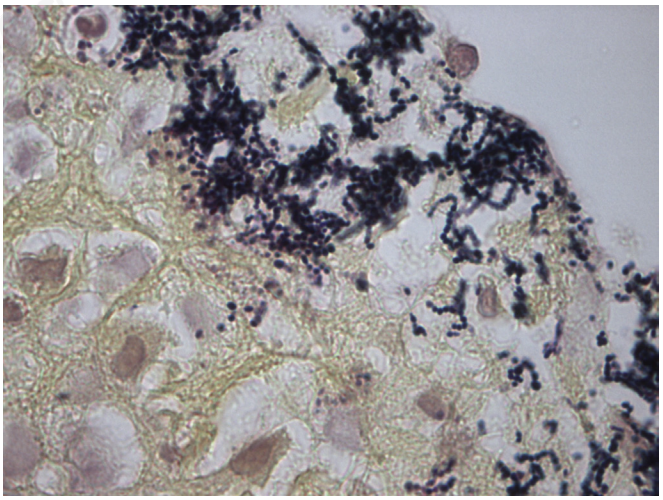

Fig. 50.1 Histopathology of the serosal surface of the liver of a 12-day-old domestic shorthair kitten that was euthanized after it was found hypothermic and tachypneic. Severe suppurative omphalophlebitis and peritonitis were present. Lesions contained numerous chains of gram-positive cocci. Brown and Benn stain, 1000× oil magnification.

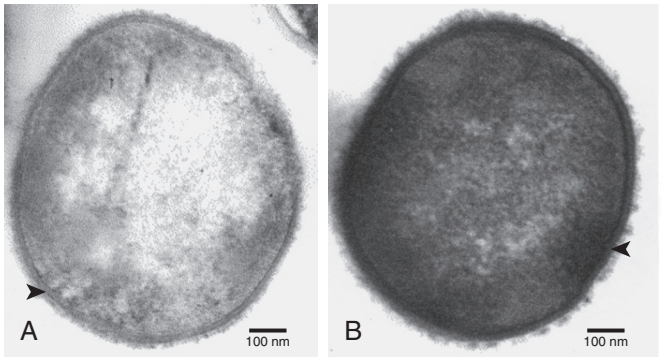

Fig. 50.2 Electron micrograph of (A) *Streptococcus pyogenes* and (B) *Streptococcus canis*. Proteinaceous cell surface fibrillae are present on *S. canis* that resemble the M-protein surface fibrils of the human pathogen *S. pyogenes*. The M protein is a key virulence factor of *S. pyogenes*. (From DeWinter LM, Low DE, Prescott JF. Virulence of *Streptococcus canis* from canine streptococcal toxic shock syndrome and necrotizing fasciitis. *Vet Microbiol.* 1999;70:95–110.)

methods are still in use by laboratory staff, microbiologists, and clinicians, most modern laboratories now use MALDI-TOF or possibly kit biochemical systems to identify these bacteria to their correct genus (*Enterococcus*, *Streptococcus*) and species.

Streptococci invade tissues opportunistically when there is a breach in normal host barriers. This leads to a wide variety of clinical disease manifestations, such as arthritis, cellulitis, endocarditis, meningoencephalitis, pyoderma, pneumonia, osteomyelitis, and UTIs. Severe and life-threatening manifestations of streptococcal infection include necrotizing fasciitis/myositis (NFM) and streptococcal toxic shock syndrome (STSS). The past decade has had a resurgence of severe invasive group A human streptococcal infections characterized by septic shock associated with multiple organ failure and with or without NFM.

Predisposing conditions for streptococcal infections in dogs and cats may include atopic dermatitis, wounds, foreign bodies (such as migrating grass awns), immunosuppressive drug treatment, and young age (especially neonates).[3] The most common clinical manifestation among fetuses and neonates is streptococcal bacteremia and sepsis, which can result in abortion and death. Streptococcal pneumonia may occur in association with infections with other respiratory pathogens, such as respiratory viruses, or occur secondary to bronchitis, hematogenous spread, or aspiration. In one study, streptococci were isolated from sick dogs more frequently in summer months.[3]

Streptococcus canis

Streptococcus canis is the streptococcal species most frequently isolated from dogs and cats.[3] It is a β-hemolytic, group G (pyogenic) streptococcus that colonizes the pharynx, GI tracts (especially the mouth), genital mucosa, and skin of healthy dogs and cats. It has also been isolated from other animal species, such as foxes, mice, mink, rabbits, and rats. Infection with *S. canis* may be associated arthritis, bacteremia, bronchopneumonia, cervical lymphadenitis, cholangiohepatitis, discospondylitis, endocarditis, ulcerative keratitis, mastitis, meningoencephalitis, NFM and STSS, neonatal bacteremia/sepsis, osteomyelitis, otitis externa, peritonitis, pharyngitis, postoperative incision or wound infections, pyometra or metritis, pyothorax, rhinitis and necrotizing sinusitis, and UTIs. Neonatal infections can occur when organisms are transmitted from the vaginal tract during parturition; they can also occur if organism accesses the systemic circulation via the umbilical vein. In juvenile kittens (3 to 7 months old), cervical lymphadenitis may follow a subclinical episode of pharyngitis and tonsillitis. Streptococcal meningitis results from direct extension from the sinuses or middle ear, or from bacteremia. Other embolic complications may accompany bacteremia with *S. canis*. Although opportunistic infections with *S. canis* occur sporadically, outbreaks of group G

TABLE 50.1 Classification of Streptococci Isolated from Dogs and Cats

Species	Lancefield Group	Hemolytic	Comments
S. canis	G	β	Most common. Dogs and cats are natural hosts. Causes a variety of clinical syndromes. Primary cause of streptococcal toxic shock syndrome and necrotizing fasciitis in dogs and cats.
S. equi subsp. *zooepidemicus*	C	β	Causes pneumonia and sinusitis, primarily in group-housed animals. Has also been associated with meningitis.
S. dysgalactiae	C	β	Uncommon. Has been isolated from dogs with bacteremia, dermatitis, or pneumonia.
S. bovis group (*S. gallolyticus* and *S. infantarius*)	D	α or γ	Uncommon. Has been isolated from dogs with urinary tract infections and endocarditis.
S. agalactiae	B	β or γ	Rare. Isolated from dogs and cats with endocarditis and neonatal bacteremia.

streptococcal infection have been reported in group-housed animals, which suggested spread of a virulent strain.[4–6]

Severe manifestations of *S. canis* infection, such as STSS and NFM, have been increasingly recognized in dogs and cats years, sometimes in the absence of obvious immunosuppressive underlying conditions or wounds.[7–10] In most cases, affected animals were previously healthy adult dogs or cats younger than 1 year of age. Although toxic shock syndrome can also be caused by staphylococci, STSS is defined as any streptococcal infection associated with the sudden onset of shock and organ failure. Mechanisms of shock and organ failure identified in human group A streptococcal infections include elaboration of pyrogenic exotoxins by streptococci, which act as superantigens. Superantigens stimulate T-cell responses through their ability to bind to, and cross-link, the MHC class II complex of antigen-presenting cells, and the T-cell receptor, which bypasses normal MHC-restricted antigen processing (Fig. 50.3). This leads to sudden and massive cascade of cytokine release, which in turn causes signs of fever, vomiting, and hypotension, together with tissue damage, DIC, and multiple organ dysfunction.[11] Cats with STSS had bacterial embolic localization with lesions in the lungs, heart, and liver.[12] Other streptococcal virulence factors also contribute to proinflammatory cytokine release and the development of hypotension. Laboratory abnormalities include thrombocytopenia, azotemia, hypoalbuminemia, and metabolic acidosis. Death can occur within 48 hours after the onset of illness. Specific criteria are used for diagnosis of STSS in human patients, and similar definitions could be used for diagnosis of STSS in dogs and cats (Box 50.1). Because relatively few dogs and cats with STSS have been described, predisposing factors have not been fully identified but in dogs include bites and use of anti-inflammatory drugs.[7,9] Importantly, there is also evidence that use of fluoroquinolones can predispose dogs with initially minor existing *S. canis* infections to developing STSS.[7,9] In humans, predisposing conditions include diabetes mellitus, alcoholism, surgical procedures, penetrating and nonpenetrating trauma, viral skin infections such as varicella, and possibly the use of NSAIDs. However as in dogs, predisposing factors are not always identified.

NFM is a bacterial infection of the deep subcutaneous tissues and fascia, characterized by extensive necrosis and gangrene of the skin and underlying tissues. It often begins as a minor wound and progresses rapidly over 24 to 72 hours, and it may be accompanied by STSS (Fig. 50.4). The popular term "flesh-eating bacteria" has been used to describe the organisms involved in "flesh-eating disease." Streptococcal NFM has been described in both dogs and cats. Bacteria at the inoculation site synthesize proteolytic enzymes and other products that facilitate the organism's spread via fascial planes and into muscles. Periosteal involvement, adjacent to involved muscle, has also been reported.[13] Lesions usually involve a limb (although have been described in one dog on the ventral thorax) and are intensely painful, with localized heat and swelling and accumulation of exudate along the fascial planes that requires drainage and debridement. In some dogs, extensive sloughing of necrotic skin occurs.[7] Bacteremia and complications that result from septic emboli may accompany NFM.[8] Outbreaks of NFM, arthritis, sinusitis, and meningitis caused by *S. canis* have been reported in cats in shelters,[4] breeding colonies,[14] and hoarding facilities.[6] In a spectacular report described in a grossly unhygienic and overcrowded institutional hoarding facility, the range of multiple

BOX 50.1 Criteria Used for Diagnosis of STSS in Human Patients, with Suggested Modifications for Diagnosis of STSS in Dogs and Cats

I. Isolation of *Streptococcus canis*

A. From a normally sterile site

B. From a nonsterile site

II. Clinical signs of severity

A. Hypotension: systolic blood pressure < 90 mmHg in dogs and < 80 mmHg in cats *and*

B. Two or more of the following signs:

1. Renal impairment: creatinine above the upper limit of the reference range
2. Coagulopathy: thrombocytopenia or DIC (prolonged clotting times, low serum fibrinogen concentration, and increased fibrin degradation products)
3. Liver involvement: serum AST, ALT, or total bilirubin concentrations at least twice the upper limit of the reference range
4. Acute respiratory distress syndrome defined as acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure, or evidence of diffuse capillary leak manifested as acute onset of pulmonary edema, or pleural or peritoneal effusions with hypoalbuminemia
5. A generalized erythematous macular rash that may desquamate
6. Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *DIC,* disseminated intravascular coagulation; *STSS,* streptococcal toxic shock syndrome.

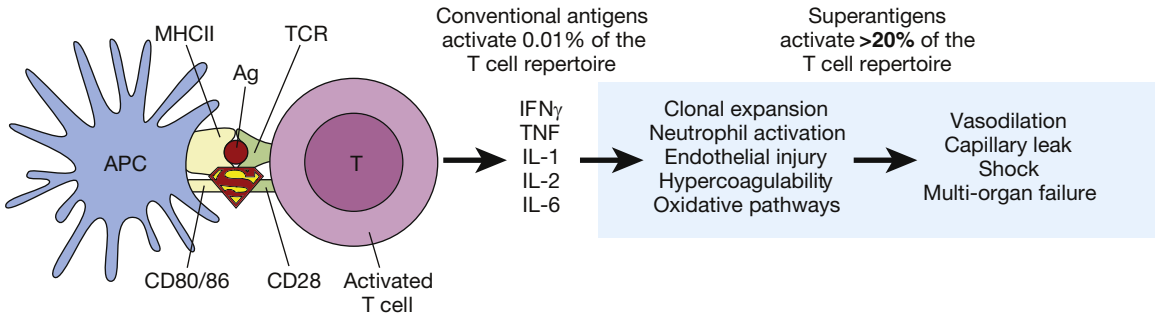

Fig. 50.3 Pathophysiology of toxic shock syndrome. *Streptococcus* superantigens bind first to MHC class II molecules on antigen-presenting cells, which stimulates cytokine expression and release, as well as expression of costimulatory molecules that promote T-cell receptor binding and activation. Subsequently, T-cell receptor binding occurs through the variable region on the receptor's beta chain (Vβ). Because superantigens can bind to multiple types of Vβ regions, a large proportion of the T-cell population can be simultaneously activated. For example, conventional antigens might activate < 0.1% of the T-cell population, whereas superantigens might activate > 20% of the population.

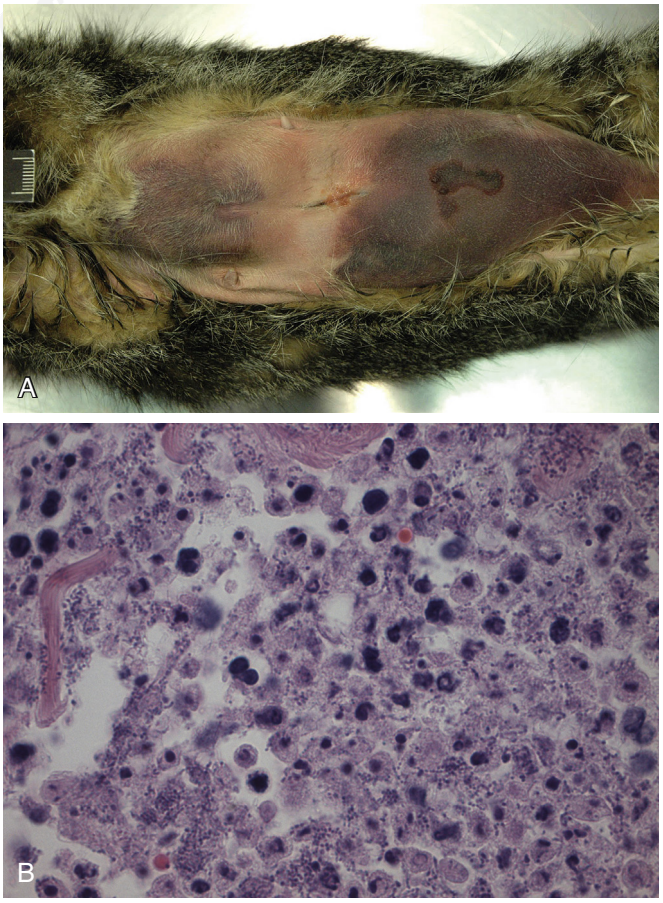

Fig. 50.4 (A) A 2-year-old female spayed domestic shorthair cat that was euthanized with necrotizing cellulitis, myositis and fasciitis, and peritonitis that developed after an ovariohysterectomy site became infected with *Streptococcus canis*. (B) Histopathology showed severe necrotizing cellulitis, myositis, and cellulitis with intralesional cocci that sometimes formed chains. Hematoxylin and eosin stain, 1000× oil magnification. (Courtesy of the University of California, Davis, Veterinary Anatomic Pathology Service.)

syndromes in numerous affected cats included acute rhinitis, cervical lymph node abscessation, severe septic arthritis, meningitis, otitis, STSS, and NFM.[6] Molecular typing (by pulsed-field gel electrophoresis) of isolates from one outbreak revealed that isolates were clonally related, which indicated spread of a virulent strain,[15] but another study of unrelated cases has not identified clonal spread[16] so that strain virulence may be less important than host predisposition.

Despite the recognition of severe disease manifestations in some dogs and cats, relatively little is known about virulence factors of *S. canis*. A protein analogous to M protein, a major virulence factor of *S. pyogenes* with important antiphagocytic properties, has been identified in *S. canis* and was shown to bind plasminogen and degrade thrombi.[17] This M protein, named SCM, has also been shown to bind IgG.[18] Genes that encode other virulence factors identified in *S. pyogenes*, such as pyrogenic exotoxins (*Spe* genes), streptococcal superantigen (SSA), streptokinase (Ska), and C5a peptidase (Scp, which cleaves the fifth component of complement), have not been detected.[19] However, one important study showed that exposure of *S. canis* to the fluoroquinolone antibiotic enrofloxacin caused bacterial cell lysis through inducing bacteriophage development, as a result of induction of the "SOS" response in strains containing these bacterial viruses, and the associated release of a bacteriophage-encoded lymphocyte mitogen

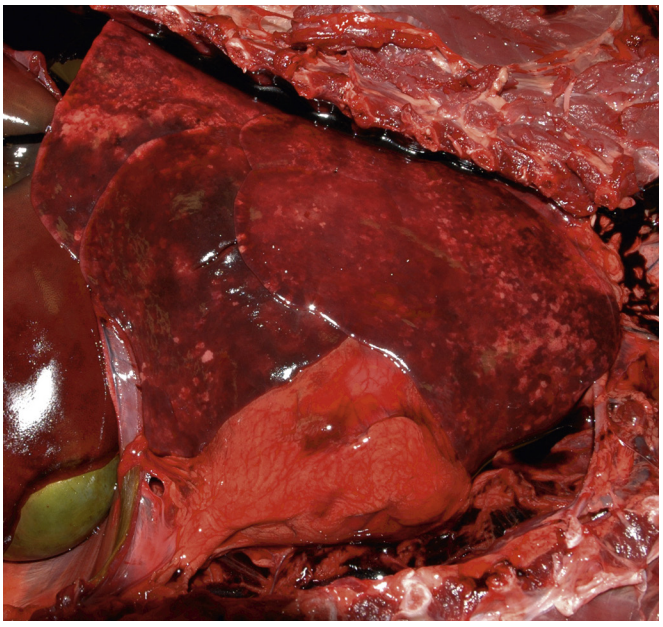

Fig. 50.5 Pneumonia in a shelter dog caused by *Streptococcus equi* subsp. *zooepidemicus*. The lungs are consolidated and dark red. (Courtesy of Dr. Patricia Pesavento, University of California, Davis.)

related to pokeweed mitogen.[20] The presence of this mitogen gene on enrofloxacin-induced bacteriophages may explain the frequently noted association between fluoroquinolone treatment and the occurrence of STSS/NFM in dogs[7] because of a superantigen-like response of lymphocytes. Many of the dogs reported with STSS/NFM had received enrofloxacin in the early stages of disease, but the drug was not effective in halting the progression of the disease despite marginal *in vitro* susceptibility in some cases.[7] In fact, as suggested, enrofloxacin may have triggered the pathologic events caused by these virulent streptococci.[7,20] Fluoroquinolones are thus contraindicated in the treatment of dogs with *S. canis* infections.

Streptococcus equi subsp. *zooepidemicus*

Streptococcus equi subsp. *zooepidemicus* is a β-hemolytic, group C streptococcus that is a commensal of the upper respiratory and lower genital tracts, and mouth, of many species including cats, dogs, guinea-pigs, horses, rabbits, seals, sheep, and swine. It is best known as the major opportunist pathogen of horses in which it causes wound infections, respiratory disease, endometritis, and abortion, among many other manifestations. Infections have also been reported in a variety of other animal species noted above but also less frequently in cattle, monkeys, seals, and humans. Different strains of *S. equi* subsp. *zooepidemicus* exist that may vary in pathogenicity and host tropism, and severe infections have been identified in several different host species, including the dog and cat. Infected horses can be a source of infection for dogs in some situations[21] but in most cases, there is no history of horse contact.

Several outbreaks of hemorrhagic, fibrinosuppurative, and necrotizing pneumonia associated with *S. equi* subsp. *zooepidemicus* infection have been described in group-housed dogs, such as those in kennels, research colonies, and shelter environments, from a variety of geographic locations worldwide and with an apparently increasing frequency (Fig. 50.5).[22–25] The pneumonia progresses rapidly in some dogs and may be accompanied by signs suggestive of STSS, such as fever and systemic hypovolemia. In some dogs, severe tachypnea and death occur within 24 to 48 hours of the first signs of respiratory disease, or

dogs may be found dead without any preceding clinical signs. Other infected dogs show only mild signs of respiratory disease. Outbreaks of pneumonia, purulent rhinosinusitis, and meningoencephalitis have also been described in cats.[26–28] *Streptococcus equi* subsp. *zooepidemicus* meningoencephalitis occurred in a cat as a result of extension of otitis media/interna.[29]

The pathogenesis of infection with *S. equi* subsp. *zooepidemicus* in dogs and cats is unclear, but there is no doubt that this virulent organism can cause very severe disease, as it can in other species, including humans. Different strains are involved in outbreaks of severe disease in dogs and cats, so increasing reports cannot be attributed to clonal expansion of virulent clones. There is no evidence that there are differences in protective immunogenicity among these strains.[23] Co-infection with other contagious respiratory pathogens may initiate infection and can contribute to the severity of disease. Co-infections with CDV, CAdV-2, CHV-1, CIV, *Bordetella bronchiseptica*, or *Mycoplasma cynos* have been documented in some, but not all, affected dogs with *S. equi* subsp. *zooepidemicus* pneumonia.[22] Experimentally, co-infection of dogs with both CIV and *S. equi* subsp. *zooepidemicus* was associated with more severe clinical manifestations of disease than when either organism is inoculated alone.[30] Other environmental factors such as overcrowding may predispose to disease and its severity; in large prevalence surveys of respiratory pathogens in dogs with CIRD, *S. equi* subsp. *zooepidemicus* is rarely detected when compared with other pathogens in the complex.[31,32] Superantigen genes have been detected in some isolates of *S. equi* subsp. *zooepidemicus* from dogs,[33] but there has been no correlation between the presence of these genes and the severity of histopathologic lesions. However, expression of proinflammatory cytokines such as TNF-α, IL-6, and IL-8 in the lungs of affected dogs suggests that a potent inflammatory response is involved in the pathogenesis of disease.[24]

Other Streptococcal Species

Streptococci other than *S. canis* and *S. equi* subsp. *zooepidemicus* are of relatively minor significance in dogs and cats. *Streptococcus equi* subsp. *equi*, the etiologic agent of strangles, was isolated from a dog with tonsillar and submandibular lymphadenomegaly caused by pharyngeal foreign body penetration.[34] Genetic characterization confirmed the isolate as this usually highly equine-specific pathogen. The dog lived on premises where horses were kept; unexpectedly, no clinical cases of strangles had been identified in the horses in the local environment.

Group B streptococci (*S. agalactiae*) have been associated mainly with neonatal bacteremia and postpartum metritis in humans and mastitis in cows. Factors at the time of delivery, such as low birth weight or difficult delivery, precipitate the development of clinical illness. Skin, pharyngeal, and wound infections can occur. Immunosuppressed people can develop bacteremia, meningitis, and endocarditis as a result of infection. Group B streptococci are more frequently isolated than group G from people with these syndromes. *Streptococcus agalactiae* infections are rare in dogs and cats, although there are reports of involvement in bacteremia in a dog, in endocarditis, endometritis, and neonatal sepsis ("fading puppy syndrome"). Peritonitis with bacteremia and parturient endometritis and placentitis have been described in cats. Whether canine and feline strains are indigenous or of human or other animal origin is uncertain.

Streptococcus dysgalactiae is a β-hemolytic, group C streptococcus, like *S. equi* subsp. *zooepidemicus*. There are two subspecies, *S. dysgalactiae* subsp. *equisimilis* and *S. dysgalactiae* subsp. *dysgalactiae*. After *S. canis* and *S. equi* subsp. *zooepidemicus*, S. *dysgalactiae* subsp. *equisimilis* was the third most common β- or γ-hemolytic streptococcal species isolated from dogs at a veterinary teaching hospital in the United States, but was detected in only 13 of 393 dogs with streptococcal infections. Affected dogs had bacteremia and sepsis, dermatitis, or pneumonia.[3] *Streptococcus dysgalactiae* subsp. *dysgalactiae* has been reported in association with systemic neonatal infections and death in a litter of great Dane puppies.[35]

The porcine streptococcus, *Streptococcus suis,* has occasionally been isolated from cats with meningoencephalitis, pyothorax, or dermatitis.[36,37] *Streptococcus suis* was also isolated from the urine of a systemically unwell dog that had fever and bacteriuria in Canada.[38] The dog had no known exposure to swine; however, it had been allowed to chew on pig ear treats. It can be isolated from the anus, tonsils, and skin of healthy dogs and cats.[39] *Streptococcus suis* has been classified into serotypes, which have epidemiologic importance. Human infections are usually serotypes 2 and 14. The cases reported in dogs and cats have not belonged to these serotypes.

Other streptococcal species isolated from dogs and cats include the human pathogen *Streptococcus constellatus* (a *Streptococcus anginosus* group organism), which was isolated from a dog with pyoderma.[40] *Streptococcus bovis* group organisms are α- or nonhemolytic and usually possess Lancefield group D antigens. Biotypes that belong to this group, which differ in their biochemical characteristics, were reclassified as distinct species, *Streptococcus gallolyticus* and *Streptococcus infantarius*.[41] *Streptococcus bovis* group organisms are commensals of the GI tracts of humans and other animals, especially ruminants, and are important causes of bacteremia and endocarditis in humans, accounting for 11% to 17% of all endocarditis cases. They frequently affect multiple valves and are associated with embolic complications. For unknown reasons, fecal carriage of *S. bovis* group organisms by humans has been strongly associated with colorectal cancer. This especially seems to be true for *S. gallolyticus* subsp. *gallolyticus*.[42] Rarely, *S. bovis* group organisms are isolated from dogs and cats with UTIs. They have also been isolated from the blood of dogs with mitral valve endocarditis, one of which also had sternebral osteomyelitis.[43,44]

Enterococcus spp.

Enterococci are α- or nonhemolytic gram-positive bacteria that usually possess Lancefield group D antigens, and are commensals of the GI tracts of humans and other animals. In humans and pets, they have predominantly caused infections in hospitalized patients as nosocomial complications and are problematic in veterinary hospital settings because of their ability to persist in the environment as well as develop multiple antibacterial resistance. Enterococci form pairs or short chains of organisms that cannot morphologically be discriminated from streptococci. Enterococci can survive harsh environmental conditions, and are more likely than streptococci, especially β-hemolytic species, to survive in clinic and hospital settings. They are able to proliferate in medium that contains 6.5% NaCl, at temperatures that range from 10°C to 45°C (50°F to 113°F), and can be metabolically active in the presence of 40% bile salts, which in turn explains their improved ability to grow in the intestine when compared with the less robust genus *Streptococcus*. The genus *Enterococcus*, which contains 55 species, was separated from *Streptococcus* in the mid-1980s.[2]

Not only are enterococci environmentally hardy but they are often resistant to a wide variety of different antimicrobial drug classes. MDR enterococcal infections, especially those that are also resistant to vancomycin (vancomycin-resistant enterococci [VRE]), are a significant problem in human medicine. Of great clinical importance, resistance among enterococci occurs as a result of both intrinsic and acquired resistance mechanisms. Intrinsic resistance to low levels of most β-lactam antimicrobials occurs because enterococci possess low-affinity PBPs, making penicillins generally bacteriostatic, not bactericidal, against enterococci. Enterococci also have low-level intrinsic resistance to aminoglycosides, which results from decreased drug uptake. However, uptake of aminoglycosides is enhanced when enterococci are

exposed to β-lactams, explaining the synergistic activity of this combination that is sometimes taken advantage of in treatment. Enterococci are resistant to trimethoprim-sulfamethoxazole because they utilize exogenously produced folate. Thus, even if the organisms appear susceptible to trimethoprim-sulfamethoxazole *in vitro* (when exogenous folate is lacking), the drug is not effective *in vivo*. Many laboratories therefore will not report MICs for this organism-drug combination. Enterococcal resistance to other antimicrobials, such as macrolides and vancomycin, results from acquired resistance mechanisms. Extensive multidrug resistance has been well documented in enterococci isolated from dogs and cats, but there are few reports of enterococci with acquired vancomycin resistance from dogs in the literature. These have been reports from the United Kingdom, New Zealand, and the United States.[45–47] All other isolates examined have been vancomycin susceptible. In contrast, in humans from Europe and North America, VRE account for up to 30% of enterococcal infections, notably in hospital-associated infections.[48]

Clinical microbiology laboratories should identify and distinguish between *Enterococcus faecalis* and *Enterococcus faecium,* the most prevalent species in humans. These two species differ in their epidemiology, antimicrobial susceptibility, and virulence properties. Since these are often hospital-associated infections, their identification to species may be a clue to their presence as contaminants in the environment, which may further be suggested if they have a common resistance profile. *Enterococcus faecium* is more likely to show high-level resistance (HLR) to penicillins, and to show multidrug resistance, than *E. faecalis*, and as a result, in humans, the prognosis for serious *E. faecium* infections may be worse than that for *E. faecalis* infections.[49] However, *E. faecalis* is more likely to produce biofilms than *E. faecium* and therefore are more likely to colonize catheters.[50] Although most infections in humans have been *E. faecalis,* an increase in the prevalence of MDR *E. faecium* infections has occurred, especially in hospitals. In particular, ampicillin- and fluoroquinolone-resistant *E. faecium* strains that belong to hospital-adapted strains of the clonal complex 17 (CC17) have emerged.[51] Strains belonging to this clade are a defined, globally disseminated population that is associated with hospitalized human patients but only rarely found in the community; it might be concluded that they have adapted to human hospitals. CC17 isolates have been found in dogs but belong to a different clade from those found in hospitalized humans. Their virulence gene profile and antimicrobial susceptibility profiles have differed from those of human isolates.[51–53] In contrast to *E. faecium,* clones of *E. faecalis* are not found only in hospitals but are also present in healthy humans and animals, and animals may therefore represent a source of infection for humans.[51,53] As in humans, the two most common species of *Enterococcus* associated with disease in dogs and cats are *E. faecalis* and *E. faecium*.[54]

In healthy dogs and cats, enterococci can be found on the skin and within the oral cavity, nasal cavity, and GI tract. In the United States, the most prevalent species in dogs appears to be *E. faecalis,* which comprised 68% of 155 isolates.[54] In the cat, in one study it was *Enterococcus hirae*, which comprised 52% of 121 isolates,[54] but in a more recent study it was *E. faecalis* (77%) followed by *E. faecium* (13%).[55] Other species isolated from sick dogs and cats include *Enterococcus casseliflavus*, *Enterococcus durans*, and *Enterococcus gallinarum*; *Enterococcus canintestini* has been isolated from healthy dogs.[56–58]

Although less pathogenic than many β-hemolytic streptococci, important virulence factors have been identified in enterococci that enable them to invade tissues and cause disease. These include a cytolysin, gelatinase, and a serine protease, as well as several surface proteins (e.g., the Ace protein, which allows the organism to adhere to connective tissue components, such as collagen). Enterococci also possess pili that play an important role in adherence. The ability of many enterococci to form biofilms means they can colonize catheters or other surfaces and be very difficult to eradicate, because in biofilms they are more likely to resist phagocytosis and antimicrobial drugs.[50] In addition, because enterococci are intrinsically resistant to a number of antimicrobials, treatment with broad-spectrum antibiotics (which destroy competing bacteria) selects for mucosal, including intestinal, colonization by enterococci. The development of enterococcal UTIs may be promoted by repeated use of antimicrobial drugs to treat recurrent UTIs if the underlying cause of infection is not identified or cannot be resolved. Because of these features and their robust nature, enterococci can contaminate the hospital environment and survive for long periods on fomites (door knobs, stethoscopes, monitoring devices), as well as be transmitted via the hands, gloves, and clothing of hospital personnel. Inoculation may occur via urinary, IV, or other invasive devices, or organisms may enter the body from a damaged GI tract.

Severe concurrent illness and immunosuppression may predispose to infection but is compounded by the resistance of these bacteria to antibiotics and their ability to proliferate in the large intestine and be shed in feces when the competing microflora has been removed by antibiotics. In addition to UTIs, enterococci may be isolated from dogs and cats with bacteremia and endocarditis, cholangiohepatitis, discospondylitis, hepatic abscesses, mastitis, pancreatitis, peritonitis, pyoderma, otitis externa, and wound infections. There have been rare reports of GI illness in association with enterococcal infection of the GI tract in dogs and cats. In affected cats, an association with diarrhea was supported by the presence of large mats of enterococci in association with the GI mucosa.[59,60] Frequently, enterococci are isolated from lesions in mixed infections with other GI microorganisms.

There is some evidence that *E. hirae*, a commensal species, plays a protective role in kittens infected with atypical enteropathogenic *Escherichia coli* (aEPEC).[61] Preparations that contain *E. faecium* strains have been investigated as probiotics in dogs and cats, with mixed results.[62–66]

Physical Examination Findings

Physical examination findings in dogs and cats with *Streptococcus* or *Enterococcus* infections vary with the anatomic site(s) of infection. Streptococcal infections are an important differential diagnosis in "fading" neonates; dogs with physical examination findings suggestive of endocarditis; dogs and cats with severe pneumonia and pyothorax; STSS and NF; rapid onset of systemic illness in association with a wound; or outbreaks of severe purulent upper respiratory disease, hemorrhagic pneumonia, and systemic illness in group-housed animals.

Findings suggestive of streptococcal or enterococcal endocarditis include fever, lethargy, tachycardia, joint pain and swelling, systolic heart murmurs, and signs of embolic complications such as lameness, limb edema, weak or absent pulses, or neurologic signs (see Chapter 122). Animals with streptococcal pneumonia may have a fever (up to 106.3°F or 41.3°C), cough, tonsillar enlargement and hyperemia, mucopurulent nasal discharge, and/or tachypnea with increased lung sounds. Lung sounds may be decreased if pleural effusion is present. Animals with NFM have variable extents of regional cutaneous erythema, sometimes in association with a wound; cutaneous ulceration, swelling, edema, intense pain, and warmth on palpation of the affected area. In human patients, the "finger test" has been used to assist recognition of NFM, whereby the area of suspected involvement is infiltrated with a local anesthetic, and a 2-cm incision is made in the skin and extended into the deep fascia. A lack of bleeding is a sign of NFM. A sterile double-gloved finger is then used to probe the incision, and the test is considered positive if tissues separate with little resistance.[67] In some animals, extensive skin sloughing can occur. In two dogs, acute onset of posterior paresis

with lower motor neuron deficits developed because of the presence of septic emboli in blood vessels of the gray matter of the spinal cord and extension of infection into the surrounding connective tissue, muscle, and peripheral nerves.

Animals with STSS may be obtunded, with weak pulses, tachycardia, tachypnea, and prolonged CRT. Rectal temperatures may exceed 106°F (41.1°C), although the presence of fever is variable. Icterus may be present in animals that develop multiple organ dysfunction syndrome in association with STSS.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

Dogs and cats with severe manifestations of streptococcal infections (such as endocarditis, pneumonia, NF, and STSS) usually have a neutrophilic leukocytosis with a left shift, toxic neutrophils, lymphopenia, and monocytosis. A degenerative left shift or circulating metamyelocytes may be present. STSS may be accompanied by thrombocytopenia as a result of DIC, azotemia and/or increased liver enzyme activities, hypoalbuminemia, and hypoglycemia. Serum creatine kinase activity may be increased with muscle involvement. The urinalysis of dogs and cats with streptococcal or enterococcal UTIs may reveal pyuria, proteinuria, or hematuria, and cocci in pairs or chains may sometimes be evident on sediment examination.

Clotting Function

Dogs and cats with STSS that develop DIC may have clotting function abnormalities including prolonged coagulation times, increased fibrin degradation product and D-dimer concentrations, and decreased antithrombin concentrations.

Cytologic Abnormalities

Cytologic examination of specimens (respiratory lavage fluid, aspirates of affected tissues, or pus) from dogs and cats with streptococcal or enterococcal infections typically reveals large numbers of degenerate and nondegenerate neutrophils. Coccoid bacteria in pairs or characteristically in chains may also be seen. Cytologic examination of fine-needle aspirates from swollen areas in dogs and cats with NFM is essential to speed confirmation of infection and institute early appropriate antimicrobial therapy, because virulent strains of gram-negative bacteria can also cause this syndrome.

Microbiologic Tests

Isolation and Identification

Streptococci and enterococci that infect dogs and cats are readily isolated on routine bacteriologic media from aspirates, tissue biopsies, body fluids, and lavage specimens. Inoculation of complex solid media that contain blood is recommended and is the usual practice in laboratories. Streptococci may grow well in anaerobic incubation conditions, but these are not required because of their facultative nature. The laboratory may use selective media for specimens that are heavily contaminated with other bacteria. Species are identified based on their phenotypic characteristics (such as colony morphology and hemolytic properties), biochemical reactions, grouping with Lancefield antisera, and most frequently now by MALDI-TOF (see Chapter 3). Molecular typing methods such as pulsed-field gel electrophoresis or multilocus sequence typing may sometimes be done to investigate outbreaks in group-housed animals or hospital environments, largely for research purposes.

Antimicrobial susceptibility testing for β-hemolytic streptococci is often not performed by veterinary diagnostic laboratories, because virtually all such strains are penicillin (and amoxicillin) susceptible. This is also true for group A β-hemolytic streptococci (GAS, *S. pyogenes*) that infect humans. However, an increased prevalence of penicillin resistance, which occurs as a result of altered PBPs, has been detected in *S. pneumoniae*, which is primarily a human pathogen.[56] *Streptococcus pneumoniae* may also be resistant to other β-lactam drugs and macrolides. Acquired resistance may occur in non-β-hemolytic streptococci in dogs and cats, and so susceptibility testing is recommended for these bacteria. Some laboratories may falsely report β-hemolytic streptococci as resistant to trimethroprim-sulfamethazine because of the antagonistic effect of thymidine in bacteriologic media containing blood. Laboratory assessment of antimicrobial susceptibility is of critical importance for enterococci because of the high prevalence of resistance in this group, particularly among *E. faecium* isolates. Isolates with a consistent antibiotype (pattern of antimicrobial susceptibility) may indicate that a clinic or hospital has an *Enterococcus* contamination problem.

Pathologic Findings

Pathologic findings in *Streptococcus* infections vary depending on the organ system affected. Gross findings in *S. canis* sinusitis include accumulation of purulent material within the frontal sinus with osteolysis, and distortion of the nasal bridge in cats.[4] When meningitis is present, purulent material may be found in association with the meninges (Fig. 50.6). Lesions of NF in dogs and cats consist of edema, ecchymoses, and necrosis that extend within the fascia and subcutis in association with ulcerative skin lesions (see Fig. 50.4). An accumulation of pus may be found between fascial planes. Congestion of a variety of organs may be present in animals that have accompanying STSS. When *S. canis* or *Enterococcus* endocarditis is present, adherent and friable mass lesions may be seen in association with the mitral and/or, less commonly, the aortic valves. Dogs with streptococcal endocarditis are more likely to have concurrent polyarthritis than dogs with other bacterial causes of endocarditis.[43] On histopathology, valve lesions generally contain large numbers of degenerate and nondegenerate neutrophils, hemorrhage, necrosis, fibrin thrombi, and abundant gram-positive cocci (Fig. 50.7). Septic thromboemboli may be present in a variety of organs. Histopathologic lesions in neonates that die of sepsis include severe inflammation and necrosis, as well as septic emboli in a variety of tissues (see Fig. 50.1).

Grossly, the lungs of dogs with *S. equi* subsp. *zooepidemicus* pneumonia may be red, consolidated, and fail to collapse (see Fig. 50.5).

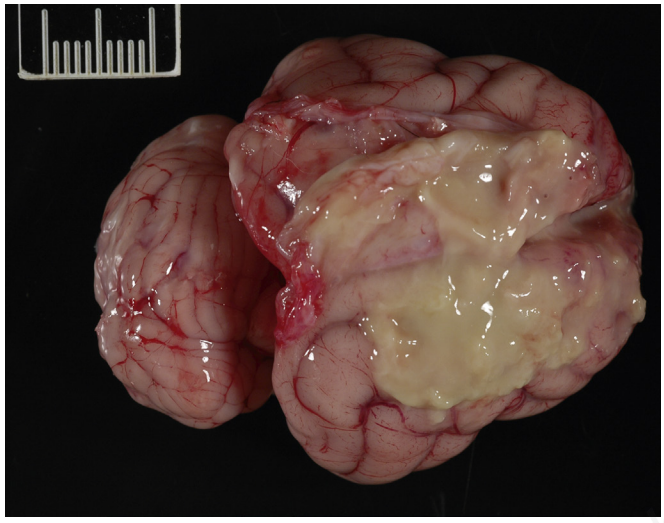

Fig. 50.6 Accumulation of purulent exudate over the meninges in a shelter cat that died of *Streptococcus canis* meningitis. (Courtesy of Dr. Patricia Pesavento, University of California, Davis.)

There may be variable quantities of hemorrhagic pleural effusion, petechial and ecchymotic hemorrhages on pleural surfaces, and bloody exudate within the airways and nasal cavity.[24] Typical histopathologic changes include fibrinous, necrotizing, and/or suppurative pneumonia or bronchopneumonia; fibrin thrombi; and intralesional clusters or chains of coccoid bacteria. Within lymph nodes, marked lymphoid depletion may be present, but lymphoid hyperplasia has also been reported. Occasionally, septic thromboemboli may be present in tissues or organs such as the lymph nodes, renal glomeruli, adrenal glands, brain, and splenic sinusoids.[68,69]

TREATMENT AND PROGNOSIS

In general, streptococcal infections should be treated with a β-lactam drug, preferably an aminopenicillin such as amoxicillin or a first-generation cephalosporin (Table 50.2). Early diagnosis and prompt treatment with appropriate antimicrobial drugs are essential to prevent more severe complications such as NF or STSS. In animals that present with severe signs such as septic shock or life-threatening pneumonia, initial treatment should be with a broad-spectrum antimicrobial drug combination, such as a β-lactam including amoxicillin and an aminoglycoside, which together commonly also has synergistic activity against streptococci, namely group C streptococci (*S. equi* subsp. *zooepidemicus*).

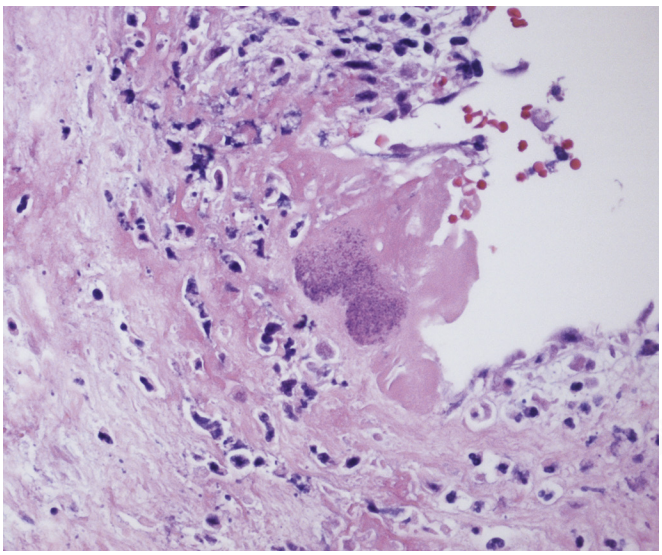

Fig. 50.7 Histopathology of the mitral valve of an 8-year-old male neutered springer spaniel that was seen for a 1-month history of right thoracic limb lameness, anorexia, and lethargy. There is severe, subacute, fibrinonecrotic endocarditis with intralesional cocci. When the dog was first evaluated, the platelet count was 9,000 platelets/μL and the dog was treated with vincristine for immune-mediated thrombocytopenia. Subsequently, the dog developed vomiting and diarrhea and became obtunded. Blood cultures grew *Streptococcus canis*. At necropsy, septic emboli were present in the kidneys, spleen, and lymph nodes. Necrotizing fasciitis was also present in multiple limbs, which was thought to have developed as a result of septic embolization.

Necrotizing Fasciitis and Streptococcal Toxic Shock Syndrome

Prompt surgical exploration and debridement is of critical importance in NF, because shock and organ failure will continue to progress in the face of antimicrobial treatment when necrotic tissue persists. Use of negative pressure wound therapy was associated with successful outcomes in three dogs.[10] Surviving animals often must have extensive skin grafting or dermoplasty to close open wounds created by the necrotic process. Imaging techniques such as ultrasound may be useful to help characterize the extent of lesions before surgery. Extremely aggressive fluid resuscitation with crystalloids and blood products may also be required, while blood pressure is monitored. STSS is a clinical emergency and requires IV benzyl penicillin as the drug of choice because of its exquisite activity.[70] In human patients, deep-seated streptococcal infections (NF and STSS) are often treated with *both* high-dose penicillin and clindamycin. This is because clindamycin suppresses exotoxin production by GAS, is more active than penicillin in experimental NF, and has a longer half-life than penicillin.[70,71] However, a low prevalence of clindamycin resistance exists in GAS, whereas all GAS are susceptible to penicillin.[70,71] Approximately 10% to 15% of contemporary *S. canis* isolates from dogs in Europe and nearly 18% of isolates from dogs in Japan have demonstrated clindamycin resistance.[72–74] Given this finding, the same combination could be used to treat NF in dogs and cats. In humans, IV immunoglobulin treatment is also recommended on the basis of clinical trials.[70] As noted earlier, fluoroquinolone antibiotics should be avoided in treatment of *S. canis* infections because they promote an endogenous bacterial mitogen production.[20] In addition, they are not of value in streptococcal infections because of their low activity.

Meningitis/Meningoencephalitis

High-dose penicillin or amoxicillin was the drug of choice for treatment of streptococcal meningitis in human patients caused by *S. pneumoniae* before the emergence of penicillin resistance in this species. It is the drug of choice for meningitis caused by β-hemolytic

TABLE 50.2 Suggested Antimicrobial Drugs for Treatment of Streptococcal Infections in Dogs and Cats

Drug	Dose mg/kg	Interval (Hours)	Route
Penicillin G potassium or sodium[a]	20,000–40,000 U/kg	6–8	IV, IM
Ampicillin sodium[a]	10–20	6–8	IV, IM, SC
Amoxicillin	6.6–20	8–12	PO
Cefazolin sodium	20-35	8	IV, IM
Cephalexin	10–30 (dogs), 15–20 (cats)	12	PO
Trimethoprim-sulfamethoxazole[b]	30	12	PO, IV

[a]Consider use with clindamycin, 10 mg/kg q12h IV or IM for necrotizing fasciitis or myositis; consider addition of gentamicin sulfate, 9–14 mg/kg q24h IV, IM, or SC for dogs with *S. equi* subsp. *zooepidemicus* pneumonia because of synergy of this combination for group C streptococci.
[b]Consider use for treatment of streptococcal meningitis as alternative to penicillin G.

TABLE 50.3 Suggested Medications for Treatment of Enterococcal Infections in Dogs and Cats

Drug	Dose mg/kg	Interval (Hours)	Route
Ampicillin sodium[a]	10–20	6–8	IV, IM, SC
Amoxicillin[a]	6.6–20	8–12	PO
Vancomycin[b]	15	8	IV
Linezolid[b]	10 (dogs)	8	PO
Chloramphenicol	40–50 (dogs), 12.5–20 (cats)	6–8 (dogs), 12 (cats)	PO, IV, IM
Nitrofurantoin[c]	2–3	8	PO

[a]In human patients, used with gentamicin sulfate, 1 mg/kg q12h IV for systemic enterococcal infections caused by enterococci susceptible to high-level aminoglycosides, because of the synergy of this combination.
[b]For enterococci that show high-level aminoglycoside resistance or when aminoglycosides cannot be used because of toxicity (animals with renal failure). Use in veterinary patients is controversial. Refer to Chapter 10 for additional information on the use of vancomycin. These drugs are critical human drugs and should be therefore used only after susceptibility testing and in the absence of any alternative treatments.
[c]For resistant urinary tract infections.

streptococci despite the relatively limited penetration of the CSF in uninflamed meninges; this is because of the strong susceptibility of these streptococci to penicillin and the greater penetration of penicillin in inflamed meninges. Trimethoprim-sulfamethoxazole has been used with apparent success to treat some dogs and cats with streptococcal meningitis.[27,75] See Chapter 129 for additional information on treatment of bacterial meningitis. Ceftriaxone has been used as an alternative to benzylpenicillin for treatment of human streptococcal meningitis and attains higher concentrations in the CSF with the advantage that its spectrum of activity covers gram-negative bacteria.

Bacteremia and Endocarditis

The reader is referred to Chapter 122 for information on treatment of bacteremia and endocarditis.

Enterococcal Infections

Suggested antimicrobial treatments for treatment of enterococcal infections in dogs and cats are shown in Table 50.3. Successful treatment of enterococcal infections requires awareness of the intrinsic resistance of enterococci to low levels of β-lactams and aminoglycosides, the synergistic effect of high doses of these drugs, the lack of efficacy of trimethoprim-sulfonamide combinations *in vivo*, and the ability of enterococci to acquire resistance genes to a large number of other antimicrobial compounds. Susceptibility testing is, therefore, always recommended when isolates are believed to be clinically relevant. Aminopenicillins such as amoxicillin generally have more activity against enterococci than penicillin or the carbapenems. Bactericidal regimens, which consist of a β-lactam and gentamicin, are used in human patients to treat systemic infections such as endocarditis or bacteremia. Enterococci are usually resistant to aminoglycosides at dilutions used in routine broth microdilution methods (low-level resistance). When the synergistic combination is indicated, but low-level resistance is present, isolates should be tested for HLR to aminoglycosides. Aminoglycoside HLR results from production of an aminoglycoside-modifying enzyme by enterococci. It emerged in the 1980s and has been a growing problem in both *E. faecium* and *E. faecalis* isolates from human patients. Aminoglycoside HLR has also been reported in *E. faecium* and *E. faecalis* isolated from dogs and cats,[45,46,76] but most isolates are susceptible to high concentrations of gentamicin. In human patients, a combination of ceftriaxone and ampicillin has been recommended to treat endocarditis caused by aminoglycoside HLR enterococci.[49] When enterococci show penicillin resistance, vancomycin can be substituted for penicillin, but this requires prolonged hospitalization for IV administration and is best avoided unless there is no alternative therapy, because vancomycin is a critical antimicrobial for treatment of resistant bacterial infections in humans. Single-agent treatment with linezolid (see Chapter 10) is an oral alternative for treatment of serious penicillin-resistant enterococcal infections, but in human patients it is recommended that this only be used when combinations of β-lactams and gentamicin cannot be used because of resistance, toxicity, or treatment failure.[48] Although most strains of enterococci isolated from humans are susceptible to linezolid, resistant strains have appeared.[77] Of concern, linezolid- and multidrug-resistant enterococci were described in raw commercial dog food in Europe in 2019 and 2020.[78] Use of linezolid may also be associated with adverse effects of anemia and gastrointestinal signs in dogs and cats.[79] Chloramphenicol may be successful for treatment of resistant enterococcal bloodstream infections when administered orally, but it is bacteriostatic, and concerns regarding adverse effects in humans exist (see Chapter 10).

Treatment of enterococcal UTIs with β-lactams such as ampicillin or amoxicillin may be successful even when resistance is documented in the susceptibility panel, because of the high concentrations that these drugs achieve in the urine.[48] Nitrofurantoin has also been useful for treatment of resistant enterococcal UTIs in humans, but routine treatment of subclinical bacteriuria caused by MDR enterococci is not recommended (see Chapter 127).[80] When enterococci are present with other bacteria, especially in the urinary tract, treatment of the nonenterococcal pathogen may be sufficient to resolve the infection.

PREVENTION

Because outbreaks of streptococcal infections in dogs and cats have been associated with overcrowding, co-infections, and other stressors, appropriate shelter and kennel management and hygiene, as well as vaccination against other respiratory pathogens, may help to prevent streptococcal infections. The predisposing factors may however not be clear. Proper wound care may prevent serious streptococcal infections such as bacteremia, endocarditis, NF, and STSS. Methods to reduce nosocomial infections by enterococci are outlined in Chapter 15. Resistant enterococcal infections may be prevented through restricted and appropriate use of antimicrobial drugs and proper management of underlying disorders that predispose to bacterial infections.

PUBLIC HEALTH ASPECTS

Streptococci include some of the most important bacterial pathogens of humans. The β-hemolytic GAS *S. pyogenes* causes streptococcal pharyngitis ("strep throat") and scarlet fever, as well as poststreptococcal rheumatic fever, rheumatic heart disease, and glomerulonephritis. In 2005, it was estimated that globally, GAS cause more

than 616 million new cases of pharyngitis each year.[81] GAS have also been associated with other disease manifestations, which include NF, STSS, myositis, vaginitis, and bacteremia. As a result, *S. pyogenes* is the most extensively studied of all streptococci. There are more than 100 different serotypes, which are classified based on the sequence of the M protein gene (known as *emm* typing). M protein, a filamentous macromolecule that traverses the cell wall (see Fig. 50.2), is a key virulence factor of GAS. Chronic subclinical carriage of infection in the oropharynx occurs in some individuals. GAS can survive extremes in environmental temperature and humidity; however, most infections are associated with direct or close contact among susceptible individuals. Prevalence rates for GAS are higher in young children, especially those in daycare or classroom situations. The prevalence of positive throat culture findings in such circumstances may approach 50%, even in the absence of an obvious epidemic. Symptomatic, rather than carrier children, are most likely to bring infection into the home. Under such circumstances, the isolation rate in other people in the household approaches 25% to 50%. If the child is asymptomatic, the rate is only 9%. Although family pets have been implicated as a reservoir in households with recurrent streptococcal pharyngitis,[82–84] colonization or infection of dogs and cats with GAS appears to be rare or nonexistent when accurate streptococcal identification methods have been performed, although the idea that pets can be reservoirs seems to remain an enduring and unfortunate myth. One study found no evidence of oropharyngeal colonization by GAS in pets that were in contact with children with acute pharyngitis.[1] When domestic pets come into close contact with infected individuals, some pets may apparently develop pharyngeal colonization with GAS. Infected pets show no clinical illness or tonsillar enlargement and usually eliminate their infection within 2 to 3 weeks after they are removed from the household. Treatment of infected humans is generally limited to only those that are symptomatic, so it is not rational to screen pets for evidence of colonization.

Streptococcus pneumoniae is an important commensal of the human respiratory tract that causes a variety of diseases including bacteremia, meningitis, and pneumonia, otitis media, and sinusitis. Children are regarded as the most important reservoir. Although extremely rare in dogs and cats, infections with *S. pneumoniae* have been reported in a dog with meningoencephalitis,[64,85] a cat with arthritis,[72,86] and a cat with cellulitis.[73,87] It is likely that the dog and cats acquired the infection from humans, because humans are the natural hosts for *S. pneumoniae*.

Reports of human infection with *S. canis* and *S. equi* subsp. *zooepidemicus* exist, and represent a more genuine threat than the potential for zoonotic transmission of *S. pyogenes* or *S. pneumoniae* from companion animals discussed above. *Streptococcus canis* has increasingly been recognized as a cause of soft tissue infections in dog owners and has been isolated from humans with bacteremia, endocarditis, UTIs, osteomyelitis, and pneumonia.[88–92] Population genetic studies suggest that *S. canis* is a single population that can infect multiple animal species including humans, suggesting that the potential for human infection from dogs and cats is always present.[92] The situation can be complicated because human group G streptococci can be confused with *S. canis*, which is also Lancefield group G. Rarely, *S. equi* subsp. *zooepidemicus* has been isolated from humans with bacteremia, endocarditis, meningitis, acute nephritis, pneumonia, osteomyelitis, septic arthritis, or STSS. Most human infections with *S. equi* subsp. *zooepidemicus* have been traced to an animal source, such as contact with horses, or consumption of inadequately pasteurized milk products or pork. However, apparent transmission of *S. equi* subsp. *zooepidemicus* from a dog with *S. equi* subsp. *zooepidemicus* pneumonia to a handler, who developed severe systemic illness, has been described.[93] The sometimes very serious nature of *S. canis* and *S. equi* subsp. *zooepidemicus* infections in humans means that dogs or cats with severe streptococcal infections should be handled with appropriate precautions by anyone in contact with them. The risk can probably be contained by wearing gloves and protective clothing when handling dogs with STSS or NFM.

Dogs and cats are also a potential source for human infection by MDR enterococci. In one study, dogs that left a veterinary intensive care unit (ICU) were colonized with MDR enterococci with the capacity for biofilm formation and horizontal transfer of antimicrobial resistance genes.[94] Enterococcal infections in humans usually require significant host predisposition, although this is less the case for *S. canis* and *S. equi* subsp. *zooepidemicus* infections. Vancomycin-resistant enterococci with the same genotype as those found in people have been recovered from the feces of pet dogs and cats, and the discovery of linezolid- and multidrug-resistant enterococci in raw commercial dog food in Europe has significant public health implications.[79]

Because of the potential for transmission of streptococci and enterococci between dogs, cats, and humans, preventative measures such as hand washing after pets are handled, household disinfection, and avoidance of close contact (such as allowing pets to lick wounds or mucous membranes) should be considered, especially for immunocompromised pet owners. Dogs and cats should not be fed raw diets, even if commercially available as frozen raw food for pets. Veterinarians should also recognize the potential for clinics and hospital environments to become contaminated with *E. faecalis* and *E. faecium*, and take appropriate hygiene steps if this is recognized to have occurred.

CASE EXAMPLE 1

Signalment

"Rigby," an 8-year-old neutered Boston terrier from Central Ohio.

History

Rigby was evaluated by the emergency service of the Ohio State University Veterinary Medical Center for acute swelling of the entire left pelvic limb distal to the stifle. Two days prior to examination, he had been hospitalized in another facility where he was treated with activated charcoal, crystalloids, and GI protectants after ingestion of an unknown amount of deracoxib. Upon discharge from the other facility, the owner noticed a small swelling on the left hock which progressed rapidly towards the stifle during that day. The owner reported that Rigby had decreased energy and inappetence.

Physical Examination

Body weight: 10.9 kg.

General, cardiovascular, and respiratory: Bright, alert, and responsive. Hydrated. T = 103.5°F (39.7°C), HR = 112 beats/minute, II/VI left apical systolic murmur, strong femoral pulses, panting, BCS = 3/5, mucous membranes = pink, CRT < 2 seconds, BP = 195 mmHg (Doppler) right thoracic limb.

Integumentary and musculoskeletal: Ambulatory and weight-bearing on all limbs. The left pelvic limb was warm and erythematous with pitting edema that extended from the tarsus to the proximal tibia. The dog was able to fully flex the tarsal joint, however he was painful upon deep palpation.

Peripheral lymph nodes, external genital, neurologic, and ear/nose/throat examinations were all within normal limits.

CASE EXAMPLE 1—cont'd

Laboratory Findings

CBC, serum chemistries, and urinalysis were within normal limits.

Cytologic evaluation of an aspirate from a fluid pocket on the left tarsus revealed marked neutrophilic inflammation with both intracellular and extracellular cocci that occasionally formed chains.

Case Progression

Rigby was admitted to the ICU and managed with IV crystalloids and ampicillin/sulbactam with a differential diagnosis of severe cellulitis or NFM. Over the next several hours, the proximal left pelvic limb also became edematous and amputation was performed without complication (Fig. 50.8). The amputated limb revealed a positive finger test,[65] and subsequent histopathologic characterization of the tissue revealed extensive acute, diffuse, severe fibrinosuppurative cellulitis and dermatitis with hemorrhage and edema, compatible with NFM. The next morning, aerobic culture of the fluid aspirate yielded a pure, heavy growth of *S. canis*. Rigby's management in the ICU was continued for 2 additional days, and he was discharged on oral amoxicillin, tramadol, gabapentin, and douxo wipes for his amputation site. The heart murmur, which was appreciated on presentation and may have indicated concern for streptococcal endocarditis, was not recognized subsequently.

Fig. 50.8. Necrotizing fasciitis myositis of the proximal left pelvic limb caused by *Streptococcus canis* in an 8-year old male neutered Boston terrier. The limb was amputated and the image shows purulent material between fascial planes.

CASE EXAMPLE 2

Signalment

"Jazz," a 6-year-old female spayed miniature pinscher from Fairfield in northern California.

History

Jazz was brought to the University of California, Davis, Veterinary Medical Teaching Hospital, for evaluation of anorexia, lethargy, and diarrhea. Two days previously, the dog had been seen by the dermatology service for a focal area of alopecia and scaling on the dorsal midline in the thoracolumbar region that first appeared 7 months previously, enlarged to 6 × 4 cm in diameter over 2 months, and then remained static in size for the subsequent 5 months. Skin scrapings and fungal culture were performed, and four skin biopsies were obtained. An underlying vasculitis was suspected, and treatment with vitamin E (200 U, PO, q12h) and an oral fatty acid supplement was recommended pending the results of the diagnostic tests. The following day the owner noted edema of the right pelvic limb and discontinued the medications. Over the next 24 hours, Jazz became lethargic, inappetent, and developed liquid diarrhea and polydipsia. Jazz had been vaccinated regularly for canine distemper, adenovirus, and parvovirus infections and rabies and normally ate a commercial dry dog food. She was last vaccinated just after the skin lesion first appeared. The dog was mostly indoors, going outside on leash walks only, and there were no other pets in the household.

Other Medical History

Jazz had been spayed 5 weeks previously, at which time pyometra was an incidental finding and was treated with a 7-day course of amoxicillin.

Physical Examination

Body weight: 3.3 kg.

General: Lethargic, alert and ambulatory, but weak. Vocalized on palpation of the thorax and abdomen. T = 102.2°F (39.0°C), HR = 120 beats/minute, RR = 60 breaths/minute, mucous membranes pink, CRT = 1 second.

Eyes, ears, nose, and throat: Mild conjunctival hyperemia and bilateral serous ocular discharge were present.

Integument: There was mild subcutaneous edema and a small amount of serosanguinous fluid in the region of the skin biopsies, but sutures remained intact. There was a single, raised erythematous lesion adjacent to the skin biopsies that measured 0.5 × 0.5 cm in diameter. Severe edema was noted in the cranioventral thoracic region, which extended over an area that was 9 × 5 cm in diameter.

Other systems, including peripheral lymph nodes: No clinically significant findings.

Laboratory Findings

CBC: HCT 53.1% (40%–55%), MCV 71.2 fL (65–75 fL), MCHC 36.7 g/dL (33–36 g/dL), nucleated RBC 24/100 WBC, WBC 2,200 cells/μL (6,000–13,000 cells/μL), neutrophils 792 cells/μL (3,000–10,500 cells/μL), band neutrophils 748 cells/μL, metamyelocytes 88 cells/μL, myelocytes 44 cells/μL, lymphocytes 308 cells/μL (1,000–4,000 cells/μL), monocytes 220 cells/μL (150–1,200 cells/μL), platelets 97,000/μL (150,000–400,000 platelets/μL).

Markedly toxic band neutrophils, metamyelocytes, and myelocytes; moderately toxic neutrophils; and rare reactive lymphocytes were present.

Serum chemistry profile: Sodium 128 mmol/L (145–154 mmol/L), potassium 4.4 mmol/L (3.6–5.3 mmol/L), chloride 90 mmol/L (108–118 mmol/L), bicarbonate 21 mmol/L (16–26 mmol/L), phosphorus 8.7 mg/dL (3.0–6.2 mg/dL), calcium 10.0 mg/dL (9.7–11.5 mg/dL), BUN 63 mg/dL (5–21 mg/dL), creatinine 0.9 mg/dL

Continued

CASE EXAMPLE 2—cont'd

(0.3–1.2 mg/dL), glucose 75 mg/dL (64–123 mg/dL), total protein 5.6 g/dL (5.4–7.6 g/dL), albumin 2.2 g/dL (3.0–4.4 g/dL), globulin 3.4 g/dL (1.8–3.9 g/dL), ALT 185 U/L (19–67 U/L), AST 128 U/L (19–42 U/L), ALP 539 U/L (21–170 U/L), cholesterol 526 mg/dL (135–361 mg/dL), total bilirubin 0.5 mg/dL (0–0.2 mg/dL).
Urinalysis: SpG 1.021; pH 5.0, 1+ protein (SSA), 1+ bilirubin, 4+ hemoprotein, no glucose, no ketones, rare WBC/HPF, 0–2 RBC/HPF, few amorphous crystals, no bacteria seen.

Imaging Findings

Abdominal ultrasound: Enlargement of the uterine stump was present dorsal to the bladder. There were no cystic structures within the stump and no evidence of fluid in this region or lymphadenopathy.

Cytologic Findings

Needle aspiration of edema fluid from a region adjacent to the right axilla revealed large numbers of cocci, some in pairs, in the absence of significant numbers of leukocytes.

Microbiologic Testing

Aerobic bacterial culture (aspirate of edema fluid): Large numbers of *S. canis* colonies were isolated after overnight culture, and identified by MALDI-TOF the same day. A subsequent blood culture failed to yield any bacteria.

Treatment and Outcome

Treatment with IV fluids (0.9% NaCl with 20 mEq KCl/L) was initiated before the culture results were obtained. Ampicillin (20 mg/kg, IV, q6h), enrofloxacin (5 mg/kg, IV, q24h), and butorphanol were administered. The dog's body temperature subsequently dropped to 98.0°F (36.7°C) and blood glucose concentration dropped to 30 mg/dL. Fluids were supplemented with dextrose and a warming pad was used, and the dog's temperature returned to normal limits. Within hours, the edema had spread to the abdomen, and evidence of bruising appeared on the right thorax and ventrum. The raised erythematous lesion on the dorsum ulcerated, and dehiscence of the biopsy site adjacent to this region became apparent. Blood work showed a hematocrit of 39%, 2,700 WBCs/μL, 1,323 band neutrophils/μL, 702 neutrophils/μL, 162 lymphocytes/μL, 513 monocytes/μL, and 37,000 platelets/μL; serum sodium concentration was 142 mmol/L, potassium 3.7 mmol/L, creatinine 0.4 mg/dL, BUN 23 mg/dL, albumin 1.2 g/dL, globulin 3.1 g/dL, cholesterol 221 mg/dL, and total bilirubin 2.3 mg/dL. The activities of ALT, AST, and ALP were 79 U/L, 136 U/L, and 292 U/L, respectively. Treatment with dextran and plasma was initiated, but systolic blood pressure dropped to 80 mmHg, and the region adjacent to the biopsy sites became firm and painful and tore when palpated. Ampicillin was replaced by penicillin G (40,000 U/kg, IV, q6h), and enrofloxacin treatment was stopped. Forty-eight hours after admission, the dog was anesthetized and a large portion of necrotic skin was surgically debrided from the dog's dorsum. The debrided region was covered with a stent. During recovery, the dog was tachypneic, had increased lung sounds, and systolic blood pressure dropped to 50 mmHg. The dog developed respiratory arrest, and an endotracheal tube was placed, from which bloody fluid emanated. Cardiac arrest then ensued, and there was no response to closed cardiopulmonary resuscitation efforts.

Necropsy Findings

At necropsy, necrosis extended through the intercostal musculature of the right thoracic wall. Histopathologic lesions included severe, focally extensive, hemorrhagic and necrotizing panniculitis and fasciitis with intralesional bacteria and multifocal thrombi; diffuse necrotizing myositis of the right thoracic wall with intralesional bacteria; severe congestion and mild, multifocal hemorrhage and thrombosis within the kidneys; centrilobular congestion and severe bile stasis within the liver; congestion and hemorrhage within the lung; and generalized lymphoid depletion and sinusoidal histiocytosis within lymph nodes. Around the uterine stump, there was focal fibrosis and mild granulomatous serositis, but very few *S. canis* were cultured from the uterine stump. Histopathology of the biopsy specimens that had been collected before the onset of systemic illness showed severe, diffuse adnexal atrophy; mild, chronic, lymphoplasmacytic mural folliculitis; focal granulomatous furunculosis with hyperkeratosis; and mild, multifocal, perivascular neutrophilic dermatitis. No microorganisms were seen, although only special staining with PAS and Gomori's methenamine silver (GMS) was performed.

Diagnosis

NF, myositis, and STSS associated with *S. canis* infection.

Comments

This rare detailed case description illustrates how rapidly NF can progress and the ineffectiveness of antibiotic treatment in the presence of devitalized tissue. Clinical findings more than satisfied the criteria for diagnosis of STSS and NF in Box 50.1. The source of infection and the role that the uterine stump infection played was unclear. The effect of treatment of Jazz with the fluoroquinolone antibiotic, enrofloxacin, on development of STSS/NF is unclear, but this class of antibiotics is contraindicated in cases of *S. canis* infection since they may exacerbate disease as discussed earlier.[19]

Staphylococcal Infections

J. Scott Weese, John F. Prescott

KEY POINTS

- First Described: 1882, Scotland (Alexander Ogsten).
- Causes: In dogs and cats, the most common staphylococcal pathogens are *Staphylococcus pseudintermedius, Staphylococcus aureus,* and *Staphylococcus schleiferi.*
- Geographic Distribution: Worldwide.
- Mode of Transmission: Transmission is primarily through direct contact. Indirect transmission via fomites or the environment can occur.
- Major Clinical Signs: Pyoderma, otitis externa, surgical site infections, osteomyelitis, bacteremia and endocarditis, bronchopneumonia, urinary tract infections, ocular surface infections, rarely necrotizing fasciitis and toxic shock syndrome, pyothorax and peritonitis, discospondylitis, arthritis.
- Differential Diagnoses: Clinical signs are indistinguishable from infections caused by other opportunistic bacterial pathogens.
- Human Health Significance: Humans can become colonized or infected with staphylococcal isolates that colonize or infect dogs and cats. Methicillin-resistant *S. aureus,* which can persistently colonize humans, is of greatest concern, although human-pet transmission is probably much more common than pet-human transmission. *Staphylococcus pseudintermedius,* which can persistently colonize dogs, has occasionally been isolated from sick and healthy people who are in contact with dogs, and is of possible concern because of its tendency to show a high degree of MDR.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

The genus *Staphylococcus* contains a diverse genus of facultatively anaerobic bacteria that are widespread to ubiquitous commensals and opportunistic pathogens. They are gram-positive, catalase-positive cocci that tend to occur in clusters. As colonizers of mucous membranes and the skin, various *Staphylococcus* species can be found in or on most healthy animals. Widespread in healthy animals, staphylococci are classic opportunistic pathogens that can cause mild to life-threatening infections.

The clinical relevance of different staphylococcal species varies greatly. While virtually any species can cause disease, just a few species account for the vast majority of clinical infections. Staphylococcal species are divided into two main groups based on the production of the enzyme coagulase. Coagulase-positive staphylococci are the most virulent group and are most often associated with disease. The most important coagulase-positive species in dogs and cats are *Staphylococcus pseudintermedius*, *Staphylococcus aureus*, and *Staphylococcus schleiferi* subsp. *coagulans*. All can be found in healthy animals, but they account for a large percentage of opportunistic infections, including skin, ear, soft tissue, and urinary tract infections, and are leading causes of surgical site infections (SSIs).[1–5] *Staphylococcus intermedius* was previously considered the main *Staphylococcus* in dogs and cats, but it is now known that what was previously identified as *S. intermedius* is truly the closely related species *S. pseudintermedius*.[6,7]

Coagulase-negative staphylococci (CoNS) are common commensals that are often isolated as contaminants, but they can cause disease in certain situations. This group includes *Staphylococcus epidermidis*, *Staphylococcus haemolyticus*, *Staphylococcus xylosus*, *Staphylococcus sciuri*, *Staphylococcus schleiferi* subsp. *schleiferi*, and *Staphylococcus felis*, among others. Typically, CoNS infections involve compromised hosts and sites that have been injured by foreign bodies and invasive devices (e.g., IV catheters). Primary infections are uncommon, with the possible exception of *S. schleiferi* subsp. *schleiferi* pyoderma[8] and otitis and *S. felis* UTI.[9] Interpretation of the clinical relevance of CoNS is often complicated by their common presence at skin and mucosal surfaces and the corresponding potential for contamination during specimen collection.

There are differences in the epidemiology of staphylococcal colonization and infection between different staphylococcal species and between dogs and cats. Staphylococci have often been referred to as host-adapted species, but it is clear that dogs and cats can be infected by many different staphylococcal species. Regular transmission of staphylococci between species (e.g., human-pet) likely occurs and staphylococcal status is dynamic. While the term "colonization" is widely used to refer to the presence of staphylococci in or on healthy individuals, it is clear that there is no consistent "colonization" state. After exposure to a *Staphylococcus*, multiple outcomes may occur. The organism may be rapidly eliminated, reside in or on the haircoat or mucous membranes transiently (sometimes referred to as "contamination"), multiply and live on the host for a short period of time ("transient colonization"), or live on the host for prolonged periods of time. The degree of host adaptation of the *Staphylococcus* species and possibly the strain, and patient factors (e.g., immune status, commensal microbiota), presumably influence the outcome, although other factors such as genetics could also be involved. As a host-adapted *Staphylococcus*, *S. pseudintermedius* appears to be able to cause prolonged colonization in at least some dogs,[10] whereas, in contrast, *S. aureus* colonization in dogs appears to be more transient.[11,12]

The incidence of staphylococcal disease is poorly described, but staphylococci account for a large percentage of skin and soft tissue infections encountered in dogs and cats, along with a variety of less common conditions. Most, if not all, staphylococcal infections are secondary to an underlying cause (e.g. skin disease, wounds) and the constituents or basis of those underlying causes are the main factors associated with risk of staphylococcal infection.

Staphylococcus pseudintermedius

Staphylococcus pseudintermedius is a true canine commensal and is found on the skin or mucosal surfaces of a large percentage of dogs. Isolation rates of 31% to 68% have been reported in healthy dogs,[13–16] with higher rates (up to 100%) in puppies.[17] It is likely that the vast majority of dogs, if not all, harbor this species at least periodically. Colonization starts early in life, with puppies acquiring *S. pseudintermedius* from the dam within 8 hours after birth.[17] Various body sites can be colonized, particularly the nasal passages, oral cavity, skin, and perineal mucosa, although the pharyngeal mucosa seems to be a main colonization site.[18]

Staphylococcus pseudintermedius is less prevalent in cats, being reported in 6.8% to 22% of healthy cats.[15,19–21] As with dogs, opportunistic infections can develop, but the influence of long-term or transient colonization on risk of disease is unknown. In parallel with colonization rates, *S. pseudintermedius* infections are less common in cats than in dogs.[4]

Methicillin-resistant *S. pseudintermedius* (MRSP) has emerged as an important pathogen in veterinary medicine.

Staphylococcus aureus

Staphylococcus aureus is a well-recognized pathogen and common commensal, although it is less commonly found in dogs than *S. pseudintermedius*. It can be isolated from up to 12% to 14% of clinically healthy dogs and 4.3% to 20% of clinically healthy cats, but it may not truly be a commensal organism (at least in dogs) as carriage tends to be transient. Colonization may be highly human influenced, since the *S. aureus* strains found in dogs are often indistinguishable from those found in their human contacts.[15] It is possible that isolation of *S. aureus* often represents transient colonization or contamination acquired from humans. This appears to be particularly true with dogs. A study of dogs and their owners reported that in 50% of households where *S. aureus* was isolated from both a dog and family member, the *S. aureus* strains were indistinguishable, strongly suggesting interspecies transmission.[15] The situation with cats is less clear. Given the higher apparent prevalence of *S. aureus* colonization in cats in some studies and the lack of another predominant coagulase-positive *Staphylococcus* species commensal in cats, it is possible that *S. aureus* is a true feline commensal. Regardless, it can clearly be isolated from a small but still appreciable percentage of clinically healthy dogs and cats and can also cause disease in certain situations. The highest isolation rates are from skin and ear infections.[22] Risk factors for colonization have not been adequately investigated and may relate to the amount or degree of human contact.

Staphylococcus schleiferi subsp. *coagulans*

Staphylococcus schleiferi contains two subspecies; the coagulase-positive *S. schleiferi* subsp. *coagulans* and the coagulase-negative *S. schleiferi* subsp. *schleiferi*. *Staphylococcus schleiferi* subsp. *coagulans* is less commonly identified than *S. pseudintermedius* and *S. aureus*, but can be found in 0.8% to 4% of healthy dogs and 0% to 2% of healthy cats.[1,15,19,23,24] It is most commonly implicated in otitis externa and pyoderma,[8,19,25,26] but is rarely identified in other types of infections.[27] There appears to be prominent geographic variation in reports of this pathogen. Whether this is a result of true geographic variation or differences in laboratory identification is unknown. This species may be misidentified as *S. pseudintermedius* or *S. intermedius* group if methods aimed at differentiating it from those similar species are not used. This may be of little clinical consequence given the identical approach to management of infections caused by these species.

Coagulase-Negative Staphylococci

The coagulase-negative *Staphylococcus* spp. group contains a large number of species that are commonly found in healthy dogs and cats, along with virtually all other mammalian species. They are essentially ubiquitous inhabitants of the skin, nasal and oral cavities, pharynx, perineal mucosa, GI tract, and conjunctiva of dogs, cats, and other species. Commonly reported species from dogs include *S. epidermidis*, *S. xylosus*, *S. schleiferi* subsp. *schleiferi*, and *S. sciuri*, with *S. epidermidis*, *S. felis*, *S. haemolyticus*, *Staphylococcus saprophyticus*, and *Staphylococcus simulans* often reported in cats.[9,17,28–38] However, a broad range of other species can be encountered. As diagnostic laboratories rapidly move to methods such as MALDI-TOF MS that provide more accurate speciation (as opposed to the common generic identification of isolates as CoNS), the range of CoNS that are encountered will probably increase. Genus-level identification of CoNS has predominated in the past because of the effort required to speciate isolates, particularly when speciation would have little to no impact on diagnosis or management of cases. However, as more information about different species becomes available, it is likely that differences in the epidemiology and clinical relevance of different CoNS will be identified.

Despite widespread colonization, CoNS infections are uncommon. While most, if not all, CoNS are opportunistic pathogens with the potential to cause disease, virulence tends to be limited and CoNS are most often isolated as commensals or contaminants, not pathogens. In human medicine, CoNS are primarily a concern in hospitalized individuals, where skin, soft tissue, bloodstream, and invasive device infections predominate.[39–41] The role of CoNS in disease in dogs and cats is poorly investigated and complicated by studies that report any isolation of CoNS as "infection." Differentiation of infection versus contamination is a challenge, with most CoNS being of minimal concern, but some species (i.e., *S. schleiferi* subsp. *schleiferi*, *Staphylococcus lugdunensis*, and *S. felis*) are potentially important causes of community-onset disease. While rare, invasive *S. lugdunensis* infections have been reported in dogs,[42,43] and this may be a more virulent CoNS.

Methicillin-Resistant Staphylococci

While staphylococci are inherently susceptible to most antimicrobials, acquired resistance emerged as a concern shortly after the start of the "antibiotic era." Staphylococci have demonstrated an impressive ability to acquire new resistance genes in response to continued antimicrobial development, and resistant staphylococci have serious impacts on the health and welfare of both humans and animals.

Methicillin resistance is of particular concern. While methicillin is not used clinically in animals, the mechanism that confers resistance to methicillin (*mecA*) renders staphylococci resistant to virtually all beta-lactam antimicrobials—penicillins, cephalosporins, and carbapenems. This encompasses a large percentage of the antimicrobials that are used, particularly empirically. Additionally, methicillin-resistant staphylococci (MRS) commonly possess other resistance genes, further limiting effective antimicrobial options. Methicillin resistance has emerged in all clinically relevant staphylococci, and MRS have been isolated from a wide range of companion animal, food animal, exotic, and wildlife species.

As with methicillin-susceptible staphylococci, MRS can be found as part of the commensal microbiota of healthy individuals. Indeed, the majority of humans and animals that harbor MRS do so without any evidence of disease. Methicillin resistance is not, itself, a virulence factor, since it simply confers resistance to antimicrobials. Infections caused by MRS are the same as those caused by susceptible staphylococci, and occur in situations where secondary infections can develop. However, they are harder to treat because of the limited options and failure of empirical therapy can have a negative impact on outcome.

Much of the attention regarding MRS in dogs and cats initially focused on methicillin-resistant *S. aureus* (MRSA).[44–51] The emergence of MRSA in dogs and cats appears to be a direct reflection of the spread of MRSA in the human population; MRSA infections in pets were noted after MRSA emerged as an important cause of disease in

the general human population and with MRSA strains from animals usually reflecting predominant human strains.[48,51–54] Whether MRSA is truly established in the dog and cat population, or whether colonization and infection of those species is a result of direct infection from humans is unclear. Regardless, MRSA can be isolated from a small percentage (e.g., 0% to 4%) of clinically healthy dogs cats.[48,55–63] Higher rates can be encountered periodically in animals in veterinary facilities; however, most instances of MRSA isolation are not associated with veterinary hospitals. Ownership by a human health care worker and participation in hospital visitation programs are risk factors for MRSA colonization in dogs,[11] as might be expected based on the increased likelihood of exposure to colonized people. Other risk factors for MRSA infection or colonization have been identified, with varying strength of evidence, particularly antimicrobial exposure and hospitalization.[22,59,64–66] Contact with children has also been identified as a risk factor.[11] Although these, and potentially other, risk factors should be considered, MRSA can be identified in any animal, and absence of known risk factors should not lead to excluding MRSA from consideration. In humans and horses, MRSA colonization is a risk factor for clinical MRSA infection in certain circumstances (e.g., after admission to the hospital).[67,68] It is reasonable to assume that this also applies to dogs and cats, yet this is not proven. Although MRSA colonization has zoonotic concerns (see below), the animal health implications of MRSA colonization in clinically healthy animals are likely minimal.

While MRSA was the first prominent methicillin-resistant *Staphylococcus* sp. in animals, MRSP has surpassed MRSA in its impact on dogs and cats. As with methicillin-susceptible strains, MRSP can be found in or on clinically healthy dogs and cats, with a wide range of reported prevalence (e.g., 0% to 17%).[29,61,63,69–76] MRSP is an opportunistic pathogen, and colonization does not necessarily lead to disease. Carriage of MRSP prior to tibial plateau leveling osteotomy (TPLO) was shown to be a risk factor for MRSP SSI,[77] but whether this applies to other surgical procedures or other diseases is unknown. It is reasonable to assume that colonization poses some degree of risk of subsequent infection in many situations, albeit presumably rather low and dependent on the presence of factors that predispose to development of an opportunistic infection. Reported risk factors for MRSP colonization or infection include antimicrobial exposure (particularly beta-lactams, immunosuppressive therapy, and hospitalization).[75,78–80] MRSP infections are not distinguishable clinically from those caused by susceptible strains, but are increasingly problematic because of the limited treatment options, particularly since MRSP isolates in many regions are commonly resistant to most available antimicrobials.

Methicillin resistance is not uncommon in commensal CoNS. Studies have reported prevalence ranging from 5% to 13% in clinically healthy dogs, and 5% in clinically healthy cats.[34,55,81] Methicillin-resistant strains are no more pathogenic than methicillin-susceptible strains, and the implications of colonization with methicillin-resistant CoNS are typically inconsequential although these strains are likely sources of acquired methicillin resistance for more virulent staphylococcal species.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Staphylococci can possess a wide array of potential virulence factors; however, the role that many of these play in the actual development of disease is variable. Some virulence factors facilitate adhesion to, and colonization of host tissues. Others encode secreted enzymes and toxins that are responsible for invasion as well as local and distant disease. The pathophysiology of disease is complex and only superficially understood, reflecting the variable presence of numerous staphylococcal virulence determinants in different strains of the more pathogenic species. Interactions between various virulence factors are presumably critical, because no single virulence factor has been shown to be sufficient to establish an infection.

The ability to colonize body sites is a critical component of virulence, because it allows staphylococci to remain on or in the body waiting for an opportunity to cause an infection, particularly after an underlying insult such as a break in the body's physical or immunologic barriers. Important among these factors are surface adhesins, which do not directly result in damage to host tissues, but create an environment where staphylococci can persist. Adhesins may also facilitate evasion of the immune system. For *S. aureus*, the most important is probably protein A, which binds to the Fc portion of IgG.[82] Other surface proteins that include clumping factors, fibronectin-binding proteins, coagulase, and collagen-binding protein are important, since they each give pathogenic staphylococci the ability to readily colonize breaks in the skin or mucosal surfaces as the first part of the infection process. Once the organism reaches a sufficient density at this local site of infection, release of a peptide signal through the Agr quorum-sensing system activates many of the toxins and degradative enzymes while downregulating the numerous adhesion molecules. Various hemolysin toxins can lyse erythrocytes and other body cells. Proteases can cleave antibodies, play a role in protection against neutrophil defensins and platelet microbicidal peptides, contribute to destruction of tissue protein, and potentiate invasion.[83] Hyaluronidase and hyaluronate lysate may further contribute to virulence through digestion of hyaluronic acid in connective tissue and promoting degradation of tissues.[84,85] Lipase has a negative effect on the host's immune function and may help the bacterium harvest nutrients from the local environment. Alpha toxin is a potent membrane-damaging toxin that can produce local cell damage. Leukocidins damage leukocytes and lipid membranes. One, the Panton-Valentine leukocidin, has received much attention because of its apparent role in severe MRSA skin and soft tissue infections, as well as necrotizing fasciitis and necrotizing pneumonia in humans.[86–89] This leukocidin has been found in MRSA from dogs and cats,[90,91] but its role in disease is still unclear. Enterotoxin production is mediated by several staphylococcal enterotoxin genes, many of which can be found in *S. aureus* from dogs.[92,93] However, it is unclear whether staphylococcal enteric disease is of relevance in dogs and cats. Other toxins of note include exfoliative toxins A and B, which cause staphylococcal scalded skin syndrome, and toxic shock syndrome toxins, which cause toxic shock syndrome.

Less is known about *S. pseudintermedius*, but evidence indicates that this species has numerous virulence factors similar to those of *S. aureus*, such as protein A, leukocidins, exfoliative toxins, other exotoxins, fibronectin-binding protein, and biofilm-producing factors.[94,95] The exfoliative toxin of *S. intermedius* can be found in *S. pseudintermedius* isolates from a large percentage of dogs and cats,[96–100] and it may play a role in pyoderma and otitis, but that has not yet been proven.

Another potentially important aspect of staphylococcal virulence is the ability to form biofilms (see Chapter 121) (Fig. 51.1). Biofilm may be most relevant for infections of implants and invasive devices (e.g., IV catheters). Biofilm formation has been demonstrated for various staphylococci, including *S. pseudintermedius* and *S. aureus*.[95,101–103] The role of biofilm formation in disease is not well understood, but it probably plays an important role in development of chronic disease and resistance to treatment in certain situations, particularly surgical implant and invasive device infections.

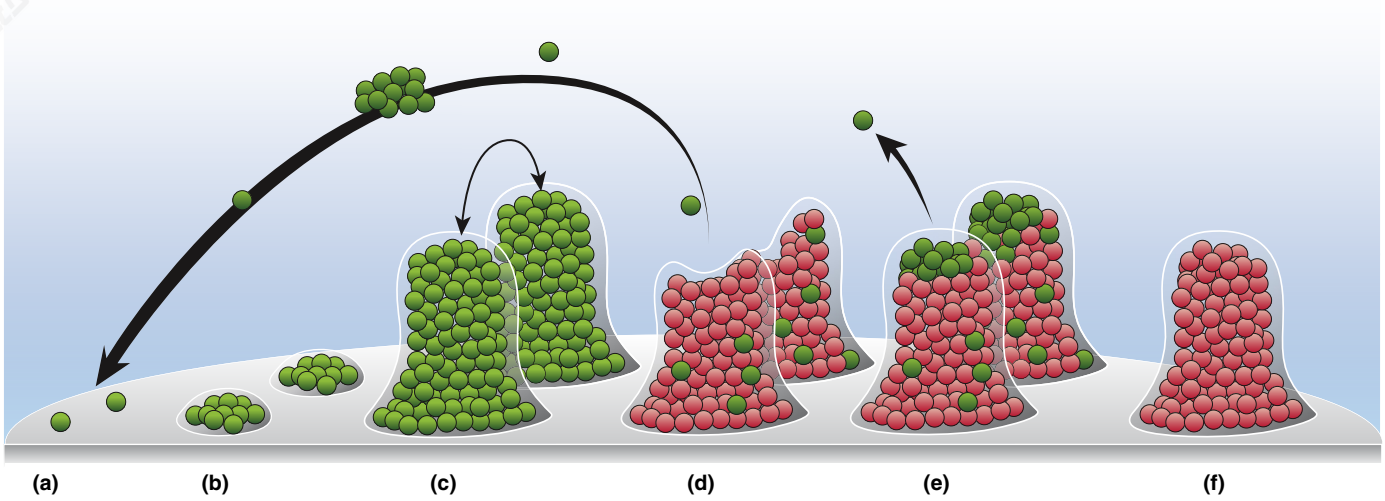

Fig. 51.1 Model of *agr* expression in staphylococcal biofilms. After initial colonization by individual cells *(a)*, microcolonies reach sufficient cell density for *agr*-dependent gene expression *(b)* and perhaps signaling between microcolonies *(c, arrows)*. Portions of the biofilm detach *(d)* as either large aggregates or individual cells. Simultaneously, parts of the biofilm population become metabolically inactive and lose membrane integrity. This is followed by new growth in the voids left by detached cells *(e)*, and the cycle is repeated. The microcolony finally reaches a relatively quiescent state where growth is slow and *agr* expression is undetectable *(f)*. Green = metabolically active bacteria that are producing virulence factors. Red = bacteria with states of relative inactivity.

Staphylococci cause a wide range of opportunistic infections, particularly acute bacterial skin and skin structure infections (also referred to as skin and soft tissue infections). Clinically, these can range from mild pyoderma to rapidly fatal necrotizing fasciitis. Any body system can be affected, including otherwise sterile sites (invasive infections). Severe manifestations of staphylococcal infection include staphylococcal toxic shock syndrome, bacteremia/sepsis, and necrotizing fasciitis (see Chapter 50). There is little to no difference in the clinical appearance of infections caused by different staphylococcal species, and no difference between methicillin-resistant and methicillin-susceptible infections. Additionally, staphylococcal infections cannot be differentiated from infections caused by other opportunistic pathogens without diagnostic testing.

Staphylococcus pseudintermedius

Staphylococcus pseudintermedius accounts for the vast majority of staphylococcal infections (and probably overall opportunistic infection) in dogs, and a lesser percentage in cats. The most common clinical manifestation of infection is pyoderma, including superficial and deep disease. *S. pseudintermedius* also causes a range of other infections including, in general order of occurrence, wound infections, SSIs, abscesses, UTIs, septic arthritis, osteomyelitis, discospondylitis, endocarditis, peritonitis, and ocular infections. The severity of disease is highly variable. Serious invasive infections including fatal toxic shock and cellulitis have been reported,[104,105] but these are rare. Most infections are mild to moderate in severity.

Staphylococcus aureus

A similar range of infections as produced by *S. pseudintermedius* can be produced by *S. aureus*. The main difference between *S. pseudintermedius* and *S. aureus* is the lower incidence of disease caused by the latter rather than disease location or severity. *S. aureus* infections may be more common in cats than in dogs, which probably relates to a lower prevalence of *S. pseudintermedius* colonization in cats. It is possible that infections more commonly associated with human contact (i.e., wound and SSIs contaminated by hands of owners or veterinary personnel) are more likely to be caused by *S. aureus* (including MRSA), but objective data are lacking.

Staphylococcus schleiferi subsp. *coagulans*

The main apparent difference in clinical expression of disease between *S. schleiferi* subsp. *coagulans* and other coagulase-positive staphylococcal infections is the rarity of infections beyond the skin and ears. However, the role of this staphylococcal species in disease may be underestimated because of the failure of many diagnostic laboratories to differentiate it from *S. pseudintermedius*. It has been suggested that *S. schleiferi* subsp. *coagulans* may tend to produce more superficial skin disease than *S. pseudintermedius* and *S. aureus*,[4] but supporting evidence is limited.

Coagulase-Negative Staphylococci

Interpretation of the role of CoNS in disease is difficult because they are often found in cultures as contaminants. Since most species are of limited virulence and often found at mucosal and skin sites, interpretation of the relevance of isolation of CoNS and the potential role in disease is a challenge. Further, as discussed above, while CoNS are generally considered as a group, it is possible that there are differences in clinical expression of disease among CoNS species. In particular, *S. schleiferi* subsp. *schleiferi* has been implicated as a cause of pyoderma and otitis.[8,19,27] A primary role of *S. felis* as an important cause of UTIs in cats has been suggested,[9] but remains unclear. *Staphylococcus lugdunensis* may also be a more pathogenic species. CoNS likely pose a greater risk for infections of invasive devices, surgical incisions, and other compromised sites.

DIAGNOSIS

There are no clinical, clinicopathologic, or diagnostic imaging results that are pathognomonic or even highly suggestive of staphylococcal infection.

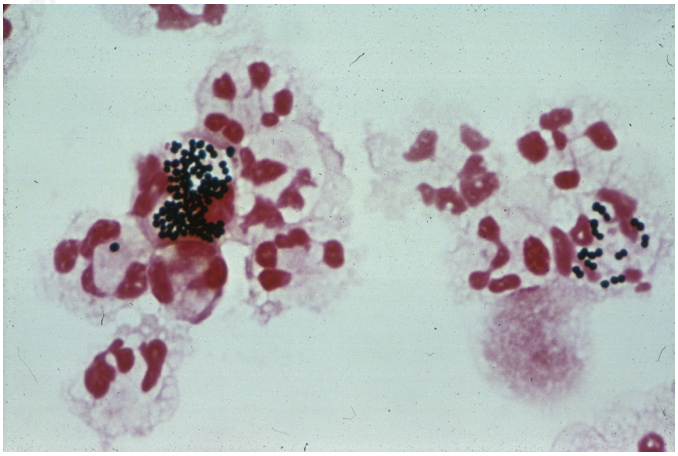

Fig. 51.2 *Staphylococcus aureus* engulfed in neutrophils. Note the "clumps" of gram-positive cocci characteristic of staphylococci.

Microbiologic Tests

Cytologic Diagnosis

Evaluation of smears or aspirates can indicate the presence of bacterial sepsis, and the presence of cocci, particularly clusters of gram-positive cocci, is suggestive of staphylococcal infection (Fig. 51.2). Cytologic evidence of an infectious inflammatory response, particularly an abundance of neutrophils and intracellular bacteria, is particularly suggestive.

Culture and Susceptibility Testing

Isolation of staphylococci from an infected site is the standard for diagnosis; however, whereas isolation of staphylococci tends to be relatively easy, interpretation of results can be challenging. Because staphylococci are common commensals, contamination of specimens, particularly those from skin and soft tissue infections, is a major problem in diagnosis. Care should, therefore, be taken to avoid contamination when collecting culture specimens. Particular care must be taken in diagnosing infections caused by CoNS, since they are common contaminants and are uncommonly pathogenic. This includes methicillin-resistant CoNS, which are not uncommonly isolated from healthy animals. Isolation of CoNS from a superficial site should be interpreted with caution. If a CoNS and another potential pathogen are identified concurrently, the CoNS is typically considered a contaminant. Isolation of CoNS from sterile sites (e.g., blood, pleural cavity) is more indicative of disease as long as samples were collected and handled properly; however, in human medicine, a single blood culture of CoNS is often dismissed as a likely contaminant.[106] If quantitative or semiquantitative culture results are provided, low growth (1+) of CoNS is of questionable relevance and quite possibly contamination, not infection.

Speciation of staphylococci is variably handled among diagnostic laboratories. Some laboratories provide only superficial identifications. However, speciation is required for proper antimicrobial susceptibility testing, as interpretive breakpoints differ among different species of *Staphylococcus* (see Chapter 3).[107,108] Speciation can also be useful for infection control purposes to help assess likely sources of infection and potential public health concerns, particularly when MRS are involved. It is also useful when trying to determine whether multiple culture results could indicate a cluster of hospital-associated infections, because infections with different species would rule out a common source exposure. It has often been considered that there is less need for speciation of CoNS because they are, in general, less pathogenic, with limited difference between species. However, if certain CoNS are potentially important primary pathogens (e.g., *S. schleiferi* subsp. *schleiferi* in pyoderma or *S. felis* in UTIs in cats), then speciation could be important for interpreting the relevance of isolation of CoNS.

Given the variability in susceptibility patterns among staphylococci and the emergence of MDR MRSP and MRSA, it is important that proper susceptibility testing be performed to guide treatment. Veterinarians should ensure that the diagnostic laboratory they use follow standard Clinical and Laboratory Standards Institute (CLSI) guidelines for performance and interpretation of susceptibility testing results.[109] In general, methods to detect antimicrobial susceptibility among staphylococci are well developed and validated. Problems with identification of methicillin resistance in *S. pseudintermedius* have been previously encountered,[107,108,110] although changes in CLSI guidelines for susceptibility testing of *S. pseudintermedius* have improved this situation. Problems with assessment of doxycycline susceptibility have also been identified, with use of human interpretative breakpoints leading to false reporting of doxycycline susceptibility in some *S. pseudintermedius* isolates.[111,112] Revised breakpoints have been recommended,[113] but these are not necessarily used by all diagnostic laboratories. Another area of concern is determination of clindamycin resistance because of inducible resistance, as is discussed under Systemic Antimicrobials.

Molecular Diagnosis Using Nucleic Acid–Based Testing

While the movement to rapid diagnostic testing will continue, there are currently no validated rapid tests for diagnosis of staphylococcal infections in dogs and cats. Although molecular assays based on PCR offer the potential for a rapid result, adequate test development and validation is required to ensure sensitivity and specificity. Of greater interest are assays that will rapidly identify MRSA or MRSP to guide initial treatment decisions. There are commercial assays for rapid detection of MRSA in humans; however, these have not been validated in animals, and investigation of one test in horses demonstrated poor performance.[114] A similar test for MRSP is not available, and clinicians must be aware that commercial veterinary "MRSA" PCR assays may simply be tests to detect *mecA*, the resistance gene that can be found in any MRS species, including CoNS.

TREATMENT AND PROGNOSIS

Management of staphylococcal infections is highly variable because of the diverse nature of disease. The general approach to treatment varies little between different staphylococcal species, and indeed between infections caused by staphylococci versus other opportunistic pathogens. Infection site and severity are key determinants of the required approach. Factors such as surgical intervention and supportive care may be required, and are sometimes the most important measures, but are not covered here.

Antimicrobials are not always needed for staphylococcal infections. In some situations, local approaches using biocides such as chlorhexidine or other antibacterial substances may be effective. The best example of this is superficial folliculitis, where topical therapy with chlorhexidine has been shown to be effective in the absence of concurrent systemic antimicrobials[115,116] and where topical therapy alone is the recommended first-line approach.[117] Other common situations may be amenable to nonantimicrobial approaches. Biocides as well as other substances with antibacterial activity (e.g., honey) can also be useful sole or adjunctive approaches to wound infections. Incision and drainage is the preferred approach for treatment of abscesses that are not associated with evidence of systemic infection or significant localized cellulitis. Similarly, mild superficial SSIs may be effectively managed through removal of skin sutures and cleaning of the site. Thus,

while systemic antimicrobials are often required for the treatment of staphylococcal infections, there are many instances where other treatment approaches may be effective.

Systemic Antimicrobials

Treatment with systemic antimicrobials is ideally based on the results of culture and susceptibility testing. This has become particularly true as the prevalence of MDR staphylococci has increased. The prevalence of resistance to different antimicrobials varies between (and even within) regions, so knowledge of local susceptibility patterns is useful. Knowledge of typical clinical response to empirical antimicrobials can be useful to guide decisions, particularly in situations where culture specimens are uncommonly submitted. Published data from research papers or laboratory data compilations can provide interesting information but are potentially biased since, in most regions, culture specimens are disproportionately submitted from infections that are recurrent or have not responded to initial antimicrobial therapy. Therefore, these can be expected to over-represent (sometimes profoundly) the prevalence of antimicrobial resistance. Databases from referral institutions can have similar biases. Thus, care should be taken when making clinical decisions from such data sets, and thought must be given to how well the dataset represents the individual clinical case. Knowledge of resistance trends in the practice is more useful to guide empiric therapy and treatment while awaiting culture results, but nothing takes the place of culture and susceptibility data from an individual patient.

Drug options and dosages for treatment of staphylococcal infections are listed in Table 51.1. In general, resistance is uncommon to first-generation cephalosporins (e.g., cephalexin) or β-lactamase-resistant penicillins or penicillin/β-lactamase inhibitor combinations (e.g., amoxicillin-clavulanate), and these drugs are widely used as first-line treatments, although the increase in methicillin resistance in many regions has impacted the use of beta-lactams. In most situations, the prevalence of methicillin resistance is still sufficiently low that beta-lactams/beta-lactamase inhibitor combinations or cephalosporins can be used as initial or empirical therapy.

Clindamycin is another excellent option if the isolate is susceptible *in vitro*, and has been recommended as a first-line treatment for superficial folliculitis.[117] However, inducible clindamycin resistance must be considered, particularly in *S. aureus*.[118–120] With this phenomenon, isolates appear to be susceptible to clindamycin *in vitro*; however, resistance is induced on exposure *in vivo*, and treatment failure is expected. One study reported inducible resistance in 71% of MRSA strains from animals,[119] whereas another study reported that 55% of

TABLE 51.1 Selected Antimicrobial Options for the Treatment of *Staphylococcus* Infections

Drug	Dose (mg/kg)	Route	Interval (Hours)	Comments
Amoxicillin	22	PO	12	Only use based on culture and susceptibility testing because of the high prevalence of beta-lactamase production.
Amoxicillin-clavulanic acid	12.5–25	PO	8–12	Good empirical drug for suspected staphylococcal infections.
Cephalexin	22–25	PO	12	
Clindamycin	D: 10 C: 10–15	PO/SC	12	Excellent antistaphylococcal drug. D-test or equivalent must be used to rule out inducible resistance, particularly in MRSA.
Fluoroquinolones	Varies depending on specific drug			Avoid enrofloxacin in cats. Typically, the high end of the dosing range is preferred. Ciprofloxacin should be avoided because of unpredictable bioavailability.
Doxycycline	D: 5 C: 10	PO	12 24	Ensure that *S. pseudintermedius* testing is based on current interpretive breakpoints to avoid false indication of susceptibility.
Minocycline	D: 5 C: 8.8 or 50 mg/cat	PO	12 24	Useful if doxycycline is not available and for some doxycycline-resistant staphylococcal infections.
Trimethoprim-sulfamethoxazole or trimethoprim-sulfadiazine	15–30	PO	12	Schirmer's tear testing is recommended in dogs as a baseline and periodically if treatment of > 7-day duration is planned.
Chloramphenicol	D: 40–50 C: 12.5–20	PO/SC/IM/IV PO/SC/IV	8 12	Use with caution because of potential human exposure risks.
Amikacin	D: 15–30 C: 10–14	IV/IM/SC	24	Monitoring of renal function is advised.
Fosfomycin	D: 40	PO	12	Reserve for multidrug-resistant infections. Limited veterinary experience. Adverse gastrointestinal effects are not uncommon. Administer with food. Treatment should probably be limited to short durations. Should not be used in cats.
Nitrofurantoin	4–4.5	PO	8	Reserve for multidrug-resistant infections. Only for cystitis, not tissue-associated infections (including pyelonephritis).
Cefovecin	8	SC	Can be repeated in 7–14 days	Should be reserved for cases where the duration of treatment is required and when oral dosing with a first-line option such as amoxicillin +/– clavulanic acid, clindamycin or cephalexin is not possible.
Cefpodoxime	5–10	PO	24	Reserve for cases where oral dosing with a first-line option such as amoxicillin +/– clavulanic acid, clindamycin or cephalexin is not possible.

C, cats; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *MRSA,* methicillin-resistant *Staphylococcus aureus*; *PO,* oral; *SC,* subcutaneous.

erythromycin-resistant, clindamycin-susceptible MRSA from dogs were inducibly resistant.[118] Inducible resistance can be detected in the laboratory using a "D-test" and it is important to know what testing methods are used when diagnostic laboratories report clindamycin susceptibility. *S. aureus* isolates that are reported as erythromycin resistant but clindamycin susceptible should be considered resistant to clindamycin unless the D-test (or equivalent) has indicated the absence of inducible resistance. Inducible resistance is not a concern if erythromycin susceptibility is reported. Inducible resistance appears to be rare in *S. pseudintermedius* but, because it has been reported,[118,121] it is prudent to avoid clindamycin for the treatment of serious infections caused by erythromycin-resistant *S. pseudintermedius* without demonstration of absence of inducible clindamycin resistance. The same likely applies to other staphylococci as limited information is available.

Tetracyclines can be useful antistaphylococcal drugs, but resistance is not uncommon. Doxycycline is the most commonly used tetracycline and can be an effective treatment for various staphylococcal infections. Potential problems with the use of older doxycycline breakpoints for *S. pseudintermedius*, as discussed in more detail above, must be considered. If laboratories are using currently recommended breakpoints (susceptible if MICs are < 0.125 μg/mL or > 25 mm zone diameter),[113] doxycycline is a reasonable choice when *in vitro* susceptibility is reported. Minocycline has a somewhat broader spectrum of activity since some doxycycline-resistant staphylococci remain susceptible to minocycline.[111,112,122] This depends on the genetic mechanism of resistance, and the prevalence of minocycline susceptibility among doxycycline-resistant staphylococci varies depending on the *S. pseudintermedius* strain and the geographic region. Specific testing for minocycline is required when doxycycline-resistant isolates are encountered.

While most often used to target gram-negative pathogens, aminoglycosides can be excellent antistaphylococcal drugs, although the parenteral route of administration can be problematic and nephrotoxicity is a concern. Despite these concerns, amikacin has become a common treatment for MRSP infections because of the very limited options. Clinically relevant nephrotoxicity appears to be uncommon in systemically stable patients and is typically reversible if amikacin administration is stopped. Gentamicin can also be considered but is somewhat more toxic than amikacin, and lack of availability of amikacin would be the main reason to consider gentamicin.

Fluoroquinolones can have excellent intrinsic activity against staphylococci. Given their *in vitro* activity, their ability to penetrate the skin, the availability of oral formulations, and once-daily dosing requirement, fluoroquinolones have been popular choices for staphylococcal infections. They can be highly effective clinically, but concerns about fluoroquinolone resistance, in terms of both clinical treatment failure and public health consequences, have led to recommendations that they be reserved as second-line choices for many types of infections (e.g., bacterial cystitis, superficial folliculitis)[117,123] and be used only when resistance to other antimicrobials is present or likely. In humans, fluoroquinolones are not generally recommended as monotherapy for MRSA because of poor clinical response and rapid development of resistance.[124] This has not been objectively investigated in dogs and cats but there is no reason to suspect that it would be different in these species, so fluoroquinolones probably should be avoided whenever possible as treatments of resistant staphylococcal infections such as MRSA and MRSP when other viable alternatives exist. There has been less discussion about their indication in methicillin-susceptible infections. These should perhaps be approached with caution as well, because the presence or absence of methicillin resistance should be of limited relevance to the likelihood of treatment failure or emergence of resistance with quinolone treatment and because fluoroquinolone exposure is a well-documented risk factor for MRS infections in humans and dogs.[22,124,125] It is reasonable, therefore, to recommend prudent use of this drug class for any staphylococcal infection and to avoid empirical use of fluoroquinolones in any serious or life-threatening staphylococcal infection if possible.

Trimethoprim-sulfonamide is commonly active against MRS *in vitro*. Safety concerns exist, including keratoconjunctivitis sicca, arthropathy, and other idiosyncratic effects. These are most relevant with long durations of treatment but can occur with short-term therapy. Trimethoprim-sulfonamide can be used safely in most patients and is appropriate in situations with few other viable options. It should be avoided in animals with a history of/risk factors for keratoconjunctivitis sicca.

Chloramphenicol is also often active against staphylococci *in vitro* and anecdotally *in vivo*. There are human health concerns relating to fatal aplastic anemia from exposure to chloramphenicol, although this is an exceptionally rare idiosyncratic reaction. Careful drug handling instructions and client education as to its risks must be given. Chloramphenicol can also cause bone marrow suppression (particularly in cats) and is contraindicated in animals being treated with other myelosuppressive drugs. If chloramphenicol is to be used for a prolonged period of time, periodic (every 14 to 28 days) monitoring of a CBC count is advisable. Florfenicol might be a potential alternative to chloramphenicol, because it is not a health risk to humans. It can be administered orally, although it may be refused because of its taste. Although florfenicol has been used with anecdotal success in the treatment of MRSP and MRSA infections in dogs, treatment failure and development of resistance during treatment have been reported, and objective evaluation of efficacy is lacking.

Fosfomycin is uncommonly used in dogs, mainly as a treatment for resistant bacterial cystitis, but is a consideration for other staphylococcal infections. Fosfomycin resistance is currently uncommon in staphylococci[126] and fosfomycin represents a potential oral treatment option of MDR staphylococci. Clinical data are lacking and adverse GI effects are not uncommon. This drug should not be used in cats because of nephrotoxicity.[127]

Nitrofurantoin is a potential option for treatment of staphylococcal cystitis. While ineffective for infections other than cystitis (including pyelonephritis), nitrofurantoin is an option for some MDR staphylococcal cystitis cases. Resistance to nitrofurantoin is uncommon, but can occur.

As MRS become more prevalent and some strains become highly drug resistant, isolates that are resistant to almost all available drugs are being encountered in some regions. This has led to the consideration for use of antimicrobials that are critically important in human medicine, such as vancomycin and linezolid. Vancomycin, linezolid, tigecycline, and quinupristin-dalfopristin are drugs that are important for treatment of serious MDR infections in humans. Their use in animals raises many ethical questions that are difficult to answer. Concerns include increased pressure toward resistance of animal-harbored staphylococci and their subsequent transmission to humans. The concerns of public health risk are often opposed with concerns about animal health and welfare if proper treatment is not provided, and the fact that animal use makes up a minuscule percentage of overall use of these drugs. There is currently no consensus on the topic, but use of these drugs in animals is banned in some countries (e.g., The Netherlands, Sweden). At a minimum, these drugs should be reserved for situations where there are no other viable treatment alternatives, where the infection is not amenable to other (e.g., local) therapy, and where the infection is life threatening but potentially treatable. Before considering drugs such as these, all other therapeutic options should be considered and experts in infectious diseases should be consulted

if possible. Currently, it is rare to require drugs such as these because there is almost always another treatment option.

Local Antimicrobial Therapies

Local or regional administration of antimicrobials can deliver high antimicrobial concentrations that can result in clinical efficacy even in the face of *in vitro* resistance. This is dependent on the amount of drug that reaches the site, the duration that those levels are achieved, and the MIC of the specific bacterial isolate. Various approaches can be used, most commonly involving concentration-dependent drugs (e.g., aminoglycosides). Intra-articular injection of antimicrobials (e.g., amikacin) can be considered in cases of septic arthritis to achieve high local concentrations. This approach is most commonly used in horses but is practical in many small animal patients, especially surgery-associated stifle infections in large-breed dogs. Local administration of antimicrobial-impregnated materials such as beads or collagen sponges[128–131] can sometimes produce sustained high drug levels (see Chapter 121). This approach can be particularly useful in implant-associated infections or infections of poorly vascularized sites such as bone. Other methods to deliver high drug levels to a site of infection are under investigation or development, and new options will likely be available in coming years.

Topical Antimicrobials

Topical antimicrobial therapy may be a useful adjunctive or sole therapy. The ability to deliver high concentrations of antimicrobial directly to the site of infection, with minimal systemic exposure, is a desirable approach. Clinically relevant resistance of staphylococci to topical antimicrobials such as mupirocin and fusidic acid is uncommon,[132–136] and the high local antimicrobial levels that can be achieved may largely offset acquired resistance.

The main limitations to topical therapy are potential difficulties getting topically applied antimicrobials to the infection site and providing an adequate duration of contact. Thus, topical therapy is best reserved as a sole method for treatment of very focal superficial infections, such as superficial wound infection and focal surface pyoderma, including otitis externa. Systemic therapy or a combination of systemic and topical therapy should be used for deeper infections or infections that do not respond completely to topical monotherapy. Whether topical antimicrobials offer any advantage over topical application of biocides (e.g., chlorhexidine) is unclear.

Other Topical Treatments

Direct topical application of biocides is a potential option for some skin and skin structure infections and is a preferred approach for the treatment of superficial pyoderma.[117] The potential efficacy of biocides involves a balance between the bactericidal activity of the compound and the tissue damage from biocide application. Some compounds have profound antibacterial properties but are not useful because of the degree of tissue damage that can ensue. For some biocides, the costs versus benefits of antibacterial properties and tissue damage are not well understood.[137]

As with topical antimicrobials, the ability of the biocide to reach the infection site and limited contact time are the main limitations. Biocides may be effective as the sole treatment of superficial infections, or as adjunctive therapy for deeper infections. Available options include chlorhexidine, povidone-iodine, and benzoyl peroxide gel. Topical use of chlorhexidine can be as effective as antimicrobials in resolving skin lesions in dogs with pyoderma, including infectious caused by MRSP,[115,116,138] and this is a recommended first-line approach for superficial folliculitis.[117] Other compounds such as accelerated hydrogen peroxide have also been proposed as topical therapies, but there is currently little information about their use. Silver-coated dressings may be useful for treatment of skin and wound infections. Essential oils are gaining popularity as topical therapies, although clinical efficacy data are limited. Various essential oils, including tea tree oil, geranium oil, lavender oil, and grapefruit seed extract, have been shown to possess antibacterial properties, including activity against MRSA and MRSP.[137,139,140] They may have an added effect whereby the vapor generated by their oils within bandage materials can penetrate more deeply into infected sites than the liquid form.[139,141] However, an overlooked aspect is the potential for tissue damage, because essential oils can have cytotoxic effects on mammalian cells.[142] Concerns about cytotoxicity have led to a recommendation that tea tree oil not be used in the treatment of burns.[141] Ingestion of a small volume of tea tree oil has caused neurologic disease in children,[143,144] and the risk to pets from licking topically applied oil or ingestion of treated bandage material is unclear. Further study of efficacy and safety are required.

Topical application of honey is another appealing alternative to antibiotic treatment that is safe. Honey has bactericidal effects against various bacteria, including staphylococci, *in vitro* and *in vivo*.[145–148] There are differences in bactericidal activity among different types of honey, and the best investigated honey has been Manuka honey, produced from the blossoms of *Leptospermum scoparium* (Manuka). Basic use of honey in dogs and cats simply involves direct application of food-grade honey to an infected site, covered by a bandage. A preferred method of application involves the use of dressings impregnated with Manuka honey because of the enhanced and more predictable bactericidal activity of this type of honey and pre-sterilization of the honey and dressing. There are theoretical concerns about bacterial contamination of honey, particularly with *Clostridium botulinum*. Although *C. botulinum* can be found in honey, honey-associated botulism in humans is almost invariably from ingestion of contaminated honey by infants. Tissue infection would require clostridial spores in honey reaching a deep, anaerobic site, something that is unlikely, and the authors are unaware of any infections linked to topical application of honey.

Other Considerations

Both *S. aureus* and *S. pseudintermedius* are important causes of surgical implant–associated infections.[5,149–152] These infections can be very difficult to treat because of the implant and its associated biofilm.[95,103,153] Antimicrobial therapy can often result in amelioration of clinical signs or initially apparent clinical cure; however, relapse is very common after cessation of antimicrobials. Elimination of infection can be difficult to impossible with implants in place, and removal of implants should be considered as soon as possible.

PREVENTION

Prevention of staphylococcal infections largely involves prevention or control of underlying risk factors (e.g., management of allergic skin disease), since staphylococcal infections are virtually always secondary, opportunistic infections. Measures to reduce SSIs and other hospital-associated infections are discussed further below and in Chapters 15 and 76.

Perioperative Prophylaxis

Staphylococci are leading causes of SSIs and perioperative antimicrobial prophylaxis, when indicated, should include excellent staphylococcal coverage. Most often, the first-generation cephalosporin cephazolin is used. Other options include clindamycin or ampicillin; however, the commonness of beta-lactamase–producing staphylococci may preclude use of ampicillin in many regions. When broad gram-negative coverage is needed, a second-generation (e.g., cefoxitin) or third-generation (e.g., cefotaxime) cephalosporin can be used, or

a drug with better efficacy against gram-negative bacteria (e.g., aminoglycoside, fluoroquinolone) can be added. Routine use of third-generation cephalosporins and fluoroquinolones should be minimized because of the importance of those drug classes in human medicine. While MRS, particularly MRSP, are important causes of SSIs, routine prophylaxis targeting MRS is discouraged because of the limited treatment options and concerns that routinely using the few drugs available for therapy (e.g., amikacin) will increase the risk of resistance and even further treatment challenges. There may be limited situations where targeting MRS is indicated, such as when the patient has a concurrent or recent MRS infection, since MRSP colonization has been identified as predisposing to MRSP SSI.[77] More information on perioperative and postoperative prophylaxis for SSIs can be found in Chapter 76.

PUBLIC HEALTH ASPECTS

Staphylococcus aureus

Public health concerns regarding pets and *S. aureus* have almost exclusively involved MRSA, even though pet-to-human methicillin-susceptible *S. aureus* infections probably occur. Colonization of humans in contact with infected or colonized dogs and cats has been widely reported,[48,57,90,154–158] although the direction of transmission is usually unclear and it is likely that most pet-human pairs with MRSA reflect human-to-pet transmission since *S. aureus* seems to be more adapted to colonization of humans than colonization of dogs and cats. MRSA isolates from pets tend to reflect strains that predominate in people in any given geographic region, likely a testament to the human origin of MRSA in pets. Pets have been implicated as sources of infection for humans in households[15,159]; however, this has been based on circumstantial evidence. MRSA should be considered a potentially zoonotic pathogen and infection control measures should be instituted, as is discussed below. However, it should be realized that the incidence of pets being a source of human disease is probably low, and most instances of MRSA infection or colonization in pets are probably a result of the pet acquiring MRSA from a human source.

Notwithstanding the predominant association of MRSA with humans, there may be occupational health risks for veterinary personnel. Numerous studies of MRSA colonization in veterinary personnel have been performed, generally reporting colonization rates of up to 18% in small animal veterinary personnel.[160–166] It cannot be determined with certainty that these colonization rates reflect acquisition of MRSA from animals; however, identification of higher rates than present in the general population and similarity between human and animal strains support the possibility of occupational origin.

Infection Control Precautions in Veterinary Clinics

MRSA and MRSP pose challenges in veterinary clinics as they can be associated with clusters of infections in animals, as well as potential transmission to veterinary personnel. Infection control efforts need to be directed both at controlling the endemic level of disease and preventing outbreaks. The risks posed by MRSA and MRSP are poorly defined, as is the efficacy of different control measures. The response to MRSA and MRSP can vary among facilities based on the facility design, risk status of the patient population for MRSA/MRSP colonization, risk status of the patient population from MRSA/MRSP acquisition, risk adversity, and other aspects. While there is no standard approach, some basic concepts can be applied to all facilities and both MRSA and MRSP. These include the use of good general hygiene practices (especially handwashing), use of enhanced barriers (e.g., gown or dedicated protective outerwear, gloves) with animals that are known to be infected or colonized, routine and enhanced cleaning and disinfection, and the use of a variety of other standard infection control practices such as surgical asepsis (see Chapter 15).

When MRSA or MRSP infections are identified, a plan should be in place regarding how to handle that animal in the clinic and during subsequent examinations. All infected or colonized animals should be considered carriers until proven otherwise, and handled with contact precautions (gloves, dedicated protective outerwear). In clinics, they should be housed in isolation (or mini-isolation, with posted precautions and limited handlers) whenever possible and have no direct or indirect contact with other patients. Although there is little risk of aerosol transmission, housing infected animals in isolation decreases the likelihood of transmission via personnel or fomites. Infected or colonized outpatients should be admitted directly to an isolation area or examination room, rather than allowing them to remain in a waiting area. The practicality and impact of these approaches will vary between facilities. For example, in a dermatology practice, a large percentage of patients may be MRSP or MRSA carriers. Use of these measures on such a large number of animals may be impossible and the implications of MRSP/MRSA exposure of patients may not be as great as in a facility with a large elective orthopedic surgery caseload, where MRSP SSIs can be highly problematic. However, the higher likely MRSA and MRSP burdens in the patient population could pose increased risk to clinic personnel. Therefore, concurrent increases in hygiene and personal protective equipment use (e.g., handwashing and proper use of dedicated outerwear and gloves) may be more important than attempting to isolate potential animals infected and colonized with MRSA or MRSP. In contrast, in facilities with a greater population of patients with greater risk or implications of MRSA or MRSP infections (e.g., orthopedic surgery, immunosuppressed or critically ill patients), there may be more indication for isolation of known or high-risk patients infected or colonized with MRS.

MRSA in Clinic Personnel

MRSA exposure, colonization, or infection of veterinary hospital personnel can be a difficult area to address because of the general lack of understanding of the issues and the high-profile nature of MRSA. Concerns are often present when people realize that they have had contact with an MRSA-infected or -colonized animal, and the potential for occupational exposure is certainly present based on the high rates of MRSA colonization in veterinary personnel. Sometimes, people express a desire to have themselves or their staff tested for MRSA colonization. However, this is rarely indicated and is associated with many potential problems. Given the reported colonization rates of veterinarians and the presumably frequent exposure to colonized animals, routine infection control practices should be established to reduce the risk of MRSA transmission from unknown carriers (staff or pets). Testing of staff for MRSA colonization is not recommended. MRSA rates are high in veterinary personnel and it would not be surprising to find positive individuals in the absence of known MRSA transmission. Exclusion of colonized personnel from work is not reasonable considering the high MRSA colonization rates that have been identified and ongoing risk of exposure. Treatment directed at MRSA decolonization of involved humans is unlikely to be recommended by physicians, because it is uncommonly used in people in the general population in most regions. Furthermore, even with successful decolonization, there would be a continued risk of occupational exposure.

Veterinary personnel who become aware that they are colonized with MRSA should be especially diligent in following all hand hygiene protocols in the clinic and avoidance of hand-to-nose contact (because the nares are the most common site of colonization in humans, and hands are the prime source of transmission). There is no indication to remove a colonized individual from patient care duties, although restriction of contact with very high-risk patients (e.g., some surgical patients) could be considered. However, because the vast majority of veterinary personnel are not aware of their MRSA status, clinic

personnel should assume that both they and their patients could be colonized. Employees who are concerned about MRSA colonization (e.g., those who have been working with an MRSA-positive animal) should be encouraged to see their physicians. Veterinary personnel should also be aware of their likely increased risk of MRSA infection and ensure that their physician knows that they may be at higher risk than the general population, something that might be important to consider when empirically treating infections or deciding whether preoperative MRSA screening is indicated.

Infection Control in Households

The principles of MRSA control for households are the same as those for veterinary clinics. Infected sites on pets should be covered with an impermeable barrier whenever possible. A key point is recognition of additional high-risk body sites (nose, mouth, and perineum) and avoidance of direct and indirect contact with those sites. Owners should be counselled on good household infection control practices, particularly regular hand hygiene. Infected or colonized pets should be prevented from having contact with pets outside the household until they are no longer infected or colonized. Although MRSA can be transmitted in households, the incidence is unclear, as are risk factors. Owners who have concerns, particularly if the concerns relate to the presence of high-risk people in the household (very young or very old, immunocompromised individuals), should be encouraged to seek advice from their physicians. Routine testing of clinically healthy pets whose owners have MRSA infection or of clinically healthy owners whose pets have MRSA is not indicated.

Pet Owners Diagnosed with MRSA Infection

Infected or colonized owners can be a source of infection for their pets, although the incidence of transmission from infected owners to pets is unknown. Owners diagnosed with MRSA infection should be told to wash their hands thoroughly before and after handling their pet, in order to prevent transmission of MRSA to the pet, and transmission from the pet should it subsequently become colonized. Owners should not kiss their pets or allow their pets to lick their faces or any broken skin. Screening of pets for MRSA carriage is rarely indicated, and should only be done if there is a clear plan to act on the results. Testing animals in the absence of testing all human contacts is illogical, and testing of animals can result in much confusion and the potential for poor decision-making if is it not conducted as part of a comprehensive household investigation with a plan of action in place to deal with the results. Pet screening may rarely be indicated as part of a whole-household intervention, which includes simultaneous screening and MRSA decolonization of all people.

Staphylococcus pseudintermedius

While *S. pseudintermedius* can cause infection in humans, the incidence of this appears to be very low. When one considers the high prevalence of *S. pseudintermedius* carriage by healthy dogs and the millions of dog-human contacts that occur on a daily basis, it is apparent that the risk posed by this bacterium is limited.

Colonization of humans with *S. pseudintermedius* occurs more often than overt clinical infection but is still uncommon, with reported rates of 1% to 4% in veterinary personnel and pet owners.[66,167,168] Presumably, this low rate of *S. pseudintermedius* carriage reflects pet-human transmission, as indistinguishable pet and human isolates are common in households where concurrent carriage is identified.[168] Like methicillin-susceptible strains, MRSP can be found in a small percentage of pet owners and veterinary personnel[66,167,169] and MRSP infections have been reported in humans.[170–172] The risk posed by MRSP should be considered low; however, given the highly drug-resistant nature (and associated treatment difficulty), care should be taken to use good infection control practices around infected animals in households and veterinary clinics. Good hygiene in households and veterinary clinics should greatly minimize the risk of MRSP transmission from colonized animals.

Other Staphylococci

Public health concerns regarding other staphylococci are currently limited. Since CoNS (including methicillin-resistant CoNS) are common in both animals and humans and tend to be of limited pathogenicity, they are not considered a relevant public health concern. Although many of the same CoNS species can cause disease in both humans and pets, it is unclear whether animals are a potential source of infection. Most human infections occur in hospitalized individuals, and there is currently no evidence suggesting that isolation or other enhanced infection control practices are required for pets with CoNS infections. Good general hygiene practices should be more than adequate in most, if not all, situations. This is probably most important as an act of prudence for infected pets that will potentially have contact with high-risk (very young, elderly, immunocompromised) individuals.

SCREENING FOR METHICILLIN-RESISTANT STAPHYLOCOCCI AND DECOLONIZATION

Carriage of MRSA or MRSP at colonization sites such as the nose, pharynx, GI tract, or skin may be found in a small percentage of healthy animals. Carriage is very common in animals with clinical MRS infections and may persist for some time after resolution of infection. MRSA carriage tends to be transient and self-limiting, but prolonged carriage of MRSP can occur in some dogs.[10] Because of the potential for transmission of these important staphylococci to other individuals and the role of these organisms in disease, measures to detect and eliminate screening would be desirable. In humans, MRSA screening is a key component of MRSA control in hospitals, but not the general population. Active decolonization, often using topical antimicrobials such as mupirocin or fusidic acid, sometimes with concurrent oral antimicrobial therapy, is used as a means of MRSA control in some situations in some regions, such as in individuals undergoing certain surgical procedures.[68,173] Even though long-term MRSA colonization can occur, the need for decolonization therapy in otherwise healthy individuals in the community is controversial and not universally performed because of variable efficacy,[174] questionable need, and concerns about development of further antibacterial resistance. Decolonization is most commonly used in specific populations, such as healthcare workers, patients undergoing surgical procedures, patients in intensive care units, or individuals in households with recurrent MRSA infections, and even in those situations, it is not universally applied and is not always effective when it is performed.

While active elimination of MRSP or MRSA colonization in dogs and cats could be desirable to reduce the risk of development of clinical infection or transmission to other individuals, there is no evidence that therapy to eliminate colonization is indicated or even potentially efficacious in dogs and cats. Adequate topical application of an antimicrobial to the entire nasal passages and pharynx of a dog or cat is not realistic, and incomplete treatment could lead to further antibacterial resistance. Because MRSA colonization appears to be transient in most if not all dogs and cats, and the use of good general hygiene measures to reduce reinfection almost invariably results in spontaneous decolonization, it is questionable whether active decolonization is even indicated. An active approach to MRSP decolonization would be more appealing because of the potential for long-term shedding in dogs. However, effective decolonization regimens have not been described.

CASE EXAMPLE

Signalment
"Meg," an 8-year-old FS Labrador retriever in southern Ontario, Canada.

History
This overweight but otherwise healthy dog was examined because of acute onset of left pelvic limb lameness. After being let out at night, Meg was heard barking and ran away, and was thought to be chasing a raccoon. Upon returning, she was non-weight bearing on the left pelvic limb. The next morning, the lameness was improved although still present. The dog would bear limited weight on the leg.

Upon initial examination, Meg was bright, alert, and responsive. She was overweight, with a BCS of 7/9. Grade 4/6 left pelvic limb lameness was present. Otherwise, physical examination was unremarkable. She resented manipulation of the left pelvic limb. A mild pain response was noted on palpation of the stifle. Moderate stifle effusion was noted. A positive cranial drawer sign and tibial thrust were noted. Radiographs of the stifle revealed moderate increase in soft tissue opacity within the joint, most consistent with joint effusion, and mild to moderate degenerative joint disease. Cranial cruciate ligament rupture was diagnosed and the dog underwent a TPLO procedure the following day. Cephazolin was administered approximately 30 minutes prior to incision, with one intraoperative dose 120 minutes after the initial dose and two postoperative doses (22 mg/kg, IV, q12h). A CBC, serum biochemistry profile, and urinalysis were performed for preoperative health screening, and no abnormalities were present. Surgery was without complication, and postoperative radiographs indicated appropriate tibial plateau leveling and appropriate positioning of the implant. The dog experienced a normal postoperative recovery and was treated with cephalexin (22 mg/kg, PO, q12h) for 48 hours after surgery. However, 14 days after surgery, the dog developed worsened lameness, with reluctance to bear weight on the surgically corrected limb.

Physical Examination Findings
On examination, Meg was bright, alert, and responsive. She would stand on the affected limb but exhibited grade 3-4/6 lameness. The surgical site was red and inflamed. It was noticeably warm on palpation and a mild amount of pus was extruded when the incision site was manipulated. The joint appeared stable.

Laboratory Findings
None were performed initially upon re-presentation.

Imaging Findings
Radiographic findings were consistent with those normally identified 2 weeks after a TPLO procedure.

Cytologic Findings
Using aseptic technique, an aspirate was collected from the soft tissue overlying the surgical implant site. Marked suppurative inflammation was noted, with abundant cocci within neutrophils.

Microbiologic Testing
Culture of the aspirate ultimately yielded MRSP. Beyond beta-lactams, the isolate was resistant to doxycycline, clindamycin, enrofloxacin, marbofloxacin, and trimethoprim sulfa. It was susceptible to amikacin and chloramphenicol. Minocycline MIC testing was requested, and the MIC was 0.125 μg/mL (susceptible).

Diagnosis
Results were consistent with a deep SSI caused by MRSP.

Treatment
The dog was anesthetized, and skin sutures were removed. Upon removal of the skin suture, it was apparent that there was substantial infection of the subcutaneous tissues (Fig. 51.3). In addition, the deep fascia overlying the implant had dehisced. The infected site was thoroughly lavaged and treatment with minocycline (5 mg/kg, PO, q12h) was started. Clinical signs improved over the next 3 days and the amount of discharge rapidly decreased. Antimicrobials were stopped after 28 days, at which point the dog was clinically normal with evidence of appropriate wound healing. However, 21 days after cessation of antimicrobials, mild (grade 1-2/6) lameness was noted. Mild stifle effusion was identified upon palpation. The surgical site looked unremarkable grossly. An aspirate from over the plate was collected and moderate suppurative inflammation was evident cytologically. Culture of the specimen yielded an MRSP isolate with an indistinguishable susceptibility pattern from that isolated previously. Radiographs were taken and complete healing of the osteotomy was evident. After discussion with the client, it was decided to remove the implant as it was suspected to be colonized with biofilm-embedded MRSP, with a poor prognosis for elimination of the infection with the implant left *in situ*. Amikacin (20 mg/kg IV) was administered preoperatively and implant removal was unremarkable. Amikacin was continued for 3 days (20 mg/kg, SQ, q24h) postoperatively. No subsequent problems were encountered with the limb.

Comments
MRSP is a leading cause of TPLO SSI, and TPLO infection rates can be high. MRSP isolates are often strong biofilm producers, and elimination of implant-associated infections can be difficult because of the ability of MRSP to elude the effects of antimicrobials and the immune system while embedded within biofilm on a surgical implant. While some infections are treatable with systemic antimicrobials, sometimes with adjunctive approaches such as antimicrobial-impregnated beads or gels, long-term cure is often not achieved. Removal of the implant is typically required for full resolution of the infection. In implant-associated infections, antimicrobials are sometimes required systemically until the time that bone healing permits implant removal. In this case, infection of the bone seemed to be limited and there was little apparent impact on bone healing. It is debatable whether antimicrobials are required after implant removal, but a short course (as was used here) is often administered.

Miscellaneous Gram-Positive Bacterial Infections

Joshua B. Daniels, Jane E. Sykes

KEY POINTS

- Cause: Uncommon to rare gram-positive bacterial infections in dogs and cats include those caused by *Rhodococcus equi* (synonym *Rhodococcus hoagii*), *Corynebacterium* spp., *Listeria monocytogenes*, *Erysipelothrix* spp., and *Bacillus anthracis.*
- First Described: *Rhodococcus equi*: 1923, Sweden, in horses (Magnusson)[1]; *Corynebacterium urealyticum*: 1947, Spain, in humans (Cifuentes and Soriano)[2]; *L. monocytogenes*: 1927, England, in laboratory rabbits and guinea pigs (Murray)[3]; *Erysipelothrix* spp.: 1876, in mice (Koch)[4]; *B. anthracis*: 1850s, France, in sheep and cattle (Rayer, Devaine, Pollender).[5]
- Affected Hosts: *Rhodococcus equi* (horses, pigs, cattle, dogs, cats, humans), *C. urealyticum* (dogs, cats, humans), *L. monocytogenes* (many domestic mammals, poultry, humans), *Erysipelothrix* spp. (especially pigs, turkeys, and laying hens; but also other mammals including humans, dogs and cats; birds, fish and reptiles), and *B. anthracis* (primarily herbivorous mammals such as cattle, sheep and goats; but also humans and rarely dogs and possibly cats).
- Geographic Distribution: Worldwide; anthrax is most prevalent in Africa, the Middle East, and Latin America.
- Route of Transmission: Inhalation, inoculation, or ingestion (*R. equi*); invasion of normal microflora (*Corynebacterium* spp.); ingestion (*L. monocytogenes*); inoculation and possibly ingestion (*Erysipelothrix* spp.). Anthrax can be acquired through ingestion, inoculation, or inhalation; most cases in dogs result from ingestion, whereas humans are most commonly infected through cutaneous inoculation.
- Major Clinical Signs: *Rhodococcus equi*: cutaneous abscesses (cats), signs that depend on systemic organ involvement; *Corynebacterium* spp.: lower urinary tract signs (*C. urealyticum*), respiratory signs (*Corynebacterium ulcerans*), otitis externa (*Corynebacterium auriscanis*); *L. monocytogenes*: febrile gastroenteritis, neurologic signs, abortion, cholecystitis, abdominal lymphadenitis (*L. monocytogenes*); *Erysipelothrix*: fever, lameness, cardiac murmurs, spinal pain, erythematous cutaneous lesions (erysipelas); *B. anthracis*: fever, inappetence, edema of tissues surrounding the upper GI tract.
- Differential Diagnoses: Other gram-positive and gram-negative bacterial infections.
- Human Health Significance: All of these organisms are capable of causing disease in humans, and many infections in humans result from exposure to animals or animal products. Humans are not usually exposed as a result of contact with dogs and cats, but care should be taken when handling infected companion animals to avoid exposure through needle-stick injuries or ingestion (i.e., hand hygiene after handling infected animals). Isolation is not required. Companion animals exposed to *B. anthracis* should be decontaminated by thorough bathing.

RHODOCOCCUS EQUI (SYNONYM *RHODOCOCCUS HOAGII*) INFECTION

Rhodococcus equi is a pleomorphic, facultatively intracellular, gram-positive bacillus that has been primarily associated with pyogranulomatous pneumonia in foals, suppurative lymphadenitis in pigs, and granulomatous lymphadenitis in cattle. Although a revised name, *Rhodococcus hoagii,* has been proposed for this organism, this name has been disputed in the taxonomic literature, so the name *Rhodococcus equi* will continue to be used from this point forward.[6] It belongs to the Nocardiaceae family which also includes *Nocardia, Mycobacterium*, *Corynebacterium*, and *Gordonia.* Infection is acquired by inhalation from soil, inoculation into wounds or mucous membranes, or ingestion. Reports of infections in dogs and cats are rare, and are usually associated with immunosuppression such as that caused by chronic glucocorticoid administration[7] or retrovirus infection. *Rhodococcus equi* has rarely been cultured from the mucosal surfaces and skin of healthy dogs, as well as from dogs with myositis, hepatitis, osteomyelitis, dermatitis, endocarditis, pulmonary abscessation and pyothorax, endophthalmitis, and lymphadenitis.[7–9] *Rhodococcus equi* pneumonia was described in a dog from Brazil that was co-infected with *Toxoplasma gondii* and CDV.[9] Infection with CDV was thought to have led to immunocompromise and opportunistic infections with *T. gondii* and *R. equi.*

Rhodococcus equi is commonly recovered from soil that is enriched with herbivore manure and directly from feces of herbivores. The organism may enter the body through a contaminated penetrating wound and subsequently spread via lymphatics to regional lymph nodes and hematogenously to the liver, spleen, and visceral lymph nodes. Affected foals are typically infected through inhalation of dust. The organism then invades macrophages and inhibits phagolysosomal fusion by means of a complex cell wall, which results in pyogranulomatous to granulomatous inflammation. Dissemination occurs as a result of underlying immunosuppression. The virulence of *R. equi* has been related to plasmids that encode a virulence-associated protein (Vap), which allows it to persist in macrophages. Pathogenic strains of *R. equi* have been described as virulent or intermediately virulent based on carriage of host-adapted circular VAP plasmid types. The VAPA and VAPB plasmids have been associated with equine and porcine strains, respectively. The VAPA plasmid was detected in a cat with cutaneous rhodococcosis; the cat had a history of contact with horses.[10] A linear plasmid type, pVAPN, been associated with bovine and caprine strains. This plasmid type has been detected in *R. equi* isolates from two dogs,[7,9] as well as in immunocompromised humans.[11] A conserved conjugal transfer protein gene, *traA*, is present in all strains that carry plasmids. Strains that lack *VapA* or *VapB* genes (and are *traA*–) are considered avirulent, but have been associated with disease in immunocompromised animals.[7]

Most cats have abscesses or pyogranulomatous cellulitis that involve an extremity,[12–14] although a 2020 case series of 40 cats from Malaysia described pulmonary disease in 36 cats; 4 cats had only cutaneous lesions. Most of the cats in this study (25/40) were under 10 months of age.[15] Localized swelling with ulcerations or fistulas and purulent drainage have been found. Unlike typical bite wound abscesses, the lesions are generally not painful, and systemic signs of fever and anorexia are usually absent. Pyothorax and mediastinal lymphadenitis may be associated with anorexia, weight loss, and dyspnea.

Clinical findings in dogs and cats vary considerably depending on sites of dissemination, and have included abdominal distention with a palpable fluid wave, hepatomegaly, and mesenteric lymphadenomegaly; corneal ulceration; endophthalmitis; abscesses; cutaneous ulceration; cough, tachypnea and dyspnea (Fig. 52.1).[7] In one infected dog, generalized hyperesthesia was present.[8] Dissemination to many organs was associated with necrotizing pyogranulomatous hepatitis, osteomyelitis, and polymyositis.

Hematologic abnormalities may consist of leukocytosis with a left shift, monocytosis, and thrombocytopenia.[15] Hypoalbuminemia (22%) and hyperproteinemia (64%) were frequent findings in cats with rhodococcosis from Malaysia.[15] Radiographs have revealed soft tissue swelling; osteolytic and osteoproliferative changes in bones; thoracic lymphadenopathy; hepatomegaly; lung masses with pleural pneumothorax; effusion; and pulmonary interstitial or alveolar-interstitial patterns.[7,15]

Gram staining of aspirates or smear preparations of purulent discharge may reveal large, pleomorphic, gram-positive bacilli, which may be found inside macrophages. Thoracic or abdominal effusions are typically exudates with high protein (more than 3.5 g/dL) and nucleated cell counts (above 10,000 cells/μL); the majority of cells are lymphocytes or nondegenerate neutrophils. Organisms may not be apparent. Gross pathologic findings include peripheral abscesses, often with sinus tracts and purulent drainage; and enlarged and necrotic lymph nodes with a similar discharge on sectioning. Histologic examination reveals pyogranulomatous or granulomatous lesions with necrotic foci.[7] Macrophages contain phagocytized gram-positive bacteria. The organisms also stain positive with Fite's acid-fast stain. Pyogranulomatous to granulomatous lesions containing bacteria may be observed in a variety of parenchymal organs such as the liver, lung, and heart valves in animals with disseminated disease.

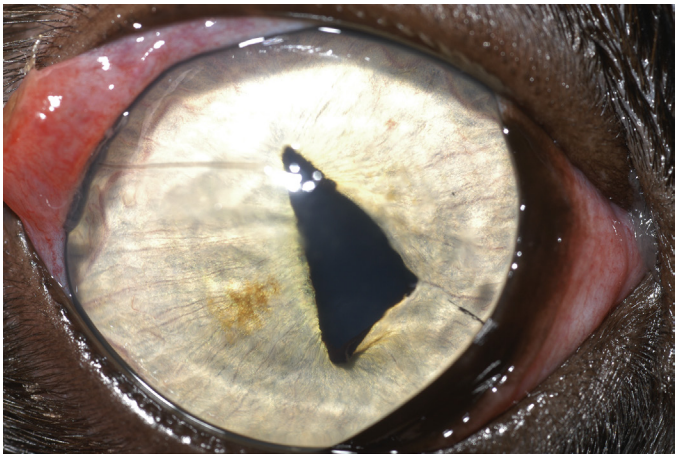

Fig. 52.1 Right eye of a 5-year-old female spayed domestic shorthair with dyscoria secondary to a retrobulbar abscess associated with *Rhodococcus equi* infection. The cat tested negative for feline leukemia virus and feline immunodeficiency virus. (Image courtesy University of California Davis Veterinary Ophthalmology Service.)

In the laboratory, *R. equi* grows readily in an aerobic environment and has distinctive colonial characteristics, but laboratories not familiar with equine isolates may fail to identify it correctly. The use of MALDI-TOF MS is likely to improve identification. Clinicians should communicate any suspicion for *R. equi* infection to the laboratory to ensure that proper microbiologic techniques are used to enhance colony growth. Culture of macerated tissue specimens appears to be more sensitive than culture of swabs of exudates or infected tissues.[14]

Surgical removal of extremity lesions is only temporarily effective, and new lesions commonly develop even after limb amputation. Surgical drainage of abscesses is an essential adjunctive procedure. Antimicrobial susceptibility testing should always be performed because resistant strains have been identified. In general, *in vitro* susceptibility is greatest to erythromycin, fluoroquinolones, rifampin, aminoglycosides, glycopeptides, and carbapenems.[16] In cats, treatment with lincomycin and gentamicin has been effective, and results with erythromycin have varied. Cats with disseminated lesions also respond poorly. Treatment with amoxicillin-clavulanate has been effective in reducing the size of lesions when used for a minimum of 14 to 16 days[13] but is a poor choice of antibacterials because of poor penetration of macrophages and common resistance to beta-lactams. In humans with pneumonia, only long-term treatment with erythromycin, combined with either rifampin or vancomycin, has been effective.[17] Monotherapy is not recommended.[18] As with treatment of other persistently intracellular organisms, combination treatment of lipophilic drugs that penetrate cells well is superior. The standard, highly effective treatment in foals is prolonged oral administration of erythromycin and rifampin. This combination can be recommended for cats, although greater toxicity may occur. However, the combination of clarithromycin-rifampin was superior to erythromycin-rifampin or azithromycin-rifampin in clinical improvement and radiographic resolution of pneumonia in infected foals.[19] Cats have been successfully treated with rifampin in combination with either clarithromycin, azithromycin, or a fluoroquinolone.[15,20] In humans, two- or three-drug combinations are recommended that include a macrolide, rifampin, carbapenem, fluoroquinolones, and/or an aminoglycoside.[18] Several months of treatment may be required, and in some cases, long-term treatment may be required to prevent relapse (Table 52.1).

Infections with *R. equi* are recognized in immunocompromised humans, including those infected with HIV (80% of cases), diabetics, organ transplant recipients, hemic neoplasia, lung cancer, and those with alcoholism. Infections in humans with HIV infection appear to be declining in incidence as a result of highly active antiretroviral therapy.[18] Pulmonary lobar infiltration with cavitation, similar to that observed with tuberculosis, has been the most frequently observed syndrome in human patients with AIDS[18]; *R. equi* was the most common microbiologically confirmed cause of pulmonary cavitation in HIV-infected humans in one study, accounting for 9% of cases.[17,18,21] Extrapulmonary lesions occur in about 20% of people with pulmonary infection. Infected cats or dogs have not been considered a major source of infection for people, who usually acquire the infection from environmental exposure. Nevertheless, infected pets with draining lesions could pose a minor theoretical risk to immunocompromised owners.

CORYNEBACTERIUM INFECTIONS

Corynebacteria are club-shaped, aerobic, gram-positive rods that are widely distributed in soil and water, and may contaminate the hospital environment. Numerous seemingly nonpathogenic corynebacteria have been isolated as microflora of dogs and cats. Some have been reported as causing otic infections or UTIs.[22,23] Many veterinary

TABLE 52.1 Antimicrobials Used To Treat Miscellaneous Gram-Positive Bacterial Infections

Drug	Indication	Species	Dose (mg/kg)	Route	Interval (Hours)
Penicillin G	A, L, E	D, C	20–40 × 10^3 U/kg	IV	8
Ampicillin sodium	A, L[a], E	D, C	20	IV	6
Amoxicillin	A, L[a], E	D, C	20	PO	8–12
Erythromycin	R[b]	D, C	10–20	PO	8
Clarithromycin	R[b]	D, C	7.5–12.5	PO	12
Rifampin[c]	R	D, C	15	PO	8
Doxycycline	CU, A[d]	D, C	5	PO	12
Gentamicin sulfate	L[e]	D	14 5–8	SC, IM, IV	24
Trimethoprim-sulfamethoxazole	L[e]	D, C	30[f]	PO, IV	12
Chloramphenicol	CU	D C[g]	40–50 12.5–20	PO, IV, IM	6–8 12
Ciprofloxacin	A	D, C	10	IV	12
Enrofloxacin	A	D	5–20	PO, IV[h], IM	24
Vancomycin	R, CU	D, C	15	IV[h]	8

[a]In combination with gentamicin or trimethoprim-sulfonamide.
[b]In combination with rifampin.
[c]Rifampin should be used only in combination with another drug such as erythromycin or clarithromycin. Adult cats have been treated with a total dose of 75 mg every 24 hours.
[d]For prophylaxis after exposure.
[e]In combination with ampicillin.
[f]Dose listed is for combined components, i.e., 5 mg of trimethoprim and 25 mg of sulfonamide.
[g]Avoid long-term use in cats. Monitor complete blood count with long-term use. Warn owners that human exposure to chloramphenicol may cause bone marrow disease. Avoid in animals with hepatic failure.
[h]Dilute in saline and give slowly over 30 minutes.
A, anthrax; *C*, cats; *CU*, *Corynebacterium urealyticum*; *D*, dogs, *E*, *Erysipelothrix*; *L*, *Listeria*; *R*, *Rhodococcus*.

diagnostic laboratories do not speciate *Corynebacterium* spp. isolated from dogs and only report them at the genus level. As molecular diagnostic instrumentation (e.g., MALDI-TOF) becomes more common in service laboratories, associations between members of *Corynebacterium* spp. and clinical syndromes will become more known to veterinarians.

Corynebacterium urealyticum has been occasionally associated with lower UTIs in dogs and cats with compromised urinary defense mechanisms,[24] including urinary retention secondary to compressive myelopathy, urethral obstruction, catheterization, and urologic surgery.[24–28] Anatomic defects, extensive antimicrobial use for other causes of UTI, immunosuppressive drugs, and foreign bodies have all been implicated as predisposing causes. The infection is uniquely characterized by the concurrent presence of alkaline urine, struvite, and calcium phosphate crystals that may precipitate to form calculi with or without encrusting urocystitis, which may be severe. Urinalysis typically reveals alkaline urine, struvite crystalluria, pyuria, hematuria, and variable bacteriuria.[24] Ultrasound examination of the urinary bladder may reveal thickening of the bladder wall, echogenic debris, and hyperechogenicity of the urinary bladder wall (encrusting cystitis) (Fig. 52.2). Urolithiasis may also be observed.[24] Findings suggestive of encrusting pyelitis have also been described. A cat with a *Corynebacterium jeikeium* UTI has been described with similar lesions.[29] Treatment involves appropriate antimicrobial therapy and thorough mechanical debridement of plaques associated with the bladder wall, which is essential for resolution. Cystoscopic debridement has been described as a minimally invasive treatment in veterinary patients.[30] In addition to these treatments, oral administration of urinary acidifiers has been used to treat human infections and may be beneficial. Many isolates are resistant to multiple antimicrobial drug classes, and so susceptibility testing is essential to guide therapy. In human patients, vancomycin is the treatment of choice. In order to preserve the use of vancomycin for serious human infections, doxycycline has been used in veterinary patients as an alternative. Doxycycline achieves concentrations in canine urine that exceed plasma concentrations and is likely appropriate for multiple uropathogens.[31] Susceptibility to chloramphenicol has been described in many isolates, and this also may represent an effective treatment.[24]

Corynebacterium ulcerans is capable of expressing diptheria toxins and has been associated with an exudative pharyngitis in humans that is indistinguishable from that caused by *Corynebacterium diphtheriae*.[18] Toxigenic strains *of C. ulcerans* have been isolated from clinically healthy dogs, which may serve as a source of infection for other dogs and animals.[32] *Corynebacterium ulcerans* was isolated, along with other bacteria, from transtracheal washings of a dog with suppurative bronchopneumonia.[33] It was also isolated from nasal swabs from two cats with nasal discharge.[34] These isolates were found to contain the bacteriophage that codes for diphtheria toxin and may have been responsible for the clinical illness in these cats. Isolates from cats and dogs are genetically similar to those from humans, and have been incriminated in zoonotic spread of infection to humans.[35–37] In one report, an immunocompromised person developed a diphtheria-like illness, and the organism was isolated from the throat and the tonsils, nose, and labial area of the person's dog that had chronic rhinorrhea.[36] However, consumption of raw milk or its unpasteurized products or close association with horses or cows is thought to be a more common source of infection for humans than exposure to dogs or cats.

Corynebacterium auriscanis has been implicated in polymicrobial otitis externa in the dog, usually as a mixed infection with *Staphylococcus pseudintermedius*.[22] Infection with *C. auriscanis* has

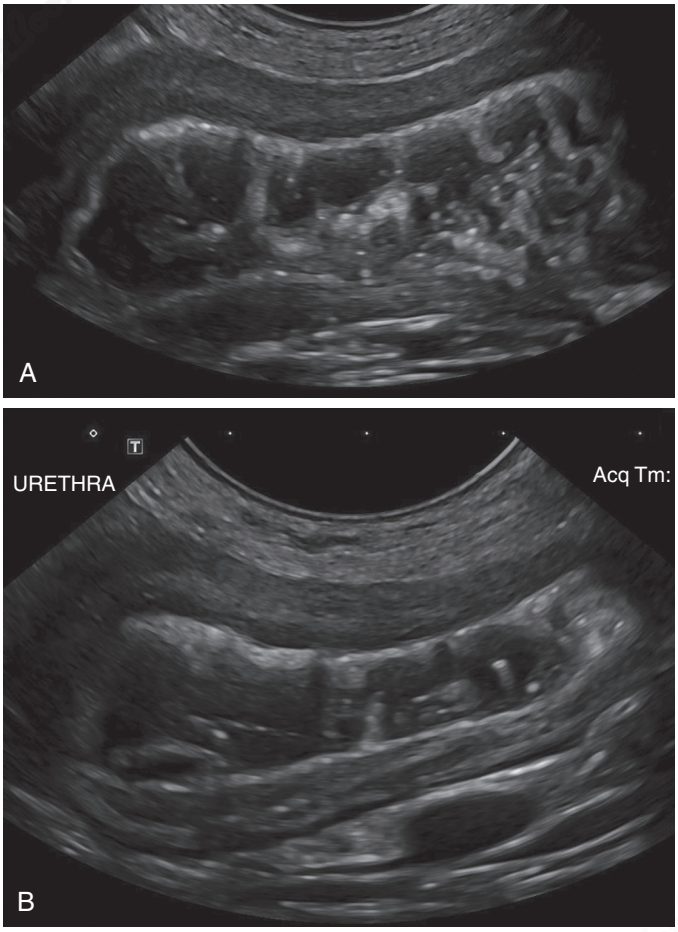

Fig. 52.2 Ultrasound images of the urinary bladder of an 8-year-old French bulldog with encrusted cystitis due to *Corynebacterium urealyticum*. There is a moderate amount of mineralized echogenic debris within the urinary bladder and proximal urethra. (A) The bladder wall is markedly thickened and irregular and has a hyperechoic lining with mild partial acoustic shadowing. (B) Mucosal thickening and the hyperechoic lining is also present in the urethra.

also been associated with superficial pyoderma[38] (usually also polymicrobial) and has been reported in one human dog-bite case.[39] From the limited antimicrobial susceptibility data that have been published about *C. auriscanis*, chloramphenicol, tetracyclines, macrolides, and amikacin are the most effective *in vitro*. However, because these infections are almost always polymicrobial, it is unclear how clinically relevant targeted antimicrobial therapy is for this organism when more virulent components of infections (e.g., coagulase-positive staphylococci, *Pseudomonas aeruginosa*) are adequately addressed by antibiosis.

LISTERIOSIS

Listeria monocytogenes is a pathogenic, partially β-hemolytic, gram-positive, rod-shaped facultative anaerobe that is morphologically indistinguishable from diphtheroids and may be mistaken for a contaminant in tissues, or misidentified as a diphtheroid, streptococcus, or enterococcus. It is motile as a result of possession of one to six polar flagellae. It is capable of growing in a wide range of temperatures, including refrigerator temperatures (4°C to 10°C), which have been used to select for its growth in the presence of contaminants. Although at least 16 serotypes of the organism exist based on H or O antigens, most disease is caused by types 4b, 1/2a, and 1/2b.[40] Isolates from companion animals, when typed, have also been 4b,[41] 1/2a,[42] or 1/2b.[43] As a ubiquitous saprophyte, *L. monocytogenes* can be isolated from soil, water, sewage, dust, and decaying vegetation. Pathogenic strains of *L. monocytogenes* can also be recovered from the stool of healthy animals, including humans. A study of fecal specimens from animals in Japan found a prevalence of 0.9% in dogs, but no bacteria were isolated from cats.[44] Commonly, *L. monocytogenes* can be found in farm animal feed and silage and in food products made from these animals. Recovery rates of 15 to 70% have been reported from raw vegetables, raw milk, cheese, and meats, including processed meats from delicatessen counters. Outbreaks of disease in humans have been associated with poor hygiene practices in the food production industry. Significant outbreaks have been associated with contaminated coleslaw,[45] turkey delicatessen meat (which resulted in the largest recall of meat ever in the United States),[46] chocolate milk,[47,48] and canteloupes.[49] Approximately one third of sporadic cases have been linked to ingestion of soft cheeses or delicatessen meats. Most humans that develop invasive disease are women in their third trimester of pregnancy (which may result in spontaneous abortion, stillbirth, premature labor, and neonatal infections), those over age 60, or those immunosuppressed due to hematologic malignancy, organ transplantation, HIV/AIDS, or glucocorticoid therapy. However, immunocompetent individuals may develop febrile gastroenteritis. A localized cutaneous infection was described in a veterinarian after contact with an aborted calf.[50] *Listeria monocytogenes* has also been isolated from raw pet foods, including those that include beef or chicken.[51] In one study from the Netherlands, 54% of raw food products for pets were contaminated with *L. monocytogenes*.[52] In a study from the United States, 12% of 576 raw pet food products tested positive.[53] In general, the source of infection in companion animals is not identified, but some cats have had a history of being fed raw food diets.[54] Underlying immunosuppressive illnesses identified in dogs have included endocrinopathies (diabetes mellitus and hyperadrenocorticism), hemic neoplasia,[42] and immunosuppressive drug therapy[42,43]; one affected cat tested positive for FeLV.

Natural infection usually results from ingestion of contaminated food; damage to the intestinal mucosal integrity is not necessary. More than 10^9 organisms are needed to infect healthy mammals. Alkalinization of the stomach by antacids may promote infection. Listeriosis in dogs and cats is uncommon; when it occurs, it is usually associated with ingestion of contaminated meat or meat by-products. The incubation period in humans ranges from 11 to 70 days. Reports of bacteremia due to *L. monocytogenes* in dogs and cats after oral ingestion of contaminated food have been rare. After penetration of the intestinal mucosa, *L. monocytogenes* localizes in mononuclear phagocytes. Resultant bacteremia may be associated with formation of septic emboli of many organs. The organism has a particular predilection for the CNS (especially the brainstem [rhombencephalitis] and meninges [meningitis]) and placenta. *Listeria* endocarditis has also been described in humans.

Vaccines have been developed that use attenuated strains of *L. monocytogenes* as a vector for expression of tumor antigens, which concurrently activate cytotoxic T cells. There are rare reports of such vaccines causing listeriosis in vaccinated humans. A conditionally licensed canine osteosarcoma vaccine with a live *Listeria* vector (COV-LLV, Aratana Therapeutics, Inc., KS, USA; at time of writing now owned by Elanco Animal Health) was shown in preliminary studies to significantly improve survival time when used in addition to standard-of-care amputation and chemotherapy.[55] One dog developed a cavitary rib mass following vaccination. The vaccine strain of *L. monocytogenes* was isolated from aspirates of the mass, and histopathology of the mass revealed metastatic osteoblastic osteosarcoma.[56] The dog remained alive over a year after removal of the mass with no further disease progression. A subsequent study described *Listeria* infections in 4 of 49 vaccinated dogs with osteosarcoma, and concerns were raised about the possibility of zoonotic transmission.[57]

Listeria monocytogenes can persist indefinitely in macrophages and escape humoral immune responses. A cell surface protein, internalin, interacts with E-cadherin on epithelial cells and macrophages, inducing phagocytosis (Fig. 52.3). The main virulence factor possessed by

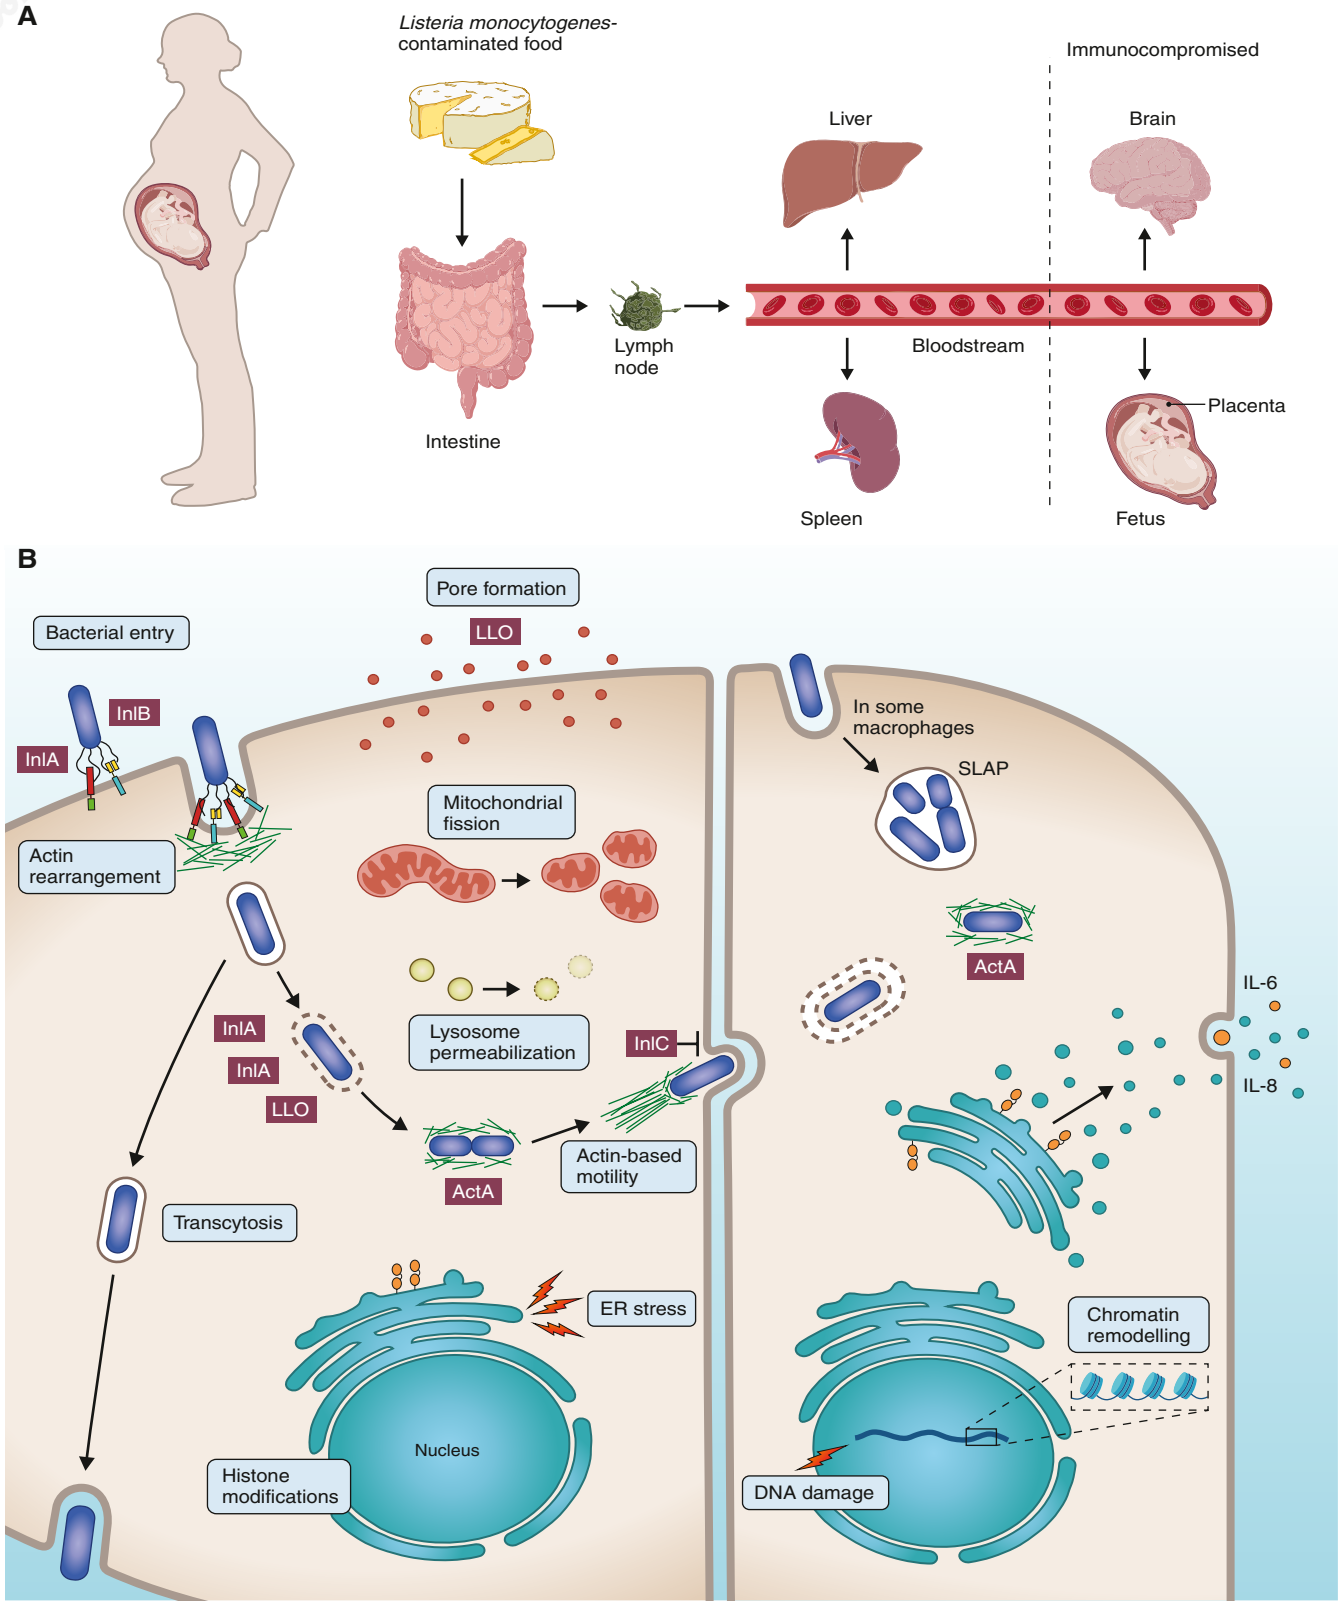

Fig. 52.3 Pathogenesis of *Listeria monocytogenes* infection. (A) After ingestion of contaminated food, *L. monocytogenes* can cross the intestinal barrier and spread into the bloodstream through the lymph nodes to disseminate to target tissues, such as the liver and spleen. In immunocompromised individuals, *L. monocytogenes* can cross the blood-brain barrier or placental barrier and cause meningitis, sepsis, premature birth, or abortion. (B) *Listeria monocytogenes* enters nonphagocytic cells, such as epithelial cells, through receptor-mediated endocytosis, and in most cases, it escapes from the vacuole. In some macrophages, it can replicate in spacious *Listeria*-containing phagosomes (*SLAPs*). Upon vacuolar escape, *L. monocytogenes* can polymerize actin and spread from cell to cell. Listeriolysin O (*LLO*), phospholipase A (PlcA), and PlcB mediate vacuolar escape. LLO also leads to changes in histone modification, mitochondrial fission, endoplasmic reticulum (*ER*) stress, and lysosomal permeabilization. Infection also leads to DNA damage, and the host cell combats infection by upregulating cytokine secretion. *ActA,* actin assembly-inducing protein; *IL,* interleukin; *Inl,* internalin. (Modified from Radoshevich L, Cossart P. *Listeria monocytogenes*: towards a complete picture of its physiology and pathogenesis. *Nature Rev Microbiol.* 2018;16:32–46. With permission.)

L. monocytogenes is listeriolysin O, which is a porin that induces T-cell unresponsiveness. This porin, together with phospholipases, enables the organism to escape phagosomes. In the cytoplasm, the organism pushes pseudopod-like projections outward (known as filopods), which are ingested by adjacent macrophages, enterocytes, or hepatocytes. The bacterial surface protein ActA is responsible for actin polymerization that promotes intercellular spread and evasion of the host immune response.[58]

Clinical signs are caused by the degree of intestinal inflammation and the sites of embolic microabscess formation. Fever, diarrhea, and vomiting have been most frequently reported. Neurologic signs, abortion, subclinical bacteriuria, and bacteremia have been apparent in some cases.[41,42,59] Localized infections can also occur.[42,60] Cholecystitis was described in one dog; *L. monocytogenes* was isolated from bile collected using cholecystocentesis.[43] Listerial myocarditis with congestive heart failure was reported in a 14-week old puppy from southeastern Australia that was evaluated for dyspnea, lethargy, and inappetence.[61] Cytologic evaluation of bone marrow from one dog with bacteremia revealed coccobacilli within macrophages and neutrophils.[62] In cats, peritonitis, pneumonia, hepatic involvement, encephalitis, and cutaneous abscesses have been described.[63–65] Systemic listeriosis in association with pleural mesothelioma was identified in one stray cat in the southern US at necropsy.[66] In a case series of three cats with abdominal lymphadenitis secondary to *L. monocytogenes* infection, two of three affected cats had a history of being fed raw food diets.[54] All of the affected cats were oriental breeds (Siamese, Tonkinese, Burmese), and a genetic predisposition for infection was speculated.

Diagnosis of infection may be made antemortem or at necropsy, because infected animals often succumb to bacteremia. Cytologic examination of affected tissues may reveal pyogranulomatous inflammation; organisms appear as short, intracellular and extracellular gram-positive bacilli to coccobacilli. Microabscess formations and focal necrotic lesions may be grossly or microscopically visible in many organs, especially the liver and spleen.

Listeria monocytogenes can be cultured and identified within 36 hours using routine media. Because the organism can be commonly isolated from the GI tracts of healthy animals, stool cultures may not be meaningful. Strain characterization can then be performed using serotyping, multilocus sequence typing, or whole genome sequencing.[67]

Antimicrobial agents that are active against *Listeria* are penicillin and ampicillin, erythromycin, chloramphenicol, rifampin, tetracycline, trimethoprim-sulfonamide, and aminoglycosides. First-choice treatments in humans with CNS infections are a combination of ampicillin and gentamicin, or ampicillin and a trimethoprim-sulfonamide; the latter combination has been associated with the lowest failure rate and fewer neurologic sequelae.[40] Treatment with cephalosporins or chloramphenicol has been associated with failure and relapse in treated people. Quinolones are ineffective. Treatment of *Listeria* gastroenteritis with antimicrobials is not recommended as the disease is self-limited.

Listeria infection in animals has not always been considered a public health risk because animals and people are exposed to the same source of environmental contamination. Nevertheless, an association has been made between human outbreaks and contact with food-producing animals or their products. Direct transmission from animals has occurred in veterinarians and farm workers through contact of unprotected skin or mucous membranes with infected animal tissues.[64,68] Most outbreaks occur in urban areas, where foodborne contamination is suspected. Infants, older adults, and pregnant women are most commonly affected. Recommendations for practices that prevent foodborne listeriosis have been developed,[40] including avoidance of certain foods (soft cheeses, delicatessen meats, smoked seafood) for people at higher risk. In a case of reverse zoonosis, listerial gastroenteritis was suspected in a litter of puppies and a newborn infant who received *Listeria*-infected milk discarded from the human mother's mammary gland.[69]

ERYSIPELOTHRIX INFECTIONS

Erysipelothrix rhusiopathiae and *Erysipelothrix tonsillarum* are small, gram-positive, nonmotile, nonsporulating pleomorphic facultatively anaerobic rods. These organisms, which are found worldwide, are associated with swine production. *Erysipelothrix rhusiopathiae* is the causative agent of swine erysipelas and other diseases in animals such as joint-ill in sheep and cattle and bacteremia in turkeys, ducks, and laboratory mice. The organism can be cultured from the tonsils of clinically healthy swine, the skin of freshwater and saltwater fish, and the decomposing plant and animal matter in their environments. Occupational exposure to these sources of bacteria may cause localized cutaneous or systemic infections in humans.

Initially, the genus *Erysipelothrix* was thought to have a single species—*rhusiopathiae*—but biochemical and genetic analyses have identified *E. tonsillarum*, a nonpathogenic commensal of the tonsils of swine.[70] In dogs, endocarditis, diskospondylitis, arthritis, and bacteremia were initially thought to be caused by *E. rhusiopathiae* after natural[71] and experimental[72] inoculation. However, all available isolates from these conditions reported in dogs have been now reclassified as serovar 7 of *E. tonsillarum*, which is nonpathogenic for swine.[70,73,74] DNA hybridization studies have confirmed this relationship.[75] There are rare reports of dogs with bacteremia and cutaneous lesions (erysipeloid lesions/erysipelas) associated with confirmed *E. rhusiopathiae* infection (Fig. 52.4).[76] Some affected dogs had been treated with immunosuppressive drug therapy before recognition of infection.[77,78]

Clinical signs of fever, lameness due to septic/embolic arthritis, spinal pain, with or without recent-onset heart murmur are typically present in dogs infected with *E. tonsillarum* (see Chapters 121 and 122). The dogs infected with *E. rhusiopathiae* had fever, lethargy, inappetence, and cutaneous lesions that consisted of alopecia and erythematous macules in one dog; and well-demarcated, diamond-shaped, erythematous and indurated lesions in another; evidence of endocarditis was not evident, although echocardiography was only performed in one dog.[76,77] One of the dogs had GI signs. Laboratory abnormalities include leukocytosis due to a neutrophilia, bandemia, thrombocytopenia, and serum biochemistry findings that reflect bacterial thromboembolic complications. The organism is readily cultured from blood, and PCR assays have been used to identify the organism and differentiate *E. tonsillarum* from *E. rhusiopathiae*.[76,79]

Erysipelothrix isolates have been susceptible to penicillin, ampicillin, cephalosporins, clindamycin, carbapenems, and quinolones *in vitro* but resistant to aminoglycosides, vancomycin, and sulfonamides.[70,80] The treatment of choice for serious infections in humans is penicillin G; ampicillin and ceftriaxone have also been used with success. Many cases of *Erysipelothrix* bacteremia in dogs are associated with endocarditis; therefore, high doses of antimicrobials are recommended for at least 6 to 8 weeks. Relapses are often reported in infected animals and humans. Most human infections are acquired through occupational exposure; infections are found in slaughterhouse workers, food handlers, and animal trappers.[68] Infected dogs do not seem to pose a public health hazard.

ANTHRAX

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Anthrax, a disease found in mammals worldwide, is caused by *Bacillus anthracis*, a large (1 to 1.2 μm × 3–6 μm), gram-positive, aerobic, spore-forming bacillus. The disease and species name is derived from the black, charcoal-appearing cutaneous lesion it causes in humans (Greek *anthrakis*, meaning "coal"). Microscopically, the organisms may appear as long chains of gram-positive, square-ended bacteria, similar to a string of boxcars; shorter chains of two to three cells may be seen (Fig. 52.5). Vegetative *B. anthracis* cells produce a polypeptide capsule visible when the organism is stained with polychrome

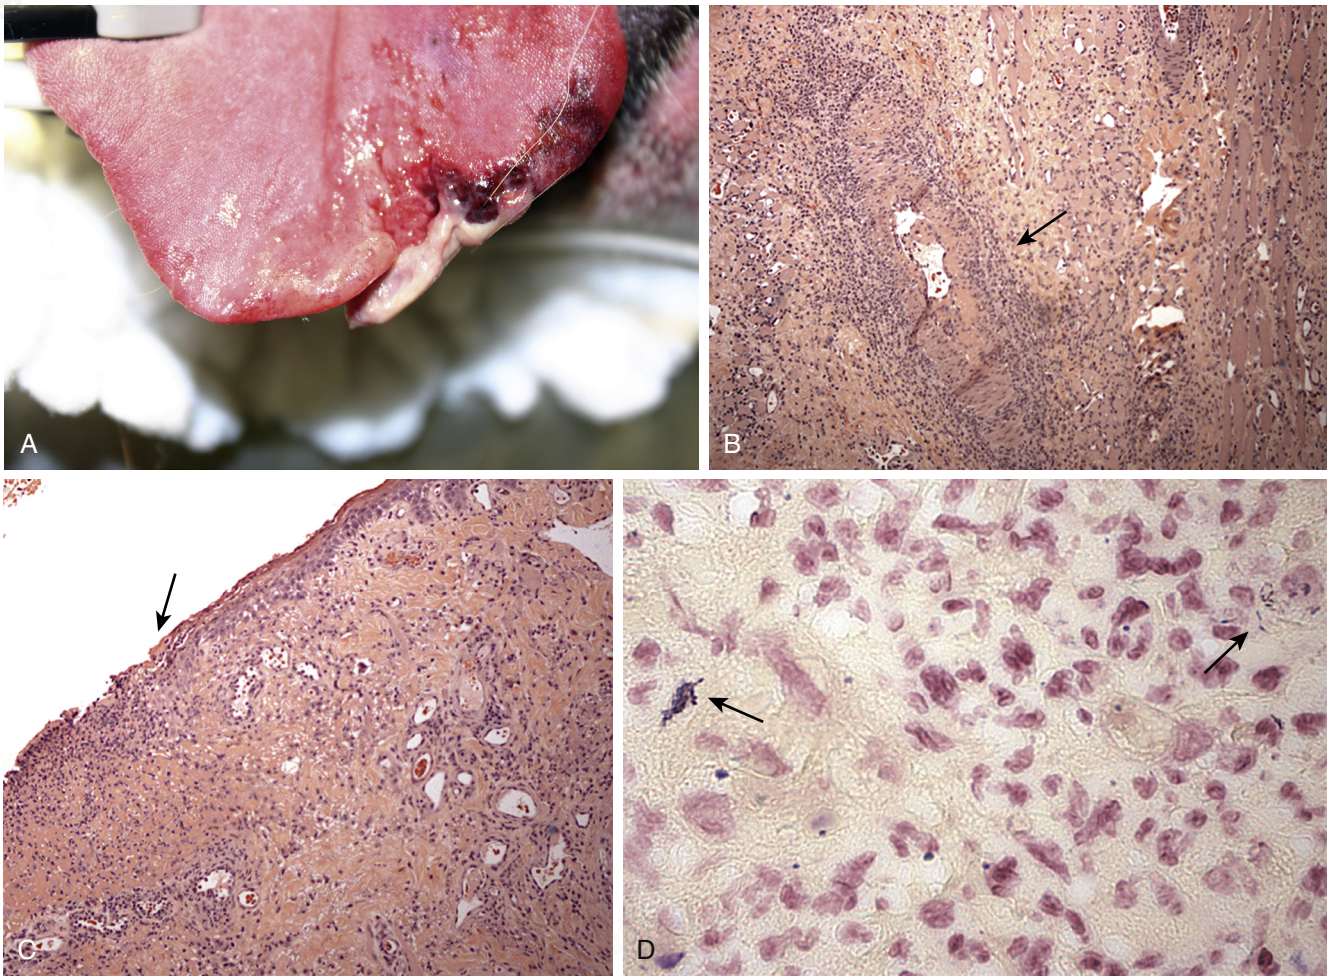

Fig. 52.4 (A) Necrotizing glossitis in a 2-year-old male neutered boxer dog with *Erysipelothrix rhusiopathiae* bacteremia. The dog also had focal dermatitis (6-cm elliptical plaque-like lesion over the left lumbar region) and septic polyarthritis. No evidence of infective endocarditis was found on echocardiography. (B) Histopathology of the tongue revealed severe multifocal subacute neutrophilic and histiocytic perivasculitis with necrotizing arteritis *(arrow)*; (C), glossitis with thrombosis and necrosis *(arrow)*; (D), intralesional gram-positive rods *(arrows)*. (B and C) Hematoxylin and eosin stain, 40× magnification. (D) Brown and Benn stain, 1000× oil immersion magnification. methylene blue or Giemsa stains. Encapsulated anthrax organisms are refractory to phagocytosis, which enhances their ability to produce disease. Exotoxin production and capsule synthesis by the bacteria are mediated by plasmids pX01 and pX02, respectively.

Bacillus anthracis begins to sporulate at the end of the growth phase in its life cycle, an adaptation crucial to the perpetuation of the organism in nature. Spores are not seen on direct staining of specimens; however, they appear in culture when nutrients are depleted. Atmospheric oxygen is considered necessary for sporulation because sporulation does not occur in the unopened carcass of an animal succumbing to anthrax. Anthrax spores are very resistant to heat, radiation, disinfectants, and desiccation, resulting in their persistence for more than 40 years in certain soils and environments. However, in most soils, the organism has to compete with other soil bacteria, so survival is generally for months and rarely more than 4 years.[81]

Anthrax is most prevalent in Africa, the Middle East, and Latin America. Anthrax has been sporadically reported in livestock in the United States, most commonly in the central and the Mississippi Delta regions, from Texas and Louisiana north to the Dakotas and Minnesota (Fig. 52.6). Warm temperatures (above 18°C [60°F]), moisture, and alkaline soils with high nitrogen content allow vegetative growth and proliferation of spores that have been released into the soil from carcasses of animals that died of anthrax.[82] Epizootics tend to occur in summer or fall after heavy rainfall or flooding preceded by drought conditions. Livestock usually become infected by ingesting spores while grazing or by eating contaminated feed (Fig. 52.7). Isolated infections in dogs have been recorded during major anthrax outbreaks in farm animals. Based on evidence from natural and experimental infections, dogs and cats are considered relatively resistant,[83] humans have intermediate resistance, and ruminants and horses are most susceptible to infection. Many dogs and cats may experience subclinical infections. Domestic dogs have been used as a sentinel for surveillance efforts based on serologic surveys with ELISA assays.[84,85]

Naturally occurring anthrax in dogs is extremely rare and most commonly caused by ingestion of meat or hides from infected carcasses, or possibly ingestion of spores from grooming contaminated fur. There are no contemporary reports of anthrax in domestic cats, and older reports are poorly documented.[86] Infections in captive wild canids and felids have also been recorded after feeding on raw meat from contaminated carcasses. In 2001 in the United States, there was documented terrorist dissemination of anthrax spores to induce inhalation anthrax in humans (the anthrax attacks, or "Amerithrax" from its FBI case name).[87] Increased risk for inhalation anthrax may therefore exist for police, guide, or search-and-rescue dogs.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Infection occurs after inert *B. anthracis* spores enter the host body by ingestion (typical route for dogs), by inhalation, or through a break in the skin. The incubation period is usually 3 to 7 days. At the point of entry in the GI mucosa, a primary focal hemorrhagic lesion is produced. Bacteria migrate to regional lymph nodes and the spleen.

Fig. 52.5 Gram stain of *Bacillus anthracis* demonstrating long chains of bacilli that form when the organism is grown in culture. Prominent central or paracentral spores do not stain with Gram stain and appear as clear areas in many of the bacilli in chains. (From Centers for Disease Control and Prevention Public Health Image Library. ID 2105. https://phil.cdc.gov/Details.aspx?pid=2105.)

In experimentally infected dogs, lesions have been restricted to local foci in the lungs because the organisms are generally contained by fibrin and cellular infiltrations.[82] After spores contact the pulmonary alveoli, they are phagocytized by macrophages that migrate through the alveolar membrane and enter pulmonary lymphatics, eventually reaching hilar lymph nodes. Within host cells, the spores quickly germinate into fully encapsulated vegetative cells that release toxins. Vegetative cells respond to the host factors of high body temperature and carbon dioxide levels, resulting in transcriptional activation of capsule and toxin genes. The capsule is thought to be an antiphagocytic factor, and the toxin induces large-scale generation of cytokines such as IL-1 that result in septic shock.[88] Anthrax lethal toxin may also contribute to shock by inhibitory effects on glucocorticoid receptor function.[89] Bacterial replication results in death of the phagocytes, with release of organisms into the bloodstream. Although most *Bacillus* species are nonpathogenic to animals and humans, *B. anthracis*, through its pXO1 plasmid, expresses three proteins: protective antigen (PA), edema factor (EF), and lethal factor (LF). The three components are serologically distinct and cause no lesions when injected separately, but in binary combinations they produce edema toxin (PA and EF) and lethal toxin (PA and LF). PA mediates the entry of either EF or LF into the cytosol of host cells. EF is an adenylyl cyclase that inhibits TNF-α synthesis and impairs host defenses. LF, a metalloprotease, inhibits mitogen-activated protein kinases and induces macrophage lysis.

The clinical expression of anthrax may be peracute, acute, or subacute/chronic. In one report, the only clinical sign was anorexia.[90] After oral exposure, the infection in dogs and cats is usually manifest as fever (39.4°C to 40.5°C [103°F to 105°F]); anorexia; and local inflammation, necrosis, and edema of the upper GI tract—the first tissues to contact ingested bacteria. Swelling of head and neck tissues is usually apparent. Subsequent spread to the local and mesenteric lymph nodes, spleen, and liver typically occurs, causing enlargement of these organs. Acute

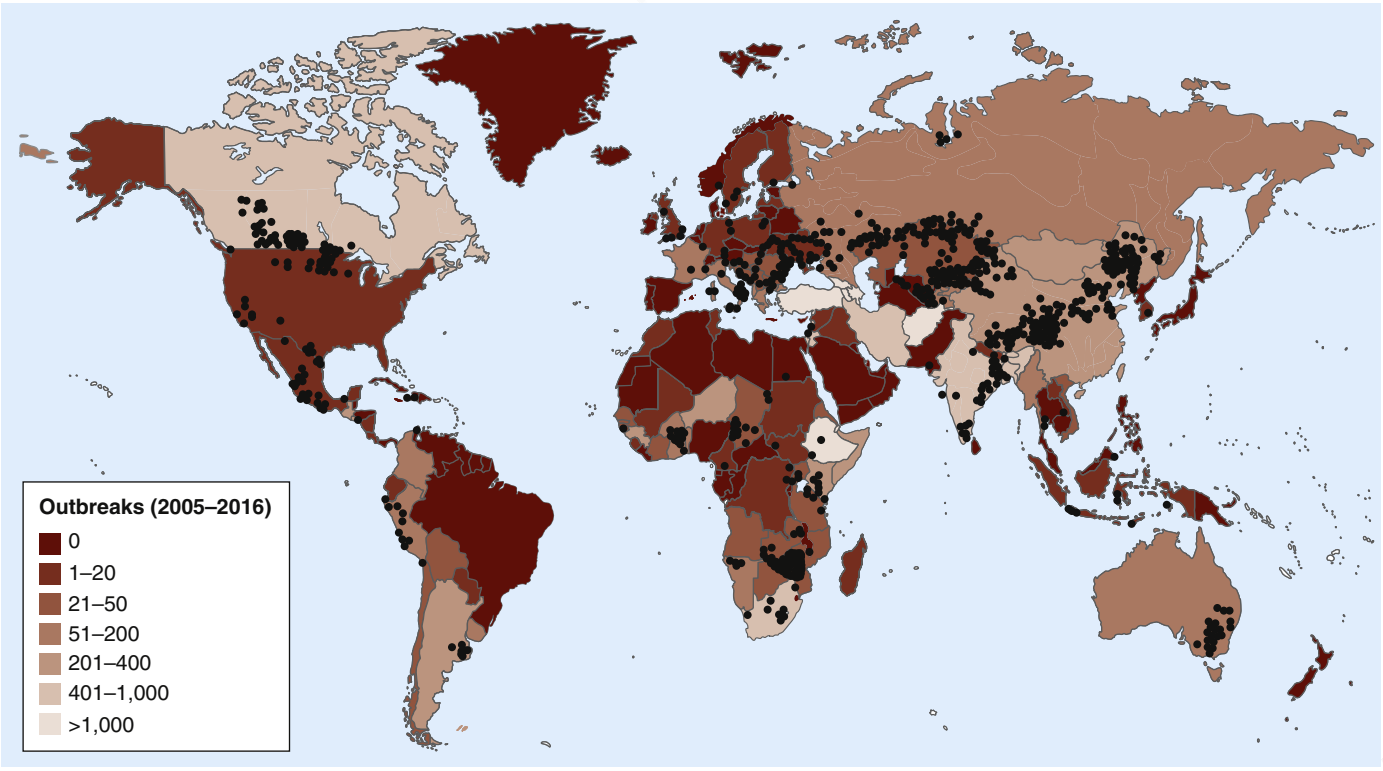

Fig. 52.6 Global distribution of anthrax outbreaks by country and geographic locations of anthrax events (January 2005 to August 2016). Black dots represent individual outbreak locations. (Modified from Carlson CJ, Kracalik IT, Ross N, et al. The global distribution of *Bacillus anthracis* and associated anthrax risk to humans, livestock and wildlife. *Nature Microbiol* 2019;4:1337–1343.)

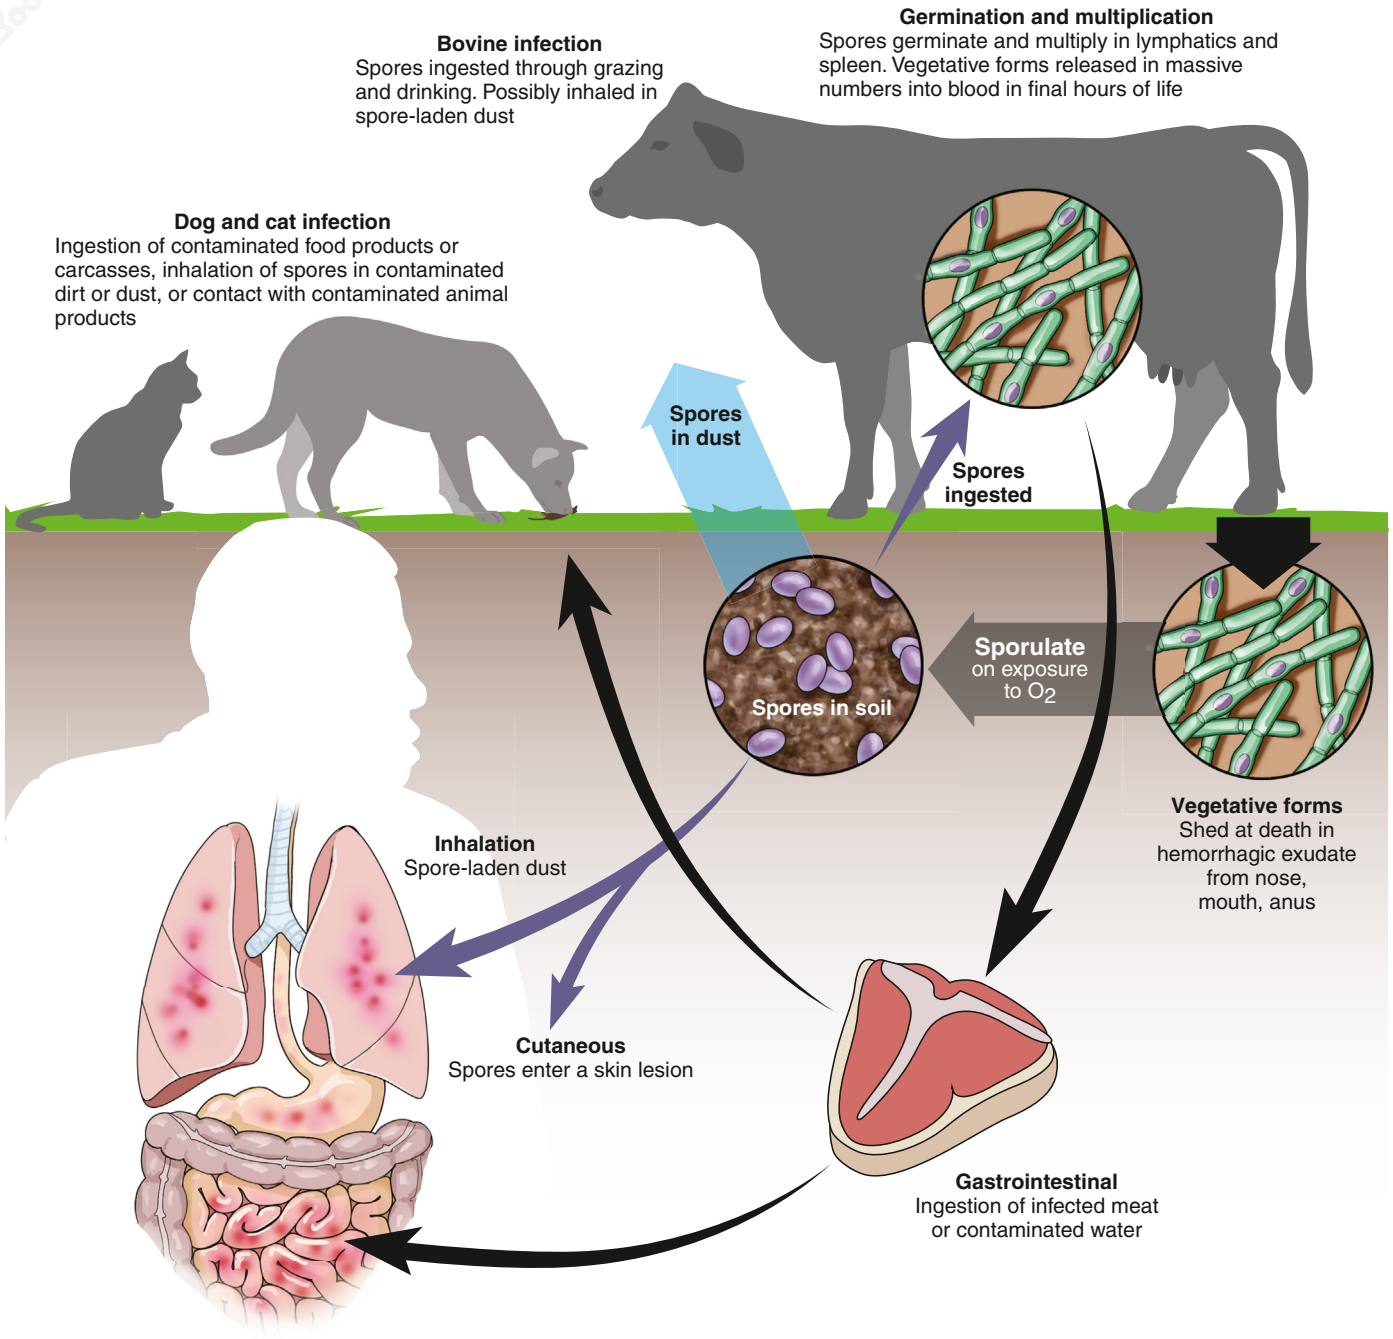

Fig. 52.7 Epidemiology of anthrax. Humans (and dogs and cats) become infected through ingestion of contaminated food products or carcasses, inhalation of spores in contaminated dirt or dust, or contact with contaminated animal products.

gastroenteritis, which is often hemorrhagic, can occur, as may sudden death, particularly in younger animals. Signs in younger or immunocompromised dogs and cats may resemble systemic anthrax in more susceptible species, described as fulminating bacteremia in which the principal lesions are edema, hemorrhage, and necrosis.

Cutaneous anthrax, the most common manifestation in humans worldwide, is rarely the primary clinical form in canids or felids. The initial cutaneous lesion at the site of inoculation appears first as a papule, progresses to a vesicle, ruptures, and develops into a black eschar secondary to focal necrosis. Experimental exposure of dogs to aerosolized anthrax spores did not reliably produce clinical disease other than short-term fever and anorexia.[82] In more susceptible species with suspected natural inhalational exposures, clinical signs include fever, lethargy, cough, and dyspnea, as well as signs that relate to bacteremia.

DIAGNOSIS

Anthrax is usually suspected based on history and clinical signs. Mild pulmonary infiltrates and pleural effusion may be detected radiographically in animals with inhalation anthrax.

Pus or tissue specimens from animals suspected of infection should be Gram stained to show gram-positive bacilli (which have the "boxcar" appearance) and stained with polychrome methylene blue to show the polypeptide capsule (which has the "string of pearls" appearance) (Fig. 52.8). Examination of stained smears of blood

from a peripheral vein or of fine-needle aspirates is the most effective and safest means of making a diagnosis.

Serologic testing using ELISA to detect IgG to *B. anthracis* PA and capsular antigen in people is highly sensitive and specific,[91,92] although some people with prior exposure to herbivorous animals or their by-products have seropositive test results. A fourfold changing titer is needed to confirm active infection or recent exposure. Use of this test has been recommended because some cutaneous cases have been culture- or PCR-negative.[93] Few other antemortem tests are recommended. A skin test for diagnosis of anthrax in humans was used in the former Soviet Union. This anthrax skin test, which detects heightened CMI against the organism, was usually positive after 3 days of illness in 97% of those affected.[94]

Necropsy of affected carcasses is not advisable because sporulation occurs, releasing the resistant spores into the environment. *Bacillus anthracis* can be isolated from clinical specimens on routine culture media if the materials are fresh. Colonies are gray-white to white and nonhemolytic. The isolates are nonmotile and have a capsule. Vegetative cells may be isolated from blood, sputum, CSF, eschar, and feces (in gastrointestinal anthrax cases). In cases of suspected inhalation exposure, *B. anthracis* spores may be collected for culture using sterile water–moistened swabs taken from the nares and haired muzzle or face within 24 to 48 hours of exposure to aerosolized spores.[95]

Immunocytochemical direct FA examination of nasal swab specimens, pleural fluid smears, or pulmonary biopsy specimens using antibodies to *B. anthracis* cell wall and capsule has been used to diagnose inhalation anthrax in humans.[96] When available, PCR of sterile body fluids (blood or pleural effusion) can rapidly confirm a diagnosis. Diagnostic pathology laboratories and shippers should always be alerted before receiving shipments of materials suspected of containing *B. anthracis.* Specimens or intact carcasses should be shipped using a biosecure procedure; they should be wrapped in plastic and kept refrigerated during transit.

Pathologic Findings

Carcasses of animals that have died of anthrax generally show little or no rigor mortis, and dark, nonclotting blood is usually seen oozing from the oral and nasal cavities and anus. The carcass often is bloated and decomposes rapidly. If necropsy is inadvertently performed on an infected animal, characteristic lesions will be observed. Extensive gelatinous edema with focal areas of hemorrhage and necrosis is commonly seen at the site of GI entry, and may be present around lymph nodes and elsewhere in the GI tract. Diphtheritic membranes and ulceration may be present on tonsillar surfaces. Splenomegaly and a friable liver are often observed. Petechial hemorrhages may be noted on serosal surfaces. On histopathology, extensive areas of necrosis in submucosal tissues are accompanied by neutrophilic infiltrates. Gram-positive bacterial colonies may be identified in mucosal fibrinous exudates.

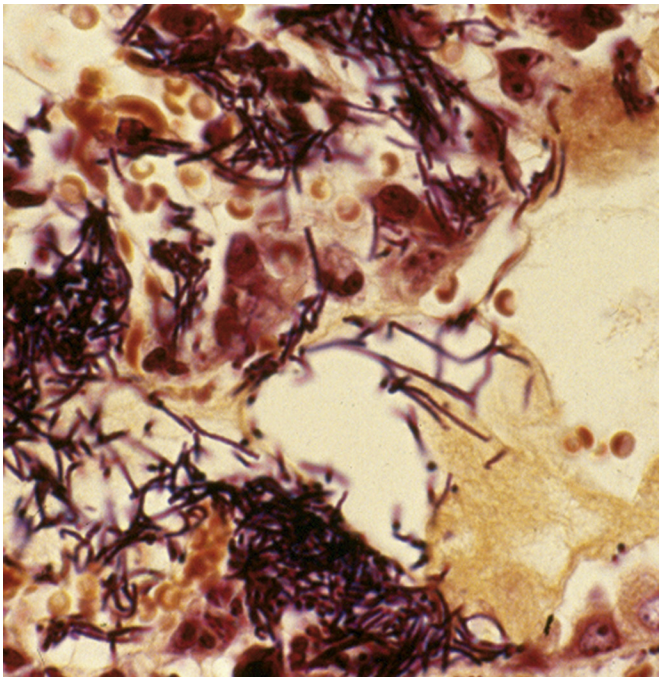

Fig. 52.8 Vegetative *Bacillus anthracis* with edema and hemorrhage in the lung of inhalation anthrax laboratory model (Brown and Hopps, ×400). (Courtesy Armed Forces Institute of Pathology, Washington, DC.)

Studies of inhalation anthrax lesions in dogs describe discrete, dark, firm pulmonary lesions, consisting of a hemorrhagic core surrounded by dense masses of fibrin and a highly cellular periphery formed from dense accumulation of neutrophils, plasma cells, monocytes, and large macrophages.[82] This intense fibrinous and cellular local response has been interpreted as a restrictive reaction by the resistant canine host to contain the *B. anthracis* invasion. Intrathoracic lymph nodes were enlarged because of reactive hyperplasia, but bacilli were not observed during histologic examination. In humans, lymph node enlargement causes mediastinal widening, a pathognomonic radiographic sign in the diagnosis of inhalation anthrax.

In pathologic specimens, anthrax can be confirmed by specific immunohistochemical staining with an antibody conjugate that specifically identifies the galactose-*N*-acetyl-D-glucosamine polysaccharide unique to *B. anthracis.*[97]

TREATMENT AND PROGNOSIS

Information regarding the recommended treatment of dogs or cats with suspected or confirmed clinical anthrax is extrapolated from literature reports of other species. *Bacillus anthracis* is susceptible to a wide range of antimicrobials, including penicillin, fluoroquinolones, and tetracyclines (see Table 52.1). Other antimicrobials that are active *in vitro* but that have not been clinically evaluated are chloramphenicol, erythromycin, aminoglycosides, and sulfonamides. Because of bacterial production of a cephalosporinase, *B. anthracis* isolates are typically resistant to cephalosporin antibacterials; potentiated sulfonamides are also ineffective. Initial doses of antimicrobials should be administered intravenously. The recommended treatment for people with systemic anthrax is a combination of a quinolone and a beta-lactam, such as meropenem; penicillin G could be used in dogs.[81] Although tissue cultures become negative within 24 hours after treatment is started, antibacterials are usually administered for 7 to 14 days. Although cutaneous infection usually resolves without medical treatment, antibacterials are recommended because cases may progress to systemic involvement (the fatality rate is 10% to 20% without treatment).[93] Humans with cutaneous anthrax are treated with doxycycline or ciprofloxacin monotherapy.

Additional supportive care may also be indicated. Animals with respiratory compromise from cervical edema may need treatment with glucocorticoids or tracheostomy. Pleural effusion may require drainage. Dressings with drainage from lesions should be incinerated, autoclaved, or disposed of as biohazardous waste. A dog or cat with suspected coat or skin exposure to anthrax aerosol should be thoroughly bathed with soap and water, as disinfectants that inactivate *Bacillus* spores are generally too caustic to use on skin. Use of accelerated hydrogen peroxide shampoos could also be considered. Persons decontaminating the haircoat of a pet should wear disposable gloves, mask, and gown. Isolation of affected animals is not required because anthrax is not transmissible after animals have been decontaminated.

IMMUNITY AND VACCINATION

If not superseded by bacteremia and death, the host response involves specific IgG antibodies against PA, with antibodies functioning to inhibit spore germination and stimulate phagocytosis by macrophages. Although livestock at risk should receive annual vaccinations, currently marketed, these have not been tested in companion animals, nor are they licensed or recommended for use in these species. Animal vaccines approved for large animals in endemic regions commonly use an avirulent nonencapsulated (pXO2-deficient) spore strain (Sterne strain). In contrast, an anthrax vaccine licensed in the United States for use in people is a cell-free filtrate containing protective antigen and alum. Five intramuscular injections (at 0 and 4 weeks and 6, 12, and 18 months) are required for immunity, and annual booster injections are recommended for maintenance.[93] An attenuated live vaccine for people, which was developed in the former Soviet Union, has been effective; however, it is not available in other countries.

PREVENTION

In endemic areas or during an outbreak, all meat fed to dogs and cats should be thoroughly cooked to eliminate the risk of exposure. To minimize environmental contamination by anthrax spores, carcasses of animals dying from anthrax should be destroyed by incineration or buried deep with a covering of quicklime (anhydrous calcium oxide). Decontamination involves a sporicidal solution of lye because ordinary disinfectants are ineffective (5% NaOH for 1.5 hours at 27.8°C or 3.6 hours at 21.1°C kills 99% of spores).[98] Soaking impervious articles in 10% formaldehyde or 4% glutaraldehyde for a minimum of 2 hours is sporicidal.[99] In the laboratory, surfaces can be decontaminated with 5% hypochlorite. Instruments used should be autoclaved or boiled at 100°C for 10 minutes.[98] All areas, equipment, and buildings that may have contacted infected animals should be cleaned and disinfected. Control of flying insects and scavenging insects and animals should be implemented. Personnel who are cleaning up after an outbreak or terrorist attack that kills livestock must wear protective clothing and respirators.

Postexposure prophylaxis protocols for people recommend at least 60 days of antibacterial administration because of concerns about environmental and pulmonary spore persistence.[100] Tetracyclines are preferred for postexposure prophylaxis, although amoxicillin or ampicillin may be substituted when the treatment course is prolonged or when contraindicated in pregnancy or lactation. The American Academy of Veterinary Pharmacology and Therapeutics and the American College of Veterinary Clinical Pharmacology have recommended that exposed working dogs be treated with doxycycline (5 mg/kg, PO, q24h) for 45 to 60 days.[101] Postexposure vaccination is also done for people using a CDC investigational drug protocol, at 0, 2, and 4 weeks SC.

PUBLIC HEALTH ASPECTS

Anthrax is a notifiable disease and should be reported to state and federal agencies. Care must be taken when handling infected tissues or carcasses because the organism can penetrate cuts in the skin, resulting in localized infection with subsequent dissemination. It has been estimated that between 2,000 and 20,000 cases occur worldwide each year.[93] In developed countries, 95% of naturally occurring cases in humans are cutaneous. They generally result from exposure to infected animals or contaminated animal products (wool, hair, bone, horns, hides).[93] Lesions are painless, pruritic papules, sometimes surrounded by vesicles, with an ulcerated, circular, black necrotic scab (Fig. 52.9). Although less common, inhalation or ingestion can result in either a highly fatal bacteremia caused by hemorrhagic pneumonitis or an oropharyngitis and gastroenteritis, respectively. Anthrax has been developed as a biologic warfare agent by Japan, the United Kingdom, the United States, Iraq, and the former Soviet Union. One millionth of a gram of inhaled anthrax spores is a lethal dose to a person. Apart from terrorist events, infection in people is almost always transmitted from infected animals or their by-products.

CASE EXAMPLE

Signalment

"Jimmy," a 4-year-old male neutered German shepherd (Fig. 52.10).

History

Jimmy was evaluated by the University of California-Davis VMTH Internal Medicine service for chronic weight loss, inappetence, and diarrhea that was refractory to medical therapy for inflammatory bowel disease. The clinical signs had been present for 13 months, and were first noticed shortly after Jimmy's owners moved from Hawaii to a 5-acre farm in northern California. The local veterinarian suspected inflammatory bowel disease or antibiotic-responsive diarrhea. Fecal flotations and a *Giardia* ELISA assay performed at that time were negative for parasites. Jimmy was treated with tylosin and a therapeutic diet trial with a prescription hydrolyzed protein diet. This was associated with moderate clinical improvement. Laboratory testing performed over the next 6 months revealed persistent mild hypoalbuminemia and severe hypocobalaminemia, which was treated with parenteral cyanocobalamin.

A year after the signs were first noted, the diarrhea recurred and weight loss was noted with mildly decreased appetite. The diarrhea was characterized by soft to liquid stool with increased frequency of defecation (3–4 times a day), some mucus and occasional mild hematochezia and tenesmus. Full thickness intestinal biopsies were obtained via exploratory laparotomy. Histopathology revealed chronic inflammatory gastroenteritis with a prominent eosinophilic component and mild lacteal dilation (suggestive of possible lymphangiectasia). Treatment with methylprednisolone (0.5 mg/kg, PO, q12h) and cyclosporine (5 mg/kg, PO, q24h) was not associated with clinical improvement. Around the same time, oral and nasal planum ulcerations were noted. Biopsy of these lesions was consistent with a diagnosis of cutaneous lupus erythematosus. Based on recommendations from a veterinary dermatologist, cyclosporine was substituted with leflunomide (5 mg/kg, PO, q24h), and the methylprednisolone dose was reduced (0.5 mg/kg, q24h). This was followed by improvement in the cutaneous lesions but the diarrhea continued. A second diet trial with a different commercial hydrolyzed diet was commenced.

From that point on, there was progressive weight loss, variable appetite, occasional urinary accidents in the house, and intermittent mixed large and small bowel-type diarrhea with hematochezia. The week before the dog was evaluated, the owner noted a marked decrease in Jimmy's energy and appetite.

Current Medications

Methylprednisone 0.5 mg/kg, PO, q24h and leflunomide 5 mg/kg, PO, q24h.

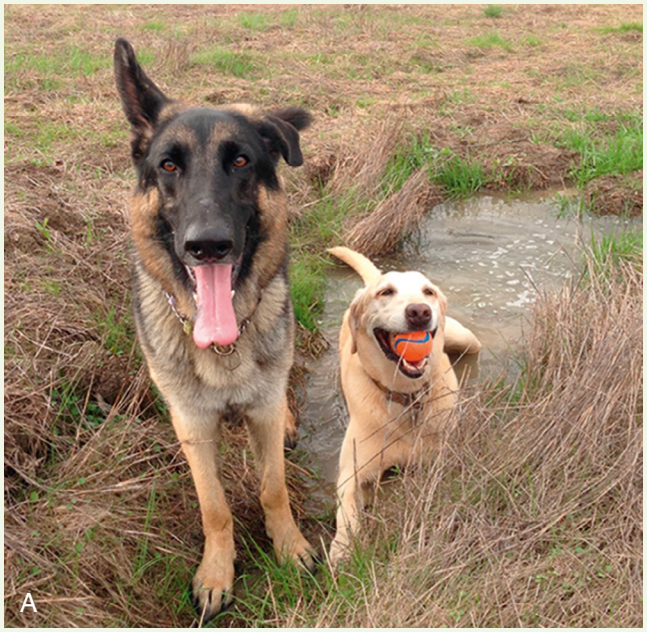

Fig. 52.10 "Jimmy," a 4-year-old male neutered German shepherd with chronic inflammatory bowel disease, cutaneous lupus, and listeriosis *(left)*.

Other Medical History

No significant previous medical history. Jimmy spent time both indoors and outdoors, with access to 5 acres of meadows, pastures of dairy cattle, sheep, goats, chicken, and geese. There was a Labrador retriever and another German shepherd on the ranch.

Physical Examination

Body weight: 23.8 kg.

General: Quiet, alert, responsive, hydrated. T = 103.3°F (39.6°C), HR = 110 beats/minute, RR = 24 breaths/minute.

Integument: Multiple 1-cm ulcerations were present on lateral metatarsus and carpus. There was a focal 6-cm area of alopecia and erythema over the left caudal dorsum.

Eyes, ears, nose, and throat: Mucous membranes pink, moist, CRT < 2 seconds. Multiple small depigmented ulcerative lesions on hard palate.

Musculoskeletal: Thin body condition, ambulatory, appeared weak in the pelvic limbs. Bilateral moderate temporal muscle atrophy.

Cardiovascular: No murmurs or arrhythmias noted. Moderate femoral pulses.

Respiratory: Panting, harsh lung sounds on auscultation of right thorax, referred to all lung fields.

GI and genitourinary: Moderate cranial organomegaly detected on abdominal palpation.

Lymph nodes: No peripheral lymphadenopathy.

Laboratory Findings

CBC: HCT 41.% (40%–55%), MCV 69 fL (65–75 fL), MCHC 34.7 g/dL (33–36 g/dL), WBC 22,170 cells/μL (6,000–13,000 cells/μL), neutrophils 19,288 cells/μL (3,000–10,500 cells/μL), band neutrophils 443 cells/μL, lymphocytes 1,109 cells/μL (1,000–4,000 cells/μL), monocytes 887 cells/μL (150–1200 cells/μL), platelets clumped. There was slight neutrophil toxicity and rare schistocytosis.

Serum chemistry profile: Sodium 140 mmol/L (145–154 mmol/L), potassium 4.1 mmol/L (3.6–5.3 mmol/L), chloride 106 mmol/L (108–118 mmol/L), bicarbonate 16 mmol/L (16–26 mmol/L), phosphorus 3.0 mg/dL (3.0–6.2 mg/dL), calcium 8.9 mg/dL (9.7–11.5 mg/dL), BUN 4 mg/dL (5–21 mg/dL), creatinine 0.3 mg/dL (0.3–1.2 mg/dL), glucose 83 mg/dL (64–123 mg/dL), total protein 4.7 g/dL (5.4–7.6 g/dL), albumin 2.6 g/dL (3.0–4.4 g/dL), globulin 2.1 g/dL (1.8–3.9 g/dL), ALT 514 U/L (19–67 U/L), AST 91 U/L (19–42 U/L), ALP 277 U/L (21–170 U/L), creatine kinase 138 U/L (51–399 U/L), GGT 9 U/L (0–6 U/L), cholesterol 237 mg/dL (135–361 mg/dL), total bilirubin 0.3 mg/dL (0–0.2 mg/dL), magnesium 1.4 mg/dL (1.5–2.6 mg/dL).

Urinalysis: SpG 1.011; pH 6.5, negative protein, 3 mg/dL bilirubin, 10 erythrocytes/μL, hemoprotein, no glucose, 0–3 WBC/HPF, 3–5 RBC/HPF, few lipid droplets.

Imaging Findings

Thoracic radiographs: The cardiovascular and pulmonary structures appeared within normal limits.

Abdominal ultrasound: Multiple fluid-filled small intestinal loops were identified with mucosal hyperechogenicity but normal wall layering. There was a scant volume of anechoic free peritoneal fluid. The liver was mildly hyperechoic. There was mild splenomegaly and prominent mesenteric lymph nodes.

Microbiologic Testing

Urine aerobic culture and susceptibility: 10^3 CFU/mL *L. monocytogenes* (identified using MALDI-TOF), susceptible to aminoglycosides, beta-lactams, trimethoprim-sulfamethoxazole, chloramphenicol.

Blood culture (aerobic and anaerobic): Blood samples were collected at times 0, 20, and 60 minutes. Large numbers of gram-positive rods were seen on a Gram-stained smear after incubation, which were also identified as *L. monocytogenes.*

Diagnosis

Listeria monocytogenes bacteremia.

Chronic enteropathy associated with inflammatory bowel disease.

Cutaneous lupus of German shepherd dogs.

Treatment

Leflunomide was discontinued and treatment with ampicillin (20 mg/kg, IV, q6h) and gentamicin (10 mg/kg, SC, q24h) was initiated. Methylprednisolone was continued.

CASE EXAMPLE—cont'd

Magnesium citrate was also administered (5 mg/kg, q24h) for hypomagnesemia that likely resulted from chronic malabsorption. At a recheck 1 week later, Jimmy's owners reported significant improvement in his activity level and appetite. His temperature had been normal at home and he was playing with the other dogs. He ate almost all of his food but did not ever seem very hungry, but his body weight increased by 0.6 kg. No urinary accidents in the house had occurred. Blood and urine cultures were negative. Although bandemia had resolved on the CBC, there was a persistent mature neutrophilia (27,245 cells/μL) and serum chemistry abnormalities persisted, with further increase in the serum ALT (1925 U/L). On physical examination, a new cardiac murmur was detected (grade II/VI systolic left apical). An echocardiogram revealed mild mitral valve regurgitation, reduced systolic function, and a 1-cm circular echogenic lesion that was adherent to the caudal apical surface of the left ventricular endomyocardium (Fig. 52.11A and B). This was suspected to be a mural thrombus. Serum troponin I concentration was increased (0.97 ng/mL, reference range: 0.09–0.17). Treatment with amoxicillin (20 mg/kg, PO, q8h) was continued and gentamicin was discontinued. Treatment with clopidogrel was considered, but withheld because of concerns that it might lead to dislodgement of a clot. However, approximately 1 week later, Jimmy developed acute onset of left thoracic limb lameness. On physical examination, his entire limb distal to the carpus was cool to the touch. No murmur was detected. A repeat echocardiogram showed that the mural mass was half the size it had previously been, with ragged edges. Abdominal ultrasound examination showed lesions consistent with multiple venous thrombi in the caudal vena cava, common iliac, hepatic, and renal veins. Wedge-shaped hypoechoic lesions were identified in the renal parenchyma and diffuse mixed echogenic regions were in the liver, suggestive of infarcts secondary to thromboemboli. Jimmy was treated with clopidogrel (1.5 mg/kg, PO, q24h), enoxaparin (1 mg/kg, SC, q8h), enalapril (0.5 mg/kg, PO, q12h) and pimobendan (0.3 mg/kg, PO, q12h). Amoxicillin was also continued.

One month later the lameness had resolved, there had been a 5-kg weight gain, and Jimmy's appetite and energy level were normal. Bloodwork showed resolution of laboratory abnormalities, including serum troponin I concentration, and echocardiography showed resolution of the mural lesion, persistent mild mitral regurgitation, and improved systolic function. Abdominal ultrasound examination showed resolution of thrombi within the major veins and static chronic renal changes consistent with infarcts. All medications except the clopidogrel and methylprednisolone were discontinued; at a recheck 2 months later, clopidogrel was discontinued and methylprednisolone dose was halved, and vitamin B12 supplementation was commenced (1500 μg, SC, q2weeks) because serum B12 concentration was low (219 ng/L, reference range 271–875 ng/L). Six months later, there was worsening of cutaneous lupus lesions, with appearance of multiple severe oral ulcerations (Fig. 52.11C). The inflammatory bowel disease was relatively well controlled with only mild intermittent diarrhea. Treatment with cyclosporine was commenced (5 mg/kg, PO, q24h), which was associated with resolution of the ulcers. However, 6 months later, Jimmy became hyporexic and weight loss was noted. The most significant finding on an extensive work-up that included bloodwork, blood cultures, echocardiography, and abdominal ultrasound was moderate thrombocytopenia (59,000 platelets/μL). Vector-borne disease serology was negative. Four months later (2 years after the diagnosis of listeriosis) he was brought to the UC Davis veterinary emergency service and was in cardiopulmonary arrest. A necropsy revealed disseminated, intravascular B-cell lymphoma in the lung, brain, kidney, pancreas, liver, small and large intestine, stomach, omentum, adrenal gland, heart, and periocular haired skin as well as moderate, chronic, diffuse, lymphoplasmacytic enteritis.

Comments

This dog likely developed *L. monocytogenes* bacteremia and mural endomyocarditis with thromboembolic complications secondary to immunosuppressive drug therapy and exposure to farm animal species. Although the listeriosis was treated successfully, ultimately persistence of immune-mediated disease necessitated ongoing immunosuppression with cyclosporine. It is possible that the use of cyclosporine predisposed to the ultimate cause of death, disseminated B-cell lymphoma.[102]

Gram-Negative Bacterial Infections

Virginia Sinnott-Stutzman, Jane E. Sykes

KEY POINTS

- First Described: Gram-negative bacteria were first described in Berlin by the Danish scientist Hans Christian Gram in 1884 when he used Gram stain to visualize *Klebsiella pneumoniae* in the lungs of people who died of pneumonia.[1]
- Causes: Examples include *Escherichia coli, Salmonella, Enterobacter, Citrobacter, Klebsiella, Campylobacter, Pseudomonas,* and *Acinetobacter*.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Direct contact or contact with contaminated fomites; the bacteria often invade opportunistically.
- Major Clinical Signs: Affected sites include UTIs, wound infections, pneumonia, pyothorax, peritonitis, pyometra, ocular surface infections, otitis externa, pyoderma, bacteremia, and endocarditis, but virtually any body system can be affected.
- Differential Diagnoses: Infections with gram-positive bacteria such as *Staphylococcus* spp. and *Streptococcus* spp.; to a lesser extent, infections with nonbacterial pathogens such as fungi.
- Human Health Significance: Gram-negative bacteria shed by dogs and cats have the potential to colonize humans, especially those with impaired host defenses. They may also be responsible for infections of dog or cat bites. Infections caused by gram-negative pathogens resistant to all available antibiotics have resulted in the death of human patients.[2]

ETIOLOGIC AGENTS, EPIDEMIOLOGY, AND CLINICAL FEATURES

Gram-negative bacteria are ubiquitous agents of opportunistic infections in dogs and cats and primarily cause disease when host defenses are impaired. They are important causes of nosocomial disease; several species belong to the ESKAPE group of bacteria (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae, Acinetobacter baumannii*, *Pseudomonas aeruginosa* and *Enterobacter* spp.), a term that was developed to reflect the ability of these organisms to escape antimicrobial activity through resistance and highlight their importance as significant causes of morbidity and mortality in human healthcare facilities. Distinguishing the gram-negative species in this group from gram-positive bacteria is a complex outer membrane that contains LPS, as well as structures known as *porins* that regulate transport of molecules in and out of the cell including antimicrobial drugs. Between this outer membrane and the inner (cytoplasmic) membrane is a periplasmic space, which contains the structural polymer peptidoglycan (or *murein*) (Fig. 53.1). The peptidoglycan layer of gram-negative bacteria is much thinner than that of gram-positive bacteria, approximately one layer, or 7 to 8 nm thick (compared with many layers, or 20 to 80 nm thick for gram-positive bacteria). The inner cytoplasmic membrane contains many different proteins that are lipoproteins anchored into the outer lipid bilayer leaflet, transmembrane proteins, or peripheral membrane proteins that lie adjacent to the bilayer leaflets. Of particular clinical relevance are efflux pumps which can allow an organism to become resistant to multiple antibiotic classes. The pump type that most commonly causes such resistance is called the resistance-nodulation-cell division (RND) pump. This pump system, when active, can extrude a variety of molecules from gram-negative bacteria, including antimicrobial agents of various classes, conferring multidrug resistance to gram-negative organisms of several genera including *Escherichia coli*, *Klebsiella*, and *Pseudomonas* species.[3]

LPS is a large molecule that varies in composition from one bacterial species and strain to another. It contributes to the structural integrity of gram-negative bacteria and is a potent virulence factor. It consists of the *lipid A* backbone, a *core oligosaccharide,* and the *O antigen* side chain. Lipid A is a phosphorylated disaccharide to which long, hydrophobic fatty acid chains are attached, which anchor the LPS into the outer membrane (Figs. 53.1 and 53.2). The lipid A component is also known as *endotoxin* because it is the biologically active portion of the molecule, in that it stimulates a potent host inflammatory response (see Chapter 123). The core oligosaccharide connects lipid A to the O antigen side chain. Its composition differs between bacterial species. The O antigen is a repeating polysaccharide that projects from the surface of the bacterial cell and varies in length from 1 to 60 repeats. It is the antigenic portion of the molecule and is responsible for serogroup classification of gram-negative bacteria.

Gram-negative cocci, such as *Moraxella* or *Neisseria,* are not widely recognized as significant pathogens of dogs and cats. However, as commensals of the canine and feline oral cavity, they can cause bite wound infections in humans,[4] and *Neisseria canis* was isolated in pure culture from a deep mandibular abscess from one dog.[5] Gram-negative rods are classified into Enterobacterales (previously Enterobacteriaceae) and non-Enterobacterales species. Enterobacterales that cause disease in dogs and cats include *E. coli, Proteus, Salmonella, Enterobacter, Citrobacter, Serratia, Klebsiella*, and *Providencia*. Non-Enterobacterales species include the Pasteurellaceae *(Pasteurella multocida)*, as well as *P. aeruginosa, Acinetobacter,* and *Ralstonia*. Other gram-negative bacteria are coccobacilli or spiral-shaped organisms and include *Bartonella, Bordetella, Campylobacter, Francisella, Helicobacter,* and *Brucella*.

Like gram-positive cocci, some gram-negative bacteria have tremendous ability to form biofilms, or bacterial aggregates that are embedded in a matrix of exopolysaccharide (bacterial slime), which form on living or nonliving surfaces. These protect the bacteria, and organisms in biofilms can resist the effect of antimicrobial drugs

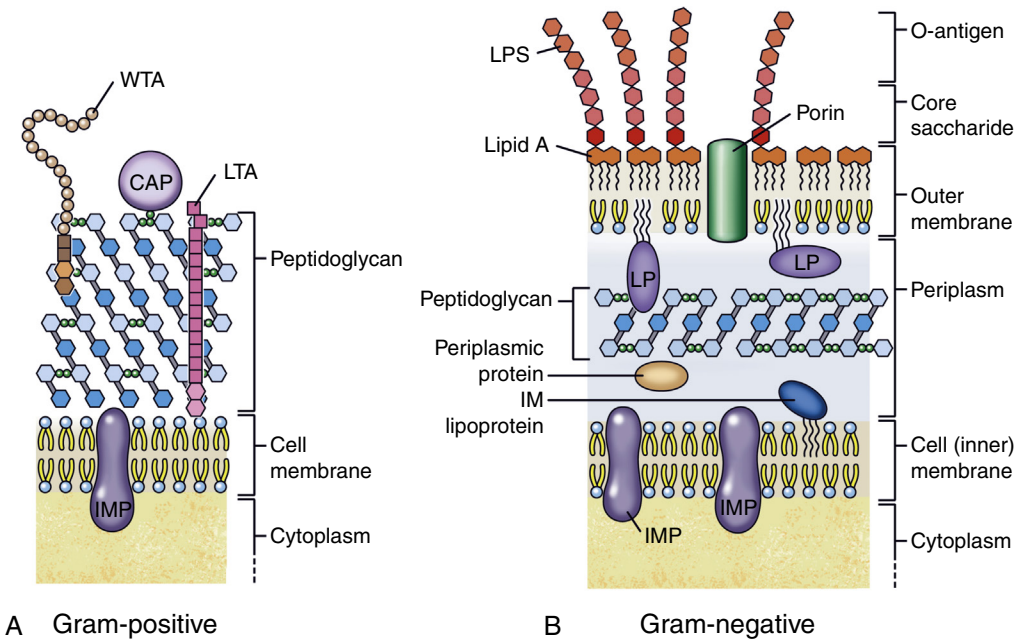

Fig. 53.1 Structure of the envelope of gram-positive (A) and gram-negative (B) bacteria. The thickness of the peptidoglycan layer is greater in gram-positive bacteria than in gram-negative bacteria. *WTA,* wall teichoic acid; *CAP,* covalently-attached protein; *LTA,* lipoteichoic acid; *LPS,* lipopolysaccharide; *IMP,* integral membrane protein; *IM,* inner membrane.

and disinfectants. In addition, expression of efflux pumps has been shown to be a key component of biofilm formation in gram-negative organisms.[6]

Virulence Factors

While the majority of gram-negative infections are caused by opportunistic pathogens that take advantage of weakened host immune systems, some gram-negative organisms have virulence factors which allow them to: (1) persist in host tissues that they do not normally colonize; (2) evade immune responses, and/or (3) adhere to, invade, or damage host cells. Different serotypes of the same species may vary greatly in their potential to cause disease. For example, *E. coli* O157:H7 is often isolated from cases of hemolytic uremic syndrome because it expresses two powerful virulence factors, Shiga toxin (Stx-2) and verocytotoxins (Shiga-like toxins). These induce necrosis of endothelial cells, which results in widespread thrombosis, thrombocytopenia, and often death. In contrast, *E. coli* strain VR50 is associated with asymptomatic bacteriuria in humans, and is currently being investigated as a therapeutic inoculum to prevent recurrent symptomatic UTIs in women.[7]

As whole genome sequencing is becoming an increasingly commonplace aspect of microbiology, hundreds of individual virulence factor genes across several genera of gram-negative organisms have been identified. These can be divided into several categories based on how they contribute to establishing infections and causing disease.

Adhesion Molecules

Adhesion mechanisms among gram-negative bacteria vary widely, but the general motif involves the interaction between bacterial surface organelles and either epithelium or an abiotic surface (i.e., surgical implant). Surface organelles include fimbriae, pili, and flagella. In most cases, genes involved in adhesion are regulated alongside genes that are involved with biofilm development. The virulence factor that allows *E. coli* VR50 to adhere to the mucosa of human bladders has been identified as the gene for afimbrial adhesion (*afa*).[8]

Invasion

Organisms that can cross epithelial barriers and/or invade host cells must possess enzymes that can break down membranes and connective tissue. As such, the host of invasion virulence factors include genes coding for various isoenzymes of phospholipase, collagenase, hyaluronidase, and lecithinase. In contrast to factors that mediate adhesion, invasion virulence factors generally cause some level of damage to target tissues. Genes that encode phospholipase D (*pld*) are key virulence factors that allow *A. baumannii* to penetrate the pulmonary epithelial barrier.[9]

Competition for Iron and Nutrients

Iron is tightly bound to proteins (such as hemoglobin) in mammals; free iron concentration in the host environment is minute. To facilitate survival, gram-negative bacteria express iron acquisition systems that are not required in iron-rich environments. Iron-sequestering proteins produced by gram-negative bacteria are among the most efficient iron chelators in the natural world. Examples of efficient bacterial iron chelators are enterobactin in *E. coli* and pyoverdine in *P. aeruginosa*.[10]

Resistance to Host Immunity

Microorganisms can evade host immunity in myriad ways. While most gram-negative organisms are not innately pathogenic and thus have little genome space dedicated to this task, pathogenic strains of *E. coli* modulate the host's response to endotoxin by inserting tyrosine-based inhibitory motifs into cell membranes which dampen the production of proinflammatory cytokines in response to the presence of endotoxin and other pathogen-associated molecular patterns. Additionally, *E. coli* can bind the Fc receptor of macrophages directly (without antibody present) and induce an inhibitory response, blocking phagocytosis.[11]

Toxin Secretion

Gram-negative pathogens can express genes which interrupt normal metabolic functions of host cells. In general, far greater numbers of gram-negative organisms possess these genes than express them, likely because there is a "fitness cost" (ATP cost) associated with their expression. These toxins are sometimes used to create a more favorable

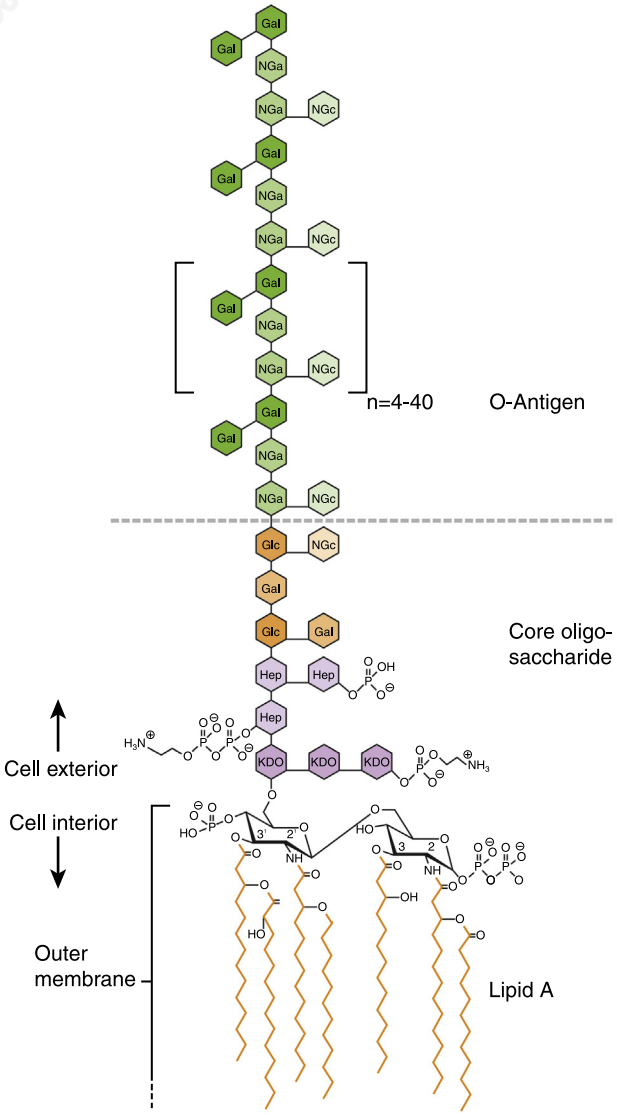

Fig. 53.2 Structure of bacterial lipopolysaccharide.

environment for bacterial replication. For example, in microanaerobic conditions, *P. aeruginosa* can produce exotoxin A, which inhibits protein synthesis by host cells, presumably so that competition for oxygen is reduced.[12]

Bacterial Motility

Gram-negative bacteria that possess flagella are not necessarily able to demonstrate coordinated motion. Motility patterns such as twitching, swimming, and swarming (which involves communication between organisms and activation of "quorum sensing" genes) are associated with ascending UTIs and medical device–related infections. Twitching is more commonly found in *Proteus* isolated from catheter-associated UTIs than in *Proteus* isolated from the feces of healthy individuals.[13]

Virulence Plasmids

Plasmids are packets of genetic material which bacteria can trade among one another. Many plasmids confer groups of potent virulence factors, often genes for cytotoxins, as well as antimicrobial resistance genes. In this way, an otherwise innocuous bacterial clone can quickly acquire both pathogenicity and antimicrobial resistance. Toxins associated with *E. coli* O157:H7 are largely encoded for on a virulence plasmid, *pO157*, and include enterohemolysin, serine protease, and catalase-peroxidase. Each of these enzymes alone is capable of interrupting cellular metabolism, initiating coagulation, or inducing apoptosis under certain conditions. Expression of all three as well as Shiga toxin can result in devastating diarrheal illness and hemolytic uremic syndrome.[14]

Enterobacterales

Many Enterobacterales contribute to the normal gastrointestinal flora of animals. Enterobacterales are non-spore forming, non-acid fast, facultative, anaerobic, gram-negative rods. They possess a capsule (*K antigen*) and may be motile via flagella (*H antigen*). Highly encapsulated species, such as *Klebsiella* and *Enterobacter,* have a mucoid appearance when they grow in culture. The flagella project from the bacterial cell and contain the filament-forming protein *flagellin,* which (with LPS) can stimulate the host inflammatory response. An internationally recognized classification system for Enterobacterales has been established based on differences in the antigen surface molecules, O (LPS), K (capsular), H (flagellar), with serotypes identified by a numerical assignment to each antigen they possess listed after the genus and species name (i.e., *E. coli* O157:H7). Additionally clonal strains of species of specific microbiologic or pathologic interest can be identified by serial alphanumeric designation (i.e., *E.coli* 83972 and *E. coli* VR50, two strains causing asymptomatic bacteriuria in women). The Enterobacterales also possess fimbriae or pili, which are thinner than flagella and play a role in adhesion and sometimes bacterial aggregation. Finally, they possess a variety of complex secretion systems (type I, II, III secretion systems). These facilitate export of toxins such as hemolysins, and molecules that are inserted into, and form pores in, host cell membranes.

Escherichia coli

More than any other species of Enterobacterales, *E. coli* possess the potential to be true pathogens, capable of causing communicable disease in otherwise healthy individuals. Diarrheagenic *E. coli* are a leading cause of human diarrheal disease in the developing world and a source of outbreaks in the developed world. Outbreaks of foodborne illness occur when produce becomes contaminated with animal (usually cattle) feces. Based on the virulence factors they express, enteropathogenic *E. coli* (EPEC) are classified into six major pathovars (i.e., groups defined by the specific pathologic lesions they produce). The reader is referred to Chapter 63 for more complete information on intestinal *E. coli* infections; however, those pathovars known to cause illness in dogs and cats are discussed below.

Enteropathogenic *Escherichia coli.* Organisms collectively called EPEC may comprise several serovars of *E. coli*. The group is defined by its pathogenesis, which is characterized by the distinctive lesions they create on the surface of intestinal epithelial cells. Termed "attaching and effacing," all EPEC express the *eae* gene for intimin, an adhesion protein partially responsible for the denuding of microvilli, but they do not express genes encoding for Shiga toxin. EPEC has been isolated from cats with and without diarrhea.[15] Dogs have long been implicated as carriers of EPEC, and healthy dogs without diarrhea can harbor EPEC.[16] This complicates the question of whether EPEC causes diarrhea in dogs. EPEC has been detected in dogs with diarrhea, but many of these dogs were also infected or colonized with other enteropathogens, so it was unclear if EPEC was a secondary pathogen or a primary cause of diarrhea.[17] In a case series in which a reasonable attempt was made to exclude other pathogens, EPEC were detected based on PCR analysis of *E. coli* isolated from all of seven dogs with hematemesis and/or hemorrhagic diarrhea.[18] Given the infrequency with which molecular diagnostics are performed in veterinary cases of diarrheal illness, EPEC may be underreported as a cause of diarrhea. EPEC should be among the differential diagnoses in cases where

multiple members of a household or community of dogs are affected by diarrhea, keeping in mind the zoonotic potential of this pathogen.

Enterotoxigenic *Escherichia coli*. Enterotoxigenic *E. coli* (ETEC) produces either heat-stable toxin (ST), heat-labile toxin (LT), or both. There is little genomic homology among strains of ETEC and conserved genes do not encode proteins associated with pathogenesis. Instead, it is thought that the acquisition of plasmids that encode for colonization factors (to allow adhesion to intestinal epithelium) and ST, LT, or both define ETEC.[19] Diarrhea is induced by ST and LT, which stimulate secondary messenger systems that in turn open the cystic fibrosis transmembrane conductance regulator (CFTR) of enterocytes. The end result is bulk chloride loss into the intestinal lumen. As water and sodium follow, voluminous watery diarrhea results. ETEC has been identified in dogs with diarrhea.[20,21]

Adherent invasive *Escherichia coli*. Unlike most other pathovars of *E. coli*, adherent invasive *E. coli* (AIEC) is still defined by its phenotype because virulence genes associated with invasiveness have yet to be identified in this pathovar. An *E. coli* is defined as AIEC if it can invade and replicate within cell cultures efficiently enough to escape inactivation by gentamicin.[22] Adherent and invasive *E. coli* induce disease through a combination of host genetic predisposition and immune stimulation. These organisms adhere to and invade ileal cells (humans) and ileal and colonic cells (dogs), which is associated with Crohn's disease and granulomatous colitis, respectively. The microorganisms replicate within epithelial cells as well as macrophages, with inhibition of macrophage apoptosis. This results in high levels of TNF-α with associated intestinal inflammation and granuloma formation in patients with Crohn's disease.[19,23] Boxer dogs and French bulldogs with granulomatous colitis have AIEC associated with their lesions. Remission associated with fluoroquinolone administration suggests a similar pathogenesis.[24,25] Given the emergence of resistance and the microbiologically catastrophic effect of antibiotics on the gut microbiome, alternate therapies are being investigated in humans with Crohn's disease. Nonantibiotic therapies targeted at blocking AIEC adhesion and colonization are under investigation.[26]

Extraintestinal pathogenic *Escherichia coli*. Following the same nomenclature system used for EPEC, organisms that cause disease outside of the intestinal tract are often designated as extraintestinal pathogenic *E. coli* (ExPEC). An important subset of ExPEC, serovars or clones with virulence attributes that allow for urinary tract invasion, are often referred to as uropathogenic *E. coli* (UPEC). *Escherichia coli* is the most common cause of UTIs in dogs and cats and can also be isolated from dogs and cats with pyometra, prostatitis, peritonitis, cholangitis, cholecystitis, bacteremia and endocarditis, bronchopneumonia (such as that secondary to aspiration), and pyothorax.[27] There are two reports of severe soft tissue infections (necrotizing fasciitis) in dogs associated with *E. coli* infection.[28,29] Antimicrobial resistance in *E. coli* isolates from dogs and cats is an increasing problem; 51% of 376 isolates collected from sick dogs and cats in the United States in 2005 showed resistance to at least one drug, and 29% of the 376 isolates were MDR (defined as resistant to three or more classes of antimicrobial drugs).[30] Another investigation similarly found an increasing trend for resistance to fluoroquinolones, tetracyclines, and cephalosporins for nonurinary tract *E. coli* infections from 2002 to 2011.[31] A European investigation found that beta-lactamase production among *E. coli* respiratory infections in dogs was high, with only 37% of isolates sensitive to ampicillin but 83% susceptible to amoxicillin-clavulanic acid.[32] The prevalence of resistance in 395 isolates from healthy dogs and cats from Canada was lower (19%).[33] In a prevalence study in the United Kingdom, 1.9% of dogs visiting veterinary clinics had *E. coli* that expressed extended-spectrum beta-lactamase (ESBL) genes in their feces, and recent antibiotic use and being fed raw poultry were identified as risk factors for carrying resistant *E.coli*.[34] ESBL enzyme production has also been identified in *E. coli* isolates from dogs and cats in the United States,[35] and a few isolates were found to express New Delhi metallo-beta-lactamase (NDM-1), which hydrolyses carbapenems.[36] Nosocomial infections with MDR *E. coli* have also been described in dogs and cats.

In humans, strains of UPEC that cause UTIs differ from those that cause diarrhea, and there is some evidence that this may also be true for strains that cause UTIs versus pyometra in dogs and cats.[37–39] These strains possess a number of virulence factors, such as siderophores, type 1 and P fimbriae, hemolysin, and cytotoxic necrotizing factor. Specific virulence factors, as well as biofilm-forming capacity, have been associated with persistent or relapsing UTIs,[40,41] and UPEC can invade and persist within bladder epithelial cells. In a recent study of 194 UPEC specimens obtained from clinical human UTI cases, the most commonly expressed virulence genes (expressed in 58%–68% of strains) were two genes that permit adhesion to bladder epithelium (*fim, iha*), a gene coding for a capsule which may allow the organism to evade the immune system (*kpsMT*), and a gene for a toxin which is associated with the development of pyelonephritis (*usp*).[42] In one study, canine *E. coli* UTIs were more likely to be recurrent than those associated with other uropathogens.[43] Another investigation revealed that recurrent *E. coli* UTIs are more likely to be increasingly resistant to antibiotics.[31] There has been concern that dogs may act as a source of *E. coli* strains that are pathogenic for humans.[39,44] In other extraintestinal *E. coli* infections, *E. coli* more closely resemble commensal strains, and host factors may be more important than bacterial virulence factors.[45]

Proteus

Proteus mirabilis is a common cause of upper and lower UTIs in dogs as well as otitis externa and uncommonly pyoderma. It produces a potent urease and can contribute to development of struvite urolithiasis. Uroliths harbor bacteria that can emerge as the uroliths dissolve. *Proteus* has a characteristic swarming motility and may obscure the growth of other co-infecting microorganisms when grown in the laboratory on agar. Recently, highly resistant *P. mirabilis* isolates sharing some homology with human isolates have been identified in canine patients in France.[46] *Proteus penneri,* an uncommon cause of nosocomial infections and bacteremia in humans, has rarely been isolated from wound infections in dogs seen at the editor's hospital.[47]

Klebsiella

The most common species of *Klebsiella* that infects dogs and cats is *K. pneumoniae. Klebsiella oxytoca* is a nosocomial pathogen in humans and has been reported in association with IV catheter colonization in puppies with parvoviral enteritis.[48] *Klebsiella oxytoca* has also been isolated from clinical veterinary specimens (either cultures from patients or pathology specimens) in both Italy ($n = 24$) and Japan ($n = 14$, 7 of which were from urine).[49,50]

Klebsiella pneumoniae primarily causes upper and lower UTIs in dogs and cats, but can also cause pneumonia, sometimes with abscessation (Figs. 53.3 and 53.4). It has been isolated from dogs with hepatic abscesses.[51] *Klebsiella pneumoniae* is an important cause of nosocomial infections and may be associated with bacteremia, endocarditis, and postoperative skin and soft tissue infections. The capsule of *K. pneumoniae* is a major virulence factor. It inhibits phagocytosis and is responsible for the mucoid appearance of the organism in culture (Fig. 53.5A).

All strains of *K. pneumoniae* are resistant to ampicillin because they possess a chromosomal gene that encodes a penicillin β-lactamase. Some isolates, such as nosocomial isolates or those from persistent UTIs, possess plasmids that contain resistance genes for multiple antimicrobial drugs. Of greatest concern are *Klebsiella* isolates that express ESBL enzymes, which hydrolyze third-generation cephalosporins. The

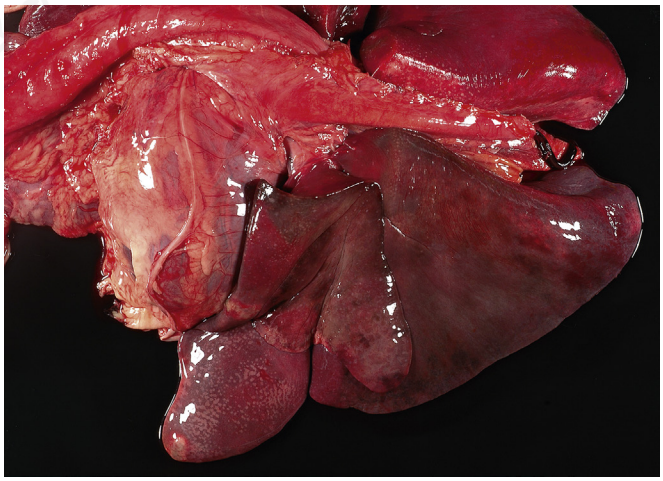

Fig. 53.3 Lungs of an 11-year-old intact male German shepherd dog with severe, acute, suppurative, necrotizing, and hemorrhagic bronchopneumonia due to *Klebsiella pneumoniae* infection. The lung lobes are severely congested. Five days before death, multiple laminectomies had been performed for intervertebral disc disease, and 2 days later the dog developed aspiration pneumonia that necessitated mechanical ventilation. Euthanasia was elected when there was further deterioration in the dog's condition, and bloody exudate was present in the endotracheal tube just before euthanasia.

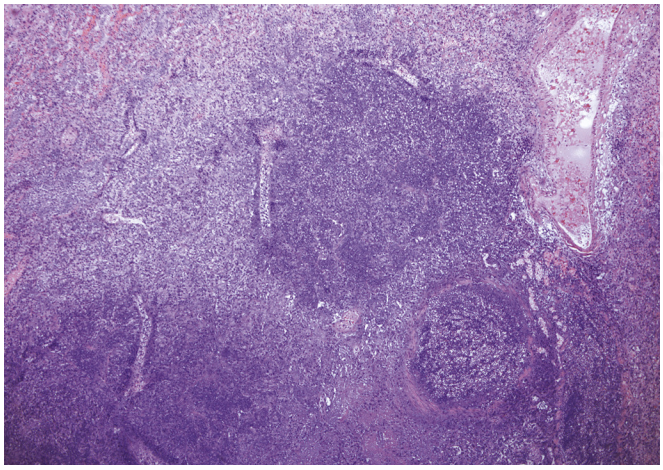

Fig. 53.4 Histopathology of the lung from a 4-month-old intact male Newfoundland dog with severe, multifocal, necrotizing lung abscesses. Intralesional rod-shaped bacteria were also present. *Klebsiella pneumoniae* was isolated from the lesions. Hematoxylin and eosin stain, 40× magnification.

genes that encode ESBLs are often located on plasmids that also contain genes for aminoglycoside resistance. Although MDR *K. pneumoniae* are not uncommonly isolated from dogs and cats, ESBL-producing *K. pneumoniae* isolates are rarely encountered but have recently been isolated from veterinary specimens in Switzerland.[52] Treatment options for MDR *K. pneumoniae* may be limited to aminoglycosides, carbapenems, and sometimes trimethoprim-sulfamethoxazole.

Serratia marcescens

Serratia marcescens is an important cause of nosocomial infections in both human and veterinary medicine. In human patients, infections with *S. marcescens* are often linked to IV drug use. The organism has a tremendous ability to survive in the environment and may contaminate and remain viable in disinfectant solutions.[53] It has been isolated from saline vials used in a multiple-dose fashion to dilute drugs in a veterinary hospital.[54] It sometimes grows as a contaminant, such as in blood cultures. Some, but not all, strains of *S. marcescens* produce a red pigment when grown in culture.[55]

In dogs, *S. marcescens* infection has been associated with UTIs, bacteremia and aortic valve endocarditis,[56] catheter-related infections in canine parvoviral enteritis,[43] and necrotizing fasciitis.[57] Contamination of blood products was linked to an outbreak of bacteremia in cats.[58] It has also caused severe necrosuppurative myositis in a young cat.[59] *Serratia* is resistant to ampicillin and first-generation cephalosporins as a result of a chromosomal β-lactamase. It may also acquire plasmid-mediated resistance to other antimicrobial drugs.

Enterobacter

Enterobacter cloacae and, to a lesser extent, *Enterobacter aerogenes* represent the majority of *Enterobacter* species isolated from clinical specimens from dogs and cats.[60] *Enterobacter* spp. are mainly isolated from dogs and cats with UTIs but occasionally cause wound or catheter-related infections and have been isolated from samples from the ear, skin, and eye.[60] They generally are intrinsically resistant to ampicillin and first-generation cephalosporins and may also be resistant to multiple other antimicrobial drug classes.

Citrobacter

Citrobacter species are named for their ability to use citrate as a sole carbon source. *Citrobacter freundii* is most commonly isolated from dogs and cats with UTIs but can also cause catheter-related infections, bacteremia, and endocarditis.[61,62] *Citrobacter koseri* was isolated from puppies with myocarditis.[63] Like *Enterobacter* and *Serratia, Citrobacter* are usually resistant to ampicillin and first-generation cephalosporins and may acquire a number of plasmid-mediated resistance genes, including those that encode ESBLs and resistance to fluoroquinolones.

Non-Enterobacterales

Pasteurella

Pasteurellaceae are small, fastidious, nonmotile bacilli or coccobacilli that are commensals of the oral cavities and upper respiratory tracts of dogs and especially cats. The most common species of *Pasteurella* associated with disease in dogs and especially cats is *P. multocida*. Other species include *Pasteurella canis, Pasteurella dagmatis,* and *Pasteurella stomatis. Pasteurella* spp. have been associated with a wide variety of disease manifestations that include pyothorax, upper respiratory tract infections (usually secondary to viral infections or chronic rhinosinusitis), bronchopneumonia, UTIs, ocular surface infections, wound infections, cutaneous abscesses, otitis externa, bacteremia, and, rarely, infective endocarditis. They may be found in mixed infections with other bacteria, such as *Streptococcus canis,* other gram-negative bacteria, or anaerobes. In humans, they are an important cause of animal bite wound infections.[4,64] *Pasteurella* spp. are usually broadly susceptible to antimicrobial drugs, and the treatment of choice is a penicillin such as penicillin G, ampicillin, or amoxicillin.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is the main pathogenic species in the family Pseudomonadaceae. It is known for its ability to produce a variety of pigments when grown in culture, such as pyocyanin (blue), pyorubin (red), pyomelanin (black), and pyoverdin (yellow-green to yellow-brown and fluorescent), and for its characteristic "corn taco" or "grape"-like odor (Fig. 53.5B and C). *Pseudomonas aeruginosa* has one polar flagellum and is covered in thin, hair-like pili (Fig. 53.6). It can

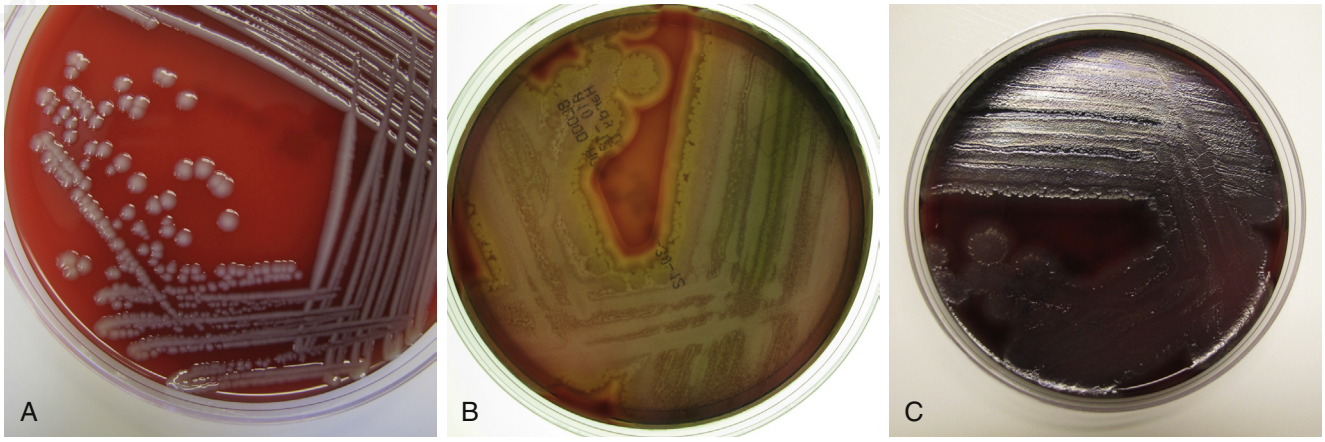

Fig. 53.5 Gram-negative aerobic bacteria growing on blood agar. (A) Mucoid colonies of *Klebsiella pneumoniae*. (B) *Pseudomonas aeruginosa*. Transillumination using a light box revealed the presence of hemolysis and production of a green pigment (pyoverdin). (C) The plate in (B) had a fruity odor and a "mother-of-pearl" appearance when not transilluminated.

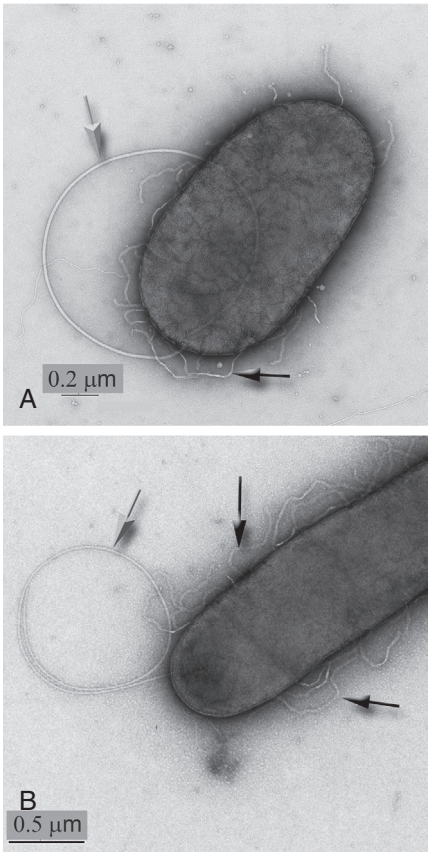

Fig. 53.6 Transmission electron micrograph image of Pseudomonas aeruginosa showing polar flagellum (gray arrows). (From Zaborina A, Holbrook C, Chen Y, et al. Structure-function aspects of PstS in multi-drug-resistant *Pseudomonas aeruginosa*. *PLoS Pathogens*. 2008;4:e43.)

also produce an extracellular polysaccharide known as *alginate,* which results in a mucoid colony appearance.

Pseudomonas aeruginosa is widespread in the environment and can grow in a huge variety of different conditions, reflecting its importance as a nosocomial pathogen. It is commonly found on plants, water, and soil. It can survive in disinfectants and grow in diesel and jet fuel. It is occasionally isolated from the skin, mucous membranes, and feces of healthy animals and humans. Almost any site of the body that is subject to injury can become colonized and subsequently infected. In humans, community-acquired infections can occur as a result of exposure to contaminated hot tubs, swimming pools, and contact lens solutions. In the hospital environment, *P. aeruginosa* often colonizes moist environments such as sinks, endotracheal tubes, and ventilator equipment. It also colonizes damp, macerated tissues such as the ear canals, damaged cornea, traumatized skin (such as wounds and burns), and the interdigital space. Because the organism can be resistant to a large number of different antimicrobial drugs, repeated treatment of secondary bacterial infections in sites where impaired host defenses exist with a variety of antimicrobials can select for MDR *P. aeruginosa* infection at these sites. Examples of such conditions in dogs and cats include recurrent aspiration pneumonia and/or bronchiectasis, cystitis, prostatitis, chronic feline rhinosinusitis, and otitis externa/media.

Pseudomonas aeruginosa possesses virtually every type of bacterial virulence factor, including exotoxins, a type III secretion system, LPS, pili, flagella, several proteases, phospholipases, iron-scavenging mechanisms such as pyoverdin production, and the ability to form extensive biofilms. Alginate protects the organism from phagocytosis, and the pigment pyocyanin produces reactive oxygen species, which in turn damage host cells. Multidrug resistance results from the production of specific β-lactamase enzymes (which can include ESBLs), antibiotic efflux pumps, enzymes that modify aminoglycosides or alter antibiotic-binding sites (such as DNA gyrase for fluoroquinolones), and decreased bacterial permeability.

Infections with broadly susceptible *P. aeruginosa* isolates could be treated with an antipseudomonal β-lactam (e.g., piperacillin, a carbapenem, cefepime, ceftazidime) alone or in combination with an aminoglycoside or a fluoroquinolone. As the MIC of most *P. aeruginosa* isolates is often closer to the breakpoint for fluoroquinolones than it is for other gram-negative organisms, it is wise to use the higher end of the dose range for fluoroquinolones with flexible dosing options.[65] The combination of an aminoglycoside and an antipseudomonal penicillin has synergistic activity against some *P. aeruginosa* infections. Currently, most MDR *P. aeruginosa* isolates from dogs and cats remain

susceptible to carbapenems (such as meropenem) and aminoglycosides (especially amikacin), and so the usual treatment of choice is: (1) a combination of these two drugs, (2) removal of any foreign or necrotic material and, (3) if possible, resolution or management of any other underlying cause for impaired host defenses. Because parenterally administered aminoglycosides do not effectively penetrate airway mucus, nebulized tobramycin has been used to treat resistant *P. aeruginosa* infections of the airways in human patients, but these may not adequately penetrate consolidated lung tissue and the use of inhaled aminoglycosides is not recommended in the most recent guidelines for antimicrobial use in respiratory infections due to lack of evidence.[66] Effective treatment of MDR *P. aeruginosa* infections when they occur in locations such as the feline nasal cavity may be extremely difficult, if not impossible, because of irreversible turbinate loss, the requirement for injectable antimicrobial drugs, poor penetration of aminoglycosides to the site of infection, and an inadequate ability to effectively treat all surfaces of the nasal cavity with topical aminoglycosides.

Investigation of suspected nosocomial outbreaks of *P. aeruginosa* infection generally requires typing of isolates from affected animals and the environment with molecular methods such as pulsed-field gel electrophoresis or multilocus sequence typing. Use of antibiograms alone does not adequately discriminate between strains.

Acinetobacter

Like *P. aeruginosa*, *Acinetobacter* is an important nosocomial opportunistic pathogen. *Acinetobacter* is present in soil and water and can be found in frozen foods, pasteurized milk, and an enormous array of inert objects in the hospital environment, where it may persist for months. It colonizes the skin and mucous membranes of healthy humans as well as those of dogs and cats.[67,68] The main species that cause disease in animals are *A. baumannii* and, to a lesser extent, *Acinetobacter lwoffii* and *Acinetobacter calcoaceticus*. MDR isolates of *A. baumannii* have been responsible for outbreaks of nosocomial infections in veterinary hospitals[69,70] and, like MDR *P. aeruginosa*, may be resistant to a wide variety of antimicrobial drug classes. Carbapenem-resistant *A. baumannii* have been isolated from humans as well as animals.[70,71] Clinical manifestations of *Acinetobacter* infections in dogs and cats include nosocomial UTIs (e.g., after invasive urinary procedures such as catheterization), surgical wound infections, pneumonia, catheter-related bacteremia, and, rarely, endocarditis. Necrotizing fasciitis associated with *A. baumannii* infection was described in a cat.[72] When *Acinetobacter* is grown from a specimen, care should be taken to differentiate infection from contamination. Most veterinary isolates are susceptible to aminoglycosides and carbapenems; some are susceptible to trimethoprim-sulfamethoxazole and fluoroquinolones.[69]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

Dogs and cats with superficial gram-negative infections of sites that drain to the exterior, such as wounds, the external ear canal, the nasal cavity, and the lower urinary tract, often have no clinically significant laboratory abnormalities. Deep tissue or systemic infections with gram-negative bacteria may be associated with marked neutrophilia and a left shift, toxic neutrophils, or a degenerative left shift, sometimes with circulating metamyelocytes. Thrombocytopenia may be present in dogs and cats that develop disseminated intravascular coagulation (DIC). Anemia of inflammatory disease, lymphopenia, and monocytosis may be present. The urinalysis of dogs and cats with gram-negative bacterial UTIs may reveal pyuria, proteinuria, hematuria, and sometimes bacterial rods on sediment examination.

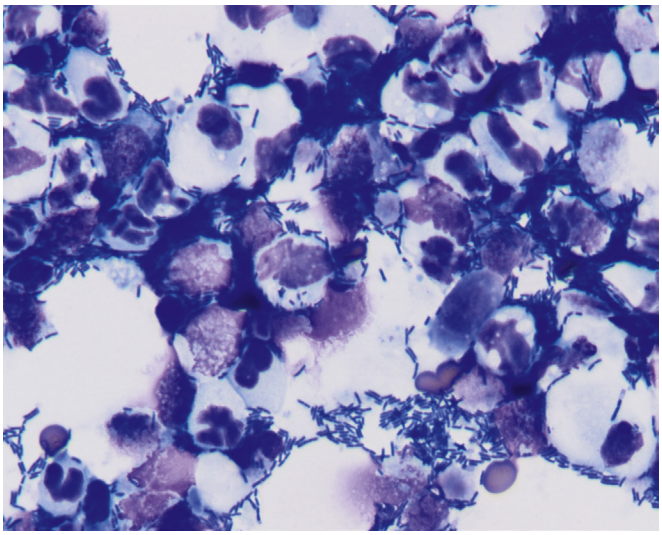

Fig. 53.7 Cytospin preparation of abdominal fluid from a dog with a traumatic bladder rupture and a concurrent *Escherichia coli* urinary tract infection. Note the numerous intracellular and extracellular blue-staining rod-shaped bacteria as well as numerous neutrophils and less abundant monocytes and macrophages. Diff-Quik stain, 1000x magnification. (Photo courtesy of Dr. Patricia Ewing, Angell Animal Medical Center.)

Clotting Function

Systemic gram-negative bacterial infections may be associated with evidence of DIC due to activation of the coagulation cascade by endotoxin. Elevations in PT, APTT, D-dimers, and reduced or falling platelet counts are common in DIC. Viscoelastic coagulometry (thromboelastography or thromboelastometry) in animals with sepsis often reveals a hypercoagulable state most noticeable in the maximum amplitude or maximum clot formation value, although in dogs with septic peritonitis (which commonly involves gram-negative infections), it was found that nonsurvivors were less likely to be hypercoagulable.[73]

Microbiologic Tests

Cytologic Diagnosis

The presence of rod-shaped bacteria on cytologic examination of Wright-Giemsa or Diff-Quik-stained smears of affected tissue aspirates, lavage fluid or purulent exudate suggests presence of a gram-negative organism in most cases of infection in the dog and cat, with Gram stain being confirmatory (Fig. 53.7). Large numbers of degenerate and/or nondegenerate neutrophils and lilac debris that suggests necrosis may be observed.

Isolation and Identification

Gram-negative bacteria are readily isolated from aspirates, tissue biopsies, body fluids, blood, and lavage specimens. MacConkey and blood agar are usually used to isolate gram-negative bacteria, which usually grow within 24 to 48 hours. *Pasteurella* spp. are more fastidious, and species that infect dogs and cats do not grow on MacConkey agar. Isolated organisms are traditionally then identified based on colony morphology and biochemical reactions. MALDI-TOF permits identification of rapid identification of organisms at the first sign of growth to the species level, and has the potential to rapidly identify genetic elements conferring resistance and thus informing antibiotic selection 24 to 48 hours before susceptibility results are available. Evaluation of antimicrobial susceptibility is important for all Enterobacterales, *P. aeruginosa*, and *Acinetobacter* spp., given their propensity to develop resistance to many antimicrobial drug classes.

TABLE 53.1 Examples of Systemic Antimicrobial Drugs That Could Be Selected for Treatment of Gram-Negative Bacterial Infections in Dogs and Cats

Infecting Species	Drug	Dose (mg/kg)	Interval (Hours)	Route
Pasteurella	Amoxicillin	20	8	PO
	Ampicillin	20	6–8	IV, IM, SC
	Penicillin G	20,000–40,000 U/kg	6–8	IV, IM
Susceptible Enterobacterales	Trimethoprim-sulfamethoxazole	30	12	PO, IV
	Amoxicillin–clavulanate potassium	20	8	PO
	Enrofloxacin	10–20	24	PO, IM, IV
MDR Enterobacterales, *Pseudomonas*, or *Acinetobacter*	Amikacin[a]	D: 15–30 C:10–14	24	IV, IM, SC
	Gentamicin[a]	D: 9–14 (dogs) C:5–8 (cats)	24	IV, IM, SC
	Piperacillin-tazobactam	50 Life-threatening infections: 4 mg/kg loading dose followed by 3.2 mg/kg/h IV	6 or constant rate infusion	IV
	Meropenem	12–25	88	SC, IV
	Ceftazidime	30	6	IV

[a]Use aminoglycosides in combination with an antipseudomonal β-lactam such as piperacillin, meropenem, or a third-generation cephalosporin.
C: cats; *D*: dogs; *IM,* intramuscular; *IV,* intravenous; *MDR,* multidrug resistant; *PO,* oral; *SC,* subcutaneous.

TREATMENT AND PROGNOSIS

The approach to treatment of gram-negative infections depends on patient history, the site of infection, and the severity of disease (Table 53.1). Identification and management of the underlying cause are also important to minimize selection for resistant organisms. Any foreign material (such as catheters or implants) must be removed, and necrotic tissue debrided. Biofilm-producing bacteria are more likely to be associated with deep tissue and bone infections, and higher doses and longer duration of therapy should be considered if biofilm is suspected.[74] When systemic antimicrobial drug treatment is required, it should preferably be based on the results of susceptibility testing. In cases of life-threatening infection, it is impractical to wait until such results return to commence therapy. Previous antibiotic therapy may select for resistant organisms and, given the ability of gram-negative organisms to rapidly acquire both multidrug resistance and virulence, a thorough consideration of the expectation of resistance is warranted prior to antibiotic selection. First, a thorough history which includes all antibiotics the patient has received in the last 6 months should be obtained, and inquiry into antibiotic use in co-habitating animals and humans is also reasonable. Avoidance of drugs of the same class as used previously is reasonable, especially in life-threatening infections. Second, consideration of whether the infection could be hospital acquired is indicated. A hospital-acquired infection should be considered if the patient shows signs of infection after admission to the hospital or within 2 to 3 days after discharge form the hospital. Additionally, if the region of infection was associated with a procedure or invasive device (i.e., signs of UTI after urinary catheterization), hospital-acquired organisms should be suspected. In such cases, treatment should also be based on knowledge of local resistance patterns among gram-negative bacteria, which may vary from region to region and practice to practice.

Pasteurella spp. are generally susceptible to penicillin or aminopenicillins such as amoxicillin. Because gram-negative bacteria have higher MICs to penicillins than do gram-positive bacteria, the high end of the dose range and more frequent administration may be necessary. In cases of severe infections, for time-dependent drugs of short half-life, a continuous infusion may be indicated at least for the first 2 to 3 days to allow drug concentrations to remain above the target MIC for 100% of the dosing interval. Some Enterobacterales are intrinsically resistant to ampicillin and first-generation cephalosporins, and initial treatment of serious infections while awaiting the results of susceptibility testing should include an aminoglycoside, a third-generation cephalosporin, or a fluoroquinolone. Trimethoprim-sulfamethoxazole, amoxicillin, or clavulanic acid–amoxicillin are reasonable initial choices for treatment of UTIs associated with bacterial rods.[75]

PREVENTION

Prevention of gram-negative infections involves resolution of impairment in host defenses and strict hospital infection control practices (see Chapter 15).

PUBLIC HEALTH ASPECTS

Strains of *E. coli* and other MDR gram-negative bacteria harbored by dogs resemble pathogenic strains isolated from humans.[44,71] As a result, concern has been raised that companion animals may be a source of organisms for human infection, especially those that reside with humans with compromised host defenses. It has been suggested through genomic sequencing of *phylogenetic group B2* infections in humans and companion animals that cats and dogs may be a spillover host for MDR *E. coli* (meaning pets are exposed to these strains by their owners but then the organism persists in the companion animal).[76,77]

Pasteurella multocida is the most commonly isolated organism from human dog and cat bite wounds.[4] *Pasteurella* spp. can also colonize the respiratory tracts of humans with underlying respiratory disease such as bronchiectasis or chronic sinusitis, and they occasionally have been reported in association with peritonitis, bacteremia, and endocarditis. Most of these humans have had contact with domestic animals in the household, and isolates from affected humans have been shown by molecular methods to be identical to those colonizing animals in the household.[78]

Thus, immunocompromised owners or those with impaired anatomic barriers should be instructed to wash their hands after handling their pet and perform regular household cleaning and disinfection. Companion animals should not be allowed to lick open wounds, the region that surrounds healing surgical incisions, or the owner's face.

CASE EXAMPLE

Signalment

"Lottie," a middle-aged, female spayed domestic shorthair from northern California.

History

Lottie was evaluated for chronic nasal discharge. Since her rescue as a stray 2.5 years earlier, intermittent sneezing and bilateral mucopurulent nasal discharge had been noted, and the discharge sometimes contained blood. Ten months before the evaluation, Lottie had been anesthetized for a nasal flush at a local veterinary clinic, but developed respiratory distress on recovery and was hospitalized with oxygen supplementation for 24 hours. She was ataxic, leaned to one side, and did not eat well for days, but over the subsequent months the ataxia and leaning gradually resolved. For the 2 weeks before the evaluation, Lottie had stertorous respiration and intermittent episodes of open-mouth breathing. For the past 9 months, Lottie had been treated with marbofloxacin and prednisolone. Before that, treatments for the nasal discharge included clavulanic acid–amoxicillin, doxycycline, or azithromycin, as well as L-lysine supplementation. Lottie lived with six other cats, all of which had access to the outdoors, and she was fed commercial canned and dry cat food. The FeLV and FIV status of these cats was unknown.

Current medications: marbofloxacin (5 mg/kg PO q24h) and prednisolone (1 mg/kg PO q24h).

Physical Examination

Body weight: 4 kg.

General: Bright, alert and responsive, hydrated. T = 100.3°F (37.9°C), HR = 220 beats/minute, purring, BCS 7/9.

Eyes, ears, nose, and throat: Mucopurulent nasal discharge was present that was most profuse on the left side. Nasal airflow was absent on the left side. Mild dental calculus was present, but there were no oral masses or ulceration.

Respiratory: An inspiratory stertor was present, and referred upper airway noises were detected on auscultation of the thorax.

Cardiovascular, GI and genitourinary, and lymph nodes: No clinically significant abnormalities were detected. It was difficult to palpate abdominal structures due to the presence of abdominal fat.

Neurologic examination: There was a mild, intermittent, left-sided head tilt. No other abnormalities were detected on full neurologic examination.

Laboratory Findings

CBC: HCT 39.1% (30–50%), MCV 44.7 fL (42–53 fL), MCHC 29.9 g/dL (30–33.5 g/dL), reticulocytes 111,400 cells/μL (7,000–60,000 cells/μL), WBCs 21,210 cells/μL (4,500–14,000 cells/μL), neutrophils 16,713 cells/μL (2,000–9,000 cells/μL), lymphocytes 4,115 cells/μL (1,000–7,000 cells/μL), monocytes 297 cells/μL (50–600 cells/μL), eosinophils 64 cells/μL (150–1,100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 316,000/μL (180,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 151 mmol/L (151–158 mmol/L), potassium 3.7 mmol/L (3.6–4.9 mmol/L), chloride 113 mmol/L (117–126 mmol/L), bicarbonate 19 mmol/L (15–21 mmol/L), phosphorus 5.8 mg/dL (3.2–6.3 mg/dL), calcium 10.2 mg/dL (9.0–10.9 mg/dL), BUN 49 mg/dL (18–33 mg/dL), creatinine 1.4 mg/dL (1.1–2.2 mg/dL), glucose 128 mg/dL (63–118 mg/dL), total protein 8.7 g/dL (6.6–8.4 g/dL), albumin 3.6 g/dL (2.2–4.6 g/dL), globulin 5.1 g/dL (2.8–5.4 g/dL), ALT 33 U/L (27–101 U/L), AST 21 U/L (17–58 U/L), ALP 36 U/L (14–71 U/L), GGT 0 U/L (0–4 U/L), cholesterol 192 mg/dL (89–258 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.044, pH 6, 75 mg/dL protein, no glucose, bilirubin or ketones, 250 erythrocytes/μL hemoprotein, >100 RBC/HPF (traumatic cystocentesis), 0–1 WBC/HPF.

Imaging Findings

Thoracic radiographs: Cardiovascular structures were within normal limits. There was a small amount of air in the cervical esophagus (likely due to aerophagia) and a mild diffuse bronchointerstitial pattern that was attributed to an obese body condition.

Skull computed tomography scan: Contiguous transverse 0.6-mm collimated images of the skull were available for review without contrast administration. There was moderate turbinate destruction of both right and left nasal passages with lobular soft tissue attenuating material present along their length (Fig. 53.8A). There was stenosis of both frontal sinuses to the point where the left frontal sinus was completely occluded. The right frontal sinus was almost completely filled with soft tissue attenuating material. The ear canals were within

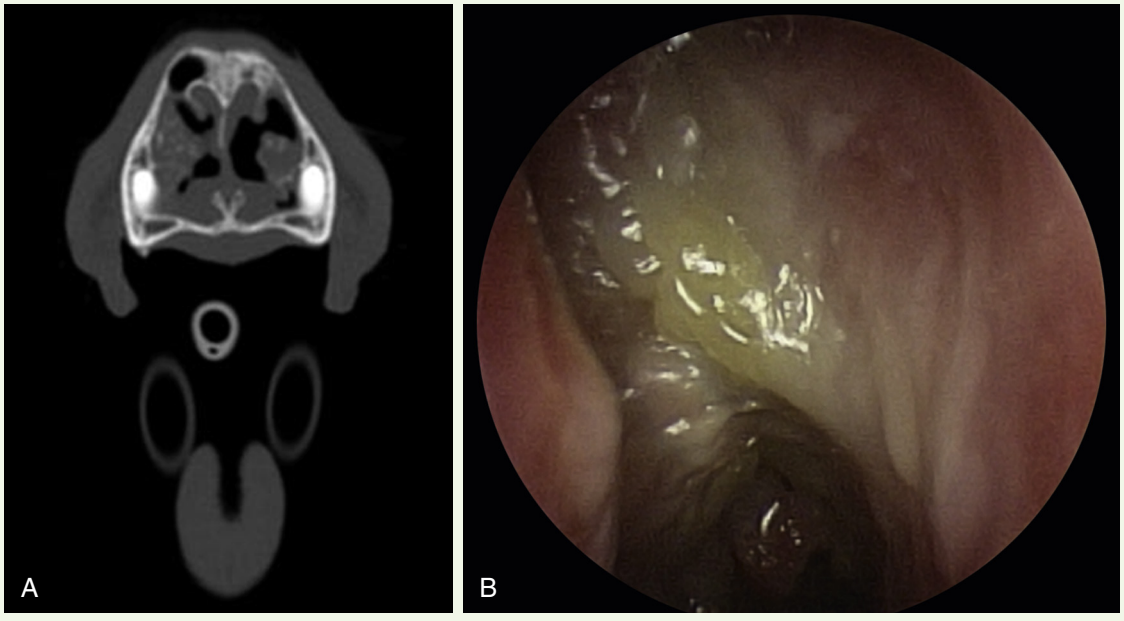

Fig. 53.8 Nasal cavity of a middle-aged, female spayed domestic shorthair with chronic rhinosinusitis and secondary infection with multidrug-resistant *Pseudomonas aeruginosa*. (A) Computed tomographic scan showing destruction of the turbinates of the left and right nasal passages. (B) Rhinoscopic findings included severe turbinate destruction, hyperemia, and accumulations of thick green mucus.

Continued

CASE EXAMPLE—cont'd

normal limits bilaterally. The mandibular lymph nodes were prominent but symmetrical.

Rhinoscopy: Severe turbinate destruction with diffuse hyperemia and large accumulations of inspissated green mucus was present throughout the nasal passages (Fig. 53.8B). Several biopsies of the right and left nasal cavities were obtained for histopathology.

Microbiologic Testing

Aerobic bacterial culture and *Mycoplasma* culture (nasal brush specimen): a direct smear showed moderate numbers of neutrophils, but no organisms were seen. Moderate numbers of *P. aeruginosa* were isolated. The *P. aeruginosa* was resistant to amoxicillin–clavulanic acid, ampicillin, cefazolin, cefovecin, cefoxitin, cefpodoxime, ceftiofur, chloramphenicol, doxycycline, enrofloxacin, marbofloxacin, ticarcillin, ticarcillin–clavulanic acid, and trimethoprim-sulfamethoxazole. It was susceptible only to amikacin (≤4 μg/mL), gentamicin (2 μg/mL), and imipenem (≤1 μg/mL).

Histopathology of Nasal Biopsy Specimens

The submucosa was markedly expanded and multifocally effaced by sheets of lymphocytes and plasma cells, with neutrophils and fewer numbers of mast cells surrounding irregular spicules of woven bone extending from primary turbinates. Less affected sections contained similar, predominately lymphoplasmacytic infiltrates that separated submucosal glands and elevated the superficial epithelium. Pathologic diagnosis: severe, chronic, and extensive lymphoplasmacytic and neutrophilic rhinitis with turbinate remodeling.

Diagnosis

Feline chronic rhinosinusitis with suspected opportunistic MDR *P. aeruginosa* infection.

Treatment and Outcome

The nasal cavity was lavaged. The prednisolone was tapered over 1 week, then discontinued, and 7 days later, treatment with piroxicam was commenced (0.3 mg/kg, PO, q24h for 7 days, then q48h thereafter). Other medications discussed with the owner were *N*-acetylcysteine and intranasal gentamicin drops, but the prognosis given for disease resolution was poor.

Comments

The underlying cause of feline chronic rhinosinusitis is poorly defined, but infection of kittens with respiratory viruses such as FHV-1 is suspected to play a role. Severe turbinate destruction predisposes to secondary opportunistic infections with a variety of bacteria, which include staphylococci, *Bordetella bronchiseptica, S. canis, Mycoplasma* spp., *E. coli, P. multocida,* and *P. aeruginosa.* In this cat, selection for MDR *P. aeruginosa* likely resulted from repeated and chronic use of a variety of antimicrobial drugs. The reticulocytosis and increased serum BUN concentration likely was secondary to chronic epistaxis and swallowed blood. The cat's neurologic signs and head tilt were thought to be due to peripheral vestibular disease, possibly due to otitis media, but there was no evidence of middle ear disease on the CT scan.

Anaerobic Bacterial Infections

Dubraska Diaz-Campos, Jenessa A. Winston, Jane E. Sykes

KEY POINTS

- First Described: 1860s (Louis Pasteur).[1]
- Causes: *Bacteroides*, *Prevotella*, *Porphyromonas*, *Peptostreptococcus*, *Fusobacterium*, *Clostridium*, *Actinomyces*, *Propionibacterium*, other species.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Abscess formation in a variety of tissues, pyothorax, peritonitis, pyometra, periodontal disease, osteomyelitis, bacteremia.
- Differential Diagnoses: Bacterial infections caused by gram-positive and gram-negative aerobes.
- Human Health Significance: Anaerobes of the oral cavity of dogs and cats are an important component of animal bite wound infections in humans.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Anaerobic infections are of great importance in human and veterinary medicine. Although anaerobic bacteria were discovered in the middle of the nineteenth century, the identification and isolation of these microorganisms were, and still are, a challenge. Obligate anaerobes are defined as microorganisms that require a reduced oxygen tension for growth and fail to form colonies on the surface of solid media in 10% CO_2, in air (18% oxygen).[2] They cannot grow in the presence of molecular oxygen because anaerobes do not make superoxide dismutase, and most do not produce catalase. These enzymes are necessary for the breakdown of reactive oxygen intermediates (e.g., superoxide anion, hydrogen peroxide) that are normally generated when bacteria grow in the presence of oxygen.[3] Species of obligate anaerobic bacteria and their morphology on Gram-stained smears are described in Table 54.1.

Normal host microbiota is responsible for a significant portion of innate immunity; however, some of these microorganisms also have the potential to become important opportunistic pathogens.[4,5] Anaerobes exist in the environment and make up a significant portion of the normal microbiota of dogs and cats.[6–9] The predominant microorganisms that colonize most mucosal surfaces are anaerobes, and metabolic by-products produced by this group are important in the regulation of the numbers of aerobic species (facultative and obligate) that also make up the normal microbiota. Thus, anaerobic bacteria play an important role in protection of mucosal surfaces from interactions involving other microorganisms with pathogenic potential.[7] For example, approximately 1 million salmonellae are needed to produce disease in animals with intact anaerobic gut microbiota, whereas fewer than 10 salmonellae are needed to produce disease in animals with few anaerobes. The importance of this observation is seen clinically; dogs are more susceptible to salmonellosis when they are medicated with antimicrobials, especially those effective in reducing the anaerobic component of the normal gut microbiota (e.g., ampicillin).[10]

Compromise of a mucosal surface or an adjacent area by perforation or other trauma may provide a portal of entry for the normal anaerobic microbiota into a normally sterile site. At this point, anaerobes and other members of the normal microbiota become opportunistic pathogens. These are important considerations because, to effectively prevent anaerobic infection, antibacterial therapy is commonly started before results of microbiologic analysis of collected clinical specimens are received. Knowledge of the normal microbiota at a specific site helps in making an educated guess about the microorganisms likely to be causing the infection. If anaerobic bacteria are involved in an infectious process, on average, two different species are almost always present with aerobic bacteria. The most commonly associated aerobic bacteria are enterics (mainly *Escherichia coli*), and members of the genus *Pasteurella, Staphylococcus* spp. and *Enterococcus* spp.[11]

If anaerobic bacteria possess appropriate virulence factors, they may also cause mucosal disease. In addition to periodontal disease, anaerobes are associated with disease in other regions of the GI tract; the most important of these anaerobes within the intestine are *Clostridioides difficile* (previously *Clostridium difficile)* and *Clostridium perfringens* (see Chapter 64).[12,13] Both of these species may be a part of the normal gut microbiota of dogs and cats, although evidence suggests that both may be passed to previously uncolonized animals.[14–16]

In human patients, infectious processes involving structures above the diaphragm are more likely to contain anaerobes originating in the mouth, whereas disease below the diaphragm usually involves anaerobes from the intestinal tract.[17] In dogs and cats, anaerobic bacteria are indigenous in different body sites. *Actinomyces* spp., *Porphyromonas* spp., and *Fusobacterium* spp. are the most prevalent genera of anaerobic bacteria in the oral microbiota of dogs.[6,9] In humans and in animals, bite wounds are frequently associated with polymicrobial infections with a component of anaerobic bacteria.[6,18]

The GI tract is loaded with a myriad of microorganisms, including anaerobic bacteria. Members of the order Clostridiales such as *C. perfringens* and *C. difficile* are also considered normal gut microbiota in dogs and cats. *Bacteroides* spp. and *Fusobacterium* spp. among other anaerobes are also found in the GI tract.[6,15,16,19–21]

Disease produced by *C. difficile* is the result of its proliferation in the enteric tract of the host after a trigger event (e.g., certain antimicrobial and chemotherapeutic agents). Epidemiologic evidence from human hospitals suggests that the agent can be spread from patient to patient, which results in outbreaks of *C. difficile*–associated disease.[22] Such observations imply that the organism either is, or has the

TABLE 54.1 Obligate Anaerobic Bacteria Most Commonly Isolated from Dogs and Cats, Source, and Gram-Stain Morphology

Microorganism	Source	Morphology
Gram-negative bacilli		
Bacteroides spp.	Important component of gut, genital tract, and other mucosal microbiota of mammals. Primarily cause abdominal infections, but also infections in different body sites	Pale rod
Porphyromonas spp.	In dogs and cats, part of the normal oral microbiota. Associated with periodontal disease and other conditions	Pale rod (coccobacillus)
Prevotella spp.	Indigenous microbiota in mucosa and gastrointestinal tract; associated with a variety of suppurative conditions	Pale rod (pairs or short chains)
Fusobacterium spp.	Normal oral and gut microbiota in mammals. In dogs and cats, *Fusobacterium* spp. have been associated with infections in body sites such as the bone, liver, gallbladder, among others	Negative (pale) Rod, usually thin
Gram-positive, non–spore-forming bacilli		
Actinomyces spp.	Colonize the oral cavity and gastrointestinal tract. After a break in the mucocutaneous barrier, infections occur in the oral cavity (abscesses) and other organs. *Actinomyces* spp. are frequently associated with bite wound infections	Positive Rod
Cutibacterium acnes (*Propionibacterium acnes*)	Skin and mucosal commensal. This is not considered an important pathogen and it is a contaminant in cultures	Positive Rod
Gram-positive cocci		
Peptostreptococcus spp.	Gastrointestinal tract, upper respiratory tract, urogenital tract, and skin of mammals. *Peptostreptococcus* have been linked to infections in multiple body sites.	Positive Cocci
Gram-positive, spore-forming bacilli		
Clostridium and *Clostridioides* spp.	Only species of this genus form endospores anaerobically. *Clostridium perfringens* produces enterotoxins, producing diarrhea or enterotoxaemia. Some strains are histotoxic and cause tissue infections (e.g., gas gangrene). *Clostridioides difficile* has been related to diarrhea in dogs and cats. Both microbes are considered normal inhabitants of the gastrointestinal tract in mammals. Other clostridiales are etiologic agents of infections in different body sites.	Positive Rod (spores)

potential to be, contagious. Determining whether *C. difficile* is truly a contagious pathogen is difficult because it is so prevalent in the enteric tract of clinically healthy animals.[12,15,16] There is evidence that the canine claw bed and nasal cavity can be colonized by toxigenic *C. difficile*; thus, they could disseminate this microorganism or its spores between households and environment and potentially contribute to community-relevant sources for *C. difficile* infection in humans.[15,23–25]

Although *C. perfringens* is commonly associated with GI infections, it has also been implicated in other clinical conditions in dogs and cats.[26,27] It is unclear whether toxigenic *C. perfringens* is contagious. It likely causes disease when it proliferates in the intestinal tract and produces enterotoxin. Novel pore-forming toxin genes (*netE* and *netF*) were identified in a *C. perfringens* type A strain associated with acute hemorrhagic diarrhea in dogs and foals.[28–30] Factors that stimulate proliferation of *C. perfringens* are unknown. It must also be determined whether the source of the agent is endogenous, acquired from another infected animal, or acquired from the environment. The report of outbreaks of *C. perfringens*–associated diarrhea in small animal hospital settings suggests that it may be contagious, although it is important to remember that some *C. perfringens* are present in the enteric tract of clinically healthy dogs.[13,31,32] Detectable levels of *C. perfringens* enterotoxin are not often found in the feces of clinically healthy animals.[33]

Bacteroides spp. represent an important component of the microbiome in dogs and cats.[34] In particular, *Bacteroides fragilis* frequently cause anaerobic infections in dogs and cats, often associated with the GI tract and abdominal fluid, body organs (lung, liver, kidney), abscesses, and subcutaneous tissues.[26,27,34] The genus *Fusobacterium* is also an important component of the oral mucosal and GI normal microbiota.[34,35] *Fusobacterium canifelium* is common in the oral cavity of dogs and cats and has been isolated from dog and cat bite wounds in humans.[36] Unfortunately, this organism is typically resistant to quinolones, unlike human isolates. Data compiled from 4,333 anaerobic cultures submitted to 10 institutions showed that *Clostridium*, *Bacteroides*, and *Peptostreptococcus* spp. were the three most frequently isolated species of obligate anaerobes from dogs and cats (Table 54.2).

Pathogenesis

Most commonly, obligate anaerobic bacteria cannot live in healthy tissue. On certain mucosal surfaces (e.g., intestinal tract, gingival crevices, genital tract), they live with other microorganisms (facultative anaerobes) that scavenge molecular oxygen, which generates a local environment with very low redox potential (E_h, a measure of oxygen tension). Likewise, in compromised tissue, inflammatory cells and coinoculated aerobic microorganisms lower E_h sufficiently for anaerobes to grow. Factors that predispose to anaerobic infections are shown in Box 54.1.

Components of anaerobic bacteria elicit potent inflammatory responses. Gram-negative anaerobes possess LPS with endotoxic activity. The peptidoglycan of gram-positive anaerobes incites the same inflammatory response as gram-positive aerobic microorganisms. Some anaerobic bacteria have capsular antigens (e.g., *B. fragilis*, pigmented *Prevotella* spp., and *Porphyromonas* spp.), which incite inflammatory responses that result in abscess formation; capsules without viable bacteria can also induce abscess formation.[17,19,37] Some evidence

TABLE 54.2 Bacterial Species Isolated in Anaerobic Cultures from Dogs and Cats

Organism	Number of Positive Anaerobic Cultures[a,b](%)
Clostridium spp.	1,332 (21.4)
Bacteroides spp.	1,202 (19.3)
Peptostreptococcus spp.	517 (8.3)
Fusobacterium spp.	501 (8.1)
Propionibacterium spp.	219 (3.5)
Prevotella spp.	217 (3.5)
Actinomyces spp.	178 (2.9)
Porphyromonas spp.	155 (2.5)

[c]Species accounting for < 1% of total cultures.
Data compiled from 10 veterinary institutions (CityU Hong Kong, Cornell University, Kansas State University, Missouri Veterinary Diagnostic Laboratory, The Ohio State University, University of Illinois, University of Nebraska Veterinary Diagnostic Laboratory, University of Guelph, Virginia Maryland College of Veterinary Medicine, Washington State University), 2009–2019.

BOX 54.1 Factors That Contribute to Development of Anaerobic Infections

Causes of Physiologic Injury
Immunosuppression
Cytotoxic chemotherapy
Glucocorticoid therapy
Malignancies
Neutropenia
Hypogammaglobulinemia
Narrow-spectrum aerobic antibacterial therapy
Diabetes mellitus

Altered Tissue Oxygenation
Vascular compromise
Hypotension
Tissue anoxia
Gastrointestinal obstruction

Tissue Trauma
Tissue Contamination
Gastrointestinal or urogenital perforation
Bite or puncture wounds of soft tissue
Foreign body migration

suggests that co-inoculated aerobic microorganisms induce anaerobe capsule formation. Capsules also play a more traditional role by inhibiting phagocytosis.[38]

Aerobic and anaerobic microorganisms have a synergistic relationship.[38,39] Anaerobes act with facultative aerobes such as *E. coli* to induce abscess formation more rapidly than either bacterial group alone. *Actinomyces*, a facultative anaerobe, is commonly found in association with foreign body migrations, pyothorax, or peritonitis.[40,41] Facultative bacteria lower the oxidation-reduction potential of the tissue environment, facilitating anaerobic bacterial proliferation. Necrotic and abscessed tissue protect facultative organisms and anaerobic bacteria from antimicrobials, as well as body defenses such as phagocytosis. Aerobic organisms also scavenge oxygen and curtail phagocytosis of anaerobes (and vice versa).[42] Enzymes such as β-lactamase produced by one member of the aerobic-anaerobic partnership protect susceptible microorganisms in the vicinity from being inactivated by β-lactam antibacterials. These synergistic interactions are important to keep in mind when designing therapeutic regimens, because antibacterial therapy should be directed at both populations for optimal resolution of the infection.

Some anaerobes produce toxins. *Fusobacterium necrophorum* produces a toxin that forms pores in leukocyte membranes.[43] *Clostridioides difficile* produces toxins (A and B) that disrupt the cytoskeletal elements of the intestinal epithelial cell, resulting in cell death.[15,22,31] *Clostridium perfringens* produces an enterotoxin that interacts with the target cell membrane, resulting in the formation of pores that are made partly by the enterotoxin and partly by the target cell. Electrolytes are lost through these pores, resulting in reversal of ion and water flow (diarrhea) and, finally, death of the cell.[32,33] A pore-forming toxin within the leukocidin/hemolysin superfamily family, NetF, has been associated with canine hemorrhagic gastroenteritis and foal necrotizing enteritis (see Chapters 64 and 125).[28] Other studies have also suggested that *C. perfringens* strains that possess *netE* and *netF* genes may play a role in dogs with acute hemorrhagic disease syndrome.[29,30]

Some species of anaerobes produce adhesins (pili or fimbriae), which have been associated with virulence.[44] However, adhesins probably do not play a major role in pathogenesis other than by way of their association with specific locations on mucosal surfaces. For example, blood or abscess isolates of *B. fragilis* are rarely piliated, whereas those found on mucosal surfaces almost always have pili.[38]

CLINICAL FEATURES

Anaerobic bacteria stimulate pyonecrotic inflammation in a variety of organs. This process stems primarily from the inflammatory response triggered by anaerobic capsule material, cell wall constituents of microorganisms, and thwarted attempts at phagocytosis (which leads to deposition of lysosomal contents into surrounding tissue). The prevalence of anaerobic bacterial infections varies depending on the anatomic site of infection. Most anaerobic bacteria cultured from dogs and cats are associated with GI tract disorders, followed by pleural or abdominal fluids, abscesses, or respiratory tract infections (Table 54.3).[45]

Clinical findings in anaerobic infections also depend on the affected body site (Table 54.4). Exudates from infectious processes that contain anaerobes often are malodorous and may be darkly discolored. Fever, leukocytosis, hypoglycemia, increased serum ALP activity, and hypoalbuminemia reflect the systemic manifestations of an acute-phase reaction to the anaerobic infection. Hypoalbuminemia may be compounded by loss of serum proteins into effusions or from draining wounds.[41]

Anaerobes of the oral cavity are important contributors to periodontal disease; tooth root abscessation and mandibular osteomyelitis; retrobulbar abscesses; and bite wound infections. Along with other bacteria, anaerobes may be isolated from the lungs and pleural cavity of dogs or cats with aspiration pneumonia and pyothorax, respectively. Intestinal anaerobes may be isolated from the abdominal cavity of animals with septic peritonitis that has resulted from intestinal or cecal rupture. The female genital tract is also heavily colonized with anaerobic bacteria, and pyometra may sometimes be associated with mixed

TABLE 54.3 Relative Frequency of Isolation of Obligate Anaerobic Bacteria with Respect to Disease Process or Site in Dogs and Cats

Specimen Source	Number of Positive Cultures[a] (%)	Number of Positive Cultures by Species[b,c] (%)
Miscellaneous	924 (21.3)	Dog: 780 (22.4) Cat: 144 (17.1)
Gastrointestinal tract	495 (11.4)	Dog: 395 (11.3) Cat: 100 (11.8)
Fluid Pleural Abdominal Unknown Other	471 (10.9) 143 (3.3) 137 (3.2) 105 (2.4) 86 (2.0)	Dog: 341 (9.8) Cat: 130 (15.4)

[a]Total anaerobic cultures performed: 4,333.
[b]Total canine anaerobic cultures performed: 3,489.
[c]Total feline anaerobic cultures performed: 844.
Data compiled from 10 veterinary institutions (CityU Hong Kong, Cornell University, Kansas State University, Missouri Veterinary Diagnostic Laboratory, The Ohio State University, University of Illinois, University of Nebraska Veterinary Diagnostic Laboratory, University of Guelph, Virginia Maryland College of Veterinary Medicine, Washington State University), 2009–2019.

aerobic and anaerobic infections that include the anaerobic species *Bacteroides*, *Prevotella*, *Fusobacterium*, and *Peptostreptococcus*.

Plant awn migration in dogs and cats may lead to abscess formation in a variety of tissues, including retroperitoneal tissues and the brain. These abscesses usually contain a mixed population of aerobes and anaerobes, especially *Fusobacterium*, *Actinomyces*, and *Bacteroides* spp. Brain abscessation can follow direct extension of anaerobic bacterial infection from otitis, or tooth root infection. Alternatively, spread may occur via the hematogenous route (Fig. 54.1).

Periodontal Disease

Periodontal disease is one of the most common disorders seen in veterinary medicine and may result in chronic pain, decreased appetite, and loss of teeth. Periodontal disease begins with formation of dental plaque, a bacterial biofilm comprised primarily of gram-positive facultative aerobes, which occurs as a result of poor oral hygiene and other host factors. Subsequently there is proliferation of pathogenic bacteria, which include gram-negative rods and especially anaerobes, which secrete toxins and incite an inflammatory response. Anaerobes implicated in canine and feline periodontal disease (such as *Porphyromonas gulae*) appear to differ than those isolated from human periodontal disease (*Porphyromonas gingivalis*).[46–49] Periodontal disease is manifested as gingival erythema, edema, gingival bleeding, and halitosis, with accumulation of calculus, gingival recession, alveolar bone loss, and sometimes the presence of purulent exudate (Fig. 54.2).

Retrobulbar Abscesses

Retrobulbar or orbital abscesses may result from tooth root abscessation, penetrating foreign bodies such as grass awns, or penetrating trauma to the orbit. They are characterized by unilateral exophthalmos, protrusion of the third eyelid, conjunctival hyperemia, serous to mucopurulent ocular discharge, inappetence, fever, and pain on opening the mouth (Fig. 54.3). A fluctuant swelling or draining tract posterior to the last ipsilateral molar may be present on examination of the oral cavity. In one study, *Bacteroides* spp. and *Clostridium* spp. were the most frequent anaerobes isolated from 34 dogs with retrobulbar abscesses; other frequently isolated bacteria were *Staphylococcus*, *E. coli*, and *Pasteurella* spp. In cats, the most frequent anaerobe was *Bacteroides vulgatus*, and the most common non-anaerobe was *Pasteurella* spp.[50]

Skin and Soft Tissue Infections

Cat bite abscesses may be one of the most common reasons that cats are brought to veterinary clinics. Clinical signs include fever, lethargy, inappetence, pain, and firm or fluctuant subcutaneous swellings, which may rupture and drain purulent material. In addition to *Pasteurella multocida*, oral anaerobes are frequently isolated from these abscesses.[51] Anaerobic species involved include *Peptostreptococcus anaerobius*, *Porphyromonas* spp., *Clostridium* spp. (e.g., *Clostridium villosum), Fusobacterium* spp., *Bacteroides* spp. (especially *Bacteroides tectum*), and *Prevotella* spp.[52]

Other skin and soft tissue infections associated with a variety of anaerobes include foreign body penetrating wounds and dog bite wounds (see Chapter 75). Necrotizing fasciitis has generally been associated with toxigenic microaerophilic gram-positive bacterial infections in dogs and cats (Chapter 50), although gram-negative organisms may also be involved. Necrosis and spread of infection can be associated with co-infecting anaerobic bacteria that contaminate the site of infection. In some cases, anaerobic bacteria are isolated as the predominant organisms.[53]

TABLE 54.4 Comparative Clinical Features of Anaerobic Infections

Site	Clinical Features	Sources
Integument	Fever, firm subcutaneous swellings, fluctuance or gas pockets, ulceration with discharge	Puncture or bite wounds, hematogenous[84,85]
Head and Neck	Cranial or cervical abscesses: subauricular swelling, anorexia, odynophagia, gingivitis and stomatitis, para-aural abscesses, tonsillar abscesses, inner ear infections	Traumatic ear canal separations,[86] pharyngeal foreign body penetration (stick injuries),[87,88] dental infections,[46,89] chronic sinusitis,[90] tonsillar or salivary gland abscesses, chronic otitis media,[91] bite wounds, meningitis[92]
	Meningoencephalitis, brain abscess: hyperesthesia, neurologic deficits, ataxia	
	Orbital: exophthalmos, pain when opening mouth, ocular discharge, conjunctival hyperemia, panophthalmitis[50,93]	
	Corneal ulcers: miosis, lacrimation, photophobia, corneal opacity[93,94]	Preexisting corneal damage from ocular trauma or surgery, often mixed with aerobes
Intrathoracic		
Pulmonary	Cough, fever, dyspnea, lobar or multifocal consolidation (abscesses), hypertrophic osteopathy	Pneumonia, endocarditis,[95] aspiration pneumonia[45,96]
Intrapleural or mediastinal	Fever, dyspnea, muffled heart sounds, leukocytosis, pyothorax[41]	Penetrating chest injuries, inhaled foreign bodies, esophageal foreign body perforation[97–99]
Intra-Abdominal		
Peritoneal	Fever, abdominal distention, anorexia, intra-abdominal abscesses, adhesions[100]	Postoperative foreign suture materials (e.g., silk, multifilament nylon, braided material), ovariohysterectomy, migrating foreign bodies, bowel leakage, genital tract infections, actinomycosis
Hepatobiliary	Anorexia, lethargy, vomiting, diarrhea, fever, dehydration, hepatomegaly, icterus, mucosal bleeding	Bacteremia, hepatic trauma, necrosis or neoplasia, ascending biliary infection[20,21,101]
Enteric	Diarrhea, which may be hemorrhagic	Intestinal stasis, blind loop syndrome, colitis, colonic ulceration
Retroperitoneal	Swelling in lumbar flank, sinus tracts or drainage, pain, fever, anorexia, reluctance to walk	Osteomyelitis of lumbar vertebrae from plant awns, ovarian or uterine ligatures,[102] actinomycosis, ruptured urethra and perirenal abscess[103]
Paraspinal	Pain, reluctance to walk, fever, paraspinal hyperesthesia, paresis or paralysis	Usually epidural from local penetration or extension of paraspinal or nasopharyngeal infection, bite wounds. Meningitis: less likely anaerobic and often from hematogenous sources[104]
Musculoskeletal	Osteomyelitis, fever, lameness, limb swelling with variable fluctuance or gas pockets[105]	Bite or puncture wounds, compound fractures, hematogenous sources[106]
Urogenital		
Renal	Pyelonephritis[107]	Ascending bacterial infection from the distal urogenital tract
Genital	Pyometra[108]	

Pneumonia and Pyothorax

Anaerobic bacteria such as *Fusobacterium* spp., *Peptostreptococcus anaerobium*, *Prevotella* spp., and *Porphyromonas* spp. can be isolated from dogs and cats with aspiration pneumonia, foreign body pneumonia (especially that due to plant awn migration), and pyothorax.[54] Dogs with plant awn migration develop multifocal necrotizing pneumonia with abscess formation. Anaerobic bacterial pneumonia can also result from aspiration of anaerobes within the oral cavity. This usually occurs in animals with underlying esophageal or laryngeal defects, neurologic disorders, altered consciousness, or dysphagia. In some cases, aspiration pneumonia may be followed by lung abscess formation (Fig. 54.4). In human patients, a period of 6 to 7 days after aspiration is required for necrosis and abscess formation to occur, and so aspiration pneumonia with lung abscess formation is generally a chronic disease process.

Clinical signs of pulmonary infections include fever, lethargy, inappetence, cough, and tachypnea. The reader is referred to Chapter 124 for more detailed descriptions of bacterial pneumonia and pyothorax.

Peritonitis

Septic peritonitis that involves anaerobes may result from rupture of the intestinal tract, especially the cecum or colon. Anaerobes such as *Bacteroides* spp. and *Clostridium* spp. may be more likely to be isolated from these infections. Other anaerobes that may be present in dogs and cats with septic peritonitis include *Fusobacterium* spp. and *Propionibacterium* spp.[55] Disease that results from bowel perforation often contains a population of organisms that reflect the bowel microbiota at the site of perforation, which may include anaerobes, aerobic gram-positive bacteria (such as *Enterococcus* spp.), *Candida* spp., and gram-negative aerobes such as *E. coli*. Rupture of the female genital tract secondary to pyometra may also be associated with peritonitis that involves anaerobes.

Bacteremia

Anaerobic bacteremia in dogs and cats can be associated with seemingly localized anaerobic infections, such as peritonitis or pyothorax, although it is not often recognized.[56,57] When anaerobes are

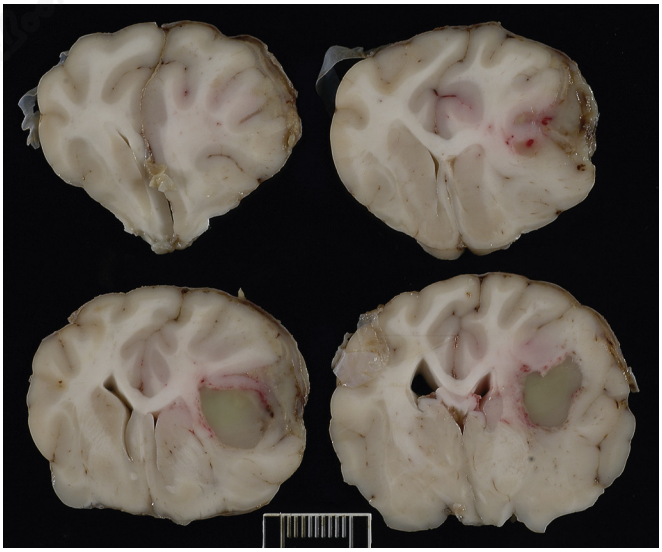

Fig. 54.1 Abscess in the white matter of the right frontal lobe of a 2-year-old female spayed Chihuahua that had a 1-month history of difficulty chewing food and lethargy and a 3-week history of progressive obtundation, neck pain, and tetraparesis. Signs initially improved following treatment with prednisone, but then recurred as the prednisone dose was reduced. The abscess in the frontal lobe communicated with the overlying meninges, which were expanded by a chronic and fibrosing suppurative inflammatory infiltrate. Another abscess was present in the midbrain, which suggested hematogenous spread of infection. Although no bacteria were seen within the lesions with special stains, *Actinomyces canis* and *Fusobacterium nucleatum* were cultured from the lesions. (Image courtesy of the University of California, Davis Veterinary Anatomic Pathology Service.)

Fig. 54.2 Periodontitis in a dog. There is significant gingival inflammation, plaque and calculus accumulation, and purulent exudate. Gingival recession and contact ulceration of the buccal mucosa are also present. (Courtesy Frank J.M. Verstraete, UC Davis Dentistry and Oral Surgery Service.)

occasionally isolated from dogs and cats with bloodstream infections, they are usually polymicrobial infections together with aerobic bacteria. In a European study of 66 bacteremic cats, 12% of bacterial isolates from the bloodstream were obligate anaerobes.[56] In a study of 140 dogs with bacteremia, anaerobes comprised 9% of the isolates.[57] Of 39 dogs and 10 cats with critical illness and bacteremia from Colorado, anaerobes were isolated from 31% of the dogs and 40% (4 of 10) of the cats. The most common anaerobic bacterial species isolated from

Fig. 54.3 Retrobulbar abscess and endophthalmitis secondary to a migrating grass awn foreign body in a 10-month-old intact male Labrador retriever. (A) Note the mucopurulent ocular discharge from the right eye, as well as buphthalmos (enlargement of the eye) and exophthalmos. The nictating membrane and conjunctiva are hyperemic and there is diffuse corneal edema. Hypopyon and iris bombe were also present. Globe retropulsion was reduced and painful on the right side. (B) Multiple grass awns were present all over the dog's hair coat and an awn (shown) was removed from the gingiva posterior to the last right maxillary molar tooth. The right eye was subsequently enucleated. No additional grass awns were found. Histopathology of the globe showed severe chronic fibrinosuppurative panophthalmitis with focal, 0.3 cm scleral rupture in the caudal sclera near the optic nerve, regional orbital granulation tissue, and rupture of the lens. (Images courtesy of the University of California, Davis Veterinary Ophthalmology Service.)

the dogs was *C. perfringens* (nine dogs), followed by *Bacteroides* species (two dogs).[58] The cats were infected with *Bacteroides* or *Fusobacterium* species. The possibility of bacteremia due to a mixed population of aerobic and anaerobic bacteria should be considered in dogs with systemic grass awn migration. Anaerobic bacteria appear to be a very rare cause of endocarditis in dogs (see Chapter 122).[59]

DIAGNOSIS

Abnormalities that suggest an anaerobic bacterial infection include a putrid odor, discolored purulent discharge, gas production within tissues (especially with *C. perfringens* infections) (Fig. 54.5), a bite or puncture wound, penetrating foreign bodies, abscessation, pyothorax, aspiration pneumonia, damage to mucosal surfaces with which anaerobes are usually associated, and/or necrotic or gangrenous tissue

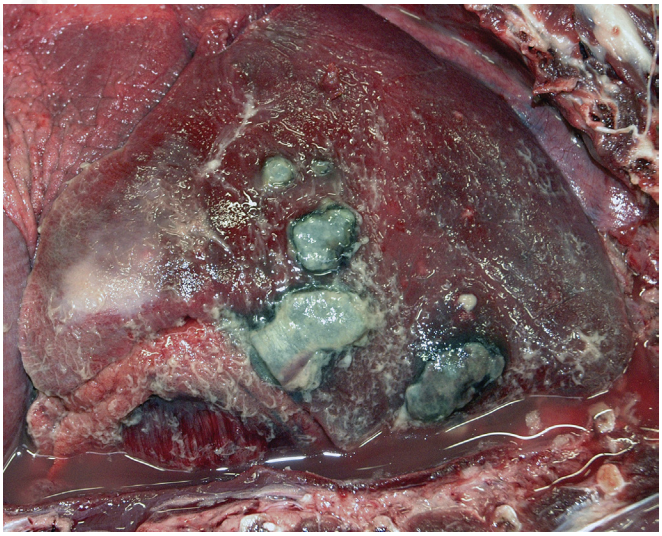

Fig. 54.4 Necropsy findings in an 11-year-old male neutered Labrador retriever with severe aspiration pneumonia secondary to laryngeal tie-back surgery for laryngeal paralysis, which occurred 2 months before death. Aspiration led to bronchopneumonia with multifocal abscessation, pleural rupture, pyothorax, and pneumothorax. There are multiple to coalescing black to dark gray, soft, irregular, foci that measured up to 4.5 cm in diameter at the level of the cardiac notch and caudal aspect of the right cranial lung lobe. On cut surface, dark gray to black material oozed from the parenchyma. Aerobic bacterial culture yielded large numbers of organisms that included *Streptococcus canis*, nonfermenter group 3 organisms, and *Pasteurella canis*. Anaerobic culture yielded large numbers of *Peptostreptococcus anaerobius*. (Image courtesy of the University of California, Davis Anatomic Pathology Service.)

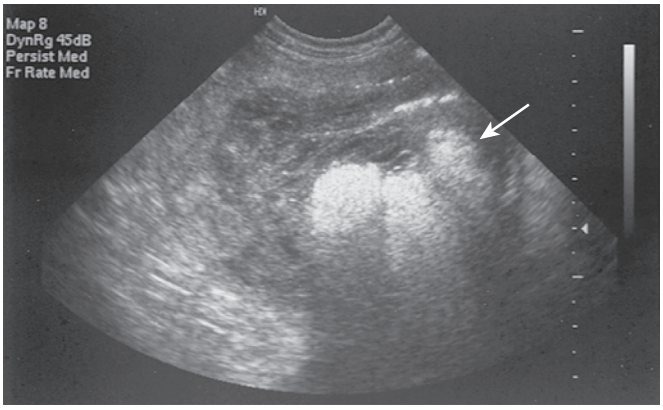

Fig. 54.5 Splenic abscess in an 11-year-old male neutered Labrador mix that also had duodenal lymphoma. Ultrasound image of a large splenic mass that contains numerous hyperechoic foci, consistent with the presence of gas. Necropsy showed severe, focally extensive, neutrophilic, and necrotizing splenitis. The duodenum was perforated at the site of the neoplasm. *Escherichia coli*, *Bacteroides tectus*, and a *Prevotella heparinolyticus*-like organism were cultured from the splenic abscess.

(Box 54.2). However, absence of these features does not rule out infection with anaerobes, and some of these abnormalities can occur in association with isolated aerobic bacterial infections. For example, although anaerobes such as *Clostridium* spp. may be involved in emphysematous cystitis in humans and dogs, the most common cause of emphysematous cystitis are gram-negative aerobes, especially *E. coli*.

BOX 54.2 Clinical Findings That Suggest Anaerobic Infection

Fever, pain, and swelling
Bite or puncture wound
Foul-smelling wounds or discharges
Unexpected gas in tissues or body cavities
Abscess formation
Contiguous infection to mucosal surface with anaerobic microflora
Necrotizing fasciitis (co-infection)
Necrotic or devitalized tissue
Gangrenous tissue
Dark, discolored exudates
Presence of sulfur granules in exudates
Mixed population of organisms or filamentous forms shown by microscopy
Failure to culture organisms with routine methods

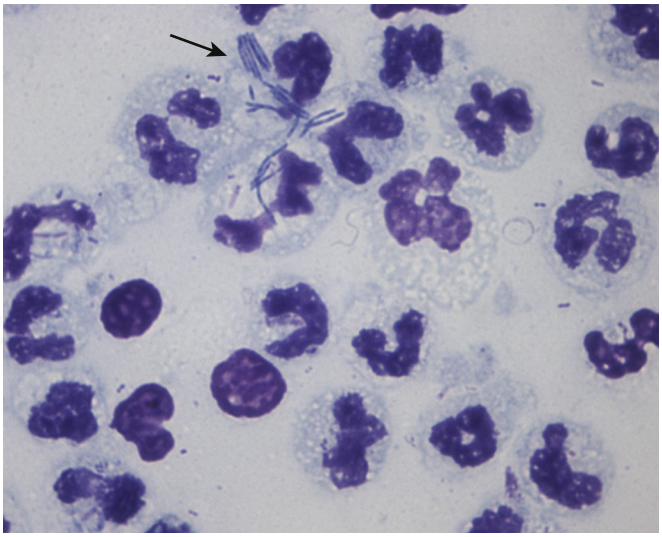

Fig. 54.6 Cytology of pleural fluid collected using thoracocentesis from an 8-year-old female spayed domestic shorthair cat with pyothorax that shows the presence of a mixed population of bacteria that includes filamentous organisms suggestive of anaerobes. Aerobic and anaerobic bacterial culture yielded a mixed growth of *Prevotella* spp., *Peptostreptococcus anaerobius*, *Fusobacterium* spp. and an unidentified anaerobic gram-positive rod *(arrow)*.

Laboratory Abnormalities

Complete Blood Count, Biochemistry, and Urinalysis Findings

No specific CBC, biochemistry, or urinalysis findings suggest anaerobic infection. Infections may be associated with leukocytosis due to a neutrophilia with a left shift and toxic neutrophils.

Microbiologic Tests

Cytologic Diagnosis

In addition to clinical features, cytologic analysis of specimens can help to determine whether an anaerobic infection is present. Abundant degenerative neutrophils are usually found with multiple and often morphologically diverse forms of intracellular and extracellular bacteria. Large and filamentous morphology is often typical of anaerobes (Fig. 54.6).[60,61] Some gram-negative anaerobic rods are pale-staining and they are often thin, can be sometimes misshapen, and occasionally have pointed ends.

Extracellular bacteria may result from bacterial contamination of a specimen or contamination of the staining solution. Microscopic evaluation for morphologic shape and Gram staining should be performed

TABLE 54.5 Acceptable and Unacceptable Specimens for Anaerobic Culture[45,109]

Body Site	Acceptable Specimens	Unacceptable Speciments
Abdominal cavity	Abdominal/peritoneal fluids; bile aspirates; surgical biopsies	Swabs
Abscesses	Closed abscess: needle aspirates collected after surface decontamination Open abscess: see Wounds	
Blood	Aseptically collected blood inoculated in blood culture bottles following the manufacturer recommendations	Catheter or catheter tips
Body organs (tissues)	Deep biopsy; percutaneous needle aspiration into deeper tissues	Swab
Bone	Deep aspirates of drainage; bone biopsies	Swab, soft tissue samples
Dental or respiratory sinus tissue	Biopsy or aspirate after decontamination	Swab
Feces	At least 2 g of stools only for screening fecal pathogens (*Clostridioides difficile* or *Clostridium perfringens*)	Swab
Female genital tract	Tissue biopsies; guarded uterine swab	Vaginal, cervical swab
Joint	Synovial fluid collected by arthrocentesis inoculated in blood culture bottles following the manufacturer recommendations	Surface swab
Wounds; soft tissues	Deep biopsy specimens; deep wound aspirates at the advancing wound edge after debridement and cleaning the surface	Surface swabs, pus, sinus tracts

when the specimen is collected so that the results can be compared with culture results or the type of organism can be predicted by its shape and staining properties (see Table 54.1). The prediction of an anaerobic infection based on cytologic (Gram stain) findings may guide the empiric use of therapeutic agents targeted for this class of microorganisms.[26,61]

Culture

Anaerobes are difficult to isolate in clinical practice unless precautions are taken. Errors in specimen collection, handling, and submission are the primary reasons anaerobes are not routinely isolated. Therefore, attention to collection practices, minimizing transport time, optimizing transport temperature, and use of appropriate transport media are fundamental if anaerobic culture is performed (see Chapter 3) (Table 54.5).[19,60,62,63] Anaerobes are sensitive to oxygen and because they grow slowly, they are also easily overgrown in specimens that contain aerobes; greater than 70% of cultures are mixed. In addition, multiple anaerobes are often found in the same specimen (Table 54.6). Because swabs tend to dry out and become oxygenated, their use is discouraged. If swabs are used, the tip should be moistened with a pre-reduced medium such as brain-heart infusion broth and maintained in anaerobic conditions. Refrigeration has been shown to be detrimental to the isolation of anaerobic bacteria; thus, specimens should not be held at temperatures lower than 4°C (see Table 54.5). In comparison, aerobes multiply at 25°C and in some cases overgrow the anaerobic component. At 15°C, aerobes do not multiply to any significant extent, and anaerobes remain viable. Acceptable time periods between specimen collection and culture depend on specimen type, volume, and whether transport medium is used. Anaerobic microorganisms in large pieces of tissue or quantities of fluid (greater than 2 mL) are relatively protected from toxic interaction with oxygen and can survive for up to 24 hours before culture, whereas anaerobes in smaller specimens or swabs usually cannot. Anaerobic transport media greatly increase the survival of anaerobes and discourage the growth of aerobes. Anaerobic media are available for transport of aspirated material, tissue or biopsy material, and material collected on swabs.[62,64] Culture of anaerobic bacteria

TABLE 54.6 Occurrence of Anaerobic Bacteria from Positive Cultures by Specimen

Number of Isolate(s) per Specimen[a]	Number of Positive Cultures[b] (%)	Number of Positive Cultures by Species[c,d] (%)
1	3076 (71)	Dog: 2,499 (71.6)
		Cat: 577 (68.4)
2	844 (19.5)	Dog: 668 (19.1)
		Cat: 176 (20.9)
3	284 (6.6)	Dog: 218 (6.2)
		Cat: 66 (7.8)
4	83 (1.9)	Dog: 72 (2.1)
		Cat: 11 (1.3)
5	24 (0.6)	Dog: 15 (0.4)
		Cat: 9 (1.1)
6	10 (0.2)	Dog: 6 (0.2)
		Cat: 4 (0.5)
7	7 (0.2)	Dog: 6 (0.2)
		Cat: 1 (0.1)
8	5 (0.1)	Dog: 5 (0.1)
		Cat: 0

[a]Indicates the number of anaerobic bacteria isolated from a single specimen from a total of 6,221 (including four unknowns).
[b]Total anaerobic cultures performed: 4,333.
[c]Total canine anaerobic cultures performed: 3,489.
[d]Total feline anaerobic cultures performed: 844.
Data compiled from 10 institutions (CityU Hong Kong, Cornell University, Kansas State University, University of Missouri Veterinary Diagnostic Laboratory, The Ohio State University, University of Illinois, University of Nebraska Veterinary Diagnostic Laboratory, University of Guelph, Virginia Maryland College of Veterinary Medicine, Washington State University), 2009–2019.

is laborious, expensive, and time consuming. At the laboratory, media must be inoculated with specimens as soon as they are received. Use of pre-reduced, anaerobically sterilized media improves the success of isolation. After inoculation, media is placed in an anaerobic chamber with an atmosphere of 5% carbon dioxide, 5% hydrogen, and 90% nitrogen, or in an oxygen-free carbon dioxide until it can be put in the chamber. During culture follow-up, culture plates must always be handled in an anaerobic hood or a chamber that has been flushed with anaerobic gas mix. Commonly, the isolation and identification of an anaerobe in a sample containing only one species takes 2–4 days.[60,62,63]

Anaerobic culture is costly and most infectious processes contain an average of two different species of anaerobes and at least one aerobe. This significantly increases the effort and cost associated with anaerobe isolation. Use of phenotypical and biochemical methods for identification is laborious and requires well-trained personnel. The adoption of MALDI-TOF MS has allowed laboratories to more accurately and rapidly identify new anaerobes (see Chapter 3).[65–67] However, the acquisition of this technology is cost prohibitive for small laboratories.

Mucosal disease produced by anaerobes is somewhat more difficult to diagnose. Isolation from sites where obligate anaerobes are part of the resident microbiota, such as the oral or pharyngeal cavity, vagina, external auditory meatus, conjunctiva, or skin, can be difficult to associate with pathogenicity. Diagnosis of GI disease caused by *C. difficile* and *C. perfringens* requires the use of specialized agar for isolation, immunologic tests to determine the presence of microorganism or toxin in feces or in broth culture, or molecular assays that detect toxin genes in feces or the isolates themselves.[60,68]

Few veterinary laboratories perform susceptibility testing for anaerobes because it is difficult and expensive. Guidelines for testing have been established by the CLSI.[69] The agar dilution assay has been considered the only validated and recommended method for all anaerobic organisms; however, this method can be labor intensive and the assay results have not always been repeatable or consistent for all anaerobic species.[63,69,70] The CLSI recommends broth microdilution method only for testing *Bacteroides* spp. and *Parabacteroides* spp.[69] Some laboratories use commercial gradient strips (E-testing) because these are more convenient for routine testing (see Chapter 3).[26] However, a lack of agreement when using this method has also been described.[63,71]

A disc test can be performed to determine whether an isolate produces β-lactamase (Nitrocefin Disc, B.D. Sparks, MD, USA). For this test, a portion of an isolated colony is smeared onto a disc that contains a substrate that changes color when a β-lactamase is present. The most common anaerobic β-lactamases are encoded by the *cepA* gene, and more than 97% of *B. fragilis* carry this gene.[72,73] These strains are resistant to penicillin, ampicillin, amoxicillin, and most of the cephalosporins, except cefoxitin. Clavulanate irreversibly binds to these enzymes. Cefoxitin resistance is most commonly due to a β-lactamase encoded by the *cfxA* gene. Cefoxitin resistance rates in *B. fragilis* group organisms range from 3.7% to 19% by species in the United States and 9.6% to 75% internationally.[72] The presence of *cepA* and *cfxA* have been reported in *Bacteroides* spp. isolated from domestic animals.[27] Table 54.7 summarizes the prevalence of β-lactamase production found among various anaerobes isolated from dogs and cats in one study.

Because of the cost and difficulties of culture and low sensitivity especially when specimens cannot reach the laboratory within hours, presumptive diagnoses of anaerobic infections are often made based on history, anatomic site, characteristics of the exudate (e.g., odor and sometimes color), and results of cytologic examination (see Box 54.2, Table 54.1, and Fig. 54.6). Antimicrobial treatment of a suspected anaerobic component is usually empiric.

TABLE 54.7 Prevalence of β-Lactamase-Producing Strains of Anaerobic Gram-Negative Bacteria Isolated from Dogs and Cats

Organism	Species	Number	β-Lactamase Positive (%)	β-Lactamase Negative (%)
Bacteroides fragilis	Dog	40	36 (90)	4 (10)
	Cat	18	16 (89)	2 (11)
B. fragilis group	Dog	26	19 (73)	7 (27)
	Cat	11	10 (91)	1 (9)
Other *Bacteroides*	Dog	22	11 (50)	11 (50)
	Cat	18	14 (78)	4 (22)
Porphyromonas spp.	Dog	21	7 (33)	14 (67)
	Cat	10	5 (50)	5 (50)
Prevotella spp.	Dog	46	21 (46)	25 (54)
	Cat	16	8 (50)	8 (50)
Fusobacterium nucleatum	Dog	4	0	4 (100)
	Cat	5	1 (20)	4 (80)
Fusobacterium spp.	Dog	1	0	1 (100)
	Cat	3	0	3 (100)
Miscellaneous species	Dog	48	19 (40)	29 (60)
	Cat	30	16 (53)	14 (47)
