PART I Principles of Diagnosis, Treatment and Control of Infectious Diseases

INTRODUCTION TO PART I

SECTION 1 Principles of Infectious Disease Diagnosis

Jane E. Sykes, Shelley C. Rankin

1 **Isolation in Cell Culture, 3**
Edward J. Dubovi, Shelley C. Rankin
2 **Immunoassays, 11**
Jane E. Sykes, Shelley C. Rankin, Rance K. Sellon, James F. Evermann
3 **Isolation and Identification of Aerobic and Anaerobic Bacteria, 19**
Stephen D. Cole, Shelley C. Rankin
4 **Laboratory Diagnosis of Fungal Infections, 31**
Barbara A. Byrne, Shelley C. Rankin
5 **Diagnostic Techniques for Identification of Parasites, 42**
Susan E. Little, Yoko Nagamori
6 **Molecular Diagnostic Methods for Pathogen Detection, 51**
Emir Hodzic, Jane E. Sykes, Shelley C. Rankin
7 **Clinical Epidemiology in Infectious Diseases and Interpretation of Diagnostic Tests, 64**
Janet E. Foley, Rance K. Sellon, W. Zach Mills, James F. Evermann, Jane E. Sykes, Shelley C. Rankin

SECTION 2 Anti-infective Drugs

MARK G. PAPICH

8 **Principles of Anti-infective Therapy, 73**
Jane E. Sykes, Mark G. Papich
9 **Antiviral Chemotherapy and Immunomodulatory Drugs, 83**
Katrin Hartmann, Jane E. Sykes, Mark G. Papich
10 **Antibacterial Drugs, 103**
Jane E. Sykes, Mark G. Papich
11 **Antifungal Drugs, 127**
Polina Vishkautsan, Jane E. Sykes, Mark G. Papich
12 **Antiprotozoal Drugs, 140**
Jane E. Sykes, Mark G. Papich
13 **Antiparasitic Drugs, 149**
Lindsay A. Starkey, Byron L. Blagburn

SECTION 3 Principles of Infection Control

Jane E. Sykes, J. Scott Weese

14 **Cleaning and Disinfection, 162**
J. Scott Weese
15 **Prevention of Infectious Diseases in Hospital Environments, 171**
Brandy A. Burgess, J. Scott Weese
16 **Prevention and Management of Infectious Diseases in Multiple-Cat Environments, 187**
Miranda Spindel, Jane E. Sykes
17 **Prevention and Management of Infection in Canine Populations, 197**

28 **Miscellaneous and Emerging Canine Respiratory Viral Infections, 332**
Simon L. Priestnall, Jane E. Sykes
29 **Canine Parvovirus Infections and Other Viral Enteritides, 341**
Colin R. Parrish, Jane E. Sykes
30 **Feline Panleukopenia Virus Infection and Other Feline Viral Enteritides, 352**
Jane E. Sykes, Colin R. Parrish
31 **Feline Coronavirus Infections, 360**
Niels C. Pedersen, Jane E. Sykes
32 **Feline Leukemia Virus Infection, 382**
Katrin Hartmann, Regina Hofmann-Lehmann, Jane E. Sykes
33 **Feline Immunodeficiency Virus Infection, 414**
Julia A. Beatty, Jane E. Sykes
34 **Feline Herpesvirus Infections, 429**
Jane E. Sykes, Michael R. Lappin, Sara M. Thomasy, Julia A. Beatty
35 **Feline Calicivirus Infections, 443**
Alan Radford, Maria Afonso, Jane E. Sykes
36 **Feline Foamy (Syncytium-Forming) Virus Infection, 455**
Chrissy Eckstrand
37 **Paramyxovirus Infections, 459**
Hans Lutz, Claire R. Sharp, Jane E. Sykes
38 **Feline Poxvirus Infections, 466**
Conor O'Halloran
39 **Pseudorabies, 470**
Diana Henke, Marc Vandevelde
40 **Papillomavirus Infections, 477**
Jennifer A. Luff, John S. Munday
41 **Arthropod-Borne Viral Infections, 489**
Jane E. Sykes, Andrea Tipold
42 **Bornavirus Infection, 501**
Jonas Johansson Wensman, Mikael Berg, Karin Hultin Jäderlund
43 **Emerging and Miscellaneous Viral Infections, 507**
Jane E. Sykes

SECTION 2 Bacterial Diseases

Jane E. Sykes

44 **Ehrlichiosis, 522**
Shimon Harrus, Trevor Waner, Mathios E. Mylonakis, Jane E. Sykes, Barbara Qurollo
45 **Anaplasmosis, 542**
Jennifer Granick, Michael R. Lappin, Trevor Waner, Shimon Harrus, Mathios E. Mylonakis
46 **Spotted Fever Rickettsioses, Flea-Borne Rickettsioses, and Typhus, 555**
Linda Kidd, Edward B. Breitschwerdt
47 **Neorickettsiosis, 571**
Jane E. Sykes
48 **Coxiellosis and Q Fever, 582**
Jane E. Sykes, Jacqueline M. Norris
49 **Chlamydial Infections, 589**
Jane E. Sykes
50 **Streptococcal and Enterococcal Infections, 597**
John F. Prescott, Jane E. Sykes, Joshua B. Daniels
51 **Staphylococcal Infections, 611**
J. Scott Weese, John F. Prescott
52 **Miscellaneous Gram-Positive Bacterial Infections, 627**
Joshua B. Daniels, Jane E. Sykes
53 **Gram-Negative Bacterial Infections, 643**
Virginia Sinnott-Stutzman, Jane E. Sykes
54 **Anaerobic Bacterial Infections, 655**
Dubraska Diaz-Campos, Jenessa A. Winston, Jane E. Sykes
55 **Bordetellosis, 669**
Krystle L. Reagan
56 **L-Form Infections, 679**
Victoria J. Chalker
57 **Mycoplasma Infections, 682**
Victoria J. Chalker, Jane E. Sykes
58 **Hemotropic Mycoplasma Infections, 690**
Emi N. Barker, Séverine Tasker
59 **Actinomycosis, 704**
Jane E. Sykes
60 **Nocardiosis, 714**
Jane E. Sykes
61 **Mycobacterial Infections, 723**
Carolyn R. O'Brien, Conor O'Halloran, Danièlle A. Gunn-Moore, Jane E. Sykes
62 **Salmonellosis, 750**
Jane E. Sykes, Patrick L. McDonough
63 **Enteric *Escherichia coli* Infections, 759**
Jane E. Sykes
64 **Enteric Clostridial Infections, 766**
Jane E. Sykes, Stanley L. Marks
65 **Campylobacteriosis, 774**
Els Acke
66 ***Helicobacter* Infections, 785**
Jane E. Sykes
67 **Miscellaneous Enteric Bacterial Infections, 797**
Jane E. Sykes
68 **Leptospirosis, 802**
Simone Schuller, George E. Moore, Jane E. Sykes
69 **Borreliosis, 824**
Meryl P. Littman, Reinhard K. Straubinger, Jane E. Sykes
70 **Bartonellosis, 853**
Pedro Paulo V.P. Diniz, Bruno B. Chomel, Lynn Guptill, Edward B. Breitschwerdt
71 **Canine Brucellosis, 876**
Autumn P. Davidson, Jane E. Sykes

Index, 1762

PREFACE

With a global zoonotic coronavirus pandemic which at the time of writing has infected over 480 million people and contributed to the death of over 6 million people worldwide, a knowledge of infectious diseases of companion animals has never been more important. To highlight this, the cover of this book features the iconic coronavirus virion as depicted by the Center for Disease Control and Prevention's medical illustrators, Dan Higgins and Alissa Eckhert.[1] In 2017-2018, the U.S. Pet Ownership & Demographics Sourcebook reported that there are 76.8 million owned dogs and 58.4 million owned cats in the United States, and that 38.4% of households own at least one dog and 25.4% own at least one cat,[2] so exposure of dogs and cats to a virus which is infecting up to 1 in 5 people tested in some parts of the United States[3] is significant. Many of the authors of this book have been called upon by governing bodies to consult on SARS-CoV-2 infections in dogs and cats, or by media outlets to inform the public about the risks of transmission of this virus to animals and back to their owners.

Every chapter in this fifth edition of *Greene's Infectious Diseases of the Dog and Cat* has received a major overhaul to ensure that the information provided is current, clinically relevant, and organized logically to help the reader find needed information. Illustrations and photographs have been updated, and the start of each chapter features a series of Key Points. Detailed information on the public health significance of each infection is provided, including information on related human conditions to inform not only those in the veterinary profession who are seeking to understand zoonotic potential, but also those in the human medical field who might be reading this book with interest in the veterinary perspective. Commenting on his coronavirus illustration, Higgins noted, "this virus, often referred to as invisible, suddenly has a face and is brought to life".[1] Thanks to the work of illustrators like Ted Huff and Kip Carter, I hope that the information and illustrations in this book do the same for all of the pathogens described.

In Part I, Section 1 focuses on diagnostic testing and epidemiological concepts. Information on antimicrobial pharmacology, including tables with drug doses, is located in Section 2. Principles of hospital infection control, now foremost in the operation of many veterinary clinics worldwide as a result of the pandemic, are detailed in Section 3, and specific pathogens and clinical syndromes are located in Part II. For the first time, the book contains a section on helminth and ectoparasite diseases. Inclusion of this section led to some angst over the book's title, as the definition of infection according to *Dorland's Medical Dictionary* is: "the invasion and multiplication of microorganisms in body tissues, which may be clinically inapparent or result in local cellular injury because of competitive metabolism, toxins, intracellular replication or antigen-antibody response."[4] As pointed out to me by one of the contributors to this book and a dear friend who seeks to ensure that my grammar and terminology are correct, non-protozoal parasites are not strictly microorganisms. In addition, some argue that while these parasites reproduce, they do not multiply in the host, so the term "infestation" is more appropriate. By another definition, infestation implies ectoparasitism, where the parasite is located externally to the host. Perhaps the title of this book should be "Infectious Diseases and Infestations of the Dog and Cat". Nevertheless, the term "infection" is widely used in both veterinary and human parasitology texts and so to avoid sounding awkward, that convention has been maintained.

I would like to acknowledge Dr. Craig Greene, Professor Emeritus at the University of Georgia, for his mentorship and inspiring me to pursue a career in clinical infectious diseases of dogs and cats. It was the early editions of this book which introduced me to the field, and I hope this edition will inspire more veterinarians who are beginning their careers. Much of the text in this edition builds upon Craig Greene's previous contributions, which are so significant they cannot even be quantified. Other mentors whose enthusiasm for infectious diseases, internal medicine and scientific writing has been a source of encouragement are Glenn Browning, Jane Armstrong, Peter Irwin, Robert Hardy, Richard Nelson, Edward Breitschwerdt, and Michael Lappin.

I would like to thank the Section Editors for their valuable input, all of the chapter contributors who made this book possible, and the team at Elsevier. Many friends and colleagues at the University of California-Davis, other veterinary academic and private practices, as well as those in industry have provided motivation and humor, even during challenging times (including bilateral broken wrists!). I would particularly like to acknowledge my family and pets here in the United States and in Australia, my running friends, the VMTH leadership team and colleagues in the medicine service, my MBA colleagues in Atlanta, and Missy Beall, Chandra Chandrashekar, Stuart Cohen, Jonathan "JD" Dear, Andrea Fascetti, Dennis Horter, Frédéric and Kristin Jacob, Christian Leutenegger, Richard Malik, Lindsay Merkel, Zach Mills, Nicole Nosek, Krystle Reagan, and George "GR" Thompson.

ACKNOWLEDGMENTS

On behalf of all of the contributors to this text, the editor would like to acknowledge the significant contributions that the individuals below made to one or more chapters in the fourth edition of *Infectious Diseases of the Dog and Cat* (ed. Greene CE) and the first edition of *Canine and Feline Infectious Diseases* (ed. Sykes JE), which were used as the basis for many of the chapters in this edition by new authors. In particular, I would like to highlight the colossal editorial and authorship contributions of Craig E. Greene to all of the chapters in previous editions of this book.

PART I

Principles of Diagnosis, Treatment and Control of Infectious Diseases

Introduction to Part I

Part I of this book is divided into 3 sections: 1) Principles of Infectious Disease Diagnosis, 2) Anti-infective Drugs, and 3) Principles of Infection Control. The information presented is complementary to material provided in disease-specific chapters of this book (Part II). Drug doses for specific antiviral, antibacterial, antifungal, and antiparasitic drugs that are referred to in Part II are found in tables in the chapters on anti-infective therapy, together with key information on spectrum of activity, mechanism of action, and adverse effects. Vaccination strategies are discussed in Section 3, and the reader is referred to tables in the Appendix for guidance on vaccination intervals and adjustments based on animal lifestyle. A solid understanding of these principles facilitates a systematic and logical approach to diagnosis, treatment, and prevention of any infectious disease problem.

Section 1 Principles of Infectious Disease Diagnosis

1 Isolation in Cell Culture, 3
2 Immunoassays, 11
3 Isolation and Identification of Aerobic and Anaerobic Bacteria, 19
4 Laboratory Diagnosis of Fungal Infections, 31
5 Diagnostic Techniques for Identification of Parasites, 42
6 Molecular Diagnostic Methods for Pathogen Detection, 51
7 Clinical Epidemiology in Infectious Diseases and Interpretation of Diagnostic Tests, 64

Section 2 Anti-infective Drugs

8 Principles of Anti-infective Therapy, 73
9 Antiviral Chemotherapy and Immunomodulatory Drugs, 83
10 Antibacterial Drugs, 103
11 Antifungal Drugs, 127
12 Antiprotozoal Drugs, 140
13 Antiparasitic Drugs, 149

Section 3 Principles of Infection Control

14 Cleaning and Disinfection, 162
15 Prevention of Infectious Diseases in Hospital Environments, 171
16 Prevention and Management of Infectious Diseases in Multiple-Cat Environments, 187
17 Prevention and Management of Infection in Canine Populations, 197
18 Considerations and Management of Infectious Diseases of Community (Unowned, Free-Roaming) Cats, 204
19 Companion Animal Zoonoses in Immunocompromised and Other High-Risk Human Populations, 218
20 Immunization, 238

SECTION 1

Principles of Infectious Disease Diagnosis

Jane E. Sykes, Shelley C. Rankin

The accurate diagnosis of an infectious disease is critical to guide the effective treatment of an individual animal or outbreaks of disease in a population of animals. Making an accurate diagnosis requires an understanding of the principles of diagnostic testing and an understanding of the pathogenesis of the disease agent suspected. Some infectious diseases are distinctive enough to be identified clinically. However, many pathogens cause a wide spectrum of clinical signs, and a single clinical syndrome may result from infection with one of many pathogens. Diagnostic tests can generally be grouped into *organism detection tests* (culture, antigen tests, and nucleic acid tests) and *antibody detection tests.* In some situations (e.g., early in the course of illness, in immunosuppressed animals), organism detection tests are most appropriate. In others (e.g., chronic, persistent infectious diseases; identification of exposure in an animal population; acute diseases associated with an early rise in antibody titer that can be captured using acute and convalescent serology testing), antibody detection tests may be preferable. Increasingly, as new assays become available, the diagnosis and understanding of companion animal infectious diseases relies on the application of multiple diagnostic tests simultaneously.

This section, which focuses on diagnosis of companion animal infectious diseases, includes chapters on isolation of intracellular pathogens in cell culture, immunoassays, as well as clinically relevant information on specific diagnostic tests for bacteria, parasites, and fungi. Selection and collection of appropriate specimens for testing, how each test is performed, and how to best interpret the results are covered to inform and guide clinicians. A knowledge of the material presented in these chapters should provide the reader with a strong foundation in the appropriate selection and interpretation of diagnostic tests for all of the pathogens discussed in this book.

Vetbooks.ir

Isolation in Cell Culture

Edward J. Dubovi, Shelley C. Rankin

KEY POINTS

- With the increasing availability of nucleic acid–based testing and antigen capture ELISA tests, the use of cell culture for the diagnosis of infections caused by obligate intracellular pathogens in dogs and cats has decreased.
- Cell culture remains an important technique for: (1) nontargeted pathogen discovery, (2) amplification of viruses detected by molecular methods for genomic sequencing, (3) vaccine manufacture, and (4) virus neutralization assays. In certain instances, cell culture is the most sensitive and specific method for organism detection.
- Before collection of specimens, veterinary clinicians should communicate with the laboratory that is to perform the diagnostic testing to discuss the laboratory's capabilities with regard to pathogen detection and to discuss testing strategies within the context of the clinical event.
- Specimens are inoculated onto cell monolayers, and the presence of an infecting organism may be identified based on the detection of abnormal cell growth (cytopathic effects), or use of immunoassays or molecular assays for the specific agent of interest. Definitive identification of the infectious agent after growth in cell culture is by agent-specific fluorescent antibody staining or by nucleic acid–based tests.
- False-negative results may occur as a result of: (1) timing of specimen collection, (2) deterioration of organisms during transport, and (3) inability of the agent of interest to grow in the selected cell line used in the test system.
- As with all diagnostic tests, positive cell culture isolation results may not be the definitive link to the cause of an animal's signs because some organisms can be present without causing disease.

INTRODUCTION

Cell culture refers to the growth of eukaryotic cells under controlled conditions within the laboratory (*in vitro*). Infectious agents that require living host cells for replication may be isolated in the natural host (*in vivo*), in embryonated eggs (*in ovo*), or in cell culture. The development of routine growth of eukaryotic cells under defined laboratory conditions in the late 1940s ushered in an era of rapid advancement in the characterization of viral pathogens as well as the development viral vaccines, e.g., poliovirus vaccine. Virus discovery was largely confined to research laboratories, but the expansion of commercial products and cell lines moved virus culture into diagnostic laboratories. By the 1980s, there was some thought that the discovery of most viral pathogens was complete. However, the start of a new era in pathogen discovery came with the identification of hepatitis C virus exclusively using molecular cloning techniques. It was recognized that more viral pathogens existed than could be grown in standard cell culture systems. The application of polymerase chain reaction (PCR) technology demonstrated the potential of molecular techniques (nucleic acid–based detection) in diagnostic testing. Use of next-generation sequencing (NGS) may result in identification of all viruses in existence within the next few years. The sensitivity and speed of molecular diagnostic assays has led to cell culture being used less often for routine clinical diagnostic purposes because of the longer turnaround times (days to weeks) and the cost to maintain a cell culture facility (Table 1.1). Nevertheless, isolation of viral and intracellular bacterial and protozoal pathogens in cell culture remains an important technique for the discovery of new pathogens, the propagation of isolates for research purposes, the generation of organisms for vaccination purposes, and the establishment of the efficacy of novel antimicrobial drugs. Vaccines for dogs and cats that are propagated in cell culture include those for canine distemper virus (CDV), canine adenovirus, parvovirus, rabies virus, and feline viral and chlamydial respiratory tract disease agents. Veterinary clinicians should remain aware of situations where cell culture may be the best technique to identify the presence of a novel infectious agent and the ideal methods for collection and submission of specimens. Knowledge of cell culture methods can help veterinary clinicians to submit the optimum specimens, to understand laboratory turnaround times, to be aware of potential complications, and to interpret results in the proper context.

SPECIMEN COLLECTION AND TRANSPORT

Although cell cultures can be used to propagate intracellular bacteria and protozoa, it is now most often used for the diagnosis of viral infections. Proactive communication between the clinician and the laboratory that performs viral isolation is recommended to improve the chances of a successful virus isolation. Many viruses have restricted host ranges and will only grow in cells from the affected species. Submitting specimens to a laboratory that does not have broad capabilities lowers the chances for a successful test outcome. Successful detection of viruses is also highly dependent on: (1) collecting the appropriate specimens, (2) the timing of specimen collection, and (3) rapid and proper specimen transport and processing. Thus, the actions of the veterinary clinician play a critical role in ensuring positive test results when a virus is present.

Information that should be discussed with the laboratory before specimen collection, and forwarded together with the specimen, includes the clinician's differential diagnosis, the patient signalment, history, clinical signs, immune status, travel history, and the number of animals affected (Box 1.1). This information is used to guide the selection of the best

TABLE 1.1 Alternatives to Cell Culture for Diagnosis of Obligate Intracellular Pathogens That Infect Dogs and Cats

System Affected and Most Common Agents	Other Diagnostic Tests Available
Respiratory Tract	
Canine respiratory coronavirus	RT-PCR
Canine adenovirus-2	PCR
Influenza viruses	RT-PCR, serum antibody detection
Canine parainfluenza virus	RT-PCR
Canine distemper virus	RT-PCR, antigen detection using FA
Canine herpesvirus	PCR, antigen detection using FA
Feline herpesvirus-1	PCR, IHC
Feline calicivirus	RT-PCR, IHC
Pneumovirus (both canine and feline)	RT-PCR
Eye	
Chlamydia felis	PCR
Feline herpesvirus	PCR
Canine herpesvirus	PCR
Central Nervous System	
Canine distemper virus	RT-PCR, antigen detection using FA,
West Nile virus	CSF antibody detection
Encephalitis viruses	RT-PCR, IHC
	RT-PCR, IHC
Gastrointestinal Tract	
Coronaviruses	RT- PCR
Canine distemper virus	RT- PCR, antigen detection using
Canine and feline parvovirus	direct FA
	PCR, antigen detection using direct FA
Reproductive System	
Canine herpesvirus	PCR
Congenital and Perinatal	
Canine herpesvirus	PCR
Feline herpesvirus-1	PCR
Blood	
Feline leukemia virus	PCR, antigen detection (ELISA)
Feline immunodeficiency virus	PCR, antibody detection
Anaplasma phagocytophilum	PCR, antibody detection
Rickettsia rickettsii	PCR, antibody detection
Ehrlichia canis	PCR, antibody detection

array of cell cultures to achieve a successful outcome. For example, there is very little value in attempting to isolate CDV from a fully immunized 6-year-old dog with neurological signs. In the absence of vaccination history, CDV would be on the top of the differential list. Some viruses, such as feline coronavirus (FCoV), are difficult to isolate in cell culture or grow slowly, whereas others, such as feline calicivirus (FCV), replicate readily and rapidly in cell culture, and the sensitivity of cell culture is high. Viruses differ with respect to the cell type in which they prefer to replicate. As a result, specimens should be sent to the laboratory with information on the specific viruses that are suspected, but the isolation procedure in the laboratory should be nontargeted in order to isolate all viruses in the specimen, even those unknown to the clinician.

BOX 1.1 Factors to be Discussed With Diagnostic Laboratories Before Collection of Specimens for Pathogen Isolation in Cell Culture

- Patient species, breed, age, and environment
- Number of animals affected
- History and clinical signs
- Immune status of the patient
- Geographic location and travel history
- Suspected infectious agents
- Timing of specimen collection
- Type and amount of specimen to be collected
- Transport conditions, including timing and method of transportation

For acute viral infections, the timing of specimen collection is of paramount importance. Specimens should be collected as early as possible following the onset of clinical signs because viral shedding commences before the onset of signs and may continue for only a few days. The duration of viral shedding depends on the type of virus and the anatomic site sampled. For rotavirus infections, for example, fecal specimens may have undetectable agent as early as 48 hours after the onset of diarrhea. When multiple animals are affected, collection of specimens from more than one animal may increase the chance that an isolate will be obtained. If possible, antibody testing using acute and convalescent phase serology should be performed concurrently to help confirm the diagnosis (see Chapter 2).

Selection of the best specimen type and collection site for cell culture is optimized based on knowledge of the pathogenesis of the suspected infectious agent, because the optimum specimen collection site may not be the site where clinical signs are most severe. Submitting a blood sample for the isolation of canine influenza virus is largely without value as influenza virus replication in the dog is restricted to the respiratory tract. Specimen size should also be maximized (e.g., at least 5 mL of blood, body fluids, or lavage specimens) to increase the chance of a positive isolation with the use of multiple cell lines. Specimens from multiple collection sites, e.g., nasal and oropharyngeal swabs, can only enhance the chances for a successful agent detection. Swab specimens should be collected by placing a long-shafted swab in the area to be sampled, rotating the swab against the mucosa, and allowing the secretions to be absorbed for approximately 5 to 10 seconds. The type of swab used should be a plastic shaft with synthetic fiber as cotton/wood swabs may contain inhibitors that affect agent detection.

Swabs and small tissue specimens for virus isolation should be placed in buffered virus transport medium that contains antibiotics and protein stabilizer such as fetal bovine serum or bovine serum albumin. The transport medium can be obtained from the laboratory or purchased from other commercial sources.

Liquid specimens such as blood, CSF, and bronchoalveolar lavage fluid do not need to be placed in the transport medium prior to cell culture. Blood samples should be collected using sterile technique, with antiseptic preparation of the site of venipuncture, and can be submitted in EDTA anticoagulant tubes.

All specimens should be refrigerated on collection and transported as quickly as possible (preferably within 24 hours) to the laboratory because delayed transport can lead to a decrease in organism viability. If delays in excess of 2 to 3 days are anticipated, the specimen can be frozen, but whole blood should never be frozen as it becomes unusable for testing. Freezing should be avoided whenever possible, as it may lead to a loss of virus viability particularly in freezers available to clinicians. If freezing is unavoidable, freezing at –70°C is preferable to

TABLE 1.2 Specimen Collection Guide for Diagnosis of Viral and Intracellular Bacterial Infections of Companion Animals

System Affected	Possible Agents	Specimen Type
Respiratory tract	Dogs: respiratory coronaviruses, canine adenovirus, influenza viruses, parainfluenza virus, CDV, canine herpesvirus, canine pneumovirus Cats: FHV-1, FCV, influenza viruses, feline pneumovirus	Oropharyngeal swabs, nasal swabs,[1] transtracheal wash or bronchoalveolar lavage specimens: ideally 5–10 mL of fluid Lung tissue obtained at biopsy or necropsy, including an area adjacent to affected tissue
Eye	Dogs: canine herpesvirus, canine adenovirus Cats: FHV-1, *Chlamydia felis*	Conjunctival swab, scraping or biopsy
Central nervous system	Dogs: CDV, arboviruses	CSF: ideally at least 0.5–1 mL. Blood: at least 5 mL. Brain at necropsy
Gastrointestinal tract	Dogs: CDV, CPV, rotaviruses, canine coronavirus Cats: FCoV, FCV, noroviruses	Feces: ideally an olive-sized portion of formed feces or at least 5 mL of liquid stool Intestinal biopsies obtained using endoscopy or surgery, or intestinal tissue obtained at necropsy
Genital	Dogs: canine herpesvirus Cats: *Chlamydia felis*	Vesicle scrapings, vaginal swabs
Congenital and perinatal	Dogs: canine herpesvirus, CPV Cats: FHV-1, FeLV	Blood, tissues obtained at necropsy
Blood	Dogs: *Anaplasma phagocytophilum, Rickettsia rickettsii, Ehrlichia canis* Cats: FeLV, FIV, FCoV	Blood: ideally 8–10 mL

freezing at –20°C, and shipping on dry ice is preferable. The laboratory should have a submission guide that should be checked for specimen handling recommendations.

Table 1.2 provides a guide to the recommended specimen types for isolation of viruses or obligate intracellular bacteria from companion animals. Specimens should be labeled with the patient data, the site(s) from which the specimen(s) was collected, and the date of specimen collection. Specimens should be placed inside leak-proof triple packaging and transported on wet ice or cold packs to the laboratory, especially if transport is expected to take longer than 1 hour. Sufficient absorbent materials should be placed within the secondary container in order to absorb all liquid in the sample in case of a spill. Specimens to be shipped must be labeled and handled according to governmental and International Air Transport Association (IATA) regulations for shipping materials known to contain "dangerous goods." This includes infectious substances classified as Category A or Category B substances, and dry ice. Category A infectious substances are those capable of causing permanent disability or life-threatening or fatal disease in otherwise healthy animals and humans.[2] Most specimens submitted by veterinarians belong to Category B, which are any infectious substances that do not fall under the criteria for inclusion in Category A. Updated documents providing guidance on regulations for the transport of infectious substances are provided online by the World Health Organization (WHO).[2] Permits may be required for the importation of international specimens.

DIAGNOSTIC METHODS

Maintenance of Cell Cultures in the Laboratory

In general, cells are grown as monolayers on specially coated plastic surfaces either in culture flasks or plates. The cells in the monolayer can be derived directly from an animal *(primary cell culture)*, which tend to have a limited life span, or they may be immortalized *(continuous cell lines)*. Primary cell cultures have two distinct advantages for the isolation of viruses. They are generally of a mixed cell population so that a virus that only grows in an endothelial cell, for example, could still be isolated, whereas a culture of only fibroblasts would fail to isolate that virus. Also, primary cultures may maintain differentiated characteristics that are essential for virus propagation. Early attempts to grow influenza virus in cell culture were met with sporadic success. Primary monkey kidney cultures showed modest success but passaged cells failed. This was because a key factor required for growth of influenza virus in cell culture is the presence of a cellular protease, which is lost upon primary cell passage. Further subculture of primary cell lines often reduces their sensitivity to viral infection. Primary cell cultures are produced by placing tissues in an enzymatic solution, such as trypsin or collagenase, in order to produce a single cell suspension. Primary cell cultures have been used widely for the isolation of intracellular pathogens of dogs and cats,[3–6] but are now infrequently used due to cost and availability of tissue samples.

Low-passage cell lines remain viable and useful for virus propagation for 20 to 30 population doublings. *Continuous cell lines* are the type of cell line used most commonly for diagnostic, research, and commercial purposes as they are easily obtainable and have predictable characteristics. These may have been derived from cancer cells (such as the widely used HeLa cell line derived from human cervical cancer cells of a patient named Henrietta Lacks),[7] or they may have spontaneously "immortalized" during culture of primary cells, or as is now common, they were developed by targeted genetic modifications. Two such immortalization modifications include expression of the large T antigen of SV-40 and the telomerase gene (hTERT). Immortalized cells may also be genetically modified so that they express virus receptor proteins. A prime example of this is the expression of the CDV lymphocyte receptor protein (SLAM) on Vero cells, which turns a tedious isolation procedure for CDV into one of the easiest virus isolation procedures. Continuous cell lines representing a wide variety of cell types are available from commercial suppliers (Table 1.3). Laboratories that perform virus isolation for disease diagnosis will generally inoculate multiple cell lines because different viruses from the same animal species may prefer to replicate in different cell types.

TABLE 1.3 Examples of Continuous Cell Lines Used for Isolation of Viruses and Intracellular Bacteria That Infect Dogs and Cats

Cell Line	Cell Origin	Pathogen(s)
Vero cells; recombinant Vero-SLAM cells	African Green monkey renal epithelial cells	CDV[11,12] *Rickettsia rickettsii*[13] *Toxoplasma gondii*[14]

Cells for culture are stored in the laboratory in liquid nitrogen tanks. The cells are thawed, dispersed in cell culture medium, and allowed to settle on the bottom of a plastic flask (Fig. 1.1). The cell culture medium keeps the cells moist and provides the cells with nutrients. *Minimum essential medium* (MEM), also known as *Eagle's MEM*, and *Dulbecco's medium* are examples of widely used synthetic cell culture media. The cell culture medium contains a balanced salt solution, essential amino acids, glucose, vitamins, and a bicarbonate buffering system. Variations of MEM are available, some of which contain nonessential amino acids, the pH indicator phenol red, and the pH buffering agent HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), which helps to maintain a physiologic pH despite the increasing concentration of CO_2 that is produced as a result of cellular respiration. The medium often requires supplementation with animal serum, most commonly fetal bovine serum, which is essential for the establishment of primary cell cultures. Serum-free medium has been used successfully for culture of canine and feline viruses,[8] but it is impractical to use in a diagnostic laboratory if multiple cell lines are being used as each one would need to be adapted to serum-free conditions.

To prevent bacterial or fungal contamination when viral pathogens are cultured, careful attention to sterile technique is required. Cell propagation procedures are generally performed in a biosafety cabinet and the culture medium used for isolation procedures is always supplemented with broad-spectrum antibiotics (ciprofloxacin, gentamicin, ampicillin) with or without an antifungal agent (amphotericin B or nystatin). Even with these precautions, an occasional specimen will be unsuitable for the full isolation procedure due to overgrowth with bacteria or a fungus. Cell culture flasks are placed in a humidified incubator that maintains temperature usually at 37°C, and a gas mixture that typically contains 5% CO_2 if the cultures are open to the atmosphere.

The cell culture flasks are removed from the incubator and examined using an inverted, phase contrast binocular tissue culture microscope (see Fig. 1.1), which allows examination of unstained cells through the bottom of the flask. Cells grown for isolation procedures should be in a semiconfluent state so that they can continue to replicate in the early phases of the isolation procedure. Viruses such as canine parvovirus will not grow in nonreplicating cells. In order to passage the cells, the medium is removed, and a small volume of trypsin or EDTA solution is added to the monolayer. The monolayer is incubated with the solution for several minutes, after which the cells detach from the flask and are resuspended in medium. Depending on the cell type, one confluent monolayer may be "split" into 3 to 10 new cultures.

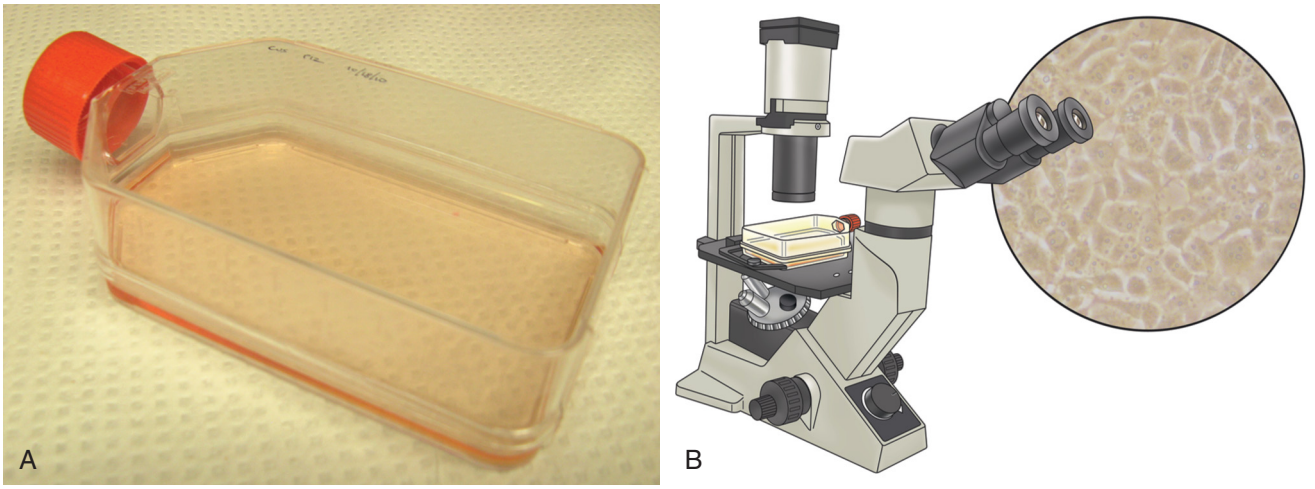

Fig. 1.1 (A) Plastic flask that contains cell culture medium. (B) A confluent cell monolayer is present at the bottom of the flask and can be visualized through the top of the flask using a binocular inverted microscope.

Occasionally, cell lines become cross-contaminated with other cell lines. The HeLa cell line is an example of a prolific and hardy cell line that commonly contaminates other cell cultures. Major cell line repositories such as the American Type Culture Collection (ATCC) use genetic typing methods to verify the identity of the cells in their collection. Receiving cell cultures from colleagues runs the risk that the culture may not be from the species claimed. Cell lines can also become easily contaminated with mycoplasmas, which pass through filters used to exclude other bacteria. The use of pipetting devices and biosafety cabinets has reduced the issue of mycoplasma contamination, but hundreds of lines are in use in research laboratories that are still contaminated. The presence of contaminating mycoplasmas can interfere with replication of other pathogens and cause alterations of cellular morphology. Mycoplasma contamination is detected using stains such as Hoechst stain (DNA stain), culture for *Mycoplasma* spp., and commercially available PCR assays that specifically detect mycoplasma DNA for the purpose of cell culture quality assurance.[9] Contamination of cell lines with noncytopathic viruses led to the spurious identification of animal viruses as human pathogens, particularly agents in the family *Paramyxoviridae.* Fetal bovine serum was certainly the source of bovine viral diarrhea virus that contaminated the Crandell-Rees feline kidney (CRFK) cell line frequently used for feline virus propagation.

Inoculation of Cell Cultures

Inoculation of a cell monolayer is accomplished by removal of overlying medium and adding a suspension of test material onto the cell monolayer. If tissue specimens are provided for culture, the specimens are disrupted in culture medium before they are inoculated onto the monolayer. Specimens may first be centrifuged to remove cell debris and bacteria. Passage through an appropriately sized filter can also be used before inoculation to remove bacteria. Organisms within the inoculum are then allowed to settle on the monolayer for approximately 1 to 3 hours before the residual inoculum is removed and fresh maintenance medium is added.

For detection of virus, the monolayer is then examined daily for evidence of cytopathic effect (CPE). CPE refers to the cellular changes induced by viral replication in the cell culture monolayer and includes cell lysis, cell rounding, or cell fusion (syncytium formation). The presence of CPE is determined by the comparison of inoculated cultures with uninoculated (control) cultures. The presence of a particular viral

(B) Hemadsorption: chicken erythrocytes adsorb to parainfluenza virus-infected cells that have incorporated hemagglutinin into the plasma membrane. (Courtesy of E. Dubovi, Cornell University.)

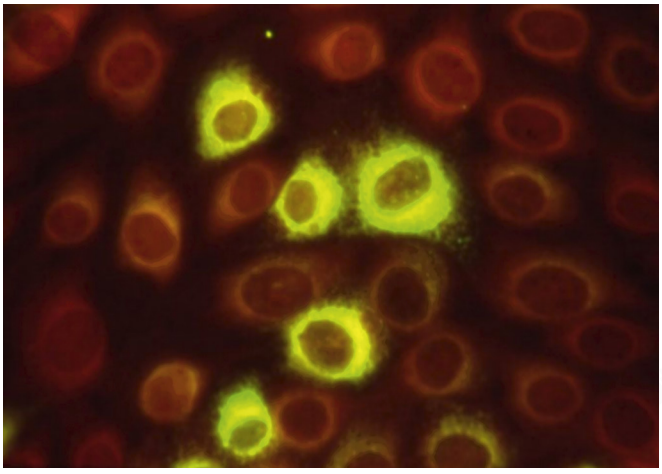

Fig. 1.4 Indirect fluorescent antibody detection of noncytopathic virus-infected cells. A cell monolayer exposed to virus for 72 hours was fixed with cold acetone. Fixed cells were stained with a mouse monoclonal antibody specific for bovine viral diarrhea virus, followed by a goat anti-mouse serum tagged with fluorescein isothiocyanate. (From Maclachlan NJ, Dubovi EJ. *Fenner's Veterinary Virology*. 4th ed. New York: Academic Press; 2011.)

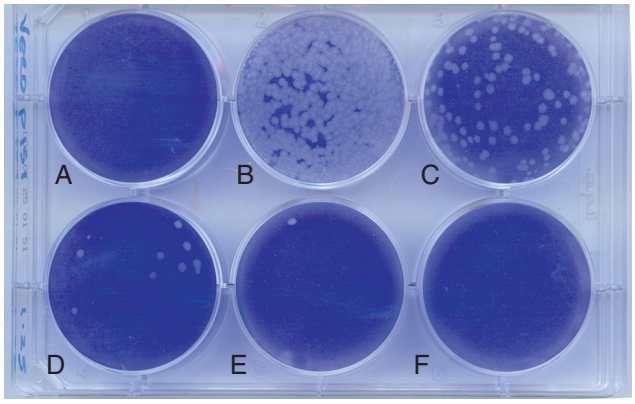

Fig. 1.5 Determination of the concentration of infectious virus using a plaque assay. Vero cell monolayers were inoculated with serial 10-fold dilutions of vesicular stomatitis virus. After a 1-hour adsorption period, cultures were overlaid with 0.75% agarose in cell culture medium containing 5% fetal bovine serum. Cultures were incubated for 3 days at 37°C in a 5% humidified CO_2 atmosphere. The agarose overlay was removed and cultures fixed and stained with 0.75% crystal violet in 10% buffered formalin. (A) Control culture. (B–F) Serial 10-fold dilution of virus: (B) 10^{-3}, (C) 10^{-4}, (D) 10^{-5}, (E) 10^{-6}, (F) 10^{-7}. (From Maclachlan NJ, Dubovi EJ. *Fenner's Veterinary Virology*. 4th ed. New York: Academic Press; 2011.)

pathogen is suspected by the appearance of characteristic CPE for that pathogen after a predicted incubation period (Fig. 1.2). For example, CPE induced by FCV is characterized by cell rounding and detachment that can occur within 24 hours, and within 16 hours for highly virulent strains.[10] Examination of the cell monolayer using light microscopy after fixation and staining can reveal additional diagnostic features, such as the presence of inclusion bodies and syncytium formation. Some viruses are relatively noncytopathogenic. The presence of some of these viruses can be demonstrated by adding washed erythrocytes to the monolayer and examination of the monolayer for evidence of hemadsorption (Fig. 1.3). Hemadsorption results from incorporation of viral surface hemagglutinin molecules into the plasma membranes of the cell culture monolayer. Parainfluenza viruses from many animal species are examples of hemadsorbing viruses that produce minimal CPE. Other, more sensitive and specific methods for identification of an organism that has infected a cell culture monolayer include fixation and staining of the monolayer with specific fluorescent antibodies (Fig. 1.4), use of molecular techniques such as PCR, or use of electron microscopy.

Plaque Assays

In 1915, with the discovery of viruses that infect bacteria, came the development of a laboratory procedure that had a profound effect on many aspects of virology. This procedure was the *plaque assay*, which permitted simple determination of the quantity of virus in a specimen. With the advent of cell culture, the same type of assay was developed for those viruses that are cytolytic for the host cells. Serial dilutions of virus are added to monolayers of susceptible cells. The monolayers are then overlaid with agar or methylcellulose, which restricts the spread of the virus to those cells adjacent to the initially infected cell. After an incubation time defined by the type of virus, "holes" in the monolayer, or *plaques*, can be visualized (Fig. 1.5). The monolayer can then be stained to make the plaques easier to see, and the number of plaques are counted in order to determine the amount of virus in the inoculum. Plaque assays are commonly used by researchers to assess the efficacy of antiviral treatments through reduction of plaque formation. This same principle of a reduction in plaque number is used to assess the amount of antibody in a serum sample. The plaque reduction

TABLE 1.4 Biosafety Levels (BSLs) Set for Diagnosis of Laboratory Practices

Level	Risk	Examples	Example Precautions
BSL 1	Minimal potential hazard to human health and the environment	CAdV-1, nonpathogenic *Escherichia coli*	Gloves, standard microbiologic practices using bench-top techniques. Routine decontamination practices (hand washing, routine bench disinfection, autoclaving of infectious waste)
BSL 2	Moderate potential hazard to human health and the environment. Organisms cause mild disease or are difficult to contract as laboratory aerosols. Agents for which effective vaccines or antibiotic treatment exist.	Most veterinary viruses, including influenza viruses	Access to the laboratory restricted when work is taking place; extreme precautions with sharp contaminated materials; use of appropriate biosafety cabinets when generation of aerosols possible. Eye protection. No requirement for directional airflow into the laboratory
BSL 3	Dangerous agents that can be transmitted by aerosol.	West Nile virus Equine encephalitis viruses, *Rickettsia rickettsii, Coxiella burnetii, Mycobacterium tuberculosis*	Laboratory is located away from high-traffic areas. Restricted laboratory access when work in progress; double door entry, ventilation providing airflow into the room, exhaust air not recirculated; special practices and protective clothing for BSL 3, including biosafety cabinet use; special floor and ceiling materials specified
BSL 4	Dangerous and exotic agents that pose a high risk of aerosol-transmitted laboratory infections, or which produce severe or fatal disease in humans	Ebola virus Marburg virus Smallpox virus Lassa fever virus	Hazmat suit and self-contained oxygen system, entrance containing multiple showers, a vacuum room, an ultraviolet light room, and multiple airlocked doors. Strict control of laboratory access to authorized personnel

neutralization test is widely used to test for antibodies to West Nile virus, Zika virus, and many other arboviruses where there is significant cross-reactivity among the neutralizing antibodies.

Laboratory Safety Concerns That Relate to Cell Culture

The processing of specimens in a biological safety cabinet not only serves to protect cultures from contamination but also acts to protect the laboratory worker from laboratory-acquired infections. Cell cultures alone are considered biohazards and disposal of the cultures and culture fluids must follow the guidelines for disposal of regulated medical waste. Most viruses grown in veterinary diagnostic laboratories are classified as pathogens that should be handled with biosafety level 2 (BSL 2) equipment and procedures. BSLs range from 1 through 4 (Table 1.4). In the United States, the Centers for Disease Control and Prevention (CDC) defines the biosafety procedures and classifies pathogens as to the BSLs needed to safely work with the pathogens. It is important that veterinary clinicians are aware that isolation of hazardous pathogens can only be conducted in specially designed and accredited laboratories.

INTERPRETATION OF RESULTS

Negative Results

Reasons for negative test results using virus isolation are numerous, so the clinician should not assume that a virus is not present when a negative test result is obtained (Box 1.2). Negative test results can occur due to: (1) a lack of viral shedding by the animal at the time of specimen collection, (2) the binding of antibodies to viruses within the specimen, (3) inadequate organism numbers at the anatomic site of specimen collection, or (4) loss of organism viability during transportation to the laboratory. Loss of viral viability is more likely to occur with enveloped viruses such as CDV than with nonenveloped, hardy viruses such as canine parvovirus or FCV. Negative test results can also occur when the cell line inoculated is not sensitive to the virus present in the specimen. This could be because the wrong cell line was used to test for a virus that could be cultured, or a viral pathogen existed in the sample for which no cell line was capable of growing *in vitro*, e.g., canine circovirus.

BOX 1.2 Reasons for Negative Test Results Following Isolation of Viruses in Cell Culture

- Virus not causing the disease
- No viral shedding at the time of sampling
- No viral shedding at the site of sampling
- Antibody interference with viral infectivity for cell culture
- Inadequate organism numbers at the anatomic site of specimen collection
- Loss of organism viability during transportation to the laboratory
- Overgrowth of one viral pathogen by another
- Overgrowth by bacterial or fungal agents
- Lack of cell sensitivity for the virus (wrong cell type inoculated)
- Laboratory inexperience with techniques required for virus isolation and identification

Inconclusive test results can also occur if the cultures are overgrown by bacteria or fungi before a virus test on the cells can be done. Although treatment of the viral transport and culture media with antimicrobials can help prevent this, resistant bacteria or fungi may still be present. Sometimes, multiple viruses are present within a specimen, and one virus overgrows another. For example, this can occur with mixed infections with FCV and FHV-1 in cats with upper respiratory tract disease. FCV rapidly infects CRFK cells and produces CPE, which obscures the concurrent presence of FHV-1.

Positive Results

It is imperative that veterinary clinicians be aware that the detection of a virus in a specimen does not always imply that the organism is the cause of the animal's clinical signs. This is especially true for specimens collected from the respiratory or gastrointestinal tracts, where multiple infectious agents may be present concurrently, and in many cases, viruses can replicate in these locations without causing clinical signs of illness. This is not as big an issue with virus isolation as it is with PCR panel tests where multiple potential pathogens are detected. In some animals, the development of severe clinical signs is more likely when there is simultaneous presence of multiple infectious agents. As noted previously for specimens that test negative, the presence of one agent

may also obscure the presence of another, more significant organism (such as with FCV and FHV-1 co-infections), which could result in the incorrect assumption that only one organism is the cause of an animal's disease.

Immunoassays

Jane E. Sykes, Shelley C. Rankin, Rance K. Sellon, James F. Evermann

KEY POINTS

- Immunoassays are commonly used in practice to detect antigen or antibody in body fluids. Immunoassays are also used to assess the need for vaccination for certain pathogens, and the need to provide booster vaccinations for animals in high-risk (e.g., kennels, catteries) environments.
- The term *serology* is most often used to refer to assays that detect antibody in serum.
- Immunoassays that detect antigen or antibody in animals suspected to have an infectious disease include enzyme-linked immunosorbent assay (ELISA), enzyme immunoassay (EIA), colloidal gold-based immunochromatographic assay (GICA), immunofluorescence assay (IFA), immunohistochemistry (IHC), western immunoblotting, agglutination tests, agar gel immunodiffusion (AGID), complement fixation (CF), and serum neutralization assays.
- Positive immunoassay results do not always imply active infection, and negative results do not rule out infection (e.g., mucosal infection).
- When interpreting the results of immunoassays, veterinarians should know what is being measured (antigen or antibody), and consider the likelihood of antigen or antibody being present in relation to the onset of illness, whether the positive test result is consistent with clinical signs, the animal's vaccination history, and immune status. The possibility of false-positive results due to immunologic cross-reactivity, as well as the analytical sensitivity and specificity of the test used (i.e., the test's performance), must also be considered.
- Additional assays, such as nucleic acid amplification tests, may be required to support or confirm a diagnosis made by an immunoassay.

INTRODUCTION

Serology is the measurement of antigen-antibody interactions for diagnostic purposes, but is most often used to refer to the detection of antibodies in serum. Assays used to measure antigen-antibody interactions can also be used on body fluids other than serum such as plasma, urine, CSF, thoracic or abdominal fluids, and aqueous humor. Assays have been designed that detect specific classes of antibodies, most commonly IgG or IgM. Methods used to detect specific antibodies can also be applied to detect specific antigens.

Assays that measure antigen-antibody interactions for diagnostic purposes are broadly referred to as *immunoassays*. Some types of immunoassay include enzyme-linked immunosorbent assay (ELISA), immunofluorescence assay (IFA), colloidal gold-based immunochromatographic assay (GICA), complement fixation (CF), agglutination tests, agar gel immunodiffusion (AGID or gel ID tests), and western blotting.[1] Many of these assays involve the use of *polyclonal antibodies* or, more commonly, *monoclonal antibodies,* which are commercially available. Polyclonal antibodies are produced in animals (e.g., rabbits or horses) as a normal response to antigen exposure. Monoclonal antibodies are derived from murine antigen-primed B cells that are fused with tumor cells to create a hybridoma cell culture line. Once in culture, virtually unlimited amounts of antibody are produced with a high degree of antigenic specificity.

In general, a blood sample is *seroreactive* (or *seropositive*) if it contains antibodies to a particular organism. Some immunoassays, such as ELISA and IFA, provide quantitative results, expressed as optical density units (ODs) or titers (e.g., 1:800, or *reciprocal titer* = 800). Exposure of an immunocompetent individual to an infectious agent results in a rise in antibody titer over time (Fig. 2.1). The first antibody class to be produced by plasma cells is IgM, after which IgG synthesis by plasma cells occurs. When infection by a pathogen occurs for the first time, there is a lag phase of 5 to 7 days before IgM antibodies can be detected in the blood *(primary antibody response).* Over time, the antibody titer, composed predominantly of IgG antibodies, increases, and if the infectious agent is cleared by the host immune system, there is a progressive decline in the titer over weeks to months. The speed and magnitude by which the antibody titer rises depends on host factors and the infectious agent involved. For some diseases, such as leptospirosis, a significant rise occurs within 3 to 4 days of the onset of clinical signs. In secondary, or anamnestic, immune responses, the lag phase is shorter, the antibody titer increases more rapidly and to a greater magnitude, and antibodies may persist for longer periods of time (months to years).

Serologic diagnosis of infectious diseases relies on an understanding of the timing of the antibody response in relation to development of clinical signs. The results of serologic testing are interpreted differently for acute infections than they are for chronic, persistent, or mucosal infections. *For infections with a short incubation period,* such as leptospirosis or Rocky Mountain spotted fever, antibody is often undetectable (i.e., the patient is seronegative) in the first week of illness, although recently available assays offer potential for earlier diagnosis of leptospirosis because of IgM detection.[2] In general, an increase in antibody titers over a 2- to 4-week period then occurs. *Seroconversion* is consistent with recent infection, and at least a fourfold increase in titer is required for the change to be considered significant (e.g., 1:4 to 1:16; 1:128 to 1:512). Because serologic test results can differ between laboratories that perform the same assay, the same laboratory should be used to determine the acute and the convalescent titer. Rather than an increase in titer, a fourfold decline in the antibody titer also may

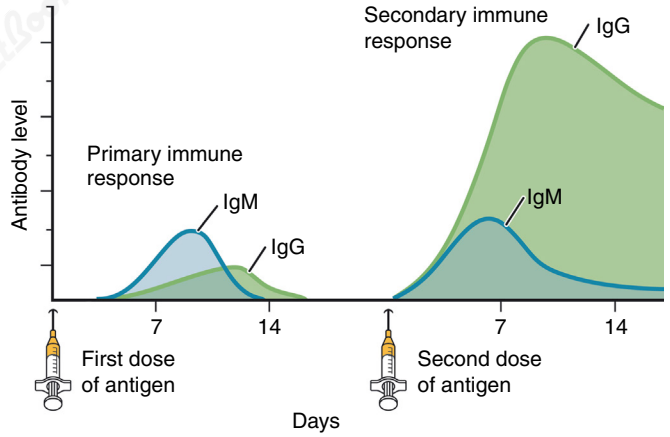

Fig. 2.1 Time course of primary and secondary immune responses, showing relative amounts of IgM and IgG produced at different times after antigen exposure. (Modified from Tizard IR. *Veterinary Immunology*. 8th ed. St Louis: Saunders; 2008.)

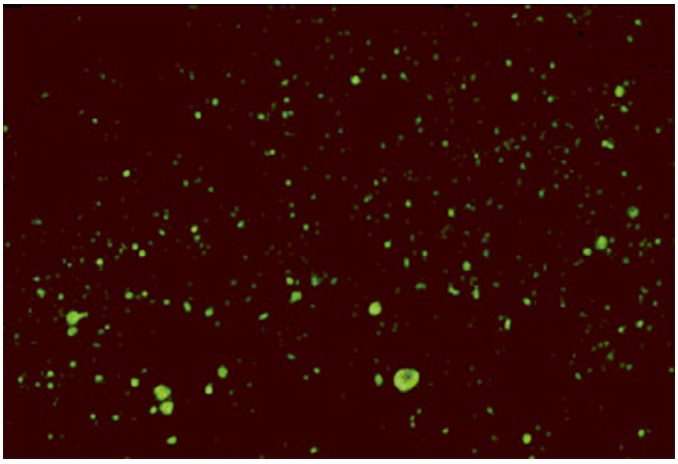

Fig. 2.2 Direct fluorescent antibody stain of brain tissue for rabies virus. Frozen tissue sections are stained with a commercial reagent that contains monoclonal antibodies specific for the rabies virus nucleocapsid. Antibodies are labeled with fluorescein. (From Centers for Disease Control and Prevention. Direct Fluorescent Antibody Test. https://www.cdc.gov/rabies/diagnosis/direct_fluorescent_antibody.html. Accessed April 28, 2022.)

be consistent with recent infection, depending on the stage of illness at which serologic testing is performed. *For chronic, persistent infections*, such as those caused by FIV or *Ehrlichia canis*, a single, positive antibody titer can indicate active infection. Titer increases do not occur when infection persists beyond 1 to 2 months, and so acute- and convalescent-phase serology is not useful for diagnosis of chronic infections.

SPECIMEN COLLECTION AND TRANSPORT

Blood collected for antibody testing should be allowed to clot, or collected in a serum separator tube. Once the serum is separated, it can be removed and refrigerated or frozen. Serum can be refrigerated for up to a week before it is shipped to the laboratory. If testing is to be delayed for longer than a week, serum should be frozen at –20°C or –80°C. Serum can be stored frozen (frost-free freezers not recommended) for years without loss of antibody titer. For serum and other body fluid specimens collected for antigen testing, assay results may be more susceptible to variation with specimen storage. The laboratory should always be contacted in order to determine specimen storage and handling requirements.

DIAGNOSTIC METHODS

Immunofluorescence and Immunoperoxidase Antibody Assays

Direct IFA (also known as direct FA) detects *antigen* in clinical specimens. IFA involves the use of an antibody that has been tagged (*conjugated*) with a fluorescent label (such as fluorescein isothiocyanate) to detect the presence a specific antigen. IFA is performed directly on a glass slide, and fluorescence is detected by microscopy. The sensitivity of direct IFA is too low to detect individual virus particles or soluble antigen, so usually IFA detects accumulated antigen present in association with eukaryotic or bacterial cells in smears or tissues fixed on a glass slide. If the antigen is intracellular, pretreatment of the slide to permeabilize the cells may be necessary. The glass slide is then incubated with a solution that contains the fluorescent antibody, washed to remove unbound antibody, and the slide examined using a fluorescence microscope (Fig. 2.2). Examples of the use of direct IFA in veterinary medicine include detection of *Giardia* oocysts, FeLV within nucleated cells in peripheral blood or bone marrow, or CDV within epithelial cells from a conjunctival scraping, or lymphocytes from a peripheral blood smear. Nonspecific fluorescence can result in false positives using these methods, but this can be overcome with the inclusion of proper controls and technical expertise.

An alternative to the use of a fluorescein-conjugated antibody is the use of an antibody that has been conjugated to an enzyme such as horseradish peroxidase (immunoperoxidase). A substrate, most commonly 3,3′-diaminobenzidine (DAB), is then added to the slides. In the presence of hydrogen peroxide, DAB is converted to an insoluble brown precipitate which can be visualized using conventional light microscopy. This technique is known as *immunocytochemistry*. The same method, when applied to tissue sections, is known as *immunohistochemistry* (IHC; Fig. 2.3).

Indirect IFA (also known as IFA testing, or IFAT) is generally used to establish a serum *antibody* titer to an infectious agent, but it can also be used to detect antigen. When used to detect antigen, it is more sensitive than direct IFA. For measurement of antibody titer, patient serum is serially diluted in the laboratory and reacted with a known antigen that has been fixed to glass slides commercially manufactured for this purpose. Slides are then washed to remove unbound nonspecific antibody. A *secondary antibody*, conjugated to a fluorescent label and designed to react with the bound patient antibodies (e.g., dog IgG or dog IgM), is applied to the slides, which are washed again. The slides are then examined using a fluorescence microscope. The highest dilution of serum that results in specific fluorescence is reported as the antibody titer to the infectious agent of interest. Examples of the use of indirect IFA for serologic testing in dogs and cats include quantitative serology for some tick-borne infectious agents (e.g., *E. canis*, *Anaplasma* spp.), and antibody titer measurements to determine if an individual animal has adequate concentrations of specific IgG (e.g., to CDV).

Veterinary IFAs have been marketed that allow multiple antigen (or antibody) targets to be mounted on novel platforms, such as fluorescent beads or wells on the surface of a spinning silicon disc that resembles a compact disc. Automated silicon disc–based assays allow rapid and simultaneous analysis of hundreds of specimens, with dramatic reduction in labor associated with traditional IFAs or ELISAs, and reduced chance of false-positive or -negative assay results due to human error. A bead-based assay is currently available in the United States for detection of antibody to *Borrelia burgdorferi* (see Chapter

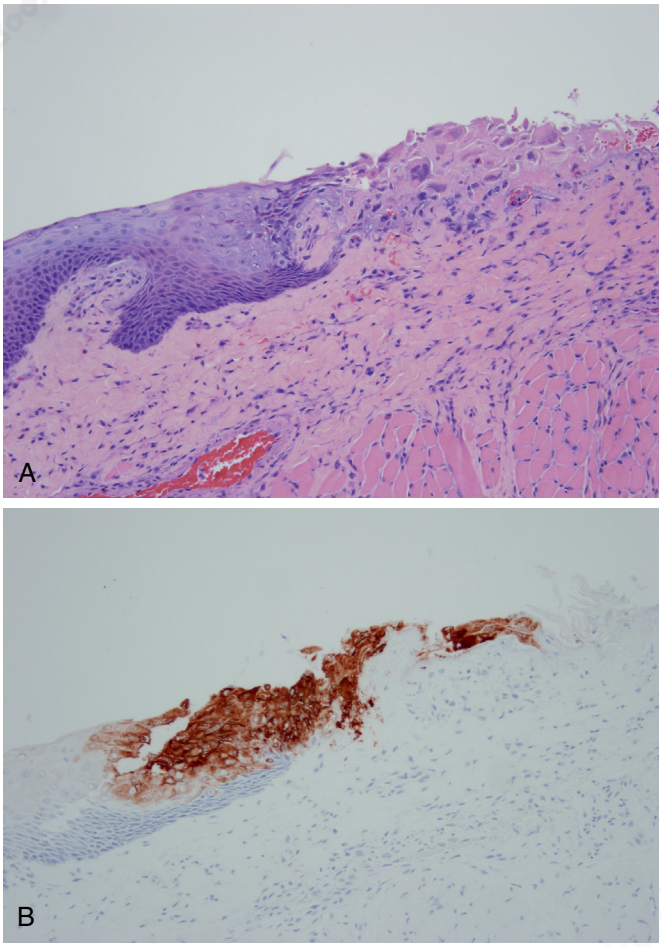

Fig. 2.3 Immunohistochemistry. (A) Hematoxylin and eosin–stained section of a lingual ulcer from a cat infected with feline herpesvirus-1. (B) The brown stained cells lining the ulcer are positive using an immunohistochemical stain for feline herpesvirus-1. (Courtesy of Dr. Patricia Pesavento, School of Veterinary Medicine, University of California, Davis.)

69) (Lyme Disease Multiplex Testing for Dogs, Animal Health Diagnostic Laboratory, Cornell University, NY, USA). A silicon disc–based assay is available in the United States for detection of antibodies to *B. burgdorferi, E. canis,* and *Anaplasma phagocytophilum* and antigen to *Dirofilaria immitis* (Accuplex 4, Antech Diagnostics, Irvine, CA, USA).

Enzyme-Linked Immunosorbent Assay (ELISA)

ELISA (also known as *enzyme immunoassay*)-based strategies can be used to detect antibody, whole antigen, or immunogenic peptides (those peptide sequences of a protein capable of inducing an immune response). In the laboratory, ELISA is usually performed in a polystyrene microtiter plate. However, modifications of the test, such as flow-through (as seen with SNAP tests by IDEXX Laboratories, ME, USA[3]), in which antigen or capture antibody is immobilized on a polyethylene matrix, are widely used as in-clinic assays in veterinary practices (e.g., for diagnosis of feline retrovirus, heartworm, *Giardia*, *Leishmania*, and tick-borne bacterial infections) (Fig. 2.4). For *antigen* detection, an unknown quantity of antigen in a clinical specimen is immobilized in the wells of the plate. The antigen is either bound directly to the surface of the plate, or is bound through the use of a *capture antibody*, an antibody adherent to the plate surface that specifically binds the antigen of interest *(sandwich ELISA)*. The antigen is then detected with an antibody, or for a sandwich ELISA, a second antibody, that is conjugated to an enzyme such as immunoperoxidase, and the substrate is added. This results in a color change, which can be read visually or using an ELISA plate reader (Fig. 2.5). The plate reader records optical density of the wells in comparison with that of the control wells, allowing assessment of the quantity of antigen present. The plates are washed with a detergent solution between steps, and this can be automated using an ELISA plate washer. Sandwich ELISAs have been used for detection of FeLV antigen in cat blood. In *competitive ELISA*, the test specimen (e.g., dog serum) that contains an unknown amount of antibody is mixed with a known amount of labeled antibody. The mixture is added to wells that contain known amounts of a capture antigen, and the labeled and unlabeled antibodies compete for antigen binding. The more

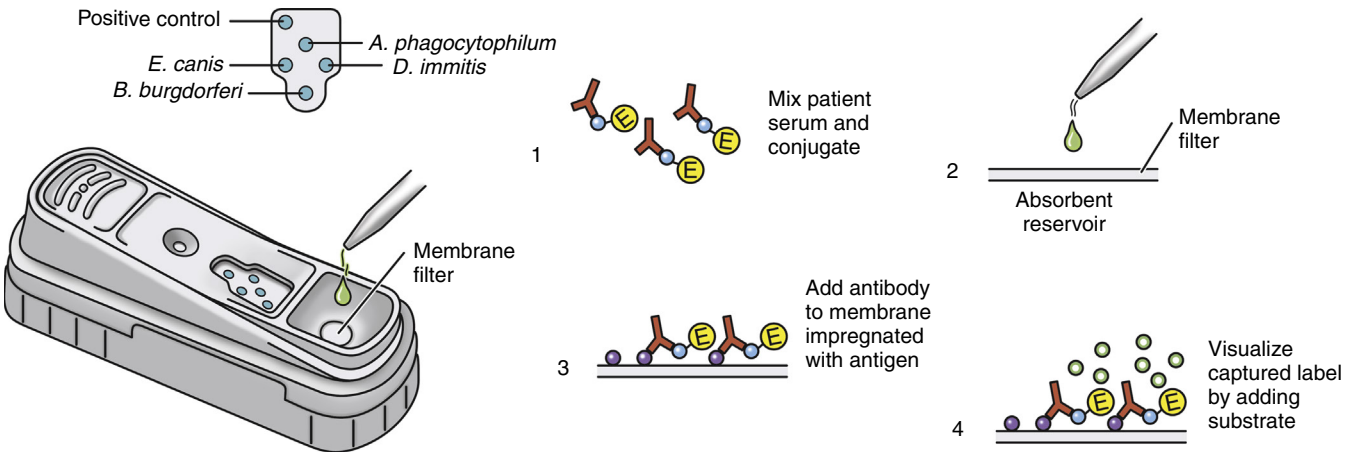

Fig. 2.4 Flow-through immunoassay device (IDEXX Laboratories, Inc.). Specific antigen (e.g., a recombinant protein) or antibody is immobilized on a membrane in the device in a spot or line. Patient serum that may or may not contain target antigen or antibody is mixed with a solution that contains conjugated antibody or antigen *(1)*. The solution is allowed to flow through the device, where it becomes captured on the membrane *(2 and 3)*. The device is activated (snapped), which releases wash and substrate reagents within the device. A positive reaction appears as a colored bar, or in this case, a dot *(4)*. Color development in designated spots on the membrane can indicate the presence of antibody to *Anaplasma* spp., *Ehrlichia* spp., and *Borrelia burgdorferi,* or the antigen of *Dirofilaria immitis.*

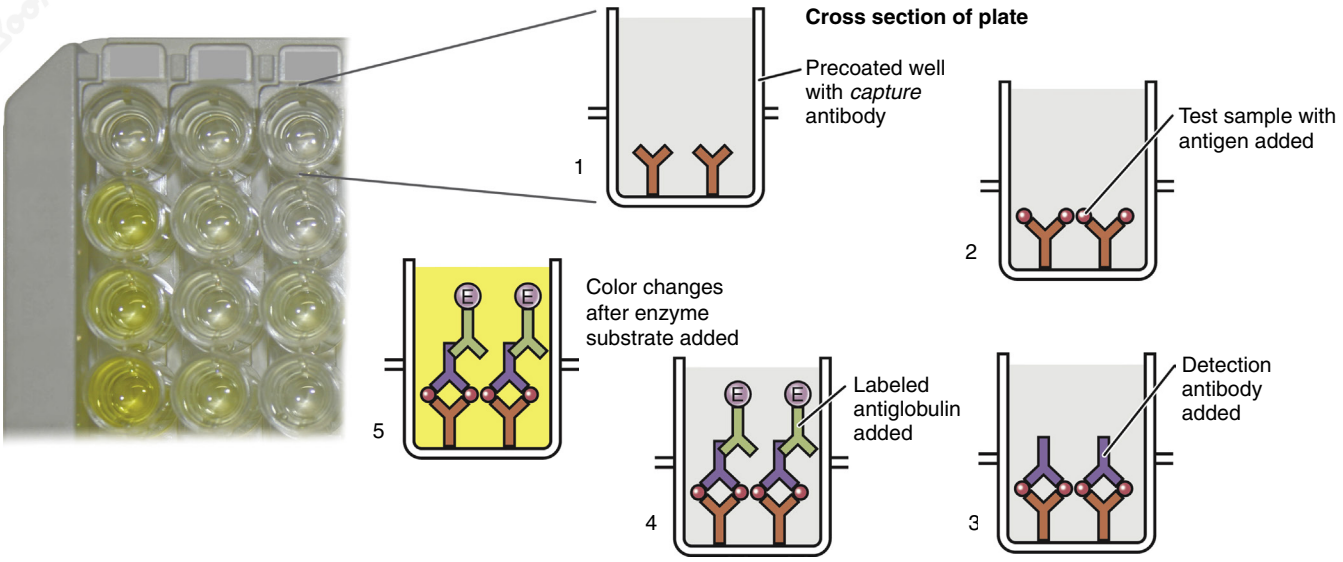

Fig. 2.5 Sandwich ELISA. An antibody is immobilized in the plate, which binds antigen in a test specimen. The antigen is then detected using an antibody that is conjugated to an enzyme such as immunoperoxidase, and the substrate is added, which results in a color change. (Modified from Tizard IR. *Veterinary Immunology*. 8th ed. St Louis: Saunders; 2008.)

labeled antibody that binds, the less antibody is present in the test specimen. Other variations of competitive ELISAs also exist.

For measurement of *antibody* titers, serial dilutions of serum can be added to a known amount of antigen fixed on a plate, and the antibodies detected using a secondary antibody.

Modifications of the ELISA test using the same principles of antibody or antigen binding to a substrate, and capture and detection strategies are also used in veterinary medicine. Examples include lateral-flow immunochromatographic tests whereby antigen or capture antibody is immobilized on a membrane filter, and detection of the antibody or antigen of interest is facilitated by gold nanoparticles (GICA), or colored nanobeads of other types, colored latex beads or fluorescent labels.[4] Because these assays do not use enzyme conjugates, they are not considered ELISAs. Paper-based platforms for immunochromatographic assays have also been explored to reduce cost and enhance ease of disposal.[5]

Western Immunoblotting

Western immunoblotting, also known as *western blotting*, is used to detect antibodies to an infectious agent in serum. After physical and/or chemical disruption of an organism, the organism's proteins are separated on the basis of molecular weight using vertical sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). The protein bands are then transferred *(blotted)* to a nitrocellulose membrane using an electric current. The membrane is cut into vertical strips, and each strip is incubated with patient serum. If there are antibodies in the serum to antigens from the organism of interest, the antibodies bind to the specific antigens on the strip. The antigen-antibody complexes can then be visualized as discrete bands using secondary antibody-based immunoperoxidase detection methods. The pattern of band reactivity is specific for an immune response to that organism (Fig. 2.6). Western blotting has been offered commercially for the diagnosis of FIV infection and *B. burgdorferi* infection and has been used in research laboratories as the gold standard for the detection of antibody responses to vector-borne pathogens such as *E. canis*. In the case of FIV infection, western blotting has been used to confirm positive ELISA test results.[6] In the case of *B. burgdorferi* infection, western blotting has been evaluated for its ability to differentiate between the response to vaccination and natural exposure,[7] although some ELISA systems that incorporate a synthetic peptide identical to one expressed during natural infection offer this ability (see Chapter 69).

Agglutination Testing

Agglutination tests detect antibody or antigen and involve agglutination of bacteria, red cells, or antigen- or antibody-coated latex particles. Such tests rely on the bivalent nature of antibodies, which can cross-link particulate antigens. Serial dilutions of serum are tested for their ability to cause or inhibit agglutination, and the highest dilution that causes or inhibits agglutination is reported as the antibody or antigen titer. IgM causes agglutination more effectively than IgG. If excess antibody is present, particles may become so coated with antibody that agglutination is actually inhibited. This is called the *prozone effect* and can result in false-negative test results if serum is not adequately diluted. Examples of agglutination tests used to diagnose infectious diseases of dogs and cats include the microscopic agglutination test (MAT) for serologic diagnosis of leptospirosis (agglutination of live leptospires) and the cryptococcal antigen latex agglutination test (agglutination of antibody-coated latex beads). Hemagglutination inhibition (HI) is used to determine antibody titers to canine parvovirus and canine influenza virus, and it evaluates the ability of serum to inhibit erythrocyte agglutination by these viruses.

Agar Gel Immunodiffusion (AGID)

For AGID (gel ID or double diffusion) tests, round wells are cut in a layer of agar on a plastic plate using a punch. One well, usually the central well, is filled with a soluble antigen, and the other wells are filled with patient serum. A positive antibody control specimen is included in each assay. The reagents are allowed to diffuse into the agar, and when antibodies and antigen meet in optimal proportions (the *point of equivalence*), immune complexes form resulting in a visible line of precipitate between the antigen well and wells that contain positive serum (Fig. 2.7). Immunodiffusion

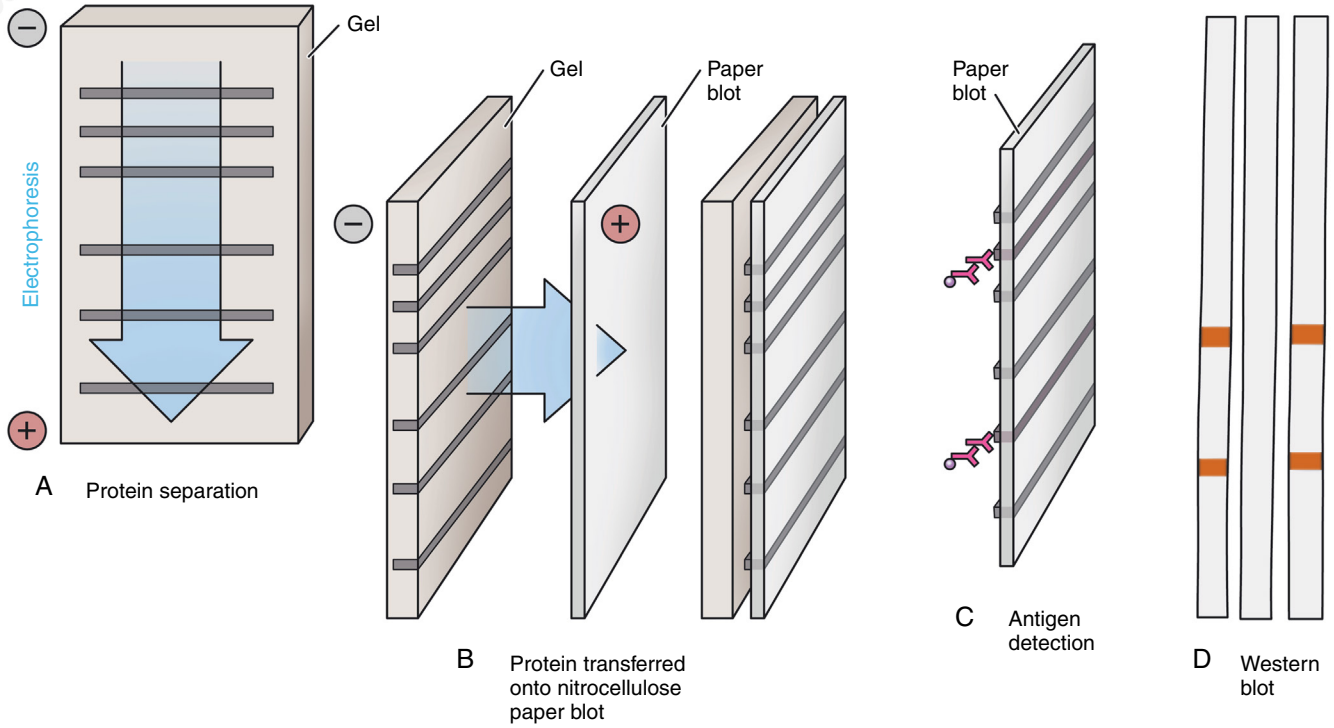

Fig. 2.6 Western blotting (immunoblotting). (A) Purified viruses or bacteria are disrupted and subjected to electrophoresis along the length of a polyacrylamide gel so that the proteins are separated according to their molecular weight. (B) The protein bands are transferred to a nitrocellulose paper membrane and (C) incubated with patient serum and then a labeled secondary antibody. (D) The outside strips represent a western blot that shows antibody reactivity to the antigens of feline immunodeficiency virus, while the middle strip reflects an absence of antibody reactivity.

tests are most often used to detect antibodies to fungal pathogens, such as *Aspergillus fumigatus*,[8] *Coccidioides* spp.,[9] and *Blastomyces* spp.,[10] and are also used to detect antibodies to *Brucella canis*.

Serum Neutralization

Serum neutralization is a technique used to determine the antibody titer to a virus. Serial dilutions of serum are mixed with a known quantity of virus particles. The mixture is incubated to allow the antibodies in the serum to bind to the virus particles, and the mixture is then added to a confluent cell monolayer. The highest dilution of serum that inhibits viral replication in the monolayer (as determined by examination for cytopathic effect or immunostaining) is the antibody titer reported by the laboratory. Serum neutralization can be used to detect antibodies to CDV and several respiratory viruses that infect dogs and cats.

Complement Fixation (CF) Testing

CF tests have largely been superseded by the use of ELISA-based tests. CF tests detect antibodies in serum. The test uses sheep red blood cells (RBCs), anti–sheep RBC antibody, and unheated guinea pig serum as a source of complement. Under normal circumstances, when these three reagents are mixed, the result is hemolysis which occurs when complement binds to antibody-coated RBC and triggers formation of the membrane attack complex, with resultant pore formation. In the CF test, a known antigen is added to patient serum heat-treated to inactivate complement in the test sample. When antigen-specific antibodies are present in the serum, addition of antigen leads to formation of antigen-antibody complexes. Guinea pig complement is then added to the mixture and is bound by the complexes. The resultant mixture is thus unable to lyse sensitized sheep RBCs. A lack of hemolysis indicates a positive CF test.

INTERPRETATION OF IMMUNOASSAY RESULTS

Interpretation of results of serology or immunoassay tests requires that the clinician knows whether the test detects antibody or antigen (Tables 2.1 and 2.2), and, if designed to detect antibody, whether the test is IgM-specific (detects early antibody responses), IgG-specific, or detects both immunoglobulin classes. Beyond diagnosis of infection, antigen detection assays can, when used serially during treatment for some infections (e.g., cryptococcosis; see Chapter 82), offer the additional advantage of predicting success (declining antigen concentrations) or failure (static or rising antigen concentrations) of therapy.

Immunoassay results should be interpreted in the context of the organism causing the infection, specifically the timing of antigen and antibody appearance in the body fluid being tested, and the prevalence of the infection in the population. Finally, the sensitivity and specificity of the test itself (i.e., the *analytical sensitivity and specificity*), which are determined during test validation should be available from the laboratory that performs the test (see also Chapter 7, Box 7.1). Some immunoassays that detect antigen will not generate a positive result unless a large amount of antigen is present in the specimen provided (low analytical sensitivity). Assays with low analytical specificity more commonly yield false-positive test results when testing animals from populations in which the prevalence of true positive test results is low, i.e., the prevalence of infection in the population is low. In this situation, a positive test has a *low positive predictive value,* and confirmatory testing may be required. A quality assurance program should be in effect in the diagnostic laboratory to ensure that specimens submitted are of adequate quality, that sufficient technical expertise is present to perform

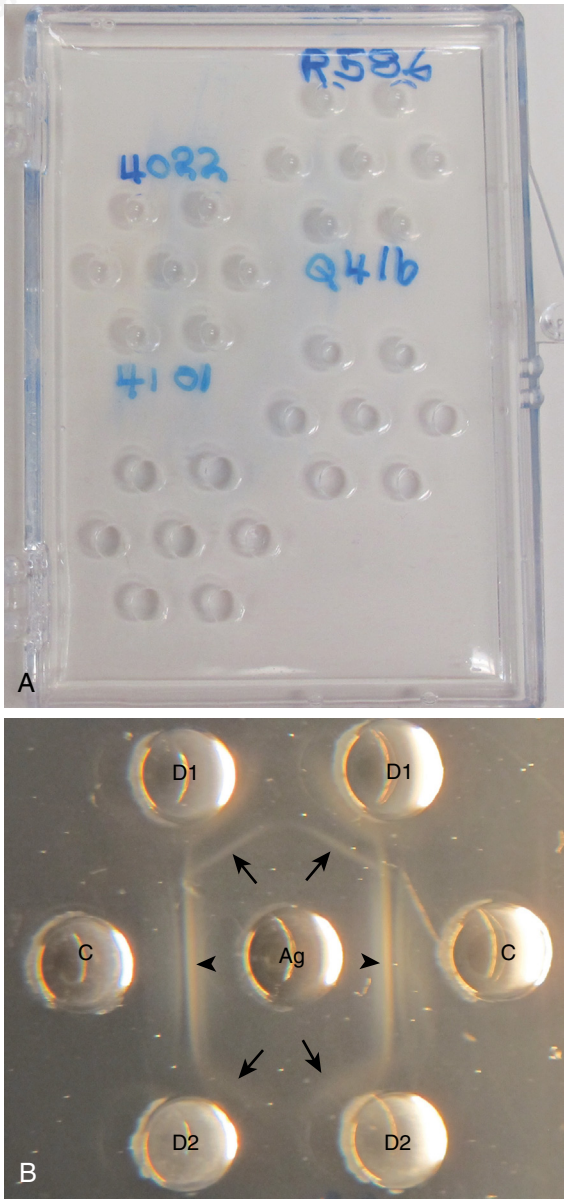

Fig. 2.7 (A) Gel immunodiffusion (or double diffusion) system used for detection of antibodies to *Aspergillus fumigatus, Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides* spp. (Meridian Bioscience, Inc.). The kit consists of an agar diffusion medium in a small plastic tray that contains four arrays of six wells arranged around a central well. An antigen preparation for each of the fungal species is placed in the central well of each array. (B) Positive gel immunodiffusion for *Aspergillus fumigatus*. The central well *(Ag)* contains a purified carbohydrate preparation from mycelial phase cultures of *Aspergillus fumigatus, Aspergillus niger,* and *Aspergillus flavus*. The top two wells *(D1)* and the bottom two wells *(D2)* contain serum from two dogs (dog 1 and dog 2) with nasal aspergillosis (performed in duplicate for each dog). After the wells are loaded, the plate is incubated at room temperature for 24 hours. Precipitin lines form when the antigen and antibody diffuse out of each well and form immune complexes. A light box is used to illuminate the plate so the precipitin bands are visible. Both dogs are positive for antibody to the *Aspergillus* species tested *(small arrows),* although the reaction is strongest for dog 1. The arrowheads point to the precipitin lines generated by the positive control antibodies *(C)*.

the tests, and that appropriate control assays are included with each test run to ensure proper assay performance.

Negative Results for Antigen Detection

A negative result for antigen will occur if the antigen is not present in the specimen being tested or if the amount of antigen is below the limit of detection of the assay (e.g., low worm burden in heartworm disease). For some infectious agents, such as FIV, antigen testing is not performed because antigen levels during infection are typically extremely low. The amount of antigen present can also vary over the course of a particular infection. For instance, a cat with a *latent* FeLV infection will be negative for the p27 antigen (see Chapter 32). Finally, false-negative results may occur when antibody present in the specimen forms complexes with antigen and makes the antigen unavailable for detection by the immunoassay.

Positive Results for Antigen Detection

A positive result for an antigen can indicate the presence of the organism in the specimen. This does not necessarily imply that the pathogen is the cause of an animal's clinical signs. Antigen can also be present in the absence of intact, viable organisms. Positive results can follow recent vaccination with the organism of interest. For example, positive parvovirus antigen test results have been suspected when tests have been performed on feces obtained several days after attenuated live parvovirus vaccination of kittens or puppies.[11,12] False positives can occur as a result of antigenic cross-reactivity with some other substance or organism in the specimen. An example is positive serum and urine antigen assays for *Aspergillus* spp. in dogs treated with Plasmalyte infusions or those infected with other molds such as *Paecilomyces* spp.[13]

Negative Results for Antibody Detection

A negative result for the presence of antibodies will occur if the patient has not been exposed to the infectious agent of interest, or if the patient has not had time to develop detectable antibody concentrations. For example, negative IgG antibody tests early in the course of illness are common with leptospirosis and canine granulocytic anaplasmosis. In this situation, a convalescent titer is required for diagnosis using serology. False-negative antibody test results can occur in severely immunosuppressed animals, such as in cats with advanced FIV infection that no longer can mount an immune response, or cats with advanced FIP (attributed to all patient antibody bound to viral particles and thus unable to bind to test substrate antigen). False-negative results may also occur because the test lacks sensitivity (i.e., low analytical sensitivity), or if the test detects the wrong class of immunoglobulin, e.g., IgG when infection is primarily mucosal and stimulating IgA production.[14]

Positive Results for Antibody Detection

A positive result for IgG antibody suggests *previous infection* with a pathogen but does not necessarily indicate active infection. Paired IgG titers spaced 1 to 4 weeks apart are required to document active infection. A single positive result for IgM-specific assays may indicate a recent infection or a chronic infection that continues to stimulate the immune system. Previous immunization may lead to positive results and is the basis for measurement of antibody titers to assess the need for additional vaccination[15] (see Chapter 20). If an infection is chronic and persistent, such as with FIV infection, positive results indicate active infection, provided there has been no history of previous FIV vaccination in a cat's lifetime. False-positive results for antibody may occur when antigenic cross-reactivity occurs. For example, dogs recovering from *Leptospira* infection have been shown to test positive on some immunoassays for the related spirochete *B. burgdorferi*.[16]

TABLE 2.1 Guidelines for Interpretation of Test Results Using Immunoassays That Detect Antigen

Antigen Test Result	Possible Explanation	Further Considerations
Negative	Pathogen of interest not present	Confirm with additional diagnostic test if necessary, (e.g., alternative antigen assay, antibody assay or NAAT)
	Antigen present, but quantity below limit of detection	Consider an antibody assay or NAAT
	Antigen present, but complexed by antibody and not available for detection	Consider an antibody assay or NAAT
	Technical error or reagent failure	Identified with inclusion of appropriate laboratory controls
	Poor assay analytical sensitivity (prone to give false-negative results)	Use an alternative assay
Positive	Pathogen of interest present	Confirm with additional diagnostic test if necessary, especially in regions with a low prevalence of infection. Antigen presence may not imply that the pathogen is the cause of disease
	Antigen present, but viable microbe absent	Confirm with additional diagnostic test
	Vaccine antigen present	Obtain vaccination history and consider a test that discriminates between vaccine and wild-type organisms, if available
	Cross-reactive antigen present from another substance or pathogen	Obtain history and consider the likelihood of infection with related agents
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay analytical specificity	Use alternative assay

NAAT, nucleic acid amplification test.

TABLE 2.2 Interpretation of Test Results Using Immunoassays That Detect Antibody

Antibody Test Result	Possible Explanation	Troubleshooting Suggestions
Negative	Exposure to pathogen of interest did not occur	Confirm with additional diagnostic test if necessary
	Too early in course of infection/illness	Obtain convalescent titer; consider an antigen test or NAAT for early diagnosis
	Severe immunosuppression	Consider an antigen test or NAAT
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay analytical sensitivity (prone to give false-negative results)	Use alternative assay
Positive	Previous natural exposure to the pathogen of interest	If infection is chronic and persistent, positive test results may equal active infection
	Previous immunization against the pathogen of interest	Obtain vaccination history; consider use of assays that discriminate between natural exposure and vaccine antibody, if available
	Immunologic cross-reactivity	Obtain history and consider the likelihood of previous exposure to related agents
	Technical error	Identified with inclusion of appropriate controls by the laboratory
	Poor assay specificity (prone to give false-positive results)	Use alternative assay. Consider the use of a confirmatory test, especially in regions with low disease prevalence

NAAT, nucleic acid amplification test.

Isolation and Identification of Aerobic and Anaerobic Bacteria

Stephen D. Cole, Shelley C. Rankin

KEY POINTS

- Aerobic Specimens: Specimens should be from appropriate anatomical sites and should be transported to the laboratory in transport medium as quickly as possible. Clinicians should never hesitate to contact their laboratory with questions.
- Anaerobic Specimens: Biopsies or aspirates are preferred for anaerobic culture. Specimens should be transported in oxygen-free containers.
- Microscopic Examination: A Gram stain can differentiate gram-positive and gram-negative organisms in clinical material. This can be important in the selection of antimicrobials before culture results are available. Acid-fast stains (such as Ziehl-Neelsen) are used to identify organisms such as *Mycobacterium* and *Nocardia*.
- Bacterial Culture: Aerobic culture of bacterial organisms typically requires 18 to 48 hours of incubation on a variety of media at 35°C to 37°C. Some organisms require other conditions (i.e., different temperature, longer incubation, etc.); therefore, communication of suspected fastidious pathogens to the laboratory is critical to help the laboratory select the most appropriate media and conditions.
- Blood Culture: Blood culture requires specialized medium or transport containers. A negative blood culture does not rule out bacteremia and should be interpreted in the context of clinical signs.
- Skin: Most commonly, the best skin specimens are from intact pustules. These are ruptured and contents collected. Alternatively, swabs from underneath crusts or over epidermal collarettes may be submitted to a laboratory. Punch biopsy of decontaminated skin should be considered for deep pyoderma.
- Body Fluids: Fluids should be collected aseptically and transported in a sterile container on ice. In general, 1–5 mL of fluid should be submitted.
- Tissues: Tissues should be submitted in a small amount of nonbacteriostatic sterile saline in a sterile container and shipped on ice. Tissues will be macerated with sterile technique in the laboratory prior to culture.
- Airway Specimens: Routine culture of upper airway specimens is not recommended due to high likelihood of contamination. Lower airway specimens should be collected by transtracheal wash, endotracheal wash, or bronchoalveolar lavage.
- Feces: Fecal culture is only performed routinely for the isolation of pathogens such as *Salmonella* and *Campylobacter*.
- Urine: Cystocentesis is the best method to obtain urine for culture. Urine specimens are plated with a quantitative loop and are incubated aerobically. Bladder biopsies or uroliths can also be considered for culture.
- Bacterial Identification: Most laboratories use phenotypic (biochemical) approaches to identify the species of bacteria isolated. Methods such as matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectroscopy or DNA sequencing are now being used more commonly.
- Susceptibility Testing: Susceptibility to antimicrobial drugs may be determined using a variety of methods. Methods are either dilution (i.e., broth microdilution) or diffusion based (i.e., Kirby-Bauer disc diffusion or ETEST strips). When possible, minimum inhibitory concentration (MIC) should be determined and considered during therapy. MIC values are interpreted by the laboratory using standardized "breakpoints" as susceptible (S), intermediate (I), or resistant (R).

INTRODUCTION

Factors that influence the detection of clinically relevant organisms in specimens collected from dogs and cats are:

1. An appropriate level of suspicion for the presence of a bacterial infection;
2. Development of a list of differential diagnoses that reflects the types of bacterial pathogens that might be the cause of clinical signs because of the requirement of some bacteria for special transport conditions, culture conditions, or prolonged incubation;
3. Collection of a sufficient amount of specimen;
4. Collection of the correct type of specimen;
5. Specimen collection from the correct anatomic location; and
6. Proper handling, storage, and transport of the specimen, which should be sent with a request for culture to the laboratory within acceptable time limits.

These factors cannot be overemphasized. Without them, time and money invested in collection of specimens and culture is wasted.

Given the increasing prevalence of multidrug resistance among bacteria that infect dogs and cats, veterinarians should attempt to confirm a bacterial infection at a normally sterile site by requesting microscopic evaluation of direct smears and culture by a laboratory, whenever possible, before the choice is made to administer an antimicrobial drug.

The purpose of this chapter is to provide information in regard to the correct way to collect and handle specimens for culture before

TABLE 3.1 Suggested Specimen Types for Bacterial Culture from Selected Anatomic Sites and Likely Pathogens Present

Specimen Type	Suggested Volume for Culture	Likely Pathogens Present
Blood	≥10 mL for patients weighing >10 kg, or 1% of patient blood volume	Gram-positive and gram-negative aerobes. Common contaminants are coagulase-negative staphylococci, *Corynebacterium* spp., *Bacillus* spp., and *Propionibacterium* spp.
Cerebrospinal fluid	≥0.5 mL	Gram-positive and gram-negative aerobes, anaerobes, *Brucella* spp. (dogs), *Nocardia* spp., *Actinomyces* spp.,[22] *Mycoplasma* spp. (cats)[23]
Middle ear	Aspirate of fluid or pus through tympanic membrane	Gram-positive and gram-negative aerobes, anaerobes, *Mycoplasma* spp., *Actinomyces* spp.[23,24]
Skin	Swab from epidermal collarette or ruptured pustule (superficial pyoderma); biopsy from which dermis has been removed (deep pyoderma)	Gram-positive aerobes (especially staphylococci), rarely *Pseudomonas aeruginosa*
External ear	Swab ear canal after removing debris and crusts from the canal	Gram-positive aerobes, *P. aeruginosa*
Cornea	Scrape or swab exposed corneal stroma and inoculate directly onto media. Referral to veterinary ophthalmologist recommended	Gram-positive aerobes, *Mycoplasma* spp., *P. aeruginosa*[25]
Abdominal fluid	1–5 mL	Gram-negative and gram-positive aerobes, anaerobes, *Actinomyces* spp.
Pleural fluid	1–5 mL	Gram-negative and gram-positive aerobes, anaerobes, *Actinomyces* spp., *Nocardia* spp., *Mycoplasma* spp.
Feces	Fresh whole stools preferred. Avoid swabs or fecal loops containing fecal matter due to low specimen size. Submit in clean, dry leak-proof container	*Escherichia coli*, *Salmonella* spp., *Clostridium perfringens*, *Clostridiodes difficile*, *Campylobacter* spp., *Anaerobiospirillum* spp.
Urine	1–5 mL urine collected using cystocentesis	Gram-negative and gram-positive aerobes, *Corynebacterium urealyticum*
Bronchoalveolar lavage specimens	1–5 mL	Gram-positive and gram-negative aerobes, anaerobes (aspiration pneumonia), *Mycoplasma* spp., rarely *Mycobacterium* spp.

they are sent to the laboratory, and to outline bacteriologic procedures performed in the microbiology laboratory that are of relevance to the small animal clinician.

SPECIMEN COLLECTION AND TRANSPORT

Specimens for Aerobic Bacterial Culture

Veterinary clinicians should collect specimens for culture using an *appropriate method* from the *correct anatomic site*. Collection of a sufficient *amount* of specimen is very important. Table 3.1 suggests optimal specimen types for detection of bacteria from specific anatomic sites. Attempts should always be made to prevent contamination with commensal bacteria during specimen collection. Clinicians should contact their laboratory before collecting specimens that are not routine to ensure optimal collection. Specimens should always be labeled with the patient's name, patient number, source of specimen, and the date and time of collection, and should be labeled, packaged, and transported according to regional and national regulations.

Specimens should be transported to the laboratory immediately where possible. If transport requires longer than 2 hours, appropriate transport medium should be used and specimens in transport medium should not be refrigerated. Fluid specimens or those that are not in transport medium should be refrigerated. Although specimens in transport medium can be held for up to 72 hours, culture of specimens older than 24 hours should be avoided if possible, even if they have been refrigerated or placed in transport media, because of increased likelihood of false-negative results with longer storage times. False-positive results can also occur with polymicrobial specimens if overgrowth occurs during transport. Transport medium for bacterial culture is usually supplied in a plastic tube with one or two swabs attached to the tube's cap (Fig. 3.1). The medium is designed to maintain bacterial viability without causing significant growth. It usually consists of a small amount of agar, reagents that maintain pH, a colorimetric pH indicator that indicates whether oxidation has occurred, and specific factors that maintain the viability of certain pathogens. Some organisms, such as chlamydiae and leptospires, have specific transport medium requirements.

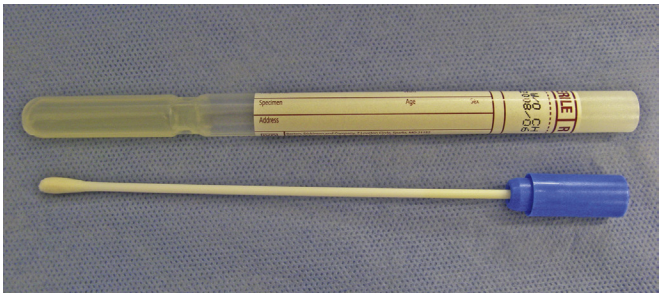

Fig. 3.1 Swab system containing transport medium for aerobic bacterial culture.

Specimens for Anaerobic Bacterial Culture

When anaerobes are suspected, aspirates or biopsies should be obtained rather than swabs, and the specimen should be stored at room temperature and not refrigerated. This is because oxygen diffuses into cold specimens more rapidly than specimens held at room temperature. If

this is not possible, separate specimens should be collected for aerobic and anaerobic culture. Specimens for anaerobic culture should preferably be transported in an oxygen-free container.

DIAGNOSTIC METHODS

Microscopic Examination of Direct Smears

A Gram stain prepared from the specimen can permit the rapid preliminary diagnosis of infection and determine whether the organism(s) present are gram positive or gram negative (Box 3.1; Fig. 3.2). This helps guide the clinician to select an appropriate empiric therapy, if necessary, while awaiting the results of culture and susceptibility testing. If sufficient material is available, examination of a direct smear also helps to determine whether a specimen is adequate for culture and aids interpretation of culture results. For swab or aspirate specimens, clinicians should consider providing a separate specimen for a direct smear in addition to a specimen for culture.

Acid-fast stains can be used on smears to assist in the identification of *Nocardia* and *Mycobacterium* spp., as well as on fecal smears to detect some parasitic oocysts, such as those of *Cryptosporidium*. These organisms stain magenta as a result of their high cell wall mycolic acid content, which in turn results in their resistance to decolorization after staining (which is often performed using an acid-alcohol solvent, hence the term *acid-fast*). Examples of acid-fast staining methods are the *Ziehl-Neelsen, Fite's,* and *Kinyoun* stains.

BOX 3.1 Procedure for Gram Staining

Heat-fix specimen on the slide by passing the slide two to three times over a gentle flame, or fix in 95% methanol for 2 minutes, and then air dry.
Flood with crystal violet solution for 15 to 60 seconds (10 g of 90% dye in 500 mL absolute methanol).
Wash with water.
Flood with iodine for 15 to 60 seconds (6 g of I_2 and 12 g of KI in 1800 mL of water).
Decolorize with acetone-alcohol (400 mL of acetone in 1200 mL of 95% ethanol)
Wash immediately.
Counterstain with safranin for 15 to 60 seconds (10 g of dye in 1 L of water).
Wash, blot dry, and examine using light microscopy.

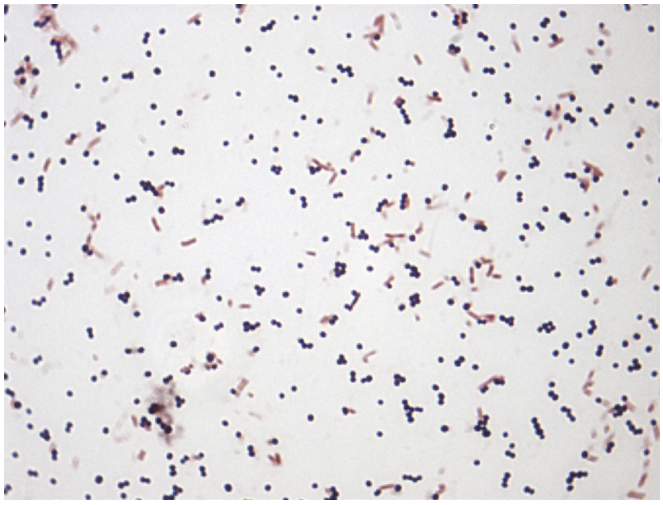

Fig. 3.2 Gram-stained smear of gram-positive cocci *(dark blue)* and gram-negative rods *(red)* (1600× oil magnification).

Bacterial Culture

Diagnostic bacterial culture requires appropriate laboratory facilities, proper BSL 2 containment, properly trained individuals, reference strains for quality control testing, and the use of standard protocols.[1] Media used for bacterial culture may be categorized as general-purpose, enriched, selective, differential, and specialized (Table 3.2). Some media belong to more than one of these categories. For example, MacConkey agar is both a selective and a differential medium (Fig. 3.3). Media for culture contains a nutrient source, most commonly peptones (hydrolyzed animal or vegetable substances), and is adjusted to a specific pH. Solid medium contains agar, which is derived from seaweed. Other nutrients may be added based on specific organism requirements. More than 100 different types of bacteriology media exist, most of which can be purchased as prepared plates or broth.

In the laboratory, media for bacterial culture should be warmed to room temperature before inoculation, and damaged media, such as dehydrated medium or medium that has changed color, should not be used. Medium is stored in the dark at 2°C to 8°C and discarded when it reaches its expiration date. After plating, incubation is most commonly performed at 35°C to 37°C in air for a minimum of 2 days. Conditions vary for specific bacteria, and growth in 3% to 5% CO_2 is preferred by some fastidious organisms. The laboratory should be informed, by providing an adequate clinical history, when pathogens with special culture requirements are suspected, such as *Campylobacter, Mycoplasma, Actinomyces, Nocardia,* and *Mycobacterium* spp. These organisms require special media or prolonged incubation times (e.g., weeks). Specimens for anaerobic culture should be plated onto appropriate media immediately and incubated in an anaerobic environment. Anaerobic containers, which create an anaerobic environment

TABLE 3.2 Types of Media Used in Bacteriology

Medium Type	Attributes	Example
Transport	Nonnutritive liquid or semisolid medium. Promotes organism viability without allowing significant growth	Amies transport medium
General-purpose	Allows growth of most aerobic and facultatively anaerobic organisms	Sheep blood agar
Enriched	Promotes growth of fastidious organisms that require specific nutrients, e.g., *Francisella*	Chocolate agar, which is enriched with heat-treated blood, which gives it a brown color
Selective	Selects for growth of certain organisms while inhibiting others	MacConkey agar, which is selective for gram-negative bacteria
Differential	Aids in preliminary identification of organisms based on colony appearance	MacConkey agar, which promotes pink colony formation by organisms that ferment lactose
Specialized	Selects for a specific pathogen through the addition of specific nutrients	Anaerobic medium, which contains hemin, vitamin K, and reducing agents

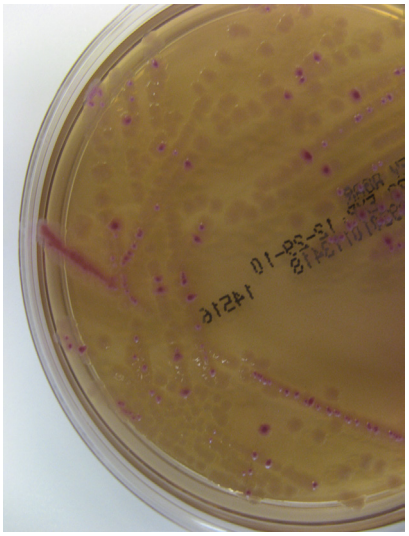

Fig. 3.3 Growth of bacteria on MacConkey medium that shows the selective and differential qualities of the medium. The medium contains substances that inhibit the growth of gram-positive bacteria. By using the lactose available in the medium, bacteria such as *Escherichia coli*, *Enterobacter* spp., and *Klebsiella* spp. produce acid when they grow on the medium, which lowers the pH of the agar and results in the formation of red to pink colonies.

Fig. 3.4 System for isolation of anaerobic and microaerophilic bacteria. The packets are opened, and the sachets inside are placed into the container with the inoculated plates. The container is sealed immediately. The sachets contain ascorbic acid. Atmospheric oxygen in the container is rapidly absorbed and replaced with carbon dioxide in an exothermic reaction process. After an appropriate incubation period, the container is opened and the plates inspected for growth. An anaerobic indicator can be placed within the box to ensure that the proper conditions are maintained.

through the use of gas-generating reagents, can be used for incubation (Fig. 3.4). Because anaerobes grow more slowly than aerobes, anaerobic cultures should be held for 7 days before being reported as negative.

Blood and Intravascular Catheters

Bacteremic animals may be continuously or intermittently bacteremic. Because of intermittent bacteremia, multiple, separate specimens that each contain 10 mL or more of blood are recommended. Pediatric bottles are available that can be inoculated with as little as 1.5 mL of blood, although the chance of a positive isolation increases as the blood volume tested increases. Therefore, as much blood should be drawn as possible, provided that collection of a large volume of blood does not jeopardize patient health. Bottles should be held at room temperature and submitted immediately to the laboratory. Two, and ideally three, blood samples should be collected using meticulous sterile technique, and the timing of blood draws should depend on the severity of the animal's illness (Box 3.2). Inoculated bottles are incubated in aerobic conditions for 7 days before being reported as negative. More than three blood samples are not recommended, because they add cost without a significant increase in sensitivity.[2] The choice to inoculate anaerobic blood culture bottles is controversial. Studies in humans have shown that the prevalence of anaerobic bloodstream infections has decreased, and routine inoculation of anaerobic blood culture bottles may not be necessary. In one veterinary study, anaerobes were not identified in any of 33 dogs with endocarditis using anaerobic culture of blood, but anaerobic bacteremia may occur with other underlying causes of bloodstream infections.[2] Common blood culture contaminants include coagulase-negative staphylococci, and *Bacillus*, *Corynebacterium*, and *Propionibacterium* spp. When only one blood culture is positive for one of these organisms, contamination is likely, but the presence of multiple positive blood cultures from separate sites suggests true bacteremia.

Blood culture media contain the anticoagulant, sodium polyanethol sulfonate (SPS), which is less inhibitory to bacterial growth than other anticoagulants. Some blood culture media (e.g., BD BACTEC Plus) contain resin beads that bind antimicrobial drugs in the patient's blood specimen, so they do not inhibit bacterial growth (Fig. 3.5). The detection of bacterial growth in blood culture systems can be automated using instrumentation that measures emission of fluorescence or a colorimetric change in a sensor. The change occurs as CO_2 concentrations within the bottle increase, which indicates the presence of bacterial growth. Some instruments detect pressure changes in the head of the bottle. The culture is monitored at regular intervals by the instrument to optimize early detection of bacterial growth. Positive blood culture bottles are then evaluated by performing a Gram stain of the broth, and subculture to appropriate media.

BOX 3.2 Suggested Procedure for Obtaining Samples for Aerobic Bacterial Blood Culture

Shave site.

Clean skin with 10% povidone iodine or 1%–2% tincture of iodine, swabbing concentrically from the center; allow to dry (wait for 1 minute).

If a catheter must be used for specimen collection, clean access port with 70% alcohol and allow to dry. Avoid collection from a catheter if possible.

Clean stopper on top of the culture tube or bottle with 70% alcohol; allow to dry (wait for 1 minute).

Perform venipuncture using sterile gloves to palpate the vein.

Inoculate blood culture bottle without changing the needle.

Space cultures based on severity of illness before starting antimicrobial therapy.

- Acute febrile illness: antimicrobials need to be changed or started immediately; two sets from separate sites, all within 10 minutes. Consideration could be given to drawing a third set using a resin bottle just before administering the second dose of antimicrobials (i.e., when trough drug concentrations are present)
- Acute endocarditis: three sets from three separate sites, within 1–2 hours
- Nonacute disease: three sets from separate sites within 24 hours, spaced at intervals of at least 3 hours

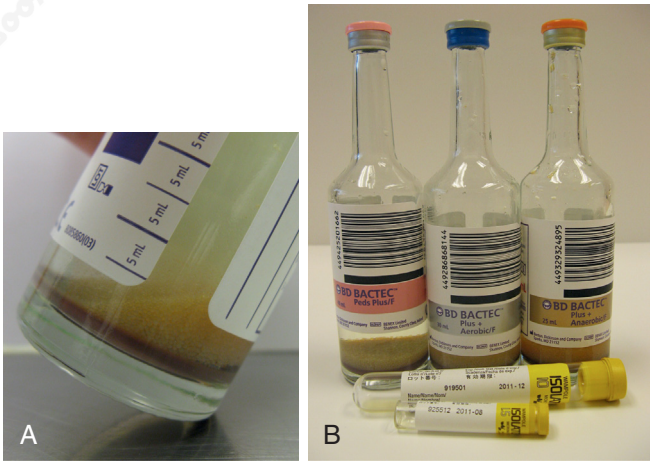

Fig. 3.5 Blood culture systems. (A) BACTEC system showing resin beads that bind antimicrobial drugs. (B) Pediatric, aerobic, and anaerobic BACTEC systems for blood culture together with adult and pediatric WAMPOLE Isolator tubes *(front)* for lysis-centrifugation culture of blood.

Another blood culture system is the Isolator lysis-centrifugation system (DuPont, Wilmington, DE, USA) (see Fig. 3.5B). In this system, blood is added to a tube that contains anticoagulant and a reagent that induces RBC lysis. The tube is centrifuged, and the pellet is plated onto agar media and incubated. This method allows colony counts to be obtained. The tubes allow isolation not only of aerobes but also some anaerobic bacteria.

Culture of intravascular catheter tips is performed to determine whether a catheter is a source of bacteremia and should only be performed simultaneously with blood culture. The catheter is removed after cleaning the skin around the catheter site with alcohol, and the distal 5 cm is aseptically removed into a sterile tube and submitted immediately.[3] In the laboratory, the catheter tip is rolled onto an agar plate and incubated overnight or placed in a thioglycollate enrichment broth, incubated overnight, and plated the following day. The result of catheter culture alone should not change treatment. Therefore, in most situations, blood culture may be all that is required.

Skin

For dogs with superficial pyoderma, specimens for culture should ideally be collected from a pustule. No surface disinfection should be performed. The hair should be clipped using sterile scissors; clippers should be avoided. A pustule is lanced with a sterile narrow-gauge needle, and pus on the needle or exuding from the pustule is applied to a sterile swab, which can then be placed in transport medium for transport to the laboratory. If a pustule cannot be found, cultures can also be obtained by lifting crusts and swabbing beneath the crust, or rolling the swab across an epidermal collarette two to three times. Papules can be cultured by biopsy after surface disinfection with 70% alcohol, allowing the surface to dry, and use of a 3- to 4-mm punch and sterile surgical instruments to collect the biopsy, which is then submitted in transport medium or a small amount of sterile saline. The biopsy site can then be sutured closed.

For deep pyoderma, a biopsy of the lesion should also be obtained after surface disinfection with 70% alcohol. The dermis should be excised with a sterile blade and the biopsy submitted as just described.

For dogs and cats with wounds, aspirates and deep tissue biopsies after surgical dissection are always preferable to swab specimens. Swab specimens are often contaminated by surface microorganisms, contain only a small amount of material, and are not amenable to optimal anaerobic transport. For this reason, collection of pus from fistulous tracts using a swab should also be avoided. If an abscess is present, an aspirate of the abscess fluid should be collected and submitted for aerobic and anaerobic culture. For dogs and cats with cellulitis, an aspirate can be attempted by injecting a small volume of sterile saline into the lesion and aspirating back into a syringe, although bacterial yields may be low and biopsy may be required in some cases.

Body Fluids

Usually, 1 to 5 mL of body fluid is required for culture. Fluid can be inoculated into blood culture bottles in the laboratory or alongside the patient. Body fluids that have the potential to clot should be submitted to the laboratory in a tube that contains an appropriate ratio of anticoagulant. In the laboratory, body fluids with volumes that exceed 1 mL may be concentrated using centrifugation and the pellet resuspended in a smaller volume (e.g., 0.5 mL) of the supernatant fluid before inoculation onto agar.

For CSF, the chance of organism isolation also increases when the volume submitted is maximized. If possible, at least 0.5 mL should be submitted for culture. CSF specimens should be immediately transported to the laboratory, preferably at room temperature.

Tissue Specimens

Attempts should be made to obtain as large a tissue specimen as possible for culture. The use of swabs to collect specimens for culture during surgical procedures is discouraged because of insufficient specimen size. Small pieces of tissue can be submitted in a small amount of sterile, nonbacteriostatic saline. In the laboratory, the tissue is minced using aseptic procedures to release organisms before smears are prepared and broth media inoculated. Because an anaerobic environment can be maintained within pieces of tissue greater than or equal to 1 cm^3 in volume, these are suitable for anaerobic culture without oxygen-free transport. Such tissue specimens may be stored at room temperature for up to 24 hours.

Airway Specimens

Specimens from the upper respiratory tract are generally contaminated with commensal bacteria. Isolation of organisms such as *Staphylococcus* and *Corynebacterium* spp., and *Escherichia coli* should be interpreted with caution. Aerobic bacterial culture of a nasal lavage specimen may be indicated in cats with chronic rhinosinusitis if an antimicrobial-resistant organism is suspected, in particular *Pseudomonas aeruginosa*. Isolation of *Bordetella bronchiseptica* may also have clinical significance in dogs and cats with signs of upper respiratory tract disease. Growth of *Mycoplasma* spp. from the nasal cavity has uncertain clinical significance, because *Mycoplasma* spp. can be isolated from the nasal cavities of both healthy cats and cats with rhinosinusitis.[4–7]

Specimens from the lower respiratory tract may be collected using transtracheal, endotracheal, or bronchoalveolar lavage. Bronchial brush specimens may also be submitted for culture after placing them in 1 mL of sterile nonbacteriostatic saline. The presence of intracellular bacteria on cytologic examination is consistent with a bacterial infection rather than contamination. Anaerobic culture could be considered for animals with aspiration pneumonia or migrating plant awn foreign body pneumonia.

Feces

Whole stools or swabs that contain fecal matter should be processed within 1 to 2 hours or refrigerated as soon as possible after specimen collection and submitted within 24 hours. The specimens should not be contaminated with barium or urine. Rectal swabs that contain fecal

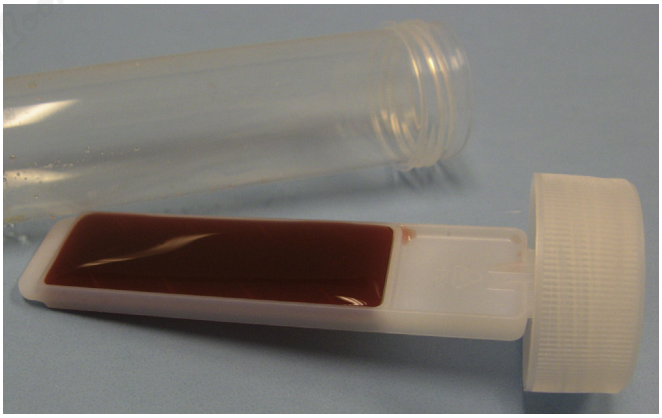

Fig. 3.6 Media paddle available for screening urine for the presence of an aerobic bacterial infection. The paddle is impregnated on each side with selective and nonselective media (in this case, eosin methylene blue medium, shown, and cysteine lactose electrolyte-deficient (CLED) media, on underside, respectively). The paddle is flooded with urine, incubated, and inspected for growth. Eosin methylene blue medium is red and selects for growth of gram-negative enteric organisms. CLED medium is initially green but turns yellow in the presence of lactose-fermenting organisms.

material can be immersed in transport medium until processing in accordance with the instructions of the swab manufacturer. Testing of more than one sequential specimen may improve detection of fecal pathogens due to the low sensitivity of fecal culture methods. Selective media are required for isolation of *Salmonella*. Because *Clostridium perfringens* and *Clostridioides difficile* are commonly detected in normal stool specimens, toxin antigen testing may be more appropriate than culture to determine the role these organisms may be playing in diarrhea (see Chapter 64). Special medium is also required for isolation of *Campylobacter* (see Chapter 65).

Urine

Urine should be collected using cystocentesis whenever possible. Collection of urine via sterile catheterization in male dogs is acceptable when cystocentesis is not possible. Quantitative cultures should always be performed. For specimens obtained by cystocentesis, any level of bacterial growth is significant, although most urinary tract infections contain greater than or equal to 10^3 CFU/mL of bacteria. For urine specimens obtained via catheter from male dogs, bacterial growth of greater than or equal to 10^5 CFU/mL has been considered significant.[8] Only aerobic bacterial culture is routinely indicated. Anaerobic urine culture may be indicated when there is radiologic evidence of emphysematous cystitis. Urine specimens should be submitted to the laboratory as soon as possible and may be refrigerated for up to 24 hours. Special urine transportation tubes can be used to preserve bacteria within the specimen, provided they are appropriate for the volume of urine collected (e.g., BD Vacutainer urine culture and sensitivity tube). Urine "paddles" are also available for in-house veterinary use. These allow inexpensive screening for the presence or absence of bacteria (Fig. 3.6). The paddles have media impregnated on them, are designed to be incubated in the clinic, and can provide some information on the infecting bacterial species present and the number of CFU/mL. Positive paddles can then be submitted to the laboratory for culture and susceptibility testing, although this does not always permit accurate identification of all bacteria present in mixed infections (see Chapter 127).

For animals with a urinary catheter in place and a suspected urinary tract infection, culture of the catheter tip is not recommended because it is generally contaminated with commensal organisms from the urethra. Instead, a urine specimen should be obtained by aspiration from a new urinary catheter, or, if feasible, using cystocentesis. If a catheter is used to collect the specimen, several milliliters of urine should be removed and discarded first to clear the catheter. Urine culture should never be performed from collection bag specimens. In the case of infection-induced urolithiasis (struvite urolithiasis), some clinicians choose to culture uroliths obtained at cystotomy.

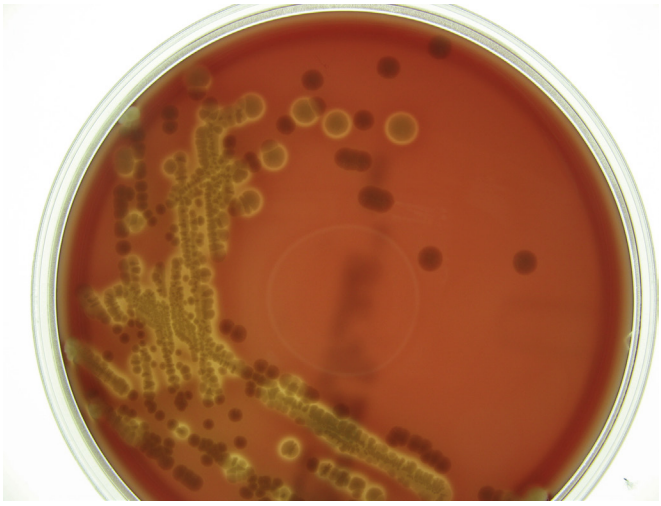

Fig. 3.7 Mixture of beta-hemolytic and nonhemolytic enteric bacteria growing on blood agar. Beta-hemolysis is characterized by complete clearing of the agar around each colony.

Fastidious and Unculturable Organisms

Some bacteria, such as *Bartonella* spp., *Borrelia/Borreliella (incertae sedis) burgdorferi*, and *Leptospira* spp., require special culture conditions (see Chapters 68–70). Others, such as hemotropic *Mycoplasma* species, are unculturable, and DNA amplification methods such as PCR are required for detection of these organisms. Cell culture is required to propagate certain bacteria. Examples include *Chlamydia felis* and tick-borne pathogens such as *Anaplasma phagocytophilum*.

Bacterial Identification

Following aerobic or anaerobic culture, presumptive bacterial identification can be made on the basis of colony morphology and microscopic morphology (e.g., Gram stain characteristics, rods or cocci). Further differentiation is generally based on a series of additional phenotypic tests, which are selected based on microscopic morphology and whether the organism is gram negative, gram positive, aerobic, or anaerobic. Microbiology laboratories use published methods to identify bacteria.[9] Preliminary tests used to identify gram-positive aerobic cocci include the presence or absence of hemolysis on a blood agar plate (for streptococci) (Fig. 3.7), a positive or negative catalase test, and the production of coagulase (for staphylococci). Identification of gram-negative aerobic bacilli relies on whether or not the organism ferments lactose, indole production, oxidase production, and the production of a variety of other enzymes. Assessment of motility and the ability to ferment carbohydrates are also used to differentiate bacteria. Biochemical test strips are available that allow multiple tests to be performed simultaneously (e.g., API strips, bioMérieux, Marcy L'Étoile, France) (Fig. 3.8) so that identification can be made within 24 to 48 hours. Automated identification systems that consist of a microtiter tray containing a variety of biochemical reagents (e.g., Sensititre, TREK Diagnostics, Cleveland, OH, USA and VITEK 2, bioMerieux, Marcy L'Etoile, France) are also in use in some veterinary diagnostic

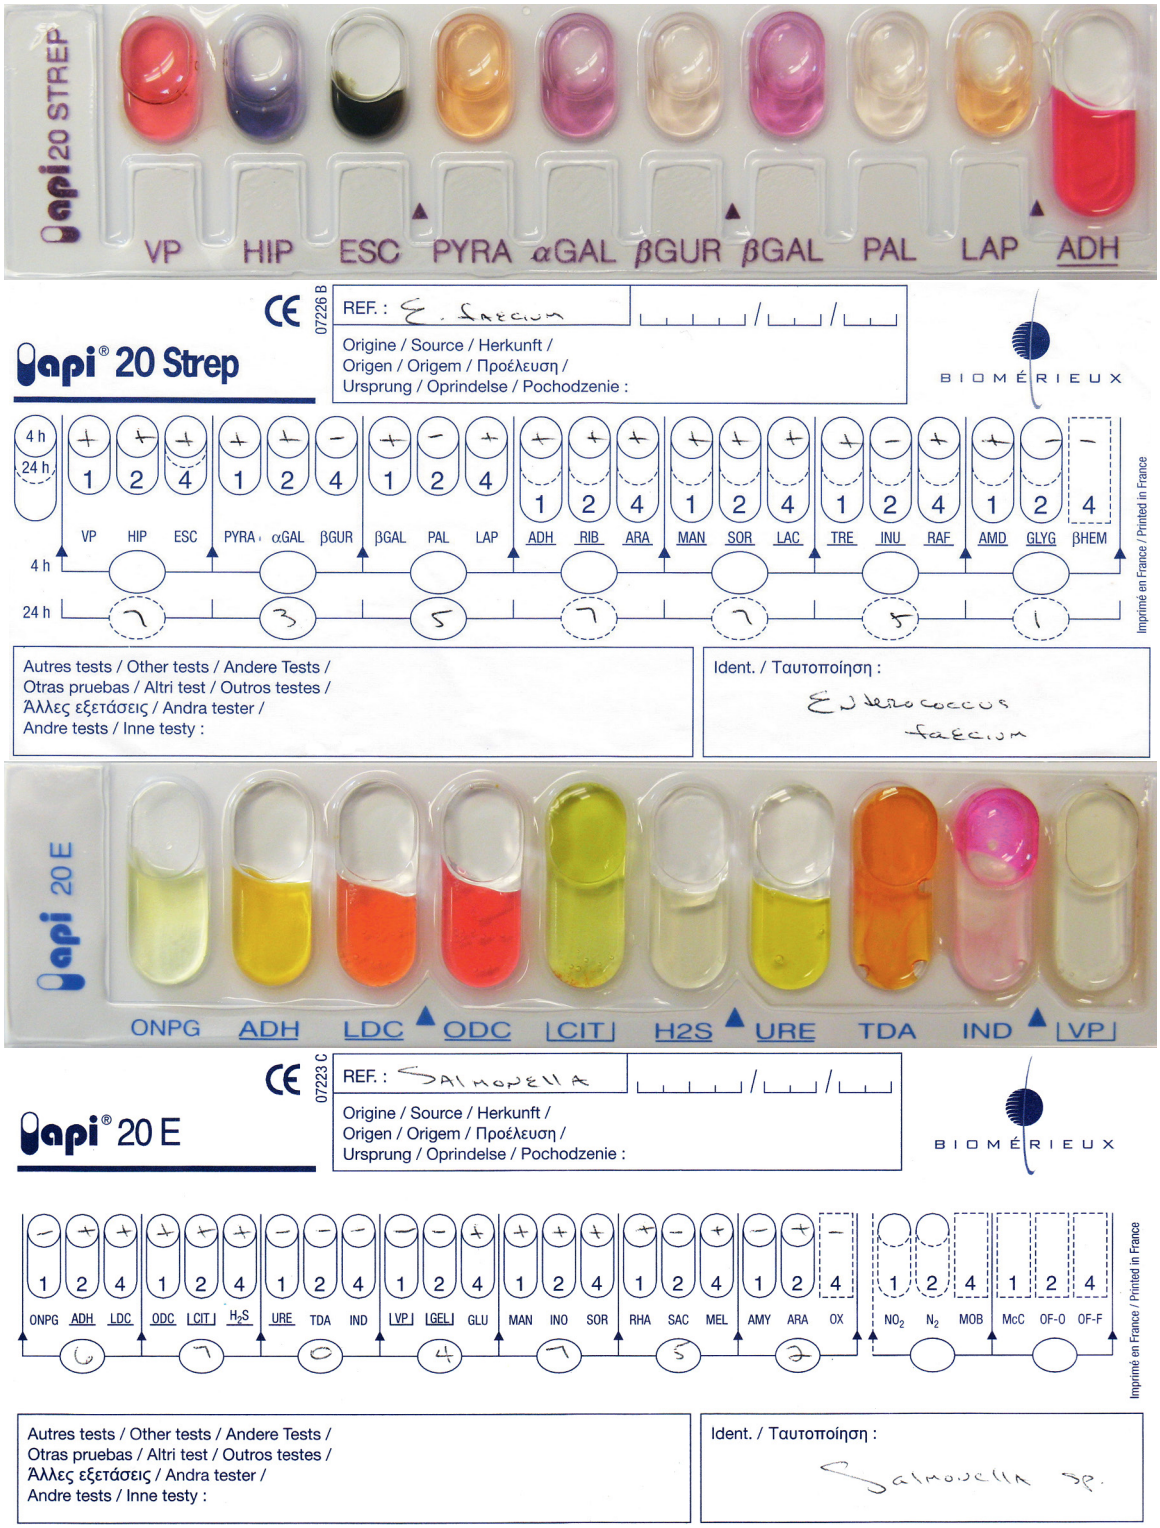

Fig. 3.8 API bacterial identification strips. Only the left half of the reaction strip is shown. Top (api20Strep): *Enterococcus faecium*. Bottom (api20E): *Salmonella* spp. Positive reactions are assigned a numerical code on the handwritten strip. The codes in each three-well group are added to generate a new (seven-number) code that can be used to identify the organism.

laboratories. Speciation of some *Mycobacterium* spp. requires analysis of mycolic acid content using high-performance liquid chromatography. Recently, the availability of MALDI-TOF mass spectrometry instrumentation (i.e., the Bruker Biotyper and VITEK MS systems) has revolutionized bacterial identification in the clinical microbiology laboratory. These systems use mass spectrometry to rapidly (on average in 6 minutes) and accurately (often >95%) identify organisms to the species level based on their chemical composition, provided a reference spectrum for the organism is available in the database used for comparison. Although the instrumentation is expensive, the ultimate

cost is lower than with conventional biochemical methods because of reduction in labor and reagent costs.[10] Molecular methods such as 16S rRNA gene PCR and sequencing are also being used to identify organisms to the species level (see Chapter 6).

INTERPRETATION OF BACTERIAL CULTURE RESULTS

Specimens That Test Negative

Negative results (or lack of growth) using bacterial culture do not imply the absence of bacteria. Negative test results can occur as a result of inadequate specimen size (such as when swabs or aspirates are submitted), when there are inadequate organism numbers at the site of specimen collection, when overgrowth with commensal organisms occurs, or when there is loss of organism viability during transportation to the laboratory. The last is particularly problematic for anaerobic bacteria, and specimens for anaerobic culture ideally should reach the laboratory within 24 hours of collection. Antimicrobial therapy at the time of culture may affect culture results. Some postulate that neutrophils and their byproducts may also affect culture results (i.e., abscesses).

Negative test results can also occur when the organism is not inoculated onto the correct media or sufficient time is not allowed for growth. Clinicians must consider whether fastidious or slow-growing organisms might be present and inform the laboratory if they are suspected. Poor laboratory quality control procedures may also lead to false-negative test results. Use of an accredited laboratory can help minimize such problems.

Specimens That Test Positive

The detection of bacterial organisms within a specimen using culture does not imply that the organism is the cause of an animal's clinical signs. Contamination is a common cause of false-positive cultures. Isolation of only one or two colonies of coagulase-negative staphylococci, or *Bacillus*, *Corynebacterium*, or *Propionibacterium* spp., suggests contamination. Isolation of large numbers of a single type of bacteria from a normally sterile site is usually clinically significant, especially when supported by cytologic evidence of bacteria within phagocytes. A significant proportion of animals have positive urine cultures without clinical signs. Current guidelines suggest that in the absence of clinical signs or immunosuppression, animals with subclinical bacteriuria should not be treated.[11] A prospective study of adult cats with subclinical bacteriuria showed no difference in survival in the absence of treatment to healthy control cats.[12]

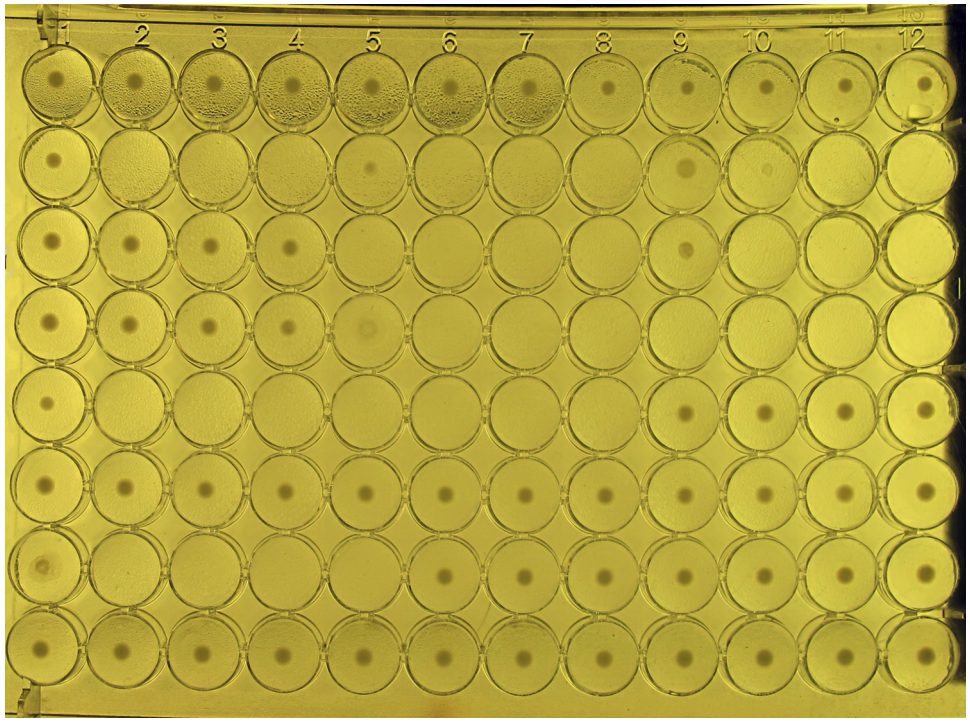
ANTIMICROBIAL SUSCEPTIBILITY TESTING

Importance of Antimicrobial Susceptibility Testing

Given the increasing recognition of antimicrobial resistance among bacteria that are isolated from small animal patients, determination of antimicrobial susceptibility can be as, or more, important to the clinician than the identity of the infecting organism. The result of antimicrobial susceptibility testing is generally available 2 to 3 days after submission of a specimen for culture. In animals that are critically ill, empiric antimicrobial therapy may already have been initiated by the time this result is available. The susceptibility results may show that the organism is resistant to a drug being used, in which case the drug should be changed to one that the organism tests susceptible to. The susceptibility pattern can also help to identify an alternate drug when the patient does not tolerate the initial drug prescribed. Susceptibility testing may indicate that the organism is susceptible to a more narrow-spectrum (and generally less expensive) antimicrobial drug than the drug initially prescribed, in which case the spectrum should be narrowed to minimize the development of antimicrobial resistance.

Methods of Susceptibility Testing

Susceptibility testing can be performed using dilution methods or diffusion methods. The *minimum inhibitory concentration* (MIC) is the lowest concentration of an antimicrobial drug that inhibits visible growth of an organism over a defined incubation period, most commonly 18 to 24 hours. The MIC is determined using dilution methods, which involve exposing the organism to twofold dilutions of an antimicrobial drug. The concentration range used varies with the drug and the organism being tested. *In vitro* factors that influence MIC include the composition of the medium, the size of the inoculum, incubation conditions, and the presence of resistant bacterial subpopulations within the inoculum. Standard protocols are published by the Clinical and Laboratory Standards Institute (CLSI) that specify medium composition and pH, inoculum size, inoculation procedures, agar depth, and incubation conditions, as well as quality control requirements.[9] Failure to comply with these protocols can lead to erroneous results, so laboratories that adhere to CLSI standards should be used whenever possible. MIC testing does not take into account *in vivo* factors such as postantibiotic effect and the effects of protein binding on antimicrobial drug activity (see Chapter 8).



Dilution Methods

Dilution methods include *broth macrodilution, broth microdilution,* and *agar dilution*. The most widely used method in North America is broth microdilution, whereby twofold dilutions of antimicrobials are made in a broth medium in a microtiter plate (Fig. 3.9). Pre-prepared frozen or freeze-dried microtiter plates for inoculation are available commercially. The results can be determined using visual examination of the plates for the inhibition of bacterial growth, or by the use of semiautomated or automated instrumentation. Dilutions can also be performed in agar, each dilution being poured onto a plate in a standardized fashion and allowed to set before inoculating it with the organism(s) of interest. Agar dilution can be used to perform susceptibility testing of fastidious bacteria with special medium requirements, such as *Campylobacter* spp.

Diffusion Methods

Diffusion methods include gradient diffusion (also known as ETEST) and disc diffusion. The ETEST involves use of a plastic strip coated with an antimicrobial gradient on one side and an MIC interpretive scale on the other side (Fig. 3.10A). An agar plate is inoculated with the organism of interest so that subsequent growth of the organism forms a "lawn" rather than individual colonies (i.e., *inoculation to confluence*). At the time of inoculation, the strips are applied to the surface of the plate. The antimicrobial drug diffuses into the medium, resulting in an elliptical zone of growth inhibition around the strip. The MIC is read at the point of intersection of the ellipse with the MIC scale on the strip. Although the strips are expensive, ETESTs have the advantage of being adaptable to use with fastidious organisms and anaerobes.

Disc diffusion, also known as Kirby-Bauer antibiotic testing, involves application of commercially available drug-impregnated filter paper discs to the surface of an agar plate that has been inoculated to confluence with the organism of interest. Commercially available, mechanical disc-dispensing devices can be used to apply several discs simultaneously to the surface of the agar. The drug diffuses radially through the agar, the concentration of the drug decreasing as the distance from the disc increases. This results in a circular zone of growth inhibition around the disc, the diameter of which correlates inversely to the MIC (Fig. 3.10B). The zone diameters are interpreted on the basis

	1	2	3	4	5	6	7	8	9	10	11	12
A	AMP 0.25	AMP 0.5	AMP 1	AMP 2	AMP 4	AMP 8	AMP 16	OXA+ 0.25	OXA+ 0.5	OXA+ 1	OXA+ 2	OXA+ 4
B	AUG2 4/2	AUG2 8/4	AUG2 16/8	AUG2 32/16	AMI 4	AMI 8	AMI 16	AMI 32	FOX 2	FOX 4	FOX 8	FOX 16

D	SXT 0.5/9.5	SXT 1/19	SXT 2/38	FOV 0.25	FOV 0.5	FOV 1	FOV 2	FOV 4	FOV 8	FAZ 4	FAZ 8	FAZ 16
E	GEN 1	GEN 2	GEN 4	GEN 8	IMI 1	IMI 2	IMI 4	IMI 8	CLI 0.5	CLI 1	CLI 2	CLI 4
F	PEN 0.06	PEN 0.12	PEN 0.25	PEN 0.5	PEN 1	PEN 2	PEN 4	PEN 8	DOX 2	DOX 4	DOX 8	POS
G	XNL 0.25	XNL 0.5	XNL 1	XNL 2	XNL 4	MAR 0.25	MAR 0.5	MAR 1	MAR 2	RIF 1	RIF 2	POS
H	ENRO 0.25	ENRO 0.5	ENRO 1	ENRO 2	ERY 0.5	ERY 1	ERY 2	ERY 4	CHL 4	CHL 8	CHL 16	POS

AMP, ampicillin; AUG2, amoxicillin/clavulanic acid (2:1 ratio); TIC, ticarcillin; SXT, trimethoprim/sulfamethoxazole; GEN, gentamicin; PEN, penicillin; XNL, ceftiofur; ENRO, enrofloxacin; FOV, cefovecin; AMI, amikacin; POD, cefpodoxime; IMI, imipenem; ERY, erythromycin; MAR, marbofloxacin; OXA+, oxacillin + 2% NaCl; FOX, cefoxitin; TIM2, ticarcillin/clavulanic acid (constant 2); CLI, clindamycin; DOX, doxycycline; CHL, chloramphenicol; FAZ, cefazolin; RIF, rifampin; POS, positive control.

Fig. 3.9 Broth microdilution to determine the minimum inhibitory concentration (MIC). A series of wells contain an antimicrobial drug at twofold dilutions in a standard format. One custom plate format is shown (TREK Diagnostic Systems Sensititre Companion Animal MIC plate). A pellet of bacteria (in this case, *Escherichia coli* from an infected feline esophagostomy tube site) settles on the bottom of each well when growth fails to be inhibited by the antimicrobial drug concentration tested in that well. The cutoff MICs that define susceptibility versus resistance are published by the Clinical and Laboratory Standards Institute in the USA. This isolate was reported as resistant to ampicillin (AMP) (>16 mg/mL), resistant to amoxicillin-clavulanic acid (AUG2) (8/4 mg/mL), susceptible to amikacin (AMI) (8 mg/mL), susceptible to cefoxitin (FOX) (8 mg/mL), resistant to ticarcillin (TIC) (>64 mg/mL), susceptible to cefpodoxime (POD) (≤2 mg/mL), susceptible to ticarcillin-clavulanic acid (TIM2) (16 mg/mL), resistant to trimethoprim-sulfamethoxazole (SXT) (>2/38 mg/mL), susceptible to gentamicin (GEN) (2 mg/mL), susceptible to imipenem (IMI) (≤1 mg/mL), resistant to doxycycline (DOX) (>8 mg/mL), resistant to enrofloxacin (ENRO) and marbofloxacin (MAR) (both >2 mg/mL), and resistant to chloramphenicol (CHL) (>16 mg/mL). The MICs for ceftiofur (XNL), cefovecin, and cefazolin were ≤0.25, 1, and ≤4 mg/mL respectively, but because breakpoints for these drugs are not available for *E. coli* isolated from feline skin and soft tissue infections, only the MIC was reported and not the interpretation (whether the isolate was susceptible or resistant). Results for some drugs tested, such as oxacillin (OXA+), are not reported for gram-negative bacteria because these drugs are used to treat gram-positive bacterial infections. CLI, clindamycin; ERY, erythromycin; PEN, penicillin; RIF, rifampin; POS, positive control.

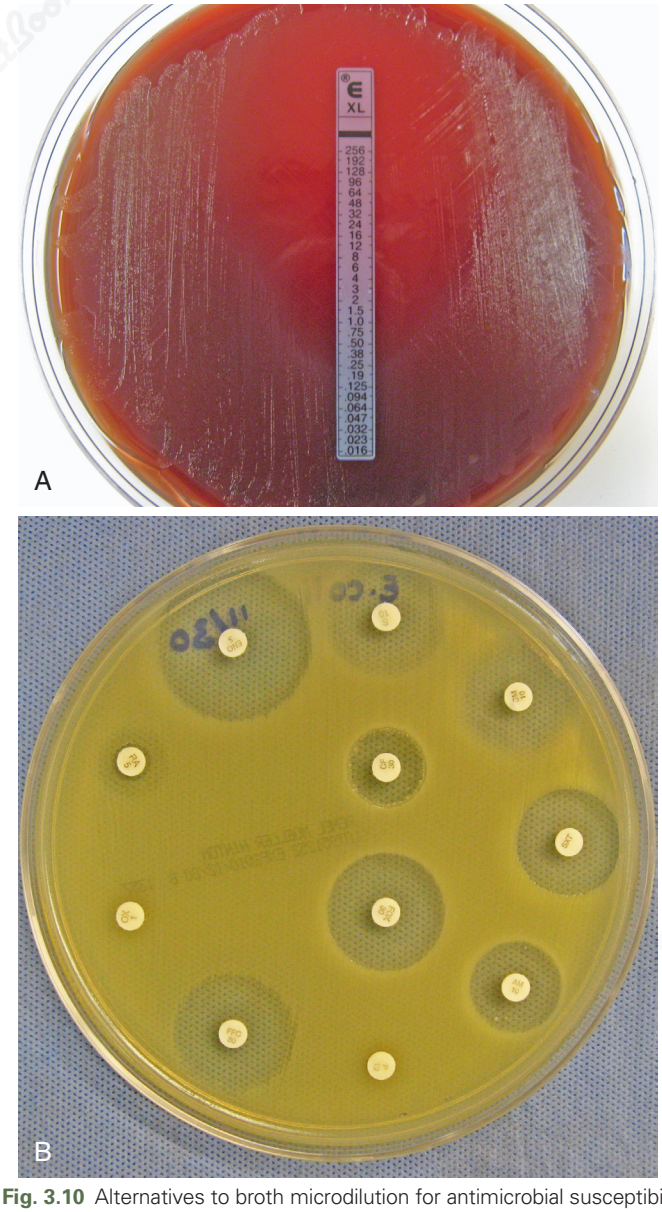

Fig. 3.10 Alternatives to broth microdilution for antimicrobial susceptibility testing. (A) ETEST that shows susceptibility of a *Bacteroides fragilis* isolate to amoxicillin-clavulanic acid. The strip in the center is impregnated with a gradient of antimicrobial drug (in this case, amoxicillin-clavulanic acid), with the highest concentration at the top of the strip. The MIC is read at the point (the ellipsis) where bacterial growth is no longer inhibited by the strip (0.19 μg/mL in this case). (B) Disc diffusion (also known as Kirby-Bauer testing) for *Escherichia coli* showing varying degrees of resistance to different antimicrobial drugs, reflected by zones of growth inhibition around discs containing each antimicrobial drug.

of guidelines published by CLSI (see Definition of MIC Breakpoints, next), and the organisms are reported as susceptible, intermediate, or resistant. Zone diameters may not correlate precisely with MIC values, and regression line analysis should not be used to extrapolate MICs from zones of inhibition. Disc diffusion can only be used to test rapidly growing organisms that have consistent growth rates, for which criteria for interpretation of zone sizes are available.

Definition of MIC Breakpoints

In vitro susceptibility test results predict *in vivo* drug efficacy. Once susceptibility testing has been performed, organisms are classified on the susceptibility panel report as "susceptible" (S), "resistant" (R), and in some cases "intermediate" (I). The growth of a "susceptible" organism is predicted to be inhibited by antimicrobial drug concentrations that are usually achievable in blood and tissues using normal dosage regimens. "Intermediate" isolates have MICs that approach usually attainable blood and tissue levels and for which response rates may be lower than those of susceptible isolates. This category implies clinical efficacy in urine, where the drugs are normally concentrated (e.g., enrofloxacin and amoxicillin) or when a higher-than-normal dose of a drug can be used. "Resistant" isolates are predicted to grow in the usually achievable concentrations of drug in blood and tissues. So how does the laboratory predict *in vivo* susceptibility on the basis of an *in vitro* test? The laboratory uses MIC breakpoints (or, for disc diffusion testing, zone diameters) that are established, published, and revised regularly by committees affiliated with standards agencies such as the CLSI. If the MIC determined in the microbiology laboratory is lower than or equal to a published breakpoint for that organism-drug combination, the organism is defined as susceptible. Breakpoints are established on the basis of multiple factors (Box 3.3), which include: (1) a knowledge of MIC distributions and resistance mechanisms for each organism-drug combination (Fig. 3.11),[13] (2) clinical response rates in humans and animal models, (3) how the drug is distributed and metabolized in the body (pharmacokinetics), and (4) whether the drug is concentration dependent or time dependent as it relates to antibacterial effect (pharmacodynamics) (see Box 3.3).[14] For simplicity, MIC breakpoints are established for antimicrobial drug concentrations in the bloodstream and are based on a specific dosage regimen for the antimicrobial drug tested. This dosage regimen is selected by the standards agency involved. Because some antimicrobials are concentrated extensively in urine, some veterinary laboratories may offer urine MIC panels, which provide breakpoints for lower urinary tract infections. These breakpoints are higher than corresponding serum MIC breakpoints, so a greater proportion of organisms tested are classified as "susceptible." Urine MIC panels have been controversial because the possibility of concurrent pyelonephritis (tissue drug concentrations rather than urine concentrations) cannot always be ruled out. Breakpoints may be reevaluated when new mechanisms of resistance appear in bacteria or when new data are generated that improve understanding of the pharmacokinetics and pharmacodynamics of an antimicrobial drug.

BOX 3.3 Factors Used by Standards Agencies to Establish Breakpoints for Antimicrobial Susceptibility Testing

Bacterial Factors
- Evaluation of MIC distributions for each bacterial species. These tend to be normally distributed (see Fig. 3.10; available for different antimicrobial drugs at www.eucast.org)[13]
- Knowledge of bacterial resistance mechanisms, as determined using phenotypic or genetic testing (e.g., testing for altered penicillin binding proteins in staphylococci)

Pharmacokinetics of the antimicrobial drug when used at a specific dosage regimen in the animal species of interest, including protein binding, taking into account variation among individuals

Pharmacodynamic indices (e.g., whether killing is concentration or time dependent) for the antimicrobial drug as they relate to organism killing (see Chapter 8)

Clinical response rates in humans and animal models, which are based on prospective, randomized controlled clinical studies with well-defined dosage regimens

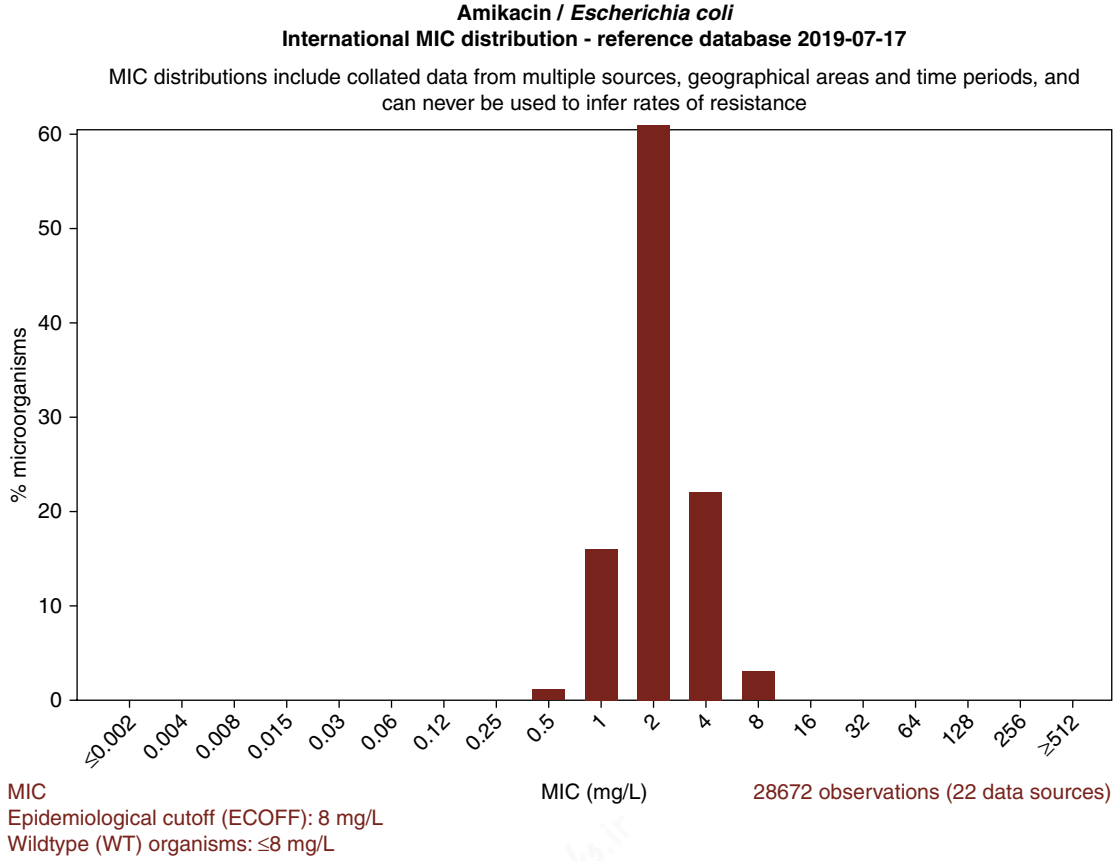

Fig. 3.11 Histogram that shows the distribution of amikacin minimum inhibitory concentrations (MICs) for isolates of *Escherichia coli*. The MICs are normally distributed. (From www.eucast.org.)

For infections in sites such as the CNS, the clinician needs to consider whether or not: (1) an antimicrobial will penetrate that site, (2) the drug is appropriate and safe, and (3) a higher dose is necessary to achieve adequate concentrations. The clinician must also consider factors such as immunosuppression and other concurrent illness or drug therapy when treating infections on the basis of antimicrobial susceptibility test results.

The bacterial species isolated determines which antimicrobials the laboratory selects for inclusion in susceptibility panels. For example, susceptibility to cephalosporins should not be reported for enterococci because of intrinsic resistance. Some antimicrobial drugs (e.g., vancomycin, linezolid, imipenem) should be reserved for treatment of multiple-drug resistant organisms that cause life-threatening infections. Consultation with a professional with expertise in infectious diseases or antimicrobial pharmacology is recommended before these drugs are selected.

Minimum and Serum Bactericidal Concentration

The *minimum bactericidal concentration* (MBC) is the minimum concentration of an antimicrobial drug that is bactericidal. It is determined by reculturing *(subculturing)* broth dilutions that inhibit growth of a bacterial organism (i.e., those at or above the MIC). The broth dilutions are streaked onto agar and incubated for 24 to 48 hours. The MBC is the lowest broth dilution of antimicrobial that prevents growth of the organism on the agar plate. Failure of the organism to grow on the plate implies that only nonviable organisms are present. The use of MBCs has been advocated by some for treatment of serious infections (such as endocarditis) or for treatment of immunosuppressed patients. Their value has been controversial, and they are not widely performed in human or veterinary medicine.

Serum bactericidal testing (SBT) is performed in the same manner as the MBC test, but uses the serum of a patient that has been treated with an antimicrobial. Serum is usually collected at expected peak and trough serum concentrations. SBT can be used to determine whether a patient has been adequately dosed, and to ensure that the antimicrobial is having the desired effect on the organism. Some data are available to support specific peak and trough SBT results required for the optimal treatment of human endocarditis, osteomyelitis, and cancer chemotherapy patients.[15–18] The SBT has not been widely used or evaluated for infections in dogs and cats and remains controversial in human medicine.

Mutant Prevention Concentration

The *mutant prevention concentration* (MPC) is the lowest antimicrobial drug concentration required to block the growth of the least susceptible bacterial cell in high-density bacterial populations.[19] Concentrations of antimicrobial in the zone between the MIC and the MPC (also known as the *mutant selection window*) allow selective amplification of resistant mutants.[20] This range is considered to be a "danger zone" for therapeutic drug concentrations. Minimizing the length of time that the antimicrobial drug concentration remains in the mutant selection window in vivo may reduce the likelihood for resistance selection during treatment.[21] The MPC cannot be extrapolated from the MIC. It is estimated using the standard agar dilution method used to estimate MIC, but with a larger inoculum ($\geq 10^9$ instead of 10^5 organisms), so as to include resistant subpopulations of bacteria. Administration of

higher doses of antimicrobial drugs that exceed the MPC may increase the chance of toxicity to the patient, but offsets the chance of selection for resistant organisms, even though infection may be cured with lower doses.[20,21] Although first evaluated for the fluoroquinolones, data are accumulating regarding the usefulness of the MPC for other drug classes. MPC estimations are currently not routinely performed in veterinary diagnostic laboratories.

Laboratory Diagnosis of Fungal Infections

Barbara A. Byrne, Shelley C. Rankin

KEY POINTS

- Fungi often grow more slowly than bacteria and can have specific culture media and incubation requirements. Many pathogenic fungi are dangerous to culture because they produce airborne conidia (spores) that may lead to laboratory-acquired infections.
- The clinician should notify the diagnostic laboratory if a fungal infection is suspected. Providing a list of suspected pathogens facilitates safe and successful culture of pathogenic fungi. The animal's signalment, clinical abnormalities, travel history, history of immunosuppressive drug therapy, and the results of cytologic or histopathologic examination should be considered.
- Specimens should be collected and transported as for bacterial culture. Refrigeration inhibits growth of some fungi, and freezing often prevents isolation of fungi from clinical specimens.
- Direct microscopic examination of specimens may provide presumptive identification of a fungal pathogen.
- Most pathogenic fungi remain predictably susceptible to antifungal drugs. Drug resistance among some pathogenic fungi has been documented, and the demand for antifungal susceptibility testing has increased. For some fungal pathogens, isolation, identification, and susceptibility testing before initiation of therapy may be advantageous.

INTRODUCTION AND DEFINITIONS

Fungi are eukaryotic microorganisms that secrete enzymes to digest organic material in the environment. The resultant nutrients are absorbed through a specialized fungal cell wall (known as *chemotrophic nutrition*). A basic understanding of fungal terminology facilitates communication between clinicians, microbiologists, and pathologists. Fungal organisms have two basic morphologic forms:

1. Molds—molds exist as filaments known as *hyphae,* which may be divided into cellular compartments *(septate hyphae).* Fungi with nonseptate or infrequently septate hyphae belong to the class Zygomycetes. A mass of filaments is known as a *mycelium.* A granule formed *in vivo* by a compacted mat of fungal filaments is a *eumycetoma* (as opposed to an *actinomycotic mycetoma*, which is a mycetoma formed by filamentous bacteria).
2. Yeasts—yeasts are single-celled organisms that reproduce by budding. In some cases, buds do not detach from the parent cell, but instead form a chain. Elongated chains of buds may resemble hyphae. These are termed *pseudohyphae* (Fig. 4.1).

Many pathogenic fungi exist as a mold in the environment, but convert to a yeast form in tissues. These fungi are called *dimorphic fungi*. Temperature can be a trigger for this conversion, and some dimorphic fungi convert from the yeast form in the animal to the infectious mold stage in the laboratory and pose a risk for laboratory personnel.

Molds can be further grouped using their asexual characteristics. Hyphomycetes (most pathogenic molds) can be categorized either as *moniliaceous* or *dematiaceous.* The hyphae and spores (conidia) of moniliaceous hyphomycetes lack visible melanin (*hyaline*) (e.g., *Aspergillus* spp.). The hyphae and spores of *dematiaceous* hyphomycetes have visible melanin (pigmented) (e.g., *Cladophialophora* spp.).

Molds reproduce by producing spores that can be produced following sexual reproduction. Sexual reproduction involves the fusion of haploid nuclei from two hyphal structures, which is followed by meiosis. Asexual reproduction (through mitosis) generates conidia that are identical to the parent cell. The asexual stage of a fungus is known as an *anamorph*, whereas the sexual stage is known as a *teleomorph*. Many fungi have two different species names to reflect these stages. For example, the teleomorph of *Cryptococcus neoformans* has been previously referred to as *Filobasidiella neoformans*. Formally, the teleomorph name has been designated to take precedence and can be used to describe both stages. Asexual reproduction predominates in most fungi, including in the laboratory during growth in culture. Thus, certain fungi, such as *C. neoformans*, have been more widely known by their anamorph name. Teleomorphs of some fungal organisms have not yet been described. Some organisms can exist in more than one asexual form, and therefore have had more than two names. Because of the confusion that has existed, with the recent Amsterdam Declaration of Fungal Nomenclature ("one fungus = one name"), there has been a move to use of only one name to describe fungal species.[1]

Diagnosis of fungal infections in animals requires laboratory procedures that include direct microscopic examination of a clinical specimen, isolation, and identification of a fungus. Diagnosis is often supported by immunologic tests to detect fungal antigen or host antibody to the fungus. Many direct specimen examinations and some antigen tests are now within the scope of POC diagnostic procedures for use in the primary veterinary practice. The development of improved methods for the rapid diagnosis of fungal infection has been directed at prepackaged identification kits, serologic kits, and molecular assays.[2] Confirmation of the identification of a specific fungus isolated from an infection frequently will be made by a specialty reference laboratory.

SPECIMEN COLLECTION AND TRANSPORT

Specimens collected for fungal isolation should be representative of the focus of infection and of adequate size or volume to permit direct examination and inoculation of media. Specimens should be obtained from an active site of infection as indicated by clinical and clinicopathologic examinations. In disseminated fungal infections,

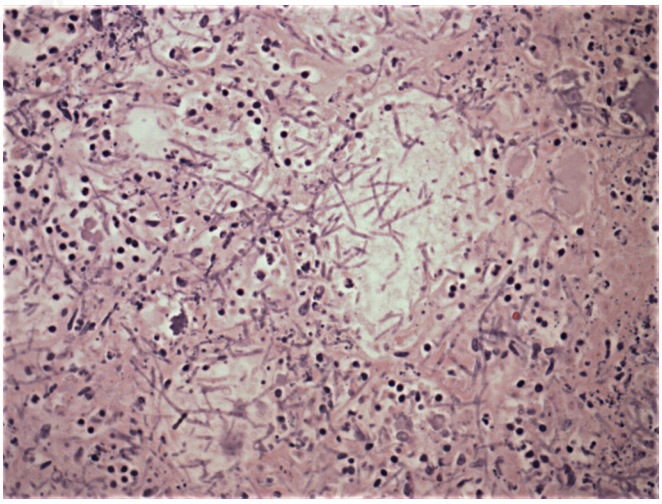

Fig. 4.1 Histopathology of the thyroid gland from a 13-year old female spayed poodle mix with disseminated *Candida albicans* infection. The dog had been treated with prednisone, cyclosporine, and azathioprine for refractory immune-mediated hematologic disease. Note intralesional pseudohyphae (hematoxylin and eosin stain, 400× magnification).

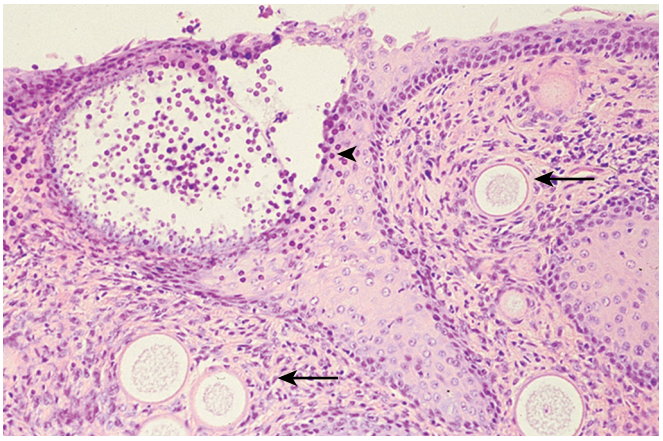

Fig. 4.2 Histopathology of a nasal polyp from a dog caused by *Rhinosporidium* spp. There are juvenile sporangia (arrows) and a mature sporangium that contains many endospores (arrowhead). (hematoxylin and eosin stain, 500× magnification). (Courtesy Spencer S. Jang, University of California, Davis, CA.)

blood culture for fungus may be indicated. Systemic mycoses are usually acquired via the respiratory tract and samples of lung tissue or airway exudate are often used. In certain disseminated mycotic infections, urine and lymph node tissue may also be appropriate specimens.[3]

For dermatophyte culture, lesions should be gently cleaned with 70% alcohol. The use of iodine should be avoided as it can inactivate dermatophytes. Surface antisepsis aids in minimizing the collection of environmental bacterial and fungal contaminants, thereby ensuring a meaningful result rather than contamination of cultures. Specimens for dermatophyte culture are best obtained by plucking hairs and crusts from the margin of the lesion. Use of a Wood's lamp may identify hairs infected with some dermatophyte species such as *Microsporum canis* (see Chapter 78). Skin scrapings can also be used for dermatophyte isolation. Brushings of affected lesions with a new, unused toothbrush can be useful for dermatophyte detection.[4] Nails are collected by clipping after treatment with 70% alcohol. Crumbled material from under the claw may be the best specimen, or an entire claw can be submitted. A biopsy may be required if fungi fail to grow from hair, scrapings, or swab specimens. Biopsy specimens should be divided and a portion placed in 10% buffered formalin for histopathologic examination to help confirm dermatophytosis. Skin scrapings, claw material, hair, and toothbrush specimens can be collected in a clean paper envelope or a sterile tube for transport to the laboratory. Envelopes are preferred to tubes because tubes retain moisture that can promote overgrowth of contaminants. Storage is best at room temperature because refrigeration can be harmful for some dermatophytes.

Swab specimens are of limited value for fungal isolation, and their use is discouraged. If no alternative collection method is available, specimens collected on swabs in a bacteriological transport medium should be inoculated onto suitable media without delay. Cotton swab specimens should not be used to make direct smears because recovery rates are poor.

Blood for fungal culture is collected directly after skin antisepsis into conventional or biphasic blood culture bottles, automated blood culture systems, or lysis-centrifugation systems.[5–7] Blood samples taken from indwelling intravenous catheters are not recommended because this may lead to growth of clinically insignificant fungi that grow and form a biofilm on the catheter.[5,7] Urine is best collected via cystocentesis. Urinary catheters may be colonized with yeast biofilms that can result in inaccurate diagnosis of funguria. Stool specimen cultures for diagnosis of fungal infections of the gastrointestinal tract are misleading since many fungi may be present in these specimens without associated disease; intestinal biopsy specimens for histologic examination are preferred. Body fluids and contents of masses suspected to contain fungi are collected through fine-needle aspiration or respiratory lavage/brushing. Large volumes that can be used for centrifugation are ideal. At least 3 mL of CSF is desirable if possible. Surgically collected material should be handled aseptically pending direct examination and culture. Corneal lesions are sampled by scraping with a sterile spatula, a surgical blade, or a nylon brush.

When rapid (<2 hours) transfer to the laboratory is not possible, storage and transport at room temperature is preferred. If transport requires longer periods, appropriate media should be used and the specimen should be refrigerated to prevent bacterial overgrowth.[6] Refrigeration may delay or inhibit proliferation of slow-growing fungi.

Urine specimens may be refrigerated for up to 24 hours before culture. Most bacteria and yeasts will multiply in urine held at room temperature. The laboratory should be informed if the patient is receiving antifungal drug treatment, which may interfere with fungal isolation.

Blood culture bottles can be held at room temperature for up to 24 hours. CSF and fluids from serous cavities and joints should be processed as soon as possible. CSF should be held at room temperature if not cultured immediately. Other sterile fluids should be held overnight under refrigeration.

Nasal biopsies and excised polyps may be divided between sterile containers for fungal isolation with 10% buffered formalin for histologic examination to assist with diagnosis of rhinosporidiosis or nasal aspergillosis (Fig. 4.2). Tissue may be moistened with a small amount of sterile saline.

Specimens should be labeled with the patient identification, source of specimen, and date and time of collection, and labeled, packaged, and transported according to regional and global regulations for shipping of infectious substances. Careful packaging and transport

TABLE 4.1 Microscopic Description of Some Common Fungal Pathogens of Dogs and Cats

Organism	Yeast or Hyphae	Diameter (μm)	Description	Geographic Distribution
Blastomyces spp.	Yeast	8–15	Round with thick, often refractile cell wall and broad-based budding	Southeastern and south central United States, upper Mid-west region
Histoplasma spp.	Yeast	2–5	Oval to round, often found in clusters within macrophages	Ohio and Mississippi river valleys, and California, United States; Central America
Cryptococcus spp.	Yeast	2–15	Round to oval, narrow-based budding, sometimes forming chains of organisms. Large capsule (see Fig. 4.6). Poorly encapsulated variants are rarely encountered	Worldwide, common in Australia and western North America
Coccidioides spp.	Spherule	10–200	Spherules vary in size and may contain endospores ("pomegranate-like"). Using cytology, they appear as empty and collapsed, deeply basophilic structures.	Central California, Arizona, Nevada, Texas; Central and South America
Sporothrix schenckii	Yeast	2–6	Oval, round, or cigar-shaped, occasionally budding. May be found intracellularly and extracellularly. Difficult to find in dogs but may be abundant in cats	Temperate and tropical zones worldwide. Most common in South and Central America
Malassezia spp.	Yeasts and pseudohyphae	3–8 (yeast), 5–10 (pseudohyphae)	Round to oval; when budding, have a "footprint" appearance (see Fig. 4.7)	Worldwide
Candida spp.	Yeast and pseudohyphae	3–4 (yeast), 5–10 (pseudohyphae)	Usually yeasts with a single bud or pseudohyphae with multiple constrictions (see Fig. 4.1)	Worldwide
Dermatophytes	Hyphae	3–15	Septate hyaline hyphae, arthroconidia may be visible along hair shafts (see Fig 4.4)	Worldwide
Aspergillus spp.	Hyphae	4–6	Septate hyaline hyphae with uniform diameter that branch at 45-degree angles (see Fig. 4.3)	Worldwide
Scedosporium spp., *Paecilomyces* spp.	Hyphae	3–12	Septate hyaline hyphae that tend to branch at wider angles than *Aspergillus* spp. (45–90 degrees)	Worldwide
Basidiobolus and *Conidiobolus* (zygomycosis)	Hyphae	10–30	Wide, non- or poorly septate irregular hyaline hyphae, branching at right angles, may be twisted or folded. Poorly stained using hematoxylin and eosin stain	Tropical and subtropical regions of the Americas, Africa, southeast Asia, and Australia
Phialophora, Exophiala, Cladophialophora, Bipolaris (phaeohyphomycosis or dematiaceous molds)	Hyphae	1.5–6	Pigmented hyphae, budding cells with single septa and chains of swollen round cells. May form granules	Worldwide
Pythium insidiosum	Hyphae	4–9	Sparsely septate, hyaline hyphae with 90-degree branches, detectable using hematoxylin and eosin stain	Tropical, subtropical, and some temperate regions of the world

is particularly important for specimens suspected to contain fungal pathogens. If organisms such as *Coccidioides*, *Blastomyces*, or *Histoplasma* spp. might be present, the laboratory should be advised and specimens marked appropriately. This information will assist the laboratory in selecting appropriate media, incubation conditions, and safety precautions.

DIAGNOSTIC METHODS

Microscopic Examination of Direct Smears

Examination of a direct smear before inoculation of media allows presumptive identification of many fungi by the laboratory (Table 4.1; Fig. 4.3). This helps the clinician make initial treatment decisions and guides media selection by the laboratory.

The search for fungal structures may involve preparation of stained or unstained wet mounts, fixed stained smears, and histologic sections. Some of these techniques are simple and rapid and may provide the clinician with a presumptive or even definitive diagnosis and a time-saving guide to therapy (Table 4.2). Others require more specialized stains or laboratory procedures.

Wet Mounts

Specimens may be suspended on a slide in saline, water, or 10% potassium hydroxide (KOH). If tissue granules are present, they can be examined by the laboratory for hyphae and cultured. Examination of smears begins under low magnification (100×) and with subdued light, with the condenser lowered. When structures suggestive of fungal elements are seen, higher magnification (400×) is used for examination.

KOH preparations can be used to examine specimens for dermatophyte hyphae and arthroconidia. The KOH clears keratinaceous and cellular debris, but fungal elements are left intact. The hair or skin scraping to be examined is placed into a drop of 10% KOH on a slide (Fig. 4.4A). The material may require soaking in KOH before further processing. Crusty material is teased apart with forceps, covered with a coverslip, and passed over an open flame several times, with care taken not to boil the mixture. The slide is then examined for fungal elements (Fig. 4.4B and C). If no organisms are observed, the slide is reexamined in 30 minutes. A more sensitive modification of the KOH preparation uses chlorazol black E and dimethylsulfoxide (DMSO, Delasco, Council Bluffs, IA, USA) which stains hyphae and/or arthroconidia green against a gray background. A mixture of 20% KOH and 36% DMSO or 25% KOH or sodium hydroxide with 5% glycerol increases penetration and clarity of specimens. Clearing of claw material may require up to 2 hours.

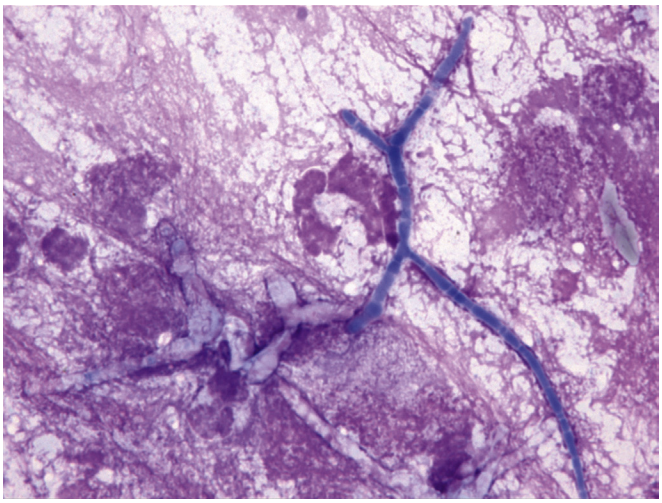

Fig. 4.3 Direct smear of an aspirate from a mediastinal mass of a 6-year-old female spayed labrador retriever with disseminated *Aspergillus deflectus* infection. Note hyphae with parallel walls that branch at 45-degree angles. Stain uptake by some hyphae is poor (Wright stain, 1000× magnification).

India ink or nigrosin (1% aqueous), when mixed on a slide with fluids or exudates, particularly CSF, containing *Cryptococcus* spp., provides a dark background that outlines the large capsules surrounding the yeast cells (see Chapter 82). Placing a drop of the specimen and a drop of India ink separately on a slide and then adding a coverslip allows for an optimal mixture gradient to form. However, less than 50% of culture-positive human CSF samples are detected by this method, so it is relatively insensitive.[5]

Less readily available methods of unstained wet mount visualization include phase microscopy, which improves visibility of fungal structures against a background of tissue debris, and fluorescence microscopy, in which specimens are prepared by mixing with an equal volume of 10% to 20% KOH and 0.5% calcofluor white (Difco, Detroit, MI, USA). Using a fluorescence microscope with a 365-nm exciter filter and a barrier filter that transmits light at 410 nm, fungal walls fluoresce (Fig. 4.5).

Fixed Smears

A Gram stain can be performed on most routine clinical specimens and can detect most fungi. Yeasts generally stain gram positive and molds tend to be gram negative or unstained. Yeasts are often detected because they retain the primary crystal violet stain (Fig. 4.6). The cell walls of molds often appear as unstained filaments. The usefulness of Gram stain for presumptive identification is generally limited to *Blastomyces, Candida, Cryptococcus, Malassezia* (Fig. 4.7), and *Geotrichum* spp., or the yeast form of *Sporothrix schenckii* spp. complex.

Romanowsky-type stains, such as Wright, Giemsa, and Diff-Quik, will stain fungi, especially yeasts, and are the stains of choice for *Histoplasma* spp. (see Chapter 81).

Histopathologic Findings

Routine hematoxylin and eosin stain of formalin-fixed paraffin-embedded tissue permits detection of fungi that cause systemic mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, and cryptococcosis). Hyphae of filamentous fungi may also be detected; these can

TABLE 4.2 Stains and Reagents Used for Direct Examination of Fungi in Clinical Specimens

Stain or Reagent	Usage	Text Figures/Disadvantages
Gram	Stains bacteria, yeasts, and other fungi	*Cryptococcus* (Fig. 4.6); *Malassezia pachydermatis* (Fig. 4.7); some fungi stain variably or not at all
Potassium hydroxide	Clearing tissue and cellular debris from variety of specimens to provide greater visibility of fungal elements	Dermatophytes (Fig. 4.4); artifacts develop after preparation time; experience required
India ink	Observation for presence or absence of capsules of fungal cells against a dark background	*Cryptococcus* (see Chapter 82); problems of artifacts can occur in the stain, poor sensitivity
Calcofluor white	A fluorescent brightener binding to polysaccharide such as cellulose and chitin	Detects variety of fungal elements; requires a fluorescent microscope
Wright	Stain for cytologic examination of peripheral blood, bone marrow, body fluids, and organ impressions	*Histoplasma* (see Chapter 81); *Aspergillus* (see Chapter 86); *Candida* (see Chapter 85); *Prototheca* (see Chapter 90); limited use
Gomori's methenamine silver	Detection of fungal elements in histologic section	Fig. 4.8; not readily available to most clinical bacteriology laboratories
Periodic acid–Schiff reaction	Detection of fungal elements in histologic section	Fig. 4.8; not readily available to most clinical bacteriology laboratories
Hematoxylin and eosin	Routine histologic stain used for detection of some fungal elements	*Rhinosporidium* (Fig. 4.2); usually requires large numbers of organisms to be detected with this stain

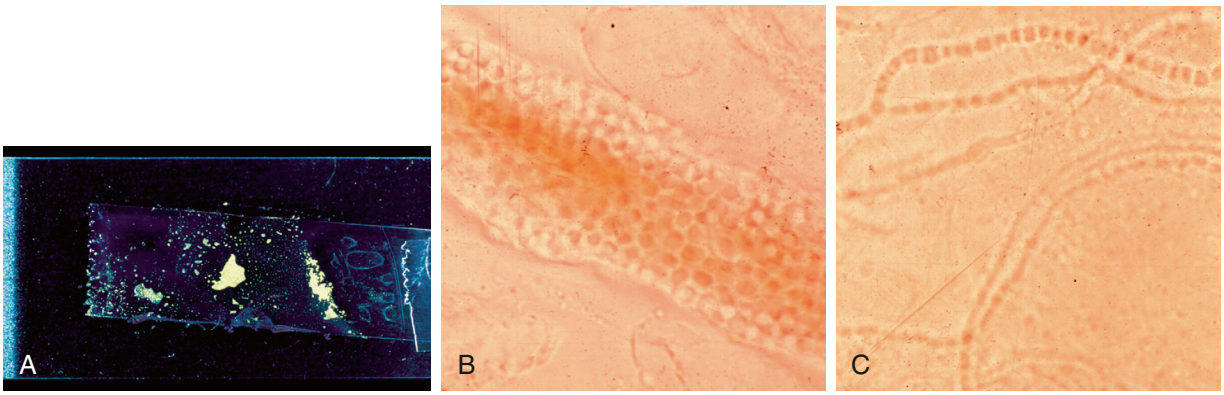

Fig. 4.4 (A) Hairs from a crusty skin lesion using a potassium hydroxide preparation (40× magnification) with (B) arthroconidia along or on the hair shaft or (C) chains of arthroconidia embedded in crusty material. (Courtesy Spencer S. Jang, University of California, Davis, CA.)

be distinguished as septate or nonseptate and pigmented or nonpigmented, helping with their classification. A more fungal-specific stain is periodic acid–Schiff, which makes mycotic elements appear dark red against a contrasting background (Fig. 4.8A), or Gomori's methenamine silver (Fig. 4.8B), which stains fungal structures brownish-black against a pale green background. Many laboratories use hematoxylin with eosin as a counterstain or hematoxylin alone, which permits better pathologic characterization of the lesion than do other procedures. Mayer's mucicarmine stain colors the capsule of *Cryptococcus* spp. red.

Fungal Culture

Before culture, clinical specimens must be prepared for inoculation on fungal growth media. Body fluids are usually centrifuged by the laboratory to concentrate fungal organisms. The sediment is then resuspended in a smaller volume of supernatant and inoculated onto media. If biopsy specimens are submitted, the tissues are minced before they are inoculated onto media.[6] Tissue grinding should be avoided because it can be harmful to fragile hyphal structures. Scrapings, swab specimens, and hair may be inoculated directly onto fungal media. For dermatophyte culture, toothbrush bristles or hairs (using sterile forceps) may be pressed into the agar.

Many types of media are available for fungal isolation, and no single medium is optimal for all pathogens (Table 4.3). Special media are available for differentiation of fungal species (see Fungal Identification). Media that contain antibacterial agents (usually chloramphenicol or gentamicin) are used to culture specimens that are likely to contain bacteria. Cycloheximide is added to dermatophyte test medium (DTM) to inhibit the growth of contaminant saprophytic molds. All plates should be sealed with oxygen-permeable shrink seal or tape to prevent exposure of laboratory personnel to potentially dangerous conidia and to minimize contamination with saprophytic mold species.

Use of the Isolator system (Wampole Laboratories, Princeton, NJ, USA) improves the sensitivity of fungal isolation, including of *Histoplasma, Coccidioides*, and *Cryptococcus* spp. from blood.[7] This system involves lysis and centrifugation of 1 to 10 mL of blood. The supernatant is removed through the blood culture bottle stopper, and the concentrate is removed from the sediment and plated onto media. It can be difficult to detect molds with conventional broth-based blood culture systems, but yeast can be isolated, particularly *Candida* spp. Nevertheless, molds may be isolated from broth-based blood culture systems, provided incubation periods are long enough. Several commercial broth-based blood culture systems support growth of fungi.[8,9]

Inoculated media is incubated at temperatures lower than those used for bacterial isolation: ~25°C or 30°C. Cultures are examined daily during the first week of incubation and twice weekly thereafter for 4 weeks before being called negative. Plates or tubes that grow filamentous fungi should be opened only in a biologic safety cabinet.

Fungal Identification

Identification of cultured fungi is based on colony morphology (size, color, and consistency), fungal growth rate, appearance of hyphae or yeast, asexual or sexual reproductive structures, physiologic tests, antigenic characteristics, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) analysis, and/or molecular analysis.

Yeast colonies resemble bacterial colonies and can be moist, dry, mucoid (Fig. 4.9A), or waxy. Mold colonies are generally dry, wrinkled, or heaped. Some molds such as zygomycetes (*Mucor, Rhizopus* spp.) grow rapidly, filling a Petri dish within 2 or 3 days. Others may not appear for a week or more and may remain as smaller colonies. Fruiting structures that produce conidia may appear as black specks in a colorless aerial mycelium (e.g., *Aspergillus niger*). Fruiting structures may be intensely pigmented, as seen by the green to blue-green colors of *Aspergillus fumigatus.* Some fungi produce soluble red or yellow pigment that diffuses through the medium (e.g., *Microsporum canis*). In others, pigment is confined to hyphae and

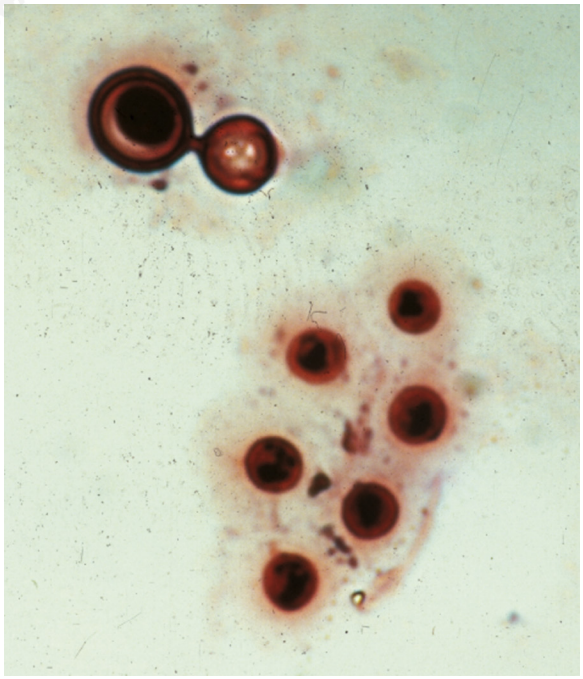

Fig. 4.6 *Cryptococcus spp.* Nasal granuloma of a cat. Budding forms, top; hazy zone around the six cells below represent capsules (Gram stain, 500× magnification). (Courtesy Spencer S. Jang, University of California, Davis, CA.)

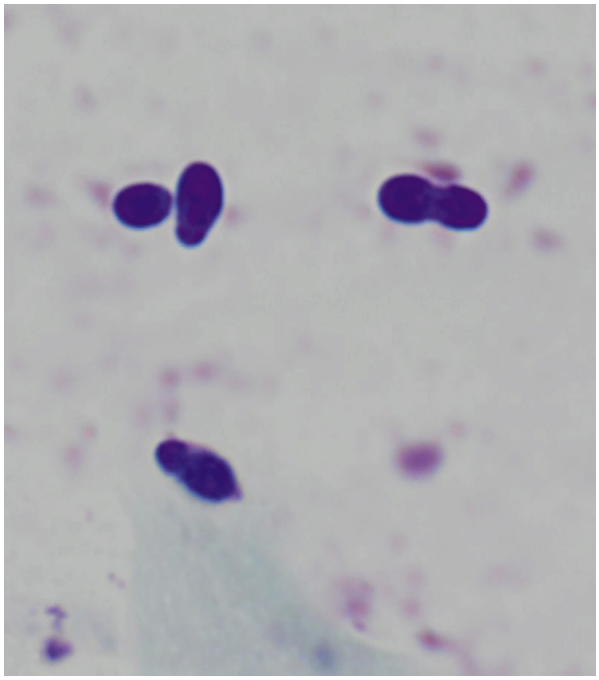

Fig. 4.7 *Malassezia* sp. ear exudate, dog. Broad-based budding yeast cells have "shoe print" appearance (Gram stain, 1000× magnification). (Courtesy Spencer S. Jang, University of California, Davis, CA.)

may be observed either on the surface or on the reverse side of the colony (Fig. 4.9B). The surface of the colony varies according to mycelial growth patterns from smooth ("glabrous") to powdery, velvety, and cottony. On DTM, dermatophytes rapidly utilize peptones in the medium, which leads to alkaline conditions and a red color change to the agar, often visible around the same time a mycelium appears. Molds that cause this color change should still be examined microscopically as some saprophytic molds may also cause the same color change; conversely, occasional dermatophytes fail to change or very slowly change the medium to red. As mentioned previously, agars with mold growth should not be opened outside of a biosafety cabinet.

Phenotypic identification of isolated molds is based on microscopic examination for hyphal characteristics: broad versus narrow, septate versus nonseptate, pigmented (dematiaceous) (Fig. 4.10) versus nonpigmented, conidia, and their supporting structures.

Microscopic examination of molds generally uses teased preparations or clear cellophane tape mounts from cultures prepared using appropriate precautions in a biosafety cabinet. Morphologic fungal structures are better preserved in their natural interrelationships in *lactophenol aniline blue (LPAB) tape mounts* (Figs. 4.11 and 4.12) or in a *slide culture*. To prepare a LPAB mount, tape is touched to the surface of a colony and placed sticky-side down in a drop of LPAB on a glass slide. Low-power microscopy aids early detection of mycelial growth, and macroconidia and microconidia of dermatophytes (Figs. 4.13 and 4.14). *Slide culture* permits LPAB examination of undisturbed fungal structures, and should not be performed for dangerous pathogens such as *Blastomyces* spp. or *Coccidioides* spp.

The *germ tube test* allows differentiation of *Candida albicans* from other *Candida* species. A standard serum, 0.5 to 1 mL, is inoculated with suspect *Candida* growth and incubated at 35°C for 2 to 3 hours. A drop of this suspension is then examined microscopically for germ tubes which can be seen sprouting from yeast cells (blastoconidia), which indicate the presence of *C. albicans* (Fig. 4.15).

A variety of broth or solid media are also used for fungal identification. For example, using chromogenic *Candida* agar can differentiate *Candida* spp., because each species has a specific colony morphology and color on this medium.[10] Commercially available test strips allow multiple biochemical identification tests for yeasts to be performed simultaneously (e.g., API 20C AUX Yeast Identification Kit, bioMérieux or RapID YEAST PLUS, Remel).[11] Other commonly used differential media include cornmeal agar for the demonstration of chlamydoconidia of *C. albicans, Trichophyton* agars for the identification of *Trichophyton* spp., and Christensen's urea agar for production of urease by *Cryptococcus, Rhodotorula, Trichophyton,* and *Trichosporon* spp.[12]

A recent innovation in identification of fungi is MALDI-TOF MS.[13–16] With this method, a yeast or mold isolate of unknown identification is spotted onto a stainless-steel slide target. A matrix is added that imparts a charge when the sample is struck with a laser and proteins fragment into peptides that pass through a vacuum tube at a rate determined by size and charge to hit a detector creating a peptide "spectrum." The spectrum of the test sample is compared to a database of spectra from known fungi, resulting in rapid (within minutes) identification. Yeast colonies can be directly transferred to the target slide, and identification is made within minutes. Molds generally require an extraction procedure before spotting the protein extract on the target for successful identification.

Fungal isolates can be identified to genus or species level by many other molecular-based methods. Both morphologic examination as well as molecular methods may be needed to identify some fungi definitively. Broad-spectrum 28S rRNA polymerase chain reaction (PCR) assays followed by testing with specific nucleic acid probes can be used.[17] A multiplex PCR approach for identification of a battery of commonly encountered yeasts and molds has also been described.[18] Commercially available DNA probes such as the AccuProbe (San Diego, CA, USA) are available for identification of fungal agents such as *Coccidioides, Blastomyces,* and *Histoplasma* spp. PCR-sequencing, especially of rRNA gene segments, can also be used for identification purposes. At present, the most commonly used regions are the D2

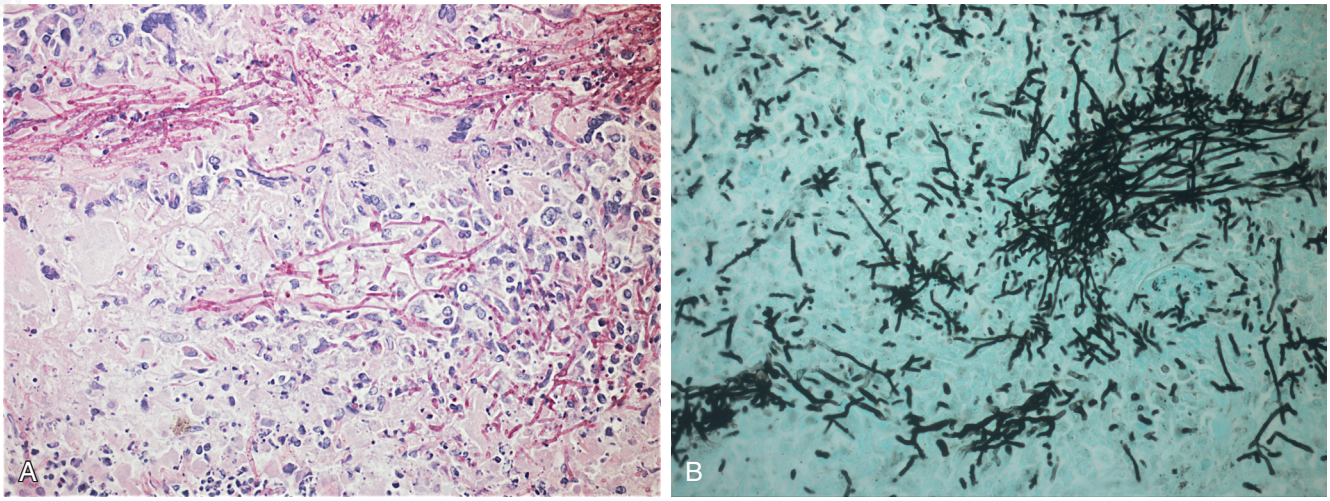

Fig. 4.8 Histopathology of the kidney from a 2-year-old female spayed German shepherd dog with disseminated paecilomycosis. (A) Periodic acid–Schiff stain. The fungal hyphae stain bright pink. (B) Gomori's methenamine silver stain. The fungal hyphae stain black (400× magnification).

TABLE 4.3 Isolation Media for Fungi

Type of Medium	Selective Features	Indications/Limitation in Mycologic Diagnosis
Sabouraud dextrose agar	Low pH; some formulations may have antibacterial agents	Cultivation of all fungi
Brain-heart infusion agar	None	Cultivation of all fungi
Potato flake/potato dextrose agar	Low pH, highly nutritious for most fungi	Cultivation of all fungi; induces sporulation of fungi
Inhibitory mold agar	Gentamicin, sometimes chloramphenicol	Cultivation of fungi when bacterial contamination is suspected; not for dermatophytes
Dermatophyte test media	Gentamicin, chloramphenicol, and cycloheximide; phenol red is color indicator	Dermatophyte isolation; media turns to red with dermatophyte growth; not for detection of conidia; may produce atypical colony growth; natural pigmentation obscured; nondermatophytes may turn yellow medium to red
Rapid sporulation medium	Cycloheximide and chloramphenicol; bromthymol blue is color indicator	For dermatophytes; media turns to blue-green to blue with dermatophyte growth; allows detection of conidia and pigment development for identification

variable region of the large-subunit rRNA gene and/or the internal transcribed spacer (ITS) regions (ITS-5.8S rRNA-ITS2).[19]

Direct Detection of Fungal DNA

Genus-specific, species-specific, or universal fungal primers can be used in PCR assays to detect fungal DNA in clinical specimens. Subsequent sequencing of PCR products also allows identification of fastidious or noncultivatable fungi. Real-time PCR can be used on peripheral blood for diagnosis of disseminated aspergillosis or *Candida* infections in people.[16,20–22] PCR assays have been used to identify *Pythium insidiosum* in specimens from dogs, and PCR-sequencing has been described for successful identification of *A. fumigatus* in formalin-fixed paraffin-embedded lung tissue from dogs.[23,24] Detection of dermatophyte DNA can aid in diagnosis of dermatophytosis.[25] Molecular-based test results should always be combined with clinical findings and, where possible, confirmed by morphologic features of the agent in tissues and/or in culture before making a final diagnosis.

Antigen and Serologic Testing

Assays designed to detect fungal antigens or antifungal antibodies in body fluids or blood are increasingly available. During cryptococcal infections, fungal capsule polysaccharide is produced abundantly, and its antigen can be detected in peripheral blood. Both latex agglutination and enzyme-linked immunoassays have been developed for cryptococcal antigen detection (see Chapters 2 and 82). Testing of body fluids, particularly urine, is available for diagnosis and treatment of histoplasmosis and blastomycosis (see Chapters 80 and 81).[26] An antigen-based test is also available for the detection of disseminated aspergillosis in dogs, and has shown high clinical sensitivity, although cross-reactivity with other fungi may occur (see Chapter 86).[27] Agar gel immunodiffusion for detection of anti-*Aspergillus* antibody has specificity for diagnosis of nasal aspergillosis, but negative results do not rule out infection.[28] An ELISA has been developed for diagnosis of pythiosis (see Chapter 88).[29]

INTERPRETATION OF FUNGAL CULTURE RESULTS

False-negative and false-positive results can occur with all types of diagnostic tests for fungal pathogens; therefore, results must be interpreted by taking into account the fungal species isolated, clinical signs, the results of cytology and histopathology, and the clinical picture.

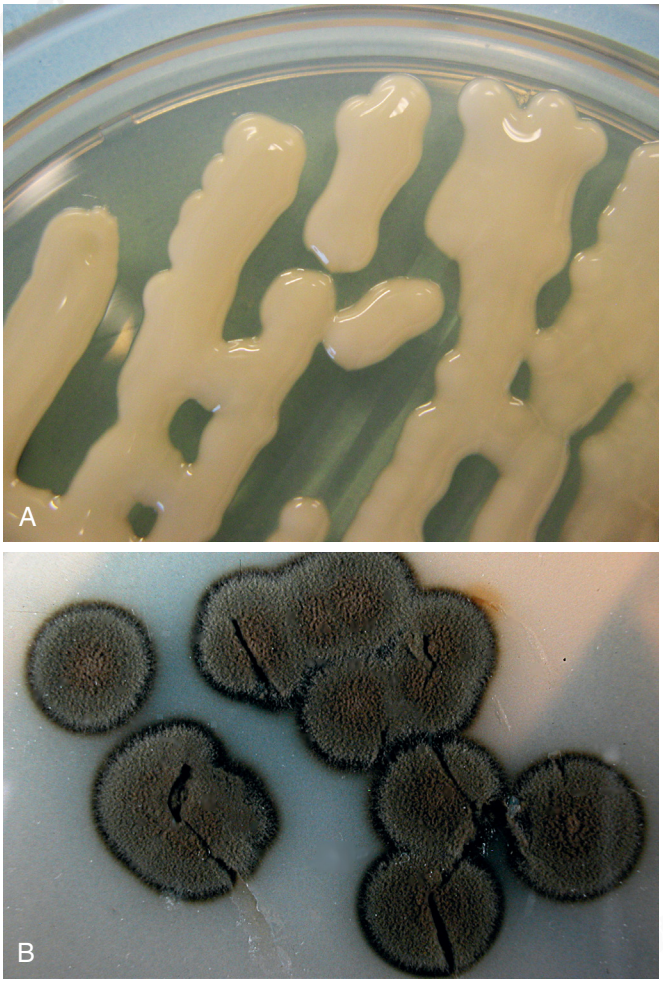

Fig. 4.9 Colony appearance. (A) Growth of *Cryptococcus gattii* yeast on potato flake agar. (B) Growth of *Cladophialophora bantiana*, a pigmented (dematiaceous) mold, isolated from canine brain tissue on potato flake agar.

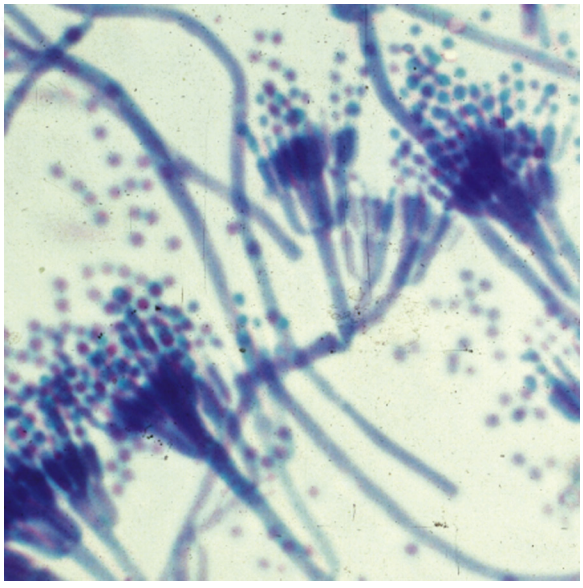

Fig. 4.12 *Penicillium* sp. fruiting structures (lactophenol aniline blue, 500× magnification). (Courtesy Spencer S. Jang, University of California, Davis, CA.)

Specimens That Test Negative

Negative test results can occur for many reasons, including, but not limited to, inadequate specimen size (such as when swabs or aspirates are submitted), inadequate organism numbers at the site of specimen collection, overgrowth with contaminating bacteria or saprophytic fungi, or loss of organism viability during specimen transportation. If a patient is receiving antifungal drugs but has not completely cleared the infection, culture may be negative.

False-negative test results can also occur when the specimen is not inoculated onto the correct media or insufficient time is allowed for

growth. It is critical that clinicians inform the laboratory if a specific fungal infection is suspected, and what organism might be involved. Poor laboratory quality control procedures may also lead to false-negative test results. Use of an accredited diagnostic laboratory can help minimize such problems.

Specimens That Test Positive

The detection of fungal organisms within a specimen does not always imply that they are the cause of clinical signs. Contamination by saprophytic fungi, especially *Aspergillus* or *Penicillium* spp., is the most common cause of false-positive fungal cultures. Organisms are more likely to be clinically significant when cytologic examination of a stained smear from the original specimen also demonstrates the presence of fungal organisms, especially in the presence of inflammation.

ANTIFUNGAL SUSCEPTIBILITY TESTING

Resistance to antifungal agents has now been documented for a variety of fungal pathogens, and intrinsic resistance to certain antifungal antimicrobials has been recognized.[30] This has led to an increased demand for antifungal susceptibility testing by clinicians. Fortunately, the reproducibility of antifungal susceptibility testing has improved in recent years, and MIC breakpoints that define susceptibility and resistance (see Chapter 10) have been established for many fungal pathogens to aid in the treatment of fungal infections in humans. Although veterinary breakpoints are still lacking, antifungal susceptibility testing allows comparison of the activity of two or more antifungal drugs, and serial testing of isolates from a single patient allows the development of resistance to be monitored over time. Methods of susceptibility testing that have been adapted for yeast and mold infections include broth microdilution, antifungal impregnated strips (ETEST, bioMérieux, France), and disc diffusion test (see Chapter 10). Common antifungal agents tested include amphotericin B, itraconazole, fluconazole, voriconazole, posaconazole, caspofungin, and flucytosine (Fig. 4.16). Limitations of antifungal susceptibility testing include the slow growth of fungal pathogens (when compared to bacteria), and the fact that some fungi may grow as yeasts or molds depending on media and incubation conditions. Partial inhibition of growth over a wide range of antifungal drug dilutions may also occur (a phenomenon known as *trailing*). Criteria have been set for interpretation of MICs in the presence of trailing for different antifungal drugs.[31] MALDI-TOF MS has been used to determine antifungal drug susceptibility among *Candida* spp. and in the future may overcome some of the difficulties in testing that currently exist.[32]

Diagnostic Techniques for Identification of Parasites

Susan E. Little, Yoko Nagamori

KEY POINTS

- Parasites are responsible for some of the easiest, and also some of the most difficult, infections to diagnose in clinical practice.
- When organisms are present in large numbers, diagnosis can be quickly achieved by direct microscopic examination of appropriate specimens. However, in many cases, parasites responsible for an infection are not present in high numbers, are not shed or circulating at the time of specimen collection, or are difficult to identify because of their small size, subtle diagnostic features, or damage associated with handling or delay in specimen submission.
- Immunologic and molecular assays are increasingly available to circumvent these difficulties. Nonetheless, direct microscopic examination of feces, blood, or other clinical specimens is still the most common approach for diagnosis of most parasitic infections.
- Many assays described in this chapter can be readily performed in clinic by trained personnel. However, because confirmation and consultation are often desired when making a diagnosis of an unusual parasite, collection and preservation of specimens for submission to veterinary diagnostic laboratories are also discussed.
- The geographic distribution of parasites is constantly changing. Novel parasites are occasionally encountered by veterinarians who may not be familiar with relatively uncommon organisms that can infect patients in a given geographic area. Submission of appropriate specimens to a diagnostic laboratory with parasitology expertise is critically important to accurately identify organisms in cases of unusual parasites or apparent treatment failures.

MICROSCOPIC EXAMINATION

Microscopic Examination of Feces

Eggs, larvae, cysts, and oocysts of several helminth and protozoan parasites are commonly found in fecal specimens. To ensure fragile stages of some protozoa (such as trophozoites of *Giardia* or *Tritrichomonas*) remain intact, fecal specimens should be examined as quickly as possible after collection. When examination of feces is delayed and the specimen is held at room temperature, eggs of hookworms may hatch, which results in larvae in the feces. However, most helminth eggs and larvae, as well as the cysts and oocysts of protozoa, will still be evident and fully recoverable from refrigerated or fixed specimens.

Collection and Storage of Feces

To maximize sensitivity and specificity, at least 5 g of feces should be collected and placed in a clean, dry, air-tight container. Freshly shed feces is ideal as specimens collected from the ground often contain free-living nematode larvae that may confound diagnosis. The amount of material retrieved by use of a fecal wand is insufficient for diagnostic testing of most intestinal parasites. Although interpretation of a positive result on direct smear from a fecal wand specimen is possible, a negative result is meaningless because of the small amount of feces examined.[1]

When the presence of trophozoites is suspected, the fecal specimen should be held at room temperature and examined within 30 minutes after collection. If specimens cannot be examined immediately, feces should be refrigerated. Tightly sealed, refrigerated specimens may be examined for cysts, oocysts, eggs, or larvae, all of which are hardier than trophozoites and persist in the environment for several days after collection.[2]

When *Tritrichomonas blagburni* (syn. *foetus*) is suspected, the saline flush technique may be employed to collect a fecal specimen; specimens obtained from nondiarrheic or dry stools are unsuitable. Stopping treatment for several days before testing is also recommended.[2] The saline flush technique involves passage of a rubber catheter into the proximal colon followed by administration and gentle reaspiration of 10 mL of sterile saline. Water should not be used because this will lyse trophozoites. The fecal-saline solution is then examined directly under the microscope for trophozoites, or a drop is inoculated into a fecal culture pouch for parasite isolation (see Trichomoniasis, Chapter 102). Alternatively, the saline flush contents are centrifuged and the pellet submitted for molecular analysis.[2]

Examination of Feces

Recommended microscopic procedures for diagnosis of intestinal parasites are listed in Table 5.1. Because dogs and cats are predators and dogs are coprophagous, some parasite stages found in fecal specimens may be the result of material the animal has ingested rather than true parasitism. For example, oocysts of *Eimeria* spp. are often observed in canine fecal specimens following ingestion of herbivore feces, usually those of a rabbit, deer, horse, or cow. In these cases, treatment is not indicated.

Direct saline smear. The direct smear technique, which can be performed on diarrheic or formed fecal specimens, is most important when trophozoites are present. No concentration of the specimen is achieved, and this approach is a poor choice to diagnose infection with other intestinal parasites. To enhance detection, the substage condenser of the microscope should be adjusted to maximize contrast. When available, phase-contrast or dark-field microscopy may aid in the demonstration of motile trophozoites (Fig. 5.1), but these are not necessary for reliable identification of motile protozoa.

TABLE 5.1 Recommended Microscopic Procedures for the Diagnosis of Common Gastrointestinal Parasites of the Dog and Cat

Organism	Stage	Procedure[16]
Protozoa		
Cystoisospora Sarcocystis, Hammondia, Besnoitia, and *Cryptosporidium*	Oocysts	Sheather's sugar centrifugation flotation technique
Giardia	Trophozoites	Direct smear, occasionally seen on flotation
	Cysts	Direct smear, zinc sulfate centrifugation flotation technique
Tritrichomonas foetus	Trophozoites	Direct smear
Nematodes		
Ancylostoma spp., *Uncinaria* spp.	Eggs	Sheather's sugar or zinc sulfate centrifugation flotation technique
Physaloptera spp.	Eggs	Fecal sedimentation; occasionally found on direct smear
Strongyloides stercoralis	Larvae	Baermann examination; occasionally found on direct smear
Toxocara spp.	Eggs	Sheather's sugar or zinc sulfate centrifugation flotation technique
Trichuris spp.	Eggs	Sheather's sugar centrifugation flotation technique
Cestodes		
Dipylidium caninum	Eggs	Observation of proglottids; rarely found on Sheather's sugar centrifugation flotation technique
Echinococcus spp., *Taenia* spp.	Eggs	Occasionally found on Sheather's sugar centrifugation flotation technique
Mesocestoides spp.	Eggs	Occasionally found on Sheather's sugar centrifugation flotation technique
Spirometra spp., *Diphyllobothrium latum*	Eggs	Sheather's sugar centrifugation flotation technique
Trematodes		
Alaria spp.	Eggs	Fecal sedimentation
Nanophyetus salmincola	Eggs	Fecal sedimentation

Fig. 5.1 Unstained *Giardia* trophozoite *(arrow)* as viewed with phase-contrast microscopy showing morphologic details such as nuclei, median body, and flagella.

A direct smear is made by placing a drop of isotonic saline on a clean microscope slide and then mixing in a very small amount of fecal material (Fig. 5.2A). The amount that adheres to the tip of a wooden applicator stick is sufficient. A coverslip is then applied, and the slide is systematically scanned using the 10× objective but alternating with the 40× objective whenever structures morphologically resembling protozoan trophozoites or cysts are encountered. The fecal-saline mixture should be transparent enough that newsprint can be easily read through the material. A smear prepared with too much fecal material cannot be accurately interpreted. Motility and structural features of protozoa are best examined using the high-dry objective (40× to 43×). The oil immersion objective (100×) is not recommended for examination of fresh wet mounts because pressure on the coverslip from the oil objective displaces the fluid medium between the coverslip and the slide, making viewing difficult. If necessary, once motility has been observed, stain may be added to the smear to aid in identification of organisms.[1]

Stained smear. Although not required, adding stain to the wet mount through the edge of the coverslip may aid in visualizing internal structures of some protozoa. For example, although *Pentatrichomonas* spp. usually have five anterior flagella and *T. blagburni* usually has three anterior flagella, it is difficult to identify these organisms using living or unstained specimens. Special stains, such as silver staining, are needed to highlight flagella and other diagnostic features of trophozoites.[3]

Iodine is the most common stain used to reveal the internal structure of protozoans and is especially useful to confirm the identity of *Giardia* cysts and trophozoites. The iodine stains the cytoplasm of cysts dark gold, while the nuclei remain pale and refractile. Other stains used to identify protozoa in feces include methylene blue, acid methyl green, aqueous eosin, and crystal violet. Methylene blue is useful to identify trophozoites, especially those of *Entamoeba histolytica,* whereas acid methyl green stains the macronucleus of *Balantidium coli.* Aqueous eosin and crystal violet are both negative stains, which stain fecal debris but leave parasitic cysts and trophozoites unstained and highlighted by the stained background.[4]

Fecal flotation. Fecal concentration methods are often necessary to detect protozoal cysts or oocysts and common helminth eggs

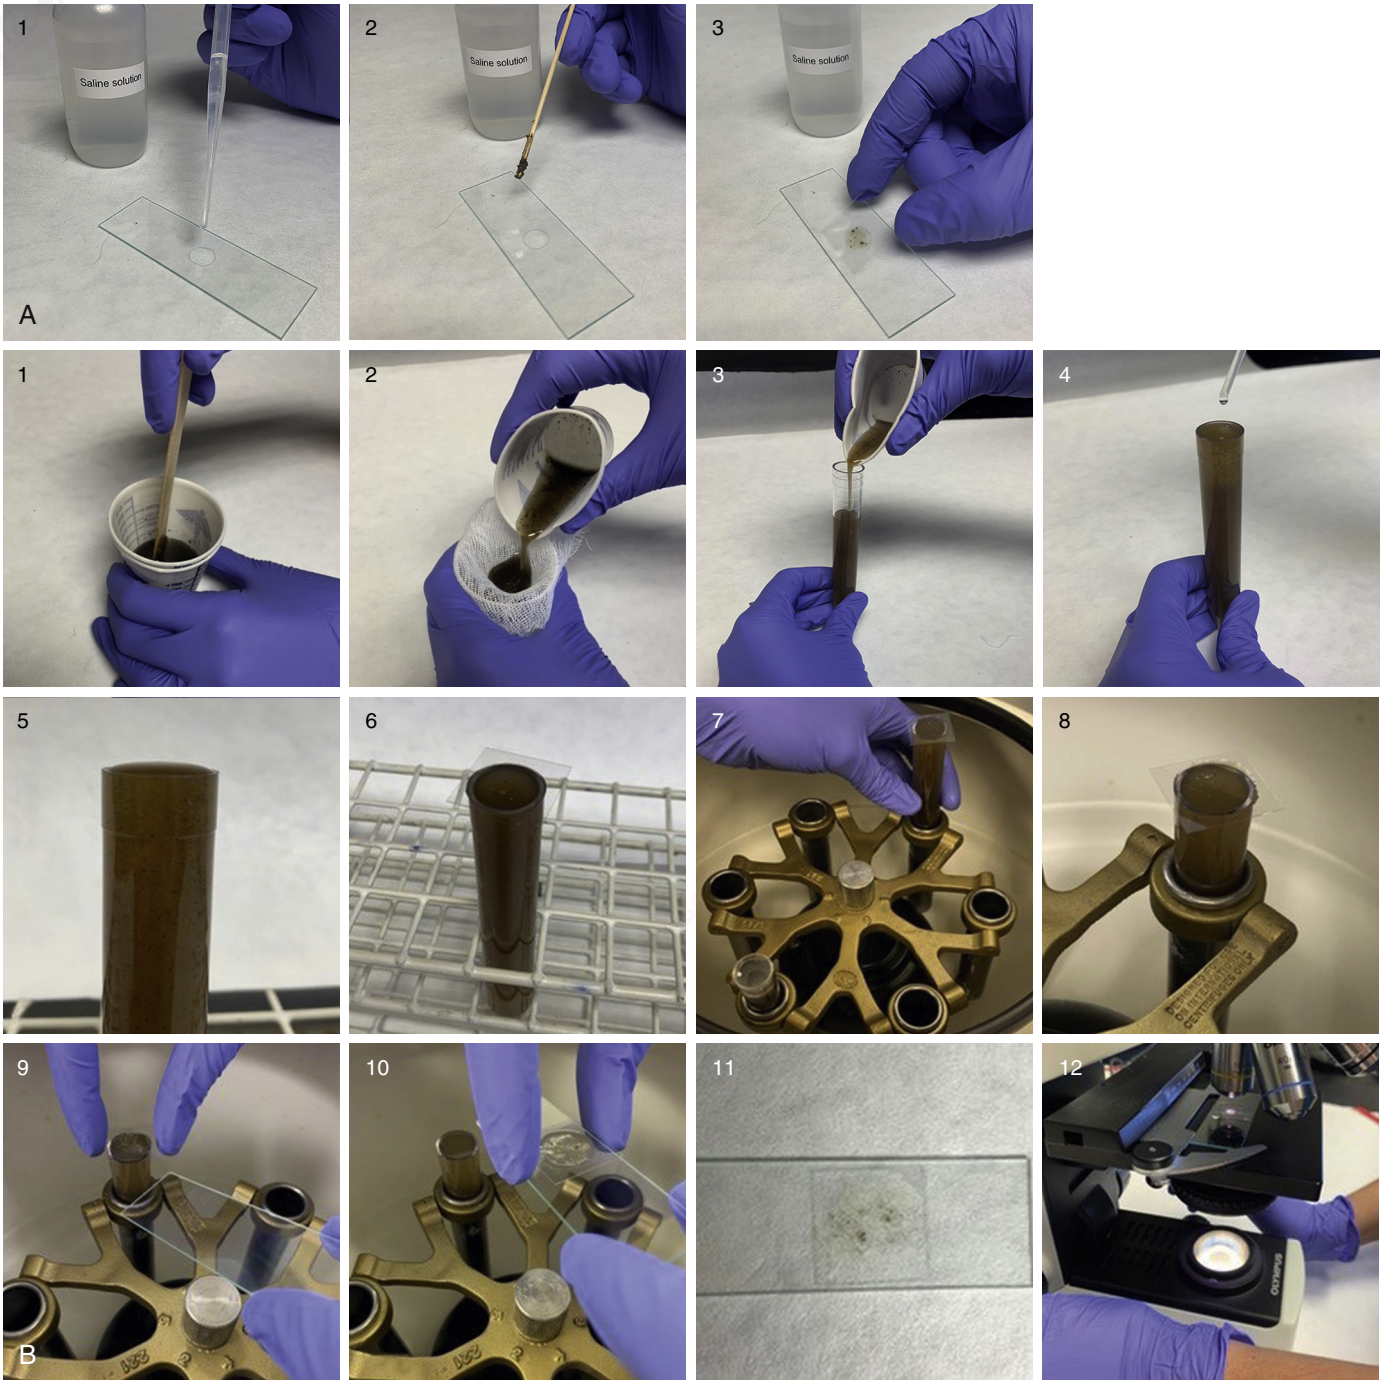

Fig. 5.2 (A) Procedure for direct fecal smear. 1. A drop of isotonic saline on a clean microscope slide. 2. An amount of fecal material is placed on the tip of a wooden applicator stick. 3. This material is stirred into the saline. A coverslip is applied and the slide is examined with the microscope. (B) Fecal procedure using swinging bucket rotor centrifuge. 1. About 5 to 10 g of feces are mixed with water to a liquid consistency. 2. The mixture is strained with gauze. 3. The strained feces-flotation solution mixture is poured into a 15-mL conical centrifuge tube. 4. Flotation solution is added. 5. A final amount is added to form a reverse meniscus at the top of the tube. 6. A coverslip is then placed on top of the meniscus. 7. The tube is placed in the centrifuge and a second tube filled with water is used to balance it. 8. A coverslip is added on the top and it is centrifuged with the coverslip in place. 9. After centrifugation, the coverslip is removed. 10. The coverslip is transferred, along with the adherent fluid, face down on a slide. 11. The unstained slide is transferred to a microscope. 12. The slide is examined as described in the text for this procedure. (Photographs provided by Kellee Sundstrom and Megan Lineberry, Oklahoma State University.)

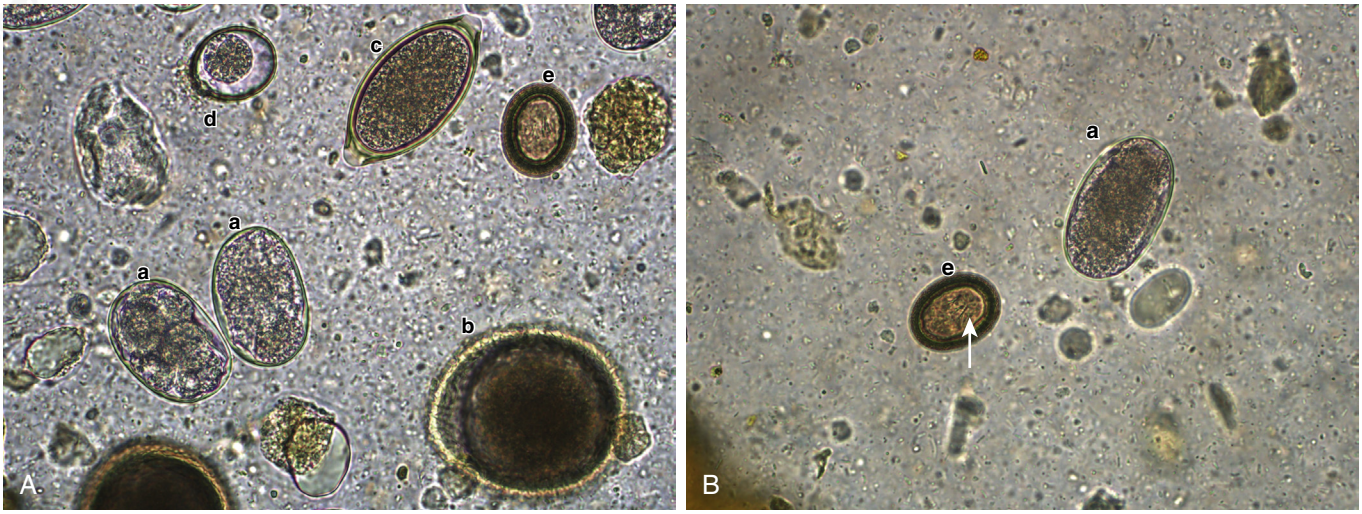

Fig. 5.3 (A) Eggs of *Ancylostoma caninum (a)*, *Toxocara canis (b)*, *Trichuris vulpis (c)*, *Cystoisospora canis (d)*, and *Taenia* sp. *(e)* in canine fecal flotation. (B) Closer view of eggs of *A. caninum (a)* and *Taenia* sp. *(e)* showing distinct hooks *(arrow)* within a *Taenia* sp. egg.

or larvae (see Table 5.1; Fig. 5.3). Sugar or salt solutions are used with centrifugation to concentrate parasites present in several grams of feces into a small volume of fluid that can be examined on a single slide. Alone, standard sodium nitrate tabletop flotation is not sensitive enough to identify infections with many intestinal parasites, although high-intensity infections consisting of numerous coccidial oocysts, ascarid eggs, or hookworm eggs may be detected. Although inactivated by the hypertonic solution and frequently lysed, trophozoites, especially those of *Giardia,* may also occasionally be seen on fecal flotation. Most platyhelminth eggs are considered too heavy to reliably float in common flotation solutions, and thus sedimentation is preferred. However, eggs of some cestodes and trematodes (e.g., *Taenia*, *Spirometra*, or *Alaria* spp.) may occasionally be recovered using flotation.

Solutions used in centrifugal fecal flotation methods include zinc sulfate and Sheather's sugar; a water wash may be included to assist in the examination of very mucoid or fatty fecal specimens. Feces are washed by combining 2 to 3 g of feces with 5 to 10 mL of water, straining the mixture through a double layer of cheesecloth, centrifuging for 5 to 10 minutes at approximately 650 × *g*, and then discarding the supernatant. The sediment is then mixed with 10 to 12 mL 33% zinc sulfate solution (specific gravity of 1.18) or Sheather's sugar solution (specific gravity of 1.25), strained through cheesecloth, and centrifuged for 5 to 10 minutes at approximately 650 × *g*.[1]

When available, a centrifuge with a swinging bucket rotor is ideal for the flotation step (Fig. 5.2B). The strained feces-flotation solution mixture is poured into a 15-mL conical centrifuge tube, and enough flotation solution is added to form a reverse meniscus at the top of the tube. A coverslip is then placed on top of the meniscus and the tube spun with the coverslip in place. A second tube of equal volume is needed to balance the centrifuge. Once completed, the coverslip is removed and transferred along with the adherent fluid face down on a slide, and the slide is examined (see Fig. 5.2B).

If only a fixed-angle bucket rotor is available, the feces-flotation solution mixture can be poured into a 15-mL centrifuge tube to the point at which it is almost full but does not spill when placed into the centrifuge bucket (approximately 13 mL). The tube is then spun without a coverslip. The top layer of the centrifuged material can be collected by carefully touching the base of a small test tube or a microbiologic loop to the surface and then transferring the adherent fluid to a slide. A coverslip is then applied and the preparation examined using a microscope.

Slides should be completely examined using the 10× and, when necessary, the 40× objective. Scanning a slide at low power (×4) is not sufficient to allow detection of many nematode eggs and most protozoan diagnostic stages.[1] Quantification methods such as the Wisconsin or modified McMaster egg counting techniques are not used for routine canine and feline fecal flotation. Some diagnostic laboratories add a comment on the report about the relative number of eggs, cysts, or oocysts detected. Nonetheless, it is critical to start with an adequate amount of feces to optimize sensitivity.

Fecal sedimentation. Sedimentation is used only for detection of helminths that shed heavier eggs (see Table 5.1). Eggs of several trematodes, cestodes, and even some nematodes (e.g., *Physaloptera* spp.) are not routinely recovered on fecal flotation. When these infections are suspected, either simple or centrifugal sedimentation, as described below, should be performed. Concentration is not as great with sedimentation as it is with flotation, but heavier eggs are more likely to be detected with these methods than by direct smear of feces alone.

For simple sedimentation, 100 mL of either tap water or saline is combined in a beaker with approximately 10 g of feces, strained through cheesecloth into a second beaker, and then allowed to settle for 1 hour. The supernatant is then decanted, more water added, and the settling step repeated. A small amount of sediment is then placed on a slide, a coverslip applied, and the slide scanned using the 10× objective. Some protocols recommend use of a smaller amount of feces and water combined in a test tube rather than in a beaker. Centrifugation accelerates the separation, but if mucus or fat are present, the fecal material should first be combined with Hemo-De (Scientific Safety Solvents, Keller, TX, USA) to facilitate separation of eggs. For centrifugal sedimentation, 1 g of feces is mixed with 10 mL of either 10% formalin or water and poured into a glass or polypropylene centrifuge tube and Hemo-De is added. The tube is capped and vigorously shaken, then centrifuged for 5 minutes at 650 × *g*. An applicator stick is used to break the top plug of debris so that both the debris plug and the supernatant can be decanted. The remaining sediment is placed on a slide, a coverslip applied, and the slide examined using the 10× objective.[1]

Baermann assay. The Baermann assay is used to recover motile nematode larvae, such as lungworm larvae (see Chapter 117) and

TABLE 5.2 Practical Techniques for the Diagnosis of Blood and Systemic Parasitic Infections

Strongyloides stercoralis (see Chapter 116), from feces (see Table 5.1). The assay should only be performed with fresh feces. Results will be confounded by larvae from hatched hookworm eggs in specimens even just a few days old, as well as by the presence of free-living nematode larvae in feces collected from the ground. Approximately 10 g of feces is placed in a double layer of cheesecloth, secured by a rubber band, and suspended at the top of a disposable wine glass with a hollow stem. The apparatus is then filled with room temperature water to completely immerse the feces and held at room temperature for 8 to 16 hours. Any larvae present in the feces will migrate into the water and collect at the base of the hollow stem. After resting, the feces is removed and discarded and a small amount of fluid removed from the base of the stem with a pipette, placed on a slide, a coverslip applied, and examined for larvae using the 4× or 10× objective.[1]

Preservation of Feces

No specific preservation or addition of fixative is necessary before routine fecal flotation for common gastrointestinal parasites. If submission will be delayed a few days, refrigeration is recommended to prevent growth of mold and delay development of nematode eggs. If examination is delayed for several days and there is a desire to preserve protozoa, fresh feces can be mixed with a preservative before shipment. Enough fixative solution should be added to the feces to ensure adequate fixation. Some commonly used solutions include polyvinyl alcohol (PVA) and 10% formalin.[4] Ten percent formalin solution is an appropriate fixative for specimens suspected to contain *Cryptosporidium,* because formalin fixation, unlike fixation with PVA, does not interfere with immunodetection assays employed to detect *Cryptosporidium* (e.g., direct fluorescent antibody).

Potassium dichromate (1%) is the solution of choice for storing specimens that contain oocysts of coccidia because it allows the oocysts to sporulate, permitting the precise measurements of sporocysts and sporozoites and complete evaluation of oocyst structure that are needed for identification.[5] A 2% solution of sulfuric acid is an acceptable alternative to 1% potassium dichromate. Historically, PVA has been considered the best choice for fixing trophozoites because permanently stained slides can be prepared from PVA-fixed fecal material. However, both PVA, which contains mercuric chloride, and potassium dichromate are potent toxins and should be handled with great care. Less toxic, more environmentally safe commercial substitutes for PVA have become available, including Proto-Fix (AlphaTec Systems, Vancouver, WA, USA) and ECOFIX (Meridian Diagnostics, Cincinnati, OH, USA).[6]

Microscopic Examination of Whole Blood

Diagnostic stages of parasites may be detected both in fresh blood and in blood collected into anticoagulants. Microfilaria are often detected in EDTA-anticoagulated blood by direct examination of a saline wet mount of whole blood or by Knott test (see Chapter 111). In contrast, the most common method used to detect protozoa in blood is by microscopic examination of a stained blood smear. Bloodborne and systemic parasites that can be detected in stained blood smears or in fresh wet mounts are listed in Table 5.2.

Collection of Blood Specimens

Appropriate collection procedures for blood are dictated, in part, by the parasites suspected to be the cause of disease. If diagnosis requires blood smear examination, care should be taken during blood collection and handling to avoid hemolysis that may destroy parasites. Smears from fresh whole blood should be made immediately after collection; blood collected into EDTA anticoagulant can be submitted for smears to be made at a later time or for examining blood for microfilaria.[7] Some protozoa, especially *Babesia* spp., are more easily found in the peripheral circulation of microcapillary beds; detection of these parasites may be enhanced by collecting from an ear margin or clipped toenail.

Testing for Microfilaria

When present in high numbers, microfilaria may be found in saline wet mounts of whole blood. However, the modified Knott test, which concentrates any microfilaria present in 1 mL of blood, allows more sensitive detection. To prepare a wet mount, a small drop of anticoagulated whole blood is placed on a slide, a drop of saline added, the specimen briefly mixed, a coverslip applied, and the material directly examined using the 10× objective for any microfilaria present. Relative numbers and motility patterns of microfilaria present on a direct wet mount can support a diagnosis of *Dirofilaria immitis* infection. However, accurate measurement of microfilaria with an ocular micrometer is only readily achieved using a Knott test.

To perform the modified Knott test, 1 mL of EDTA-anticoagulated whole blood is placed in a centrifuge tube and 9 mL of 2% formalin added. The specimen is capped and mixed briefly to lyse the red blood cells, then centrifuged at 650 × *g* for 5 minutes. The supernatant is discarded and a drop of 0.1% methylene blue added to the sediment. Stained material is then transferred to a microscope slide using a pipette, a coverslip applied, and the

specimen examined using the 10× objective for microfilaria. In the modified Knott test, microfilaria will be immobilized, fully extended, and readily measured and examined for key features that allow confirmation of their identity as either *D. immitis* or one of the other species that may be found in the blood. The stain highlights microfilarial nuclei, aiding identification (see Chapter 111 for additional tests for heartworm disease).

Preparation of Blood Films

Examination of dried blood films is often useful for diagnosis of protozoal infections. Thick films allow examination of a larger volume of blood, which increases sensitivity, but thin films are necessary for morphologic identification. If possible, multiple slides (at least two thick and two thin) should be prepared and submitted unstained.[3]

Thin films are prepared by placing a small drop of blood at one end of a clean microscope slide and then using a second slide to spread the blood. Blood should not be pushed across the slide because this may rupture parasites. To prepare thick films, two or three drops of blood are placed on a clean microscope slide and spread with the corner of another slide in a circular motion over a 2-cm area. Fresh blood should be stirred on the slide for an additional 30 seconds to prevent formation of fibrin strands. EDTA-anticoagulated blood does not need to be stirred after spreading.[3]

Both thick and thin films should be air dried at room temperature on a flat surface. The choice of stain will determine the need for additional preparation and fixation before staining. Some stains require thick films to be laked (immersed in distilled water to lyse erythrocytes) before staining. Thin films that are not stained within 48 hours should be fixed in 100% methanol. All films should be stored in a cool, dry, clean place in a sealed box.[3]

Staining Blood Films

Giemsa, Wright, and Wright-Giemsa are the most commonly used stains to detect and identify hemoprotozoa on blood smears. Diff-Quik can be used, but both detection of the presence of protozoa and subsequent morphologic identification to species may be more difficult.[7] Giemsa-stained blood smears have the added advantage of permanency; Wright-stained blood smears fade over time.

Examination of Blood Films

Stained blood films may be examined with or without a coverslip. When a coverslip is not used, a drop of immersion oil can be placed on the stained smear to reduce diffraction and facilitate microscopic examination at low power and with the high-dry objectives. Additional immersion oil should then be added and the feathered edge of the stained smear examined closely using the oil immersion objective. If preferred, a thin (#1) coverslip can be applied with neutral mounting medium before examination. The mounting medium prevents the coverslip from moving around on the stained smear and also reduces diffraction in a manner similar to immersion oil applied directly to the smear.[3] One advantage of using a coverslip is that it allows the slide to be thoroughly cleaned with lens cleaner and reexamined at a later date by another diagnostician; the surfaces of stained smears that do not have a coverslip cannot be cleaned.

Examination of Intact Parasites

Intact metazoan parasites are often recovered from vomit, feces, skin, or from other tissues collected at surgery or necropsy. Whenever possible, all available specimens should be submitted for morphologic identification to a diagnostic veterinary parasitology laboratory. Helminths may be submitted fresh in saline or, if submission will be delayed, fixed in dilute (5%) formalin; the 10% formalin used for preservation of tissues can destroy helminth structures needed for full identification. Arthropods should be submitted in 70% ethanol. All specimens from which nucleic acid will be collected for molecular identification or comparison should be placed in 70% ethanol. Formalin-fixed specimens are of limited value for molecular evaluation.

Microscopic Examination of Other Specimens

Parasites may sometimes be found on histologic examination of biopsy specimens, tissues collected at necropsy, or on cytology. Ideally, intact helminths or arthropods will be submitted directly for identification. Although intact stages of parasites may be detected and identified on microscopic examination of aspirates or impression smears and protozoa can be identified in histologic sections (see Table 5.2), thin sections of only one portion of a large metazoan parasite often precludes complete identification.

Histopathology

Parasites may be found on histologic examination of tissues with routine hematoxylin and eosin staining. Accurate identification of metazoan parasites in thin sections requires both advanced training in histoparasitology and sections made in a location that shows key features of the parasite. When tissue sections are limited or when stages are small (such as microfilaria in skin biopsies), definitive identification to genus and species by microscopy alone may not be possible. For protozoa, entire organisms are usually present on sections and identification is more readily achieved. Special stains may be used to improve detection or enhance morphologic characteristics of the stage of parasite seen, allowing more confident identification. Tissue specimens to be examined by histology for protozoan parasites should be collected and submitted quickly for frozen section evaluation when an immediate diagnosis is desired, or they should be placed in 10% formalin if processing will be delayed. Tissues on which electron microscopy will be performed should be placed in a glutaraldehyde-based fixative.[3]

Cytologic Examination of Other Body Fluids

Parasites are only rarely found on direct microscopic examination of aqueous humor, CSF, synovial fluid, urine, transtracheal wash, or bronchoalveolar lavage. *Giardia* trophozoites may occasionally be seen in duodenal aspirates collected at endoscopy. To determine if motile protozoa are present, all body fluids should be examined by direct smear immediately after collection; storage of specimens for even a short time may result in lysis of organisms and subsequent failure to detect infection. Specimens are processed for examination by centrifuging collected fluid at 2000 × *g* for 5 minutes and then making smears with the sediment and adding a small amount of associated fluid. After drying, smears should be stained as described for blood smears and examined for protozoa. Eggs of some nematodes (e.g., *Pearsonema plica*, *Dioctophyme renale*) may be found in urine sediment and directly identified (see Chapter 116). Similarly, larvae of some nematodes will be present in specimens collected by transtracheal wash or bronchoalveolar lavage; centrifugation of these specimens and direct microscopic examination of sediment enhances likelihood of detection.

Fine-Needle Aspirates

Parasites, especially protozoa, are occasionally found in fine-needle aspirates of lymph node, spleen, liver, or bone marrow. Dried smears of fine-needle aspirates are stained with Giemsa, Wright, or Wright-Giemsa and examined for protozoa as described for

blood smears. Occasionally, some stages of metazoan parasites may also be found on lymph node aspirates including microfilaria and *Demodex* spp. mites.[8,9]

Impression Smears

Examination of stained impression smears of superficial lesions or of tissue collected at biopsy or necropsy may also reveal parasites, usually protozoa (e.g., *Leishmania* spp.). For this reason, impression smears should be made of all biopsy material when a parasitic infection is suspected.

Collection of Parasites from Skin

Large arthropods such as ticks, fleas, or lice should be placed in 70% ethanol and submitted intact for identification. A fine-toothed flea comb will often facilitate recovery of larger arthropods. However, mites are more readily recovered intact on skin scrapes, by swabbing ears (e.g., *Otodectes cynotis*), or by collecting dander and examining for superficial mites (e.g., *Cheyletiella yasguri*). Occasionally, larger arthropods (e.g., *Cuterebra*) or nematodes (e.g., *Dracunculus*) may be present in subcutaneous cysts or found emerging from dermal ulcers. Whenever possible, these organisms should be removed and submitted intact for identification.

To perform a skin scrape, a sterile scalpel blade is dipped in mineral oil and then used to abrade the affected area of skin; the material adherent to the blade is then transferred to a microscope slide. To enhance recovery of mites, collecting several scrapes from different areas of affected skin is recommended.[10] When ear mites are suspected, a swab with a small amount of mineral oil is used to transfer aural exudate to a slide. A drop of mineral oil is added if needed, a coverslip applied, and the material carefully examined for mites. Whenever skin mites are suspected, a fecal specimen should also be submitted for flotation. This is particularly important in cats, as mites may be removed during grooming and not detected on a skin scrape but will be found intact and can be readily identified by fecal flotation.[11]

CULTURE, ANIMAL INOCULATION, AND XENODIAGNOSIS

Culture and Animal Inoculation

Fecal Culture

Fecal culture for parasites is occasionally helpful in small animal practice. Specialized diagnostic laboratories that perform fecal culture for parasites should be identified before specimen submission. The specimen should be fresh and sent by the most rapid means available. Preservative should not be added. In addition, attempts should be made to identify parasites present in feces as specifically as possible based on their morphologic appearance before submitting specimens for culture.

Although fecal culture for diagnosis of parasites is not common, specific media have been developed that support the growth of *T. blagburni*. The InPouch TF test (BioMed Diagnostics, White City, OR, USA) is a useful in-clinic culture technique for identification of *T. blagburni* in cat feces. The test consists of a sterile pouch that contains liquid media. The media is inoculated with feces and held at room temperature with contents examined every 48 hours for evidence of motile trichomonads. Fecal specimens collected by clients for culture or microscopic examination for *T. blagburni* should be submitted fresh, not frozen or placed in fixative, kept warm and moist, free of cat litter, and unrefrigerated before testing in the clinic.[2] *Pentatrichomonas* spp., another flagellate occasionally found in diarrheic feces of dogs and cats, grows slowly in medium in which *T. blagburni* readily replicates.[12] Therefore, it is not likely that *Pentatrichomonas* spp. would be isolated in commercial pouch systems.

Blood Culture and Animal Inoculation

Although usually reserved for research projects, blood culture and animal inoculation are occasionally performed to detect and document the presence of protozoa. However, because these are rarely performed for clinical diagnosis, arrangement should be made with the laboratory before submission of specimens and specific instructions obtained on specimen collection and handling. In general, whole blood is collected aseptically into EDTA and then submitted to the laboratory as soon as possible.

Culture of Other Specimens

In some cases, culture of tissue aspirates, biopsy specimens, or body fluids other than blood may be desired. When indicated, an aliquot of the specimen collected for cytologic evaluation is placed in a sterile tube at the time of collection. Culture or animal inoculation can then be performed with this specimen as indicated. Rapid submission to an appropriate diagnostic laboratory will increase the likelihood of successfully culturing any protozoa present. To facilitate the process and receive exact instructions on specimen handling and submission, the diagnostic laboratory to be used should be contacted before collection of specimens.

Xenodiagnosis

Xenodiagnosis is a rarely performed procedure for clinical diagnosis. Laboratory-reared, parasite-free arthropods are allowed to feed on suspected infected hosts, and then, after appropriate time for development has elapsed, the arthropods are examined for the presence of parasites. Xenodiagnosis has historically been used for the diagnosis of trypanosomiasis but may also be useful to detect other protozoa.

ANTIGEN DETECTION

Parasite antigen present in clinical specimens may be detected by ELISA, by staining via direct FA, or by immunohistochemistry (see Chapter 2). Antigen may be excreted into blood or feces or, in the case of some protozoa detected by FA microscopy, be present on the surface of the parasite (Fig. 5.4). Although not a perfect substitute for direct

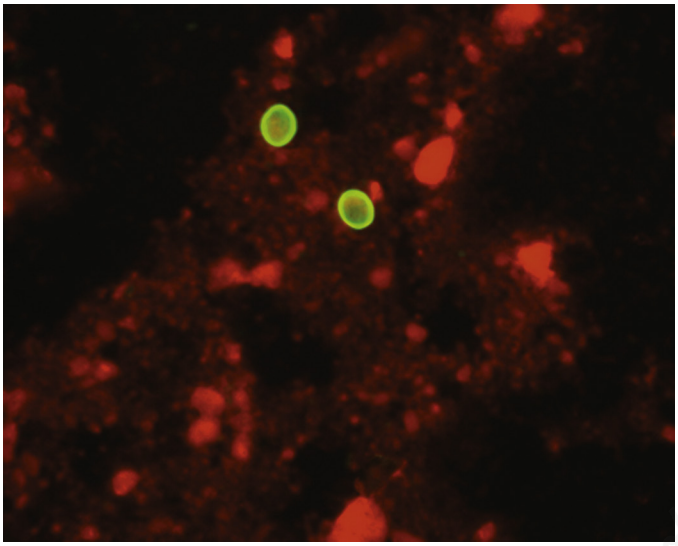

Fig. 5.4 Fluorescent antibody assay for detection of *Giardia* cysts in a fecal smear.

Fig. 5.5 (A) SoloStep CH Heartworm Test (Heska Laboratories, Loveland, CO, USA) positive for antigen of *Dirofilaria immitis*. (B) SNAP *Giardia* Test (IDEXX Laboratories, Westbrook, ME, USA) positive for soluble *Giardia* antigens.

microscopic examination, these assays enhance detection of parasites that are present in low numbers in clinical specimens or that are not yet patent and thus not shedding stages into blood or feces at all or in adequate numbers to allow microscopic detection.

Commercial immunodiagnostic assays are available for detection and identification of several helminths and protozoa. POC antigen tests are used on whole blood, serum, or plasma to diagnose infection with *D. immitis* in practice (Fig. 5.5A), and in diagnostic laboratories with microtiter plate assays. In some specimens, antigen may be present but trapped in immune complexes, which precludes detection. Treatment of the specimen to disrupt these immune complexes can increase sensitivity of detection.[13] Antigen tests are also available to detect *Angiostrongylus vasorum*, the French heartworm, in endemic areas.[14] Fecal antigen tests that detect ascarids, hookworms, and whipworms in the intestinal lumen are currently only available through a single commercial reference laboratory (IDEXX Laboratories, Inc., Westbrook, ME, USA).[15,16]

The stages of several common intestinal protozoa, including cysts of *Giardia* (Fig. 5.5B) and *E. histolytica* and oocysts of *Cryptosporidium* spp., can be detected in fecal specimens using antigen tests. Some of the assays used were originally developed for diagnosis of human infections. Care should be taken to optimize performance attributes of any assay not approved for use in veterinary specimens. At present, the Companion Animal Parasite Council (www.capcvet.org) only recommends *Giardia* antigen detection tests be used in clinically ill animals. Because other parasites may be present and because false-negative results can occur, these tests should always be performed along with microscopic examination of feces after centrifugal concentration. Parasite antigen can also sometimes be detected in fine-needle aspirates and biopsy specimens. Aliquots of specimens should be placed in a separate sterile tube at the time of collection and submitted to appropriate laboratories for direct FA or immunohistochemistry. Matching specimens should always be submitted for simultaneous cytologic or histologic examination whenever direct FA or immunohistochemical detection is pursued.

MOLECULAR DETECTION

Detection of parasite-specific nucleic acid sequences in patient specimens provides direct evidence of current or recent infection. In addition, larger metazoan parasites can often be identified by molecular methods when only damaged or partial specimens are available, precluding morphologic identification, provided the nucleic acid has not been damaged by fixation. A molecular approach to metazoan identification can prove particularly useful when attempting to distinguish between morphologically similar or identical organisms but should always be used as a complementary approach rather than the sole means of parasite identification. The most commonly used molecular techniques to detect or identify parasites in a diagnostic laboratory are PCR and in situ hybridization (see Chapter 6).

PCR has been used extensively for detection of *Giardia* spp. and *Cryptosporidium* spp. in feces from both dogs and cats, and for detection of *T. blagburni* in cats. Some PCR assays can distinguish between human-associated genotypes of *Giardia* spp. and those found only in dogs or cats.[17] Molecular diagnostic assays for intestinal protozoa are also available through diagnostic laboratories to screen animals with diarrhea. Some laboratories prefer fresh or frozen feces for PCR, whereas others suggest that a small amount (approximately 100 mg) of feces should be placed into a tube filled with 3 to 5 mL of 70% isopropyl alcohol and shipped at room temperature to the diagnostic laboratory.[2] PCR primers that amplify *T. blagburni* DNA can also amplify *Pentatrichomonas* spp. DNA, necessitating additional steps in identification, such as restriction enzyme digestion or sequencing of PCR products, to make a definitive diagnosis.[12]

PCR is also useful to evaluate blood specimens for the presence of hemoprotozoa; commercial diagnostic assays are available for *Babesia* spp., *Hepatozoon* spp., and *Cytauxzoon felis*. Whole blood specimens to be submitted for PCR should be collected into new blood tubes containing the anticoagulant specified by the laboratory; EDTA is the most common anticoagulant used. PCR can also be performed on specimens of other body fluids, fine-needle aspirates, and biopsy specimens. In situ hybridization is only performed at specialized research laboratories for a few protozoa.

SEROLOGIC TESTING

Feline heartworm antibody assays are widely used to determine if cats have been previously infected with *D. immitis* larvae (see Chapter 111). Serologic assays that detect antibodies to protozoa often are available through diagnostic laboratories. Indirect FA is the most commonly used platform, but ELISA, immunochromatographic strip (Fig. 5.6), and parasite agglutination tests are also available.

Individual laboratories should be consulted before submitting specimens. Care should be taken to prevent hemolysis during specimen collection or handling. Serum separated from the clot may be frozen before testing.

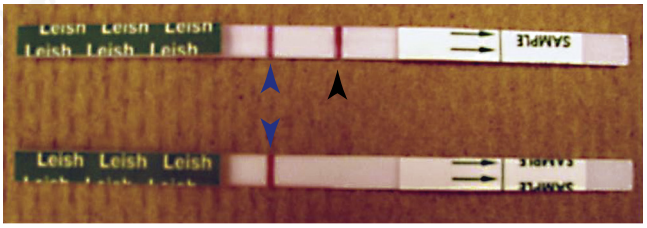

Fig. 5.6 Canine Kalazar *Detect* Rapid Test (InBios International, Seattle, WA, USA) for detection of antibody to *Leishmania* spp. Results shown include positive *(upper strip at black arrowhead)* and negative *(lower strip no black arrowhead). Blue arrowheads* are reagent control-positive result.

Serologic testing for parasites has several advantages, including ease of specimen collection and low cost of most procedures. However, most of these assays are based on detection of IgG, which develops often after clinical disease has begun and remains elevated for months to years after initial infection, complicating interpretation of a single titer in a clinically ill animal. Diagnosis of active infection with an IgG-based test is supported by demonstrating a fourfold change in titer in two paired serum specimens collected 2 to 4 weeks apart. Some IgM-based tests are available. However, the presence of IgM antibodies in the serum does not correlate directly with clinical illness in all animals. Many healthy animals have detectable antibodies to protozoa, and immunosuppressed animals may not develop antibodies despite infection and clinical disease. Different assays vary in sensitivity and specificity, and there is potential for serologic cross-reactivity (e.g., among *Babesia* species). When necessary, the diagnostic laboratory performing the assay should be consulted for assistance in interpretation of results.

Molecular Diagnostic Methods for Pathogen Detection

Emir Hodzic, Jane E. Sykes, Shelley C. Rankin

KEY POINTS

- Molecular diagnostic tests that detect nucleic acids, such as PCR assays, are now widely available for diagnosis of companion animal infectious diseases.
- Molecular diagnostic tests include tests that involve detection and amplification of nucleic acids (nucleic acid amplification tests [NAAT]), or probe-based assays that do not involve nucleic acid amplification.
- Specimens for these assays should be collected using aseptic technique in order to minimize contamination.
- Interpretation of molecular diagnostic test results requires knowledge of the problems and pitfalls of each type of assay. The results of testing at one laboratory may differ from those at another because of variations in assay design.
- With increased automation, laboratory proficiency testing, improved quality assurance, and standardization of reporting, the availability and utility of molecular diagnostic tests for companion animal infectious diseases continues to increase.

INTRODUCTION

One of Koch's postulates states that a microorganism must be isolated from a diseased organism and grown in pure culture in order to prove that it causes disease. This poses a problem, as many microorganisms are particular and fastidious in their growth requirements and cannot be cultivated on artificial media. Two major reasons have emerged to explain why most microbial agents cannot be cultured: (1) some only grow under specific nutritional conditions offered by the host, and (2) some microorganisms only grow in the presence of other microbial species.[1]

Commonly used methods of pathogen detection include microscopy, culture, biochemical methods, immunologic methods, and molecular methods.[2–8] As none of these methods are 100% sensitive and specific, it is recommended that multiple types of diagnostic assays be applied, depending on specimen type, clinical signs, and the suspected pathogen.[9] Traditional bacteriology can be time consuming because organisms have to be cultured, and usually a series of biochemical tests must be completed for identification.[10] Molecular diagnostic methods are suited to the detection of organisms that are not easily found using cytology or histopathology, are slow growing or difficult to culture, or when a rapid (<12 hours) diagnosis is required. Other applications are shown in Box 6.1.[11,12]

Although techniques for the amplification of pathogen-specific DNA sequences such as PCR are sensitive, there remain limits to this sensitivity when working with clinical specimens. Impurities within some specimens can inhibit PCR assays, and the use of small volumes for DNA extraction means that cells often have to be concentrated to increase sensitivity.[13]

ESSENTIAL PREREQUISITES FOR A POSITIVE OUTCOME WITH MOLECULAR DIAGNOSTIC TESTS

As for culture, the accuracy of molecular diagnostic tests depends on the appropriate specimen selection, collection, and transportation (Chapter 1).

Specimen Collection and Transport

When collecting specimens for molecular diagnostics, the timing of collection relative to the course of disease and the best specimen type must be considered. For acute diseases, molecular assays are most useful early in the course of disease. For chronic diseases, timing is less critical. Knowledge of organism shedding patterns can help to determine the most appropriate timing of specimen collection. For example, *Leptospira* organisms are primarily present in blood in the first week of acute illness, after which they may be shed in the urine.[14] Specimens should be collected before administration of antimicrobial drugs, although this is less critical than for specimens that are to be cultured.

Although specimen processing is usually well standardized in the diagnostic laboratory, *pre-analytical procedures* that occur before specimens arrive at the laboratory have considerable variability. For example, false-negative results may occur due to specimen degradation during transport. The main concerns during specimen transport and storage include specimen integrity, contamination, specimen identity, and the risk of environmental hazards due to infectious material. Because contamination can occur outside the PCR laboratory as well as within the laboratory, collection of specimens for nucleic acid testing should be performed aseptically to reduce the risk of false-positive results. Gloves should be worn, and disposable instruments should be used (e.g., disposable blades, punch biopsy instruments).[15–17] The recommendations for specimen collection and transport presented here are based on the guidelines published by the CLSI.[18] These guidelines are updated on a regular basis and ensure that detection of nucleic acids within clinical specimens is optimal.

For detection of pathogens that contain DNA (i.e., all bacteria, fungi, some viruses), either fresh or frozen specimens should be submitted. In general, DNA is stable in tissue for up to 24 hours at 2°C to 8°C, at least 2 weeks at –20°C, and at least 2 years at –70°C.[18] All specimens must be promptly transported to the diagnostic laboratory, preferably within 2 hours. In general, specimens for detection of bacterial agents should not be stored for more than 24 hours, and no more than 2 to 3 days at 4°C for viruses.[19] Specimens should not be stored

BOX 6.1 Applications of Nucleic Acid–Based Assays

Application	Example
Detection of microbes that are not easily detected using light microscopic examination of tissues or smears	*Bartonella* spp., viral pathogens
Detection of microbes that are difficult or impossible to culture	Hemotropic mycoplasmas, *Bartonella* spp., *Mycobacterium* spp., *Brucella* spp.
Rapid detection of microbes to allow early institution of infection control measures	Influenza virus, FCV, *Mycobacterium tuberculosis*
Detection of microbes that are hazardous to culture in the laboratory	H1N1 influenza virus, West Nile virus
Detection of microbes in the face of inactivating substances such as antimicrobials or formalin	Retrospective identification of an infecting microorganism in formalin-fixed, paraffin-embedded tissues after histopathology
Detection of antimicrobial resistance genes	*mecA*, the gene for methicillin resistance, in staphylococci
Detection of novel pathogens using broad-spectrum PCR and sequencing	*Bartonella henselae*,[11] hemotropic mycoplasmas[12]
Monitoring organism load as a measure of disease progression or response to treatment	FIV viral load
Identification of a cultured organism to the species level	*Nocardia* and *Actinomyces* spp., many fungi

FCV, feline calicivirus; *FIV,* feline immunodeficiency virus; *PCR,* polymerase chain reaction.

BOX 6.2 Guidelines for Collection and Transport of Specimens for NAAT

Specimen Type	Collection and Transport Recommendations
Whole blood and bone marrow	Use only EDTA or acid citrate dextrose (ACD) anticoagulant. Heparin may inhibit PCR.[21] The use of hemolyzed samples and frozen blood should be avoided if possible. DNA: Submit samples held at room temperature within 24 hours of collection. Samples can be stored at 2°C to 8°C for 72 hours, or at –20°C or ≤ –70°C for prolonged storage (removal of erythrocytes recommended). RNA: Use stabilization solution or send immediately to the laboratory on wet ice. For storage, freeze serum, plasma, or buffy coat specimens at ≤ –70°C.
Tissue specimens	Optimal specimen is 1 to 2 g of fresh tissue. Rinse blood from tissue using sterile saline. Wrap in saline-moistened gauze or paper. Avoid excessive dilution. Formalin-fixed, paraffin-embedded tissues can be used when no other specimen is available but are not optimal. DNA: Transport fresh tissue immediately to the laboratory on wet ice. Any storage should be at ≤ –70°C, preferably after snap-freezing in liquid nitrogen. RNA: Use stabilizing solution, process within 1 hour of collection, or snap-freeze in liquid nitrogen and store at ≤ –70°C.
Cerebrospinal fluid	DNA: Transport at 2°C to 8°C or freeze at –20°C or ≤ –70°C. RNA: Chill immediately on wet ice and deliver to the laboratory within 4 hours. Otherwise freeze immediately (removal of contaminating erythrocytes recommended) and ship on dry ice.
BAL fluid	Transport at room temperature within 24 hours of collection. If a delay is anticipated, store for up to 72 hours at 2°C to 8°C or freeze at ≤ –70°C.
Urine	Minimize storage at room temperature. Storage and transport should be according to the specific assay performed.
Feces	Use preserved specimen transport container or transport under refrigeration at 2°C to 8°C.

NAAT, nucleic acid amplification tests; *BAL,* bronchoalveolar lavage.

in frost-free freezers, as these undergo repeated freeze-thaw cycling, which can be associated with DNA degradation.[20] Box 6.2 outlines recommendations based on specimen type.[21]

RNA is highly susceptible to degradation during storage and transport. Swabs and body fluids should be immediately sent to the laboratory on wet ice. Tissue should ideally be snap-frozen at –70°C within half an hour of collection and shipped on dry ice without being thawed in the interim. RNA is stable for at least 2 years at or below –70°C. Naturally occurring ribonucleases can continue to degrade RNA at –20°C.

The optimal amount of tissue specimen for molecular testing is 1 to 2 g, although more or less may be required depending on the cellularity of the specimen.[18] Tissues stored in formalin, especially for prolonged periods, are suboptimal for PCR because the formalin cross-links the DNA in the specimen. Tissues fixed briefly in formalin (less than 18 hours) and then embedded in paraffin are preferable to tissues stored in formalin, because the formalin is removed during the embedding process. Paraffin-embedded specimens should only be used when no other specimens are available.[18]

Specimen Preparation in the Laboratory

Molecular detection methods depend more and more on proper *specimen preparation*. Clinical specimens are very heterogeneous (stool, plasma, CSF), so preparation must be a factor to consider in order to achieve results within a reasonable amount of time. The overall goals of specimen preparation are: (1) to concentrate the target, because pathogens may be present at low concentrations and molecular detection methods commonly use small volumes of specimen for nucleic acid extraction; (2) to remove or reduce the effects of inhibitory substances; and (3) to reduce the heterogeneity of specimens in order to ensure negligible variations in serially collected specimens. If homogenized thoroughly, pooling of specimens facilitates high-throughput analysis in some cases.[8,13,22]

Quality assurance and *quality control* in the diagnostic laboratory must be taken into consideration. Components that are required for validation and verification of microbiologic diagnostic tests or test systems should include: (1) internal and external controls in each run; (2) participation in interlaboratory test results comparison; (3) validation of employee competence; (4) calibration and maintenance of instruments; and (5) correlation with clinical findings.[23,24]

MOLECULAR METHODS FOR PATHOGEN DETECTION

The ultimate goal of a molecular diagnostic test is rapid, sensitive, and accurate pathogen detection. Molecular diagnostics offer many

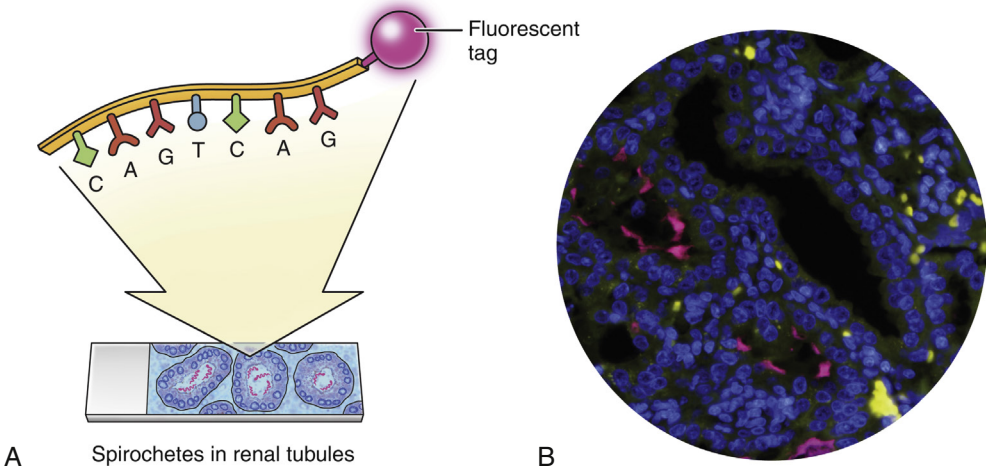

Fig. 6.1 (A) Fluorescence *in situ* hybridization (FISH). A nucleic acid probe that is complementary to a segment of leptospiral DNA that has been tagged with a fluorescent label is incubated with a tissue section on a slide. (B) Unbound probe is washed away and the section is examined using fluorescence microscopy. (*Leptospira* FISH image courtesy Dr. Richard Goldstein.)

advantages over traditional microbiologic and immunologic methods for pathogen detection. These include faster processing time as well as the potential for more accurate species identification and strain typing, which has resulted in a vastly improved understanding of infectious disease epidemiology. Molecular diagnostics has also revolutionized pathogen detection, evaluation of emerging novel infections, surveillance, early detection of bio-threat agents, and antimicrobial resistance profiling.[7,25]

Molecular assay types include endpoint (conventional) PCR, RT-PCR, real-time quantitative PCR (qPCR), isothermal amplification,[26,27] terminal restriction fragment length polymorphism (T-RFLP),[28] nucleic acid sequencing,[29] high-resolution melt analysis,[30] DNA microarrays,[31] tissue arrays,[32] and fluorescent-labelled in situ hybridization (FISH).[33,34] Despite the development of this broad range of amplification technologies, qPCR remains the most widely used method in both research and diagnostic laboratories for pathogen detection.[28,35]

Specimens vary considerably in physical properties, chemical composition, and microbial diversity, so molecular detection methods are typically developed for complex specimen types. For example, fecal matter is a complex mixture of undigested or partially digested food components as well as viable and nonviable microbial cells, with many inhibitors. The use of appropriate amplification controls by the laboratory facilitates detection of false negatives due to the presence of inhibitors. Other special requirements of molecular detection technology in order to ensure reliable results include proper establishment of quality-assured procedures, laboratory set-up, and proper training of staff in order to minimize the chance of contamination and false positives.

Direct Hybridization

Direct hybridization uses labeled oligonucleotide probes to detect bacteria, which are usually directed to 16S rRNA sequences specific to the species, genus, or other phylogenetic level of interest (Fig. 6.1). The oligonucleotide probes are small DNA or RNA segments that bind to complementary sequences within DNA or RNA molecules.[33] One end of the probe is designated the 5-prime (5′) end, and the other is the 3-prime (3′) end. A variety of oligonucleotide probes are available commercially as kits for detection of human pathogens. Some of these can also be used to detect the same pathogens in specimens from dogs or cats. Probes are widely used in human clinical microbiology laboratories to identify organisms that have been grown in culture (e.g., Gen-Probe Inc., San Diego, CA).

Probe hybridization can be performed on a nitrocellulose membrane *(solid-phase hybridization)*; on formalin-fixed, paraffin-embedded sections mounted on a microscope slide (*in situ hybridization*); or in solution *(liquid-phase hybridization)*. For solid-phase hybridization, the probe is reacted with microorganism DNA that has been immobilized on the membrane. Unbound probe is washed away, and the bound probe is detected using fluorescence, chemiluminescence, radioactivity, or color development (in the same way that bound antibody or antigen is detected in an ELISA or IFA assay). For *in situ* hybridization, formalin-fixed, paraffin-embedded specimens are sectioned and mounted on a special slide. The sections are deparaffinized, dried, and incubated with a solution that contains the probe, so both the presence and the location of the target pathogen within tissues can be identified. *In situ* hybridization assays that include a fluorescent-labeled probe are referred to as *fluorescence in situ hybridization* (FISH) assays (see Fig. 6.1).[33,36] The optimum specimen for FISH is a tissue that has been snap-frozen in liquid nitrogen after being embedded in optimal cutting temperature (OCT) medium.[18] FISH has been increasingly used to identify intralesional bacteria in companion animals, including: dogs with bacterial endocarditis,[37] histiocytic ulcerative colitis,[38] hepatitis,[39] and Lyme nephritis[40]; cats with small intestinal lymphoma;[41] and dogs and cats with gastric helicobacteriosis.[42]

Because liquid-phase hybridization occurs in solution, unbound probe cannot be washed away. To overcome this problem, a chemiluminescent acridinium ester label is attached to the probe. A subsequent chemical hydrolysis step selectively degrades only unbound probe. On addition of peroxides, the intact (hybridized) probe then emits light.[43]

Although not yet widely used for veterinary applications, *peptide nucleic acid (PNA) probes* are now increasingly available to detect target DNA. PNA probes are uncharged peptides that mimic DNA and bind to complementary DNA sequences just as a nucleic acid probe would.[44,45] PNA probes lack the net negative charge of nucleic acid probes; therefore, the electrostatic repulsion that normally occurs when two negatively charged DNA strands hybridize does not occur. The result is a more stable and specific binding of the probe to its target, which in turn can be associated with increased assay sensitivity and specificity.

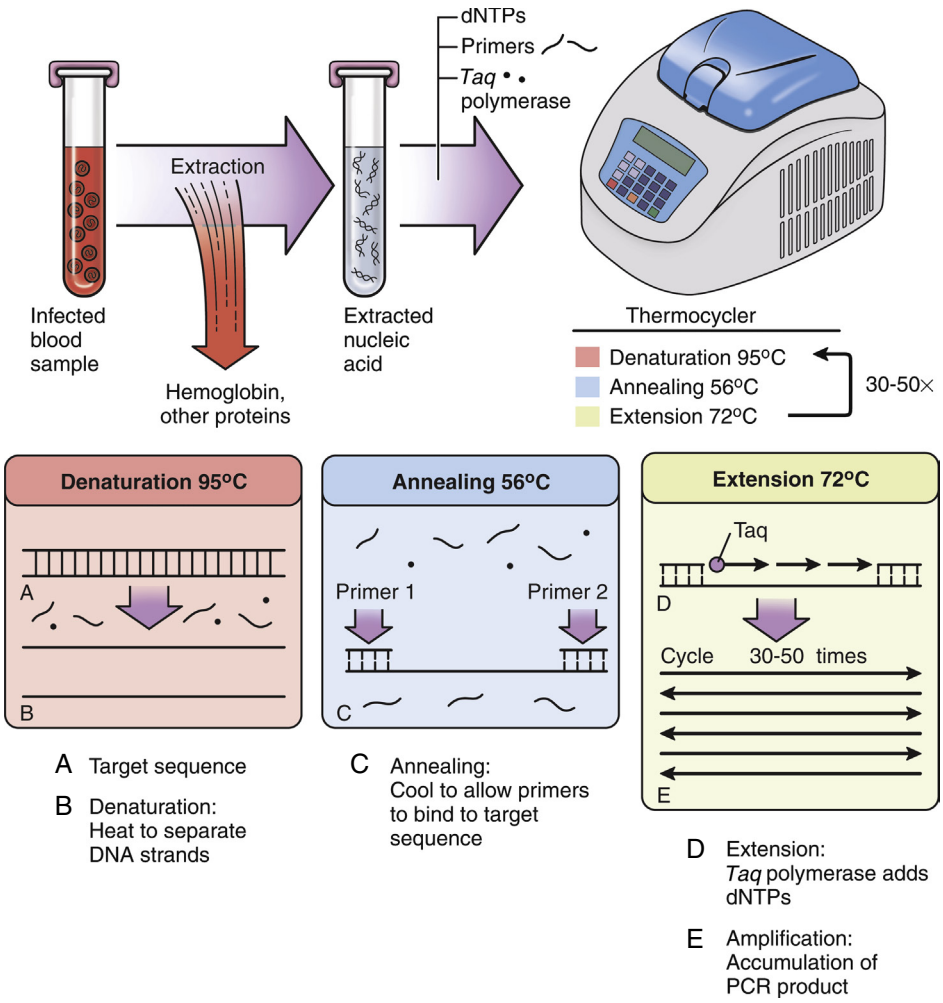

Fig. 6.2 Endpoint PCR assay. Two primers are hybridized on either side of a specific segment of a pathogen's DNA. Also present in the reaction mixture are the enzyme *Taq* polymerase, and free nucleotides for making new DNA. After addition of extracted DNA from a clinical specimen, a thermocycler is used to rapidly and repeatedly heat and cool the tubes through denaturation, annealing, and extension steps. The segment of pathogen DNA is repeatedly copied, with logarithmic accumulation of the PCR product.

Branched DNA assays and *hybrid capture assays* are highly sensitive hybridization methods that include steps to intensify the signal generated from probe hybridization.[46,47] They are not yet widely used in veterinary medicine.

Nucleic Acid Amplification

The general principles of all nucleic acid amplification technologies share common characteristics that fall into three categories: (1) target amplification systems, (2) probe amplification systems, and (3) signal amplification. These all use enzyme-mediated processes (a heat-stable DNA polymerase, such as that derived from *Thermophilus aquaticus,* a bacterium that is adapted to live in hot springs), two oligonucleotide primers, four deoxynucleotide triphosphates (dNTPs; G, T, A, and C), reaction buffer, and a target (a genomic or complementary DNA fragment). A solution (mastermix) is created in the laboratory that includes the polymerase, appropriate primers, dNTPs, and buffer, and this is then divided into aliquots for addition of DNA that has been extracted from the specimen. Once assembled, the reaction is placed in a thermal cycler, an instrument that subjects the reaction to a series of different temperatures for set amounts of time. Each round of temperature and time adjustments is referred to as one cycle of amplification. Each PCR cycle theoretically doubles the number of target DNA segments (amplicon) in the reaction. The end result is the production of millions to billions of copies of the targeted sequence in a matter of hours, and in each case, the amplification products (amplicons) can serve as templates for subsequent rounds of amplification.

Nucleic acid amplification methods include not only PCR methods (i.e., endpoint PCR, RT-PCR, nested PCR, multiplex PCR, qPCR, digital PCR [dPCR]), but also alternative technologies, such as such as strand-displacement amplification, loop-mediated isothermal amplification, ligase chain reaction, and nucleic acid sequence–based amplification.[36,48]

Types of PCR assays are broadly divided into three main groups: (1) *endpoint PCR*, (2) *qPCR*, and (3) *dPCR*.

Endpoint PCR

Endpoint PCR assays (previously referred to as *conventional* PCR assays) are the simplest PCR assays and although still widely for research purposes, their use for diagnostic purposes has decreased. In this method, nucleic acids (genomic DNA and/or total RNA) are extracted from biological specimens using a commercially available extraction kit. A pair of primers, roughly 20 nucleotides long, is then used to bracket a desired DNA sequence, which is subsequently copied using a DNA polymerase enzyme (Fig. 6.2). Initially the DNA is

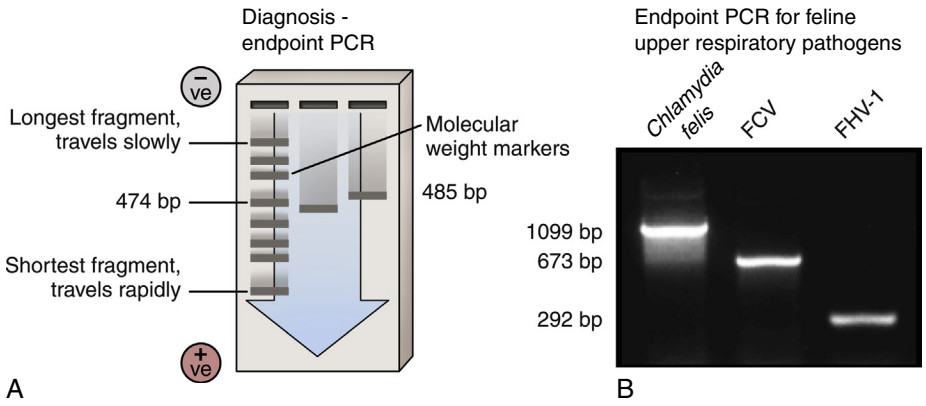

Fig. 6.3 Agarose gel electrophoresis showing detection of PCR products in an endpoint PCR assay. The longer the PCR product, the more slowly it moves through the gel. The size of the product can be estimated by running it alongside a molecular weight standard, which is available commercially. *FCV,* feline calicivirus; *FHV-1,* feline herpesvirus-1.

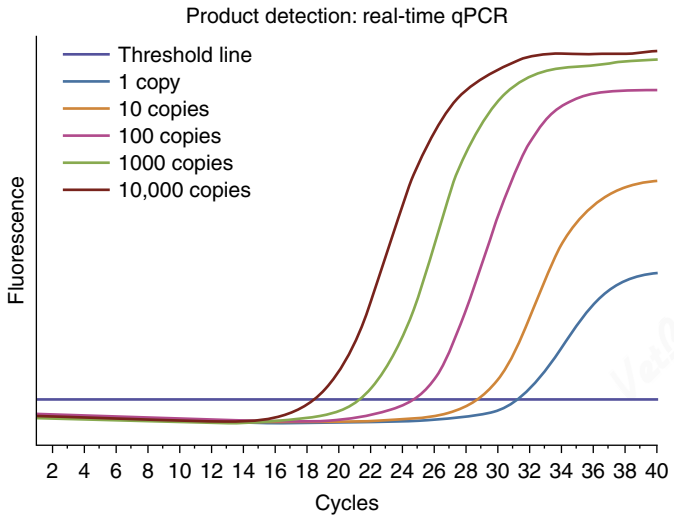

Fig. 6.4 Plot showing the emission of fluorescence during PCR product formation in real-time PCR as the number of cycles of denaturation, annealing, and extension increases. The C_T value is the number of PCR cycles required for the fluorescent signal to rise above a threshold value for fluorescence.

heated to 95°C, which causes the paired strands of DNA to separate (*denature*). Next, the tubes are cooled to a specific annealing temperature (usually 50°C to 65°C), which allows the primers to bind to their respective sequences. Finally, the tubes are heated to 72°C. This is the temperature at which the DNA polymerase adds dNTPs to the primers, extending the primers as it copies the sequence of the template DNA. The three-step cycle is repeated 30 to 50 times, which results in logarithmic accumulation of a PCR product that is an exact copy of the segment of DNA between the two primers.[7,8,36,47]

Products of PCR amplification are separated using agarose gel electrophoresis, stained with a dye that intercalates DNA (such as ethidium bromide), and the resulting fluorescent DNA bands are visualized using ultraviolet transillumination. The longer the PCR product, the more slowly it moves through the gel during electrophoresis. When a series of molecular weight markers are run alongside the end product of PCR, the size of the PCR product can be estimated (Fig. 6.3). The true identity of the product can then be confirmed using sequencing or by transferring it to a membrane and performing DNA hybridization with a specific probe. The process of loading the PCR product in agarose gels requires that the PCR tubes be opened, which can lead to aerosolization of PCR amplicons. These amplicons can then contaminate reagents, equipment, and tubes that are used for running subsequent PCR assays. Unless proper controls are included, false positives resulting from such contamination may go unidentified and lead to erroneous reporting of results.[49]

Real-Time Quantitative PCR (qPCR)

For diagnostic purposes, endpoint PCR assays have largely been superseded by qPCR, which monitors the accumulation of PCR product while the reaction takes place, usually through detection of fluorescence.[50] This provides quick, sensitive, quantitative detection of PCR products in a closed-tube format, thereby significantly reducing the risk of contamination and false-positive test results.[51,52] qPCR assays are amenable to automation, and reactions are generally loaded onto covered 96- or 384-well plates. Loading can be done robotically, further reducing the possibility of contamination and manual loading errors. qPCR instruments consist of a thermal cycler with an integrated excitation light source, a fluorescence detection system, and software. The software performs the quantitative analysis of detected fluorescence during the assay (Fig. 6.4). These instruments can simultaneously detect different wavelengths of light.[53,54] Special carousel thermocyclers are also available that rapidly heat and cool the reactions, which are placed in specially designed glass capillaries. As a result, some PCR assays can be completed in 45 minutes, instead of the 4 to 5 hours required for endpoint assays.[55]

Detection chemistries used in real-time quantitative PCR. The choice of probe chemistry used to detect PCR products in qPCR assays influences assay sensitivity and specificity, and so it can be helpful for clinicians to have an awareness of the approaches used. Fluorescent chemistries available that allow detection of target sequences during amplification can be categorized into two types: (1) double-stranded DNA (dsDNA) intercalating dyes (i.e., SYBR Green I, SYBR Gold, EvaGreen, LC Green, BOXTO, ResoLight, BEBO, SYTO, YO-PRO-1), and (2) fluorophore-labeled, sequence-specific oligonucleotide probes, which are designed to bind to the target sequence being amplified.[53,54,56]

When free in solution, dsDNA intercalating dyes exhibit little fluorescence, but when in contact with dsDNA, the dye intercalates between nucleic bases and assumes a conformation that emits fluorescence at a particular wavelength upon excitation. The fluorescent signal from a reaction is proportional to the amount of dsDNA present, and will increase as the target is amplified. Because there is no probe,

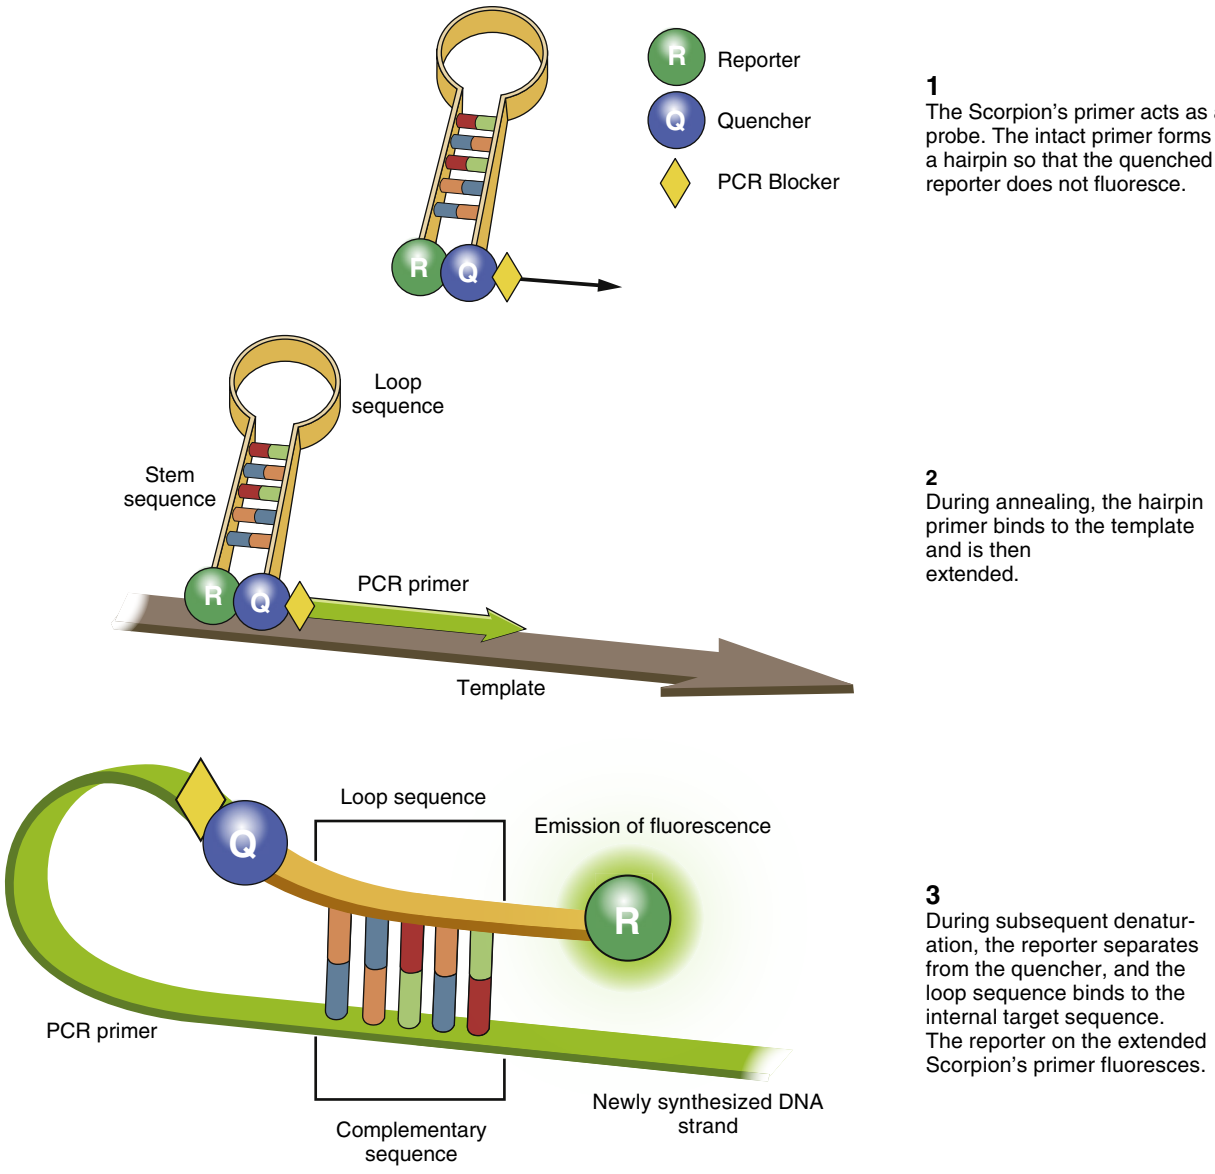

Fig. 6.5 Scorpions probe-primer assay.

carefully designed primers are required to ensure high specificity for the pathogen of interest. Intercalating dyes require melt-curve analysis to identify different reaction products. As a result, the presence of nonspecific products in a qPCR reaction may contribute to the overall fluorescence and affect the accuracy of quantification. Also, intercalating dyes cannot be used for multiplex reactions (reactions that target multiple pathogens in the same tube).[7,53]

Fluorophore primer- and probe-based chemistries can differ in their sequence geometry and binding mechanism, but nearly all share a fluorescent reporter dye partnered with a quencher dye, which are usually attached to an oligonucleotide probe. The quencher is a chromophore designed to absorb the fluorescent signal from the reporter dye when they are in close proximity, taking advantage of Förster Resonance Energy Transfer (FRET), to ensure specific fluorescence detection only in presence of amplified product. This can be accomplished by attaching a quencher molecule to the nucleic acid probe, and devising some mechanism by which the reporter and quencher become separated from one another when the probe binds to its specific target.[57] Fluorophore-labeled oligonucleotides used in the PCR reaction have been divided into three subgroups[54]:

(1) *Primer-probe* assays (e.g., Scorpions, Amplifluor, LUX, Cyclicons, Angler). In this case, one of the two PCR primers is connected to a probe by a quencher dye. The probe has a hairpin loop conformation that brings the quencher dye close to a fluorescent reporter dye attached to the 5′ end of the probe. Fluorescence emitted from primer-probe is detected and measured during the denaturation or extension phase of the qPCR. A commonly used *primer-probe* assay is Scorpions, which improves signals, has low background, and simple design.[58] During the course of PCR, the hairpin loop unfolds and the loop region of the probe hybridizes to the newly synthesized target sequence, causing the reporter dye to separate from the quencher dye and emit fluorescence (Fig. 6.5).

(2) *Probe assays* use a linear oligonucleotide that is complementary to the target nucleic acid sequence in addition to the primers, which is expected to anneal between the two primers. The oligonucleotide probe is labeled with a reporter dye on the 5′ end and quencher

dye on the 3′ end fluorophore, although the opposite orientation can also be used. The close proximity of the quencher dye to the reporter dye on the probe inhibits the reporter dye from emitting fluorescence. There are two types of probes used: (a) *hydrolysis probes* (e.g., TaqMan, Minor Groove Binding [MGB]-TaqMan, Snake assay), and (b) *hybridization probes* (e.g., Hybprobe or FRET, Molecular Beacons, HyBeacon, MGB-Pleiades, MGB-Eclipse, ResonSense, Yin-Yang or displacing). Hydrolysis probes rely on the 5′–3′ exonuclease activity of Taq polymerase. When the *Taq* DNA polymerase copies the section of DNA between the two primers, it encounters the probe and chops it into pieces, because it has inherent exonuclease activity. This causes the reporter dye to separate from the quencher dye. The reporter dye then emits fluorescence, which can be measured using a spectrophotometer.[53,54,59–61] The amount of fluorescent signal detected is directly proportional to the amount of the target amplified during the PCR reaction.[7,54] Many veterinary laboratories that offer probe-based PCR assays use TaqMan probes. MGB-TaqMan probes are designed to improve target DNA-binding specificity and sensitivity, and are becoming widely used for diagnosis of microbial pathogens. An example of a hybridization probe assay is the FRET probe assay. FRET probe assays use two probes that are predicted to lie adjacent to one another on the target sequence. The first probe is tagged at the 3′ end with one fluorophore, and the second probe contains a second fluorophore at the 5′ end, and a phosphate group attached to its 3′ end to prevent DNA amplification. When the two dyes come together during annealing, one fluorophore transfers its energy to the other, causing it to emit fluorescence, which can then be detected.[62] Currently there are only rare reports of the use of this technology for diagnosis in veterinary medicine.

(3) *Probes that are analogues of nucleic acids* (PNA, LNA, ZNA, non-natural bases: Plexor primer, Tiny-Molecular Beacon) are much shorter than nucleic acid probes due to the higher binding affinity of the analogue nucleic acid bases to standard DNA, and they are more stable in biological fluids. An analogue may have alterations in its phosphate backbone, pentose sugar (either ribose or deoxyribose) or nucleobases. Such probes only need to be 8–9 bases long.[53,54]

Primer and probe design. Primers are a critical component of PCR reactions. The primers are extended by the polymerase upon binding to the pathogen target DNA, and are designed to bind to the opposite strand to facilitate exponential amplification, which is the hallmark of PCR. The DNA polymerase synthesizes the new DNA copy by moving from the 5′ end toward the 3′ end. Both the sequence of the primers and that of the target sequence can affect the efficiency of PCR. A number of free and commercially available software programs are available for the purpose of designing primers. The following are important considerations when primers are designed:

- *Primer specificity*, as nonspecific amplification of nontarget DNA is one of the greatest challenges for successful target amplification. The specificity of primers and probes are verified using commercial software programs.
- *Primer length* (typically 16 to 28 nucleotides long).
- *Amplicon length* (usually 100 to 250 base pairs).
- *Primer G and C base pair content*, which is maintained between 35% and 65%.
- *Primer 3′ end stability*, which can contribute to nonspecific primer extension by Taq DNA polymerase, especially if the binding of the 3′ nucleotide bases is relatively tight to the nontarget template. Primers with very high 3′ terminal stability (as determined using a software program) are usually rejected.
- *Primer melting temperature (Tm).* Most primer design software programs can predict melting (annealing) temperature based on the nucleotide composition of the primers under evaluation.[7,54,63] The Tm of each primer used must be similar so that they anneal at the same temperature during PCR.

Validation and optimization of qPCR assays. In theory, the amount of fluorescence emitted during each PCR cycle doubles, and it is proportional to the number of copies of pathogen DNA in the clinical specimen. However, imperfections that result from variable pre-assay conditions, assay design, and improper data analysis can lead to inaccurate results and erroneous diagnostic conclusions. Before being used for diagnostic purposes, qPCR assays must be shown to be *sensitive, specific, reproducible,* and *efficient* through validation and verification. A number of factors can be altered to obtain optimum assay performance, which will lead to higher molecular sensitivity, specificity, and precision.

During validation of PCR assays, the laboratory uses the assay to test serial dilutions of a known amount of target DNA. For qPCR, *the limit of detection* is the lowest number of copies of the target DNA or RNA sequence that the assay can detect (also known as *analytical sensitivity*). The results are used to create a graph known as a *standard curve.* This consists of the logarithm of the initial starting quantity of DNA on the x-axis and the *quantification cycle (Cq; also known as cycle threshold* [C_T]) *values* obtained on the y-axis (see Fig. 6.4). Cq represents the number of cycles that elapse before fluorescence is detectable above a threshold value set by the thermocycler manufacturer. A standard curve is commonly generated using a 10-fold serial dilution series of at least five template concentrations. The standard curve can then be used to predict the amount of target DNA in a clinical specimen based on the Cq value.

The standard curve should result in a slope that demonstrates good efficiency, accuracy, and sensitivity. The efficiency of a qPCR reaction is the degree to which the polymerase converts reagents to produce target amplicons. Factors that affect the efficiency of a qPCR reaction include amplicon length and sequence, primer sequence, impurities and inhibitors in the sample, and cycling conditions. Once the standard curve is generated, the efficiency of the reaction is calculated from the slope of the log-linear portion of the standard curve (10-1/slope-1). A qPCR assay that has an *efficiency* of 100% doubles the number of copies of template in every PCR cycle. Efficiencies below 90% are unacceptable for quantitative assays, and ideally efficiency should be greater than 95%. Ideally, this is compared with a similar curve that uses dilutions of the standard DNA spiked into a clinical specimen, to show that inhibitors within the specimen do not affect efficiency.[64,65]

From a diagnostic standpoint, a qPCR assay may lack sensitivity (many false negatives) if the assay fails to detect all possible strains of a target organism. This can occur if the probe or primers are strain specific, rather than species specific, and many strains of the target organism exist with variable sequences (as is the case with RNA pathogens such as FCV). As part of the validation process, the assay should be shown to be *inclusive* and detect as many strains or variants as possible.

A qPCR assay has poor *analytical specificity* if false positives occur as a result of contamination or because of manual loading error. Specificity may also be poor if the primers bind to and initiate amplification of DNA from unrelated organisms or the host animal (i.e., cat, dog, human DNA). Specificity is tested during the validation process by showing that the qPCR assay fails to amplify DNA from clinical specimens that contain organisms that are genetically related to the target organism, as well as organisms that may be expected to be contaminating normal flora.[64]

BOX 6.3 Methods that may Be Used To Minimize Contamination in Diagnostic Laboratories that Perform Nucleic Acid Amplification Assays

Separation of rooms for DNA extraction, PCR and postamplification detection
Robotic DNA extraction
Automated detection of PCR products (real-time qPCR)
Opening one specimen tube at a time
Use of screw-top caps rather than snap-top tubes to prevent splashing
Use of filter-plugged pipette tips
Use of negative extraction controls and negative template controls in every run
Routine monitoring for contamination using wipes
Standard clean-up protocol that inactivates nucleic acids
Use of positive control samples of low concentration
Use of dUTP and uracil-*N*-glycosylase in the PCR mastermix

The results of qPCR assays must also be repeatable. *Repeatability* is determined for qPCR assays by determining whether the Cq value varies significantly for the same specimen when tested multiple times. Usually intra-assay (within the same run) and inter-assay (across different runs) variations are measured.[66]

Analysis of qPCR assay results. Data analysis includes an examination of the raw qPCR data, an evaluation of their quality and reliability, and the generation of reportable results. The output of a qPCR assay is an amplification curve, which is subject to background fluorescence (see Fig. 6.4). A range of factors affect the degree of background fluorescence, including choice of plasticware, unquenched probe fluorescence, and signal carryover into the neighboring sample wells. In well-designed assays, the background is low compared with the amplified signal. However, variation in the background signal may affect quantification comparisons between different specimens, so the laboratory must correct for baseline variations.

Most laboratories run approximately 40 cycles of amplification, and so specimens that generate Cq values less than 40 are considered to be positive. Said another way, if PCR proceeds to 40 cycles without emission of fluorescence (Cq = 40), then the target DNA is not detectable in the specimen, and the result is reported as negative. The lower the Cq value, the more target DNA (= organism load) is present in the specimen, because fewer cycles elapse before fluorescence is detected. Because specimen size varies, the Cq value may be normalized to the approximate number of host cells present in the specimen. Knowledge of organism load may have prognostic value for some infections, can allow infection to be monitored over time with treatment, and may be useful to differentiate low-level colonization from active infection causing clinical signs (see Interpretation of Results, later). At the time of writing, veterinary diagnostic laboratories performing PCR assays variably report organism loads to the clinician.[67]

Prevention of PCR Contamination and Quality Assurance

PCR contamination can be difficult to eradicate once it occurs, so prevention of contamination is critical (Box 6.3). Laboratories should include negative controls in every run, and a positive control should be included to ensure that the assay is working, preferably one that is also subjected to the nucleic acid extraction process. The positive control should contain a low concentration of DNA, because abundant DNA used as a positive control may serve as a source of contamination for other assays. Many laboratories run two separate negative controls. One of the negative controls contains mastermix and nuclease-free water in place of nucleic acid that has been extracted from a specimen. The other consists of water or a known negative specimen that is subjected to the extraction process to ensure that contamination does not occur during extraction (negative extraction control). When 96- or 384-well plate formats are used, negative control wells are interspersed among the test wells to monitor for plate contamination.[67]

In order to prevent contamination, some laboratories use deoxyuracil triphosphate (dUTP) instead of deoxythymidine triphosphate (dTTP) in the PCR mastermix. This substitution results in generation of PCR products that contain uracil (U) in place of thymidine (T). The enzyme uracil-*N*-glycosylase (UNG) is also added to the mix. This enzyme destroys DNA amplicons that contain deoxyuracil residues, and eliminates any contaminating DNA amplicons from previous reactions *before* PCR amplification begins. When the reaction mix is heated in the initial denaturation step, the UNG is destroyed.[68]

Many biological specimens contain components that inhibit PCR, such as hemoglobin, myoglobin, bile salts, humic acids, urea, and collagen,[13] and require extensive purification. However, extensive purification leads to losses and is expensive. Complete removal of inhibitors may not be possible. Various methods can be used to assess the presence of inhibitors within clinical specimens, as follows:

1. Determine the PCR efficiency in a test sample by subjecting serial dilutions of the sample to PCR.[69]
2. Use a *reference gene* (formerly known as a *housekeeping gene*). A reference gene is an endogenous amplification control gene that copurifies with the target nucleic acid and is amplified at the same time as the target pathogen DNA using a separate set of primers and probes. Amplification of a reference gene is usually performed on a separate aliquot of the extracted specimen at the same time as the assay for the target pathogen. Reference genes are typically host (dog or cat) genes that are expected to be present in the sample, such as canine or feline glyceraldehyde-3-phosphate dehydrogenase (GAPDH), histone, or 18S DNA. A negative reference gene PCR assay result (or a high Cq value for the assay, which is equivalent to a weak positive result) suggests that inhibitors may be present in the specimen, or that DNA in the submitted specimen may have degraded during storage or transport. Some qPCR assays use an *internal reference gene control*, in which a reference gene is amplified within the same reaction mix (known as multiplexing, see later in this chapter) with the qPCR assay for the target microorganism.
3. Use an *exogenous control, also known as a spike or SPUD gene.* The spikes typically consist of a chemically synthesized nucleic acid template (RNA or DNA, depending on the target) and two primers specific to the template and are run in the presence of SYBR Green I dye or a specific probe. The spike template is amplified in a separate control reaction, resulting in a characteristic Cq. Alongside this control reaction, the exogenous control is also spiked into specimens and the fluorescence emitted from the spike is compared with that emitted from the control. When inhibitors are not present, the Cq from the spiked clinical specimen will remain the same as the control, whereas in the presence of a contaminated specimen the Cq is higher.[70,71]

Variations of Polymerase Chain Reaction Assays

Variations of polymerase chain reaction include reverse-transcriptase qPCR, nested PCR, and multiplex PCR.

Reverse-Transcriptase qPCR

Reverse-transcriptase qPCR (RT-qPCR) is used for detection of pathogen RNA (such as RNA viruses) and gene expression studies. After extraction of total RNA from clinical specimens using a commercial kit or automated platform, the enzyme *reverse transcriptase* is used together with dNTPs to transcribe RNA into complementary DNA

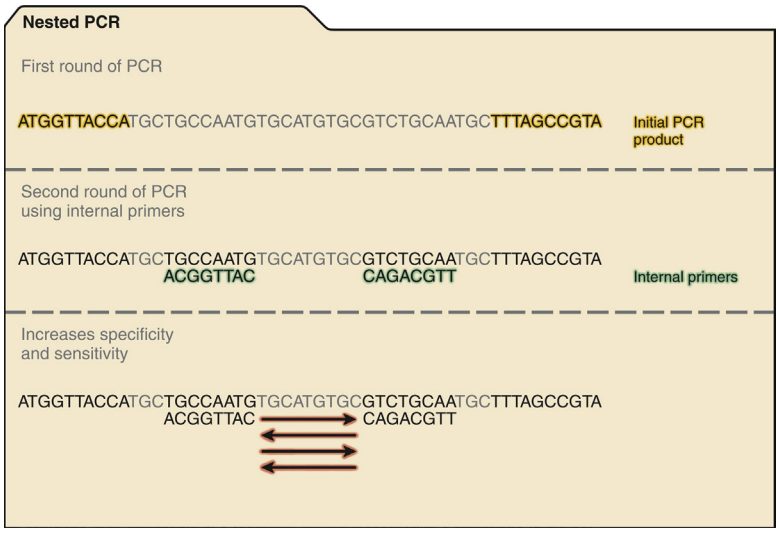

Fig. 6.6 Nested PCR. A second set of internal primers are used in a second round of PCR to increase the sensitivity and specificity of the assay.

(cDNA). The RT step can be initiated with *oligo(dT) primers* (primers that anneal to a poly-A tail), *random primers* (a mixture of primers with randomly assigned bases), a mixture of the two, or gene-specific primers. Subsequently, the cDNA is then used as the template for qPCR amplification.[72,73]

Nested PCR

In nested PCR, a small amount of amplified PCR product is subjected to a second round of PCR using another set of internal primers (Fig. 6.6). Having an additional set of primers increases the specificity of the PCR assay and also greatly increases its sensitivity.[74] Unfortunately, the increased sensitivity means that false positives due to contamination can be extremely problematic with this method, and it has lost popularity for diagnostic purposes.

Multiplex PCR

Multiplex PCR assays use multiple sets of primers *in the same reaction tube* to simultaneously detect multiple organisms (or multiple genes from the same organism). Duplex PCR assays can detect two organisms, and triplex PCR assays can detect three organisms. The potential downside of multiplex reactions is that if one organism is present in higher abundance, this may reduce the sensitivity of the assay for the other target organisms because amplification of the abundant pathogen DNA consumes reagents that are then unavailable for amplification of the other pathogen. Successful multiplexing results from careful experimental design and optimization of reaction conditions.[64,75,76]

Isothermal PCR

Isothermal PCR is a process that amplifies nucleic acids at a constant temperature, and has been the basis for in-clinic PCR assay development, because an expensive thermocycler is not required. Dozens of complex different isothermal amplification methods have been published, and some have reached the practice environment in human medicine (e.g., Loopamp MALARIA, Human Diagnostics Worldwide) and most recently in veterinary medicine (e.g., PCRun, Biogal). Examples include rolling-circle amplification and loop-mediated isothermal amplification (LAMP). In-clinic assays involve a DNA extraction step, followed by addition of reagents required for amplification, incubation in a heated block (e.g., 60°C for 1 hour), then detection of the PCR product. Detection of the products of PCR either involves the use of a lateral-flow disposable nucleic acid detection device (into which the tube containing the amplified DNA is inserted), or a small benchtop bioilluminator device that can semi-quantify the amount of DNA present in the reaction.[77] Isothermal in-clinic assays have been marketed for *Leptospira* spp., *Ehrlichia canis*, *Anaplasma platys*, *Leishmania* spp., *Babesia canis*, CPV, feline panleukopenia virus, and *Mycoplasma haemofelis*, which allow detection of a PCR product within 75 minutes. In one study, the clinical sensitivity and specificity of one assay for *M. haemofelis* (PCRun, Biogal) was compared with that of an endpoint PCR assay. Using one extraction method, the sensitivity and specificity was 94% and 96%, respectively; using a more crude extraction method recommended by the manufacturer, the sensitivity and specificity was 78% and 96%, respectively.[78] When compared with a qPCR assay, a *Leishmania* POC PCR assay offered in Europe by the same manufacturer also had high clinical specificity (100%) but low sensitivity (10% to 57%, depending on specimen type).[77] Sensitivity was also low (30%) and specificity high (100%) for an *E. canis* POC assay when compared with qPCR in experimentally infected dogs.[79] It was suggested that this may be because larger quantities of DNA must be present within a specimen for detection by the POC assays compared with detection by qPCR, based on the specimen types that tested positive for *Leishmania* and the stage of *E. canis* infection when positive results were obtained using the POC assays.[77] An insulated isothermal PCR (iiPCR) POC assay (POCKIT Nucleic Acid Analyzer, GeneReach USA, Lexington, MA) for *Babesia gibsoni* was shown to have high clinical sensitivity (90%) and specificity (99%) when compared with a qPCR assay (IDEXX Laboratories Inc., Westbrook, ME, USA), and generated results within 2 hours.[80]

DNA Microarrays

One of the limitations of culture is the inability to detect a target pathogen when it exists in a matrix that contains a large number of additional organisms. With microarray technology, the products of PCR amplification of a universal bacterial gene (such as bacterial 16S rRNA) can be hybridized onto a solid platform that contains thousands to more than a million oligonucleotide probes. These either hybridize to bacterial 16S rRNA genes; genus-, species-, or strain-specific genes; genes that specify resistance to antimicrobials; or toxin genes. The products of amplification are labeled with fluorescent dyes and the amplicon-probe interactions are measured using a laser scanner and analyzed by

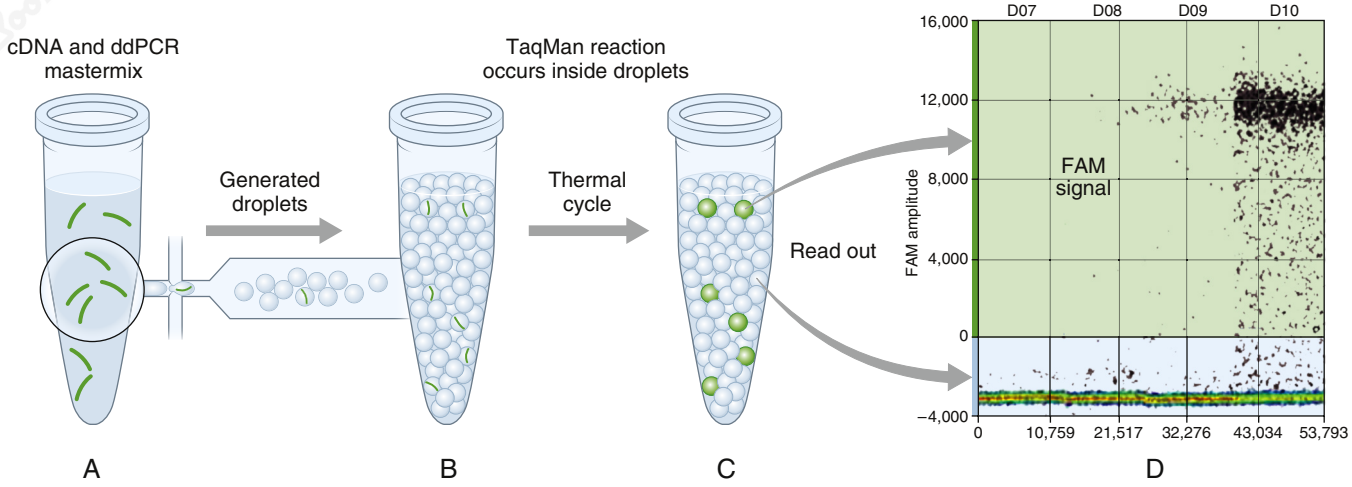

Fig. 6.7 Digital PCR. (A-C) The PCR reaction mixture is partitioned into droplets and the presence or absence of fluorescence from each droplet is measured. (D) The fraction of fluorescing droplets can be used to determine the number of target molecules present per droplet using Poisson distribution statistics.

a computer. Examples are PhyloChip (Second Generation Solutions), which has been widely used to analyze microbial communities using 16S bacterial rRNA probes, and Prove-It Sepsis (Mobidiag, Finland), which detects 60 species of bacteria and 13 fungi, as well as the *mecA* resistance gene, in blood specimens within a 3.5-hour time frame.

Digital PCR (dPCR)

First described in 1992,[81] dPCR is a refinement of PCR that can be used to more accurately quantify nucleic acids (including DNA, cDNA, methylated DNA, or RNA). In contrast to traditional PCR, the assembled reaction mixture is separated into a large number of individual portions (in microwell plates, capillaries, oil emulsions, or other chambers) and the reaction is carried out on each partition individually. After multiple cycles of PCR, the samples are checked as to whether they fluoresce or not. Poisson statistics are then used to measure the quantity of DNA present, and use of a calibration curve is not necessary; the fraction of fluorescing droplets predicts the number of target copies per droplet (Fig. 6.7). This separation allows a more reliable collection and sensitive measurement of nucleic acid amounts. It provides absolute quantification, because the number of droplets fluorescing due to proper amplification are determined, rather than DNA quantity being extrapolated using a calibration curve. The interest in dPCR has grown over the last 10 years because technologic progress makes it practical, with unparalleled precision, absolute quantification, flexibility, and increasingly affordable. dPCR may also be more reproducible and less susceptible to inhibition than qPCR. The method has been useful for viral/pathogen detection and quantification, gene expression studies, food testing, detection of point mutations, and clonal amplification for next-generation sequencing.[82,83]

INTERPRETATION OF PCR ASSAY RESULTS

A properly designed and highly efficient qPCR assay can detect very few copies (one or two) of a targeted gene, but both viable and nonviable organisms can be detected, which may be an obstacle for the clinician when trying to determine the significance of a positive qPCR result in light of an animal's disease. An understanding of the pathogenesis of infectious diseases and organism shedding patterns is crucial when interpreting positive qPCR results. Correct interpretation of the results relies on knowledge of the methods used by a laboratory and their advantage and disadvantages.

BOX 6.4 Factors that Should Be Considered When Interpreting NAAT Results

Test Result	Reason
Negative	Organism not present
	Too few organisms present
	Insufficient specimen size
	Wrong specimen type
	Improper timing of specimen collection
	Patient receiving antimicrobial therapy
	Specimen degradation during storage of transport
	Assay reagent failure
	Assay inhibitors present or extraction failure
	Reagents consumed in a multiplex assay
	Assay does not detect all strains
Positive	Viable or nonviable organisms present and causing disease
	Viable or nonviable organisms present but not causing disease
	Vaccine organisms present
	Contamination
	Loading errors
	Assay cross-reaction with other pathogens or host DNA in the specimen

NAAT, nucleic acid amplification test.

Factors that can lead to *negative test results* are shown in Box 6.4. An example of the use of the wrong specimen type would be submission of blood for a *Borrelia burgdorferi* qPCR test, when *B. burgdorferi* is found predominantly in connective tissue,[84] and only in blood for a short period of time during early infection. As discussed in this chapter, assay inhibition and specimen degradation can be identified by interpretation of reference gene control assay results, which should be performed by the laboratory; therefore, the clinician should use reliable laboratories and ensure that they use quality controls.

Factors that must be considered when interpreting *positive test results* are shown in Box 6.4. The most common reason for false-positive test results for assays that involve DNA amplification is contamination. Loading errors, in which specimen extracts are inadvertently loaded into the wrong wells on a microtiter plate, may also

lead to false-positive results and are reduced with the use of automated methods. Because of the exquisite sensitivity of qPCR, the significance of a true positive result should be interpreted with a caution. The organism may be part of the normal flora or carried subclinically (e.g., latent FHV-1 in a nasal biopsy). Several US veterinary laboratories offer qPCR "panels" for diagnostic purposes, whereby qPCR assays for several different pathogens are performed in separate reaction wells (one per pathogen) on nucleic acid extracted from a single clinical specimen. This high-throughput panel format allows assays to be offered at a substantial discount over the cost of multiple individual assays. This type of testing can occasionally result in unexpected positive test results, such as a positive result for the *Clostridium perfringens* toxin gene in a cat with diarrhea that is suspected to have trichomoniasis. In this situation, the *C. perfringens* may be an incidental finding and unrelated to the clinical problem, because healthy cats can have such toxin genes in their feces (see Chapter 64). As with any laboratory test, positive results need to be interpreted in light of the clinical history, clinical signs, and the pathogenesis of the disease in question. A positive result can also occur if an attenuated live vaccine for the target organism was recently administered. Because qPCR detects both viable and nonviable organisms, qPCR can be positive for days after antimicrobials have been administered, when culture is negative.[85–87] The duration of qPCR positivity after treatment depends on the sample type tested and the target pathogen.

CHALLENGES OF CURRENT MOLECULAR DETECTION METHODS

The reliability of a molecular diagnostic test depends on its detection limit. Some methods have limited ability to detect low numbers of organisms without steps to amplify the population in advance of PCR. Culture-based enrichment has been used reliably to expand a pathogen's population, but this technique is a time-consuming step in the analysis.[88]

Molecular techniques have limitations, such as those that relate to inhibition of PCR, lack of sensitivity in chronic infections, and differentiation of vaccine organisms from true pathogens. Often, multiple different types of diagnostic tests (culture, PCR, serology) must be performed for successful pathogen detection, and a correct diagnosis relies on interpretation of these results in light of the total clinical picture.

Pathogens are most accurately identified by sequencing the entire chromosome, or one or more genes of the unknown organism, and comparing the sequences generated to others in an identification database such as Genbank. Sequences can be generated using PCR-based technology. This technology, known as *whole genome sequencing*, can be used to identify fungi, bacteria, and viruses. It can be used to identify slow-growing organisms, or even those that cannot be cultured. The major disadvantage of whole genome sequencing is the high costs associated with it in terms of dedicated facilities, personnel training, time, and consumables.

Clinical Epidemiology in Infectious Diseases and Interpretation of Diagnostic Tests

Janet E. Foley, Rance K. Sellon, W. Zach Mills, James F. Evermann, Jane E. Sykes, Shelley C. Rankin

KEY POINTS

Epidemiology

- Epidemiology is the study of the distribution and determinants of health-related states or events in populations and the application of these principles to control health outcomes.
- The epidemiologic triangle highlights how disease outcomes depend upon: (1) pathogen factors, (2) host factors, and (3) environment.
- *Endemic* or *enzootic disease* refers to a disease that is established in a population and occurs regularly in that population at a background level, whereas an *epidemic* or *outbreak* occurs whenever cases are widespread in the community and exceed this baseline level.
- Molecular typing methods that can be used to study the epidemiology of an infectious disease include multilocus sequence typing, pulsed-field gel electrophoresis, and whole genome sequencing.
- Spatial epidemiology involves use of modeling to determine factors that influence the geographic distribution of an infectious disease.
- Multiple logistic regression analysis is often used to identify factors that increase the risk of an infectious disease while controlling for confounding.

Diagnostic Test Interpretation

- Diagnostic tests can be divided into *organism detection tests* and *antibody detection tests.*
- Before requesting a diagnostic test, veterinarians need to have an understanding of the clinical sensitivity and specificity of that test, what the target of the test is (e.g., antigen, DNA, or antibody), and whether the test is appropriate for the purpose it is being applied for. An understanding of the pathogenesis of the infectious disease, including shedding patterns and sites, and whether a carrier state or latency occurs, is critical for interpretation of test results.

CLINICAL EPIDEMIOLOGY

Epidemiologic Concepts in Infectious Disease

Epidemiology is the study of the distribution and determinants of health-related states or events in specified populations and the application of these principles to control health outcomes.[1] Clinical epidemiology can be used in medical practice to evaluate diagnostic tests, determine causality, analyze risk factors associated with the likelihood of acquiring a disease, and compile prognostic factors that will determine the course of a particular disease.

The concept of the *epidemiologic triangle* is useful in clinical epidemiology of infectious disease. The epidemiologic triangle is a model that highlights how disease outcomes are interdependent of: (1) pathogen factors, (2) host factors, and (3) environment.[2–4] Pathogen factors include the ability to survive in the environment, the propensity of the microorganism to spread, virulence factors and the manner in which they are expressed, resistance to antimicrobial drugs, and the ability to evade host immune defenses. Numerous host factors have the potential to influence infection and disease, including sex, breed, age, and immune status.[5] Environmental factors include physical (e.g., local terrain or climate), biological (e.g., insect vectors), and social (e.g., households vs. catteries). The epidemiology of FIP is a good example of the concept of the epidemiologic triangle. The prevalence of the fatal disease, FIP, in catteries can be as high as 5%, whereas the prevalence in one-cat or two-cat households is 0.02% (see Chapter 31). This increased prevalence in catteries reflects higher levels of low-virulence strains of FCoV in the environment, increased viral replication from acquired immune suppression caused by concurrent infections, pregnancy, stress of crowding, and host cat genetic factors.[6,7] These factors are thought to accelerate the accumulation of virus mutations that allow the virus to infect macrophages and cause FIP.

The progression of an infectious disease is a continuum that begins in a particular environment and a unique, susceptible (or naïve) host. Once there is exposure to an infectious agent, the timing of clinical signs (if any), and shedding of pathogens, vary depending on the individual host and the type of pathogen involved. There may then be an incubation period before the onset of clinical signs, during which time an animal may shed infectious organisms. Death or complete recovery may follow, or the host may become a carrier in the absence of clinical signs. Carrier hosts may either shed organisms (e.g., FCV infections), or harbor persistent infections in the absence of shedding. Hosts that are carriers of vector-borne pathogens do not shed organisms but may act as reservoir hosts that transmit pathogens to vectors when they feed. For example, *Ehrlichia canis* establishes a chronic, subclinical infection in dogs that can last years, providing a reservoir for infection of uninfected ticks.[8–10] Other pathogens can establish regressive or latent infections (e.g., FeLV [as provirus] or FHV-1 [in the trigeminal ganglia]), and later reactivation and shedding of these pathogens can occur with immune suppression. Typically, infected animals that show clinical signs are thought to be the most highly infectious to

other at-risk animals and humans because they shed larger quantities of organisms and/or have signs (such as sneezing) that facilitate transmission.

Analysis of contact patterns within and among populations can reveal targets for interventions that prevent spread of infectious diseases. In order to persist, some pathogens require frequent interhost transmission and constant exposure to susceptible hosts, others chronically persist in their hosts, and others succeed as a result of prolonged survival in the environment (e.g., CPV-2). It is also important to consider the potential for interspecies spread of infectious microorganisms, as for rabies, CPV-2, and influenza viruses.[8,11–14]

The potential for an infectious disease to occur in an "outbreak" or epidemic/epizootic is a concern for infectious disease epidemiologists. *Endemic* or *enzootic disease* refers to a disease that is established in a population and occurs regularly in that population at a background level. *Hyperendemic* refers to persistent, high levels of disease. An *epidemic* occurs whenever cases are widespread in the community and exceed this background level, and a *pandemic* is an epidemic that occurs over several countries or continents. An *outbreak* carries the same meaning as an epidemic but is generally used to refer to the occurrence of a greater-than-normal level of disease within a specific geographic region. Epidemics or outbreaks occur when there is an increase in the quantity or virulence of a pathogen, when a pathogen is introduced into new regions with naïve hosts, when the mode of transmission of a pathogen is enhanced, when there is a change in host susceptibility, and/or when factors increase host exposure or permit a change in the mode of transmission.[15] Outbreaks can be *common-source* (when hosts are all exposed to an infectious agent from the same source), *propagated* (when there is transmission from one host to another), *mixed* (comprising both common-source and propagated features), or *other* (where disease occurs neither as a result of common-source exposure or propagation; introduction of a vector-borne infectious disease is one example).[15]

To some extent, epidemics can be predicted using mathematical tools such as compartment models, which are sets of inter-related differential equations that model instantaneous changes in numbers of individuals who are either: (1) susceptible (S) to infection (not previously infected, or recovered but not immune); (2) currently infected (I); or (3) recovered and immune (R). This Susceptible-Infected-Recovered (SIR) model is the simplest version of a compartment model, but more elaborate models can allow for many additional factors such as no immunity, an exposed but not yet infectious state (E), arthropod vectors, and other complexities.

A crucially important value that derives from an SIR model is R_0 (R naught; also known as basic reproductive rate or basic reproduction number).[16] R_0 is meant to be a measure of the contagiousness of a disease that takes into account host behavior and pathogen characteristics; it is the number of cases that are expected to occur after the introduction of a single infectious individual into a fully susceptible population. A value of R_0 that exceeds 1 predicts continuation of an epidemic. When $R_0 < 1$, the epidemic is expected to die out. The magnitude of R_0 can correlate with the potential size of an epidemic and can be used to determine the proportion of the population that may need to be vaccinated to prevent ongoing transmission. However, it is not a measure of the severity of an infectious disease or the speed of a pathogen's spread through a population of hosts. The calculation of R_0 generally requires mathematical models that are developed using assumptions about the mechanisms of disease transmission in a population. It has been noted that R_0 is readily susceptible to misapplication and misinterpretation because many researchers that use R_0 lack sufficient training in the mathematical techniques required to accurately calculate R_0. For example, a simple R_0 may not be applicable to diseases where there is no recovered and immune state, or once the population comprises a mix of naïve and recovered individuals. Nevertheless, it remains a useful benchmark by which to compare magnitudes of predicted epidemics of different diseases or disease in different types of populations (Box 7.1, Figs. 7.1–7.3).

BOX 7.1 Terms Used in Clinical Epidemiology

Confounding: A spurious association between a risk factor and dependent outcome, caused by a variable that influences both the independent and dependent variable.

Etiologic (or Attributable) Fraction or Risk: The difference between the incidence of disease in a group of individuals exposed to a risk factor and in a group that are not exposed.

Etiologic Predictive Value: A value that informs how well a single test for a single pathogen predicts the true underlying cause of clinical signs in the circumstances where there is no single best test and when some individuals may be infected with an agent but not show signs (a carrier).

Fit-for-Purpose: An assay is "fit for purpose" if test methods and related procedures are appropriate for specific diagnostic applications in order for the test results to be of relevance.[17]

Sensitivity: The number of truly infected, test-positive individuals divided by the total number of infected individuals. This indicates how well the test detects all truly infected individuals (Fig. 7.1).

Specificity: The number of test-negative individuals who are truly uninfected, divided by the total number of uninfected individuals. This allows assessment of the likelihood of a false-positive test result.[18]

Positive Predictive Value: The positive predictive value (PPV) is the probability that an animal that has tested positive is infected with the pathogen of concern.[17]

Negative Predictive Value: The negative predictive value (NPV) is the probability that an animal that has tested negative is not infected with the pathogen of concern. The positive and negative predictive values depend on the prevalence of the disease in the regional animal population (Fig. 7.1).[17]

Risk Factor: Any characteristic or exposure that may modify the likelihood of developing a disease or being test positive. Risk factors may be positive (increasing probability of disease) or negative (protective).

Odds Ratio (OR): The relative odds of an outcome occurring (e.g., a positive test result) when there is a particular exposure or risk factor, compared with the odds of the outcome occurring in the absence of that exposure. An OR significantly greater than 1 implies that a risk factor increases likelihood of the outcome; an OR < 1 means the risk factor is protective; and an OR = 1 means that the risk factor has no effect on the outcome (Fig. 7.2).

Relative Risk: The ratio of the rate of infection or disease in animals exposed to a risk factor compared with those animals not exposed to the risk factor. As with OR, individuals with risk factors that impose a relative risk greater than 1 have increased risk of disease (Fig. 7.2).

Receiver Operating Characteristic (ROC) Curve: Plots of true-positive rates (sensitivity, y-axis) against false-positive rates (1-specificity, x-axis) for a test at different cutoff values used to define a positive test result. ROC analysis is often used to help determine the cutoff point that optimizes sensitivity and specificity. As cutoff values decrease, sensitivity increases while specificity decreases, and vice versa. The overall performance of a diagnostic test can be measured by determining the area under the ROC curve (AUC). The closer the AUC is to 1, the better the overall diagnostic performance of the test. The closer the AUC is to 0.5 (straight line, or "chance diagonal"), the closer the diagnostic test performance is to pure chance for distinguishing positive from negative results (Fig. 7.3).

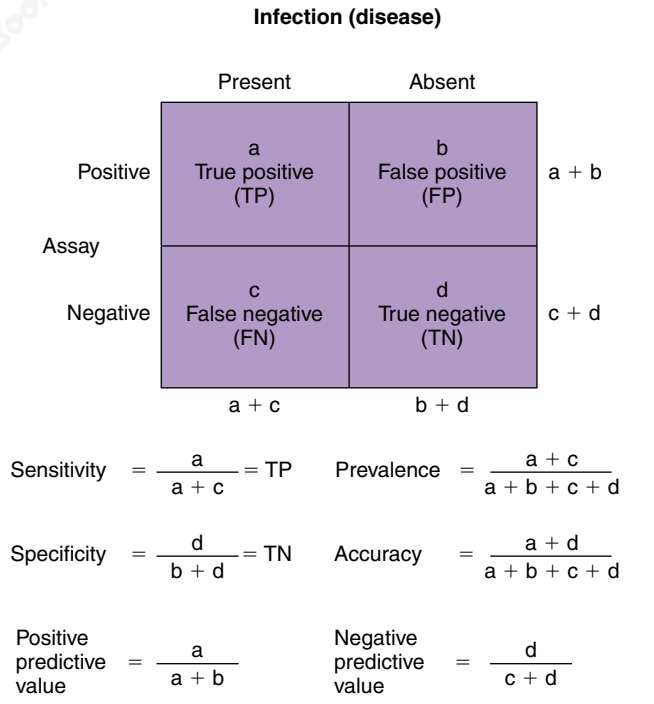

Fig. 7.1 Calculation of sensitivity, specificity, prevalence, accuracy, and positive and negative predictive value using a 2 × 2 table.

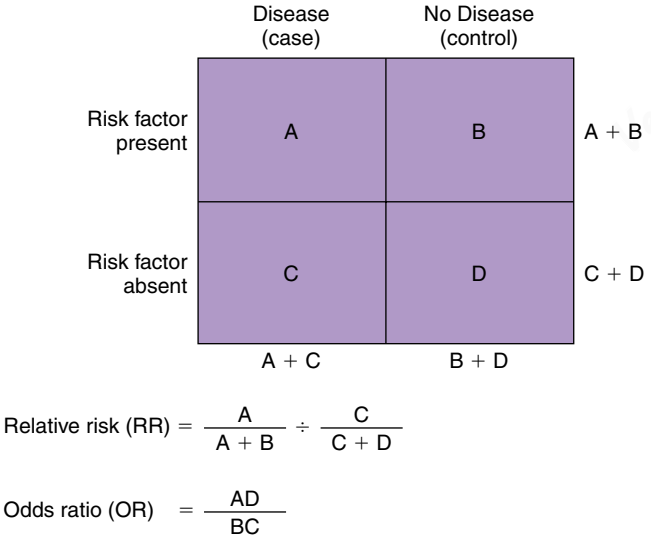

Fig. 7.2 Calculation of relative risk, odds ratio, and attributable risk using a 2 × 2 table.

Molecular Epidemiology

Molecular epidemiology focuses on how nucleic acid–based data can inform understanding of disease etiology, transmission, and distribution. Nucleic acid–based approaches can be used to understand pathogen transmission pathways, the evolution and spread of virulence genes, and host-microbe interactions and disease pathogenesis. Molecular epidemiology can reveal changes in evolving and emerging pathogens, their spread in space and emergence in new hosts, and their relationship with the environment.

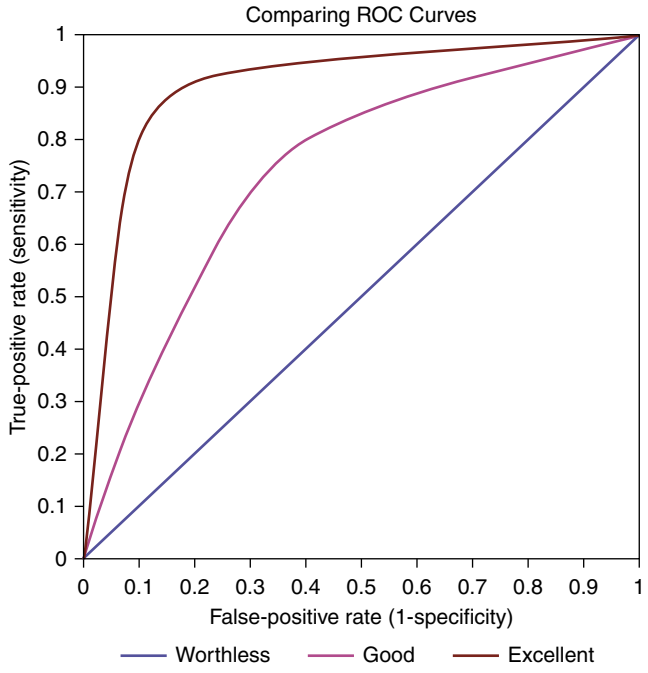

Fig. 7.3 Receiver operating characteristic (ROC) curves. Each curve represents excellent, good, and worthless assays that have been plotted on the same graph. Test accuracy depends on the degree to which the test separates those with and without the infectious disease of interest. Accuracy is represented by the area under the ROC curve (AUC). The test is perfect if the AUC is 1; an AUC of 0.5 represents a worthless test. An AUC above 0.8 is considered to be a good assay. (From Interpreting Diagnostic Tests. Thomas G. Tape, MD. University of Nebraska Medical Center; http://gim.unmc.edu/dxtests/roc3.htm)

Some molecular techniques used to study epidemiology target a small portion of a pathogen's genetic material, such as a single gene or intergenic region. Such assays can be used to document the presence of a pathogen in a host population, or to describe genetic relationships among multiple related strains and species of pathogens. Targets for single-gene studies must be chosen with care because DNA sequences that are relatively conserved among different strains are not as informative for epidemiologic studies as sequences that are moderately variable. In contrast, highly variable genes may not allow strains to be grouped at the level of resolution intended. The epidemiologic analysis of some microbes can be complicated by the diversity of evolutionary mechanisms by which microbes mutate (e.g., horizontal gene transmission by plasmids, transposons, viral vectors, homologous recombination, and other processes) that create downstream impacts on genetic lineages. *Multilocus sequence typing* (MLST) is a commonly used epidemiologic strain typing method that is referred to throughout this book. In classical MLST, a series of DNA segments (typically 7) from different parts of the genome (loci) are amplified using PCR and sequenced. The sequences of the collection of loci from different strains are compared. For example, MLST has been used to describe strains of *Leptospira interrogans* that might derive from different reservoir host species,[19] and an MLST protocol is a standard typing method for comparing *Cryptococcus* isolates.[20] Another frequently used strain typing method for comparing bacteria isolated from different sources is pulsed-field gel electrophoresis (PFGE). With PFGE, the entire genome of an organism is digested with one or more restriction enzymes which recognize specific short sequences of DNA and cut the DNA into fragments at these sequences (e.g., SmaI, which cuts in the center of the sequence "CCCGGG"). A pulsing electrical field is then used to move the DNA fragments through an agarose

gel such that they are sorted by size. The sorted pattern of fragments is characteristic of each bacterial genotype and these "fingerprints" can be compared. Strains that have identical fingerprints are generally regarded to have originated from a common source. *Whole genome sequencing (WGS)* is now practical for the molecular epidemiology of most viruses and bacteria and in some cases has replaced techniques such as PFGE and classical MLST. A hybrid approach that is increasingly being applied is core genome MLST (cgMLST), whereby the sequences of hundreds of core genes are compared among isolates following WGS. For example, a cgMLST approach that uses 545 core genome sequences has been used to type leptospiral strains.[21] This method has high discrimination power and allows identification of species, sequence types, and most probable serogroups, allowing tracking of *Leptospira* strains in different hosts and over time.[22]

Molecular typing methods have been used to recognize genetic changes in pathogens that might correlate with increased or reduced virulence (as might occur when a virus adapts to a host), the emergence of viruses that have jumped a host-species barrier, and to detect antimicrobial-resistant bacterial strains.[7,12–14,23,24] An important cause for disease emergence is when a microbe gains the ability to cross a host-species barrier, as occurred with the emergence of CIV H3N8 (Fig. 7.4). Diagnosis requires suspicion that this has occurred so that a test can be applied in the new species. As pathogens spread, molecular tools help detect changing patterns of genetic relatedness and movement, a science called *phylogenetics*. Phylogenetic approaches have been used, for example, to monitor the northward spread of a particularly aggressive but cryptic lineage of the brown dog tick, *Rhipicephalus sanguineus*, in the United States.[25]

Spatial Epidemiology

Spatial epidemiology is the study of the geographic distributions of pathogens, vectors, diseases, and risk factors for these distributions. It incorporates *spatially implicit models*, whereby precise locations of geographic regions are not accounted for but implied by a model, and *spatially explicit work*, such as risk mapping of disease, whereby precise locations are known.[26] Spatially implicit models are often based on metapopulations, which are dynamic groups of small "patches" (areas in space), each with a small subpopulation, and each connected to other patches.[27] For infectious disease modeling, the subpopulation that resides in a patch would typically be a group of host individuals. Use of metapopulations in small animal medicine is uncommon, but interested readers are referred to the suggested readings list for further information.[28]

Spatial epidemiology uses maps and studies features of disease and underlying factors, such as clustering of disease in space and time, association of disease with spatially patterned risk factors (such as soil type, weather conditions, location of water sources), and changes in disease distributions. Mapping approaches commonly use geographic information system (GIS), a computer-based system that employs widely used software applications such as GRASS or ArcMap. These applications manage spatial data, produce maps, and allow for spatial modeling and analysis. Data are mapped and often color-coded to highlight degrees of risk. Once data are mapped, clusters of risk factors or disease can be assessed visually and analyzed using statistical approaches. Merging spatial information about a disease with data on risk can allow for hypothesis testing, such as whether disease

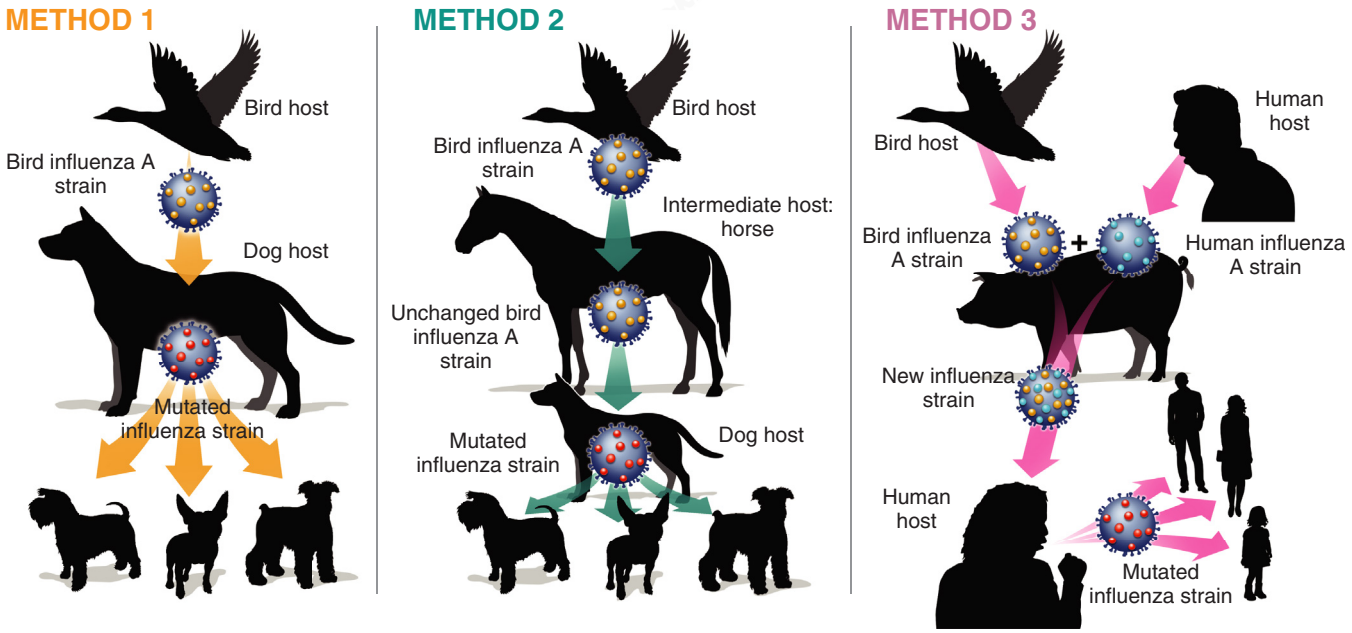

Fig. 7.4 Spread of viruses from one host species to another, with subsequent spread of infection to susceptible hosts. Influenza viruses are particularly good at crossing host-species barriers following recombination events and genetic drift. Method 1: Without further genetic change, a bird influenza A virus strain can move directly from an aquatic bird to another species, with subsequent evolution of the virus and spread within the new host species population. Method 2: The virus moves directly from an aquatic bird to an intermediate host, and then to a new host species, again with subsequent evolution and spread within the new host species population. Canine influenza virus H3N8 emerged as a result of mutation of equine influenza virus H3N8 (genetic drift), with subsequent spread to the general dog population and sustained spread within animal shelters. Equine influenza virus H3N8 was thought to have originated from birds. Recently, the overall prevalence of infection in the dog population has since declined, with some suggesting that extinction may have occurred at the time of writing. Method 3: Two different influenza virus strains from host species infect the same cells in an intermediate host, which results in generation of a recombinant virus that then spreads from the intermediate host to new hosts. There may be further mutations that allow the virus to then spread within the new host population.

is significantly associated with proximity of water sources or other predictors. GIS has also been used to examine theory of disease spread; this has been done for plague and rabies.[29,30]

Integrating Clinical Epidemiology into Practice

Primary data on infections, diseases, results of diagnostic testing, and risk factors are collected by veterinarians and diagnostic laboratories. These data are routinely used in practice to diagnose disease and inform medical management and preventative strategies for pets. They have also been used to provide information on human disease, such as when dogs act as sentinels for human disease. Clear recommendations for the expectations and limitations of diagnostic assays for diagnoses or screening are increasingly available via online technical bulletins and assay kit package inserts, and veterinarians interpreting these bulletins must have an understanding of concepts such as analytical sensitivity and specificity (how a test performs in the laboratory) and how they might relate to clinical sensitivity and specificity (how a test performs when applied to a population of animals with and without infection).[31]

Increased sensitivity and specificity of newer molecular and serologic diagnostic assays has resulted in more rapid turnaround and reduced costs. Commercial diagnostic laboratories, corporate veterinary practices, and medical scientific literature make valuable contributions to our knowledge of infectious disease epidemiology because the results of testing large numbers of specimens with the same assay are now available for analysis. These data provide evidence to inform decisions regarding vaccination frequency, which vaccines to use, what populations of animals are at elevated risk, and how likely animals are to serve as carriers and reservoirs of infection. Such data are needed for biosecurity and are particularly helpful if reported back to the clinicians and clients.

Risk Analysis

Through risk analysis, the relative importance of different risk factors associated with an animal's susceptibility to infection and disease can be assessed. Relative risk can be determined by studying groups of animals with defined risk factors (cohorts) over defined time periods for development of infection or disease. For example, introduction of a tetravalent leptospira vaccine in Switzerland was associated with a marked decrease in leptospirosis and AKI among dogs.[32] Relative risk and odds ratios do not provide information about the proportion of cases resulting from exposure to a risk factor. These values are determined by calculating the attributable risk, which accounts for the relative risk and the proportion of the population exposed to the risk factor (see Fig. 7.2).

An understanding of associations between disease and risk factors can inform decisions about targeted diagnostic testing, preventive management and intervention, and prognostication. Although a variety of statistical methods are applied depending on the study design, one common statistical approach is logistic regression analysis. Logistic regression analysis evaluates how a dependent binary variable (*binary* meaning one thing or another—diseased or not, test positive or test negative) is associated with independent variables (e.g., sex, breed, species, outdoor access) or risk factors. This highly flexible tool allows multiple risk factors to be assessed simultaneously, takes into account interactions among risk factors, controls for confounding effects, and can identify the strength of an association with each risk factor. In contrast, *univariate* analysis only allows the effect of one risk factor to be assessed at a time and does not take into account interactions or control for confounding. The ability of logistic regression analysis to control for confounding is particularly important. For example, univariate analysis might reveal that an increased frequency of leptospira vaccination increases the risk of adverse events such as anaphylaxis. However, young animals are vaccinated more frequently than older animals, and the increased rate of reactions might be due to age rather than frequency of vaccination. Logistic regression analysis controls for these effects and typically identifies a smaller number of significant risk factors when compared with univariate analysis of all of the individual risk factors included in the regression analysis.

DIAGNOSTIC TESTING FOR INFECTIOUS DISEASES

Diagnostic Versus Screening Assays

Veterinarians use diagnostic tests to diagnose acute or chronic infectious disease. The same assay may be used to assess the prevalence of disease, infection, or exposure in populations. A single assay may be validated for one or more intended purposes by optimizing its performance characteristics for each purpose. An assay that is used as a *screening assay* (to rule out an infectious disease agent) should have a high diagnostic sensitivity and a high negative predictive value. Screening an animal to show that it is free of a disease should be done with the assumption that the animal is truly free of the disease because the disease prevalence in the population represented by the animal is zero, or extremely low (e.g., *Brucella canis*). Screening tests are generally associated with a lower diagnostic specificity and positive results should be confirmed by a test with high specificity for the pathogen of interest. Clinicians need to be aware of problems associated with using tests that have been designed and validated as diagnostic tests for screening purposes in animals that are unlikely to have the disease of interest.

Types of Diagnostic Tests

Diagnostic tests for infectious diseases can be broadly divided into: (1) organism detection tests, and (2) antibody detection tests. *Organism detection tests* include culture/isolation, which detects viable pathogens; tests that detect antigen(s) of a pathogen (e.g., direct IFA, IHC, antigen detection ELISA); and tests that detect pathogen DNA or RNA such as PCR and isothermal amplification (collectively known as nucleic acid amplification tests [NAAT]), and fluorescent *in situ* hybridization (FISH). *Antibody detection tests* provide evidence of previous exposure to a pathogen and include indirect IFA assays, HI, serum neutralization, antibody detection ELISA, and colloidal gold immunochromatographic assays (GICA). Tests may be available through diagnostic laboratories or may be POC tests, which can be used in the clinic or low-resource environments such as shelters.

Serologic tests are often assumed to be antibody detection tests, but the term "serologic assay" (or immunoassay) can also refer to an assay that detects antigen if the use of antibodies is employed in test design. Clinicians need to consider whether they are trying to make a diagnosis of an *infectious disease* (and that also includes documenting *exposure* to an infectious agent) or show that the animal is free of disease. Whenever the use of a diagnostic test is considered, it is critical that clinicians understand whether the assay detects viable pathogens (culture), components of a pathogen that might be viable or nonviable (antigen or DNA), or not replicating (proviral DNA in the case of a retrovirus infection), or antibodies (exposure). The purpose of a particular test is important when syndromic panels, which are designed to detect multiple infectious agents and/or antibodies to those agents, are requested. For example, diarrhea panels are available that include culture for enteric pathogens, antigen ELISA assays for clostridial organisms, and PCR for bacteria, viruses and parasites that commonly cause diarrhea in particular animal hosts. There are also immunoassays such as the IDEXX SNAP 4Dx Plus test (IDEXX Laboratories Inc., USA) and the Antech AccuPlex 4 assay (Antech Diagnostics, USA) that detect vector-borne pathogens (Table 7.1). Use of such panels can occasionally produce unexpected positive results that may be difficult to interpret.[33] A positive PCR test result is not always a marker for active shedding or for disease status because pathogen nucleic acids

TABLE 7.1 Examples of Commercially Available Diagnostic Panels that May Be Selected for Diagnosis of Companion Animal Infectious Diseases

PCR Panel	Targets
Canine respiratory panel	Canine adenovirus-2 RNA Canine distemper virus RNA Canine parainfluenza virus RNA Canine influenza virus H3N8 RNA Canine influenza virus H3N2 RNA Canine herpesvirus DNA Canine respiratory coronavirus RNA *Bordetella bronchiseptica* DNA *Streptococcus equi* subsp *zooepidemicus* DNA

It is particularly important to understand whether panels consist of organism detection tests, antibody detection tests, or both, and the significance of a positive result for each target in light of the pathogenesis of disease.

may be present in latent and subclinical infections; or when animals have recovered but retain nonviable pathogens or free nucleic acids, damaged cells, or debris. Positive PCR results can also occur when specimens become contaminated with environmental DNA.[33] Positive test results must be assessed in light of the patient's history, clinical signs, physical examination findings, the reason the test was performed, results of other diagnostic testing, and a knowledge of the extent to which these organisms can be detected in healthy animals as opposed to those that are diseased.[18]

Serology is the foundation for serodiagnosis, serosurveillance, and studies of vaccine-induced immunity. Serodiagnosis can assist in the diagnosis of current disease, such as the use of IgM assays to detect acute infection, or the use of antigen ELISA testing for detection of heartworm and FeLV infection. Serodiagnostic assays that detect IgG can imply previous infection, while a fourfold (two-step) rise in antibody titer over 1–4 weeks (e.g., 1:4 to 1:16, 1:16 to 1:64) suggests recent, active infection. For some diseases, determination of serum antibody titers can also aid in assessment of vaccine-induced protection (see Chapter 20). For example, dogs with specific CDV and CPV antibody titers are generally considered protected against CDV- and CPV-induced diseases. Antibody titers do not correlate with protection for other diseases, such as leptospirosis. In addition, factors such as degree of environmental exposure, and level of natural and pharmacologic-induced immune suppression need to be considered when antibody titers are used to determine the need for booster vaccinations.

The limits of test sensitivity and timing of positive test results over the course of infection are important considerations in diagnosis. Early after exposure, during the acute phase of an infection, the best options for diagnosis are tests which are sensitive, detect the pathogen directly (e.g., antigen ELISA, PCR, culture), and are performed on the appropriate target specimen. Serology tests that detect antibodies can be negative early in the course of illness if clinical signs appear after a short (< 10 days) incubation period. Subsequently, IgM antibodies circulate, the presence of which usually correlates with recent infection, followed by longer lasting IgG which indicates exposure to a given, or cross-reacting, pathogen. As the infection matures, direct tests for antigen or nucleic acids reveal animals with acute clinical infection as well as those with latent infection and those which are carriers. For chronic diseases or diseases that occur after a long incubation period (e.g., Lyme borreliosis, FIP), determination of acute and convalescent phase titers over a 1- to 4-week period is generally not appropriate because a significant

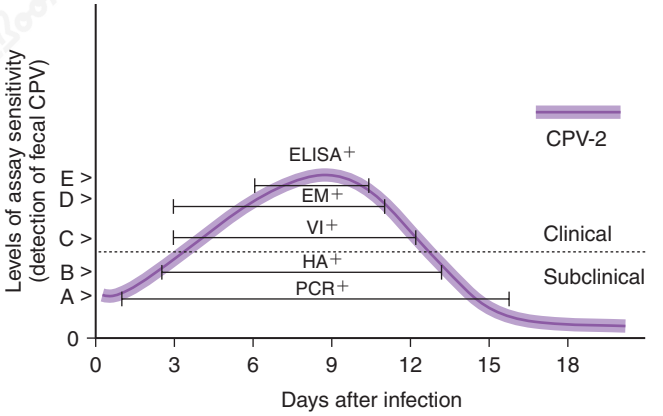

Fig. 7.5 Degrees of diagnostic assay sensitivity, with canine parvovirus (CPV) infection used as an example. There are five different types of assays *(A–E).* Some assays are more appropriate for clinical diagnosis whereas others are more likely to detect low-level (subclinical) shedding. *ELISA,* enzyme-linked immunosorbent assay; *EM,* electron microscopy; *HA,* hemagglutination; *PCR,* polymerase chain reaction; *VI,* virus isolation.

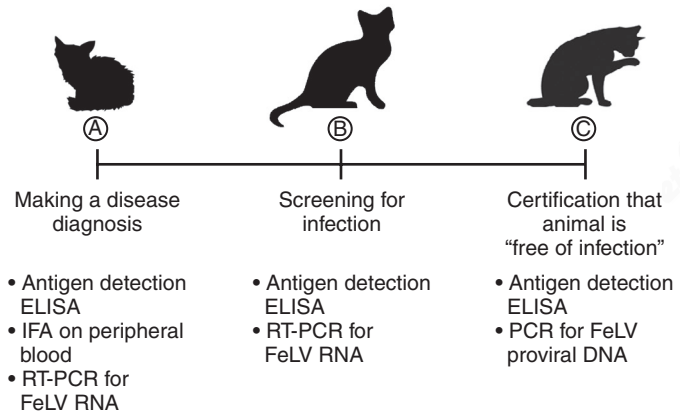

Fig. 7.6 Three reasons for using a diagnostic test. (A) Diagnosis of *disease* in a sick animal. In the case of FeLV infection, an antigen detection ELISA assay, IFA, or RT-PCR assay could be used to detect productive virus infection. However, detection of productive virus infection alone does not imply that the virus is responsible for clinical signs. (B) Screening for subclinical infection. For FeLV, this would involve use of a sensitive assay for productive virus infection, that is, an antigen detection ELISA assay or RT-PCR assay. (C) Certification that an animal is "free of infection" (e.g., for identification of blood donor cats). For FeLV, this might consist of an antigen detection ELISA assay *and* a provirus (DNA) PCR assay. *ELISA,* enzyme-linked immunosorbent assay; *FeLV,* feline leukemia virus; *IFA,* immunofluorescent antibody; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

change in titer does not occur. When different test options are available, it is best to choose a test with appropriate sensitivity and specificity for the desired purpose, and to consider the prevalence of the disease in the patient population. As an example, dogs with clinical CPV-associated enteritis are likely to be CPV fecal antigen ELISA positive and PCR positive for CPV. Both tests are a good choice for the diagnosis of CPV enteritis; however, the latter can confirm active infection and also detect dogs that are subclinically infected or recently vaccinated with attenuated live vaccines (Fig. 7.5).[8] Some laboratories that perform real-time PCR results will report cycle threshold values, or an estimate of nucleic acid target copy number (see Chapter 6), with detection of nucleic acid in high copy number being more likely to relate to clinically significant infection than detection of nucleic acid in low copy number (e.g., some assays for CDV or FeLV infections). Depending on the pathogen, testing may lend itself to a diagnostic test hierarchy (Fig. 7.6). Multiple tests may need to be applied in parallel or in series to optimize diagnosis.

SUMMARY

The interface between disease diagnosis and clinical epidemiology has continued to be fortified by the ever-increasing knowledge of the importance of animal populations and their interactions with other animals and humans. With the development of molecular diagnostic assays, the finer details of how a pathogen sustains itself in a population by establishing short- and long-term carrier states have become more apparent. These assays have also shed light on how the potential for interspecies transmission impacts the nature of emerging infections. Although clinical epidemiology involves the understanding of health and disease in populations, it is fundamental in decision-making for the individual animal. An understanding of the epidemiologic features of a particular infectious disease facilitates the early identification of an outbreak, which in turn helps the clinician select the most appropriate diagnostic test and interpret the results of subsequent diagnostic testing. This early detection is essential for the development, implementation, and monitoring of prevention and control strategies.

SECTION 2

Anti-infective Drugs

Mark G. Papich

The majority of this book deals with diagnosis, pathology, and management of specific infectious diseases in dogs and cats. However, the book would not be complete without chapters on the agents used to treat and manage these infections. In this section, there are six chapters. The first chapter is a review of general principles of antimicrobial therapy. This chapter includes the importance of identifying the organism, pharmacokinetic properties of the agents, pharmacokinetic-pharmacodynamic (PK-PD) issues, and antimicrobial drug resistance. This introductory chapter sets the stage for the chapters that follow.

The remaining five chapters in Section 2 cover the major groups of drugs that are used to treat infections in dogs and cats: antiviral, antibacterial, antifungal, antiprotozoal, and antiparasitic agents. Included with the antiviral chapter is a section on immunomodulatory agents, which are often used to manage viral infections, but have also been used for other infectious diseases. Each of these chapters accompanies the specific sections on diseases that are contained in the majority of the book.

These chapters on specific antimicrobial agents include drugs that are approved by the US Food and Drug Administration (FDA), or regulatory authorities in other countries, for treating infections in dogs and cats. However, even with these approved agents available, there are still many unmet needs. The importance of these chapters lies in the realization that there are not always drugs approved by regulatory authorities to treat all of the infections encountered in dogs and cats. For example, there are no antiviral drugs approved in the United States for dogs and cats. Except for topical agents, there is only one antifungal agent approved. The available antibacterial agents do not cover many of the most important bacterial infections. Many antiprotozoal agents are used extralabel. Therefore, extralabel (off-label) human drugs or drugs approved for other animals are often used. Because the uses, dosing information, pharmacokinetics, and adverse effects are not available for these drugs on an approved drug label, these chapters are needed to provide veterinarians with a resource for the important characteristics of these agents. Each chapter includes state-of-the-art information available from published papers and experts who have studied these medications. The use of each drug listed is based on a consensus opinion of experts consistent with good clinical practice. Each chapter is referenced to original studies or the approved drug label to support the use. The recommendations, including dosages, listed in these chapters are based on the the best available evidence at the time this book was prepared. The authors cannot guarantee safety and efficacy of all the treatments discussed, and new information may emerge that was not known at the time the book was prepared.

Principles of Anti-infective Therapy

Jane E. Sykes, Mark G. Papich

KEY POINTS

- Use of antimicrobial drugs (AMDs) selects for resistant bacterial populations, both within the targeted bacterial population and also commensal bacterial populations.
- Bacterial mechanisms of drug resistance include production of enzymes that inactivate AMDs, drug exclusion through membrane alterations and efflux pumps, protection of target sites (e.g., ribosome), and modification of the site of action (or target) of the AMD.
- Strategies that minimize selection for drug resistance include: (1) confirmation of the presence of infection before AMD treatment is commenced, (2) proper identification of the infecting organism, (3) selection of agents with activity specific to the pathogen present, (4) administration of an adequate dose of AMD, and (5) administration of AMD for the proper duration of time (often as short as possible).
- Selection of an appropriate AMD should be based on the activity of the agent against the suspected pathogen; knowledge of drug pharmacokinetics, which includes bioavailability and tissue penetration; consideration of host factors such as concurrent illness, medications, or immunosuppression; and consideration of the agent's pharmacokinetic-pharmacodynamic (PK-PD) properties. The PK-PD properties include whether the drug exhibits concentration- or time-dependent antibacterial effects, which dictates the design of the dosage regimen.

INTRODUCTION

Antimicrobial drugs (AMDs; Box 8.1) have been considered one of the greatest inventions of the 20th century. The modern era of AMD treatment began with the discovery of sulfonamides in 1935.[1] In the 1940s, the therapeutic value of penicillin and streptomycin was discovered, and by 1950, the "golden age" of AMD therapy was underway. The increased use of AMDs in people, companion animals, and livestock has been accompanied by increased rates of antimicrobial resistance—in some instances, an alarming transition to multidrug resistance that has severely limited the available antimicrobial choices. Among 1,485 non-urinary *Escherichia coli* isolates from dogs in the United States from 2004 to 2011, there was a significant increase in the prevalence of resistance to cefazolin, cefoxitin, cephalothin, enrofloxacin, and tetracycline.[2] In the United Kingdom from 2003 to 2012, the prevalence of resistance among 14,555 clinical isolates of *Staphylococcus intermedius* group organisms (primarily *Staphylococcus pseudintermedius)* increased significantly.[3] Most of the veterinary isolates of *S. pseudintermedius* are MDR, which greatly limits the choices for treatment.[4] Clonal dissemination of methicillin-resistant *S. pseudintermedius*[5] and ESBL enzyme producing *E. coli* and *Klebsiella pneumoniae*[6,7] has been reported among companion animals worldwide. This has been compounded by a declining rate of development of new classes of AMDs for veterinary use, and increased scrutiny of the use of critically important human antimicrobial agents for administration to animals.

Antimicrobial resistance genes were present in microbes long before antimicrobial agents were used in therapy. Microbe populations generally consist of a mixture of genetically susceptible and resistant organisms. The use of AMDs exerts pressure that favors selection of the resistant microbes ("survival of the fittest") within both the targeted bacterial population and other commensal bacteria (which have the potential to become pathogenic when host defenses are impaired).

The risk of emergence of resistant bacterial strains depends on factors that include the size of the inoculum, ability of the bacteria to acquire mutations, the ability of host defenses to eliminate resistant bacteria, drug concentrations at the site of infection, and the duration of exposure to AMDs. Selection pressures are highest when bacteria are exposed to suboptimal dosage regimens (i.e., concentrations of drug below the level needed to kill or suppress the growth of the bacteria). In this scenario, the most susceptible strains are eliminated, but the more resistant strains flourish because of decreased competition. Resistant bacteria are not necessarily more virulent than susceptible bacteria, but they may require drugs not commonly used, or other measures not commonly used for treatment of the susceptible strains of bacteria.

According to the Infectious Disease Society of America, *antimicrobial stewardship* refers to coordinated interventions designed to improve and measure the appropriate use of antimicrobials by promoting the selection of the optimal AMD regimen, dose and duration of therapy, and route of administration.[7] Guidelines for prudent antimicrobial use have been published by several professional veterinary organizations and societies with the intention of reducing selection for resistant bacterial pathogens.[8–14] An AVMA taskforce on antimicrobial stewardship in companion animal practice has developed an antimicrobial stewardship program that includes client educational handouts and a series of antimicrobial use "dos and don'ts" for veterinary practitioners.[15]

BOX 8.1 Antimicrobial, Antibiotic, Antibacterial, Which Is Correct?

The terms "antibiotic," "antimicrobial," and "antibacterial" are often used interchangeably. They have different meanings that are often overlooked. An *antibiotic* is a natural chemical, produced by other organisms, that is designed to suppress the growth of other organisms (including bacteria, fungi, or protozoa). An *antimicrobial* is any compound, natural or synthetic, that suppresses microbial growth. An *antibacterial* is any compound that suppresses bacterial growth. The term "antimicrobial agent" is preferred by certain groups such as CLSI. Many times, even in this chapter, the terms are used interchangeably with the same meaning.

Specific guidelines regarding antimicrobial selection, dosing and duration of treatment for infections of the urinary tract, skin, and respiratory tract have been developed by consensus of the Antimicrobial Guidelines Working Group of the International Society for Companion Animal Infectious Diseases (www.iscaid.org). Veterinary hospitals are encouraged to adapt these guidelines or develop their own hospital-specific antimicrobial guidelines based on evaluation of the local prevalence (antibiograms) of AMD resistance and local prescribing practices. Strategies that may reduce the selection for antimicrobial resistance include documentation of the presence of infection; appropriate susceptibility testing; proper identification of the infecting organism; and the use of agents that are as specific for the pathogen as possible, at the proper dose and for the proper duration of time. There are older, outdated recommendations that recommended treatment for longer than necessary, which has led to a current trend to shorten the duration of antimicrobial therapy whenever possible for companion animals.

IDENTIFICATION OF THE INFECTING ORGANISM

The detection of fever or leukocytosis does not imply bacterial infection and the need for antibiotic treatment, especially given the relatively high prevalence of sterile inflammatory and immune-mediated diseases in dogs and viral infections in cats. Selection of the most appropriate AMD relies on knowledge of: (1) the presence of an infectious agent, (2) the type of infectious agent present, and (3) the likelihood of susceptibility of the agent to the AMD prescribed. In some cases, treatment with AMDs may not be necessary even though the cause of disease is bacterial. Some infections undergo spontaneous cures without the aid of an antibiotic. For example, a cat bite abscess can often be drained and resolved without the need to administer an antibiotic (see Chapter 75). Many transmissible respiratory infections, such as those belonging to the canine infectious respiratory disease complex, are self-limited and often spontaneously resolve without antibiotics.

In some situations, collection of a specimen for cytology or histopathology permits a diagnosis of infection to be established. Some difficult to grow or fastidious infectious agents, such as rickettsial and fungal pathogens, may be presumptively identified to the genus or species level based on their morphology. If skin cytology from a dog reveals cocci (a Gram stain is not necessary to confirm the presence of gram-positive cocci), then the presence of *S. pseudintermedius* is highly probable. If, on the other hand, cytology from an ear swab reveals rods, the possibility of *Pseudomonas aeruginosa* must be considered. In either case, this knowledge is valuable for selecting appropriate initial antibacterial therapy. The use of molecular diagnostic techniques, such as nucleic acid amplification tests (NAATs), can also allow rapid identification of an infecting organism, which can help to guide AMD selection. Many commercial laboratories now use MALDI-TOF MS for rapid identification and diagnosis of pathogens (see Chapter 3).

For example, identification of a vector-borne pathogen (e.g., *Rickettsia* spp., *Ehrlichia canis*) is helpful because doxycycline is usually the first drug of choice for the majority of these pathogens. Once the pathogen is identified, or presumptively identified, antibiotics can be administered that have a high probability of success based on typical susceptibility patterns for the wild-type strains. Unfortunately, there is now greater likelihood of encountering drug-resistant (non-wild-type) organisms. Therefore, in many instances, it has become important to collect specimens for culture and susceptibility testing before treatment with AMDs is commenced. Although there is an initial cost to the client for culture and susceptibility testing, long-term costs to the client may be reduced because prompt treatment with the most appropriate agent will decrease prescription of unnecessary or inappropriate AMDs, improved likelihood of rapid resolution of the underlying disorder with early diagnosis and appropriate treatment, and reduced need for more expensive, second- or third-line AMDs. Early attainment of therapeutic targets is important for rapid clinical resolution and decreased emergence of resistant bacteria.[16] Administration of AMDs without identification of the infectious agent can also decrease subsequent chances of successful culture and proper diagnosis if the problem does not resolve. Proper interpretation of culture and susceptibility panel results is also imperative. Practitioners should examine a culture report carefully and question whether a bacterial species isolated is truly the cause of infection as opposed to a contaminant or commensal. Among the agents listed as "susceptible" in a report, the clinician will have to decide on the best choice based on drug and patient characteristics. The reader is referred to Chapter 3 for more information on bacterial culture and susceptibility testing. The Clinical and Laboratory Standards Institute (CLSI) also provides an excellent resource for the interpretation of culture and susceptibility results for pathogens from animals.[17]

In animals with life-threatening infections, institution of AMD treatment is necessary before the results of culture and susceptibility become available. The choice of treatment at this stage can be based on cytology and knowledge of the type of infections that most commonly occur at the anatomic site involved (also known as *bacteriologic statistics*). Because of the life-threatening nature of these infections, the practice of "de-escalation" (as opposed to "escalation") is employed. This is the practice of initially selecting a highly active agent that has a high probability of successful elimination of the pathogen and initiating treatment quickly; then once the infectious agent has been identified, the drug spectrum should be changed or narrowed according to culture and susceptibility results. If the infection is life threatening, highly active agents such as an aminoglycoside or fluoroquinolone, or extended-spectrum β-lactam can be selected initially. Then, if culture and susceptibility show susceptibility to other β-lactam agents, treatment should be continued with these agents alone. Routine inclusion of an "antimicrobial time-out" 48 to 72 hours after initiating AMD therapy has been recommended when culture and susceptibility data or other clinical information becomes available. During this period, the clinician should reassess whether antimicrobial therapy should be continued, discontinued or modified.[15]

When available, use of regional or hospital-specific antibiograms can also help guide appropriate empirical antimicrobial therapy. A *regional antibiogram* lists commonly isolated species of bacteria and the likelihood of susceptibility to various AMDs based on cumulative culture and susceptibility data from a practice or region. The practitioner can then select the AMD based on the likelihood of a particular bacterial species being present at the site of an infection and

its predicted resistance pattern. The term "antibiogram" has also been used incorrectly to describe an individual bacterial isolate's susceptibility pattern, so "regional antibiogram" is the recommended term to describe cumulative susceptibility data. Development of practice-specific antibiograms is recommended because antibiograms can differ considerably from one practice to another even within the same region, depending on factors such as clinician preference for AMD choices, the types of cases seen, and whether the patient population is primary or referral based.

CLASSIFICATION OF ANTIMICROBIAL DRUGS

AMDs may be classified based on their structure (e.g., β-lactams, fluoroquinolones), spectrum of activity (gram-positive versus gram-negative bacteria), mechanism of action (Table 8.1; Fig. 8.1), whether they are *bacteriostatic* (inhibit or slow growth) or *bactericidal* drugs, and their pharmacodynamic properties (see Pharmacodynamics of Antimicrobial Drugs, later).

The difference between bactericidal and bacteriostatic drugs has become more blurred in recent years. Some drugs are difficult to define because they may have different action on different bacterial species. The "static" versus "cidal" nature of many drugs depends on the concentration achieved. At low concentrations (e.g., 1 × MIC, 2 × MIC) they may be bacteriostatic, but at higher concentrations (e.g., 4 × MIC, 8 × MIC) they can be bactericidal. In reality, there are no examples where a bactericidal agent is preferred over a bacteriostatic agent based on available evidence and extensive evaluation from human clinical studies.[18] From a clinical perspective, it is more useful to describe drugs as time dependent versus concentration dependent rather than as bactericidal or bacteriostatic. This allows the clinician to consider the dosage regimen and dosing interval to optimize therapy.

Antibacterial drugs have also been classified for veterinary use as first-line, second-line, or third-line drugs[19] (in some guidelines, the authors use "first-choice," "second-choice," and so forth, and in the ISCAID guidelines the authors use first-tier, second-tier, third-tier, for the same meaning). First-line drugs are those that could be used for empirical selection in the absence of or pending the results of culture and susceptibility testing, and include amoxicillin, amoxicillin-clavulanate, cephalexin, doxycycline, minocycline, and trimethoprim-sulfonamides. Second-line drugs are those to be used

TABLE 8.1 Classification of Antimicrobial Drugs Based on Their Mechanism of Action

Mechanism Of Action	Antimicrobial Drug	Examples
Inhibition of cell wall synthesis	β-Lactams, glycopeptides, fosfomycin	Penicillin, cephalexin, meropenem, vancomycin
Cell membrane disruption	Polymyxins, daptomycin, aminoglycosides	Colistin, daptomycin, gentamicin, amikacin
Protein synthesis inhibition	Tetracyclines, aminoglycosides, chloramphenicol, lincosamides, macrolides, ketolides	Doxycycline, gentamicin, erythromycin, clindamycin, azithromycin, telithromycin
Inhibition of DNA replication	Fluoroquinolones	Enrofloxacin, marbofloxacin, pradofloxacin
Inhibition of folic acid metabolism	Trimethoprim-sulfonamides	Trimethoprim-sulfamethoxazole

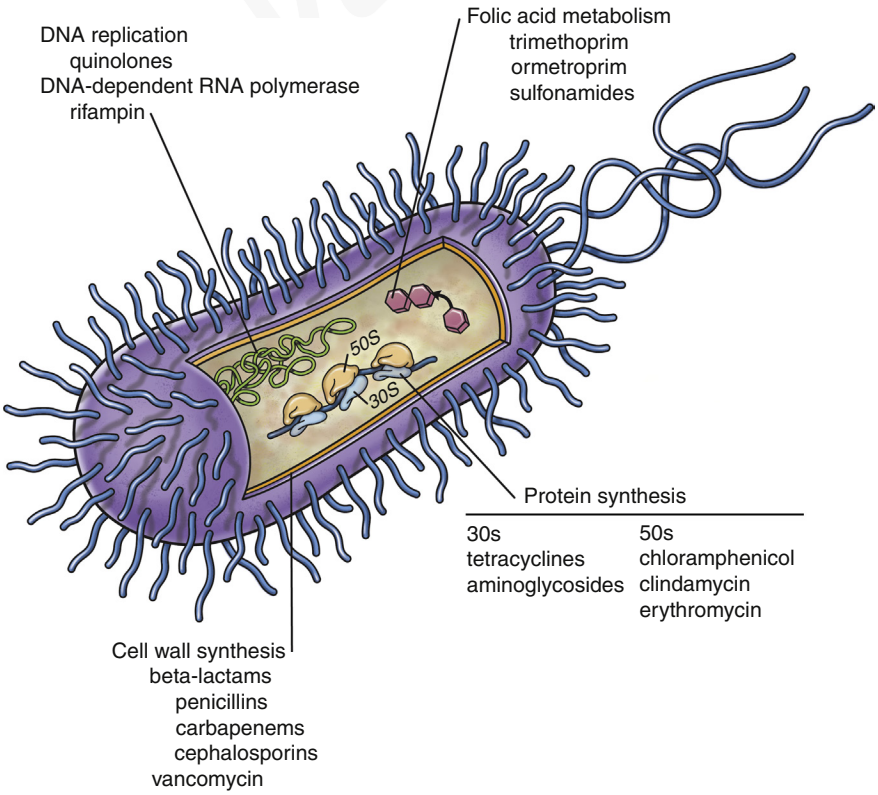

Fig. 8.1 Sites of action of antimicrobial drugs within the bacterial cell.

BOX 8.2 Criteria to Consider Before Administering a "Third-Line" Antibiotic

1. Infection must be documented based on clinical abnormalities and culture.
2. The infection is serious and has the potential to be life threatening if left untreated.
3. Resistance is documented to all other reasonable first- and second-line options.
4. The infection is potentially treatable.
5. The clinician may seek advice from an infectious disease clinician or a clinical microbiologist to discuss antimicrobial susceptibility test results, and to discuss the use of these agents if there is unfamiliarity with their use. In some instances, there may be other viable options (e.g., topical therapy).
6. The clinician should attempt for a duration of treatment that is as short as possible. (Prolonged treatment with these agents is usually unacceptable.)

on the basis of culture and susceptibility testing and because of the lack of any appropriate first-line options. These include piperacillin-tazobactam, amikacin, and third-generation cephalosporins. Some consensus documents (e.g., ISCAID guidelines, BSAVA guidelines) have considered some third-generation cephalosporins as appropriate first-line agents in special circumstances. Cefovecin may be considered when compliance may be a problem. Cefpodoxime proxetil has been considered by ISCAID to be either a "first- or second-tier" antibiotic because of its activity against staphylococci. Fluoroquinolones are usually considered second-tier antibiotics because fluoroquinolone exposure has been associated with emergence of antimicrobial resistance and treatment failures.[20] Fluoroquinolones could be considered as first-line drugs for dogs and cats suspected to have serious gram-negative bacterial infections that require treatment pending the results of culture and susceptibility testing.

The use of third-line drugs, including vancomycin, linezolid, rifampin, human-labeled third-generation cephalosporins (e.g., ceftazidime), and carbapenems such as imipenem and meropenem, is usually reserved for situations when certain criteria are met (Box 8.2).[19]

PHARMACODYNAMICS OF ANTIMICROBIAL DRUGS

Pharmacokinetic and pharmacodynamic parameters (PK-PD exposure relationships) are important determinants of the efficacy of AMDs and serve as the basis for determination of clinically effective dosage regimens and susceptibility breakpoints and for the development of guidelines for AMD use for specific types of infections.[21]

Antimicrobial activity is classified as *concentration dependent* or *time dependent*. AMDs that exhibit *concentration-dependent killing* are fluoroquinolones and aminoglycosides. These drugs work optimally when the peak concentration in the plasma (C_{max}) or the area under the curve (AUC) exceeds the MIC by a defined index factor (Fig. 8.2). These are typically bactericidal agents, and the ability to kill bacteria increases as the AMD concentrations are optimized. Target concentrations have been defined for laboratory animals and humans and have been extrapolated to veterinary patients. For example, the C_{max} to MIC ratio (C_{max}/MIC) should exceed 8 to 10 for optimum dosing of aminoglycosides. The AUC for a 24-hour interval to MIC ratio (AUC_{24}/MIC) should exceed approximately 100 for fluoroquinolones and exceed 90 for aminoglycosides. For some infections, a ratio of 125 for fluoroquinolones is better, and

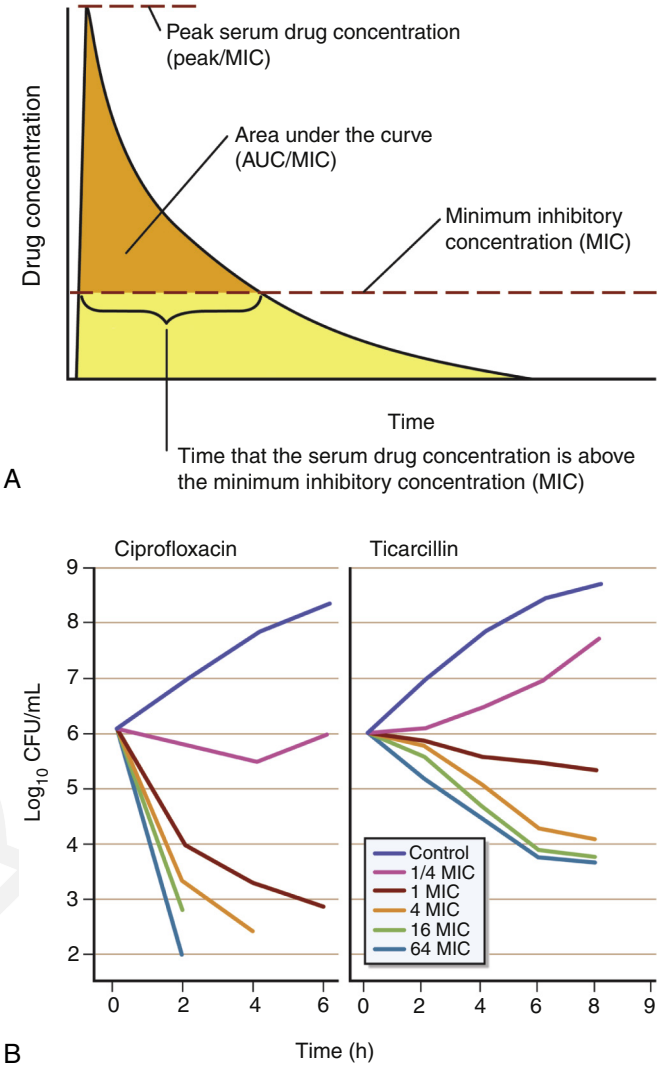

Fig. 8.2 Antimicrobial pharmacodynamics. (A) Antimicrobial drug (AMD) pharmacodynamics. Concentration-dependent drugs are most active when the peak concentration (C_{max}) or the area under the curve (AUC) in the plasma exceeds the MIC by a defined factor. For time-dependent drugs, outcome is correlated with the time that the AMD concentration at the site of infection spends above the MIC. This is usually expressed as the percent of time above the MIC during a 24-hour interval (T > MIC). (B) As AMD concentrations increase, the ability of concentration-dependent drugs such as fluoroquinolones (in this case, ciprofloxacin) to kill bacteria increases. As concentrations of time-dependent drugs such as β-lactam drugs (in this case, ticarcillin) increase, bacterial killing plateaus.

in some patients (e.g., immunocompromised patients with life-threatening infections), a ratio of 250 may be desirable. Drugs that exhibit concentration-dependent killing also have *postantibiotic effect* (PAE). The PAE is a persistent antimicrobial effect after drug concentrations at the site of infection fall below the MIC. The exact cause of the PAE varies with the drug, but it may result from irreversible binding of a drug to the target site. The duration of the PAE is influenced by the duration of antibiotic exposure, the drug concentration, the bacterial species present, and the class of antibiotic. For concentration-dependent antibiotics, administration of the total daily dose as a single dose every 24 hours is preferred to a

smaller divided dose in order to maximize C_{max} or AUC. For aminoglycosides, this also reduces risk of kidney injury.

β-lactams (penicillins and cephalosporins) exhibit *time-dependent killing*. The activity of these drugs is maximized by the time above the MIC rather than the magnitude of the concentration. This is usually expressed as the percent of time above the MIC during a 24-hour interval (T > MIC). These drugs are most effective when administered multiple times a day or as continuous-rate infusions, in order to maintain drug concentrations at the site of infection. For some drugs (e.g., some cephalosporins), a long T > MIC is achieved by virtue of a long half-life. The required time above the MIC for an AMD varies with the pathogen present, the drug, and the site of infection. For a β-lactam antimicrobial (penicillin, cephalosporin), the desired target is a plasma concentration greater than the MIC maintained for at least 40% to 50% of the dosing interval.[21] Drug dosages that achieve these target concentrations in excess of an MIC for these periods can be calculated based on pharmacokinetic data. For time-dependent AMD with long half-lives (such as macrolides, clindamycin, vancomycin, and tetracyclines), efficacy is determined primarily by the extent to which the AUC exceeds the MIC. The magnitude of the target varies with each drug class, but in general an AUC/MIC ratio of the unbound drug > 25 is a desired target.

These parameters and indices constitute the PK-PD properties of the antimicrobial agent, also known as the PK-PD cutoff. As the MIC of an organism increases, it becomes more difficult to achieve these PK-PD targets (i.e., above the PK-PD cutoff), and organisms are regarded as resistant.

SITE OF INFECTION

In general, the concentration of an AMD at the site of infection should at least equal the MIC for the infecting organism, but the exact concentration and the duration of the concentration at the site varies with the class of antimicrobial. For some AMDs, the serum or plasma total (bound and unbound) drug concentrations may not reflect the drug concentration in tissues. Examples are the highly lipophilic macrolide antibiotics (e.g., azithromycin) for which the tissue drug concentration is much higher than plasma drug concentration because of sequestration inside cells. On the other hand, tissue concentrations greatly underestimate the plasma or serum drug concentration for poorly lipophilic agents such as aminoglycosides or β-lactams. Antimicrobial selection for different body sites are suggested in Box 8.3.

The concentration of an AMD at the site of infection is affected by factors such as lipid solubility, protein binding, pH at the site (or cell), and other factors reducing permeability, such as the presence of large amounts of pus, scar tissue, foreign material, devitalized tissue, and bone. Lipid-soluble drugs such as chloramphenicol, rifampin, fluoroquinolones, tetracyclines, and trimethoprim are most adept at crossing membranes, including the blood-brain, alveolar, and prostatic barriers. In contrast, poorly lipophilic, polar drugs such as penicillins and aminoglycosides do not cross lipid membranes and will not achieve adequate concentrations in tissues in which there is a barrier to penetration (e.g., prostate, brain, eye, or intracellular sites). In human patients, aminoglycosides and amphotericin B have been administered intrathecally to treat CNS infections,[22,23] but this is a rare treatment in veterinary medicine. In order to use β-lactam antibiotics to treat these infections, high doses are required because of a poorly penetrated blood-brain barrier. Even in the face of inflammation, the brain/blood concentration ratio of these drugs is low. Water-soluble AMDs are excreted in active form by the liver and concentrated in bile, such as tetracyclines, aminopenicillins, and cephalosporins; therefore, they are acceptable choices for susceptible hepatobiliary infections (see Chapter 126). Lower urinary tract infections can be successfully treated with drugs such as amoxicillin, amoxicillin-clavulanate, cephalosporins, and trimethoprim-sulfonamides, because these agents are highly concentrated in the urine of animals with healthy kidneys (see Chapter 127).

BOX 8.3 Examples Of Appropriate Initial Antimicrobial Drug Choices For Treatment Of Bacterial Infections In Different Anatomic Sites

Site	Appropriate Empiric Antimicrobial Drugs
Skin	Cephalexin
	Amoxicillin-clavulanate
	Clindamycin
Urinary tract	Amoxicillin
	Amoxicillin-clavulanate
	Cephalosporins
	Trimethoprim-sulfamethoxazole
Prostate	Trimethoprim-sulfamethoxazole
	Fluoroquinolones (enrofloxacin, marbofloxacin, orbifloxacin, levofloxacin)
Respiratory tract	Tetracyclines (doxycycline, minocycline)
	Fluoroquinolones
Intestinal tract (animals with hepatic encephalopathy)	Ampicillin
	Neomycin
Biliary tree	Amoxicillin-clavulanate
	Cephalosporins
	Fluoroquinolones
Brain	Metronidazole (anaerobes only)
	Fluoroquinolones
	Trimethoprim-sulfonamides
Bone	Clindamycin
	Cephalosporins
	Amoxicillin-clavulanate

OTHER HOST FACTORS

Other host factors that should be considered in AMD selection and route of administration include the following:

1. History of adverse drug reactions. These are most commonly gastrointestinal in dogs and cats, but may include hypersensitivity reactions. Examples include trimethoprim-sulfonamides and penicillins.
2. Age. The administration of systemic tetracyclines is contraindicated in young animals because of the potential for teeth discoloration (see Fig. 10.5). Doxycycline is less likely to produce this reaction if administered for a short course. Fluoroquinolones have the potential to cause cartilage and joint toxicity in dogs aged between 7 and 28 weeks.[24,25]
3. Species. Dogs and cats differ in their susceptibility to adverse drug reactions. For example, dogs can develop severe cutaneous reactions to 5-flucytosine. Dogs are the species most susceptible to adverse reactions to sulfonamides (see #4 below). Cats are susceptible to acute retinal degeneration following treatment with enrofloxacin doses above 5 mg/kg. Cats also are prone to esophageal ulceration from oral doxycycline hyclate or clindamycin hydrochloride. To avoid this effect, these drugs can be administered with a bolus of water or food to ensure passage of the medication into the stomach.

4. Sulfonamides. Dogs are the species most susceptible to reactions from sulfonamides (including trimethoprim-sulfonamides) because of an inability to acetylate the parent drug for elimination. Subsequently, some breeds of dog convert the drug to a cytotoxic metabolite that produces hypersensitivity-like reactions following trimethoprim-sulfonamide administration. Doberman pinschers may be at higher risk for this problem. Keratoconjunctivitis sicca (dry eye) is also a risk when administering sulfonamides to dogs.
5. Gastric acidity. The absorption of some AMDs, such as ketoconazole and itraconazole, is impaired by medications that suppress gastric acid production.
6. Concurrent medications. Drug interactions, such as concurrent use of drugs that require metabolism using cytochrome P450 enzymes, can affect the choice or dose of AMD used. For example, chloramphenicol and ketoconazole are well-known P450 enzyme inhibitors, whereas rifampin is an enzyme inducer. Fluoroquinolone and tetracycline antibiotics can chelate with divalent and trivalent cations, which inhibits oral absorption. Therefore, administration of these drugs with supplements containing aluminum, iron, magnesium, or calcium can diminish oral absorption.
7. Pregnancy. Penicillins, cephalosporins, aminoglycosides, and macrolides are generally considered safe during pregnancy. The volume of distribution in pregnancy is greater, and so higher doses may be required to achieve equivalent serum concentrations. On the other hand, azole antifungals, griseofulvin, and trimethoprim-sulfonamides carry risks during pregnancy.
8. Renal and hepatic function. The dose of AMDs that are dependent on renal elimination may require reduction in these animals with impaired renal function in order to minimize toxicity. For example, fluoroquinolones may be more likely to cause seizures or retinal toxicity in animals with kidney disease. The use of nephrotoxic drugs such as amphotericin B or aminoglycosides may be more likely to worsen kidney injury (and should be avoided) in animals with kidney disease.[26] Adverse effects may be more common when drugs that require hepatic metabolism, such as azole antifungals, metronidazole, rifampin, sulfonamides, or chloramphenicol, are administered to animals with impaired liver function.

ROUTE OF ADMINISTRATION

The most common routes of administration for AMDs in dogs and cats are topical, intravenous, intramuscular, subcutaneous, and oral. For localized infections of the skin, eye, or ear canal, topical administration has the advantage of delivering a high concentration of the AMD to the site, which may overcome bacterial resistance mechanisms and minimize systemic exposure to the drug. Parenteral administration, especially intravenous administration, provides maximum bioavailability when there may be questions regarding oral absorption or when oral medications must be avoided. This route is recommended for: (1) treatment of life-threatening infections, (2) systemic administration of antimicrobials with poor oral bioavailability (such as aminoglycosides and some injectable β-lactam antibiotics), and (3) when gastrointestinal signs or malabsorption preclude effective drug administration via the oral route. Because parenteral AMDs are generally administered in hospital, compliance with this mode of administration is also likely to be greater. Absorption may be delayed after subcutaneous or intramuscular administration when perfusion of these tissues is impaired; therefore, these routes are avoided unless the patient is well hydrated and tissues are well perfused. Peak plasma drug concentrations are achieved immediately after intravenous bolus administration. Therefore, bolus administration is an optimum approach for a concentration-dependent antimicrobial provided rapid injection does not produce toxicity (such as may occur with fluoroquinolones). For a time-dependent drug such as a β-lactam, a slow infusion, or a constant rate infusion (CRI) optimizes the time-dependent activity and can improve the outcomes in animals with severe infection.

Provided gastrointestinal function is healthy, administration of many oral AMDs results in acceptable bioavailability. For drugs that have oral absorption less than 100%, the low absorption is accounted for in the adjustment of the dosage regimen. However, it should be remembered that when oral absorption is low, more active drug remains in the intestine and may alter the intestinal bacterial population. Drugs with the highest oral bioavailability in dogs and cats are the fluoroquinolones; β-lactams have low and variable bioavailability depending on the drug. Nevertheless, once the animal can tolerate oral medications and its clinical condition becomes stable, a switch can be made from parenteral to oral antimicrobials. Peak plasma concentrations are always lower with oral administration than with intravenous administration, but for time-dependent drugs or for drugs that achieve efficacy on the basis of an AUC/MIC exposure relationship, this route is acceptable for a cure. Early switch from intravenous to oral therapy in human patients has gained increased favor in recent years because of reduced lengths of hospitalization, lowered costs, fewer intravascular catheter-related infections, and decreased selective pressure on nosocomial bacterial infections.[27–29] The oral bioavailability of some drugs can be maximized if they are administered with food (e.g., clavulanic acid-amoxicillin) or without food (e.g., azithromycin, tetracyclines). Some drugs are simply not absorbed orally and must be administered parenterally or by the topical route. These drugs include penicillin G, piperacillin, aminoglycosides, many cephalosporins (cefazolin, cefotaxime, cefoxitin), meropenem, imipenem, and vancomycin. Some drugs are not absorbed orally unless administered as a prodrug. An example is cefpodoxime proxetil. The proxetil portion of the molecule is cleaved off at the time of intestinal absorption to allow for adequate systemic concentrations.[30]

ANTIMICROBIAL RESISTANCE

Infectious agents may be intrinsically resistant to an AMD, or acquire resistance through genetic variations. *Intrinsic resistance* refers to the innate ability of an organism to resist the effects of an AMD owing to structural or functional characteristics of that organism. For example, enterococci are intrinsically resistant to cephalosporins because they lack the PBPs that bind these antibiotics.[31] Anaerobic bacteria are intrinsically resistant to aminoglycosides because oxygen is required for entry of the drug to the bacteria. Bacteria of the Enterobacterales (for example *E. coli* and *Enterobacter*) are intrinsically resistant to macrolide antibiotics. Mycoplasmas have intrinsic resistance to penicillins because they lack a cell wall. A list of *Intrinsic Resistance* is available in Appendix B of the CLSI VET01 document[32] and laboratories may use this information to avoid testing some drug-bacteria combinations.

Bacterial resistance should not be defined by whether they are *wild-type* or *non-wild-type bacteria.* Wild-type strains of bacteria are those that have an absence of acquired and mutational resistance mechanisms. Non-wild-type strains of bacteria are those that have the presence of an acquired or mutational resistance mechanism to the drug in question. Wild-type strains may include bacteria that have inherent resistance to antimicrobials as described above. However, clinical resistance, as defined below, is a measure of the bacteria to respond to clinically achievable drug concentrations. Wild-type bacteria can be clinically resistant (e.g., Enterobacterales are resistant to aminopenicillins), and non-wild-type bacteria can be susceptible to some antibacterial agents.

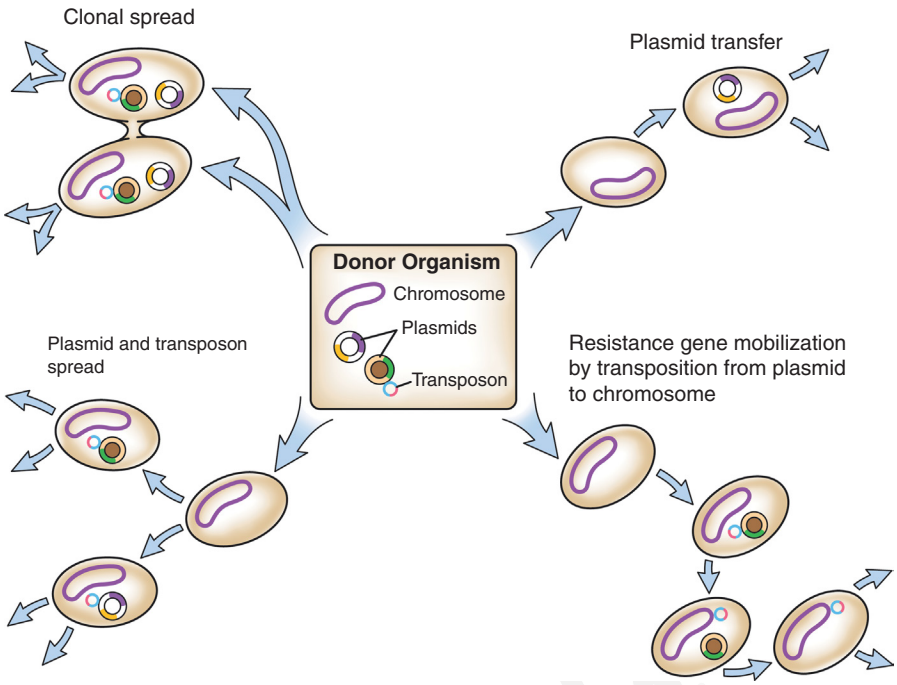

Fig. 8.3 Genetic mechanisms of resistance in bacteria.

The definition of *resistance* (or *clinical resistance)* used by CLSI relies on PK-PD cutoff targets, MIC distributions (wild-type cutoff), and clinical response (clinical cutoff). If sufficient drug concentrations can be achieved to attain a clinical cure—even in some cases when the bacteria are non-wild-type—the bacteria can be considered "susceptible." On the other hand, if drug concentrations after a standard dose cannot meet the PK-PD target defined for that drug-bug combination, the bacteria are reported as "resistant." In other words, the pathogen is considered resistant when standard dosage regimens cannot reach the PK-PD target of a particular C_{max}, AUC, or time above MIC.

Genetic resistance to an AMD may occur as a result of point mutations, DNA rearrangements, or acquisition of foreign DNA. Point mutations can result in alteration of the target site of an AMD, such as the susceptibility of bacterial DNA gyrase to fluoroquinolones.[33] DNA rearrangements may include inversions, deletions, duplications, insertions, or transpositions (including chromosome to plasmid) of large segments of DNA. The single most important mechanism of antibacterial resistance is acquisition of foreign DNA by horizontal transfer, especially that carried by plasmids and transposons.[34] Plasmids are circular, double-stranded DNA molecules that are capable of independent replication and can be transferred from one bacterial strain or species to another through the process of bacterial conjugation. Transposons are small, mobile segments of DNA that are flanked by inverted repeats and encode one or more resistance genes (Fig. 8.3). They depend on the chromosome or plasmids for replication. Plasmid-associated genes that confer AMD resistance are frequently on transposons and can move from the plasmid to the bacterial chromosome. A single plasmid may contain resistance genes for more than five different AMDs and represents an important mechanism for rapid spread of resistance genes among bacterial populations, including from one bacterial species to another.

Mechanisms of Antimicrobial Resistance

Antimicrobial Inactivation

Bacterial enzymes capable of inactivation of AMDs include β-lactamase enzymes, enzymes that modify aminoglycoside structure, chloramphenicol acetyltransferase, and macrolide (erythromycin) esterase. β-lactamase production is ubiquitous among *Staphylococcus* spp., and these enzymes hydrolyze penicillins and aminopenicillins, but not cephalosporins. β-lactamases are the most important mechanism of resistance to β-lactam antibiotics among gram-negative bacteria.[34] A vast array of β-lactamase enzymes have been discovered, which have been extensively classified into groups.[35,36] ESBLs can hydrolyze not only penicillins and first-generation cephalosporins, but also extended-spectrum cephalosporins such as cefotaxime and ceftazidime (which contain an oximino group). To date, ESBLs have only been described in gram-negative bacilli and are most commonly produced by *E. coli* and *K. pneumoniae*. Some, but not all, ESBLs can be inhibited by β-lactamase inhibitors such as clavulanic acid. The ESBL with the most importance at the present time for small animals are the CTX-M β-lactamases, which hydrolyze cefotaxime and other third-generation cephalosporins. Other types of β-lactamase enzymes include AmpC β-lactamases, which are encoded by chromosomal genes, and metallo-β-lactamases.[34,37] These types of β-lactamase enzymes are resistant to clavulanic acid. The most recent and alarming development has been the discovery of metallo-β-lactamases that can inactivate carbapenems such as meropenem and imipenem. These *carbapenemases* render the bacteria resistant to practically all available antibiotics.

Membrane Alteration

Protein channels called *porins* facilitate the passage of hydrophilic AMDs into gram-negative bacteria. Acquisition of porin mutations can result in conformational changes of or reduced expression of porins. The result is exclusion of AMDs such as β-lactams and fluoroquinolones.[38]

Efflux Pump Induction

Expression of efflux pumps by bacteria allows them to exclude certain AMDs. This is a major mechanism of resistance to tetracyclines in gram-negative bacteria. A variety of efflux pumps have been described.[39] Efflux pumps may not be specific for one particular class of antimicrobial; in other words, one MDR bacterial species can "pump" out

different classes of drugs. Therefore, these have been termed "multidrug" efflux pumps and mediate multidrug resistance. The acquisition of MDR mechanisms greatly reduces the effective options for therapy. MDR organisms such as *P. aeruginosa* and *Acinetobacter baumannii* can utilize multidrug efflux pumps in concert with a variety of other resistance mechanisms, including β-lactamase enzyme production, drug target alterations, and AMD modification enzymes.

Target Modification

Methylation of ribosomal targets by bacterial methyltransferases can lead to resistance to tetracyclines, lincosamides, aminoglycosides, and especially macrolide antibiotics. Expression of altered PBPs is an important mechanism of resistance to β-lactam antimicrobials. Expression of PBP2a by staphylococci, which is encoded by the *mecA* gene, confers resistance to all β-lactam antimicrobials, including β-lactamase-resistant penicillins such as methicillin and oxacillin (methicillin-resistant staphylococci). Mutations of DNA gyrase can confer resistance to fluoroquinolones.[34] Resistance to trimethoprim-sulfonamides can result from altered dihydropteroate synthetase and dihydrofolate reductase enzymes.[40]

Target Protection

Target protection[41] is another mechanism of conferring resistance that serves a similar purpose as target modification. Target protection mechanisms are best known for tetracycline antibiotics; they can confer resistance to chloramphenicol and related drugs, oxazolidinones, fluoroquinolones, and others. In target protection, the target is not modified; instead, a target protection protein binds to the target to prevent the antibiotic from inhibiting the target mechanism.

Novel Approaches to Antimicrobial Drug Resistance

With rapid spread of MDR bacterial pathogens, alternatives to antibiotics have been investigated.[42] One approach is bacteriophage therapy. Bacteriophages are viruses that infect bacteria, and because of their specificity for certain bacterial species, they can deliver targets to one type of organism without harming others.[43,44] Bacteriophage infections may result in bacterial lysis, or delivery of a gene to the bacterial cell that increases its susceptibility to a given class of AMD.[42] Bacteriophage treatment may also be more successful than AMD treatment in the presence of biofilms, which impair antibiotic penetration. Barriers to implementation of phage therapy include the host immune response to the phage, bacterial resistance mechanisms, and uncertainties relating to dosing and the impact of other unidentified genes that might be present in bacteriophages. Other approaches that are under investigation include use of bacterial lysins, cationic antimicrobial peptides, antisense antibiotics, and antibacterial antibodies.[42] Bacterial lysins are derived from bacteriophages and are active only on gram-positive bacteria. Cationic antimicrobial peptides are derived from eukaryotic cells, have immunomodulatory properties, and rapidly kill a variety of bacteria.[45] Although it is difficult for bacteria to develop resistance to these peptides, multiple resistance mechanisms have been described. Antisense antibiotics are oligonucleotides that bind to the DNA of pathogenic microorganisms and inhibit gene expression.[46]

ANTIMICROBIAL DRUG COMBINATIONS

When an infectious agent is suspected but has not yet been identified, the use of AMD combinations is tempting because of the added broad spectrum of coverage that they provide. However, use of AMD combinations does not necessarily reduce the chance of selection for a resistant organism, adds expense, and may predispose to drug toxicity. Theoretically, drug combinations may have additive, synergistic, or antagonistic effects (Fig. 8.4). These properties are not as well established in clinical situations. For example, antagonism between

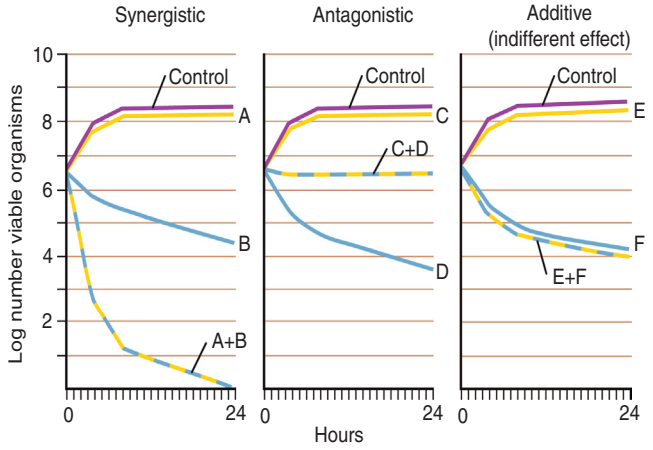

Fig. 8.4 Synergistic, antagonistic, and additive effects of antimicrobial drug combinations. Drugs used are referred to using letters of the alphabet. Control = no drug.

a bacteriostatic antibiotic (e.g., tetracycline) and a bactericidal antibiotic that requires bacterial growth for efficacy (e.g., a β-lactam) is also theoretically possible, but there is only one clinical example of this occurrence, published in the 1950s.[47] Such antagonism has not been replicated since that time.

The use of antibiotic combinations may be justified in some scenarios, such as:

1. Some drugs are administered in combination with other drugs to prevent rapid development of resistance compared with the use of a single agent. Examples are 5-flucytosine for antifungal treatment and rifampin in combination with macrolides for treatment of *Mycobacterium* spp. infections.
2. If a polymicrobial infection is present, combination drugs broaden the spectrum of activity.
3. If the nature of an infection is not known and infection is life threatening, it is reasonable to commence treatment with a broad-spectrum combination (e.g., a fluoroquinolone and a β-lactam), based on knowledge of the likely pathogen present and local prevalence of AMD resistance, pending the results of culture and susceptibility testing. Once the results of culture and susceptibility testing are available, de-escalation should be performed.
4. Certain combinations of AMD are synergistic for treatment of specific infections. For example, the combination of a β-lactam and an aminoglycoside may be synergistic for treatment of enterococcal infections, but not likely helpful for other infections. The relatively slow bactericidal activity of the β-lactam is enhanced by the addition of the aminoglycoside, such that shorter durations of treatment or extension of the dosing interval becomes possible without affecting outcome.[18] Combination therapy has been recommended for treatment of resistant *P. aeruginosa* infections, brucellosis, gastric helicobacteriosis, and some mycobacterial infections..
5. Some drugs are not effective against anaerobic bacteria (e.g., aminoglycosides and fluoroquinolones with the exception of pradofloxacin). They should be combined with an agent active against anaerobes (e.g., clindamycin or metronidazole) when a mixed infection with anaerobic and aerobic bacteria is suspected.
6. When a vector-borne pathogen is suspected, doxycycline may be administered until the results of further diagnostic tests confirm or eliminate this suspicion. In these cases, patients are frequently administered doxycycline in combination with another active agent to treat alternative bacterial infections that have not yet been ruled out.

MONITORING THE RESPONSE TO TREATMENT

The response to antimicrobial treatment is best monitored based on clinical assessment, which may include follow-up cytologic examination or cultures. However, in some situations such as bacterial cystitis, follow-up cultures are not recommended because the aim of AMD therapy is clinical cure rather than microbiological cure. Therapeutic drug monitoring can be used to ensure adequate serum drug concentrations when treating with aminoglycosides, vancomycin, and azole antifungal drugs, but these assays are rarely available in commercial veterinary diagnostic laboratories. Veterinary clinicians can check with local laboratories (e.g., human laboratories) to locate the availability of these assays in their area. It should be remembered that reference ranges for these laboratories are established from the human use of these drugs; veterinary therapeutic ranges are not established.

PROPHYLACTIC ANTIMICROBIALS

Prophylactic use of AMDs to prevent anticipated infections is controversial because of the increased risk of selecting for resistant microorganisms. In general, prophylactic AMD use is discouraged, with the exception of perioperative AMD therapy to prevent surgical infections when contamination is expected, treatment of deep bite wounds, and following chemotherapy when moderate to severe neutropenia develops (<1000 neutrophils/μL).[48] When used perioperatively to prevent surgical infections (e.g., orthopedic surgery) the administration should be as short as possible—rarely is there a need to extend the administration beyond the duration of the surgical procedure. For cancer chemotherapy prophylaxis, treatment for 3 to 7 days has been recommended if severe neutropenia is identified. Although more controversial, antimicrobial prophylaxis has also been suggested following chemotherapy in patients with a high risk of sepsis, including small breed dogs, those with hemic malignancy, and those treated with vincristine or doxorubicin.[48] In one prospective study, dogs administered trimethoprim-sulfadiazine following treatment of osteosarcoma or lymphoma with doxorubicin had significantly reduced hospitalization rate, nonhematologic toxicity, and gastrointestinal toxicity when compared with dogs that did not receive prophylactic antimicrobials.[49] Use of prophylactic antimicrobials for clean surgeries, routine elective surgery, dental procedures (in the absence of abscessation), and following placement of urinary catheters is strongly discouraged.

Antiviral Chemotherapy and Immunomodulatory Drugs

Katrin Hartmann, Jane E. Sykes, Mark G. Papich

KEY POINTS

- Most antiviral drugs available for treatment of feline and canine viral infections are nucleoside analogues with greatest activity against retroviruses, herpesviruses, and coronaviruses.
- Antiviral drugs also affect the function of host cell machinery; therefore, they have considerable potential for toxicity.
- Antiviral drugs are widely used in human medicine for treatment of HIV, herpesvirus infection, and other viral infections. Much less is known about these medications in cats and dogs, and there are only few diseases of cats and dogs for which efficacy has been demonstrated.
- There are important differences between human and animal virus infections; therefore, it should not be assumed that the use of an antiviral agent in humans can be translated to a use in animals unless there is evidence of safety and efficacy.
- The most common indication for antiviral drugs in animals is treatment of FHV-1 infections with famciclovir and cidofovir. Zidovudine, an antiretroviral drug, has been used to treat FIV and FeLV infections. In addition, new antiviral drugs are now used to treat FIP.
- Antiviral drugs can act synergistically with immunomodulatory agents.
- Immunomodulators include microbial products, plant-derived immunomodulators, naturally occurring mammalian proteins, and synthetic drugs. The effect of many of these drugs on outcome in cats and dogs with infectious diseases has not been fully evaluated with well-designed studies.
- The parenteral use of natural or recombinant human cytokines in cats and dogs can produce neutralizing antibodies after 1 to 2 weeks of treatment, which can cross-react with endogenous proteins.
- Antiviral treatments are intended to suppress viral entry, multiplication, or transmission. Some of these antiviral agents can produce a remission or assist the patient's immune system to limit the course of the viral disease.

INTRODUCTION

This chapter describes the antiviral and immunomodulating agents used in cats and dogs. Unfortunately, there are limited approvals of drugs for these indications, and their use has relied on *in vitro* and *in vivo* studies, which have produced variable success. Only those drugs currently approved in the United States or Europe for use in animals or humans are discussed in this chapter with few exceptions of promising experimental drugs.

ANTIVIRAL DRUGS

Antiviral drug administration is still relatively uncommon in veterinary medicine, and the number of controlled studies of the efficacy of these drugs is limited. In contrast to antibacterial, antifungal, or antiprotozoal therapy, antiviral drugs are *virustatic*, that is, they do not inactivate viruses or achieve elimination of the virus. The benefit of these agents is to limit the spread of the virus, shorten duration of clinical signs, or improve patient well-being. Diagnosis of viral infections is often made after the viral replicative phase; thus, antiviral drugs are commonly used to treat chronic viral infections and to prevent reactivation of latent infections.

Antiviral drugs depend on host cell activity for their action. Subsequently, adverse effects in treated patients can be common, and many antiviral drugs active *in vitro* are not commercially available for this reason. Many others can only be given topically to avoid systemic toxicity. With the exception of feline interferon (IFN)-ω (not available in the United States), no antiviral drugs are specifically licensed for use in dogs and cats. Many human antiviral drugs were developed to treat HIV infection. Some of these compounds have activity against FIV, and sometimes FIV treatment studies were conducted to screen new compounds before their use in HIV-infected patients. Feline herpesvirus-1 (FHV-1) infection can be treated with several topical antiviral drugs (Table 9.1) and one promising oral compound.[1,2] New compounds for treatment of FIP are promising and undergoing evaluation (see Chapter 31).[3–5]

Some drugs used to treat FIP have been used investigationally or repurposed for investigations to treat humans with COVID-19 caused by SARS-CoV-2. A list of these agents are provided in Table 9.2. In dogs, treatment of viral infections is mainly supportive, and antiviral drugs are rarely used.

Antiviral drugs can be assigned to different drug classes based on the stage(s) of virus replication they interfere with (Table 9.3).[6,7] Potential targets in the retroviral replication process for antiviral drugs include binding of virus to specific cell surface receptors, entry into the cell and uncoating of the virus, reverse transcription of viral genome, integration of proviral DNA into host genome, viral protein processing, virion assembly and maturation, and virion release.[6,8,9] Combinations

TABLE 9.1 Antiviral Drugs in Use in Small Animals

Antiviral Drug	Mechanism Of Action	Human Applications	Small Animal Applications
Acyclovir/valacyclovir	Guanosine analogue. Interferes with viral DNA polymerase and DNA synthesis. Activity requires viral TK.	Treatment of herpesvirus infections, especially HSV and varicella-zoster virus	FHV-1 infections (poorly effective)
Penciclovir/famciclovir		Treatment of herpesvirus infections, especially HSV and varicella-zoster virus	FHV-1 infections
Cidofovir	Deoxycytidine monophosphate analogue. Activity independent of viral TK.	Systemic treatment of cytomegalovirus retinitis; topical treatment of papillomavirus infections	Topical treatment of FHV-1 ocular infections
Idoxuridine	Iodinated thymidine analogue. Interferes with viral DNA synthesis.	Topical treatment of HSV keratoconjunctivitis	Topical treatment of FHV-1 ocular infections
Trifluridine	Fluorinated thymidine analogue. Interferes with viral DNA synthesis.		
Vidarabine	Adenosine analogue. Interferes with viral DNA synthesis.		
Zidovudine	Thymidine analogue. Interferes with reverse transcription of virus RNA to DNA.	Systemic treatment of HIV infections	Systemic treatment of FIV and FeLV infections

FeLV, feline leukemia virus; *FHV-1,* feline herpesvirus-1; *FIV,* feline immunodeficiency virus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *TK,* thymidine kinase.

TABLE 9.2 Drugs of Clinical Interest in Veterinary Medicine Investigated for Treatment of Human Patients with COVID-19

Drug	Comment
Remdesivir	Although remdesivir has not been used in animals, it is chemically similar to the investigational antiviral drug GS-441524, which has been investigated for treating FIP.
Dexamethasone	Widely used corticosteroid anti-inflammatory medication in veterinary medicine. In human patients with COVID-19, it improves outcomes in severe cases by decreasing lung inflammation. It is commonly used as supportive treatment for FIP.
Hydroxychloroquine and chloroquine	Used on a limited basis in animals to treat some protozoal infections. Controversial results in patients with COVID-19.
Azithromycin	Often used in dogs and cats to treat bacterial infections (see Chapter 10). In human patients with COVID-19, the effects are controversial. NIH recommends against the use of hydroxychloroquine plus azithromycin, except in the context of a clinical trial, because of the potential for toxicities.
Ivermectin	Widely used antiparasitic agent in dogs and cats and a heartworm preventative. Theoretical potential for treatment of COVID-19 based on intracellular mechanisms, but concentrations achieved in patients with standard doses are not high enough to produce antiviral effects.
Famotidine	Widely used agent in dogs and cats to treat gastric problems exacerbated by high acidity. Investigated as a treatment for patients with COVID-19, but the mechanism of action is unknown.
Ascorbic acid (Vitamin C)	Antioxidant properties might protect host cells against infection-induced oxidative stress and can help host defenses against infection. NIH guidelines state there are insufficient data to recommend for or against use of vitamin C in noncritically ill patients or in critically ill patients.
Vitamin D	Used in some patients with COVID-19, but vitamin D supplements have not been shown to prevent or treat COVID-19.

FIP, feline infectious peritonitis; NIH, National Institute of Health.

of antiviral drugs with different mechanisms of action and combinations that include immunomodulatory drugs are increasingly used to treat human viral infections. For example, most HIV infection protocols consist of a combination of drugs that allows for a decrease in toxicity and reduction in selection for resistant mutants. Experience with combination treatment in cats and dogs is limited.

Nucleoside Reverse Transcriptase Inhibitors

The retroviral enzyme reverse transcriptase transcribes viral RNA into proviral DNA, which is subsequently integrated into the host cell's genome.[10] Compounds that inhibit this step have become the cornerstone of successful anti-HIV therapy. Reverse transcriptase inhibitors can be divided into three categories: nucleoside reverse transcriptase inhibitors (NRTIs), nucleotide reverse transcriptase inhibitors (NtRTIs), and non-nucleoside reverse transcriptase inhibitors (NNRTIs). Of these, NRTIs are the most commonly used drugs in human medicine.

NRTIs are analogues of mammalian 2′-deoxynucleosides and inhibit the polymerase function of the retroviral reverse transcriptase enzyme. Nucleosides are building blocks for the formation of DNA or RNA that are composed of a nitrogenous base and a five-carbon sugar (ribose or deoxyribose; Fig. 9.1). Like natural nucleosides, NRTIs must first be converted to a 5′-triphosphate form (nucleotide) through phosphorylation. In this form, they compete with host nucleotides and are incorporated into the elongating proviral DNA strand, thus functioning as competitive substrate inhibitors. However, NRTIs lack a 3′-hydroxyl group on the deoxyribose moiety, and this leads to strand termination as the subsequent nucleotide cannot form the next 5′-3′ phosphodiester bond necessary

TABLE 9.3 Classification of Antiviral Drugs

Category/Stage Of Replication Inhibited	Subcategory	Examples
Reverse transcriptase inhibitors	Nucleoside reverse transcriptase inhibitors	Zidovudine, fozivudine, didanosine, stavudine, zalcitabine, lamivudine, decitabine, gemcitabine
	Nucleotide reverse transcriptase inhibitors	Adefovir, tenofovir
	Non-nucleoside reverse transcriptase inhibitors	Suramin
DNA or RNA synthesis inhibitors	Nucleoside analogue DNA/RNA synthesis inhibitors	Acyclovir, valacyclovir, penciclovir, famciclovir, ganciclovir, cidofovir, idoxuridine, trifluridine, vidarabine, GS-441524, remdesivir
	Nucleotide synthesis inhibitors	Foscarnet, ribavirin
Protease inhibitors (maturation)		Nelfinavir, GC376
Entry inhibitors (virus attachment)	Receptor blockers Fusion inhibitors	Plerixafor
Integrase inhibitors (integration of proviral DNA)		Raltegravir
Nucleocapsid inhibitors (maturation)		Fused tetrathiocines, bis[1,2]dithiolo[1,4]thiazines and bis[1,2]dithiolopyrrole derivatives, 5-thieno-, 5-oxo-, 5-imino-1,2,3-dithiazole derivatives
Neuraminidase inhibitors (extrusion)		Oseltamivir, zanamivir, peramivir
Ion channel blockers (uncoating)		Amantadine
Antiviral amino acids		L-lysine

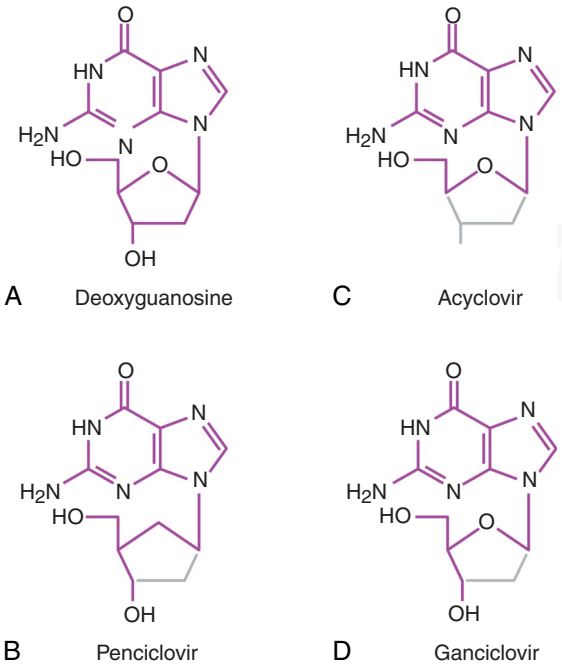

Fig. 9.1 Chemical structures of deoxyguanosine (a nucleoside) and antiherpesviral nucleoside analogues. The grey portion is missing in the nucleoside analogues. (A) Deoxyguanosine. (B) Penciclovir. (C) Acyclovir. (D) Ganciclovir.

to extend the DNA strand. Latent viral infections are not affected because the replication of latent virus is suspended. However, reactivation of these infections can be prevented or reduced in frequency. Many NTRIs have documented *in vitro* activity not only against HIV but also against FIV, including zidovudine,[11,12] stavudine,[12–15] didanosine,[12,14] and zalcitabine.[14,16] To date, only zidovudine (AZT) has shown evidence of *in vivo* activity against feline retroviral infections with acceptable toxicity. Fozivudine, didanosine, stavudine, zalcitibine, lamivudine, decitabine, and gemcitabine might have *in vitro* activity against FIV and FeLV, but have not been evaluated in cats, have insufficient *in vivo* efficacy or are too toxic to administer to cats (Table 9.4). Therefore, discussion is limited to zidovudine.

Zidovudine (AZT)

Zidovudine (3′-azido-3′-deoxythymidine, AZT) is a thymidine analogue first synthesized in the 1960s as a potential anticancer agent.[11] In 1987, it was the first drug to be approved by the FDA for the treatment of HIV, and it remains an important component of HIV treatment protocols.[17,18] Inside host cells, it is converted to the active triphosphate form.

Zidovudine is available as a 10 mg/mL suspension and a 10 mg/mL injectable formulation. It has good oral bioavailability in cats and high distribution in tissues, including the CNS. It is metabolized to an inactive form by the liver and excreted by the kidneys. Dosage reduction has been recommended for cats with renal failure. Some cats treated with zidovudine develop dose-related hematologic adverse effects, most commonly nonregenerative anemia and neutropenia; therefore, the CBC should be monitored during treatment. Adverse effects can be confused with retrovirus-induced cytopenias.

Zidovudine inhibits FIV replication in infected cats. It reduces plasma viral load, improves the immunologic and clinical status of FIV-infected cats, increases quality of life, and prolongs life expectancy. In placebo-controlled trials, zidovudine improved stomatitis and increased the CD4:CD8 ratio in naturally FIV-infected cats.[19–23] Viral load was significantly lower in treated cats after 6 months of therapy compared with pre-treatment, while untreated cats showed a significant increase in viral load.[23] Neurologic abnormalities can improve with treatment, sometimes within days of therapy.[24] A decrease in viral load was even more significant when lamivudine was used in combination with zidovudine.[24] Zidovudine-resistant FIV mutants can arise after only 6 months' use as a result of a single-point mutation in the reverse transcriptase enzyme.[25–29]

Zidovudine is active against FeLV *in vitro*.[30–32]Activity against FeLV was also documented in experimentally infected cats when treatment was initiated less than 3 weeks after infection. When treated less than 1 week after experimental infection, cats were protected from bone marrow infection and persistent viremia.[32,33] In naturally infected cats,

TABLE 9.4 Nucleotide Reverse Transcriptase Inhibitors and Non-Nucleoside Reverse Transcriptase Inhibitors Evaluated for Treatment of Feline Retroviral Infections

Drug	Use In Humans	Use In Cats
Zidovudine	HIV	FIV and FeLV infection
Fozivudine	HIV	Insufficient *in vivo* activity against FIV
Didanosine	HIV	Activity *in vitro* against FeLV and *in vivo* against FIV, but causes toxic neuropathy
Stavudine	HIV	No *in vivo* data
Zalcitabine	HIV	No *in vivo* data for FIV; insufficient activity against FeLV; too toxic for use (thrombocytopenia, death)
Lamivudine	HIV	Insufficient activity in cats infected with FIV; too toxic for use (hematologic)
Decitabine	Myelodysplasia, HIV	*In vitro* activity against FeLV, *in vivo* activity unknown
Gemcitabine	Pancreatic neoplasia, HIV (in combination with decitabine)	*In vitro* activity against FeLV, *in vivo* activity unknown; might be too toxic for use (cytopenias)
Adefovir	Viral hepatitis	Insufficient *in vivo* activity against FeLV; active *in vivo* against FIV, but toxic (anemia)
Tenofovir	HIV	*In vitro* activity for FeLV and FIV, *in vivo* activity unknown; not available commercially
Suramin	Protozoal infections, neoplasia	FeLV *in vitro* activity; potentially very toxic; no long-term benefit in treated cats

FeLV, feline leukemia virus; *FIV,* feline immunodeficiency virus; *HIV,* human immunodeficiency virus.

however, treatment for 6 weeks did not lead to improvement of clinical, laboratory, immunologic, or virologic parameters.[34] Thus, the efficacy of zidovudine in FeLV-infected cats is less promising than in FIV-infected cats. Nevertheless, improvement in stomatitis, reduced antigenemia, and decreased incidence of lymphoma have been reported in naturally and experimentally infected cats treated with AZT.[22,35]

Nucleotide Reverse Transcriptase Inhibitors

NtRTIs also interact with the catalytic site of the viral reverse transcriptase and are incorporated into the elongating proviral DNA strand, causing strand termination.[36,37] They compete with the natural nucleotides and thus, also function as competitive substrate inhibitors. However, in contrast to NRTIs, NtRTIs contain a phosphate group and therefore need only two intracellular phosphorylation steps to be converted into their active forms.[36] This circumvents the first and often rate-limiting phosphorylation step.[37,38] Compounds in this group with *in vitro* activity against FIV are adefovir and tenofovir.

Non-Nucleoside Reverse Transcriptase Inhibitors

Unlike NRTIs and NtRTIs, which bind to the catalytic site of reverse transcriptase, NNRTIs interact with a single allosteric site of the enzyme[36] and are not incorporated into the proviral DNA strand.[37] They do not require intracellular activation.[9,37] The interaction with the allosteric site leads to conformational changes within reverse transcriptase.[39,40] This causes a decrease in the interaction between the DNA primer and the polymerase domain of the enzyme and inhibition of virus replication.[39,40] Most NNRTIs are highly specific for HIV. The only compound that has been used in veterinary medicine is suramin.

Nucleoside Analogue DNA/RNA Synthesis Inhibitors

The nucleoside analogue DNA/RNA synthesis inhibitors act similarly to the nucleotide analogues that inhibit reverse transcriptase, but mainly are used for treatment of herpesvirus infections. Nucleoside analogues used in human patients with herpesvirus infections are acyclovir and penciclovir, and their prodrugs valacyclovir and famciclovir, respectively. These drugs are activated by the herpesviral enzyme thymidine kinase (TK), which phosphorylates them to a monophosphate form. Host cell enzymes then phosphorylate the drugs further to triphosphate forms, which concentrate in virus-infected cells and interfere with viral DNA replication by inhibition of the viral DNA polymerase enzyme. The DNA polymerases of different herpesviruses are inhibited to varying degrees by each drug, and thus, not all herpesvirus infections are equally susceptible. Drug resistance results from reduced viral TK activity, altered TK, or altered viral DNA polymerase. The drugs cidofovir, idoxuridine, trifluridine, and vidarabine are not dependent on TK for phosphorylation. Therefore, they have greater host cell toxicity than other drugs that require phosphorylation such as acyclovir. One of those agents regularly used in cats is famciclovir. In small animal medicine, the drugs not depending on viral TK have been mainly used as topical treatments for ocular FHV-1 infections (Table 9.5).

New drugs have recently been developed that have strong efficacy against coronaviruses, including feline coronavirus (FCoV). The nucleoside analogue GS-441524 is the prodrug of remdesivir and thus closely related to remdesivir, the antiviral drug used to treat COVID-19. GS-441524 has recently been evaluated for treatment of FIP, and shows promise, but it is not yet commercially available.[3,5] Ultimately remdesivir may also prove to be an effective treatment for FIP, and more widely available than GS-441524.

Acyclovir

Acyclovir (acycloguanosine, 9-[2-hydroxyethoxymethyl]guanine) is a synthetic nucleoside analogue that is widely used to treat a variety of herpesvirus infections. It interferes with actively replicating herpesviruses, but not when in a latent stage. Acyclovir is given parenterally, orally, and topically in humans to treat mucocutaneous and genital herpesvirus infections caused by herpes simplex virus (HSV), varicella-zoster virus (e.g., shingles), and parenterally to treat herpesvirus encephalitis. Resistance of human herpesviruses to acyclovir occurs. Among the nucleoside analogues, acyclovir exhibits a particular selectivity for herpesvirus over host DNA polymerases because it is only activated in virus-infected cells, and the viral DNA polymerase is 10-fold more sensitive to the activated drug than the host enzyme.

In cats, acyclovir has been used systemically or topically to treat ocular FHV-1 infections. Oral administration of 50 mg/kg acyclovir to cats results in low peak plasma concentrations due to poor bioavailability.[41] Systemic administration can cause bone marrow toxicity.[41] When given in higher doses, the parent drug can precipitate in the renal tubules, causing obstructive nephropathy if diuresis is inadequate. In these cases, needle-shaped acyclovir crystals can be detected in the urine sediment.

TABLE 9.5 Antiviral Drugs Used for Treatment of Feline Herpesvirus Infections

Drug	Dose	Interval	Route	Comments
Famciclovir	90 mg/kg	q8h	PO	Reduce dose for cats with chronic kidney disease.
Cidofovir	0.5% solution	q12h	Topical ophthalmic	Monitor for ocular irritation. Solution prepared from commercial 7.5% intravenous solution by dilution in sterile saline. Diluted solution can be stored up to 6 months at 4°C, –20°C, and –80°C. Can also be obtained from compounding pharmacies.
Idoxuridine	0.1% solution or 0.5% ointment	q4h	Topical ophthalmic	Monitor for ocular irritation and ulceration. Compounding might be required.
Trifluridine	1% solution	q4h	Topical ophthalmic	Might be poorly tolerated.
Vidarabine	3% ointment	q4h	Topical ophthalmic	Well tolerated.
Lysine	250 mg (kittens) 500 mg (cats)	q12h	PO	Questionable efficacy. Bolus administration preferred over dietary supplementation.

CBC, complete blood (cell) count; *PO,* by mouth.

Urinalysis should be performed regularly in long-term acyclovir treatment. Renal failure is reversible with adequate rehydration.

Acyclovir is about 1000-fold less active against FHV-1 *in vitro* than against HSV, and is significantly less active against FHV-1 than other antiherpesviral drugs.[42–44] The main reason for poor efficacy against FHV-1 versus HSV is reduced phosphorylation by FHV-1 TK; the activity of this enzyme is markedly lower in FHV-1 than in HSV.[45] It has been suggested that acyclovir could be combined with human IFN-α or feline IFN-ω in cats because these drugs might have synergistic activity with acyclovir, as demonstrated *in vitro.*[46] Application of acyclovir as 0.5% ophthalmic ointment q5h in cats with ocular disease attributable to FHV-1 led to resolution of clinical signs after 10 days in a nonmasked, nonplacebo-controlled study.[47] However, in cats treated q8h, it took approximately twice as long. Therefore, frequent application (q4h) is necessary, and this, combined with its low activity against FHV-1, limits its use.

Valacyclovir

Valacyclovir (2-[(2-amino-1,6-dihydro-6-oxo-9*H*-purin-9-yl) methoxy] ethyl L-valinate hydrochloride) is a prodrug of acyclovir. It is the L-valine ester of acyclovir and has the same antiviral spectrum but a threefold to fivefold increase in oral bioavailability when compared with acyclovir. In humans, it is mainly used for treatment of herpes zoster, treatment of genital herpesvirus infection, and cytomegalovirus prophylaxis in kidney transplant recipients. In humans, it is rapidly absorbed orally and hydrolyzed to acyclovir and L-valine. Although plasma concentrations of acyclovir exceeding the IC_{50} for FHV-1 can be achieved after oral administration of this drug to cats, cats under treatment have developed renal tubular epithelial and hepatocellular necrosis, and severe bone marrow suppression.[48] Thus, valacyclovir should not be administered to cats.

Ganciclovir

Ganciclovir (2-amino-9-{[(1,3-dihydroxypropan-2-yl)oxy]methyl}-6,9-dihydro-3*H*-purin-6-one) is used to treat human herpesvirus infections.[49] Ganciclovir is a nucleoside analogue of 2′-deoxyguanosine and is phosphorylated to a deoxyguanosine triphosphate analogue, which is the active form. Ganciclovir resembles acyclovir except that it has an additional hydroxymethyl group on its acyclic side chain (see Fig. 9.1). In humans, ganciclovir is widely used to treat cytomegalovirus infections, which can be life threatening in immunocompromised individuals. Systemic administration of ganciclovir to humans is associated with a high incidence of adverse reactions, especially cytopenias and CNS signs; therefore, the use of ganciclovir is limited to humans with life-threatening or sight-threatening infections. It is available for oral or intravenous administration in humans, but is associated with more severe neurologic toxicity, neutropenia, and bacterial infections than is acyclovir.[50,51] Additionally, an intravitreal sustained-release ganciclovir implant has been developed for treatment of cytomegalovirus retinitis in humans,[52] and a 0.15% ophthalmic gel is commercially available for treatment of acute human herpetic keratitis.[53] A prodrug form with improved oral bioavailability (valganciclovir) also has been developed.[54] Ganciclovir is approximately 10-fold more active against FHV-1 *in vitro* than acyclovir.[42,43,55] Anecdotal reports of its topical administration to cats in Europe are very promising. However, safety, efficacy, and pharmacokinetics of ganciclovir or valganciclovir have not been reported in cats.

Penciclovir

Penciclovir (2-amino-9-[4-hydroxy-3-(hydroxymethyl)butyl]-6,9-dihydro-3H-purin-6-one) is a nucleoside deoxyguanosine analogue with a similar mechanism of action to acyclovir. Like acyclovir, it requires viral and cellular phosphorylation. However, it is present at much higher concentrations and for longer duration in cells than is acyclovir, which permits less frequent dosing. Penciclovir is absorbed poorly when given orally, and it is used mainly as a topical treatment (e.g., against HSV in herpes labialis). In a rabbit model of human HSV-1 keratitis, a 3% penciclovir ointment administered one, two, or four times daily decreased the severity of epithelial keratitis. Thus, a topical ophthalmic penciclovir ointment might be effective in cats with FHV-1 ocular disease, but there are no commercially available preparations available for ophthalmic use.[56] While 2-amino-9-(3-acetoxymethyl-4-isopropoxycarbonyloxybut-1-yl)- purine was not successful as an oral prodrug for penciclovir,[57] famciclovir is an effective prodrug of penciclovir with good oral bioavailability.

Whereas acyclovir showed very poor ability to inhibit FHV-1 replication *in vitro*, penciclovir and cidofovir were nearly equally highly effective. When the FHV-1 inoculation dose was raised, penciclovir was more active than cidofovir.[58,59] An implantable cylindrical device made from penciclovir-impregnated silicone for long-term, steady-state delivery of this drug suppressed primary infection of FHV-1 in a cell culture system.[60] Penciclovir-resistant mutants of FHV-1 with altered TK have been described.[59]

Famciclovir

Famciclovir is a prodrug of penciclovir with improved oral bioavailability. In humans with HSV infections and herpes zoster, famciclovir

is as effective as acyclovir. In cats, penciclovir (and thus famciclovir) are much more potent inhibitors of FHV-1 replication than acyclovir.

In humans, famciclovir is well absorbed orally and rapidly metabolized to penciclovir.[61] This requires di-deacetylation to BRL42359 in blood, liver, or small intestine, with oxidation to penciclovir by hepatic aldehyde oxidase.[62–64] Most drug is eliminated unchanged in urine. In humans, concurrent food administration decreases peak plasma concentrations without affecting bioavailability. Neither famciclovir nor BRL42359 are active against FHV-1,[65] so metabolism to penciclovir is required. However, hepatic aldehyde oxidase activity in cats is minimal.[66] Famciclovir pharmacokinetics in the cat are complex and nonlinear (i.e., doubling of famciclovir dose does not lead to doubling of plasma penciclovir concentration), presumably due to saturation of the hepatic oxidase.[67,68] High plasma concentrations of BRL42359 accumulate,[67] but clinical responses occur in cats with both acute and chronic clinical signs of FHV-1 infection with negligible adverse effects.[69,70] Responses typically occur within a week of treatment. However, a single dose of famciclovir (125 or 500 mg) administered to cats at shelter intake was not efficacious in reducing clinical signs when 40% of the cats were already shedding FHV-1.[71]

There is controversy about the optimum famciclovir dose in cats. Doses used have ranged from 8 mg/kg q24h[70] to 140 mg/kg q8h.[72,73] In a masked, placebo-controlled trial, cats experimentally infected with FHV-1 and administered famciclovir at 90 mg/kg q8h PO achieved a peak plasma penciclovir concentration of 2100 ng/mL.[69] Compared with control cats, treated cats had reduced clinical signs, serum globulin concentrations, histologic evidence of conjunctivitis, viral shedding and serum FHV-1 titers, as well as increased conjunctival goblet cell density.[69] However, administration of one dose of 40 mg/kg PO to healthy cats achieved nearly identical plasma penciclovir concentrations to those achieved with a dose of 90 mg/kg.[74] Naturally infected client-owned cats with spontaneous disease administered famciclovir at 40 mg/kg q8h had tear penciclovir concentrations likely to be effective against FHV-1 for at least 3 hours after a dose of 40 mg/kg q8h.[73] Based on a study of healthy cats treated with famciclovir at 30, 40, or 90 mg/kg q12h or q8h, it was recommended that cats receive a dose of 90 mg/kg q12h because this regimen achieved comparable plasma and tear penciclovir concentrations to those achieved with 90 mg/kg q8h.[67] Furthermore, when famciclovir was administered to 59 client-owned cats, the median duration of therapy required for clinical improvement was significantly longer in cats administered 40 mg/kg (33 cats) than in cats treated with 90 mg/kg (26 cats).[72] Costs of care were estimated to be lower in the cats treated with the higher dose due to reduction in treatment duration, and potentially the number of recheck examinations required. Adverse events, which were mostly minor gastrointestinal signs, were reported in 17% of cats receiving 40 or 90 mg/kg q8h, with no difference between the two doses.[72] Although famciclovir is safer than acyclovir, cats administered famciclovir should be closely monitored, and assessment of the CBC and serum biochemistry panel should be considered in cats with known concurrent disease or cats expected to receive famciclovir for long periods. As in humans,[75] reduction in dose frequency should be considered in cats with renal disease.[67,72] Human famciclovir tablets are commonly too large for some cats and can be difficult to administer. Some veterinary compounding pharmacies have prepared oral formulations of compounded famciclovir for cats. However, testing of these formulations showed poor quality, inconsistency, and failure to show that the concentrations in these compounded forms were as stated on the label. These products made by veterinary compounding pharmacies failed to meet the United States Pharmacopeia (USP) (www.usp.org) compendial standards for compounded products and thus, cannot be recommended for cats. Instead, veterinarians are encouraged to use a pharmacy that adheres to the USP standard or modify the human-approved tablets.

Cidofovir

Cidofovir is a nucleotide analogue of deoxycytidine monophosphate. Thus, cidofovir already contains a monophosphate group,[76] and its metabolism to the active diphosphate form by host cellular enzymes is not dependent on viral TK. Therefore, it can be used to treat acyclovir- and famciclovir-resistant infections. Its safety arises from its relatively high affinity for viral DNA polymerase compared with human DNA polymerase.[77] In human patients, cidofovir is also used to treat cytomegalovirus retinitis. Cidofovir has extremely low (<5%) oral bioavailability, so it has to be administered intravenously, intravitreally, or topically. Cidofovir has a prolonged intracellular half-life, which enables infrequent parenteral dosing regimens in human patients (weekly, and then every other week for maintenance). Cidofovir applied q12h as a 0.5% or 1.0% ophthalmic solution in rabbit models of human herpetic keratoconjunctivitis was as effective as trifluridine q3–6h.[56,78] This makes it the topical treatment of choice for ocular FHV-1 infections. Local irritation and scarring of the nasolacrimal duct has been reported with topical administration in humans and rabbits with keratoconjunctivitis,[79,80] so treated cats should be monitored for nasolacrimal cicatrization. Cidofovir 0.5% retains efficacy when compounded with saline and refrigerated (4°C) or frozen (–20°C or –80°C) in plastic or glass for up to 6 months.[81] Cidofovir is highly active against FHV-1 *in vitro*.[42,43] It was also effective in a feline whole corneal explant model supporting FHV-1 replication.[82] In cats with experimental FHV-1 infection, cidofovir administration was associated with a significant improvement in clinical scores and ocular virus shedding when compared with placebo.[83]

Cidofovir also has *in vitro* activity against canine herpesvirus-1 (CHV-1).[84] Cidofovir was used to treat dendritic ulcerative keratitis in a 4-year-old dog associated with CHV-1 infection based on positive PCR results and rising serum antibody titers.[85] In dogs with experimentally induced ocular CHV-1 infection, application of topical 0.5% cidofovir ophthalmic solution q12h reduced duration of viral shedding, but caused ocular irritation leading to higher ocular disease scores and higher conjunctival and corneal leukocyte infiltration scores.[84]

Idoxuridine and Trifluridine

Idoxuridine and trifluridine are halogenated thymidine analogues that are phosphorylated by cellular enzymes to active triphosphate forms, which act as pyrimidine antagonists. Both drugs cause myelosuppression when given systemically, and so are only applied topically.[86,87] They are used in humans to treat HSV keratitis and dermatitis. When not commercially available, topical idoxuridine can be obtained from a compounding pharmacy as a 0.1% ophthalmic solution. Trifluridine is available as a 1% ophthalmic solution. Frequent application of both of these drugs is required (q4–6h). Local application is generally well tolerated, but prolonged use can cause corneal irritation or ulceration.[88] Trifluridine has better corneal penetration than idoxuridine,[89] but is more likely to cause ocular irritation in cats than idoxuridine.[90]

Idoxuridine and trifluridine are active against FHV-1 *in vitro*,[43,55] although both are more active against HSV.[43,55] In cats with ocular disease attributed to FHV-1, 0.1% idoxuridine solution was used q4–6h with improvement of clinical signs in three cats and no improvement or worsening in four cats.[87] Treatment with 1% trifluridine solution q4–8h was associated with improvement in one cat and no improvement or worsening in two cats.[87]

Corneal ulcerations associated with a naturally occurring CHV-1 infection appeared to respond to topical idoxuridine or trifluridine treatment.[91] Frequent topical ocular application of 1% trifluridine ophthalmic solution was well tolerated by dogs with experimentally induced recurrent ocular canine CHV-1 infection and reduced disease scores and viral shedding duration.[92]

Vidarabine

Vidarabine (9-β-D-arabinofuranosyladenine monohydrate, adenine arabinoside) is a purine nucleoside that is phosphorylated by host cellular enzymes to vidarabine triphosphate. It was originally developed as a cancer chemotherapeutic. Vidarabine triphosphate disrupts DNA synthesis by interfering with DNA polymerase. It has activity against herpesviruses, poxviruses, and retroviruses, as well as idoxuridine-resistant herpesvirus strains. In humans, it is used to treat smallpox and HSV keratitis, dermatitis, and encephalitis.[93] Systemic toxicity has restricted its use in veterinary practice to topical treatment as a 3% ophthalmic ointment. Local application in cats is well tolerated, but frequent application (q4–6h) is necessary.[90] Where not available commercially, it can be obtained from a compounding pharmacist.[2]

Vidarabine is active against FHV-1 *in vitro*[55] and has been used topically in ocular FHV-1 infections, although cidofovir has largely replaced its use because it can be applied less frequently. In a retrospective study of cats with ocular disease attributed to FHV-1, treatment with vidarabine was associated with improvement in one cat and no improvement or worsening in two cats.[87]

Vidarabine also has *in vitro* activity against FCoV,[94] but studies have not been performed to demonstrate efficacy in cats with FIP.

GS-441524

Treatment with the nucleoside analogue GS-441524, which is the prodrug of the COVID-19 antiviral drug remdesivir, reversed disease in 10 research cats when given subcutaneously once daily for 2 weeks.[3] Two of these cats required a second course of treatment, but were disease-free 8 months later. In a field study, 31 naturally infected cats without neurological or ocular FIP were treated with GS-441524 (2 mg/kg q24h SC, increasing to 4 mg/kg q24h SC).[5] Five of the cats died or were euthanized within 26 days of starting treatment. The remaining 26 cats received the full 12 weeks of treatment, and of these, 8 had relapses in 3 to 84 days, and the remaining 18 were healthy at the time of publication. In some of the cats that relapsed, remissions were obtained with another course of treatment, and ultimately, at the time of publication, 25 cats remained healthy. The time of diagnosis to the time of publication was 18 to 22 months. With increased availability of remdesivir following the COVID-19 pandemic, remdesivir might have the potential to be useful for treatment of FIP although it is less potent than GS-441524.

Nucleotide Synthesis Inhibitors

There are two types of nucleotide synthesis inhibitors: (1) pyrophosphate analogues that directly inhibit DNA and RNA polymerase (e.g., foscarnet) and (2) inhibitors of triphosphate synthesis that inhibit inosine monophosphate dehydrogenase, an essential enzyme for synthesis of nucleotides (e.g., ribavirin). Nucleotide synthesis inhibitors usually have a broad antiviral spectrum but also marked toxicity.

Foscarnet

Foscarnet (phosphonoformic acid, PFA) has *in vitro* activity against FIV, FeLV, and FHV-1.[95,96] However, its short half-life, poor oral absorption, and adverse effects have limited its use in cats. No *in vivo* studies in cats with virus infections have been published.

Ribavirin

Ribavirin(1-β-D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide,RTCA) is active against a significant number of feline and canine viruses *in vitro*, including FIV, FeLV, FHV-1, FCV, FCoV, Borna disease virus (BDV), as well as CDV and canine parainfluenza virus.[97–99] However, its clinical usefulness is limited because of its systemic toxicity, and it is not used in veterinary medicine. It is also no longer recommended for treatment in humans. Still, ribavirin might have the potential to be a promising drug for treating dogs with CDV. Further studies are required for understanding pharmacokinetics and toxicity of ribavirin in dogs.

Protease Inhibitors

Protease inhibitors are widely used to treat HIV infection and hepatitis C in humans. They prevent viral replication by selectively binding to viral proteases and blocking proteolytic cleavage of protein precursors needed for the production of infectious viral particles. Protease inhibitors currently on the market are highly selective for HIV and are not active against FIV. However, experimentally designed protease inhibitors had activity against FIV or FIV/HIV chimeras.[100–102] In addition, commercially available protease inhibitors, such as nelfinavir, have been evaluated for their activity against FCoV, and new protease inhibitors with potential activity against FCoV have been engineered.[103] The use of nelfinavir was also reported in a few cats with FIP in the field,[104,105] but toxicity and pharmacokinetics of nelfinavir in cats and its efficacy for treatment of FIP in controlled studies remains unknown.

GS376

Inhibitors that target 3C-like protease with broad-spectrum activity against important human and animal coronaviruses have recently been created.[106] One protease inhibitor (GS376) was shown to have activity against FCoV *in vitro*[107] and was effective to treat FIP in an experimental setting, but is not yet commercially available. Prolonged remissions were documented in some naturally infected cats. In one field study, 6 of 20 cats were in remission 18 months after 12 weeks of treatment, administered subcutaneously twice a day.[4] One of the challenges was treatment of neurologic FIP, likely because of failure of drug penetration of the CNS. Further field studies with this drug are required, and the compound is not yet commercially available.

Receptor Blockers

Receptor blockers belong to a group of antiviral drugs known as *entry inhibitors*, which also include fusion inhibitors. Receptor blockers are either homologs or antagonists of cellular viral receptors or co-receptors. If receptor blockers bind to the virus or to the cellular receptor, they inhibit attachment of the virus to the cell surface. Most receptor blockers on the market or under development are highly selective for HIV and not useful for veterinary medicine. One exception are bicyclams (e.g., plerixafor), because of the similarity between HIV and FIV in regards to chemokine receptor usage.[108–112] Plerixafor (1,1'-(1,4-phenylenbismethylene)-bis(1,4,8,11-tetraazacyclotetradecane)-octachlo-ride dehydrate, AMD3100) is the prototype bicyclam drug. It is used in humans for stem cell mobilization.[113] Plerixafor is active against FIV *in vitro*.[114] In naturally FIV-infected cats in a placebo-controlled double-blind clinical trial, treatment with plerixafor resulted in a significant decrease in provirus load, but also a decrease in serum magnesium levels, which however was not clinically relevant.[115] It has been administered to cats at a dose of 0.5 mg/kg q12h. Magnesium and calcium levels should be monitored during treatment.[115]

Integrase Inhibitors

The retroviral enzyme integrase catalyzes strand transfer (3′-end joining), which inserts both proviral DNA ends into a host cell chromosome. The high degree of conservation of integrase active sites for many retroviruses suggests that FIV and FeLV could be sensitive to integrase inhibitors.[116]

Raltegravir

In human patients, raltegravir is approved for treatment of HIV infections and is used in combination with other antiretroviral drugs.

Raltegravir is highly active *in vitro* against FeLV.[116,117] Concentrations in the effective range were not toxic to cell monolayers. However, raltegravir is partly eliminated as glucuronide. Some (but not all) glucuronide pathways are deficient in cats. This might increase the risk of toxicity in cats.[113] The efficacy and safety of raltegravir in a non-controlled study of seven cats with experimentally induced progressive FeLV infection was investigated.[118] Raltegravir was administered at 40 mg q12h PO for 6.5 weeks and then 80 mg q12h PO for 2.5 weeks. The treatment reduced viremia in each cat, with up to 1 $\log_{10}$ reduction in viral RNA in four of seven cats, and the drug attained therapeutic plasma concentrations at both doses, with no adverse effects noted. However, viremia rebounded in all cats following drug removal. Raltegravir also had activity against FHV-1 in cell culture as well as in a feline whole corneal explant model.[82]

Nucleocapsid Inhibitors

Nucleocapsid inhibitors interact with viral assembly and disassembly through NCp7 zinc finger-targeted agents.[119] Such zinc finger inhibitors or zinc ejectors are compounds that interact adversely with zinc and cause them to release their zinc from its binding site, disrupting the conformation of the polypeptide chain and rendering the zinc fingers ineffective, thereby preventing them from performing their associated cellular functions. Zinc fingers are involved in mRNA regulation, reverse transcription, protection of synthesized viral DNA, transcription inhibition, and initial integration processes. Nucleocapsid inhibitors are used to treat HIV, but many other human viruses, such as Ebola virus, measles virus, and polio virus, have similar zinc finger motifs and could potentially benefit from zinc finger inhibitor technology. Several novel nucleocapsid inhibitors, such as fused tetrathiocines, bis[1,2]dithiolo[1,4]thiazines and bis[1,2]dithiolopyrrole derivatives, and 5-thieno-, 5-oxo-, and 5-imino-1,2,3-dithiazole derivatives, have been synthesized and evaluated for activity against FIV. These new compounds display potent nanomolar activity and low toxicity against FIV *in vitro*,[61,120,121] but they are not yet available.

Neuraminidase Inhibitors

Neuraminidase inhibitors prevent release of virus from the host cell. They inhibit virus replication by binding the viral enzyme neuraminidase, a viral surface glycoprotein. Oseltamivir is the only agent from this class that has been used in cats and dogs.

Oseltamivir

Oseltamivir, ethyl (3R,4R,5S)-5-amino-4-acetamido-3-(pentan-3-yloxy)-cyclohex-1-ene-1-carboxylate, is the prodrug of oseltamivir carboxylate, a potent inhibitor of influenza virus neuraminidase (Fig. 9.2). Oseltamivir is active against viruses that have neuraminidase in their envelope, including influenza viruses, parainfluenza viruses, and paramyxoviruses, and is used in the treatment and prophylaxis of influenza virus A and influenza virus B infections in humans. The viral neuraminidase cleaves sialic acid residues on the surface of infected cells, which allows new virus particles to be released from host cells. It also prevents aggregation of virus particles after they are released and facilitates spread of virus through the mucus of the respiratory tract by cleaving sialic acid residues in mucin.

Oseltamivir was the first orally active neuraminidase inhibitor to be commercially developed. It is a prodrug, which is hydrolyzed in the liver to an active metabolite, the free carboxylate of oseltamivir. A lipophilic side chain of the active drug binds to the viral neuraminidase, blocking its ability to cleave sialic acid residues, resulting in an inability of cells to release progeny virions. In humans and dogs, oseltamivir has high oral bioavailability.[122] Oseltamivir is used early in the course of human influenza to shorten the duration of illness by approximately 20 hours.

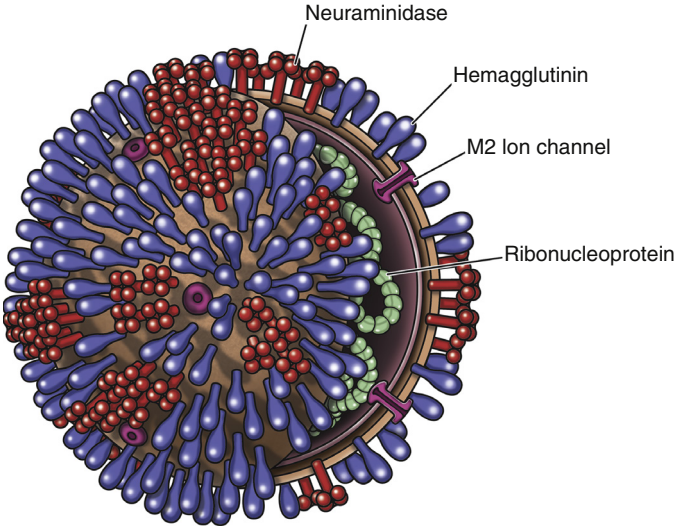

Fig. 9.2 Structure of an influenza virus. The M2 protein, which is only present in influenza A viruses, is inhibited by tricyclic amines such as amantadine. Oseltamivir inhibits the viral neuraminidase.

Oseltamivir has been used to treat canine parvovirus enteritis in puppies, with anecdotal reports of improved outcome. Although it does not have activity against CPV, and CPV does not possess a neuraminidase, it was used in a prospective, randomized, masked, placebo-controlled trial of 35 dogs with CPV-induced enteritis. Dogs treated with oseltamivir (2 mg/kg PO q12h) had no significant drop in their white blood cell count, whereas untreated dogs had white blood cell count decrease in the first 5 days of hospitalization.[123] Treated dogs also gained weight during hospitalization, whereas untreated dogs lost weight. However, there was no difference in hospitalization time, treatments needed, clinical scores, morbidity, or mortality between the two groups, and the number of dogs in each group was small. As CPV has no neuraminidase, it was hypothesized that oseltamivir instead might act on the neuraminidases of bacteria that are normally responsible for secondary bacterial infections in CPV enteritis, which are primarily those of the gastrointestinal tract. The role of bacterial neuraminidases in the pathogenesis of enteric bacterial infections and bacterial translocation is unknown. Bacterial neuraminidase enzymes might play a role in biofilm formation and help bacteria to invade mucin layers of the respiratory tract.[123,124] It has been suggested that gut bacteria might use neuraminidase to cleave sialic acid residues on gastrointestinal epithelial cells, which exposes receptor sites for bacterial adherence.

Ion Channel Blockers

The uncoating of viruses can be blocked by ion channel blockers that bind to viral proteins, such as influenza A virus M2 proteins, which normally function as ion channels for proton influx into the virus. Blocking the M2 protein leads to a pH change that inhibits viral fusion and internalization of the virus by endocytosis. Cycloalkylamine derivatives are used for this purpose in human medicine, mainly against influenza virus infections. Amantadine is the most important example of a cycloalkylamine derivative, and the only one that has been used in veterinary medicine. Related drugs include rimantadine, which has equal or greater efficacy to amantadine with reduced CNS adverse effects but more gastrointestinal

irritation, and tromantadine, which is used topically to treat human herpesvirus infection. New experimental compounds that inhibit viroporins, viral proteins with ion channel activity that are possessed by several viruses, including FCoV, have been investigated *in vitro*,[125] but are not commercially available.

Amantadine

Amantadine (tricyclo[3,3,1,13,7]dec-l-ylamine hydrochloride, L-adamantanamine) is a stable cyclic amine with activity against enveloped RNA viruses. Amantadine was once applied as prophylaxis of human influenza, but it is rarely used for this indication currently because there are newer more potent agents available. As a dopaminergic drug, amantadine has been used to treat Parkinson's disease, cocaine dependence, and apathy in multiple sclerosis. It has also been also used in cats and dogs to treat neuropathic pain and osteoarthritis.[126] Data on the usefulness of amantadine in dogs and cats as an antiviral drug are limited. Amantadine was active against BDV *in vitro* in one study,[127] but in a different study, there was no *in vitro* activity in concentrations that were effective against influenza virus.[128] Anecdotal reports of successful outcomes following amantadine treatment exist in cats with BDV infection in northern Europe.

Antiviral Amino Acids

Amino acids and peptides can act as antivirals when they competitively inhibit translation and virus assembly.

L-Lysine

Initial interest in L-lysine arose from *in vitro* data and clinical trials in humans.[129]Arginine is essential for FHV-1[130] and HSV[131] replication, and it has been suggested that lysine antagonizes the availability or utilization of arginine by these viruses during protein synthesis. Protein fraction-I of the histone layer around the DNA of the eukaryotic or host cells is 28% L-lysine and 3% to 4% arginine. In contrast, the capsid protein composition of herpesviruses has approximately three times more arginine than lysine.[132] Thus, it was originally hypothesized to preferentially affect protein synthesis of the virus over that of the host because viral proteins had a higher arginine-to-lysine content than did human (and feline) proteins[132]; however, recent analyses suggested that the difference in feline and FHV-1 protein amino acid content is minimal.[133] Both an excess arginine and an absence of arginine interferes with the replication of HSV *in vitro*.[134,135] Excess L-lysine in the media has the same effect, likely by acting as an analogue of arginine, or by competing for cellular transport mechanisms, or both.[131,136] Markedly elevated L-lysine concentrations in combination with low arginine concentrations suppressed HSV-1[131,135] and FHV-1[130] replication *in vitro*. However, this did not occur with physiologic amino acid concentrations.[137] In a more recent study, various L-lysine concentrations did not inhibit *in vitro* replication of FHV-1 at arginine concentrations sufficient to maintain cell growth.[137] Thus, data on *in vitro* activity of L-lysine are controversial.

L-lysine is inexpensive and well tolerated in cats, with only mild and reversible gastrointestinal disturbances reported for some cats.[138] No adverse effects were seen in cats fed diets supplemented to up to 8.6% (dry matter) with L-lysine.[139] However, *in vivo* data regarding the efficacy of L-lysine in cats with FHV-1 infection are also contradictory. Although L-lysine is promoted by sponsors of dietary supplements for cats (which are not FDA regulated), the clinical results have not shown a benefit in naturally occurring infections. A recent meta-analysis, published by two biologists who owned cats with chronic FHV-1 infection presented multiple levels of evidence that L-lysine supplementation is not effective for the prevention or treatment of FHV-1 infection in cats.[133] Lysine does not antagonize arginine in cats, and evidence that low intracellular arginine concentrations would inhibit viral replication is lacking. Furthermore, lowering arginine levels is undesirable since cats cannot synthesize this amino acid themselves, and arginine deficiency might result in hyperammonemia, which could be fatal. Contradictory to this meta-analysis, administration of 500 mg L-lysine PO q12h beginning 6 hours before inoculation of cats with FHV-1 was associated with less severe conjunctivitis without a change in virus shedding when compared with placebo.[138] The effects of L-lysine administration on clinical signs and ocular shedding of FHV-1 were studied after reactivation of latent infection. Treated cats had fewer viral shedding episodes after stress of rehousing compared with the control group cats. Fewer cats and eyes had conjunctivitis, and onset of clinical signs of infection was delayed in cats receiving L-lysine.[140] In cats latently infected following experimental inoculation but without clinical signs at the time of the study, oral administration of 400 mg L-lysine q24h reduced viral shedding compared with placebo-treated cats.[140] However, in the only study to assess bolus administration of L-lysine in naturally infected cats, 144 shelter-housed cats received 250 mg (kittens) or 500 mg (adult cats) L-lysine q24h for their entire shelter stay. Outcomes were compared with an untreated control group. No significant treatment effect was detected for any parameter.[141] There was concern that the stress of tablet administration actually contributed to disease in these cats. Dietary supplementation with L-lysine also appears to have no beneficial impact on upper respiratory tract disease in shelters.[141–143] In fact, cats that received a supplemented diet had more severe disease and more frequent viral shedding than cats that received a nonsupplemented diet, despite a detectable increase in plasma lysine concentrations.[143] The supplemented diet did not affect plasma arginine concentration; therefore, altered arginine levels did not contribute to increased disease severity.[2] Thus, L-lysine has not demonstrated clear benefit in naturally occurring infections.

IMMUNOSTIMULANT DRUGS

"Immunomodulator" is a nonspecific term that has also been referred to as biologic response modifiers. These drugs include agents that suppress the immune system (e.g., glucocorticoids) and those that stimulate the immune system. In this chapter, only drugs that stimulate the immune system are discussed. Some of these compounds not only affect the immune system but also possess antiviral activity (e.g., IFNs). Probiotics also have immunomodulatory activity and have been used to treat viral infections (e.g., FHV-1).[83,144] These compounds are discussed in Chapter 125. Specific neutralizing antibodies (passive immunization), such as against FHV-1, FCV, FPV, CPV, CDV, and infectious canine hepatitis virus, have also been used for treatment of virus infections with variable results[145–147] but are not the subject of this chapter. Vaccines, such as intranasal vaccines, also have been used as therapeutic immunomodulators (see Chapter 20).

Categories of immunomodulators are shown in Table 9.6. Treatment of canine and feline viral infections with immunostimulating drugs has commonly produced disappointing results. Data from large, prospective, controlled clinical trials are lacking, and many are used infrequently or are not widely available (Table 9.7). Because of this, only those currently in use that appear to have some clinical benefit are discussed in detail. Doses of immunostimulants evaluated in dogs and cats are shown in Table 9.8.

Naturally Occurring Cytokines

Interferons

Interferons are polypeptide molecules that mediate antiviral and antigrowth responses and modulate the immune response.[148] A number of

TABLE 9.6 Immunostimulating Drugs Examined For Activity Against Canine and Feline Viral Infections

Category	Subcategory	Examples
Naturally occurring cytokines	Interferons	IFN-α, IFN-β, IFN-ω, IFN-γ
	Colony-stimulating factors	G-CSF, GM-CSF, erythropoietin
Naturally occurring biologic response modifiers	Mammalian- and insect-derived biologic response modifiers	Lactoferrin, melittin
	Microorganism-derived biologic response modifiers	Bacille Calmette-Guérin, staphylococcal protein A, staphylococcal phage lysate, *Serratia marcescens*, *Cutibacterium acnes*, parapoxvirus ovis (PIND-ORF)
	Plant-derived biologic response modifiers	Acemannan, polyprenyl immunostimulant, *Galanthus nivalis*-like compound, lambda-carrageenan, fucoidan, proanthocyanidin A2
Synthetic compounds	Antiparasitic and antibacterial compounds	Levamisole, diethylcarbamazine, mefloquine, ivermectin, doxycycline
	Other synthetic compounds	Pentoxifylline, propentofylline, leflunomide, indomethacin, suberoylanilide hydroxamine

G-CSF, granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IFN,* interferon.

different interferons have been identified that are subdivided into type I, type II, and type III interferons.[149] IFN-α, IFN-β, IFN-ω, and IFN-γ have been used in veterinary medicine. The first three belong to type I IFNs, while IFN-γ is a type II IFN. Type I interferons (IFN-α, IFN-β, and IFN-ω) are produced by virus-infected cells,[88,150] whereas type II interferon (IFN-γ) is produced by activated T cells and natural killer cells in response to recognition of infected cells.[151]

Interferons bind to specific cell surface receptors and stimulate expression of proteins that interfere with various stages of viral replication.[152] Viral protein synthesis is not affected, so the antiviral activity of interferons is thought to be related to interference with later stages of viral replication, such as virion assembly and release.[150,153] Interferons also trigger virus-infected cells to undergo apoptosis.[151,153] Thus, interferons prevent the spread of virus from infected cells and aid in the clearance of viral infection.[151] Recombinant interferons that are commercially available, mostly used in cats and dogs, are human IFN-α and feline IFN-ω. IFN-γ plays a critical role in the clearance of intracellular pathogens by macrophages. Recombinant human IFN-γ has been used to treat chronic granulomatous disease caused by intracellular bacteria and fungi in humans, but few studies have been performed in cats and dogs. Low-dose feline IFN-γ and interleukin (IL)-12, experimentally prepared by a method known as *Sequential Kinetic Activated*, have been used in cats experimentally infected with FHV-1 with some success.[154] Recombinant adenoviruses engineered to contain IFN-γ genes had antiviral activity against CPV.[155]

Human Interferon-α. Naturally occurring IFN-α represents a group of more than 20 molecules that vary slightly in composition. They inhibit viral nucleic acid and protein synthesis. A variety of recombinant and natural human IFN-α preparations are available, including pegylated forms that have prolonged half-lives. IFN-α is active against many DNA and RNA viruses.[152] There are two common treatment regimens for use of IFN-α in cats, SC injection of high-dose (10^4 to 10^6 IU/kg q24h) IFN-α or oral application of low-dose (1 to 50 IU/kg q24h) IFN-α. When given parenterally to cats, human IFN-α becomes ineffective after 3 to 7 weeks because of development of neutralizing antibodies.[33] IFN-α can be given orally for a longer period, as no antibodies will develop during oral treatment. Given orally, IFN-α is inactivated by gastric acid and destroyed by trypsin and other proteolytic enzymes in the duodenum.[156] Therefore, immunomodulatory activity is thought to result from stimulation of oropharyngeal lymphoid tissue, which leads to cytokine release and a cascade of immunologic responses that ultimately act systemically.[157,158]

IFN-α is active against FIV *in vitro*.[159] Although it is sometimes used for treatment of FIV-infected cats, no controlled studies that evaluated the effect of high-dose parenteral human IFN-α in FIV-infected cats have been conducted. Use of low-dose oral human IFN-α in sick cats with natural FIV infections (50 IU/kg on the oral mucosa q24h for 7 days on alternating weeks for 6 months, followed by a 2-month break, and then repetition of the 6-month treatment) resulted in improvement of clinical signs in a placebo-controlled double-blind study.[160]

In vitro, FeLV replication is inhibited by human IFN-α.[161] Treatment of cats that had persistently high FeLV antigenemia with high-dose SC human IFN-α following experimental infection resulted in decreases in circulating FeLV antigen beginning 2 weeks after initiation of therapy.[33] However, because of anti-IFN-α antibody development, cats became refractory to therapy after several weeks.[33] In a placebo-controlled double-blind study in naturally FeLV-infected cats, a similar high-dose treatment regimen with human IFN-α (1×10^5 IU/kg SC q24h for 6 weeks) did not lead to improvement of clinical, laboratory, immunologic, or virologic parameters.[34] Low-dose oral IFN-α was used in a placebo-controlled study in experimentally induced FeLV infection.[157] Eight cats were treated with 0.5 IU/cat and five were treated with 5 IU/cat on 7 consecutive days on alternate weeks for a period of 1 month after challenge. There was no difference in development of viremia between groups, but treated cats had fewer clinical signs and longer survival times than the placebo group (with a better response in the cats given 0.5 IU). Uncontrolled field studies have reported apparent responses in a limited number of cats treated with low-dose oral IFN-α.[162,163] Significantly longer survival times were reported in 69 clinically affected cats treated with low-dose oral IFN-α (30 IU/kg for 7 consecutive days on a 1-week-on 1-week-off schedule) when compared with historical controls.[163] However, in a placebo-controlled study, treatment of sick client-owned FeLV-infected cats with the same protocol did not result in a significant difference in FeLV status, survival time, clinical or hematologic parameters, or subjective improvement in the owners' impression when compared with a placebo group.[164] Improvement in clinical signs and laboratory abnormalities in FeLV-infected cats were noted with low-dose oral IFN-α in other studies,[165,166] but concern was raised about evidence of a rebound effect after treatment was discontinued. These studies lacked a control group.

In vitro studies with dosages of 1×10^5 to 5×10^5 IU/mL of IFN-α showed reduced FHV-1 concentration and FHV-1-induced cytopathic effects without observable cytotoxicity to a feline corneal cell line[167] or Crandell-Rees feline kidney (CRFK) cells.[168] Administration of 108 IU/kg IFN-α SC q12h for 2 days (beginning a day before challenge) to 12 kittens experimentally infected with FHV-1 led to reduction of clinical signs over a 14-day period when compared with placebo.[169] FCV replication is also inhibited when cell cultures are treated with

TABLE 9.7 Immunostimulants with Unclear Benefit for Treatment of Canine and Feline Viral Infections

Name	Description	Proposed Mechanism	Activity
Melittin	26-amino acid peptide, component honey bee venom	Viral membrane lysis	*In vitro*, HIV, murine leukemia viruses, tobacco mosaic virus, HSV, FIV. Not effective in double-masked, placebo-controlled pilot study of 20 FIV-infected cats (500 μg/kg SC q12h for 6 weeks) or placebo.[226]
Staphylococcus aureus phage lysate and purified staphylococcal protein A (SPA)	Phage lysate: components of *Staphylococcus aureus* and a bacteriophage. Staphylococcal protein A (SPA): polypeptide purified from cell walls of *Staphylococcus aureus* Cowan I.	Combines with immune complexes at the Fc region of IgG. Activation of complement, T cells, natural killer cells, and IFN-γ production.	Available commercially for treatment of canine pyoderma (see Chapter 119). No clear benefit of SPA when used to treat cats with natural or experimental FeLV infections.[164,227]
Cutibacterium acnes (formerly *Propionibacterium acnes*)	Inactivated bacteria	Stimulates macrophage release of cytokines and IFNs, enhances T-cell and natural killer cell activity in mice	Used as adjunct treatment for chronic recurrent canine pyoderma (see Chapter 119). Moderately sized uncontrolled studies suggested clinical benefit in cats with FeLV infection in conjunction with supportive care, but no prospective or controlled studies have been performed.[228,229] In one study, 74 cats with experimentally induced FIP received *C. acnes*, SC IFN-α, a combination, or placebo. Administration of *C. acnes* in combination with IFN-α did not reduce mortality in treated *versus* untreated cats, but the mean survival time was prolonged for 3 weeks.[230]
Inactivated parapoxvirus avis (PIND-AVI) and parapoxvirus ovis (PIND-ORF) (Europe)	Inactivated poxviruses	"Paramunity inducers." Might induce IFNs and colony-stimulating factors and activate natural killer cells.	No benefit in placebo-controlled trials for treatment of FeLV infection,[231,232] feline upper respiratory tract disease,[233] or CPV infection.[234]
Acemannan	Mucopolysaccharide derived from aloe vera plant	Stimulates macrophages to secrete a variety of cytokines, including IFN-γ, TNF-α, prostaglandin E2, IL-1, and IL-6	Veterinary product available for intralesional injection of canine and feline tumors, including feline injection-site sarcomas.[235,236] Beneficial effects reported in uncontrolled trial of clinically affected FIV-infected cats for 12 weeks (IV or SC once weekly or PO q24h).[237] Immunostimulatory effects might promote viral replication. No clear benefit in a non-controlled trial of 50 cats with FeLV infection (2 mg/kg IP every 7 days for 6 weeks).[238]
Galanthus nivalis agglutinin	Mannose-binding plant lectin	Antineoplastic, antifungal, and antiviral activities. Blocks fusion of HIV with target cells and results in deletion of glycan in the HIV envelope protein, which triggers formation of neutralizing antibody against exposed epitopes.[239]	*In vitro* activity against feline coronavirus in combination with nelfinavir.[104]
Lambda-carrageenan	Seaweed extract that contains sulfated polysaccharides		*In vitro* activity against FHV-1. Ophthalmic application did not reduce clinical signs in small numbers of cats infected with FHV-1.[240]
Fucoidan	Sulfated polysaccharide in brown algae and brown seaweed	May inhibit viral infection by interfering with early steps of virus replication and inhibiting virus-mediated cell fusion.[241]	*In vitro* activity against CDV.[241]
Proanthocyanidin A2	Phenolic dimer, condensed tannin present in plants such as lychee	Antioxidant, anti-inflammatory, and antimicrobial properties.[242,243]	CDV.[244,245]
Mefloquine	4-quinolinemethanol derivative, antimalarial	Prevents viral replication	JC virus, FCV (additive with rfIFN-ω).[246]
Suberoylanilide hydroxamine	Synthetic compound	Binds to active site of histone deacetylases and chelates zinc ions. Antineoplastic, antifibrotic, and anti-inflammatory activity	Activates latent HIV infections for immune recognition and destruction.[247] When administered with food to 4 FIV latently infected research cats and 1 uninfected control cat, associated with an increase in FIV RNA and decrease in viral DNA burden.

CPV, canine parovirus; *FCV,* feline calicivirus; *FeLV,* feline leukemia virus; *FHV-1,* feline herpesvirus-1; *FIP,* feline infectious peritonitis; *FIV,* feline immunodeficiency virus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *IFN,* interferon; *IL,* interleukin; *JC virus,* John Cunningham virus; rfIFN-ω, recombinant feline interferon-ω; TNF, tumor necrosis factor.

TABLE 9.8 Doses of Commercially Available Immunomodulators Used to Treat Infectious Diseases of Dogs and Cats

Drug	Dose	Interval	Species	Route	Comments
Acemannan	2 mg/kg	Weekly	C	SC	For treatment of fibrosarcomas; efficacy unclear for FIV and FeLV infections
Feline recombinant interferon omega	1 million U/kg	q24h for 5 consecutive days on days 0, 14, and 60	C, D	SC	For FeLV infections
	0.1 million U/kg	q24	C	Oromucosal	For refractory caudal stomatitis associated with FCV infection
Filgrastim	5 μg/kg	q24h	C, D	SC	Monitor CBC weekly during treatment. Long-term use (>2 weeks) can lead to development of neutralizing antibodies.
Lactoferrin	200 mg powder or 40 mg/kg solution	q24h	C	Topical	For refractory gingivitis and stomatitis. Must be purchased from chemical suppliers
Lymphocyte T-cell immunomodulator	1 mL	Weekly	C	SC	For treatment of FeLV and FIV infections
Human recombinant interferon alpha	10^4 to 10^6 U/kg	q24h	C	SC	Monitor CBC weekly during parenteral treatment. Long-term parenteral use can lead to development of neutralizing antibodies
	1 to 50 U/cat	q24h		PO	
Pentoxifylline	15 mg/kg	q8h	D	PO	Benefits for treatment of FIP unclear. Co-administration of cytochrome P450 inhibitors may increase serum drug concentrations
	¼ of a 400 mg tablet	q8h	C		
Polyprenyl immunostimulant	3 mg/kg	Three times weekly	C	PO	Possible benefit for treatment of noneffusive FIP
Cutibacterium acnes, killed (formerly *Propionibacterium acnes*)	0.1 mg dogs < 7 kg	Twice weekly. After 14 days, weekly until remission, and monthly thereafter to maintain remission	D	IV	For pyoderma. Available as a 0.4 mg/mL solution
	0.2 mg 7–20 kg				
	0.4 mg 20–34 kg				
	0.8 mg > 34 kg				
Staphylococcus aureus phage lysate	0.5 mL	Once or twice weekly	D	SC	For pyoderma

CBC, complete blood count; *FCV,* feline calicivirus; *FeLV,* feline leukemia virus; *FIP,* feline infectious peritonitis; *FIV,* feline immunodeficiency virus.

IFN-α.[170] When IFN-α was given SC (10^5 IU/kg q24h for 14 days) to seven shelter cats with chronic upper respiratory tract disease that tested positive for FHV-1 or FCV by PCR, there was some improvement of clinical signs,[171] but further studies are needed to evaluate this approach in a larger cat population. IFN-α also has been administered orally to FHV-1 infected cats, but no controlled studies have been performed.[87] In cats with ocular disease, topical IFN-α q4-6h for 1 week beyond clinical resolution has been recommended. In cats with naturally occurring viral keratoconjunctivitis, ocular administration of high doses of IFN-α q12h for 14 days did not improve clinical disease or virus shedding when compared with saline.[172] With availability of famciclovir, topical IFN-α is used less frequently, or it is being used in combination with other drugs, based on observations of *in vitro* synergistic activity against FHV-1 or HSV-1 when combined with acyclovir.[46,173] Investigations of the efficacy of nucleoside analogues in combination with IFN-α in cats are warranted.

The antiviral activity of IFN-α against a FIP-causing FCoV strain was demonstrated *in vitro*.[174] A combination of IFN-α with ribavirin resulted in antiviral effects that were greater than the sum of the effects from either ribavirin or IFN-α alone,[174] but the combination was not effective *in vivo*. In one study, 74 cats (52 treated, 22 controls) with experimentally induced FIP received IFN-α, *Cutibacterium acnes*, a combination, or placebo. Prophylactic and therapeutic administration of high-dose (10^4 or 10^6 IU/kg) IFN-α did not reduce mortality in treated cats, but the mean survival time in cats treated with 10^6 IU/kg IFN-α with *C. acnes* was significantly prolonged for 3 weeks.[175]

IFN-α inhibits replication of CDV *in vitro*, with or without ribavirin,[176] but no *in vivo* studies have been published. IFN-α has been used to treat dogs with viral papillomatosis, but controlled studies are lacking.[177] In humans with papillomatosis, IFN-α has been used at 10^6 IU/person parenterally until regression occurred. A similar treatment regimen, intralesional injection or oral low-dose treatment, might be effective in dogs.

Feline Interferon-ω. Recombinant feline interferon-ω (IFN-ω) is licensed for use in cats and dogs in Europe, Asia, and Australia. It is not available in the United States. It has been used for treatment of viral infections in cats and dogs as well as for treatment of some tumors (e.g., feline mammary tumors)[178] and canine atopic dermatitis.[179] In healthy dogs, IFN-ω enhances the activities of whole blood cells, macrophages, and natural killer cells.[180] IFN-ω is produced in silkworms using a recombinant baculovirus. It can be used in cats for long periods without antibody development.[150] In FIV and FeLV infection, a dose of 10^6 IU/kg SC q24h on 5 consecutive days is suggested. No severe adverse effects have been reported in cats,[181] but transient lethargy, fever, vomiting, mild diarrhea, and anorexia have been documented in some treated cats, especially at higher doses (2.5×10^6 U/kg). Mild neutropenia, eosinophilia, and reversible increases of serum AST activity have also been described.[182] IFN-ω inhibits the replication of

FIV,[159] FeLV,[183] FCoV,[184] FHV-1 and FCV,[167,168,170] FPV and CPV,[184] and CDV[185] *in vitro*.

When used in a placebo-controlled multicenter trial to treat 62 naturally FIV-infected cats (10^6 IU/kg SC q24h on 5 consecutive days), there were no changes in survival in treated cats when compared with a placebo group, although some clinical improvement was noted.[181] In naturally FIV-infected cats housed in a shelter, clinical improvement was observed, but there was no control group included. Oral administration of a lower dose of IFN-ω (10^5 U/cat PO q24h for 90 days) to clinically affected, naturally FIV-infected cats was associated with improvement of clinical scores.[186] The improvement was not different from that observed in a historical control group treated with 10^6 IU/kg SC IFN-ω, which suggested that PO administration of the lower dose of IFN-ω could be used as an alternative to the licensed protocol at reduced cost. In a follow-up study of naturally FIV-infected cats treated either with PO or SC IFN-ω, there was no change in viremia and most cytokine concentrations measured,[187] which raised questions about the efficacy noted in the previous trials that lacked placebo-treated controls. It is possible that the clinical improvement observed resulted from an effect of IFN-ω on secondary infections rather than on the FIV infection itself.[150] Indeed, 16 naturally FIV- and/or FeLV-infected cats that were followed for 65 days during IFN-ω treatment had reduced excretion of co-infecting viruses (FCV, FHV-1, FCoV, and FPV).[88] Additional randomized, placebo-controlled, and double-blind studies are required to fully determine the efficacy of IFN-ω for treatment of FIV infections.

In one study, 48 cats with naturally occurring FeLV infection were treated with IFN-ω (10^6 IU/kg SC q24h SQ for 5 days). This treatment was applied three times, separated by several treatment-free weeks. There was a significant difference in the survival time of treated versus placebo-treated cats in a 9-month follow-up period, but not after 1 year.[181] Some clinical improvement was noted with IFN-ω treatment of FeLV-infected cats housed in a shelter, but no placebo group was included.[88] No studies have been published on the use of PO low-dose IFN-ω in FeLV-infected cats.

In an uncontrolled study, 12 cats that were suspected to have FIP were treated with IFN-ω in combination with glucocorticoids and supportive care.[188] Although most cats died, four cats with abdominal effusion survived 2 years, suggesting that treatment of cats with IFN-ω might increase survival time. In a randomized double-blind treatment trial, 34 cats with FIP were treated with glucocorticoids in conjunction with placebo or IFN-ω (10^6 IU/kg SC q48h until clinical improvement, then once weekly).[189] In all cats, FIP was confirmed by histology and/or immunohistochemical or immunofluorescent staining of FCoV antigen in effusion or tissue macrophages. Some cats in both groups survived for weeks to months (longest survival 200 days). There was, however, no significant difference in the mean survival time or quality of life of cats treated with IFN-ω when compared with placebo.[189]

At higher concentrations, the effect of IFN-ω on FHV-1 replication appears to be greater than that of IFN-α.[168] However, when used topically to treat experimentally infected cats with conjunctivitis, IFN-α had higher efficacy than IFN-ω, and cats treated with IFN-ω even had a worsened conjunctivitis score.[190] In cats with naturally occurring viral keratoconjunctivitis, ocular administration of IFN-ω q12h for 14 days did not improve clinical disease or virus shedding compared with treatment with saline solution.[172] In a noncontrolled field study, cats with suspected acute FCV infection showed improvement in clinical signs (e.g., upper respiratory tract disease or stomatitis) following treatment with IFN-ω (2.5×10^6 IU/kg IV q48h, 3 times).[191] However, in a placebo-controlled study, treatment with IFN-ω was not effective in ameliorating clinical signs.[192] In a prospective, randomized, placebo-controlled, double-blind clinical trial, 37 cats with acute FCV- and/or FHV-1-induced clinical signs were treated with IFN-ω (2.5×10^6/kg SC once, followed by 0.5×10^6 topically on the conjunctiva, intranasally, and orally q8h for 21 days). Treatment with IFN-ω was not effective in ameliorating clinical signs when compared with placebo, but accelerated a reduction in FCV load in infected cats.[192] Local injection of IFN-ω into oral lesions in cats with chronic gingivostomatitis, some of which were infected with FCV, was followed by some improvement, but the cats were also treated with other drugs and dental procedures, and a control group was not included.[193] In a controlled study, oromucosal administration of IFN-ω to cats with FCV-associated chronic gingivostomatitis had the same efficacy as glucocorticoid treatment, suggesting that IFN-ω might be an alternative to glucocorticoids.[194] In conclusion, data do not support the use of IFN-ω for treatment of FHV-1 infection, but there might be some efficacy for treatment of FCV infections, especially in cats with chronic gingivostomatitis.

In a case series that included five cats with cowpox virus pneumonia, two cats survived, both of which were treated with IFN-ω.[195] However, controlled studies are lacking.

When used to treat beagle puppies that were experimentally infected with CPV, the number of dogs that developed clinical signs did not differ significantly between the treated dogs and the placebo groups, but clinical signs were less severe in dogs treated with IFN-ω.[196] In one double-blind trial, 10 beagle puppies with experimentally induced CPV disease were randomized to two groups of five dogs each. Four days after challenge, one group was treated with saline and the other with IFN-ω (2.5×10^6 IU/kg IV q24h for 3 consecutive days). All five dogs in the placebo group died within 10 days. In the treated group, one animal died on day 2 after treatment was started, whereas the other four dogs recovered.[197] In a randomized, double-blind, multicenter field study in France, 92 dogs aged 1 to 28 months were treated with either IFN-ω (2.5×10^6 IU/kg IV q24h for 3 consecutive days) or placebo. Clinical signs in treated animals improved significantly in comparison with control animals, and in the IFN-ω group, 3 dogs died compared with 14 in the placebo group.[198] In a similar field study in Japan, mortality was also reduced in the dogs treated with IFN-ω (14/72) when compared with the control group (13/21).[199] These data suggest that IFN-ω improves clinical signs and reduces mortality due to CPV. There are no controlled studies of the use of IFN-ω to treat cats with panleukopenia. IFN-ω was not effective in preventing panleukopenia in cats after entering a cattery.[200]

Lymphocyte T-cell Immunomodulator

Lymphocyte T-cell immunomodulator (LTCI) is a protein derived from thymus epithelial cells. According to the product brochure, LTCI upregulates IL-2 production *in vitro* and regulates CD4 T-cell function. It was also reported to stimulate platelet production in mice with chemotherapy-induced thrombocytopenia. LTCI has been conditionally approved in the United States as an aid for treatment of FIV and FeLV infections, and for the associated signs of cytopenias and opportunistic infections, but controlled independent studies of the efficacy of LTCI in cats are required.

Naturally Occurring Biologic Response Modifiers

Lactoferrin

Commercial lactoferrin is a mammalian iron-binding glycoprotein of bovine origin with immunomodulatory properties. Lactoferrin is produced by the mucosal epithelial cells of all mammals and is present in secretions, especially in milk. It has been used for its local immunomodulatory effect in the oral cavity, and it has been shown to increase cellular phagocytic activity.[201] It binds iron, reducing its availability for bacteria, and thus has not only antibacterial but also antifungal, antiprotozoal, and antiviral activity, and its antitumor activity has also been

investigated.[202] Lactoferrin inhibits influenza virus hemagglutination and cell infection.[203] A protective effect of lactoferrin during lethal bacteremia has been reported in mice.[204] Long-term oral administration of bovine lactoferrin to a dog with β_2-integrin-related neutrophil dysfunction was associated with increased neutrophil function and recovery from opportunistic infections.[205] Lactoferrin was also administered long term to two canine littermates with familial neutrophil dysfunction and improved their clinical signs.[206] Adverse effects have not been reported.

Topical application of lactoferrin (40 mg/kg q24h for 14 days) to the mouth of a small number of FIV-infected and noninfected cats with stomatitis was associated with improved appetite and reduced oral inflammation, salivation, and pain, and increased neutrophil phagocytic activity.[201] Treatment with lactoferrin might also have the potential to improve functions of overactivated lymphocytes by modulating the cell proliferation, cell cycle, and cytokine expression in cats in the terminal stage of FIV infection.[207] Lactoferrin has antiviral activity against FHV-1, CHV-1, and FCV *in vitro*.[208–210] No *in vivo* data are available so far in cats infected with FHV-1. Lactoferrin appeared to reduce the clinical signs in cats with chronic gingivostomatitis in one study, but it is unknown whether the cats were infected with FCV.[211] One cat with stomatitis and FCV infection was treated with lactoferrin powder (200 mg) that was applied directly to lesions for 22 months. Clinical signs began to resolve after 11 months, and resolution of clinical signs coincided with the cessation of FCV shedding.[212] However, the cat also received other medications, and because spontaneous resolution of this condition can occur, further studies are necessary.

Plant-Derived Biologic Response Modifiers

A few plant-derived biologic response modifiers are on the market, such as polyprenyl immunostimulant. Other plant extracts with antiviral activity have undergone preliminary *in vitro* assessment, but safety or clinical efficacy have not been reported.[213] Polyprenyl immunostimulant is a plant-derived veterinary biologic that is made of phosphorylated, linear polyisoprenols. *In vitro*, it upregulates synthesis of Th1 cytokines and has antiviral and antineoplastic properties.[214,215] Polyprenyl immunostimulant appeared to have a beneficial effect in two cats with histologically confirmed and one cat with suspected FIP without effusion.[216] One cat survived 14 months, and the other two cats were still in clinical remission after 24 and 28 months, respectively. In a field study, treatment with polyprenyl immunostimulant was evaluated in 60 cats that were suspected to have FIP by primary care and specialist veterinarians, but FIP was not confirmed. None of the cats had effusion. There was no control group. Of the 60 treated cats, 8/60 survived over 200 days and of those, 4/60 survived over 300 days. Veterinarians of treated cats that survived over 30 days reported improvements in clinical signs and behavior. The survival times were significantly longer in cats who were not treated with corticosteroids concurrently.[217] Use of polyprenyl immunostimulant might hold some promise for treatment of cats with FIP that have no effusion, while its use in cats with FIP with effusions has been disappointing. However, controlled studies in cats with confirmed FIP would be very important.

According to the manufacturer, cats with experimentally induced FHV-1 infection had a decreased severity and duration of upper respiratory tract signs when treated with polyprenyl immunostimulant in comparison with cats receiving placebo, but independent controlled studies are lacking.

Synthetic Compounds

Antiparasitic and Antibacterial Compounds

Some antiparasitic compounds nonspecifically stimulate cell-mediated or humoral immunity and thus have immunomodulatory activity. The antiparasitic agent ivermectin has been investigated for treating human patients with SARS-CoV-2 infection. Although ivermectin has theoretical potential for this use,[218] the concentrations achieved in patients with standard doses are not high enough to produce antiviral effects.[219] Some antibiotics also have immunomodulatory properties, including the macrolides, doxycycline, and metronidazole, but there are no prospective studies using these drugs in virus-infected cats and dogs.

Other Synthetic Compounds

Pentoxifylline and propentofylline are synthetic methylxanthines derived from theobromine. Propentofylline is marketed in Europe as a veterinary product. Both compounds are phosphodiesterase inhibitors with a variety of immunomodulatory properties. In rodents and humans, they inhibit tumor necrosis factor (TNF)-α, IL-1, IL-6, and IL-12 production, as well as activation of T and B cells, and increase neutrophil mobility and chemotaxis. They also increase erythrocyte cAMP levels, which results in increased erythrocyte deformability, lowered blood viscosity, and improved microcirculation and tissue perfusion. They decrease platelet aggregation and increase tissue plasminogen activator in patients with hyperaggregable platelets; thus, they can be useful for treatment of disorders that result in hypercoagulable states. Pentoxifylline has been evaluated as a treatment for equine endotoxemia. Despite decreases in TNF-α and IL-6 activity after incubation of equine monocytes with pentoxifylline *in vitro*, these effects did not occur in horses.[220] Beneficial effects of pentoxifylline are limited in horses when administered IV after challenge with endotoxin.[221] In dogs, pentoxifylline has been used to treat canine atopic dermatitis, dermatomyositis, and cutaneous vasculopathies,[222,223] as well as cognitive dysfunction in geriatric dogs.[224] In dogs, pentoxifylline has a low and unpredictable oral bioavailability and a short half-life, and q8h administration has been recommended. Adverse effects include vomiting and inappetence, which are more likely to occur when the tablets are crushed. Crushed tablets are also unpalatable to cats.

According to anecdotal reports, pentoxifylline has been used to treat some cats with FIP, with apparent improvement in clinical signs and survival time. However, when the closely related drug propentofylline was used in a double-blind trial of 23 cats with naturally occurring FIP, there was no difference in survival time, quality of life, amount of effusion, or TNF-α concentration in cats treated with propentofylline versus placebo.[225]

Antibacterial Drugs

Jane E. Sykes, Mark G. Papich

KEY POINTS

- An understanding of the mechanisms of action, spectrum of activity, pharmacokinetics, pharmacodynamics, and adverse effects of antibacterial drugs facilitates optimal treatment of bacterial infections while minimizing the chance for: (1) selection of resistant bacteria, (2) adverse reactions, and (3) drug interactions.
- The importance of appropriate administration of antibiotics, compliance issues, and potential adverse effects of the drug chosen should be discussed with the pet owner when antibiotics are prescribed.

INTRODUCTION

This chapter reviews the classification, mechanisms of action, spectrum of activity, resistance mechanisms, tissue penetration, clinical use, and adverse effects of the major classes of antibiotics used to treat dogs and cats. Antimicrobials have been grouped together in order according to their mechanism of action (cell wall synthesis, nucleic acid, and then protein synthesis inhibitors). Tables are dispersed throughout the text with drug dosages for each group of antibiotics. The reader is encouraged to review the accompanying text when using the tables. Not all antibiotics are reviewed here. Antibiotics that have specific uses, such as certain antimycobacterial drugs and nitrofurantoin, are reviewed in the relevant chapters of this book. Chapter 8 provides an overview of the basic principles of antimicrobial treatment and antimicrobial stewardship.

INHIBITORS OF CELL WALL SYNTHESIS

Inhibitors of cell wall synthesis include the beta-lactams (penicillins, cephalosporins, and carbapenems), fosfomycin, and glycopeptides.

Beta-Lactam Antibiotics

β-Lactam antibiotics have a β-lactam ring in their molecular structure (Fig. 10.1). They include penicillins, cephalosporins, monobactams, and carbapenems. They are bactericidal antibiotics (see Chapter 8) that bind covalently to and inhibit PBPs. These PBPs are needed to catalyze the cross-linking (or *transpeptidation*) of the peptidoglycan layer of bacterial cell walls, which is continuously remodeled by bacteria (Fig. 10.2). When PBPs are inactivated by β-lactam antibiotics, bacterial enzymes that hydrolyze the peptidoglycan cross-links during cell wall remodeling continue to function, which breaks down the cell wall further. The accumulation of peptidoglycan precursors also triggers activation of cell wall hydrolases, with further digestion of intact peptidoglycan. The end result is bacterial rupture.

The peptidoglycan layer of gram-positive bacteria is 50 to 100 times thicker than that of gram-negative bacteria and is highly cross-linked, which maintains the structural integrity of gram-positive bacteria.[1] Therefore, compared to gram-negative bacteria, gram-positive bacteria are more easily inactivated by β-lactam antibiotics and typically have lower MICs. Bacteria possess multiple PBPs, which are assigned numbers based on their molecular weight. PBPs vary in their affinities for different β-lactam antibiotics, which in part explains the difference in spectrum of activity and bactericidal action of β-lactam antibiotics. For example, inhibition of PBP1a and PBP1b leads to cell lysis, whereas inhibition of PBP2 results in rounded cells called spheroblasts. Drugs that produce rapid lysis (e.g., carbapenems) are the most bactericidal and have highest affinity for PBP1.

Resistance to β-lactam antibiotics was recognized soon after the discovery of penicillin in the 1930s. Resistance has increased gradually and is now common. Resistance results primarily from β-lactamase production.[2] It can also result from production of altered PBPs (such as PBP2a, which is encoded by the *mecA* gene and characterizes MRS) and, among gram-negative bacteria, exclusion of drugs that normally diffuse through porins to their site of action or removal by efflux transporters. Gram-negative β-lactamases are strategically located just beneath the outer LPS layer, which acts as the barrier to drug penetration. Gram-positive bacteria secrete β-lactamases into their immediate surroundings. There are hundreds of different β-lactamase enzymes that vary in their specificity for β-lactam drugs.

Most β-lactam antibiotics have a short half-life unless administered in slow-release formulations and exhibit time-dependent pharmacodynamics (see Chapter 8). Exceptions to this general description are described below. Drug concentrations should be maintained above the MIC (T > MIC) for approximately 50% of the dosing interval. For penicillins and carbapenems, T > MIC can be less than 50%, but aiming for a target of 50% ensures that most patients will have adequate exposure. Time of exposure (30% vs. 40%, vs. 50%, and so on) determines the extent of *in vitro* decline in CFUs in laboratory infection models, usually expressed as net bacterial stasis, 1-$\log_{10}$ reduction, 2-$\log_{10}$ reduction, or 3-$\log_{10}$- reduction in bacterial counts.[3] Immunosuppressed patients or severe life-threatening infection (e.g., pneumonia, sepsis) should have longer T > MIC than immunocompetent animals. To maintain this target, some β-lactam antibiotics with short half-lives require frequent administration or slow infusion. For other drugs, a long half-life prolongs the T > MIC to allow for infrequent administration. For example, cefpodoxime proxetil has a longer half-life than other oral cephalosporins, so it can be administered only once per day.

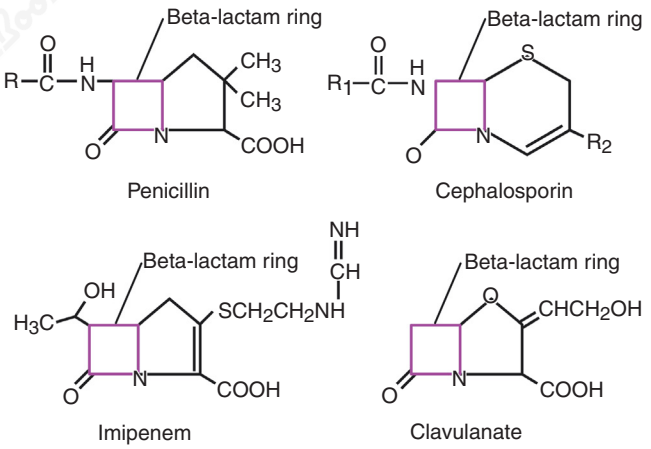

Fig. 10.1 Structure of β-lactam antibiotics.

Cefovecin has an extremely long half-life in dogs and cats and can be effective for some infections when administered at 14-day intervals. For other cephalosporins (e.g., injectable drugs with short half-lives such as ceftazidime), three- to four-times-daily dosing may be required for treatment of gram-negative bacterial infections.

Penicillins

Classification, Spectrum of Activity, and Resistance Mechanisms

Penicillins are derived from *Penicillium* molds. They are classified as naturally occurring penicillins such as penicillin G (benzyl penicillin), the semisynthetic aminopenicillins such as ampicillin and amoxicillin, penicillinase-resistant penicillins, and extended-spectrum penicillins. Table 10.1 shows the classification of the penicillins and their respective spectra of activity.

Penicillin G must be given parenterally because of poor oral absorption. Gram-positive bacteria that are susceptible to penicillin G are more susceptible to penicillin G than to aminopenicillins such as ampicillin. The aminopenicillins have some activity against gram-negative bacteria, but generally not bacteria of the Enterobacterales (e.g., *Escherichia coli)*, or nonfermenters (e.g., *Pseudomonas aeruginosa)*. Most of the gram-negative bacteria are resistant because they produce β-lactamases. Ampicillin and amoxicillin have an almost identical spectrum, but amoxicillin has approximately twice the oral absorption of ampicillin and is a better choice for oral administration.

Penicillinase-resistant penicillins (also known as β-lactamase-resistant penicillins or antistaphylococcal penicillins) such as methicillin have a structure that resists inactivation by staphylococcal β-lactamase enzymes. These drugs include methicillin, cloxacillin, and dicloxacillin. These drugs are rarely (if ever) used for small animal treatment today. Their oral absorption is poor, and many formulations are no longer available. Oxacillin is used by the laboratory to test for methicillin-resistant strains of *Staphylococcus* spp. This phenotypic test is highly reliable for detecting resistance caused by bacterial possession of the altered PBP2a, which leads to resistance to all β-lactam antibiotics.[4] It should be noted that that the cefoxitin test for this resistance mechanism in *Staphylococcus aureus* cannot be reliably used for *Staphylococcus pseudintermedius.*

Extended-spectrum penicillins (antipseudomonal penicillins) have enhanced activity against gram-negative bacteria, but must be given parenterally. Their short half-lives (less than 1 hour) frequently require administration or a CRI. These drugs include the carboxypenicillins, such as ticarcillin and carbenicillin, and piperacillin, an ureidopenicillin. The only agent in this group currently available is piperacillin,

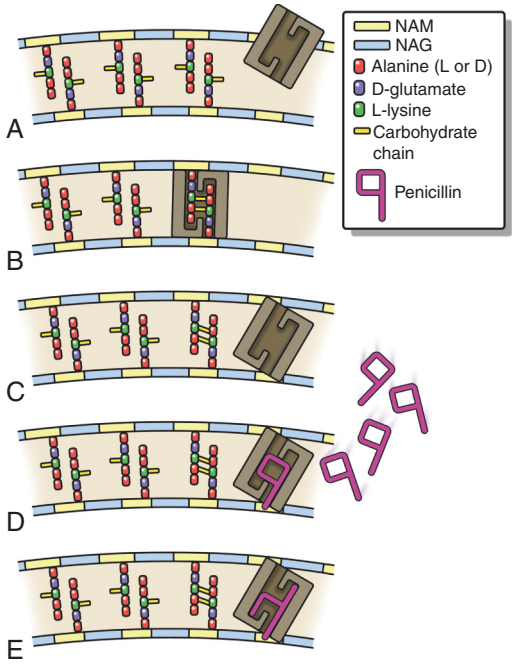

Fig. 10.2 Interference of peptidoglycan production by β-lactam antibiotics. The bacterial cell wall consists of *N*-acetylglucosamine *(NAG)* and *N*-acetylmuramic acid *(NAM)* subunits. (A) The penicillin-binding protein *(PBP, brown squares)* binds (B) peptide side chains and forms a cross-link. (C) The PBP dissociates from the wall once the cross-link has been formed. (D) Penicillins enter the active site of the PBP. (E) The β-lactam ring of the penicillin is irreversibly opened when it reacts with the PBP, which permanently blocks the active site.

which is only available as the combination of piperacillin and tazobactam (discussed later in this chapter). Other drugs in this group have been withdrawn by the manufacturer.

Clavulanic acid, sulbactam, and tazobactam are β-lactamase inhibitors that are administered in conjunction with penicillins, which increase the spectrum of activity. β-Lactamase inhibitors possess weak intrinsic antibacterial activity. The combination of amoxicillin and clavulanate is a popular oral antibiotic for dogs, cats, and humans. The pharmacokinetics allow for oral absorption of both drugs (marketed for animals in a 1:4 ratio of clavulanate:amoxicillin) to maintain an effective plasma drug ratio throughout the dose interval. Sulbactam has been combined with ampicillin for IV injection. Sulbactam is not as active as clavulanic acid against some gram-negative β-lactamases. Tazobactam is combined with piperacillin. Piperacillin-tazobactam ("Pip-Taz") is a highly active combination against gram-positive and most gram-negative bacteria, including *P. aeruginosa* and many ESBL-producing Enterobacterales. Because of the short half-life in dogs (approximately 30 minutes), it must be administered IV frequently, or with a CRI. Ticarcillin-clavulanate, once a popular agent in veterinary hospitals, has been withdrawn from the manufacturer and is no longer available.

Clinical Use

Penicillin dosages for dogs and cats are listed in Table 10.2. The absorption and duration of activity of penicillins depends on the dose administered, the vehicle containing the drug, the solubility of the salt formulation, and the presence or absence of food. Penicillins are distributed to the extracellular fluid of most tissues. Because of low penetration across the blood-brain barrier and blood-ocular barrier, high doses are needed in order to attain effective levels in these tissues.

TABLE 10.1 Classification and Spectrum of Activity of Penicillin Antibiotics

Penicillin Group	Examples	Antibacterial Spectrum
Natural penicillins	Penicillin G	Gram-positive aerobic bacteria (especially streptococci) and anaerobes. *Pasteurella multocida* may also be susceptible
Aminopenicillins	Ampicillin Amoxicillin	Gram-positive aerobic bacteria (cocci and bacilli) and anaerobes; some susceptible gram-negative bacteria
Penicillinase-resistant penicillins	Methicillin Oxacillin Cloxacillin Dicloxacillin	Susceptible β-lactamase-producing gram-positive aerobic bacteria (*Staphylococcus* spp.). Less active against penicillinase-susceptible organisms than penicillin G
Extended-spectrum carboxypenicillins	Ticarcillin *(no longer available)* Carbenicillin *(no longer available)*	Increased activity against susceptible gram-negative aerobes, which includes *Pseudomonas aeruginosa*, *Proteus* spp., *Klebsiella*, and anaerobes. Some reduction in gram-positive spectrum. Destroyed by β-lactamases
Ureidopenicillins	Mezlocillin Piperacillin (always in combination with tazobactam)	Susceptible gram-positive and gram-negative aerobes, which include *Pseudomonas aeruginosa*. Some loss of anaerobic spectrum. Destroyed by β-lactamases
Penicillin–β-lactamase inhibitor combinations	β-Lactamase inhibitors: clavulanic acid, sulbactam, tazobactam. Examples: amoxicillin-clavulanate, piperacillin-tazobactam, ampicillin-sulbactam.	Susceptible β-lactamase-producing gram-positive and gram-negative aerobic bacteria and anaerobes

TABLE 10.2 Suggested Penicillin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints(μg/mL)
Penicillin G potassium or sodium	20,000–40,000 U/kg	6–8	D, C	IV, IM		≤8 for enterococci; ≤0.12 for staphylococci and streptococci
Ampicillin sodium	10–20	6–8	D, C	IV, IM, SC	Administer IV over 3 minutes. When reconstituted with sterile water to 250 mg/mL, vials should be used within 1 hour. When reconstituted with 0.9% NaCl to 45 mg/mL, stability is maintained for 48 hours if refrigerated	≤0.25 for staphylococci, streptococci, and gram-negative bacilli; ≤8 for canine urinary tract pathogens
Ampicillin-sulbactam	10–20	8	D, C	IV, IM	See ampicillin. Dose according to ampicillin component	≤8/4[a] for staphylococci and gram-negative bacteria
Amoxicillin	10–20	8–12	D, C	PO		See ampicillin.
Amoxicillin-clavulanate potassium	12.5–25	12	D, C	PO	More frequent or higher doses recommended for gram-negative infections	≤0.25/0.12[a] for staphylococci, streptococci, *Escherichia coli* and *Pasteurella multocida*
Ticarcillin disodium, ticarcillin-clavulanate[b] *(No longer available)*	33–50	4–6	D, C	IV	When reconstituted with 0.9% NaCl, stable for up to 14 days when refrigerated	≤64/2[a] for *Pseudomonas aeruginosa*, ≤16/2 for gram-negative enteric bacteria
Piperacillin sodium/ piperacillin-tazobactam[b]	40	6	D, C	IV	Reconstituted solution should be used within 7 days if refrigerated	See ticarcillin

[a]The "/" distinguishes the ticarcillin from clavulanic acid concentrations.
[b]It is recommended that the use of these drugs be reserved for life-threatening infections that are susceptible to these drugs but resistant to other drugs, on the basis of culture and susceptibility testing.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

Penicillins undergo rapid renal elimination, and active drug is concentrated in the urine; therefore, they are useful for treatment of bacterial UTIs. Liver impairment has little effect on the pharmacokinetics of penicillins. In animals with kidney disease, increasing the length of the dose interval in proportion to the degree of kidney impairment should be considered to prevent accumulation from repeated doses. Potassium-containing penicillins should not be given IV to patients with oliguric acute kidney injury because of the risk of hyperkalemia.

Adverse Effects

Penicillins are generally well tolerated by dogs and cats. The most common adverse effects in dogs and cats are vomiting, diarrhea, and

TABLE 10.3 Classification and Spectrum of Activity of Cephalosporin Antibiotics

Cephalosporin Generation	Examples	Antibacterial Spectrum
First	Cephalexin Cefazolin Cefadroxil	Methicillin-susceptible staphylococci and streptococci and aerobes; some activity against gram-negative aerobes (especially cefazolin). Unpredictable activity against anaerobes
Second	Cefaclor Cefotetan *(no longer available)* Cefoxitin	Improved activity against gram-negative aerobes and anaerobes compared with first-generation drugs. Cefoxitin has greater stability against anaerobic β-lactamases (such as those produced by *Bacteroides* spp.) than other second-generation drugs
Third	Cefixime *(oral but no longer available)* Cefpodoxime *(only oral product in this group)* Ceftiofur Cefotaxime *(no longer available)* Ceftriaxone Cefovecin Ceftazidime	Activity primarily against gram-negative bacteria. Some drugs in this group have less activity against gram-positive bacteria and anaerobes
Fourth	Cefepime	Gram-positive cocci, gram-negative bacilli, many β-lactamase-producing gram-negative bacteria. Reserve for life-threatening infections where no other alternative is available

inappetence. These are more likely to occur with amoxicillin when clavulanic acid is administered concurrently. Hypersensitivity reactions that include fever, cutaneous reactions, immune-mediated cytopenias, and anaphylaxis are possible, especially in dogs, but are less common than in human patients (approximately 15% of people are allergic to penicillin). The use of penicillins should be avoided in animals with a history of such reactions. Rarely, rapid IV infusion or administration of high doses of penicillins to animals with co-existing renal failure is followed by development of neurologic signs, such as seizures. This effect is caused by inhibition of γ-aminobutyric acid (GABA) in the CNS. Pain or tissue reactions can occur when penicillins are administered IM or SC.

Cephalosporins

Classification and Spectrum of Activity

The cephalosporins were originally derived from *Acremonium* spp. (previously known as *Cephalosporium* spp.). They have been broadly grouped into first-, second-, third-, and fourth-generation cephalosporins based on their spectrum of activity. As the generation increases, there is an increase in gram-negative spectrum, and fourth-generation drugs have truly broad-spectrum activity (Table 10.3). An exception to this pattern is the newest addition to the group, ceftaroline. It has activity against MRS as a result of an affinity for PBP2a and has been considered a "fifth-generation" cephalosporin. Cephalosporins are resistant to staphylococcal β-lactamase, and the extended-spectrum cephalosporins (primarily third-generation drugs) are resistant to many gram-negative β-lactamases. However, bacterial plasmid-encoded ESBL enzymes and the chromosomally encoded AmpC β-lactamase can hydrolyze even third-generation cephalosporins and present an important therapeutic challenge. ESBLs are typically not detected using routine susceptibility testing but should be suspected when there is resistance among gram-negative bacteria to third-generation cephalosporins. A laboratory can confirm the presence of ESBL if an isolate is suspected.

Clinical Use

Cephalosporin dosages for cats and dogs are listed in Table 10.4. First-generation cephalosporins such as cephalexin are moderately absorbed orally and distributed into extracellular fluids. In general, they have poor penetration of the blood-brain barrier, even in the face of inflammation, but penetration into other extracellular fluids are sufficient. Most are excreted unchanged in the urine, and so are useful for treatment of UTIs. Cefazolin has greater activity against a wider range of bacterial isolates than the oral first-generation cephalosporins (e.g., cephalexin and cefadroxil).[5] Cefazolin has been a popular injectable antibiotic for perioperative use in small animals. This perioperative use of cefazolin is with the intention to prevent postsurgical infections, particularly in orthopedic surgery (see Chapter 121).

Use of second-, third-, and fourth-generation cephalosporins may be indicated when there is resistance to first-generation cephalosporins and there are no other reasonable alternatives available. Three third-generation cephalosporins are approved by the US FDA for use in small animals: ceftiofur, cefpodoxime proxetil, and cefovecin. These agents are approved for treatment of skin and soft tissue infections (cefpodoxime proxetil and cefovecin) and UTIs in dogs (ceftiofur). Although their use in small animal medicine has been controversial because of concerns that relate to selection for resistant bacteria,[6] there is no evidence at this time that these agents are more likely to select for resistance among isolates from dogs and cats than other agents. The injectable third-generation cephalosporins approved for humans have greater *in vitro* activity than cefpodoxime or cefovecin and occasionally have been used in dogs and cats (e.g., cefotaxime, ceftazidime, cefoperazone). Of these, ceftazidime is the most often used, and cefotaxime is no longer available in the United States. These drugs have a high degree of activity, but must be administered frequently by injection. Therefore, the use of these agents is limited to in-hospital use in which repeated IV injections or CRIs are possible.

Distribution and excretion into urine and bile is variable. Cefpodoxime proxetil is the most commonly used oral third-generation drug in small animals, approximately 50% of which is excreted in the urine in active form. Cefovecin is approved for use in dogs and cats in Europe and North America as a SC injection. The high protein binding and slow clearance result in a very long half-life in these species (approximately 7 days in cats and 5 days in dogs). Administration of cefovecin results in a duration of activity of at least 14 days in cats, and for at least 7 to 14 days in dogs (depending on the pathogen).

TABLE 10.4 Suggested Cephalosporin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Route	Species	Comments	CLSI Breakpoints (μg/mL)
Cephalexin	25 15–20	12 12	PO	D C	Use 30 mg/kg q12h for pyoderma	≤2 for susceptible organisms.
Cefadroxil	22	12 24	PO	D C		See cephalexin
Cefazolin sodium	20–35	8	IV, IM	D, C	22 mg/kg q2h during surgery if indicated	See cephalexin
Cefaclor[b]	15–20	8	PO	D, C		≤8 for all susceptible organisms
Cefoxitin sodium[b]	30	6–8	IM, IV	D, C	Pain on injection IM	See cefaclor
Cefixime[b]	10	12	PO	D, C	Use 5 mg/kg q12–24h for urinary tract infections	≤1 for all susceptible organisms
Cefpodoxime proxetil[b]	5–10	24	PO	D[a]	Of all third-generation cephalosporins, most active against staphylococci. Less active against gram-negative and anaerobic infections	≤2 for all susceptible organisms
Ceftiofur sodium[b]	2.2–4.4	24	SC	D[a]	For treatment of otherwise resistant urinary tract infections	Not established for dogs and cats
Cefotaxime sodium[b] *(no longer available)*	50 20–80	126	IV, IM	D C	Partially metabolized by the liver to desacetyl cefotaxime which contributes to antibacterial activity. Good CNS penetration. Stable for 5 days in the refrigerator after reconstitution	See cefpodoxime
Ceftazidime[b]	30	6	IV	D, C	Potent antipseudomonal activity	≤4 for Enterobacterales, ≤8 for *Pseudomonas aeruginosa* and staphylococci
Cefovecin[b]	8	14 days	SC	D, C	Approved for use for skin and soft tissue infections and in some countries, urinary tract infections. Efficacy for treatment of infections in other sites not established	No approved breakpoint. ≤2 for all susceptible organisms is suggested
Cefepime[b]	40	6	IV, IM	D[a]	Reduce frequency in dogs with renal failure (q12–24h)	≤ 8 for all susceptible organisms

[a]Dose not established for cats.
[b]It is recommended that the use of most second-, third-, and fourth-generation cephalosporins be reserved for serious infections that are susceptible to those drugs but resistant to other reasonable alternatives on the basis of culture and susceptibility testing.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *CNS,* central nervous system; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

Adverse Effects

Adverse effects of cephalosporins in dogs and cats are similar to those of penicillins, with GI signs and hypersensitivity reactions being most frequent. Although the incidence is low, cross-sensitivity can occur between penicillins and cephalosporins, so cephalosporins should be used with caution in animals that have a history of reactions to penicillin. Injectable cephalosporins can cause phlebitis and pain on injection. Cephalosporins have the potential to cause false-positive results on test strips that use copper reduction for urine glucose detection. Certain cephalosporins, such as cefotetan (no longer available) and ceftriaxone, may exacerbate bleeding tendencies due to vitamin K antagonism.[7] Reversible bone marrow suppression has been reported in dogs given long-term high doses of ceftiofur, cefonicid, and cefazedone.[8]

Monobactams (Aztreonam)

Aztreonam is a synthetic β-lactam antibiotic that is resistant to some β-lactamases. It is effective against a wide range of gram-negative bacteria, including *P. aeruginosa,* but not gram-positive or anaerobic bacteria. In human medicine, aztreonam is used to treat patients with serious gram-negative infections who are allergic to penicillins and cannot tolerate aminoglycosides.[9] Dosages have not been established for dogs and it is rarely used.

Carbapenems

Spectrum of Activity and Clinical Use

Carbapenems are highly resistant to almost all bacterial β-lactamases and include imipenem, meropenem, ertapenem, and doripenem. Of these, meropenem is the most frequently used in small animals because it is easier to administer and has a favorable spectrum and few adverse effects. They penetrate the outer membrane of gram-negative bacteria more effectively than many other β-lactam antibiotics and bind to a variety of PBPs, which leads to rapid lysis of a broad spectrum of bacteria.[10] In contrast to other β-lactam antibiotics, carbapenems have a postantibiotic effect (see Chapter 8) similar to that of aminoglycosides and fluoroquinolones. Although effective against many gram-positive, gram-negative, and anaerobic bacterial infections, the use of carbapenems is reserved for treatment of serious, MDR gram-negative infections, especially caused by *E. coli, Klebsiella pneumoniae,* and

TABLE 10.5 Suggested Carbapenem Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (µg/mL)
Imipenem-cilastatin	5	6–8	D, C	IV, IM, SC	250–500 mg of reconstituted drug should be added to no less than 100 mL of fluids and administered IV over 30–60 minutes. Stable for 24 hours after reconstitution when refrigerated. For IM injections, reconstitute with 1% lidocaine	≤1 for Enterobacterales, ≤2 for *Pseudomonas aeruginosa*
Meropenem	10 (for *Escherichia coli)* 30 (for *Pseudomonas aeruginosa)* 10	8 8 12	D D C	IV, IM, SC IV, IM, SC IV, IM, SC	SC injections may cause alopecia at the injection site.	Although an official breakpoint is not available at this time, use ≤1 µg/mL (S) for Enterobacterales (*E. coli*) and ≤2 µg/mL (S) for *P. aeruginosa.*

Carbapenems should be used for serious infections resistant to other reasonable alternatives, on the basis of culture and susceptibility testing.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *MIC,* minimum inhibitory concentration; *PO,* oral; *S,* susceptible; *SC,* subcutaneous.

P. aeruginosa, that are resistant to other antibiotics. MRS are resistant to carbapenems. Carbapenems must be administered parenterally because they are not absorbed after oral administration. Pharmacokinetics for meropenem have been reported for dogs.[11] Ertapenem has a narrower spectrum of activity and is less active against *P. aeruginosa* than the other agents. Dosages for dogs and cats are listed in Table 10.5.

The identification of carbapenemase production by some strains of gram-negative bacteria has raised great concern, because this confers resistance to a broad range of β-lactam antibiotics. Carbapenemase-producing *K. pneumoniae* (KPC), and carbapenem-resistent Enterobacterales (CRE), are resistant not only to all β-lactam antibiotics but also to fluoroquinolones and aminoglycosides.[12] *Klebsiella pneumoniae* that produce a plasmid-encoded metallo-β-lactamase enzyme (NDM-1) appeared in India in 2008 and have subsequently spread worldwide.[13] The only options left for treatment of these infections are tigecycline, polymyxins, and newly developed human drugs which have not been used in animals at this time.[14] The potential for spread of *K. pneumoniae* isolates that are resistant to all commercially available antibiotics now exists. Carapenemase (NDM-1) production has been detected in *E. coli* isolates from dogs and cats in the United States[15] and an *Acinetobacter lwoffii* isolate from a cat in China.[16]

Adverse Effects

Imipenem is degraded by dehydropeptidase-1, a brush border enzyme in the proximal renal tubules, which results in production of an inactive metabolite that is nephrotoxic. In order to prevent nephrotoxicity and maximize imipenem's antibacterial activity in the urine, imipenem is administered with cilastatin, which inhibits the dehydropeptidase-1 enzyme. Newer carbapenems such as meropenem are resistant to dehydropeptidase-1.

Adverse effects of carbapenems are otherwise rare and include vomiting, nausea, and pain on injection. Neurologic signs, including tremors, nystagmus, and seizures, can occur following rapid infusion of imipenem-cilastatin or in animals with renal insufficiency. Imipenem must be administered slowly in IV fluids (see Table 10.5). Slow administration is not required for meropenem, which is more soluble, and more stable after reconstitution. SC injections of meropenem have produced alopecia at the injection site,[17] but otherwise these injections have been very well tolerated and have eradicated infections associated with MDR gram-negative bacteria.

Glycopeptides

Mechanism of Action and Clinical Use

Glycopeptides are cyclic glycosylated peptide antimicrobials that inhibit the synthesis of peptidoglycan by binding to amino acids (D-alanyl-D-alanine) in the cell wall, preventing the addition of new units. Vancomycin, teicoplanin, and decaplanin are all glycopeptides. Only vancomycin has been used in small animals, but its use is rare.

Vancomycin was discovered in the 1950s, but has not been frequently used in small animals because it is not absorbed orally; therefore, IV infusion is required for treatment of systemic infections. When administered IV, it can be valuable for treatment of MDR gram-positive bacterial infections, such as MRS infections, resistant enterococcal infections, and encrusting cystitis caused by *Corynebacterium urealyticum*. The last is an emerging infection of dogs, cats, and immunocompromised human patients, treatment of which requires surgical debridement of the bladder in conjunction with glycopeptide administration.[18,19] Vancomycin is a valuable agent for treatment of MRS because resistance among these organisms is extremely rare and the bactericidal activity can be an advantage when treating immunocompromised patients. In human patients, oral vancomycin has been used to treat GI infections caused by resistant *Clostridioides difficile*.

Vancomycin-resistant methicillin-resistant *S. aureus* (MRSA) isolates are extremely rare in humans and have only been described in specific geographic locations. Vancomycin-resistant *S. pseudintermedius* isolates have not yet been described. Vancomycin-resistant enterococci (VRE) are well documented in human patients and can present a therapeutic challenge. Although currently rare, the existence of VRE has been reported in companion animals.[20,21] Resistance to vancomycin results from bacterial alteration of the terminal amino acid to which vancomycin binds. Because veterinary breakpoints for testing are not available, laboratories must use human interpretive categories for testing. In order to reduce inappropriate use of vancomycin, some laboratories do not report results for vancomycin susceptibility unless reporting is indicated on the basis of resistance in the remainder of the susceptibility panel.

There are new agents available for human medicine similar to vancomycin from the class of lipoglycopeptides. Dalbavancin (Dalvance) is a long-acting IV lipoglycopeptide, similar to telavancin (Vibativ). Oritavancin (Orbativ) is a long-acting IV lipoglycopeptide, similar to telavancin. The half-life of dalbavancin and oritavancin in humans is approximately 14 days, which allows for a single treatment. Telavancin (Vibativ) is a lipoglycopeptide for once-daily administration in humans. Because of the high cost of these drugs and reluctance to use valuable drugs for human use, the administration of these agents to animals for treatment of resistant infections has not been described.

Adverse Effects

Vancomycin is not commonly used to treat small animals, and so adverse reactions have not been well documented. The most common

TABLE 10.6 Suggested Vancomycin Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (µg/mL)
Vancomycin[a]	15 12–15	6–8 8	D C	IV	Reconstituted drug is added to 0.9% NaCl or 5% dextrose and administered over 30 to 60 minutes. It can also be administered in 5% dextrose as a CRI, with a loading dose of 3.5 mg/kg, and then 1.5 mg/kg/hour IV. Therapeutic drug monitoring recommended to ensure that effective concentrations are achieved.	≤4 for *Enterococcus* and *Staphylococcus*

[a]The use of vancomycin should be reserved for gram-positive infections that are susceptible to vancomycin but resistant to all other reasonable alternatives, on the basis of culture and susceptibility testing.
C, cats; *CLSI*, Clinical and Laboratory Standards Institute[41,42]; *CRI*, constant-rate infusion; *D*, dogs; *IV*, intravenous.

reaction in human patients is the "red man syndrome" caused by histamine release after rapid infusion. This can be prevented through the use of antihistamines and slower infusion rates. Other adverse reactions are rare. Previously cited nephrotoxicity from vancomycin may be exaggerated because of its frequent co-administration with aminoglycosides, although a series of cases in dogs and cats with coexisting morbidities have been reported. Current formulations are of better quality and purity and less likely to produce kidney injury. Vancomycin is given by IV infusion over 30 to 60 minutes through a central or peripheral catheter (Table 10.6). Trough plasma concentrations can be monitored and should be greater than 10 µg/mL for skin and soft tissue infections, and 10 to 20 µg/mL for more complicated infections. Intramuscular administration should be avoided because it is painful and irritates tissues.

Fosfomycin

Mechanism of Action and Clinical Use

Fosfomycin is an antibiotic from *Streptomyces* spp. It is bactericidal and inactivates the bacterial enzyme UDP-*N*-acetylglucosamine-3-enolpyruvyltransferase (MurA), which catalyzes the first step in peptidoglycan synthesis. This is a unique mechanism of action that differs from that of β-lactam drugs and glycopeptides. Fosfomycin enters bacterial cells by the glucose-6-phosphate-inducible hexose monophosphate transport system and to a lesser extent, the L-alpha-glycerophosphate transport system. Bacteria with mutations of these transport systems can be resistant to fosfomycin. Other mechanisms of resistance include modification or overexpression of MurA or inactivation by plasmid-encoded bacterial enzymes such as *fosA, fosB, fosC,* and *fosX*.[22] Resistance in *E. coli* is currently rare, including among isolates from dogs and cats,[23] but fecal carriage of resistant isolates was detected in 2.4% and 0.8% of dogs and cats, respectively, from Hong Kong in 2008 to 2010.[24] Among 31 canine methicillin-resistant *S. pseudintermedius* isolates from North America, 84% were susceptible to fosfomycin.[25]

Clinical Use

Fosfomycin is available commercially as fosfomycin tromethamine. It has a broad-spectrum activity that includes aerobic and facultative gram-negative and gram-positive bacteria. It is primarily indicated for treatment of MDR gram-positive and gram-negative bacterial UTIs, and in humans a single dose is recommended as a first-line treatment for acute uncomplicated cystitis. Fosfomycin exhibits concentration-dependent bacterial killing, with a long postantibiotic effect. The use of fosfomycin in veterinary medicine is currently limited by its high cost and relative unfamiliarity with the drug. Its use in dogs should be reserved for serious infections associated with clinical signs of lower urinary tract disease, where no other treatment option is available.

In humans, fosfomycin distributes widely into tissues after oral administration. It is not metabolized, and 54% to 65% of unaltered drug appears in the urine through glomerular filtration, attaining high concentrations in the urine.[22] Excellent tissue penetration and activity against biofilm is thought to be the result of the drug's low molecular weight and low plasma protein binding (< 0.5%).[26,27] This makes it appealing for treatment of bacterial prostatitis and pyelonephritis. Pharmacokinetic information for fosfomycin disodium when administered IM, SC, and PO (40 mg/kg and 80 mg/kg) has been described for dogs, but an oral dose that resulted in tissue concentrations necessary for effective bacterial killing was not established.[27] A combination of fosfomycin and clarithromycin was shown to have synergistic activity *in vitro* against *S. pseudintermedius* biofilm.[28]

Adverse Effects

In humans, fosfomycin administration is well tolerated, with the main adverse effect being diarrhea.[29] Administration of fosfomycin to dogs at a dose used to treat UTIs (40 mg/kg PO or IV q12h for 3 days) was not associated with hematologic or biochemical adverse effects, but young and adult cats developed acute kidney injury that was associated with tubular necrosis.[30] Therefore, until a safe dose has been established, fosfomycin should not be used to treat cats. More studies are also required to establish safe and effective doses of fosfomycin tromethamine for treatment of UTIs and systemic infections in dogs.

DRUGS THAT DISRUPT THE CELL MEMBRANE

Polymyxins

Mechanism of Action

The polymyxins are a group of closely related, cationic, cyclic peptides. Of the types A through E, polymyxin B and polymyxin E (colistin) are therapeutically most important. The most common use of this group in animals is from the formulations that contain polymyxins in a topical form, usually in combination with other agents (e.g., "triple antibiotic" that contains polymyxins B, neomycin, and bacitracin). Colistin is used as the last resort to treat serious gram-negative infections in humans. Polymyxins are cationic detergents that bind to LPS and increase the permeability of gram-negative bacteria. Most gram-negative organisms are susceptible. Increased use of polymyxins to treat infections in humans has been followed by appearance of resistant strains that most often have bacterial modifications of the lipid A component of LPS. Of major concern, plasmid-mediated resistance has been described in MDR *E. coli* from China that results from possession of the *mcr-1* gene, including among isolates from companion animals.[31] Other resistance mechanisms include complete loss of LPS and efflux pump mechanisms.[32]

Clinical Use and Adverse Effects

In dogs and cats, polymyxins are primarily used in combination with neomycin and bacitracin or tetracycline as topical preparations for treatment of localized ocular and otic infections. Colistin is given IV to humans to treat serious resistant infections. It has been the only agent active against some carbapenem-resistant Enterobacterales (CRE). Nephrotoxicity has limited the usefulness of these drugs for systemic therapy. Polymyxins are poorly absorbed when given orally and topically. They do not produce high plasma concentrations after parenteral administration, presumably because of high affinity for host cell membranes. Polymyxins diffuse poorly through biologic membranes and are excreted unchanged in urine.

Daptomycin

Daptomycin is a cyclic lipopeptide from *Streptomyces roseosporus* that is used parenterally in humans to treat serious infections caused by gram-positive bacteria (typically MRS and VRE). Daptomycin has a unique mechanism of action whereby it inserts into the bacterial cell membrane, which leads to permeabilization and depolarization of the membrane.[33] The extent to which this occurs depends on the amount of phosphatidylglycerol in the membrane, and resistant bacterial strains may have decreased synthesis of phosphatidylglycerol. Daptomycin has a bactericidal effect in a concentration-dependent manner. Adverse effects in human patients are uncommon but have included rhabdomyolysis and myalgia.[34] There are no reports of the use of daptomycin in dogs and cats.

NUCLEIC ACID INHIBITORS

Fluoroquinolones

Classification and Mechanism of Action

The fluoroquinolones bind to DNA gyrase (also known as topoisomerase II) and topoisomerase IV, enzymes that cleave DNA during DNA replication. The result is disruption of bacterial DNA and protein synthesis. For the veterinary fluoroquinolones enrofloxacin, orbifloxacin, and marbofloxacin, DNA gyrase is the primary target for gram-negative bacteria and topoisomerase IV is the primary target for gram-positive bacteria. Because topoisomerase IV has a lower affinity than DNA gyrase for this group of drugs, higher MICs are observed for gram-positive bacteria compared with the Enterobacterales.

Fluoroquinolones were created by addition of a fluorine group to nalidixic acid, which improves its spectrum of activity. Examples are enrofloxacin, ciprofloxacin, difloxacin, orbifloxacin, and marbofloxacin. Newer-generation fluoroquinolones inhibit *both* DNA gyrase and topoisomerase IV in gram-positive bacteria, leading to enhanced activity for treatment of gram-positive and anaerobic bacterial infections and reduced likelihood of selection for resistant mutants. Pradofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are third-generation fluoroquinolones. The only antibiotic in this group approved for use in companion animals is pradofloxacin, which is approved for use in cats in the United States, and approved for both dogs and cats in European countries. Levofloxacin is a less expensive oral human generic drug in tablets that has become popular for oral use in dogs.

Resistance to fluoroquinolones results from DNA gyrase mutations, decreased bacterial permeability, and increased drug efflux.[35] Susceptibility to one fluoroquinolone generally predicts susceptibility to others, with the exceptions of third-generation fluoroquinolones (such as pradofloxacin) and ciprofloxacin, which has higher *in vitro* activity against *P. aeruginosa* than other fluoroquinolones.[36,37] There have been associations between fluoroquinolone use and increased emergence of resistance of some bacteria in human medicine. This has led to stewardship recommendations for limiting the use of fluoroquinolones to treat routine infections. The link between fluoroquinolone use and resistance in veterinary medicine has not been established in clinical patients, but has been demonstrated in research animals. Therefore, the consensus panel guidelines have recommended to reserve the administration of fluoroquinolones to small animals for cases where other antimicrobials may not be an option. Therefore, other "first-line" drugs are often available for most infections, and fluoroquinolones should be considered for cases that cannot tolerate other drugs, or when resistance to other drugs is more likely. Appropriate pharmacokinetic-pharmacodynamic (PK-PD) principles (discussed in Chapter 8) should be followed to reduce selection of resistant isolates.

Clinical Use

Fluoroquinolones are most valuable to treat gram-negative infections because there are often few oral medication alternatives for these infections. The fluoroquinolones are also effective for infections caused by staphylococci, but staphylococci tend to have higher MICs for fluoroquinolones than gram-negative bacteria. The activity of fluoroquinolones against anaerobes is variable. Pradofloxacin has the greatest activity, followed by marbofloxacin and enrofloxacin.[38] Fluoroquinolones are concentration-dependent antibiotics with a marked postantibiotic effect, so they are best administered as a single high daily dose. Doses for fluoroquinolones are listed in Table 10.7.

Fluoroquinolones are usually well absorbed after oral administration. Poor absorption occurs when they are complexed by divalent and trivalent cation-containing medications (e.g., antacids) and supplements (aluminum, calcium, iron, zinc). Use of these should be avoided if animals are receiving fluoroquinolones by the oral route, or separate the administration by at least 2 hours. Oral absorption of ciprofloxacin is lower and more variable in dogs than in humans, which necessitates administration of a higher dose. In one study, oral absorption of generic ciprofloxacin tablets in dogs was 58%, but the coefficient of variation was 45%.[39] In cats, only 22% to 33% of orally administered ciprofloxacin is absorbed. On the other hand, the human generic drug levofloxacin is absorbed almost completely in dogs and is preferred over ciprofloxacin, especially because canine-specific testing breakpoints have been established by CLSI.[40–42] Most fluoroquinolones are highly concentrated in the urine, so they are useful for treatment of UTIs. Enrofloxacin is metabolized to ciprofloxacin, which produces an additive effect because ciprofloxacin is active. Both drugs are subsequently excreted in the urine. Approximately half of the administered dose of marbofloxacin and orbifloxacin is excreted as unchanged drug in the urine.

Fluoroquinolones have variable protein binding, but this does not inhibit distribution to tissue fluids. Because of good lipophilicity, these drugs penetrate the prostate and respiratory secretions. They also penetrate the ear canal, but high doses may be required for treatment of bacteria with relatively high MIC values (e.g., *P. aeruginosa*).[43] Fluoroquinolones can attain high intracellular concentrations and can be used to treat infections caused by intracellular pathogens such as *Mycoplasma*, *Bartonella*, and some *Mycobacterium* spp.

Adverse Effects

Both oral and parenteral administration of fluoroquinolones can occasionally result in GI signs in dogs and cats, such as decreased appetite and vomiting. Rapid IV administration can cause systemic hypotension, tachycardia, and cutaneous erythema, possibly as a result of histamine release.[44] Neurologic signs, including tremors, ataxia, and seizures, can occur in dogs and cats treated with high doses of parenteral fluoroquinolones. Although not well understood, this is thought to result from fluoroquinolone interference with the binding of GABA to its receptors in the CNS.[45] In general, fluoroquinolones should be used cautiously in animals prone to seizures. Enrofloxacin causes

TABLE 10.7 Suggested Fluoroquinolone Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Enrofloxacin	5–20 5	24 24	D C[a]	IV, IM, PO IM, PO	Interactions can occur with certain oral medications (see text). Reduce dose or increase dosage interval with renal failure. Dilute in fluids (e.g., 1:10 dilution) and infuse IV over 30 minutes	≤0.5 μg/mL for susceptible infections. Use higher dosages (10–20 mg/kg) for organisms with MICs of 1 or 2 (except in cats). A dose of 5 mg/kg may be sufficient for UTIs
Ciprofloxacin hydrochloride	20–30 10	24 24	D, C D, C	PO IV	See enrofloxacin. Oral absorption may be limited (see text)	In humans, ≤0.25 μg/mL for susceptible infections (Enterobacterales) and ≤0.5 μg/mL for *Pseudomonas aeruginosa*, but for dogs, ≤ 0.03 μg/mL should be used.
Levofloxacin	23–25	24	D	PO	Human generic drug. Much better absorbed than ciprofloxacin in dogs	≤0.5 μg/mL for *E. coli*, ≤1 μg/mL for *Pseudomonas aeruginosa*
Marbofloxacin	2.75–5.5	24	D, C	PO	See enrofloxacin	≤1 μg/mL for susceptible infections. Use higher doses for bacteria with higher MICs
Orbifloxacin	2.5–7.5	24	D, C	PO	See enrofloxacin. Orbifloxacin suspension provides lower and more variable plasma levels than the tablets. A dose of 7.5 mg/kg should be used	See marbofloxacin
Difloxacin hydrochloride *(discontinued by manufacturer)*	5–10	24	D	PO	Urine concentrations may not be sufficient for treating UTIs	≤0.5 μg/mL for susceptible infections
Moxifloxacin	10	24	D, C	PO	Moxifloxacin has enhanced activity against gram-positive bacteria and anaerobes. In humans, urine concentrations are not sufficient for treatment of UTIs	No animal breakpoint is established.
Pradofloxacin	3[b] 5–7.5[c]	24	D, C C	PO	See moxifloxacin for spectrum of activity. Food reduces bioavailability. Appears effective for treatment of UTIs	≤0.25 μg/mL for susceptible infections

[a]The use of enrofloxacin to treat cats is controversial because of the potential for irreversible retinal toxicity and blindness. Do not exceed a dose of 5 mg/kg in cats. The use of alternative fluoroquinolones such as marbofloxacin, orbifloxacin, or pradofloxacin should be considered for cats.
[b]Tablet formulation. The use of pradofloxacin at high doses in dogs has been associated with myelosuppression and is off-label in the United States, but it is approved for both dogs and cats outside the United States at a dose of 3 mg/kg (tablets).
[c]Oral suspension for cats. The dose of the oral suspension for cats is higher (5–7.5 mg/kg) owing to reduced bioavailability.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *MIC,* minimum inhibitory concentration; *PO,* oral; *UTI,* urinary tract infection.

hallucinations in humans, so it is not marketed or approved for treatment of humans.

Cats treated with high doses of enrofloxacin (generally > 5 mg/kg/day), especially parenteral enrofloxacin, have developed blindness resulting from acute retinal degeneration, manifested as bilateral mydriasis with tapetal hyperreflectivity.[46,47] This results from a functional defect in a fluoroquinolone transport protein in the cat, with subsequent accumulation of photoreactive drug in the retina.[48] In general, the blindness is irreversible, but if it is detected early and medication is discontinued, some resolution may occur. Orbifloxacin also can produce retinal injury in cats, but the dose needed for this reaction is much higher than doses used therapeutically. Studies of marbofloxacin (reported by the manufacturer) and pradofloxacin[49] showed no evidence of retinal toxicity in cats, even with high doses, although there are reports to the FDA of blindness in cats associated with the use of marbofloxacin. Cats with renal insufficiency or those treated with medications that increase plasma fluoroquinolone concentrations may be more likely to develop this adverse effect. Quinolones have limited solubility at alkaline pH and may crystallize in tissues. Dogs given high doses had subcapsular lenticular cataract formation and associated inflammation after treatment for 8 to 12 months.

Because they inhibit proteoglycan synthesis and chelate magnesium, fluoroquinolones can cause cartilage and joint toxicity in young animals, although the clinical importance of this has been questioned.[50,51] In general, prolonged (>7 days) use of fluoroquinolones during the period of rapid growth in dogs (from about 1 to 2 months of age to 28 weeks) should be avoided if possible. Cats are thought to be more resistant to development of cartilage toxicity. The US FDA has

TABLE 10.8 Suggested Metronidazole Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments
Metronidazole	15 10–15	12 24	D C	PO	Reduce dose by 50% in animals with hepatic dysfunction. An IV solution, metronidazole hydrochloride, is available but is highly acidic. It should be diluted in 100 mL of IV crystalloids and neutralized with 5 mEq sodium bicarbonate per 500 mg for a pH of 6–7. Diluted solutions are stable for 24 hours
Metronidazole benzoate	25	12	C	PO	More palatable formulation for cats may be available from some compounding pharmacies

C, cats; *D,* dogs; *IV,* intravenous; *PO,* oral.

recommended that fluoroquinolones be avoided in humans when other options exist because of the potential for neuromuscular (particularly tendon injury) adverse effects. Pradofloxacin has been associated with myelosuppression in dogs at doses greater than 10 mg/kg. All fluoroquinolones should be used cautiously in pregnant or lactating bitches.

Fluoroquinolones inhibit some cytochrome P450 enzymes, which decreases metabolism of other drugs. This occurs with theophylline in dogs; therefore, the dose of theophylline should be adjusted if administered concurrently. Like cephalosporins, fluoroquinolones can cause false-positive results on test strips for urine glucose detection. Cutaneous photosensitization occurs in human patients but is rare in animals. Other adverse effects reported in humans, but not in dogs and cats, include cardiac arrhythmias and QT interval prolongation, rupture of the aorta, pancreatitis, tendinitis and tendon rupture, altered glucose metabolism, and hepatic dysfunction.[52,53]

Metronidazole

Mechanism of Action and Spectrum of Activity

Metronidazole is a bactericidal nitroimidazole drug that is used primarily to treat anaerobic bacterial infections (both gram-negative and gram-positive), including those caused by *Bacteroides fragilis* and *Clostridium* spp., and infections with certain protozoa, such as *Giardia* spp. Metronidazole diffuses into bacterial cells as a prodrug and is activated in the cytoplasm. Once within the cell, the nitro group of metronidazole preferentially accepts electrons from electron transport proteins such as ferredoxin. A short-lived nitroso free radical is thus generated that damages DNA. The intermediate compounds then decompose into nontoxic, inactive end products.

Metronidazole has antioxidant properties that are believed to result from its ability to scavenge reactive oxygen species, and modulation of neutrophil activity.[54] It is often used at low doses to treat inflammatory bowel disease in dogs and cats,[55] but it is not known if the benefit is from the antibacterial activity or other effects on inflammatory cells. It has also been used to treat acute nonspecific diarrhea in dogs, but the value of this use has been questioned.[56,57]

Resistance to metronidazole is rare among anaerobes.[58] Mechanisms of resistance include reduced drug uptake and decreased reduction activity. Other proposed mechanisms include increased efflux, drug inactivation, and accelerated DNA repair.

Clinical Use

In dogs and cats, metronidazole is used to treat anaerobic bacterial and protozoal infections in a variety of tissues. Suggested doses are listed in Table 10.8. Metronidazole is rapidly and almost completely absorbed from the GI tract, diffuses across lipid membranes, and achieves therapeutic concentrations in tissue fluids. Metronidazole is metabolized by the liver. The metabolites, along with intact drug, are excreted in the urine.

Adverse Effects

The main adverse effect of metronidazole is neurotoxicity, which tends to occur with high doses (>30 mg/kg/day) or in animals with hepatic dysfunction. Clinical signs of neurotoxicity are reversible on discontinuation of the drug and include lethargy, truncal ataxia, hypermetria, intention tremors, head tilt, falling, vertical nystagmus, extensor rigidity, opisthotonos and seizures, and reflect injury to the vestibular system.[59,60] Although not fully understood, neurotoxicity is believed to result from antagonism of GABA in the cerebellar and vestibular systems. Neurologic signs resolve more quickly when treated with a low dose of diazepam (0.4 mg/kg PO q8h for 3 days), which confirms GABA antagonism as the potential mechanism.[59] Bilateral symmetrical cerebellar lesions, most commonly in the dentate nucleus, have been reported on MRI in human patients with metronidazole toxicity,[61] and multifocal necrotic foci were detected at necropsy in the brainstem of a cat.[60] Administration of metronidazole to animals with a history of metronidazole toxicosis is not recommended.[59]

Less commonly, metronidazole causes decreased appetite, vomiting, and diarrhea. Metronidazole suspension has a bitter taste that may be unpalatable to cats, which can be overcome by administration of the drug in gel capsules. Although not approved by the FDA, metronidazole benzoate is a more palatable formulation for cats and pharmacokinetic studies have demonstrated good absorption.[62] There have been concerns that relate to toxicity from the benzoic acid component of the formulation, which can cause CNS signs, blindness, and respiratory problems at high doses. However, this possibility is considered to be unlikely.[62] Because metronidazole benzoate is only 62% metronidazole (by weight), dosage adjustment is required when this formulation is used. Metronidazole inhibits hepatic microsomal enzymes and so may increase the concentration of drugs such as warfarin and cyclosporine. It also lowers serum lipid concentrations (including cholesterol concentrations) in human patients.[63] Metronidazole has been shown to be carcinogenic in mice and rats, and has been shown to cause reversible genotoxicity (DNA damage) in cats,[62] but there are no accounts of an increased rate of neoplasia in treated dogs or cats.

Rifamycins

Mechanism of Action and Spectrum of Activity

Named after the French crime movie *Rififi*, rifamycins are bactericidal antimicrobials that inhibit the β-subunit of DNA-dependent RNA polymerase in bacteria. This leads to impaired RNA synthesis. Only the semisynthetic drug rifampin (also known as rifampicin) has been used to any great extent in small animal medicine. Rifampin is active against staphylococci, streptococci, and only a few gram-negative organisms. When used as a component of antimycobacterial treatment regimens, it increases the chance of treatment success. Rifabutin is effective for treatment of some mycobacterial infections that are resistant to rifampicin.[64]

TABLE 10.9 Suggested Rifampin Dose for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoint (μg/mL)
Rifampin	5	12	D, C	PO	Preferably use in combination with other drugs. Avoid in animals with hepatic dysfunction. Do not administer with fatty meals. Drug interactions may occur (see text). Monitor liver enzymes with prolonged treatment. May impart a red-orange color to the urine and tears	≤1 for susceptible organisms (usually MICs of gram-positive bacteria fall below this breakpoint)

C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *MIC,* minimum inhibitory concentration; *PO,* oral.

It has been recommended that rifampin be used in combination with other antimicrobials to reduce the risk of emergence of rifampin resistance, which occurs quickly when rifampin is used alone. However, this applies primarily when it is used for long-term treatment, such as for mycobacterial infections. Monotherapy has been successful when rifampin has been used to treat MRS infections, which accounts for most of the current small animal use. Rifampin monotherapy has not been shown to be a risk factor for development of staphylococcal resistance. If combination treatment is pursued for treatment of MRS, there are often few effective alternatives with which to combine rifampin, because these infections are typically multidrug resistant. Resistance to rifampin results from a single mutation that leads to an altered RNA polymerase that does not effectively bind rifampin.

Clinical Use

One of the major advantages of rifampin is its high degree of lipid solubility, which provides the degree of intracellular penetration required for treatment of infections caused by intracellular bacteria such as *Mycobacterium* spp. and *Brucella canis*. Rifampin in combination with doxycycline has been used to treat bartonellosis.[65,66] Rifampin was not effective as monotherapy for treatment of *Ehrlichia canis* infections.[67] Because of its activity against staphylococci and the fact that it can be administered orally, it has been used for treatment of MRS infections in small animals. For other infections, rifampin is less attractive because of its adverse effect profile.

Rifampin dosing is shown in Table 10.9. Rifampin is rapidly absorbed from the GI tract and metabolized by the liver. Active metabolites are excreted in bile and, to a lesser extent, the urine. Approximately 75% to 90% of rifampin is bound to plasma proteins.

Adverse Effects

Vomiting, anorexia, and lethargy are common in dogs treated with rifampin, especially when it is administered together with other medications.[68] The drug can impart a red-orange color to the urine and, to a lesser extent, tears, saliva, the sclera, and mucous membranes. Rifampin can also be associated with increased serum liver enzyme activities and hepatopathy, especially with prolonged administration (> 36 days). Doses that exceed 10 mg/kg per day in dogs increase the risk of liver injury. When prescribing rifampin to dogs, it is advised to monitor serum liver enzyme activities and serum bilirubin concentration periodically. In humans, fever, cutaneous reactions, thrombocytopenia, acute intravascular hemolytic anemia, and acute tubulointerstitial nephritis have been reported, which appear to have an immune-mediated pathogenesis.[69] Rarely, pancreatitis has been reported in human patients receiving rifampin. Adverse effects have not been reported in cats, but some of these risks may apply to cats as well as dogs. Because of poor palatability, it is a challenge to administer to cats.

Rifampin is one of *the* most potent inducers of hepatic microsomal enzymes and efflux proteins, such as P-glycoprotein. Subsequently, it can increase the clearance of several co-administered drugs (thereby decreasing their efficacy), such as glucocorticoids, cyclosporine, itraconazole, isoniazid, barbiturates, theophylline, digoxin, and perhaps others. In human patients, recovery from the effect of rifampin on hepatic microsomal enzymes can take 4 weeks.[70]

Trimethoprim-Sulfonamides

Mechanism of Action

Trimethoprim and sulfonamides act synergistically to inhibit folic acid metabolism by bacteria. The combination interferes with purine and therefore DNA synthesis. Trimethoprim inhibits bacterial dihydrofolate reductase. Sulfonamides are chemical analogues of PABA and competitively inhibit the incorporation of PABA into dihydropteroic acid by the enzyme dihydropteroate synthetase, which also leads to decreased folic acid synthesis. Because folic acid is of dietary origin in animals, only bacterial purine synthesis is affected. When administered separately, each drug is bacteriostatic, but the combination is bactericidal and can broaden the spectrum. Preparations used to treat dogs and cats include a 1:5 ratio of trimethoprim to sulfonamide.

Resistance to trimethoprim-sulfonamide (TMS) antibiotics most commonly results from plasmid-mediated production of altered dihydrofolate reductase or dihydropteroate synthetase, with reduced binding affinities. Other mechanisms include overproduction of dihydrofolate reductase or PABA by bacteria, and reduced bacterial permeability to trimethoprim and sulfonamides. Multiple mechanisms may operate simultaneously.[71]

Clinical Use

TMS antibiotics have a broad spectrum of activity and can be used to treat gram-positive and many gram-negative bacterial infections, as well as some protozoal infections. Enterococci are intrinsically resistant to TMS antibiotics. Many anaerobic bacteria are not treated successfully because despite *in vitro* susceptibility, the drugs are less active in tissues where anaerobes proliferate. TMS antibiotics are the treatment of choice for nocardiosis. They have also been used successfully for prevention of bacterial infections in dogs being treated with myelosuppressive chemotherapeutics such as doxorubicin.[72] Prophylactic protocols have selected for resistant bacteria in humans,[73] but this has not been reported in animals. TMS combinations are available as either trimethoprim-sulfadiazine or trimethoprim-sulfamethoxazole (the latter is a human medical preparation), which are used interchangeably. However, the veterinary formulation of trimethoprim-sulfadiazine is rarely available commercially, and most veterinarians rely on trimethoprim-sulfamethoxazole. Equine formulations are usually trimethoprim-sulfadiazine. Although it is assumed that there is no difference in activity between the two formulations, this has not been sufficiently studied. The primary difference between the formulations is that sulfadiazine is more water soluble and is excreted in the urine in an unchanged form. A similar formulation to the TMS for use in veterinary medicine is ormetoprim-sulfadimethoxine, which has been

TABLE 10.10 Suggested Potentiated Sulfonamide Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Trimethoprim-sulfamethoxazole, trimethoprim-sulfadiazine	15–30[a]	12 (24 hour if using 30 mg/kg)	D, C	PO, IV	Avoid in animals with hepatic failure. Reduce dose in animals with renal insufficiency. Obtain baseline Schirmer tear test and monitor this and the CBC with prolonged treatment. Each 5-mL vial of the injectable preparation should be diluted in 75–125 mL of 5% dextrose and administered IV over 1 hour	≤2/38 for susceptible infections
Ormetoprim-sulfadimethoxine	55 on first day, and then 27.5[a]	24	D	PO	See trimethoprim-sulfamethoxazole	Use information for trimethoprim-sulfonamides

[a]Dose listed is for combined components (e.g., 5 mg of trimethoprim and 25 mg of sulfonamide).
C, cats; *CBC,* complete blood count; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IV,* intravenous; *PO,* oral.

used for the same indications as TMS. Doses for TMS combinations are listed in Table 10.10.

Trimethoprim and sulfonamide combinations are well absorbed after oral administration. As a weak base, trimethoprim is able to penetrate the blood-prostate barrier and can be used to treat prostatic infections. Both trimethoprim and sulfonamides also penetrate the CNS. They are both metabolized to some extent by the liver. Both active drug and inactive metabolites appear in the urine. Reducing the dosage is unnecessary in renal failure unless it is severe. Active TMS is highly concentrated in urine and if tolerated, it is an appropriate first choice for treatment of UTIs in dogs and cats.[74]

Adverse Effects

TMS antimicrobials cause a wide range of adverse effects, which have somewhat limited their use. These reactions are primarily caused by the sulfonamide component. People who are "slow acetylators" of sulfonamides are more prone to adverse effects from sulfonamides and dogs can show similar effects because they cannot acetylate any medications.

GI signs such as vomiting can occur. Administration of trimethoprim-sulfamethoxazole suspension to cats often results in hypersalivation, anorexia, and vomiting. Other common adverse effects in dogs are hypersensitivity reactions and include keratoconjunctivitis sicca, fever, polyarthritis, cutaneous drug eruptions,[75,76] ITP, hemolytic anemia, hepatitis, pancreatitis, meningitis, interstitial nephritis, glomerulonephritis, and aplastic anemia (Fig. 10.3).[77–79] These events are relatively uncommon, but have been documented well enough in dogs that it has discouraged their routine use among some veterinary clinicians. Reversible hypothyroidism can occur after periods of treatment as short as 10 days.[80] Hepatic necrosis can occur as an idiosyncratic reaction.[81] Ormetoprim has been associated with neurologic signs in dogs, including tremors, anxiety, and seizures. Doberman pinschers may be more susceptible than other breeds to adverse effects of TMS because of their inability to detoxify certain sulfonamide metabolites; in another study, Samoyeds and miniature schnauzers also appeared to be more susceptible.[82,83]

Because of the risk of keratoconjunctivitis sicca in dogs, Schirmer tear tests should be performed before sulfonamides are administered and tear tests should be continued when prolonged treatment is required (e.g., greater than 1 week), and the drug should be avoided in dogs with keratoconjunctivitis sicca. The prognosis for return of lacrimation is poor, but topical cyclosporine appears to be effective in some cases. Sulfonamide cystolithiasis can occur in dogs treated with high doses of sulfonamides.[84] However, this effect is associated with the older, less soluble forms of sulfonamides. This adverse effect is rarely a concern with modern formulations.

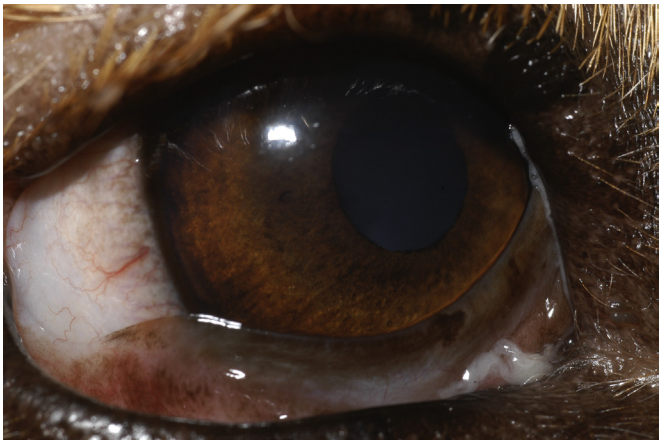

Fig. 10.3 Right eye of a 7-year-old intact male golden retriever that developed keratoconjunctivitis sicca after administration of trimethoprim-sulfamethoxazole for 3 weeks for septic peritonitis. The owner noticed the dog pawing at his eyes. Mucoid ocular discharge is present at the medial canthus. Schirmer tear test strip results were 0 mm for both eyes. (Image courtesy University of California, Davis Veterinary Ophthalmology service.)

PROTEIN SYNTHESIS INHIBITORS

Aminoglycosides

Mechanism of Action

All aminoglycosides contain an essential six-membered ring with amino-group substituents and are highly positively charged. Aminoglycosides with names that end in *-mycin* derive directly or indirectly from *Streptomyces* spp. (e.g., neomycin). Those with names ending in *-micin* are derived from *Micromonospora* (e.g., gentamicin).

Aminoglycoside mechanism of action is described by two processes. First, they bind electrostatically to the bacterial outer membrane and displace cell wall Mg^{2+} and Ca^{2+}, which normally link adjacent LPS molecules. This initial binding is greater in gram-negative bacteria than in gram-positive bacteria because of a greater presence of an outer

TABLE 10.11 Suggested Aminoglycoside Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)[a]	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Gentamicin sulfate	9–14 5–8	24 24	D C	IV, IM, SC	Ensure adequate fluid and electrolyte balance during treatment. Avoid in animals with renal impairment. Monitor BUN and creatinine. Amikacin and tobramycin are more active against some gram-negative bacteria than gentamicin, but gentamicin is preferred for *Serratia* infections. Do not mix in vials with other drugs	≤2 for susceptible infections
Amikacin	15–30 10–14	24 24	D C	IV, IM, SC	See gentamicin	≤4 for susceptible infections (dogs)
Tobramycin sulfate	9–14 5–8	24 24	D C	IV, IM	See gentamicin. For nebulization, 160 mg of nebulization solution[b] q12h for 28 days. Preferred aminoglycoside for *Pseudomonas* infections	≤4 for susceptible infections
Kanamycin sulfate	20	24	D, C	IV or IM	See gentamicin. Less active than gentamicin and amikacin	≤16 for susceptible infections
Neomycin	10–20	6–12	D, C	PO	Not absorbed systemically; used to treat hepatic encephalopathy. Use cautiously in animals with renal disease and avoid use for > 14 days	Not applicable

[a]Once-daily administration is preferred except for enterococcal endocarditis, where the continuous presence of both an aminoglycoside and a penicillin is recommended (see Chapter 122).
[b]TOBI nebulization solution. Injectable tobramycin or gentamicin can be used but may be associated with bronchospasm. They should be diluted in 3 mL of sterile saline, and albuterol should be administered just before nebulization.
BUN, blood urea nitrogen; *C,* cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *MIC,* minimum inhibitory concentration; *PO,* oral; *SC,* subcutaneous.

membrane in gram-negative organisms. The end result is disrupted cell permeability. The second mechanism of action is through protein synthesis inhibition. Aminoglycosides first enter the cell of susceptible bacteria. Because this is an oxygen-dependent process, anaerobes are intrinsically resistant to aminoglycosides. Once within the cell, aminoglycosides bind to the 30S subunit of the bacterial ribosome, which results in decreased protein synthesis.

Aminoglycosides, particularly gentamicin, amikacin, and tobramycin, are highly active compounds for which resistance is uncommon. The most common mechanism of aminoglycoside resistance is enzymatic modification of the drug by bacteria.[85] More than 50 modifying enzymes have been identified.[86] Reduced drug uptake by bacteria may also occur. Enterococci are intrinsically resistant to low levels (4 to 250 μg/mL) of aminoglycosides because of their anaerobic metabolism, and thus they require testing for high-level resistance. This is done in the microbiology laboratory using higher concentrations of aminoglycosides. Resistance to one aminoglycoside does not imply resistance to others. For example, tobramycin and amikacin are consistently more active than gentamicin against gram-negative bacteria. Kanamycin is one of the least active aminoglycosides. Because of these differences, a susceptibility panel should include gentamicin and either amikacin or tobramycin. Because of poor activity, aminoglycosides should not be used to treat infections caused by streptococci, regardless of the susceptibility test result. The activity against *Staphylococcus* spp. can vary, and may require a frequency of administration more than once per day to meet pharmacokinetic-pharmacodynamic (PK-PD) targets. Human guidelines state that aminoglycosides should always be used in combination with another antimicrobial agent (often a β-lactam antibiotic) for treating infections caused by *Staphylococcus* spp. Guidance on this use is not available in veterinary guidelines. Some susceptibility testing standards state that if a *Staphylococcus* spp. isolate is resistant to gentamicin, it should be reported resistant to all other aminoglycosides, regardless of the MIC. However, this recommendation does not exist in veterinary standards, and some *S. pseudintermedius* may test resistant to gentamicin, but susceptible to amikacin.[87]

Clinical Use

Aminoglycosides are primarily used to treat gram-negative bacterial infections and MDR staphylococcal infections. They also have activity against mycobacteria. They should not be used to treat anaerobic bacterial infections, and *Streptococcus* species, for which other more active agents are available (e.g., β-lactam antibiotics). Older recommendations suggest that aminoglycosides should be administered in combination with cell wall–active antimicrobial drugs (β-lactams and glycopeptides) for all infections, but this is no longer believed to be a therapeutic advantage. An exception may be for treating infections caused by *Staphylococcus* spp., but as noted above, this has not been studied in veterinary patients.

The aminoglycosides are water soluble, minimally bound to plasma proteins and poorly lipid soluble, so they penetrate tissue fluids well, but do not readily penetrate tissues that are dependent on lipid diffusion (prostate, brain, eye, or CSF). Penetration of bile is also poor. Oral absorption is negligible, and they should not be administered orally unless specifically intended to treat intestinal bacteria (e.g., oral neomycin for treatment of hepatic encephalopathy). Doses are shown in Table 10.11. Aminoglycosides also may be administered topically. Because they penetrate bronchial secretions poorly, nebulization has been used in order to overcome this problem in human patients as well

as dogs with bronchopneumonia caused by MDR gram-negative bacteria (see Table 10.11).[88] Topical administration was also used successfully to treat *P. aeruginosa* bacteriuria in a dog with a cystostomy tube.[89] Gentamicin-impregnated beads and cement have been used successfully to treat MRS infections in orthopedic surgery. Aminoglycosides are excreted unchanged by the kidney and concentrate 25- to 100-fold in urine within an hour of drug administration, so they can be used to treat resistant gram-negative bacterial UTIs. They also accumulate in renal tissue and remain active for several days after dosing is discontinued. Because they are not well distributed into fat, dose reduction may be indicated for obese animals.

Despite their primary mechanism of action being protein synthesis inhibition, aminoglycosides are rapidly bactericidal with a prolonged, concentration-dependent postantibiotic effect. Transient high peak drug concentrations result in faster killing and greater bactericidal activity than lower concentrations over a prolonged period of time (i.e., they are concentration-dependent antimicrobial drugs). Once-daily dosing of a high dose of an aminoglycoside is therefore preferred because it achieves optimal bacterial killing but minimizes toxicity. In order to further minimize toxicity, aminoglycosides are generally infused slowly. In human patients, it is recommended they be administered over a 15- to 30-minute period; intramuscular or SC administration to dogs and cats achieves similar slow release into the circulation. Therefore, SC and intramuscular injections of water-soluble formulations of aminoglycosides are also acceptable routes of administration, although they may cause pain in some animals.

Adverse Effects

Aminoglycosides have the potential to cause nephrotoxicity, ototoxicity, and neuromuscular blockade. Their cationic structure and the high anionic phospholipid concentrations in the kidney and inner ear play an important role in toxicity. In the presence of GI ulceration or a compromised intestinal barrier, systemic absorption of orally administered aminoglycosides can occur, with associated nephrotoxicity or ototoxicity.[90] Nephrotoxicity has also followed local tissue administration of gentamicin in dogs and cats.[91,92]

Nephrotoxicity results from apoptosis and necrosis of renal tubular epithelial cells, and direct damage to the glomerulus as well. The mechanisms involved are complex.[93] Recovery can occur when the aminoglycoside is removed, but because aminoglycosides accumulate in renal tissue, the insult can persist for some time even after treatment is discontinued. Because of an understanding of the mechanisms of nephrotoxicity, preventative measures have been developed to mitigate kidney injury. Aminoglycosides bind to megalin-cubulin complexes on the surface of the cell and are endocytosed into the cytoplasm, where they accumulate in lysosomes. The lysosomes break down, with resultant drug leakage into the cytoplasm, where interference with mitochondrial function occurs. Aminoglycosides also bind membrane phospholipids and alter their turnover. Damaged renal tubular epithelial cells are shed into and obstruct the tubular lumen, which leads to a build-up of pressure within the glomerulus, leading to decreased glomerular filtration rate. Disrupted proximal tubular cell function leads to delivery of excessive water and electrolytes to the distal nephron, which in turn triggers tubuloglomerular feedback, with constriction of afferent arterioles and further decreases in the glomerular filtration rate.[93] Tubuloglomerular feedback is designed to protect the body from massive loss of water and electrolytes.

Risk factors for nephrotoxicity include older age, reduced renal function, concomitant liver disease, dehydration, electrolyte depletion, and concurrently administered nephrotoxic drugs, most commonly NSAIDs but also furosemide and cyclosporine. Although gentamicin nephrotoxicity can occur in young animals,[94] young age is not a contraindication to use of aminoglycosides, which are used widely to treat human neonatal sepsis.[95] In fact, one study indicates that neonatal puppies were more tolerant of kidney injury from gentamicin than older dogs.[94] This difference is attributed to the distribution of renal blood flow at birth. The chance of toxicity increases with more prolonged treatment periods (≥3 days). Gentamicin and amikacin are more toxic than tobramycin. Volume and salt loading do not decrease toxicity, but high levels of dietary calcium and protein have protective effects.[96] The best preventative measure is to avoid these drugs in any patients with preexisting kidney injury. If kidney injury develops after initiating treatment, the drug should be substituted with a safer drug. Urinary biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL)[97] and urinary cystatin C[98] have been shown to be sensitive indicators of aminoglycoside-induced kidney injury in dogs and may be useful for monitoring treatment in the future.

Ototoxicity results from injury to the cochlear or the vestibular apparatus and is more likely to occur in animals with renal impairment or that are dehydrated. Cochlear toxicity results from damage to the hair cells of the organ of Corti, whereas vestibular toxicity results from damage to hair cells at the tip of the ampullae cristae. Auditory toxicity may be more common in dogs, whereas cats tend to develop vestibular toxicity.[99] Cochlear toxicity in dogs and cats may be underrecognized because it may be overlooked by pet owners. It may go unrecognized in animals because in humans it primarily affects the high frequencies.[100] In human patients, signs of vestibular toxicity can disappear with time because of compensatory mechanisms. Ototoxicity is generally irreversible, but in some human patients, gradual improvement in hearing can occur.[101]

Neuromuscular blockade is a rare but potentially life-threatening complication of aminoglycoside treatment. Severe neuromuscular blockade has not been reported in cats and dogs, but experimental studies show that it does occur when aminoglycosides are used in conjunction with some anesthetic agents.[102–104] Because of these concerns, aminoglycosides should be avoided in patients receiving anesthetic agents. Neuromuscular blockade results from decreased release of acetylcholine at neuromuscular junctions and decreased sensitivity of the postsynaptic neuron to acetylcholine. Autonomic blockade can also occur. The use of aminoglycosides should be avoided in animals with neuromuscular disease such as myasthenia gravis because aminoglycosides have the potential to exacerbate the clinical signs.[105]

Measurement of serum aminoglycoside concentrations can be used to ensure adequate plasma concentrations or to minimize toxicity.[106] Assays are offered by specialized veterinary pharmacology laboratories or through human hospitals. Aminoglycoside doses are designed to attain peak plasma concentrations approximately 8 to 10 times the MIC. If the MIC of the bacterial isolate is known, this, along with serum drug monitoring, may be used to derive individual specific therapy. Monitoring also may be useful to identify patients with disorders of drug elimination or distribution. Monitoring early in the course of therapy can identify patients with subclinical kidney disease. The effective volume of distribution for aminoglycosides is often higher in septic patients or animals that have a "third space" problem (such as pleural effusion), which may necessitate a higher dose. To perform therapeutic drug monitoring, the optimum time points are 1 hour after injection (C_{max}), followed by two additional time points in order to estimate the slope of the elimination curve. Trough levels could also be performed to minimize the chance of toxicity, with the recommendation that if high trough levels are detected, there is evidence of drug accumulation and the drug should be discontinued. In patients with normal renal function, trough levels with once-daily dosing should be in the "undetectable" range.

TABLE 10.12 Suggested Chloramphenicol Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Chloramphenicol	40–50 12.5–20	8 12	D C	PO	Avoid long-term use in cats. Monitor CBC with long-term use. Warn owners that human exposure to chloramphenicol may cause bone marrow disease. Drug interactions may occur (see text). Avoid in animals with hepatic failure	≤4 for streptococci, ≤8 for other susceptible bacteria
Florfenicol	20 22	6 8	D, C	PO, IM	Not approved for use in dogs and cats. Doses and adverse effects have not been well studied	See chloramphenicol

C, cats; *CBC,* complete blood count; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *PO,* oral.

Chloramphenicol

Mechanism of Action and Spectrum of Activity

Chloramphenicol binds to the 50S subunit of the bacterial ribosome and inhibits bacterial protein synthesis. It is usually described as bacteriostatic, but there is some evidence that chloramphenicol may be more bactericidal than previously thought. Like other ribosomal inhibitors, chloramphenicol has a broad spectrum of activity, which includes gram-positive and gram-negative bacteria, anaerobes, and some rickettsial pathogens. Because chloramphenicol can cause aplastic anemia in humans, its use in humans has greatly diminished. The use in animals is limited to the treatment of MDR bacterial infections that are not susceptible to other veterinary-approved antimicrobial drugs. Thiamphenicol and florfenicol are related compounds, the availability of which varies from country to country. Although thiamphenicol was initially promoted as not inducing aplastic anemia in humans, cases of aplastic anemia have now been identified.[107] Florfenicol is more active than chloramphenicol and thiamphenicol, but has a shorter half-life in dogs and thus requires more frequent dosing (e.g., more often than every 8 hours) in this species. It was developed for food animal species where use of chloramphenicol is illegal. The only approved formulations of florfenicol for small animals are topical ear preparations for treating otitis (discussed below).

Resistance to chloramphenicols results from porin mutations, drug efflux, or production of chloramphenicol acetyltransferase enzymes, which inactivate the antibiotic.[108] Resistance to one chloramphenicol derivative predicts resistance to the others.

Clinical Use

Chloramphenicol and florfenicol may be useful for treatment of MRS infections, enterococcal infections, and ESBL-producing gram-negative bacterial infections. Chloramphenicol was approved in the United States for dogs many years ago (Chloromycetin 100-, 250-, and 500-mg tablets) for the labeled indication of "oral treatment of bacterial pulmonary infections, bacterial infections of the urinary tract, bacterial enteritis, and bacterial infections associated with canine distemper caused by susceptible organisms." Veterinary infectious disease experts believe that this old label indication is no longer valid. Moreover, the original approved dose of 55 mg/kg every 6 hours is probably too high. For the current use, there is a need to optimize dosage regimens and establish clinical breakpoints for dogs and cats.[109] Doses used today are shown in Table 10.12. Chloramphenicol is absorbed orally with or without food. Tablets and capsules have similar oral absorption, but the extent of oral absorption varies considerably among dogs. Chloramphenicol distributes well to extracellular fluids of most tissues. Less than 50% of the drug is bound to plasma protein. Because of its high degree of lipid solubility, it also diffuses to tissues with barriers, such as the CNS and the eye. Topical ophthalmic preparations achieve high concentration in the aqueous humor. In dogs, most absorbed chloramphenicol is metabolized by glucuronidation in the liver, with inactive metabolites excreted by the kidney. The use of chloramphenicol should therefore be avoided in animals with hepatic failure. Likewise, because of the requirement for elimination through glucuronidation, cats have longer elimination rates than dogs and are more susceptible to adverse effects. Provided renal failure is not present, sufficient active drug is excreted in the urine to enable treatment of UTIs that are resistant to other drugs, such as MRS and methicillin-resistant enterococci.

The most common use of florfenicol in dogs is the topical use for ear infections. There are two FDA-approved topical otic medications that contain florfenicol (in combination with corticosteroids and an antifungal agent) described below.

Adverse Effects

Exposure of humans to even small amounts of chloramphenicol has the potential to lead to irreversible aplastic anemia, an idiosyncratic reaction, weeks to months after discontinuing treatment. The reaction is rare (1 in 24,000 to 1 in 40,000 exposed humans) and most commonly occurs when human patients are treated with oral formulations.[110] Whether use of ophthalmic preparations in human patients poses a risk has been controversial.[111,112] Nevertheless, it is recommended that owners of pets being treated with chloramphenicol wear gloves when handling the drug and to avoid splitting or crushing tablets at home. Chloramphenicol commonly causes GI adverse effects in dogs and cats, including anorexia, hypersalivation, and vomiting.[113] Another adverse effect that has emerged since the more recent use in dogs is peripheral neuropathy. This manifests as pelvic limb ataxia, weakness, and neurologic defects.[113] It appears to be more common in large-breed dogs, with a mean body weight for dogs with pelvic limb weakness of 35.3 kg.[113] Because it may be confused with other neurologic diseases, veterinarians should review the drug history in affected patients. The problem resolves in most dogs after the drug is discontinued. High doses or prolonged treatment can result in *reversible* bone marrow suppression, which also usually resolves within days after discontinuation of treatment. High doses and prolonged treatment are needed to produce this effect in dogs, but cats are considerably more susceptible and can be at risk within 1 week of administration. Chloramphenicol is a potent inhibitor of P450 enzymes, and so the potential for significant drug interactions exists, including

with NSAIDs, anticonvulsants, and analgesics. Dramatic increases in plasma methadone concentrations have been described in dogs treated concurrently with chloramphenicol.[114]

Florfenicol is available as an injectable antibiotic for livestock, a feed additive for pigs, and an oral agent for treating fish raised in aquaculture facilities. Florfenicol has not been widely used in dogs and cats because of inconvenient dose regimens and lack of an oral formulation. The safety of florfenicol in dogs and cats is undetermined. There are no safety studies reported from repeated doses, and caution should be exercised if it is used for treating drug-resistant infections in dogs and cats. Two exceptions are the topical forms approved for use in dogs by the FDA in 2014 and 2015. The product Osurnia contains 10 mg/mL florfenicol, 10 mg/mL terbinafine, and 1 mg/mL betamethasone acetate in a gel for topical administration. The product Claro contains florfenicol 15 mg/mL, terbinafine 13.3 mg/mL, and mometasone 2 mg/mL. The indication for each product is for the treatment of otitis externa in dogs associated with susceptible strains of bacteria (*S. pseudintermedius*) and yeast (*Malassezia pachydermatis*).

Macrolides, Lincosamides, and Ketolides

Classification and Mechanism of Action

The macrolides and lincosamides (clindamycin and lincomycin) are not chemically related but possess similar mechanisms of action, resistance, and antimicrobial activity. Macrolides, lincosamides, and the ketolide telithromycin inhibit protein synthesis by binding to the 50S subunit of bacterial ribosomes. Because they are weak bases, macrolides and lincosamides concentrate in the relatively acidic interior of leukocytes. The high concentrations in leukocytes may also produce immunomodulatory effects.[115–119] Macrolides, particularly the newer agents such as azithromycin, can impair leukocyte function, induce neutrophil apoptosis, interfere with superoxide production by mast cells, and suppress proinflammatory cytokine release.[115,116] These effects may suppress inflammatory reactions in some tissues, particularly the respiratory tract. These effects on immune cells and cytokine expression may be significant for treatment of respiratory infections in humans and cattle. However, the contribution of these properties to treatment of infections in dogs and cats is undetermined.

The first macrolide antibiotic discovered was erythromycin, a derivative of *Streptomyces erythreus*. Despite the common occurrence of GI adverse effects, poor GI absorption, and an extremely short half-life, erythromycin continues to have application in human medicine because of its safety in pregnancy and utility in human patients who are allergic to penicillin. Because these concerns are less important in dogs and cats, erythromycin is less commonly used in small animal patients. Adverse effects (primarily vomiting) and poor oral absorption are problems for the use in small animals and erythromycin has largely given way to the human oral drug, azithromycin, for treatment when a macrolide is indicated.

Since the discovery of erythromycin, several semisynthetic macrolides have become available. Azithromycin and other new macrolide antibiotics, such as clarithromycin and roxithromycin, have been referred to as "advanced-generation" macrolides. These have an extended spectrum of activity, with greater efficacy against atypical and some gram-negative bacteria, a longer duration of antimicrobial activity, longer half-life, improved GI absorption, greater intracellular concentrations, and a marked reduction in GI adverse effects. Clarithromycin has improved activity against streptococci and staphylococci compared with erythromycin and greater *in vitro* activity against mycobacteria. Telithromycin is an acid-stable, semisynthetic erythromycin derivative that has a 10-fold higher affinity for the 50S ribosomal subunit than erythromycin and achieves high intracellular concentrations in phagocytes. Its use is currently restricted for treatment of moderate to severe community-acquired pneumonia in human patients, based on concerns relating to adverse effects. There have been no reports of use of telithromycin to treat dogs or cats.

Azithromycin is the first drug in the group of *azalides*, which are semisynthetic derivatives of erythromycin. The structure of the newer agents includes basic nitrogen groups. They can have either two (dibasic) or three (tri-basic) nitrogen groups. The basic nitrogen groups on these newer agents produce a positive charge in an acidic environment below their pKa. The positive charge increases intracellular concentrations caused by ion trapping. It is this property that gives these agents such large intracellular distribution and a high volume of distribution. This property also renders these agents less active in acidic environments (e.g., some infected sites). Azithromycin is extensively concentrated within cells and is retained in tissues for prolonged periods, with a half-life of 30 hours in the dog and 35 hours in the cat. In human patients, a 5-day course provides therapeutic tissue concentrations for at least 10 days. Although azithromycin has an improved spectrum against some gram-negative bacteria (not Enterobacterales or *P. aeruginosa*), it has less activity against gram-positive bacteria than erythromycin.[120,121]

Susceptibility to erythromycin often predicts susceptibility to other macrolide antimicrobial drugs. Susceptibility to erythromycin does not predict susceptibility to clindamycin in staphylococci due to the phenomenon of inducible clindamycin resistance (see Chapter 51). Resistance to macrolides and lincosamides results from decreased bacterial permeability (for gram-negative bacteria), alteration in the target site, increased drug efflux, and enzymatic inactivation of certain macrolides by bacterial esterases. Alteration in the target site involves production of a ribosomal methylase that adds a methyl group to the 50S subunit RNA, preventing the macrolide from binding to the ribosome. Expression of the methylase enzyme confers high-level resistance to azithromycin, clarithromycin, and also clindamycin.

Clinical Use

Macrolides and lincosamides are primarily used to treat gram-positive bacterial infections; they are ineffective against gram-negative bacteria of the Enterobacterales and nonfermenters such as *P. aeruginosa.* They are generally considered to be bacteriostatic. Doses are shown in Table 10.13. The use of erythromycin in small animals has declined tremendously since the availability of azithromycin and clindamycin, which are effective for similar indications. The main disadvantages of erythromycin are the adverse GI effects and poor oral absorption (described below). Erythromycin tablets have a protective coating to prevent degradation by gastric acid. After absorption, erythromycin is distributed well to most tissues and body fluids, with the exception of the CNS and urine. It is excreted in high concentrations in the bile, followed by enterohepatic circulation, and ultimately eliminated in the feces. Nonabsorbed drug is also present in the feces. It has activity against some anaerobes, spiral bacteria (particularly *Campylobacter*), and many intracellular bacteria. Tylosin has been used to treat chronic colitis in dogs[122] and is also active against *Campylobacter* and enteric *Clostridium* spp. Resolution of diarrhea in dogs treated with tylosin has been associated with increased fecal populations of *Enterococcus* spp. and lactic acid bacteria.[123]

Clarithromycin and azithromycin have considerably longer half-lives than erythromycin. The intracellular concentration of clarithromycin is about twofold to sixfold that in plasma. Clarithromycin is preferred over erythromycin or azithromycin for treatment of rapidly growing mycobacterial infections in dogs and cats (usually in combination with rifampin) (see Chapter 61). In humans, clarithromycin is extensively metabolized by the liver to a variety of specific active and

TABLE 10.13 Suggested Macrolide and Lincosamide Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Erythromycin	10–20	8	D, C	PO	Do not administer to rabbits or rodents, as this may cause fatal diarrhea. Drug interactions may occur (see text)	≤0.25 for streptococci and ≤0.5 for other susceptible organisms
Tylosin	5–15 8–11	12–24 12	D, C	PO IM	See erythromycin. For colitis in dogs, use 20 mg/kg q8h with food, and taper to as low as 5 mg/kg q24h if a response occurs[a]	
Clarithromycin	7.5	12	D, C	PO	Drug interactions may occur (see text). Consider dosage reduction in severe renal failure	≤2 for staphylococci. Respiratory cures may be possible for organisms with MICs up to 8, because drug concentrates within the lung
Azithromycin	5–10	24	D, C	PO	Extended intervals of q48h to q72h have been used for some indications (see text).	≤ 2 for susceptible bacteria. Serum MIC values may not predict tissue concentrations
Lincomycin hydrochloride	15–25	12	D, C	PO	See erythromycin. A dose of 10 mg/kg PO q12h has been suggested for pyoderma	0.25 for streptococci and ≤ 0.5 for other susceptible organisms
Clindamycin hydrochloride, clindamycin phosphate	11–33 11 10	12 24 12	D C D, C	PO PO IV, IM	See erythromycin. For IV administration, dilute 1:10 in 0.9% saline and administer over 30–60 minutes. The oral suspension may be unpalatable to cats. For toxoplasmosis, use 25 mg/kg q12h PO	See lincomycin

[a]20 mg/kg is equal to 1/8th teaspoon of tylosin phosphate (Tylan) for a 20-kg dog.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *MIC,* minimum inhibitory concentration; *PO,* oral.

inactive metabolites, with some excretion of active drug and its metabolites into urine. Formation and excretion of these metabolites have not been well studied in dogs and cats.

Because of the prolonged concentrations of azithromycin in tissues and leukocytes, the plasma concentrations may fall below the MIC of pathogens, while still producing therapeutic benefit. Intracellular concentrations of azithromycin are 10- to 100-fold those in serum and can remain high within tissues several days after the drug has been discontinued. Despite the improved spectrum of activity of clarithromycin and azithromycin, with activity against some gram-negative bacteria and intracellular pathogens, many of these organisms are resistant. The primary indication for these antibiotics in small animals is in combination with other drugs such as rifampin for treatment of mycobacteriosis or bartonellosis, or atovaquone for treatment of certain systemic protozoal infections such as babesiosis and cytauxzoonosis. Azithromycin has been used to treat secondary bacterial infections in cats with URTD because its long half-life permits convenient dosing on an every-48- or every-72-hour basis. Despite its popularity for treating upper respiratory infections in cats, one study showed no benefit to this protocol over use of amoxicillin,[124] and the potential for overuse of azithromycin in this setting raises concerns in regard to selection for resistance to azithromycin. Despite the frequent administration of azithromycin for various infections (skin, soft tissue, respiratory), there are no well-controlled clinical studies that demonstrate effectiveness compared with placebo or other agents.

Lincomycin is active against gram-positive bacteria and has been used to treat staphylococcal pyoderma. However, the approved forms of lincomycin in many countries have largely been replaced by clindamycin. Clindamycin is nearly identical to lincomycin in structure. The only difference is the addition of chlorine replacing hydroxyl at one position, making clindamycin slightly more active against some bacteria than lincomycin, and better absorbed orally. An important difference is greater activity against anaerobic bacteria for clindamycin, which accounts for the common use to treat anaerobic infections in dogs and cats. Clindamycin has favorable pharmacokinetics in dogs and cats, and a variety of available formulations (tablets, capsules, oral liquid, and injection). Lincomycin and clindamycin are widely distributed in body tissues and fluids, including bile, peritoneal and pleural fluids, milk, placenta, prostatic fluid, and bone. Neither drug enters the CSF or ocular structures unless inflammation is present. Both drugs accumulate in neutrophils, macrophages, and abscesses. Clindamycin is also used to treat anaerobic bacterial infections, as well as toxoplasmosis and neosporosis (see Chapters 93 and 94).

Adverse Effects

Although otherwise very safe, erythromycin frequently causes vomiting, decreased appetite, and nausea because of stimulation of receptors of the GI hormone motilin, which increases GI smooth muscle activity.[125] In one of the pharmacokinetic studies conducted in dogs, IV and oral administration of various forms of erythromycin produced nausea and vomiting in *all* of the dogs in the study.[126] In the same study, administration of various oral formulations to dogs produced low, and likely ineffective, serum concentrations. Like other poorly absorbed oral antimicrobials, it can produce diarrhea due to changes in the GI flora. Although diarrhea and pseudomembranous colitis are serious complications of clindamycin treatment in humans, these problems are uncommon in small animals. Adverse effects are rarely reported for clarithromycin and azithromycin. Erythromycin and azithromycin inhibit P450 enzymes and so can increase the concentration of other drugs that are administered concurrently. Clarithromycin has been shown to decrease the metabolism of cyclosporine in dogs and cats.[127,128]

Clindamycin and lincomycin can cause vomiting and diarrhea, especially when clindamycin is used at high doses. Oral clindamycin

TABLE 10.14 Suggested Linezolid Dose for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Linezolid[a]	10	12	D, C	PO, IV	If administered with other drugs IV, the administration line should be flushed first	≤4 for staphylococci, ≤2 for *Enterococcus* spp.

[a]The use of linezolid should be reserved for gram-positive infections that are susceptible to linezolid but resistant to all other reasonable alternatives, on the basis of culture and susceptibility testing.
C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IV,* intravenous; *PO,* oral.

can have an unpleasant taste in cats and the hydrochloride form can produce esophagitis.[129,130]

In human patients, telithromycin causes GI adverse effects, and there have also been rare reports of rashes, headache, visual disturbances, neuromuscular blockage, and acute liver failure. Use of telithromycin in dogs and cats has not been reported.

Oxazolidinones (Linezolid)

Mechanism of Action and Spectrum of Activity

Linezolid is a synthetic antibiotic used to treat infections caused by gram-positive bacteria that are resistant to other antimicrobial drugs, especially MRS and vancomycin-resistant staphylococci. It also can be used to treat MDR enterococci. Linezolid binds to the 50S ribosome and prevents formation of the initiation complex for protein synthesis.[131] This is a unique mechanism because other protein synthesis inhibitors interfere with polypeptide extension. Resistance to other protein synthesis inhibitors is not associated with resistance to linezolid. Rarely, resistance to linezolid is due to modification of the drug's target site, but this is extremely rare because several step mutations are necessary before resistance can occur. Previously, the high cost of oral linezolid limited its use in small animals. Brand name tablets (Zyvox) have been listed as US $120–$150 per tablet. However, the recent availability of generic tablets has reduced the cost to approximately 1/10 of the brand name tablet.

The use of linezolid has been limited to dogs and cats with resistant staphylococcal or enterococcal infections for which other antibiotics are not effective or have produced adverse effects.[132,133] Linezolid has favorable pharmacokinetics in dogs,[134] with nearly 100% oral absorption, which is not influenced by food (Table 10.14). The pharmacokinetics in cats has not been published. Because linezolid is bacteriostatic, plasma concentrations should be maintained above the MIC throughout the dosing interval.

In human patients, adverse effects include vomiting, diarrhea, and, rarely, thrombocytopenia or reversible pure red cell aplasia. In humans, the concern regarding bone marrow effects is increased after 2 weeks of treatment. There have been rare reports of bone marrow suppression in dogs from administration for more than 2 weeks, but it is undetermined if the changes were caused by other factors. Likewise, the authors are aware of cats that developed reversible PRCA after treatment with linezolid, but the cause was undetermined.

Linezolid is a type A monoamine oxidase inhibitor and so can interact with serotonin reuptake inhibitors.[135] It was originally considered for treatment of depression and anxiety in humans because of effects on the CNS. Although behavioral effects are unlikely to affect treatment in dogs and cats, there have been anecdotal accounts of minor behavior changes in dogs treated with linezolid.

From the limited experience in animals, linezolid appears to be well tolerated by dogs and cats, but more experience is needed to fully document efficacy and adverse effects. Despite the concern about monoamine oxidase inhibition and bone marrow suppression in human patients, these effects have not yet been documented in dogs or cats.

Tetracyclines

Mechanism of Action and Spectrum of Activity

Tetracyclines are bacteriostatic, time-dependent antibiotics with a broad spectrum of activity that includes gram-positive and gram-negative bacteria, some anaerobes, and atypical and intracellular pathogens such as spirochetes, *Mycoplasma* spp., and rickettsiae. Although the antibacterial spectrum is generally wide, one should not assume that bacteria are susceptible to these agents based on the human interpretive categories for susceptibility testing. Because of high protein binding of doxycycline to plasma proteins in animals, as well as lower and more variable oral absorption, the CLSI[41,42] breakpoint for antibacterial susceptibility testing is lower for dogs than for humans (cat breakpoints have not yet been established). For example, bacteria isolated from humans will be reported as "susceptible" to doxycycline if the MIC is ≤ 4 μg/mL, but the MIC must be ≤ 0.125 μg/mL for the isolate to be reported as susceptible for dogs. The corresponding breakpoints for minocycline are ≤ 4 μg/mL and ≤ 0.5 μg/mL, respectively. Clinical breakpoints are not established for cats, but a susceptible range is likely lower than that for dogs because of higher protein binding and lower oral absorption.

In contrast to the macrolides and clindamycin, which bind to the 50S ribosomal subunit, tetracyclines inhibit bacterial protein synthesis by binding to the 30S subunit. Thus, resistance to macrolides does not imply resistance to tetracyclines. The tetracyclines used most often to treat dogs and cats are doxycycline and minocycline. Clinical use of tetracycline and oxytetracycline is rare in the United States because of a lack of available formulations and lack of good quality data to guide dosing. In addition, doxycycline and minocycline have some distinct advantages. Doxycycline and minocycline are longer-acting drugs, more lipophilic, better absorbed orally, and have antibacterial activity that is better than other agents in this class. Doxycycline and minocycline also have antiinflammatory and immunomodulatory properties because of inhibition of inducible nitric oxide synthase and proinflammatory cytokines such as TNF-α.[136] These properties have led to the use of tetracyclines for treatment of immune-mediated dermatopathies in dogs[135] and plasmacytic pododermatitis in cats.[137] There is evidence for beneficial effects for treating osteoarthritis in dogs, but this use is uncommon. Delayed-release formulations that produce subantimicrobial doses have been developed for use in human patients with the inflammatory skin disease rosacea. Doxycycline and minocycline also are used to treat acne in humans. Although development of tetracycline resistance in bacterial flora has not been documented in association with the use of these preparations, the possibility has not been ruled out.[138]

Resistance to tetracyclines primarily results from porin mutations that exclude tetracyclines from the bacterial cell, and increased drug efflux, mediated by the *tetK* gene. Bacteria with *tetK* may still be susceptible to minocycline, but the presence of another gene, *tetM,*

TABLE 10.15 Suggested Tetracycline Dosages for Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Comments	CLSI Breakpoints (μg/mL)
Tetracycline	15–20 4.4–11	8	D, C	PO IV, IM	Do not mix with food containing cations such as calcium, zinc, magnesium, iron, aluminum	≤2 for streptococci, ≤4 for other susceptible bacteria. Consider use of ≤1 for susceptible bacteria
Oxytetracycline	20 7.5–10	12	D, C	PO IV	See tetracycline. Administer on an empty stomach	See doxycycline
Doxycycline	5 10	12 24	D, C	PO, IV	For IV administration, dilute in 100 to 1000 mL of LRS or 5% dextrose and administer over 1 to 2 hours	≤0.125 μg/mL for *Staphylococcus pseudintermedius*, and gram-negative bacteria (*E. coli*, and other Enterobacterales)
Minocycline	5 8.8 (one 50-mg capsule)	12 24	D C	PO PO		≤0.5 μg/mL

C, cats; *CLSI,* Clinical and Laboratory Standards Institute[41,42]; *D,* dogs; *IM,* intramuscular; *IV,* intravenous; *LRS,* lactated Ringer solution; *PO,* oral.

confers resistance to all tetracyclines.[139] Therefore, resistance to doxycycline does not always imply resistance to minocycline.[140] The glycylcycline antibiotic tigecycline is a new parenteral antibiotic derived from minocycline that has greater activity than older agents, but is limited in use for treatment of MDR bacterial infections in humans.[141] For reasons that remain unclear, resistance to tetracyclines has not been a significant problem among intracellular pathogens such as *Chlamydia, Anaplasma*, and *Rickettsia* spp.[142]

Clinical Use

Doses are shown in Table 10.15. Doxycycline is the most commonly used tetracycline in dogs and cats and has fewer adverse effects than other tetracyclines. There is extensive experience with doxycycline in countries outside the United States because it is licensed for this use in Europe and other countries (e.g., Ronaxan tablets). It is the drug of choice for treatment of a variety of tick-borne infectious diseases, feline chlamydiosis, salmon poisoning disease, and leptospirosis. Many (approximately 50%) of *Staphylococcus* spp. are susceptible to doxycycline and minocycline using approved clinical breakpoints. However, because susceptibility is unpredictable, it is not a choice for empirical treatment. Doxycycline is commonly recommended for respiratory infections. In the ISCAID consensus guidelines for treatment of respiratory infections in dogs and cats,[143] doxycycline was recommended for many respiratory indications. Doxycycline was listed as the first-line drug option (i.e., first-choice) for five conditions: acute bacterial upper respiratory infection in cats, chronic bacterial upper respiratory infection in cats, CIRD complex (with a bacterial component), bacterial bronchitis in dogs and cats, and pneumonia in animals.

For treatment of vector-borne disease in dogs and cats caused by *E. canis* and other organisms, there is substantial clinical and experimental evidence for effectiveness from doxycycline at 10 mg/kg/day for 28 days, and perhaps lower doses. Two consensus statements[144,145] recommend doxycycline as the first drug of choice for these infections in dogs and cats. Another important use of doxycycline and minocycline is in the treatment of canine heartworm disease. This addition to heartworm treatment is based on the activity of these agents against *Wolbachia,* which is an obligate endosymbiont.[146] This use is considered a standard part of canine heartworm treatment and is discussed in the protocol available from the American Heartworm Society (see https://www.heartwormsociety.org/veterinary-resources/american-heartworm-society-guidelines).

Doxycycline can be administered once daily (usually 10 mg/kg), but twice-daily administration with a lower dose (5 mg/kg q12h) is frequently recommended. A lower dose given twice daily produces less GI problems (particularly vomiting) than a higher dose given once daily. Doxycycline is absorbed approximately 64% (average from all studies in dogs) from the GI tract and distributed to tissues at concentrations that often exceed the unbound plasma concentration, including the lung, bronchial secretions, liver, kidney, and, to some extent, the CNS. Minocycline can be administered as an adequate substitute for doxycycline if there are shortages in availability of doxycycline or high cost. Minocycline is more lipophilic than doxycycline, it is better absorbed orally, but oral absorption is inhibited by food.[147] (Feeding also may affect doxycycline oral absorption in dogs and cats, but this factor has not been studied.) Minocycline can produce a higher incidence of GI upset, particularly if the entire dose is administered once daily (as with doxycycline, twice-daily administration is most often recommended). Pharmacokinetic studies have shown that minocycline can be administered at similar doses as doxycycline (5 mg/kg PO q12h for dogs and 50 mg PO q24h for cats).[148,149] Higher doses have a tendency to cause vomiting in animals. Sucralfate can significantly decrease absorption of minocycline when administered concurrently because it can chelate to aluminum in this product.[150] Absorption of other tetracyclines from the GI tract is not as efficient as doxycycline and minocycline. Oral absorption is also inhibited by other di- and tri-valent cations (e.g., Fe^{+3}, Mg^{+2}). All tetracyclines are concentrated in bile. Urine concentrations of minocycline and doxycycline may not be as high as other agents that are strictly eliminated in the urine. However, the concentrations of minocycline and doxycycline may be high enough to bacteria shown to be susceptible according to the current CLSI minocycline and doxycycline breakpoints.[41,42]

Adverse Effects

The most common adverse effects of tetracyclines in dogs and cats are vomiting, decreased appetite, nausea, and diarrhea. These may be reduced when doxycycline hyclate tablets are administered intact (rather than being split or crushed) and by administering doxycycline with food, but the effect of feeding on oral absorption should be considered, as it has been shown to have a significant effect for minocycline.[147] The hyclate salt of doxycycline (containing hydrochloride) has been associated with esophagitis and esophageal strictures in cats (Fig. 10.4),[151] and life-threatening esophageal ulceration in a dog.[152] This is also a complication in humans.[153] A bolus of water or small meal should be administered immediately after dosing in order to prevent this complication, or a suspension rather than tablets should be used. Doxycycline monohydrate, another formulation available for humans, and available for

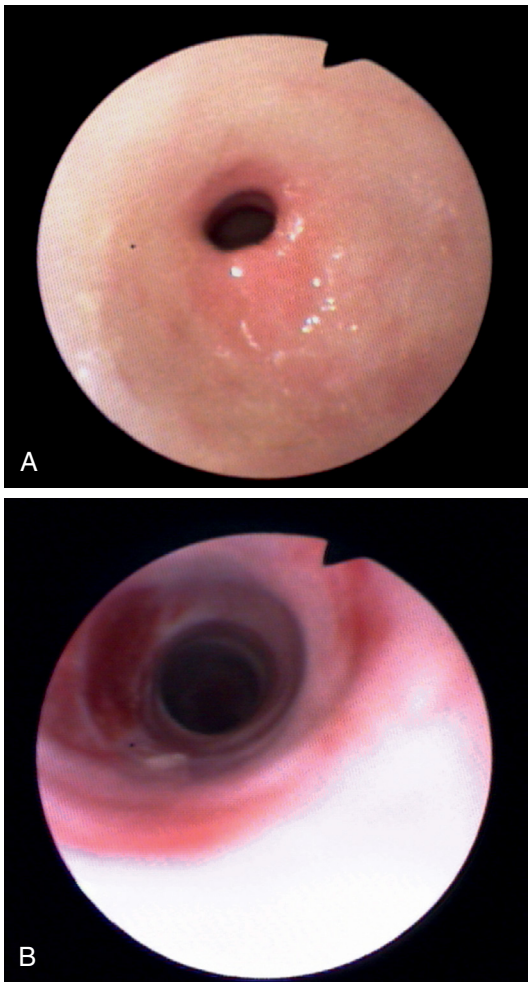

Fig. 10.4 (A) Esophageal stricture in a 9-year-old female spayed domestic shorthair cat that had been treated with doxycycline hyclate for possible hemoplasmosis. Regurgitation after eating commenced shortly after treatment was initiated. (B) The stricture was treated via repeated balloon dilatation; the image is taken immediately after the ballooning procedure was performed.

dogs and cats in some countries (e.g., Australia), has not been associated with esophageal erosions. To avoid problems with solid-dose oral forms or to decrease the cost of tablets, compounded formulations have been prepared for dogs and cats. Use of these formulations is discouraged unless the pharmacy can guarantee stability for the duration of treatment. Compounded, high-concentration (e.g., 33.3 mg/mL or 167 mg/mL) suspensions in aqueous vehicles have limited stability; suspensions in some vehicles do not retain their potency beyond 7 days.[154]

In dogs and cats with renal failure, tetracyclines other than doxycycline and minocycline should be avoided. Tetracyclines other than doxycycline can interfere with bone growth and cause significant and permanent gray-brown or yellow discoloration of the teeth (Fig. 10.5); therefore, their use is not recommended in puppies and kittens. Doxycycline is less likely to produce this effect because it binds calcium less avidly. As a result, the use of doxycycline in human pediatric medicine is now accepted for a short course.[155] All tetracyclines, including doxycycline, can cause hepatic failure and renal tubular necrosis. Cutaneous reactions (photosensitization) occur rarely in animals treated with tetracycline, but have been reported in humans.

IV preparations of doxycycline and minocycline are available but can be considerably more expensive than the oral formulations.

Fig. 10.5 Yellow discoloration of the teeth in a "puppy mill" puppy that was presumably treated with tetracycline antibiotics.

Doxycycline should be administered as a slow infusion (in humans, 1 to 2 hours is used). Thrombophlebitis can occur at the site of injection, and anaphylactic shock has been reported following parenteral administration of tetracycline to a dog.[156] On the other hand, although a slow IV infusion is also recommended for people with minocycline, the studies in dogs and cats used a short infusion of 5 minutes, without adverse events.[148,149]

Streptogramins

Quinupristin-dalfopristin is a combination of two streptogramin antibacterials in a 30:70 ratio. This combination is used for treatment of resistant gram-positive bacterial infections in humans. These agents act synergistically on the 50S ribosomal subunit to produce a bactericidal effect. This combination is approved to treat MRS and vancomycin-resistant *Staphylococcus* infections and *Enterococcus faecium* infections in humans. Quinupristin-dalfopristin is inactive against *Enterococcus faecalis*. Worldwide, a low rate of resistance exists among MDR gram-positive bacteria in humans and dogs; however, resistant strains have been identified that can methylate the ribosomal subunit, inactivate streptogramins, or that express efflux pumps.[157] Currently, there are no reports of use of quinupristin-dalfopristin in dogs and cats, which may relate to the drug's high cost, frequent adverse effects in humans, and the need to administer the drug intravenously through a central vein.[132]

Antifungal Drugs

Polina Vishkautsan, Jane E. Sykes, Mark G. Papich

KEY POINTS

- Compared with antibacterial drugs, the range of antifungal drug classes available is limited. The azole class of antifungal agents is used for systemic treatment in most animal patients. The azoles have a similar mechanism of action, but can differ in their antifungal spectrum of activity, pharmacokinetics, and adverse effect profiles. Proper understanding of these factors is most likely to result in successful treatment with minimal adverse effects.
- Drug interactions occur with many antifungal drugs.
- Although therapeutic drug monitoring could improve treatment with the azole antifungals and 5-flucytosine, this is rarely done because of variable availability of clinical assays. If performed, the interpretation of the measured concentrations is based on guidelines for humans.
- Fungal infections often require prolonged treatment durations. This may be costly for some pet owners and can increase the risk of drug adverse effects.
- Fungal organisms that are resistant to certain antifungal drugs are increasingly recognized. Although antifungal susceptibility testing can identify resistant organisms, this is often not performed because there are no standards for interpreting susceptibility tests for veterinary pathogens and antifungal drugs used in veterinary medicine.

INTRODUCTION

In human medicine, an increase in the need for agents to treat fungal infections coincided with an increase in diseases that caused immunosuppression (e.g., HIV), or treatments with potent immunosuppressive drugs. In animals, immunosuppression can also underlie opportunistic fungal infections, and the importance of fungal infections in dogs and cats is increasingly recognized. It is anticipated that global climate changes also will increase fungal infections in mammals.[1]

With the exception of itraconazole, there are no antifungal drugs approved by regulatory authorities for use in dogs and cats. Therefore, veterinarians rely on extra-label use of human antifungal drugs, with indications and dosage regimens often extrapolated from human use. Because of differences in pharmacokinetics among species for these drugs, and differences in the susceptibility to adverse effects in dogs and cats compared with humans, this approach is not optimal, but because of experience with some of these agents, veterinarians are accumulating treatment guidelines to treat these infections. Fortunately, the clinical experience and pharmacokinetic data have expanded for these human drugs, which has allowed more precise antifungal treatment in animals. Efforts also have focused on the development of new, less toxic and more efficacious antifungal drugs and treatment regimens. This chapter reviews the classification, mechanisms of action, spectrum of activity, resistance mechanisms, pharmacokinetics, clinical use, and adverse effects of the major systemic antifungal drugs used to treat dogs and cats. Topical antifungal treatments are included in other chapters of this book relevant to specific infections.

Antifungal drug treatment is usually longer in duration then antibacterial drug treatment. One reason for this difference is that fungal organisms grow more slowly, and the drugs used (primarily azoles) are fungistatic, not fungicidal. The patient's immune system is also often compromised, which may be the underlying reason for the infection. Therefore, long-term treatment is needed to inhibit fungal growth and eradicate the infection. Antifungal drug treatment of animals that have deep mycoses often must be continued for months, and in some animals, it may be weeks before any clinical improvement is evident. Thus, a "trial-and-error" treatment approach with antifungal drugs is often not useful. In addition, disease often worsens within the first 1 to 2 weeks of treatment because of the host's inflammatory response to treatment effects. This may have severe consequences for the host when there is extensive involvement of the pulmonary parenchyma or the CNS. Concurrent treatment with an NSAID or, when CNS involvement is present, judicious use of a short course of anti-inflammatory glucocorticoids, may improve outcome in these situations.[2] The prognosis for animals with disseminated mold infections with reversible underlying immunosuppression (such as drug-induced immunosuppression) may be better than the prognosis for animals with no apparent underlying immunosuppressive disease.

AZOLE ANTIFUNGALS

Mechanism of Action, Classification, and Spectrum of Activity

Azole antifungal drugs inhibit sterol 14α-demethylase, a cytochrome P450-dependent fungal enzyme involved in synthesis of ergosterol, a key component of the fungal cell wall, from lanosterol. The result is the accumulation of 14α-methylsterols, which disrupt the fungal cell membrane (Fig. 11.1). The majority of the adverse effects and drug interactions observed with these drugs relate to the cross-inhibition of mammalian P450 enzymes (Table 11.1). Hence, adverse effects relating to reduced production of testosterone, cortisol, androgen, or cholesterol may be observed with some of the compounds. In addition, ketoconazole, itraconazole, and posaconazole inhibit the transport of several drugs (anticancer agents such as vincristine, macrocyclic lactones such as ivermectin) by the efflux transporter protein, P-glycoprotein, and can inhibit cytochrome P450 metabolizing enzymes, thus increasing the risk of toxicity of these drugs. All of the azole antifungals have the potential to be teratogenic and their use should be avoided in pregnancy.

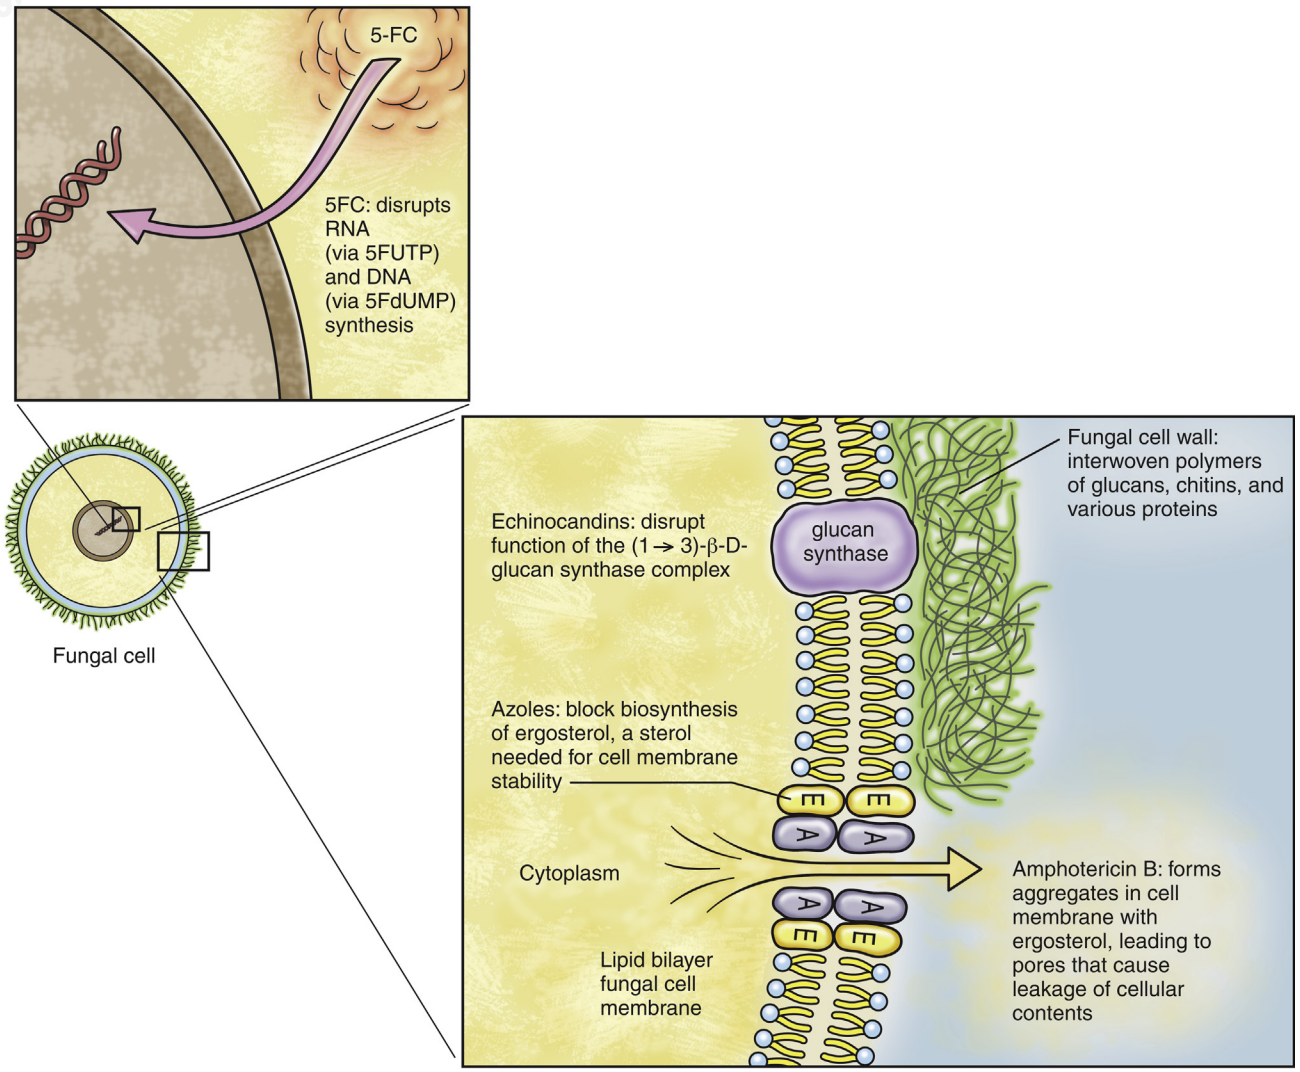

Fig. 11.1 Mechanism of action of antifungal drugs. *5FC,* 5-flucytosine; *5FdUMP,* 5-fluorodeoxyuridine monophosphate; *5FUTP,* 5-fluorouridine triphosphate; *A,* amphotericin B; *E,* ergosterol. (Modified from Rex JH, Stevens DA. Systemic antifungal agents. In: Mandell GL, Bennet JE, Dolin R, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. 7th ed. Philadelphia, PA: Churchill Livingston Elsevier;2011:549–563.)

Azole antifungals are classified as imidazoles or triazoles based on whether they possess two or three nitrogen molecules in their azole ring. Ketoconazole, enilconazole, and clotrimazole are imidazoles. The latter two drugs have poor oral bioavailability and are used topically in veterinary medicine for the treatment of superficial mycoses (see Chapters 79 and 86). Triazole antifungal drugs, such as itraconazole and fluconazole, are more slowly metabolized and have less impact on mammalian sterol synthesis than do imidazoles. Imidazoles and triazoles have been widely used to treat a variety of mycoses, which include candidiasis, cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, dermatophytosis, sporotrichosis, and aspergillosis (Tables 11.2 and 11.3).

Unfortunately, resistance to azole antifungal drugs (intrinsic or acquired) has emerged among some fungi. Intrinsic resistance is reported for cryptic *Aspergillus* species, whereas acquired resistance is increasingly described for *Aspergillus fumigatus* isolates. Resistance results from mutations in the gene that encodes the C-14α demethylase enzyme (*cyp51A*), increased production of C-14α demethylase, and increased azole efflux by fungal cell membrane transporters. Resistant strains of *Aspergillus* have been identified in the environment and in human patients naïve to and previously exposed to azole therapy. Resistance was described in canine and feline isolates of *A. fumigatus*,[3] a feline isolate of *Aspergillus felis*,[4] a feline isolate of *Cryptococcus neoformans*[5] and *Cryptococcus gattii*, and a canine isolate of *Candida tropicalis*.[6] Methods for *in vitro* susceptibility testing have been standardized for human medicine,[7,8] with improved correlation between the results of *in vitro* susceptibility testing and clinical response. However, interpretive criteria for susceptibility testing are not available for veterinary uses and testing criteria are still needed for many drug-fungus combinations. Resistance to one azole does not always imply resistance to other azole antifungal drugs.

Ketoconazole

Spectrum of Activity and Clinical Use

Ketoconazole has largely been replaced by itraconazole for treatment of many mycoses, because of the high risk of adverse effects and drug interactions compared with triazole antifungal drugs. In some countries, ketoconazole has been abandoned for human use. Decreased human use has increased the cost of generic forms for veterinary use in recent years. Nevertheless, ketoconazole continues to be used in

TABLE 11.1 Substrates, Inhibitors, and Inducers of Cytochrome P-450

Function	CYP1A2	CYP2C19	CYP2C9	CYP2D6	CYP3A4

TABLE 11.2 Spectrum of Activity and Tissue Distribution of Antifungal Drugs

Drug	Spectrum Of Activity	Tissue Distribution
Ketoconazole	Dimorphic fungi, *Malassezia* spp. Ineffective for aspergillosis.	Skin, bone, joint, lung. Poor CNS penetration.
Itraconazole	Dimorphic fungi and molds, *Malassezia* spp.	Skin, bone, lung. May enter the CNS and eye with inflammation.
Fluconazole	Some *Candida* spp., *Malassezia* spp., some dimorphic fungi. Poor efficacy against molds. *Aspergillus* spp. are intrinsically resistant.	Widely distributed including to the skin, lung, CNS, urine, and eye.
Voriconazole	Dimorphic fungi, yeasts, and molds with the exception of *Sporothrix schenckii* and zygomycetes.	CNS, eye, lung, bone. Does not penetrate the urinary tract.
Posaconazole	Dimorphic fungi, yeasts, and molds including zygomycetes and *Fusarium* spp.	Widely distributed.
Amphotericin B	Broad spectrum. Also active against *Leishmania* spp.	Limited penetration of the CNS and eye.
5-Flucytosine	*Cryptococcus* and *Candida* spp.	Widely distributed, which includes the CNS, eye, and urine.
Griseofulvin	Dermatophytes	Concentrates in skin.
Terbinafine	Activity highest for dermatophytes. To a lesser extent may have efficacy against other dimorphic and filamentous fungi in combination with another antifungal drug	Concentrates in skin and hair.
Caspofungin	*Candida* and *Aspergillus* spp. Not effective against *Cryptococcus* spp. or when given alone to treat *Coccidioides* spp.	Widely distributed. Poor penetration of the CNS and eye.

CNS, Central nervous system.

TABLE 11.3 Suggested Azole Antifungal Drug Doses for Dogs and Cats

Drug	Dose (mg/kg)	Interval (Hours)	Species	Route	Comments
Ketoconazole	10–15 5–10	12	D C	PO	Do not administer to pregnant animals. Monitor liver enzymes monthly during treatment. Drug interactions may occur (see text). Inhibits adrenal function. Antacids impair absorption.
Itraconazole	10 5 3–5 (dermatophytes)	24 12 24	D, C	PO	Do not administer to pregnant animals. Monitor liver enzymes monthly during treatment. Drug interactions may occur. Use of the oral suspension may warrant dose reduction to 3 mg/kg q24h. Monitor serum drug concentrations after 2 weeks if there is inadequate response to treatment (see text). Compounded formulations are unstable and should not be used. See Chapter 78 for treatment of dermatophytosis in cats.
Fluconazole	5–10 50 mg/cat	12 12–24	D C	PO	Do not administer to pregnant animals. Monitor liver enzymes during treatment. Drug interactions may occur.
Voriconazole	4–5 2.5	12 48–72	D C	PO	Use cautiously in animals with liver disease. In cats, a loading dose of 5 mg/kg should be given at the start of treatment, with the next dose 72 hours later. Therapeutic drug monitoring is strongly recommended in dogs and necessary in cats (see text).
Posaconazole	5 7.5 15	48 (oral tablet) 24 48	D C C	PO	Dose for dogs is for the delayed-release tablets. In cats, a loading dose of twice the daily maintenance dose is recommended. Longer intervals for dogs with oral tablets (e.g., q72h) may be considered. Utilize therapeutic drug monitoring for long-term treatment. Also see fluconazole. Antacids impair absorption.

C, cats; *D,* dogs; *PO,* by mouth.

veterinary medicine when the cost of other antifungal drugs is prohibitive. Clinical studies support the use for treatment of *Malassezia* dermatitis[9] and feline nasal and cutaneous cryptococcosis. The absorption of ketoconazole is improved when it is administered with food, and it is inhibited by concurrent use of antacids. Ketoconazole is highly protein bound, and is metabolized extensively by the liver. Nevertheless, moderate hepatic dysfunction does not alter blood concentrations of ketoconazole. Inactive products are excreted in bile, and to a lesser extent, the urine. Because of poor CNS penetration, it is ineffective for treatment of meningeal cryptococcosis and aspergillosis.[10] In one study, 38% of *A. fumigatus* isolates from dogs and cats had a ketoconazole MIC ≥ 8 μg/mL, which is higher than attainable plasma drug concentrations. Therefore, it may be an unsuitable choice for treatment of canine or feline sinonasal aspergillosis.[3]

Adverse Effects and Drug Interactions

The most common adverse effects of ketoconazole in dogs and cats are vomiting, anorexia, lethargy, and diarrhea.[11,12] These effects may be dose related. Administration of ketoconazole with food may reduce GI adverse effects. In addition, administration with food is important for optimum oral absorption because feeding stimulates acid secretion.[13] Mild increases in the activity of serum transaminases occur commonly during treatment, but do not warrant discontinuation of the drug. Less commonly, ketoconazole causes a clinically significant hepatitis, which may be accompanied by anorexia, vomiting, lethargy, increasing activities of serum ALT and ALP, and hyperbilirubinemia. The drug should be discontinued and liver enzymes monitored. After liver enzymes return to normal, consider an alternate antifungal agent for treatment. Hepatitis can occur at any time, and the onset may be extremely rapid. Pruritis and cutaneous erythema have been reported in fewer than 1% of dogs treated with ketoconazole.[11] Lightening of the haircoat color and cataract formation occur rarely.

Ketoconazole is a potent inhibitor of mammalian cytochrome P450 enzymes and efflux transporter proteins such as P-glycoprotein. Using *in vitro* assays to determine activity for dog cytochrome P450 enzymes, it was found that ketoconazole was a broad-spectrum inhibitor of all canine P450 enzymes tested.[14] Ketoconazole also can inhibit with P-glycoprotein transport. The consequence of this interaction is that oral absorption of some drugs may increase because of inhibition of the P-glycoprotein efflux transporter. This has been shown for cyclosporine, in which ketoconazole can greatly increase plasma drug concentrations of cyclosporine and reduce clearance by as much as 85%.[15] This property is used by some clinicians to increase blood levels of cyclosporine in dogs that are not responding to conventional doses of cyclosporine[16] or to reduce the cost of treatment.[17] There are concerns about whether use of ketoconazole in this way could contribute to antifungal drug resistance and increase the risk of adverse drug reactions. Ketoconazole can also produce adverse consequences by inhibiting P-glycoprotein at the blood-brain barrier. This effect increases CNS exposure to ivermectin in dogs, which results in toxicity.[11,18] It also inhibits testosterone and cortisol synthesis. As a result, it has been used to treat pituitary-dependent hyperadrenocorticism in dogs.[19] Transient infertility can occur during treatment of intact male animals. Ketoconazole should not be administered to pregnant animals.

Itraconazole

Spectrum of Activity and Clinical Use

Itraconazole is one of the most widely used azoles in veterinary medicine, and a veterinary formulation of itraconazole is available for treatment of feline dermatophytosis in North America and Europe

(Itrafungol, Elanco). Itraconazole has been used to treat blastomycosis, sporotrichosis, aspergillosis, coccidioidomycosis, dermatophytosis, histoplasmosis, phaeohyphomycosis, paecilomycosis, cryptococcosis, and *Malassezia* spp. infections. The use has included dogs and cats, but frequently extends to birds, and exotic animals. Itraconazole is highly lipophilic and practically insoluble in water. The capsule formulation of itraconazole contains sugar spheres coated with the drug, which increases surface area and solubility of the drug.[20] There are two oral solutions. The oral solution approved for use in cats is formulated as 10 mg/mL in a cherry and caramel flavor with hydroxypropyl-β-cyclodextrin, which maintains the solubility in solution. The approved human oral solution (Sporanox) contains exactly the same ingredients and solubilizing agent, in addition to other excipients such as sorbitol, propylene glycol, hydrochloric acid, and saccharin; therefore, it is expected that both formulations are bioequivalent. The formulation for cats is approved for treatment of dermatophytosis at a dose of 5 mg/kg/day on alternating weeks.[21] Itraconazole in capsules has variable absorption that is optimized when given with food because the acid secretion stimulated with feeding increases the drug solubility, which is necessary for dissolution and absorption. Because the oral solution is complexed with a solubilizing agent (beta cyclodextrin), it is dissolved in solution and administration of food does not influence absorption of this formulation. In humans and cats, oral solution is consistently better absorbed than the capsule formulation, regardless of feeding, and the capsule and oral solution are not bioequivalent and cannot be used interchangeably. Oral absorption of the solution in cats was 52%,[21] and oral absorption of the solution is 3–5 times higher than the capsules in cats.[21,22] Therefore, a dose reduction is indicated when switching from the oral capsule to the oral solution to reduce the chance of toxicity.[23] The difference between oral solution and oral capsule absorption is not as great in dogs compared with humans or cats.[24] Extent of oral absorption for the capsule was 85% that of the oral solution in dogs. The peak concentration (C_{MAX}) was 1.26 μg/mL and 1.54 μg/mL for the capsule and oral solution, respectively, when administered at the same dose.[24]

If the human formulation is used, administration of 3 mg/kg once daily to cats is usually adequate (see Table 11.3), but the approved label for cats lists 5 mg/kg daily on alternating weeks (1 week on; 1 week off). As with ketoconazole, concurrent administration of gastric acid suppressants (H_2-blockers, PPIs) may reduce absorption of the capsule. A generic capsule formulation of itraconazole (Patriot Pharmaceuticals) was slightly less bioequivalent in dogs when compared with the proprietary formulation, but pharmacokinetic data showed that therapeutic concentrations could still be achieved with its use.[20] Compounded formulations of itraconazole prepared by pharmacists from bulk powder have highly variable, poor, and even negligible oral absorption in animals,[20] in addition to being unstable formulations. As a result, compounded formulations should never be used in dogs and cats. In the authors' experience, treatment failures often occur when compounded itraconazole is used.

Like ketoconazole, itraconazole undergoes hepatic metabolism and inhibits metabolism of other P450-dependent drugs (e.g., cisapride, diazepam, cyclosporine; see Table 11.1). It is the only triazole antifungal drug that is converted to an active metabolite, hydroxyitraconazole.[25] Itraconazole is highly (99%) plasma protein bound and does not appear in the urine, CSF, or ocular tissues, although penetration of the CSF and eye may occur in the presence of inflammation. It accumulates in the skin and claws, which contributes to its long-lasting activity and allows for intermittent dosing for dermatophytes (e.g., 1 week on; 1 week off protocols).

As mentioned daily doses of 3–5 mg/kg are used in cats (see Table 11.3), and 10 mg/kg PO q24h in dogs. A loading dose of 20 mg/kg for the first dose has been used in dogs. However, in one study, the initial loading dose may have increased the risk of toxicity and did not appear to improve outcome.[26] Because of the variable absorption of oral itraconazole, monitoring of steady state plasma concentrations (e.g., 3 weeks after initiating treatment) may be helpful if clinical responses are suboptimal.[27] Trough plasma itraconazole concentrations between 0.5 and 1 μg/mL, as determined using high-performance liquid chromatography, were associated with therapeutic success in humans.[28,29] If the hydroxy metabolite is measured, combined itraconazole/hydroxyitraconazole concentrations of 2 to 4 μg/mL are preferred.

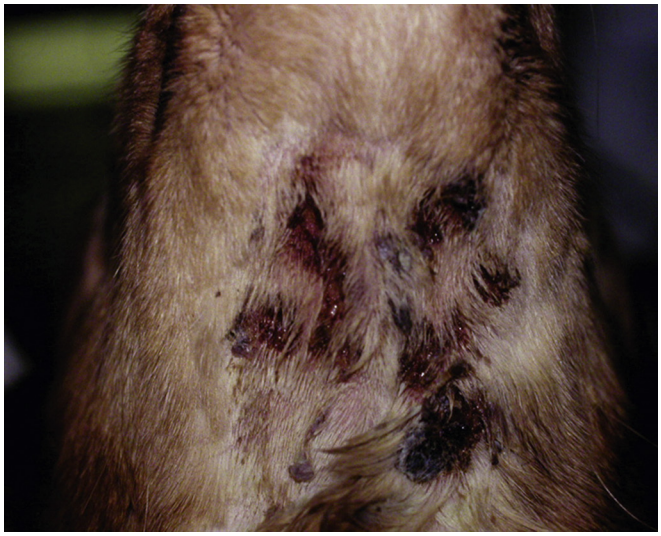

Fig. 11.2 Ulcerative skin lesions on the ventral aspect of the mandible of a golden retriever that had been treated with itraconazole for systemic blastomycosis.

Adverse Effects

The most common adverse effects of itraconazole in dogs and cats are vomiting and anorexia. Many effects are dose dependent. Dividing the total daily dose into twice-daily administration has been helpful in some animals to decrease GI adverse effects and improved absorption in human patients.[10] GI adverse effects may be more common with the oral solution. Mild to moderate increases in serum ALT activity commonly occur during treatment. If these elevations are not accompanied by inappetence or other liver enzyme elevations, treatment need not be discontinued. Significant hepatotoxicity, accompanied by anorexia, vomiting, and hyperbilirubinemia, is less likely to occur with itraconazole than with ketoconazole but has been reported in humans as well as in cats and dogs.[26,30–32] Hepatotoxicity more commonly occurs in dogs treated with 10 mg/kg/day,[26] but this dose may be necessary to attain the desired plasma drug concentration target.[24] Ulcerative or ulcerative-nodular skin lesions can occur in dogs, especially when doses of 10 mg/kg/day or higher are used (Fig. 11.2). Development of hepatitis or severe cutaneous ulceration should prompt discontinuation of the drug. It may be possible to reinstitute treatment at a lower dose once the adverse effects have resolved. Occasionally mild, focal cutaneous ulcerative lesions can resolve spontaneously, without discontinuation of treatment. Hepatic reactions also have been observed in cats. Although it is possible that this is a dose-related issue, a study in cats that administered 100 mg (total dose) q48h produced similar plasma drug concentrations in all cats, but hepatopathy occurred in 2 out of the 10 cats studied.[33] Evidence of hepatopathy was based on clinical laboratory tests during week 3 and week 5 of treatment (dose:

TABLE 11.4 Drugs that Are Substrates for the P-Glycoprotein Membrane Transporter Coded by ABCB1 (formerly known as MDR1)

Acepromazine	Ivermectin
Actinomycin D	Ketoconazole
Aldosterone	Levofloxacin
Amitriptyline	Loperamide
Butorphanol	Methylprednisolone
Cortisol	Milbemycin
Cyclosporine	Morphine
Dexamethasone	Moxidectin
Digoxin	Ondansetron
Diltiazem	Paclitaxel
Docetaxel	Phenothiazines
Doramectin	Selamectin
Docetaxel	Tacrolimus
Doxorubicin	Terfenadine
Doxycycline	Tetracycline
Eprinomectin	Verapamil
Erythromycin	Vinblastine
Itraconazole	Vincristine

P-glycoprotein is a membrane transporter responsible for transporting many drugs and other chemicals across membranes. A functional P-glycoprotein at the blood-brain barrier protects the brain from harmful effects of systemically administered drugs. P-glycoprotein may also be found at other important sites, such as the liver, placenta, kidney, and intestinal mucosa. Mutation of the gene that codes for P-glycoprotein (*ABCB1)* that produces a function deletion will expose some dogs (e.g., some herding breeds) to toxic concentrations of some drugs. Alternatively, if a drug is administered that is a P-glycoprotein inhibitor, it may decrease the effect of the membrane transporter and produce toxicity. Above are some of the P-glycoprotein substrates that may be effected by a mutation or drug inhibition.

12.3 and 26 mg/kg, respectively). Liver enzyme changes were accompanied by clinical signs (inappetence, icterus). After discontinuation of treatment, both cats recovered.

Itraconazole does not suppress adrenal and testicular function like ketoconazole, but can inhibit the metabolism of other P450 enzyme-dependent drugs, including cyclosporine, digoxin, cisapride, and vinca alkaloids (Tables 11.1 and 11.4). It can also interfere with P-glycoprotein transport of ivermectin, which results in increased plasma ivermectin concentrations.[34]

Fluconazole

Spectrum of Activity and Clinical Use

Fluconazole is the least active azole antifungal drug and has the narrowest spectrum of activity. The activity of fluconazole is limited to some *Candida*, *Cryptococcus*, and *Malassezia* spp., and some dimorphic fungi. Fluconazole has poor activity against molds, and *Aspergillus* spp. are intrinsically resistant to fluconazole. Some *Cryptococcus* spp. are resistant to fluconazole, and resistance can develop during treatment. Itraconazole is preferable to fluconazole for treatment of histoplasmosis, blastomycosis, sporotrichosis, and dermatophytosis, although fluconazole has been successfully used to treat coccidioidomycosis, blastomycosis, and *Malassezia* infections in dogs.[32]

Fluconazole is available as tablets, an oral suspension, and as an IV solution. The availability of generic fluconazole, and in turn, its cost, fluctuates. Approved generic fluconazole tablets are bioequivalent to the brand name formulation in humans. Similar bioequivalence is likely in animals. Fluconazole is more water soluble and stable than itraconazole, and the compounded oral suspensions can be used in animals with a 14-day beyond-use date. However, some compounded preparations of fluconazole for animals are unreliable, inconsistent, and of poor quality.[35] Veterinarians who prescribe the compounded formulation should use a reliable pharmacy that adheres to the compendial standards of the United States Pharmacopeia (www.usp.org).

Fluconazole is almost completely absorbed after oral administration, and bioavailability is not altered by food or gastric acidity. In contrast to itraconazole and ketoconazole, fluconazole is only weakly protein bound. Because it is more water soluble than other azoles, fluconazole diffuses into body fluids such as saliva, urine, joint fluid, and CSF. Therefore, it is the drug of choice for treating susceptible meningeal infection and UTIs caused by susceptible fungi. Renal excretion accounts for more than 90% of the elimination of fluconazole. The dosage should be decreased in animals with renal failure; this is especially important in patients receiving other P450-dependent drugs. Fluconazole will inhibit cytochrome P450 enzymes in dogs and alter the pharmacokinetics of some drugs metabolized by these enzymes.[36]

Adverse Effects

Adverse effects of fluconazole are uncommon to rare. When they occur, they are similar to those of itraconazole and include vomiting, anorexia, diarrhea, and increased liver enzymes. Dogs that fail to tolerate itraconazole may tolerate fluconazole without increases in liver enzymes.[32] Cutaneous rash, alopecia, cytopenias, and retinal edema with impaired vision have been reported in human patients.[37,38] In contrast to itraconazole, cutaneous ulceration has not been reported in dogs in association with fluconazole.

Voriconazole

Spectrum of Activity and Clinical Use

Voriconazole is a second-generation triazole that is derived from fluconazole. Voriconazole inhibits cytochrome P450-dependent 14-α lanosterol, an enzyme which catalyzes a key step in ergosterol synthesis, resulting in cell membrane disruption. This mechanism of action is fungicidal for *Aspergillus* spp. and fungistatic for other susceptible fungi. Therefore, in humans, it is the drug of choice for treatment of invasive aspergillosis.[39] It is also used to treat serious and refractory mold infections caused by *Scedosporium*, *Paecilomyces*, and *Fusarium* spp. Voriconazole is at least as active as itraconazole against veterinary isolates of *Cryptococcus* and *Candida* spp., and *A. fumigatus*.[40] It is not active against *Sporothrix* spp. or the zygomycetes.

Voriconazole is available as a tablet, oral suspension, and an IV solution in a sulfobutylether-β-cyclodextrin base. Like fluconazole, it has excellent oral bioavailability, but its absorption is reduced by food, and it should be administered prior to feeding. Voriconazole is poorly water soluble and moderately protein bound. It is extensively metabolized by hepatic cytochrome P450 enzymes and eliminated into bile. In humans, voriconazole has excellent tissue distribution and is considered the drug of choice for CNS and ocular infections. Maintenance of therapeutic concentrations in the CSF, aqueous humor, and synovial fluids in dogs appears to require twice-daily administration.[41] The cost of the human formulation has been very high; therefore, the use in dogs and cats has been uncommon. However, voriconazole has been used with some success to treat systemic mold infections in dogs.[42] Therapeutic drug monitoring is recommended because of individual variability in absorption and metabolism. The recommended trough concentration target in humans is between 1 and 5 mg/L.[28,29,39] Adverse effects can be seen above or at the high end of the concentration target.[43]

Adverse Effects

In humans, adverse effects of voriconazole include reversible visual effects such as photophobia and blurred vision, hallucinations, peripheral neuropathies, and photosensitization, as well as the same toxicities as other triazoles. Of all the triazoles, it is the most potent inhibitor of P450 enzymes. Voriconazole can induce its own metabolism over time in dogs and decrease plasma drug concentrations.[44] In a pharmacokinetic study in dogs, few of the dogs that were treated with voriconazole for 16 days exhibited mild to moderate loss of appetite and diarrhea. The authors have observed inappetence; increased serum liver enzyme activities; CNS signs, including ataxia and staring; and thinning of the haircoat and skin in dogs treated with voriconazole.

Pharmacokinetics in cats are much different than dogs. Whereas concentrations in dogs decrease with repeated doses, there is evidence that concentrations increase in cats with repeated doses.[43] Cats are very sensitive to adverse effects of voriconazole. When cats are treated with the same dose as dogs, they predictably develop inappetence as well as ocular and CNS signs including ataxia, pelvic limb paresis, mydriasis, apparent blindness, decreased pupillary light responses, and a decreased menace response.[45] Cardiac arrhythmias and hypokalemia can also occur. A pharmacokinetic study of voriconazole in cats suggested that the toxicity observed in cats results from a very long drug half-life.[43] Although additional studies are required, it may be possible to safely administer a low dose of voriconazole to cats every 2 to 3 days and still achieve therapeutic drug concentrations. It is recommended that this drug be avoided in cats or used at a low dose only if no other drug is available and therapeutic drug monitoring is used. Adverse effects in cats that were treated with a low dose of voriconazole every other day for 14 days included transient miosis when plasma drug concentrations were at the high end of the therapeutic range.[43] If voriconazole is used to treat cats, use of the tablet form is recommended, because administration of the oral suspension causes profuse salivation which in turn reduces drug availability.

Posaconazole

Spectrum of Activity and Clinical Use

Posaconazole (Noxafil) is a new azole antifungal drug, available as an oral suspension (40 mg/mL), a delayed-release tablet (100 mg), and an injectable solution. Topical otic preparations that contain posaconazole are approved for use in dogs. It is similar to itraconazole, but has a slightly different spectrum of activity and is more active (lower MIC values) than the other azole antifungal agents. In addition to other fungi in the spectrum of azoles, it is active against *Candida* and *Aspergillus* spp., Mucorales (formerly Zygomycetes) such as *Mucor* and *Rhizopus* spp., as well as *Fusarium* spp. It is used primarily in humans for *Aspergillus* and *Candida* spp. infections, but also is active against dermatophytes, *Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides* and *Cryptococcus* spp. infections. The difference in activity compared with other azoles is the additional activity against *Mucorales* and *Fusarium* spp.[25,46] It has been efficacious for treatment of several refractory deep mycoses in animals, including aspergillosis and mucormycosis in cats and invasive aspergillosis in dogs.[38,47–49]

As with itraconazole, the absorption of posaconazole is improved by a meal, especially the presence of fatty food. Gastric acid suppression can reduce the bioavailability of posaconazole.[50] Delayed-release tablets were developed to overcome absorption limitations associated with the oral suspension.[51] The pharmacokinetics of posaconazole IV solution, oral suspension, and delayed-release tablets have been evaluated in dogs and cats.[46,52,53] The delayed-release tablet in dogs and the oral suspension in cats have a long half-life, which allows for once-daily or every other day administration.[46] The oral suspension has considerably lower bioavailability in dogs when compared with the delayed-release tablets; therefore, administration of the delayed-release tablets is preferred when possible. The human extended-release tablet (Noxafil) is very expensive; however, recently a much less expensive generic tablet has become available. The authors have several anecdotal accounts of successful use of this tablet as infrequently as every 3 days (dosing frequency confirmed with plasma concentration trough monitoring as described below).

Therapeutic drug monitoring is recommended in human patients due to variable plasma drug concentrations and risk of underexposure; in humans, the target plasma trough concentrations for treatment is > 1 μg/mL.[52] Posaconazole is highly protein bound (>95%) and undergoes hepatic metabolism, with some inhibition of P450 enzymes. Most administered posaconazole is eliminated in the feces. Data on CSF concentrations of posaconazole are not yet available, but it appears to be effective for treatment cryptococcosis in the CSF.

Adverse Effects

In humans, prolonged administration of oral posaconazole has been associated with GI adverse effects. Other treatment-related adverse events have been reported at a lower rate with posaconazole compared with other azole antifungal agents. Posaconazole appeared to be safe and well tolerated in long-term treatment of disseminated aspergillosis in dogs.[53] Increases in serum liver enzyme activities were not observed.[53] Adverse effects are less common in cats when compared with voriconazole, but information is limited at the time of writing.[47–49,52,54]

Other Azole Antifungals

Other azole drugs that are undergoing clinical trials in humans include ravuconazole, isavuconazole, albaconazole, and olorofim. Isavuconazole is a novel triazole agent that has recently been approved by the FDA for the treatment of aspergillosis and mucormycosis. It may have similar efficacy to voriconazole with fewer adverse effects. Isavuconazole has fungistatic activity against yeasts such as *Candida* and *Cryptococcus* spp., but appears to be fungicidal against *Aspergillus* spp.[55] Isavuconazole is available in oral and IV formulations. The IV formulation of isavuconazole is less nephrotoxic than that of voriconazole and posaconazole because it does not contain cyclodextrin. In humans, absorption of oral isavuconazole is excellent and unaffected by food or gastric pH. It is metabolized by P450 enzymes and does not achieve therapeutic concentrations in the urine. It appears to cross the blood-brain barrier and has been effective for treating CNS infections in humans.[56] The pharmacokinetics of isavuconazole in dogs and cats have not yet been reported.

Ravuconazole is structurally similar to fluconazole and voriconazole. In humans, it has a half-life of approximately 100 hours. It has activity against *Candida*, *Aspergillus*, *Cryptococcus*, *Histoplasma*, and *Coccidioides* spp. Its safety profile appears to be similar to that of fluconazole.[57]

Albaconazole is a triazole antifungal agent that has been developed for treatment of onychomycosis in human patients. There are currently no pharmacokinetic data for this drug in dogs and cats.

AMPHOTERICIN B

Mechanism of Action and Spectrum of Activity

AMB is a polyene macrolide antibiotic produced by *Streptomyces nodosus*. It is closely related to nystatin. AMB irreversibly binds sterols in fungal cell membranes, forming pores or channels with subsequent leakage of ions (see Fig. 11.1). Although generally considered to be fungistatic, at high doses it may be fungicidal. AMB also possesses immunomodulatory effects; it activates macrophages

and enhances macrophage-killing capacity. This may help explain its efficacy against pathogens such as *Pythium insidiosum*, which lack cell wall ergosterol.

AMB has antifungal activity against all of the important small animal fungal pathogens. It is also active against *Leishmania* spp.[58–60] In human medicine, AMB is the preferred drug for treatment of rapidly progressive mycoses, immunosuppressed hosts, or fungal meningitis. Resistance to AMB is rare, although high MIC values have been observed for some molds including some isolates of *Aspergillus terreus*, *Paecilomyces* spp., and *Sporothrix schenckii*. The mechanism of resistance is not well understood, but it may relate to decreased cell wall ergosterol content.[61]

Clinical Use

AMB has poor aqueous solubility and is not absorbed from the GI tract. To administer IV, the conventional formulation is prepared as an emulsion in which it forms as a complex with the bile salt deoxycholate (Fungizone, AMB-D) (Box 11.1). The complex forms a colloid in water. Addition of electrolyte to the solution causes it to aggregate; therefore, it should be administered in 5% dextrose (D5W). It is not necessary to protect the infusion from light, as recommended in the past. In the bloodstream, AMB dissociates from deoxycholate and binds extensively to plasma proteins and cholesterol in membranes throughout tissues. Penetration of the vitreous humor and CSF is poor, but some animals with CNS infections may still respond to treatment. In human patients, AMB-D has been administered intrathecally to treat fungal meningitis and intraocularly following vitrectomy.[62]

A protocol for SC administration of AMB-D has been reported for treatment of cryptococcosis,[63] which may be less costly than IV administration. Sterile injection site abscesses occur in some animals treated using this protocol; therefore, IV administration is preferred whenever possible.

BOX 11.1 Suggested Amphotericin B Infusion Protocols for Dogs and Cats

Formulation	Protocol
All formulations	Obtain baseline CBC, kidney panel, and UA, and ensure adequate hydration before starting treatment. Recheck a kidney panel before each infusion. Administer three times weekly for 4 weeks or until azotemia is detected. For some infections, monthly administration of a single dose may be required to maintain remission.
Amphotericin B deoxycholate (IV route)	Reconstitute vial contents in sterile water to 5 mg/mL. Administer 0.9% NaCl IV at 1.5–2 times the calculated maintenance rate for 1 hour before and after AMB treatment. Ensure lines are flushed with D5W before infusing AMB. Dogs: Transfer 0.5 mg/kg to a 250- to 1000-mL bag of D5W (total fluid volume administered should be based on body weight and ability to tolerate a fluid load). Administer IV over 4–6 hours. Cats: Dilute 0.25 mg/kg in 30 mL of D5W and administer IV over 30 minutes to 1 hour.
Amphotericin B deoxycholate (SC route)	Transfer 0.5 mg/kg (cats) or 0.8 mg/kg (dogs) to bag containing 400 mL (cats) or 500 mL (dogs) of 0.45% NaCl in 2.5% dextrose. Administer SC. Fractious cats may need to be sedated or placed in a restraint bag. Sterile injection site abscess formation may occur with this protocol, especially with concentrations of amphotericin B > 20 mg/L.
Amphotericin B lipid complex (Abelcet)	Dilute to 1 mg/mL in D5W. Administer calculated dose IV over 1 to 2 hours. Dogs: 3 mg/kg Cats: 1 mg/kg

AMB, amphotericin B; *CBC,* complete blood count; *D5W,* 5% dextrose in water; *IV,* intravenous; *SC,* subcutaneous; *UA,* urinalysis.

Adverse Effects

The major adverse effect of AMB-D is kidney injury, which is dose dependent and transient if it is detected early and the drug is discontinued. Both an acute effect caused by renal vasoconstriction and a chronic cumulative effect from repeated administration occurs. Renal tubular acidosis, severe nephrogenic diabetes insipidus, hypokalemia, and hypomagnesemia can occur with treatment. Although performed rarely in dogs, aggressive IV fluid therapy and potassium supplementation has been needed in some severe cases in humans. Fluid-loading with sodium-containing fluids before the infusion may decrease nephrotoxicity.[64] Slow administration in a large volume of fluid also decreases nephrotoxicity. Concurrent use of other nephrotoxic drugs, such as aminoglycosides, should be avoided. In humans, AMB-D can also cause fever, chills, headache, nausea, vomiting, and, rarely, cytopenias and anaphylaxis.[64] Fever, inappetence, and vomiting also appear to occur in some dogs treated with AMB-D, and rarely nephrogenic diabetes insipidus. Phlebitis can occur at the IV infusion site. Other adverse effects noted in humans include infusion-related hypotension and hypochromic, normocytic anemia. NSAIDs can be administered to decrease pyrexia during treatment, but these should be used cautiously and with careful monitoring of renal parameters. Antiemetic agents are frequently administered at the time of infusion to decrease vomiting.

Lipid Formulations of AMB

Three lipid formulations of AMB are available (see Box 11.1). These are less nephrotoxic than AMB-D but are considerably more expensive. These formulations produce less injury to the kidneys because there is a lower rate of transfer of AMB to mammalian cell membranes and increased drug clearance from the blood by the mononuclear phagocyte system. This allows administration of a higher dose of the drug, sometimes with improved treatment efficacy. Nevertheless, kidney function should still be monitored. Selective uptake of lipid formulations by macrophages also facilitates treatment of pathogens that reside within macrophages, such as *Histoplasma* and *Leishmania* spp.

AMB colloidal dispersion (ABCD, Amphotec) contains AMB and cholesterol sulfate, which form disc-shaped particles. It is more likely to cause chills, fever, and hypotension in humans than AMB-D (80% vs. 12% for AMB-D), so it is given over 3–4 hours and with premedication.

Liposomal AMB (Ambisome) is a widely used formulation for treatment of human patients. It consists of AMB and a lipid mixture (phosphatidylcholine, cholesterol, and distearoyl phosphatidylglycerol). After reconstitution in D5W, it forms 80 nm vesicles. Nephrotoxicity and infusion-related reactions are much less common with liposomal AMB than with ABCD or AMB-D, and the drug appears to reach higher concentrations in the eye.[65] In human patients, it is used as salvage therapy for aspergillosis, cryptococcosis, and candidiasis.

AMB lipid complex (ABLC, Abelcet) is a mixture of AMB, dimyristoyl phosphatidylcholine, and dimyristoyl phosphatidylglycerol that forms ribbon-like sheets. ABLC is the most common formulation used

TABLE 11.5 Suggested 5-Flucytosine Drug Doses for Dogs and Cats

Drug	Dose (mg/kg)	Interval (Hours)	Species	Route	Comments
5-Flucytosine	25–50	6–8	C	PO	Monitor CBC. Use cautiously in animals with impaired renal function. Avoid use in dogs. Therapeutic drug monitoring is recommended in humans.

C, cats; *CBC,* complete blood count; *PO,* by mouth.

in veterinary medicine. Nephrotoxicity and infusion-related reactions are intermediate between AMB-D and liposomal AMB. It has been used in small animal patients to treat refractory cryptococcosis and cryptococcal meningitis and disseminated coccidioidomycosis, aspergillosis, blastomycosis, histoplasmosis, and pythiosis.

AMB cochleates are phosphatidylserine-calcium precipitates in the form of a continuous lipid bilayer sheet rolled up in a spiral. This formulation permits oral administration of AMB. Cochleates were effective when used to treat mouse models of candidiasis, aspergillosis, and most recently *S. schenckii*.[66] Cochleates remain under investigation on a research basis. Because of less experience for treating animals, significant toxicity has not been observed. Additional novel delivery systems that maintain the antimicrobial activity of AMB with reduced toxicity and improved tissue penetration are under development, such as nanoparticle formulations of AMB.[60]

5-FLUCYTOSINE

Mechanism of Action and Spectrum of Activity

Flucytosine is a fluorinated pyrimidine related to fluorouracil. It has activity only against *Cryptococcus* and *Candida* spp. These fungi deaminate flucytosine to 5-fluorouracil, which interferes with DNA replication and protein synthesis (see Fig. 11.1). Mammalian cells cannot convert flucytosine into 5-fluorouracil; therefore, injury to mammalian cells is limited. Flucytosine is synergistic with AMB and can be administered simultaneously to decrease emergence of resistance. Because marked drug resistance arises during treatment (secondary drug resistance), flucytosine must always be used in combination with other drugs, most commonly AMB. Resistance results from modifications in fungal enzymes that are required for drug uptake and metabolism.[61]

Clinical Use

The use of flucytosine in cats has been limited by its high cost, and toxicity means it cannot be used in dogs (see Adverse Effects). Flucytosine is absorbed well after oral administration and is minimally bound to plasma proteins. Penetration of the CSF and aqueous humor is excellent. In cats, flucytosine may be considered to treat severe or refractory cryptococcosis in combination with other agents. Because about 80% of the dose is excreted unchanged in the urine, high urinary concentrations can be achieved.

Adverse Effects

Administration of flucytosine should be avoided in dogs, which often develop a severe (but reversible) drug eruption within to 2 to 3 weeks of starting treatment. The combination of flucytosine and ketoconazole proved toxic to cats. The most common adverse effects of flucytosine therapy are myelosuppression and GI signs. The CBC should be monitored during treatment, and therapeutic drug monitoring should be considered. Myelosuppression is more likely to occur in patients receiving other myelosuppressive drugs. In humans, other adverse effects include rash and reversible increases in liver enzyme activities. Flucytosine toxicity may result from conversion of flucytosine to 5-fluorouracil by the intestinal microflora.

Kidney injury is another concern. The risk of flucytosine kidney injury is increased in animals with kidney disease; therefore, it should be avoided in animals with renal dysfunction unless they are monitored carefully (Table 11.5). In human patients, toxicity is correlated with 2-hour postpill concentrations greater than 100 mg/L, and concentrations of 30 to 80 mg/L are suggested for treatment of cryptococcosis.[28] Because AMB can cause impaired renal function, careful monitoring for toxicity is indicated when flucytosine is used in conjunction with AMB.

GRISEOFULVIN

Mechanism of Action and Spectrum of Activity

Griseofulvin is an oral antifungal drug derived from *Penicillium griseofulvum* that binds to fungal tubulin, leading to impaired microtubule function and mitotic arrest. It also has anti-inflammatory properties.[67] After administration, griseofulvin is rapidly deposited in keratin precursor cells in the skin and hair, but disappears from the stratum corneum within 48 to 72 hours of discontinuation of treatment. Griseofulvin is fungistatic and has a limited spectrum of activity. Because of narrow spectrum of activity, its use is limited to treatment of dermatophytosis. It is not effective against yeasts such as *Candida* and *Malassezia* spp. Resistance has been documented in some dermatophytes and may be due to altered tubulin.

Clinical Use

Because of the narrow spectrum of activity, need for prolonged duration of treatment, adverse effects, and availability of the azole antifungal agents, the use of griseofulvin has greatly diminished in small animal medicine.

The absorption of griseofulvin is increased when it is administered with a fatty meal or whole milk. The drug is available in microsized and ultramicrosized formulations, which improve absorption from the stomach and small intestine. Most veterinary preparations are microsized. The dose of the ultramicrosized formulation can be reduced by 50% because of improved absorption, but efficacy remains unchanged (Table 11.6). Prolonged treatment periods (months) are required for dermatophytosis (see Chapter 78).[68]

Adverse Effects

Griseofulvin is a potent inducer of cytochrome P450 enzymes and decreases the efficacy of other drugs metabolized by the same P450 enzymes (see Table 11.1) . Because it is extremely teratogenic, it should never be used to treat pregnant females, but can be used safely in male animals.[69] Other adverse effects of griseofulvin include inappetence, vomiting, and diarrhea. In cats, it can cause myelosuppression, which is generally reversible on discontinuation of treatment, but irreversible pancytopenia has been reported.[70] Myelosuppression may be more likely to occur in cats with FIV infection.[71] The CBC should be monitored every 2 weeks during treatment.

TABLE 11.6 Suggested Griseofulvin and Terbinafine Doses for Dogs and Cats

Drug	Dose (mg/kg)	Interval (Hours)	Species	Route	Comments
Griseofulvin (microsized)	25	12	D, C	PO	Administration with fatty food improves absorption. Dose may be increased to 50 mg/kg q12h for refractory infections. Avoid in cats with FIV infections. Do not use in pregnancy. Drug interactions possible. Monitor CBC.
Griseofulvin (ultramicrosized)	15	12	D, C	PO	Avoid in cats with FIV infections. Do not use in pregnancy. Drug interactions possible. Monitor CBC.
Terbinafine hydrochloride	30–40	24	D, C	PO	Administer with food.

C, cats; *CBC,* complete blood count; *D,* dogs; *FIV,* feline immunodeficiency virus; *PO,* by mouth.

TERBINAFINE

Mechanism of Action and Spectrum of Activity

Terbinafine is a synthetic allylamine that inhibits fungal squalene epoxidase, which blocks fungal lanosterol and ergosterol synthesis and leads to accumulation of toxic squalene, with resultant fungal cell lysis. A closely related drug of the same class is naftifine (Naftin), which is used as a topical cream for dermatophyte infections in humans. Terbinafine is most effective for treatment of dermatophytosis, but also has been used to treat *Malassezia* spp. dermatitis in dogs.[72] The efficacy of terbinafine for treatment of invasive fungal infections has not been well investigated.

Terbinafine efficacy for treating pythiosis has been inconsistent. It has been used both successfully[73] and unsuccessfully[74] in combination with other drugs to treat pythiosis in dogs. It also has *in vitro* activity against other dimorphic fungi and molds, although its activity is highest for dermatophytes.[75,76] Terbinafine may be synergistic when administered with other antifungal drugs, which may provide enhanced efficacy for treatment of refractory mycoses.[77] However, nondermatophyte molds including *Aspergillus* and *Fusarium* spp. have been detected in people with onychomycosis that failed to respond to terbinafine treatment.[78] Resistance has been reported in dermatophytes as a result of altered squalene epoxidase.[79]

Clinical Use

Terbinafine is available in 125 and 250 mg tablets (Lamisil, and generic forms) and a 1% topical cream (Lamisil available over the counter). Oral bioavailability in most species is moderate, ranging from 31% in cats to > 46% in dogs. It is better absorbed in dogs when given with food (see Table 11.6).[80]

In humans, it has the advantage of high lipophilicity and high concentrations attained in tissues such as stratum corneum, hair follicles, sebum-rich skin, and nails. In humans, after 12 days of therapy, the concentrations in stratum corneum exceed those in plasma by a factor of 75-fold. In cats after a daily dose of 30–40 mg/kg, the concentrations in hair may be 10-fold the serum concentrations and persist for weeks after discontinuation of treatment at 14 days.[81] However, these tissue concentrations have not been observed in dogs. A study in dogs showed that concentrations in canine skin, subcutaneous tissue, and sebum were not above the concentration needed to inhibit *Malassezia* spp.[82] Skin concentrations were only 1%–2% of serum concentrations.

Since terbinafine has become available as a less expensive generic product, the interest in its use in veterinary medicine has increased. Pharmacokinetic studies in which 30–35 mg/kg/day was administered to dogs[83,84] showed that sufficient concentrations can be maintained for most of the dose interval for susceptible fungi, but clinical studies are needed to confirm efficacy. By comparison, doses in humans are much lower at 125 mg twice daily (approximately 1.8 mg/kg q12h), with pediatric doses in the range of 4–8 mg/kg, once a day. The most common dose administered to dogs is 30–35 mg/kg once daily; and for cats, approximately 30 mg/kg/day, or ¼ tablet for small cats (62.5 mg), ½ tablet for medium size cats (125 mg), and one tablet for large cats (250 mg), all administered once daily. It should be administered for at least 14 days, but may be extended to 60 days.[85]

Results available to this point suggest that it is effective for the treatment of *Malassezia* dermatitis in dogs when given at 30 mg/kg PO, or 30 mg/kg twice weekly for at least 3 weeks.[86] However, the results also showed that this treatment produced insufficient resolution and only partial remission, even though there was clinical improvement in both groups.

There are two topical formulations approved for dogs, approved by the FDA in 2014 and 2015. The product Osurnia contains 10 mg florfenicol, 10 mg terbinafine, and 1 mg betamethasone acetate per mL in a gel for topical administration. The product Claro contains florfenicol 15 mg/mL, terbinafine 13.3 mg/mL, and mometasone 2 mg/mL. The indication for each product is for the treatment of otitis externa in dogs associated with susceptible strains of bacteria (*Staphylococcus pseudintermedius*) and yeast (*Malassezia pachydermatis*).

Adverse Effects

In dogs, reports of adverse effects of terbinafine are variable. One study reported effects in one-third of treated dogs, consisting of GI problems and increased hepatic enzymes. Another study[84] reported ocular problems in some dogs. Adverse effects can include GI signs, especially vomiting and increased liver enzyme activities, but these are uncommon. Facial pruritis has been reported in cats.[87]

ECHINOCANDINS

The echinocandins are lipopeptide antifungals that inhibit the formation of β-1,3-D-glucans in the fungal cell wall, a mechanism of action that is completely different from that for AMB and the azoles. The prototype drug is caspofungin acetate (Cancidas). Other drugs in this class are micafungin, anidulafungin, and most recently CD101 IV.[88] The use of these agents has been rare in dogs and cats.

Caspofungin is fungicidal against *Candida* spp., and fungistatic against *Aspergillus* spp. The echinocandins are ineffective against *Cryptococcus* spp., which possess little glucan synthase, and have been effective for treatment of *Coccidioides* spp. in a mouse model when used in conjunction with AMB,[89] as well as when used in combination with

voriconazole for refractory human pediatric coccidioidomycosis.[90] Synergism has been reported when echinocandins are used in combination with other antifungal drugs.[91] In humans, the echinocandins are used primarily to treat invasive candidiasis and have some use in salvage therapy of aspergillosis.[56] They are used in a combination with a polyene in the treatment of mucormycosis.[56] Treatment with caspofungin induced remission in a dog with disseminated aspergillosis (1 mg/kg IV in 250 mL 0.9% NaCl over 1 hour, q24h).[43] Caspofungin is given once daily as a slow IV infusion. In human patients, it is extensively protein bound and metabolized slowly by the liver, with some renal excretion. It has limited ability to penetrate the CNS and eye.[92,93] The cost is similar to that of lipid formulations of AMB. Adverse effects noted in humans include fever, phlebitis, and increased activity of serum ALT (<20% of patients). The proper dose and extent to which adverse effects occur in dogs and cats is unknown, but administration of anidulafungin to a dog treated with caspofungin was associated with the development of a severe diffuse urticarial reaction.[43] CD101 is a novel echinocandin with a very long half-life in humans that is currently being developed as a once-weekly IV treatment for candidemia and invasive candidiasis.[88] It also has activity against a broad range of *Aspergillus* spp., including *A. terreus*.[94] Given the infrequent need for administration, it may represent a useful treatment in the future for disseminated aspergillosis in dogs, but the pharmacokinetics of echinocandins in dogs requires further investigation.

OROTOMIDES

Olorofim (F901318) belongs to a promising new class of antifungal agents known as the orotomides. It targets dihydroorotate dehydrogenase, which is involved in fungal pyrimidine synthesis; the mammalian enzyme is spared.[95] It is highly active against *Aspergillus* and also has activity against dimorphic fungi. There are currently no pharmacokinetic data for this drug in dogs and cats.

COMBINATION ANTIFUNGAL DRUG THERAPY

Azole antifungals are often administered in combination with other antifungal drugs for treatment of refractory or severe deep mycoses. In some patients, treatment is initiated with amphotericin-B for several days until the patient shows a favorable response, then treatment is switched to an oral azole antifungal agent for a longer period. However, few human observational studies and small-scale clinical trials have been published to support this practice.[96] There are no data as to whether the use of antifungal combinations in dogs and cats is more effective than monotherapy. Combined use of AMB and flucytosine is synergistic in treating cryptococcal infections in human patients; presumably, AMB facilitates penetration of flucytosine into the fungal cell. A combination of terbinafine or AMB and itraconazole is recommended for treatment of pythiosis in dogs. Because use of antifungal drug combinations is associated with an increased risk of drug adverse effects, this should be approached with careful consideration of available clinical information and individual patient factors.

OTHER ANTIFUNGAL TREATMENTS

In human patients, hyperbaric oxygen therapy has been used to treat some fungal infections in combination with antifungal drugs. Whether this is beneficial or harmful is controversial and requires further study.[97]

Other agents are administered topically and will not be discussed in detail here.

Antiprotozoal Drugs

Jane E. Sykes, Mark G. Papich

KEY POINTS

- Antiprotozoal drugs often have a narrow spectrum of activity, although some are also active against bacteria and fungi. Many interfere with enzyme pathways specific to protozoal species that have little effect on the host.
- Many antiprotozoal agents are intended to inhibit growth, and treatment with antiprotozoal drugs may not consistently clear an infection.
- Resistance to antiprotozoal drugs is a growing problem among protozoal pathogens.
- Many antiprotozoal drugs with activity confined to the intestine have minimal to no adverse effects. However, some drugs have systemic effects that may limit their use.
- The availability of some antiprotozoal drugs is restricted in some countries.

INTRODUCTION

The use of antiprotozoal drugs in dogs and cats is frequently extrapolated from their use in human patients or food animal species. There are very few antiprotozoal agents approved for this use in veterinary medicine, and most are sulfonamides. The majority of these agents are used extralabel, and most antiprotozoal agents (coccidiostats mostly) in veterinary medicine are used in food producing animals (e.g., cattle, pigs, poultry) raised in close confinement. A review of the FDA list of approved animal drugs shows hundreds of products marketed for this purpose. Some antibacterial and antifungal drugs also have antiprotozoal activity, such as metronidazole, fluoroquinolones, trimethoprim-sulfonamides, clindamycin, and macrolides such as azithromycin, azoles, and amphotericin B (see Chapters 10 and 11 for a more detailed description of the use and adverse effects of these drugs). *In vitro* activity of antiprotozoal drugs, and monitoring of resistance, is more difficult for antiprotozoal drugs because standardized susceptibility testing is not routinely performed for these pathogens. Standards for testing do not exist for pathogens isolated from animals. In addition, many antiprotozoal drugs are designed to be active in the lumen of the intestine for treatment of intestinal protozoal infections, and the concentration of active drug in the intestinal lumen after oral administration is difficult to measure. Therefore, the concentration of drug to which these pathogens are exposed is often not known. The activity and dosage regimens of antiprotozoal drugs are often based on the results of clinical trials rather than pharmacokinetic-pharmacodynamic (PK-PD) concentration-exposure relationships between antiprotozoal drugs and the organism of interest.

Many antiprotozoal drugs are active only against a restricted range of protozoal species. To reflect this, drugs in this chapter are organized into antiprotozoal drugs primarily used for gastrointestinal infections; those with a broad spectrum of activity; those used to treat systemic protozoal infections (such as hepatozoonosis, toxoplasmosis, neosporosis, and sarcocystosis); those used to treat leishmaniosis; and those used to treat Chagas' disease. For many infections, treatment does not consistently result in parasitologic cure.

ANTIPROTOZOAL DRUGS USED PRIMARILY FOR GASTROINTESTINAL INFECTIONS

Amprolium

Amprolium is a thiamine analogue that is used to prevent and treat intestinal coccidiosis (Table 12.1). It is available as a feed additive for livestock and is sometimes administered in food or drinking water to puppies and kittens. To administer to dogs and cats, it is available as a 9.6% (9.6 g/100 mL) oral solution or a soluble powder in a 22.6 g packet, which then must be mixed with food. For treatment of coccidiosis, 1.25 g of 20% amprolium powder can be added to food or 30 mL of 9.6% amprolium solution to 3.8 L of drinking water for 7 days.

Adverse effects of anorexia or diarrhea are rare and primarily occur at high doses and with prolonged use. Central nervous system (CNS) signs can result from thiamine deficiency, which is reversible on addition of thiamine to the diet. However, thiamine supplementation may interfere with the drug's efficacy.

Benzimidazoles

Fenbendazole and Albendazole

Benzimidazoles bind to β-tubulin within a variety of helminths and protozoa. This leads to inhibition of tubulin polymerization and the formation of microtubules, with impaired cell division. Glucose uptake by parasites is also impaired. Resistance can result from production of altered β-tubulin by parasites, which reduces binding of benzimidazole drugs.

Fenbendazole is widely used to treat giardiasis in dogs and cats. It is safer than metronidazole, can be administered to young animals, and has higher efficacy, although treatment failure can still occur. A second course of treatment or administration of fenbendazole in combination with metronidazole can be effective in refractory cases. In one colony, elimination of infection was achieved when dogs were treated with fenbendazole for 10 days (instead of the typical use of 3 to 5 days), with bathing on day 5, separation into a clean facility, and disinfection of the original kennel. Dogs were returned to this kennel on day 7.[1] Administration with food may improve absorption, but the fat content of the food does not influence absorption.[2] Adverse effects

TABLE 12.1 Suggested Doses of Drugs Primarily Used to Treat Protozoal Infections of the Gastrointestinal Tract in Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Duration (days)	Comments
Fenbendazole	50	24	C, D	PO	5–10	Giardiasis. May be administered with food. Safe in pregnancy.
Albendazole	25	12	C, D	PO	3	Giardiasis. May cause bone marrow suppression. Do not use in pregnancy.
Metronidazole	12–15	12	C, D	PO	5–7	Giardiasis. Use caution with hepatic insufficiency. Dose for metronidazole benzoate is 25 mg/kg, but with same interval.
Tinidazole	15	12–24	D, C	PO	5	Giardiasis. Administer with food or in capsules to reduce bitterness. Administered as a single dose in humans.
Ronidazole	30	24	C	PO	14	Tritrichomoniasis. Avoid doses ≥ 60 mg/kg/day. Compounded from powder.
Paromomycin	10	8	D	PO	5–10	Cryptosporidiosis. Caution in animals with diarrhea due to possible systemic absorption. Avoid in cats.
Nitazoxanide	100 mg/animal	12	D, C	PO	3	Cryptosporidiosis. Efficacy and safety unclear. Vomiting common in cats.
Amprolium	1.25 g of 20% powder or 30 mL of 9.6% solution to 3.8 L of water	24	D, C	PO	7	Cystoisosporiasis. Add to food. Do not administer for prolonged periods.
Sulfadimethoxine	55 on day 1, 27 thereafter	24	D, C	PO	3–23 or for 48 hours after signs resolve	Cystoisosporiasis with or without a dihydrofolate reductase inhibitor.

C, cats; *D,* dogs; *PO,* oral.

of fenbendazole are very rare but can include decreased appetite, vomiting, diarrhea, and rarely reversible pancytopenia.[3] At high doses used to treat *Mesocestoides* spp. peritonitis (100 mg/kg q12h), neurologic signs have been observed.[4] Febantel is metabolized to a benzimidazole compound and has been used in combination with praziquantel and pyrantel (Drontal Plus, Elanco, USA) to treat *Giardia* spp. infection in dogs, although efficacy at label dosages has been variable and some dogs can re-shed low numbers of cysts when treatment is discontinued.[5] Albendazole has an affinity for rapidly dividing cells, and although it is used extensively for treatment of parasitic infections in human patients, it been associated with anorexia and reversible bone marrow suppression in dogs and cats especially when high doses are administered for more than 5 days.[6] As a result, fenbendazole is used more commonly in small animals.

Nitroimidazoles

Protozoa reduce nitroimidazoles to nitro anion free radicals, which cause damage to parasite's DNA. Some nitroimidazoles are mutagens and carcinogens, but carcinogenesis has not been demonstrated in dogs and cats with long-term use. Because of this undocumented occurrence in animals or humans, some regulatory authorities have advocated for removal from the carcinogen list.

Metronidazole, ronidazole, and tinidazole have primarily been used to treat enteric protozoal infections. Benznidazole is specifically used to treat infections with *Trypanosoma cruzi*.

Metronidazole

Metronidazole is used to treat giardiasis in dogs and cats, although efficacy may be as low as 50%. It also has activity against amoebic infections. The clinical use and adverse effects of metronidazole are described in Chapter 10. In one study, addition of the probiotic SF68 to metronidazole treatment appeared to have clinical benefit when used to treat dogs with protozoal diarrhea in a shelter.[7] Doses of metronidazole used for treatment of giardiasis have the potential to be associated with neurotoxicity; therefore, fenbendazole is preferred because of greater safety and efficacy. Metronidazole can be combined with fenbendazole for refractory giardiasis.

In addition to neurotoxicity that is associated with high doses, metronidazole also has a very unpleasant taste, which is difficult to administer to dogs and cats. Subsequently some pharmacies will prepare a more palatable ester formulation (metronidazole benzoate) for oral administration. It is converted to the active form in the intestine, but on a weight-by-weight basis is only 62% metronidazole; therefore, dose adjustments must be performed when prescribing.

Tinidazole

Tinidazole is a 5-nitroimidazole that has amoebicidal, giardicidal, trichomonicidal, and anaerobic bactericidal activity. It is sometimes used as a single-dose treatment for giardiasis in human patients. The efficacy of tinidazole for treatment for giardiasis in dogs and cats has not been evaluated, and the half-life in dogs (4.4 hours) and cats (8.4 hours) is shorter than that in human patients (>12 hours).[8,9] Tinidazole is very well absorbed in dogs and cats, with a bioavailability of 100%. Adverse effects are similar to those of metronidazole. Like metronidazole, tinidazole has a bitter taste. It has not been effective for treatment of feline trichomoniasis.

Ronidazole

Ronidazole is the drug of choice for treatment of *Tritrichomonas foetus* infections, which are less responsive to metronidazole and

tinidazole.[10–12] Ronidazole has not been approved by the US FDA for administration to dogs, cats or humans, and has been banned for use in food animals because of the potential for adverse effects in humans. Therefore, veterinarians have been cautioned about the use of the drug, and advised to prescribe it only when *T. foetus* infection has been confirmed.[13] Resistance to ronidazole has been identified in some isolates of *T. foetus* and is associated with treatment failure in infected cats.[14] Resistance is thought to result from increased oxygen-scavenging capacity by the parasite, whereby oxygen competes effectively with ronidazole and other nitroimidazoles for ferredoxin-bound electrons.

Ronidazole is absorbed rapidly and completely after oral administration to cats. Some compounded formulations may have decreased efficacy as a result of low ronidazole content or differences in drug release at the site of action (the large bowel). Because of rapid and complete absorption of immediate-release compounded oral forms, toxicity can occur if dosing recommendations are not followed. Decreased appetite, vomiting, and neurologic signs can occur in dogs and cats, especially at doses above 30 mg/kg q12h in cats and at doses as low as 10 mg/kg/day in dogs.[15] Once-daily dosing for 14 days is recommended because of the long half-life of the drug in cats.[13,16] Doses of 20 mg/kg or less may not effectively clear infection with *T. foetus*. Neurologic signs result from γ-aminobutyric acid (GABA) antagonism in the CNS and include ataxia, decreased mentation, agitation, tremors, and hyperesthesia, which occur up to 9 days after the start of treatment and resolve when the drug is discontinued.[15] Adverse effects may worsen for a few days after the drug is discontinued, after which time they slowly subside. A modified-release formulation that is delivered to the colon may have improved efficacy, but this was formulated in guar gum and is not available commercially, or readily prepared by compounding pharmacies.[16] When these capsules were administered to 10 cats at a dose of 30 mg/kg q24h, there were no adverse effects observed. Elimination of infection was achieved in 84% of treated cats, but because these cats were housed with placebo-treated cats, reinfections may have occurred.[17]

Owners should be advised to watch closely for adverse effects of drug therapy and discontinue treatment should signs of toxicity appear. The drug is contraindicated in pregnant or lactating queens.

Nitazoxanide

Nitazoxanide is a nitrothiazolyl-salicylamide derivative that has activity against *Giardia* and *Cryptosporidium* spp., *Sarcocystis neurona,* some anaerobic bacteria, *Helicobacter* spp., and *Campylobacter jejuni*. It inhibits the pyruvate-ferredoxin/flavodoxin oxidoreductase enzyme-dependent electron transfer reaction that is essential for anaerobic metabolism in these organisms. Resistance has been documented in *Giardia* spp.[18]

Reports of nitazoxanide use in dogs and cats have been rare. An equine formulation (Navigator, IDEXX Pharmaceuticals, USA) that was used to treat equine protozoal meningoencephalitis caused by *S. neurona* has been removed from the market due to concerns about adverse effects, primarily fatal enterocolitis. Doses have been extrapolated from those used for human patients. Nitazoxanide treatment of cats co-infected with *Cryptosporidium* spp. and *T. foetus* led to cessation of shedding during treatment, but infection was not eliminated.[19] Vomiting occurred frequently, especially at higher doses (75 mg/kg PO q12h). When used to treat dogs that were naturally infected with *Giardia* spp., nitazoxanide at doses of 75 mg/kg PO q12h and 150 mg/kg PO q12h on days 0 and 14 (7 dogs in each group) resulted in a dramatic reduction in the shedding of cysts when compared with an untreated control group.[20] Vomiting occurred in one dog treated with the high-dose protocol. In humans, nitazoxanide is rapidly absorbed from the gastrointestinal tract and metabolized to the active metabolite tizoxanide, which is highly protein bound. After hepatic glucuronidation, it is excreted in urine and bile.

ANTIBACTERIAL DRUGS WITH BROAD-SPECTRUM ANTIPROTOZOAL ACTIVITY

Folic Acid Antagonists

Trimethoprim, pyrimethamine, ormetoprim, and sulfonamides (sulfamethoxazole and sulfadiazine) inhibit parasite replication through folate antagonism. Synergistic combinations of sulfadiazine with trimethoprim or pyrimethamine are primarily used to treat toxoplasmosis, neosporosis, and intestinal coccidiosis (*Cystoisospora* spp. infections) in dogs and cats. A combination of pyrimethamine, trimethoprim-sulfadiazine, and clindamycin has also been used to treat *Hepatozoon americanum* infections.[21] Trimethoprim-sulfonamides are broadly used as antibacterial agents and the mechanisms of action, use, and adverse effects of trimethoprim and sulfonamides are discussed in Chapter 10.

Sulfadimethoxine

One of the most common oral anticoccidial agents administered to dogs and cats (especially animals in breeding facilities) is sulfadimethoxine, commonly known by its brand name Albon (Zoetis, USA). It is available as 125-, 250-, and 500-mg tablets and an oral suspension.

Pyrimethamine

Like trimethoprim, pyrimethamine inhibits dihydrofolate reductase, which is necessary for synthesis of thymidine. However, in contrast to trimethoprim, it has a greater affinity for the protozoal enzyme than the bacterial enzyme. Resistance to pyrimethamine can occur when parasites synthesize dihydrofolate reductase with an altered drug target site. Pyrimethamine is well absorbed after oral administration and penetrates a variety of tissues including the CNS. Hepatic metabolism and some renal excretion occur. Although clearance of pyrimethamine is not affected by renal disease, its use is cautioned in human patients with hepatic or renal insufficiency.

Pyrimethamine is well tolerated. Gastrointestinal signs such as vomiting, diarrhea, and decreased appetite occur in some treated animals. Bone marrow suppression can occur with prolonged treatment at higher doses as a result of folic acid deficiency. In human patients, concurrent administration of folinic acid is recommended when high doses are used for treatment of toxoplasmosis. Folinic acid, but not folic acid supplementation also reverses marrow suppression in dogs treated with pyrimethamine.[22] The CBC should be monitored weekly during treatment, and supplementation should be provided if leukopenia develops and continued treatment is necessary. Stomatitis, ulcerative glossitis, and exfoliative dermatitis have also been described in human patients as a result of folic acid deficiency. Other adverse effects of pyrimethamine-sulfadiazine combinations result from the sulfadiazine component (see Chapter 10).

Unlike trimethoprim-sulfadiazine, there are no approved formulations of pyrimethamine-sulfonamides for dogs and cats. Pyrimethamine is available as a single agent in tablets but should be administered with a sulfonamide for the best efficacy. Human formulation tablets of pyrimethamine have become extremely expensive in recent years. For example, in 2015, the price increased from $13.50 per pill to $750 per pill. Another alternative is a combination of pyrimethamine and sulfadiazine marketed as an oral formulation for horses (ReBalance, PRN Pharmaceutical, USA) to treat equine protozoal myeloencephalitis (EPM) in a formulation of 12.5 mg pyrimethamine and 250 mg sulfadiazine per mL. This product also has been administered to dogs and cats for treatment of some protozoal infections. Although off-label, it is a convenient formulation for small animal veterinarians. This formulation can be administered at a dose of 1 mg/kg pyrimethamine + 20 mg/kg sulfadiazine PO q24h. This is equivalent to 0.33 mL of the equine formulation per 4 kg of body weight for dogs and cats.

Macrolides and Lincosamides

Clindamycin, azithromycin, and clarithromycin are macrolide antibiotics with antiprotozoal activity. The use of these macrolides and lincosamides in dogs and cats as antibacterial agents and their adverse effects are discussed in Chapter 10. Clindamycin is the most widely used antiprotozoal for treatment of toxoplasmosis and neosporosis in dogs and cats, and has also been used in combination with diminazene aceturate and imidocarb dipropionate to treat canine babesiosis.[23] Although clindamycin inhibits shedding of *Toxoplasma gondii* oocysts by cats,[24] clinical efficacy of clindamycin for treatment of toxoplasmosis in dogs and cats has been questioned by experts and in published studies. An extended-release formulation of clindamycin achieved therapeutic serum concentrations for 60 hours in contrast to existing formulations, which achieved therapeutic concentrations for 12 hours.[25]

Trimethoprim-sulfonamides (discussed above) are a suitable alternative, or if clindamycin is used, pyrimethamine may be used in combination. In human patients, pyrimethamine and clindamycin are used as a substitute for pyrimethamine and sulfadiazine for treatment of toxoplasmosis in sulfadiazine-sensitive individuals. Azithromycin is used in combination with atovaquone for treatment of babesiosis and cytauxzoonosis.

Paromomycin (Aminosidine)

Paromomycin, also known as aminosidine, is the only aminoglycoside antibiotic that has efficacy against protozoa. It is poorly absorbed from the gastrointestinal tract and so has been used to treat enteric protozoal infections, particularly cryptosporidiosis. It is ineffective for treatment of tritrichomoniasis in cats.[12] Furthermore, when used to treat intestinal protozoal infections in cats, paromomycin has been absorbed systemically because of intestinal mucosal compromise, with resultant acute renal failure, deafness, and cataract formation.[26] As a result, its use has been limited. In human patients, paromomycin has been used topically to treat cutaneous leishmaniasis and parenterally to treat visceral leishmaniasis.[27] It had efficacy for treatment of nonazotemic leishmaniosis in dogs at 15 mg/kg SC q24h for 21 days, with no evidence of nephrotoxicity, although complete elimination of the parasite was not achieved.[28,29]

Tetracyclines and Ciprofloxacin

Doxycycline has primarily been used for malaria prophylaxis in humans. Ciprofloxacin is thought to inhibit DNA gyrase within a chloroplast organelle (the apicoplast) of apicomplexan parasites (see the triazines, later). It is an alternative to sulfadiazine for treatment of cystoisosporiasis in human patients. Tetracyclines and ciprofloxacin have not been widely used for prevention or treatment of protozoal infections in dogs and cats with the possible exception of doxycycline as part of combination treatment for babesiosis (see Chapter 97). Although ciprofloxacin was the fluoroquinolone of choice in the human studies, it has poor oral absorption in animals, especially in cats, and highly variable oral absorption in dogs. If indeed, ciprofloxacin is effective for some infections, it is anticipated that veterinary-labeled fluoroquinolones (enrofloxacin, marbofloxacin, orbifloxacin) would have similar effectiveness. When administered to animals, a portion of enrofloxacin is converted to ciprofloxacin. Another alternative for dogs is the human-labeled generic levofloxacin, which is available as an inexpensive tablet and has almost 100% bioavailability in dogs.[30]

ANTIPROTOZOAL DRUGS USED FOR SYSTEMIC PROTOZOAL INFECTIONS

Quinolone Derivatives

Atovaquone

Atovaquone is a hydroxynaphthoquinone that inhibits electron transport in protozoa by targeting the cytochrome bc_1 complex (Table 12.2). It has been used in combination with other antiprotozoal drugs as an alternative treatment for malaria, toxoplasmosis, and pneumocystosis in human patients.[18] In veterinary medicine, atovaquone is used in combination with azithromycin for treatment of *Babesia gibsoni*, *Babesia conradae*, *Babesia vulpes* (formerly *Babesia microti*-like or *Theileria annae*) infections and cytauxzoonosis (see Chapters 97 and 98). The drawback of using atovaquone is that it is expensive. Use of a compounded formulation in combination with azithromycin to treat 42 dogs with *B. gibsoni* infection resulted in pathogen clearance in 39 (93%) of dogs, and represents a more economical treatment protocol.[31] Resistance has been reported in *Plasmodium* spp., *T. gondii, Pneumocystis jirovecii, Cytauxzoon felis,* and canine *B. gibsoni* strains as a result of mutations in the cytochrome bc_1 complex.

Atovaquone is highly lipophilic and extensively protein bound. Little is known about atovaquone metabolism in dogs and cats. Its oral bioavailability increases significantly when food is administered concurrently. Atovaquone is available alone or in a formulation with proguanil for treatment and prevention of malaria in human patients. The combination formulation may cause vomiting and diarrhea in dogs, but otherwise atovaquone appears well tolerated by both dogs and cats.[32–34] In human patients, adverse effects have included gastrointestinal signs, headache, fever, and increased liver enzyme activities. Co-administration with metoclopramide, tetracycline, or rifampin significantly decreases plasma drug concentrations in humans and could possibly have similar effects in small animals.

A related drug, buparvaquone, which has been used to treat bovine theileriosis, was combined with azithromycin and used to treat dogs with *B. vulpes* infection. Two 5-mg/kg doses administered intramuscularly (IM) 48 hours apart were better tolerated than atovaquone, with similar outcomes as an atovaquone/azithromycin combination.[35] However, the pharmacokinetics and toxicity of buparvaquone in dogs have not been otherwise studied.

Decoquinate

Decoquinate is a 4-hydroxyquinolone coccidiostat that inhibits electron transport in protozoal mitochondria and interferes with sporozoite development. It likely has a similar mechanism of action to atovaquone, because resistance to atovaquone can result in cross-resistance to decoquinate.[36] Although developed as a feed additive coccidiostat for use in production animals, decoquinate can be used successfully and without adverse effects to prevent relapses in dogs that are chronically infected with *H. americanum*.[21] Decoquinate also appeared to be effective for treatment of *Sarcocystis* spp. myositis in a dog.[37] Its distribution and metabolism in dogs and cats have not been described.

Because there are no commercial formulations for small animals, the food animal feed additive is used. The decoquinate feed additive (27.2 g decoquinate per pound of premix) has been added to moist dog food at a rate of 0.5–1.0 tablespoons per 10 kg twice a day.

Aromatic Diamines

The aromatic diamines include imidocarb dipropionate, diminazene aceturate, pentamidine isethionate, and phenamidine isethionate. These drugs inhibit DNA synthesis in protozoa. In dogs, imidocarb and diminazene have been used most widely, primarily for treatment of *Babesia* spp. and *Hepatozoon canis* infections. In general, the use of imidocarb has been preferred over diminazene because of diminazene's narrow therapeutic index and concern about safety in animals. Pentamidine and phenamidine have also been used in dogs. Pentamidine isethionate is a second-line treatment for leishmaniasis in human patients and is used as an alternative to diminazene for treatment of African trypanosomiasis (see Chapter 100). Treatment of protozoal infections using aromatic diamines may not result in complete parasite elimination.

Imidocarb Dipropionate

Imidocarb dipropionate is primarily used to treat large *Babesia* spp. and *H. canis* infections in dogs. More effective agents have replaced imidocarb for treatment of canine monocytic ehrlichiosis and feline

TABLE 12.2 Suggested Doses of Drugs Primarily Used to Treat Systemic Protozoal Diseases Excluding Leishmaniosis and Trypanosomiasis in Small Animals

Drug	Dose (mg/kg)	Interval (hours)	Species	Route	Duration (days)	Comments
Pyrimethamine	0.5–1	24	D, C	PO	14–28	Primarily neosporosis, toxoplasmosis, and American hepatozoonosis. Use with a sulfonamide. Use caution with hepatic and renal insufficiency. Monitor CBC. Folinic acid supplementation (5 mg/day) may be required.
Pyrimethamine/ sulfadiazine	1 mg/kg pyrimethamine + 20 mg/kg sulfadiazine, in combination	24	D, C	PO	14–28	Available in an equine combination formulation with 250 mg sulfadiazine and 12.5 mg pyrimethamine per mL in a liquid suspension.
Clindamycin	22	12	D, C	PO		Toxoplasmosis, neosporosis, sarcocystosis, and American hepatozoonosis.
Azithromycin	10	24	D, C	PO	10	Babesiosis and cytauxzoonosis. Used with atovaquone.
Atovaquone	13.3–15	8	D,C	PO	10	Babesiosis and cytauxzoonosis with azithromycin. Administer with food.
Buparvaquone	5	Once, repeat in 48 hours	D	IM	N/A	Babesiosis. Pharmacokinetics has not been studied in dogs. Use with azithromycin.
Decoquinate	10–20	12	D	PO	≥365	American hepatozoonosis and sarcocystosis. Powder (6% decoquinate; 60 mg active ingredient per gram) is mixed with food. This equates to 0.5–1 tablespoon/10 kg body weight q12h.
Imidocarb dipropionate	6.6	Once, repeat in 14 days	D, C	Deep IM or SC	N/A	Large *Babesia* spp. infections. Caution with hepatic or renal insufficiency. Avoid use with other cholinesterase inhibitors.
Diminazene aceturate	3–5	Once	D	Deep IM	N/A	Babesiosis and African trypanosomiasis. Narrow therapeutic range.
Ponazuril	20–50	12–24	D	PO	3–28	Toxoplasmosis, neosporosis, cystoisosporiasis. Optimal dose, duration, efficacy, and adverse effects unknown.
Toltrazuril	10–30 5–10 30 15	24 24 Once Once, repeat in 10 days	D C (toxoplasmosis) C (coccidia) C (coccidia)	PO PO PO PO	3 2 N/A 3	Hepatozoonosis, cystoisosporiasis. One dose may be effective for cystoisosporiasis. Optimal dose and duration for hepatozoonosis unknown.

C, cats; *CBC,* complete blood count; *D,* dogs; *IM,* intramuscular; *N/A,* not applicable; *PO,* oral.

cytauxzoonosis, and its efficacy for treatment of *H. canis* infections does not appear to be high.[38]

Imidocarb is injected IM, twice, 2 weeks apart. It is generally well tolerated, except for acute effects shortly after injection. After injection, it can produce transient pain at the site of injection. Acute adverse effects result from its anticholinergic activity and include vomiting, shivering, hypersalivation, lacrimation, diarrhea, agitation, lethargy, pyrexia, and periorbital swelling. These generally resolve within a few hours. It appears to be eliminated in urine and feces.[39] A possible association between imidocarb treatment and acute renal tubular necrosis has been reported in dogs.[40] Massive hepatic necrosis was described after overdosage of dogs with 10 times the recommended dose.[41]

Diminazene Aceturate

Diminazene aceturate is administered parenterally, primarily to dogs, for treatment of babesiosis, trypanosomiasis, and infections with *Rangelia vitalii*, a protozoal pathogen of dogs from Brazil (see Chapter 105).[42] Diminazene aceturate is not readily available in the United States. Resistance to diminazene has been described in *B. gibsoni*.[43]

Although formulations for small animals are not available, a powdered commercial drug formulation (Veriben, Ceva Santé Animale, France) has been reconstituted with sterile water to a concentration of 7 mg/mL and administered IM at a dose of 3 mg/kg diminazene diaceturate for a pharmacokinetic study in cats.[44] The dose was well tolerated, but diminazene was eliminated quickly, with a half-life of only 1.7 hours and a peak concentration of only 0.5 μg/mL. The drug concentrations produced at this dose may not be consistently effective. Development of clinically effective doses from these data requires further studies. Diminazene was administered to seven cats experimentally infected with *Trypanosoma evansi* at a dose of 3.5 mg/kg IM on 5 consecutive days.[45] The treatment was 85.7% efficacious for elimination of the parasite, and no adverse effects were observed. The medication may be administered as a single treatment, or the dose can be repeated 72 to 96 hours after drug administration.

Although no adverse effects were observed in the study cited above, the doses of diminazene that are high enough to be consistently effective may produce concentrations that are toxic; therefore, caution is advised if it is used in clinical patients. Adverse effects include tachycardia and CNS signs such as ataxia, nystagmus, and opisthotonos. Death from diminazene toxicosis in association with neurologic signs and hemorrhagic necrosis within the CNS at necropsy has been described in dogs treated with consecutive daily doses.[46] In some protocols for *B. gibsoni* infections, diminazene administration has been followed a day later by treatment with imidocarb.

Triazine Antiprotozoals (Toltrazuril and Ponazuril)

Toltrazuril and its major metabolite ponazuril (toltrazuril sulfone, Marquis, Boehringer Ingelheim, USA) are triazine-based antiprotozoal drugs that have specific activity against apicomplexan coccidial infections. Toltrazuril is not available within the United States, but ponazuril and diclazuril are available in formulations used in other animals: ponazuril oral paste for horses, diclazuril oral pellets for horses, and diclazuril feed additive for poultry. In horses, these products are approved to treat EPM. Ponazuril and toltrazuril appear to act on a plastid-like chloroplast organelle (the *apicoplast*) in apicomplexan protozoa, which may have originally been acquired from a green alga.[47] This organelle contains a small circular genome and operates key biochemical pathways. Although their mechanism of action is unclear, triazines may inhibit metabolic enzymes or decrease pyrimidine synthesis within the apicoplast. The result of the action of these agents is to kill protozoa; therefore, their action is "cidal" rather than "static" against susceptible organisms.[48] Ponazuril and toltrazuril have been used in animals to treat cystoisosporiasis, toxoplasmosis, neosporosis, and EPM.[48] Triazine resistance has been described in coccidia from production animals.[49]

In dogs and cats, toltrazuril has been used to treat cystoisosporiasis and hepatozoonosis, although infection may persist in some animals.[21,50–55] In Europe, it is available in combination with the anthelmintic emodepside (Procox Oral Suspension for Dogs, Elanco Animal Health, Germany) for treatment of cystoisosporiasis and roundworm infections in puppies over 2 weeks of age. The suspension contains 18 mg/mL of toltrazuril, and a single 9-mg/kg dose is recommended. Toltrazuril appeared to be as effective as trimethoprim-sulfadiazine-clindamycin-pyrimethamine for treatment of canine American hepatozoonosis.[21] One dog with *H. canis* infection recovered after treatment with toltrazuril and trimethoprim-sulfamethoxazole,[55] but a toltrazuril and imidocarb combination did not offer benefit over treatment of *H. canis* infection with imidocarb alone.[56] A combination of toltrazuril/emodepside (15 mg/kg PO q24h for 6 days) and clindamycin (15 mg/kg PO q24h for 21 days) failed to eliminate infection in naturally infected dogs. When ponazuril paste was used to treat *Cystoisospora* spp. infections in dogs and cats in a shelter environment, a dose of 50 mg/kg PO q24h for 3 days appeared more effective in reducing shedding than a single dose of 50 mg/kg.[57] Doses of ponazuril used in other anecdotal reports of treatment of dogs and cats with cystoisosporiasis have ranged from 20 to 50 mg/kg for 2 to 5 days. In one dog, ocular toxoplasmosis that was refractory to clindamycin resolved after treatment with ponazuril for 28 days.[58]

The pharmacokinetics of the triazines in dogs has not been reported. In horses, ponazuril crosses the blood-brain barrier to some extent and achieves concentrations in CSF sufficient to inhibit protozoa. It has a long half-life in horses (>4 days) and in cattle (2 to 3 days). Because of its specific activity against apicomplexan parasites, significant toxicity in mammalian species has not been reported.

ANTILEISHMANIAL ANTIPROTOZOAL DRUGS

Antifungal Agents

Amphotericin B

Amphotericin B is a treatment of choice for human visceral leishmaniasis. The proposed mechanism of action is through binding to ergosterol in the protozoal membrane, which blocks the ability of *Leishmania* spp. to bind to and enter macrophages.[59] Lipid amphotericin B formulations have been used to treat leishmaniosis in dogs, although organism persistence and relapse have been reported in some dogs after twice-weekly treatment for up to 10 administrations (0.8 to 3.3 mg/kg IV).[60,61] In an effort to reduce selection for resistant parasites, the WHO recommends against the use of amphotericin B for treatment of canine leishmaniosis.[62] A full discussion of amphotericin B is provided in Chapter 11.

Azole Antifungals

Azole antifungals such as fluconazole have been used to treat cutaneous leishmaniasis in human patients. More effective antiprotozoal drugs are substituted for leishmaniosis. Posaconazole and ravuconazole also have activity against *T. cruzi* (see Chapter 100), and fluconazole has some activity against *Toxoplasma* spp. (see Chapter 93).

Antimony Compounds

Sodium stibogluconate (e.g., Pentostam, GlaxoSmithKline, UK) and *N*-methylglucamine antimoniate (meglumine antimoniate, Glucantime, Sanofi, France) are derived from the heavy metal antimony (Sb). They are called pentavalent antimony compounds (symbol Sb^{v}) because they contain Sb atoms that have five electrons in their outer shell. Pentavalent antimonials have been recommended as the first choice for treatment of *Leishmania* infections in humans and in dogs.[63] Their mechanism of action is still not completely clear, but it is thought that pentavalent antimony undergoes reduction to the more toxic trivalent version, possibly within macrophage phagolysosomes or within the parasite itself.[64] The trivalent compound inhibits protozoal enzymes and damages protozoal DNA.[65] Resistance to antimonials is an emerging problem in human *Leishmania* spp. isolates. This has led to the use of higher drug dosages, with an associated rise in the rate of drug toxicity. The availability of antimonial drugs is limited in the United States.

Both sodium stibogluconate and meglumine antimoniate are administered SC (Table 12.3). The treatment of choice for canine leishmaniosis

TABLE 12.3 Suggested Doses of Drugs Primarily Used to Treat Leishmaniosis or Chagas' Disease in Dogs

Drug	Dose (mg/kg)	Interval (hours)	Route	Duration (days)	Comments
Amiodarone	7.5	24	PO	—	Use with itraconazole, 5–10 mg/kg PO q24h
Meglumine antimoniate	75–100	24	SC	30–60	Leishmaniosis. Use with allopurinol. Available in ampules. Dose based on concentration of meglumine antimoniate. Caution in dogs with renal insufficiency.
Allopurinol	10	12	PO	At least 6–12 months	Leishmaniosis. Use with meglumine or miltefosine. Monitor CBC and serum chemistry in dogs with hepatic and renal insufficiency.
Miltefosine	2	24	PO	28	Leishmaniosis. Use with allopurinol.
Benznidazole	5–10	24	PO	60	Chagas' disease

CBC, complete blood count; *PO,* oral; *SC,* subcutaneous.

is a combination of meglumine antimoniate and allopurinol.[62,63,66] Complete clearance of the infection may not always occur.[67] After subcutaneous administration, more than 80% of meglumine antimoniate is eliminated by the kidneys. Pain at the site of injection is the most common adverse effect, and cutaneous abscesses or cellulitis may also occur.[68] Systemic adverse effects such as lethargy, vomiting, diarrhea, inappetence, and increased serum liver enzyme activities may be more likely to occur in the presence of renal failure, which can be a complication of leishmaniosis. Of concern, the administration of meglumine antimoniate to healthy dogs has led to renal tubular necrosis, in the absence of azotemia.[69] In human patients, other adverse effects include generalized arthralgias, abdominal pain, mild cytopenias, cardiotoxicity, and chemical pancreatitis.[27] Novel formulations of antimony compounds are under development for treatment of leishmaniosis, including lipid formulations and preparations that could be administered orally.[64]

Allopurinol

Allopurinol is a purine analogue. In parasites, allopurinol is metabolized to derivatives that are incorporated into RNA, which leads to impaired protein synthesis. Resistance can occur and appears to result from reduced activity of purine transporters and a reduced ability to accumulate purine.[70] In one study, resistance was associated with a decrease in copy number of the gene that encodes S-adenosylmethionine synthetase.[71] Although it has been used alone for treatment of canine leishmaniosis, allopurinol is most commonly used in combination with meglumine or miltefosine.

Allopurinol is rapidly absorbed from the gastrointestinal tracts of dogs. Peak drug concentrations occur 1 to 3 hours after administration.[72] Allopurinol is not bound to plasma proteins. Allopurinol rarely causes adverse effects in dogs. It inhibits mammalian xanthine oxidase, which results in decreased uric acid production from xanthine. As a result, long-term use can result in xanthine urolithiasis.[73] In human patients, allopurinol most commonly causes skin rashes. Gastrointestinal signs can also occur. Rarely administration of allopurinol to humans results in aplastic anemia or a hypersensitivity syndrome characterized by toxic epidermal necrolysis with hepatic and renal failure.[74,75] Serious adverse reactions are more likely to occur in human patients with renal insufficiency. At usual doses, allopurinol treatment leads to improvement in kidney lesions in dogs with leishmaniosis that have renal insufficiency.[76] Nevertheless, careful monitoring for adverse effects is indicated in these dogs (see Table 12.3). Serious drug interactions can occur when allopurinol is administered with azathioprine.

Miltefosine

Miltefosine is an effective alternative to pentavalent antimonials for treatment of leishmaniosis, although long-term outcomes were better in one study in dogs treated with meglumine.[66,77] It is a phospholipid analogue that activates cellular proteases in *Leishmania* spp., which results in apoptosis. It also appears to activate a Th1 cellular immune response, with production of IFN-γ and promotion of intracellular destruction of parasites by activated macrophages. Miltefosine is the first highly active oral drug for treatment of leishmaniosis. Nevertheless, despite clinical improvement in treated dogs, elimination of the parasite does not always occur.[66,78,79] Resistance to miltefosine can result from increased P-glycoprotein–mediated drug efflux and decreased drug uptake. Because miltefosine has a long half-life and must be administered for 28 days, selection for resistant isolates has been a concern, although resistant isolates from dogs have not yet been identified.

Over 90% of miltefosine is absorbed from the gastrointestinal tract of dogs after oral administration.[69] The half-life of miltefosine in the dog is approximately 6 days, so it accumulates until a steady-state plasma concentration is reached after 3 to 4 weeks of treatment. Clearance is believed to result from slow hepatic metabolism and excretion in bile. In dogs, adverse effects of treatment are mild and transient and consist of occasional vomiting and diarrhea.[80] In contrast to meglumine antimoniate, miltefosine does not appear to contribute to renal pathology in dogs.[66,69,81] It is teratogenic, so should be avoided in pregnancy.[82]

ANTIPROTOZOAL DRUGS FOR TREATMENT OF CHAGAS' DISEASE

Amiodarone

The combination of the antiarrhythmic amiodarone and an azole (itraconazole or posaconazole) has synergistic antiprotozoal activity against *T. cruzi*, and amiodarone has shown promise as an effective treatment for arrhythmias associated with chronic Chagas' disease in humans.[83] Amiodarone is a cationic lipophilic benzofuran. It is a class III antiarrhythmic that prolongs the action potential duration and the refractory period by inhibiting the repolarizing potassium channel. It also inhibits voltage-gated calcium channels. It is highly protein bound and lipophilic, with a high volume of distribution. Its antiprotozoal effects are the result of inhibition of calcium homeostasis, blockade of the action of the protozoal protease known as cruzipain, and inhibition of sterol production. It also has activity against *Leishmania* spp. and is an emerging treatment for human leishmaniasis, together with a related analogue, dronedarone. When used in a prospective, randomized trial in combination with itraconazole (10 mg/kg PO q24h) to treat dogs with naturally occurring Chagas' disease (7.5 mg/kg PO q24h), there was a significant reduction in mortality, clinical signs (such as lethargy and anorexia), electrocardiogram abnormalities, parasitemia, and overall survival time.[84] Adverse effects were primarily gastrointestinal and were associated with high plasma concentrations of itraconazole. Reduction of the itraconazole dose to attain plasma concentrations of 1 to 2 μg/mL was associated with resolution of adverse effects. Overall, the investigators reported that the combination was well tolerated.

Benznidazole

Benznidazole is a nitroimidazole that is used to treat acute Chagas' disease (see Chapter 100). It has been used alone and in combination with itraconazole, which may increase efficacy.[85] When used to treat chronic infections, although parasitemia is initially suppressed and systolic dysfunction controlled, the development of cardiomyopathy appears to be unaffected.[86] Benznidazole is activated by a parasite-specific nitroreductase to produce toxic metabolites.[87] Resistance can result from reduction in the level of activity of the nitroreductase and confers cross-resistance to nifurtimox.

Benznidazole is lipophilic, is readily absorbed from the gastrointestinal tract, and undergoes hepatic metabolism. In the United States, it is available from the CDC. The main adverse effect of treatment in dogs is vomiting. In human patients, it can cause skin rashes, peripheral neuropathy, and less commonly bone marrow suppression. It also has the potential to be carcinogenic.

Nifurtimox

Nifurtimox is a nitrofuran derivative used to treat Chagas' disease in humans. It has limited efficacy, with 70% parasitologic cure for acute disease and at best 20% for chronic disease. As with benznidazole, metabolic reduction of the nitro group by a trypanosome-specific nitroreductase leads to the formation of toxic metabolites. In human patients, it is well absorbed orally and undergoes hepatic metabolism. Gastrointestinal and neurologic signs are the primary adverse effects of nifurtimox, and like benznidazole, it has carcinogenic properties.[88] Severe adverse effects have precluded the use of nifurtimox in dogs.[89]

Antiparasitic Drugs

Lindsay A. Starkey, Byron L. Blagburn

KEY POINTS

- When considering choice of antiparasitic drugs, consultation of product labels, package inserts, regulatory documents, and current literature will provide the most up-to-date information regarding product availability and indications.
- Use of an approved product for the relevant host and parasite should be considered as the first-line treatment if available.
- Treatment for some parasitic infections, especially those caused by trematode and protozoan parasites, often requires the extra-label use of an approved drug or the use of a drug not approved for use in dogs and/or cats.
- Appropriate drug selection is only one component of treating parasitism. Use of a multimodal approach with multiple therapeutics that have unique mechanisms of action or alterations of the environment or host behavior is often necessary to appropriately break the life cycle and prevent a reinfection or reinfestation.
- Treatment failure is often due to one or many of a myriad of factors including but not limited to: inadequate dosage, improper storage, abbreviated duration, failure to control reinfection/reinfestation, lack of understanding of the life cycle, poor client compliance/adherence, or parasite resistance. Although resistance has been documented in the United States for a few parasites of dogs and/or cats, treatment failure secondary to any of the other listed reasons is still far more common.

INTRODUCTION

The antiparasitic market continues to grow with the advent of new pharmaceuticals and the combination of existing drugs; however, there still does not exist the single, perfect product to control all things parasite-related. Each patient is an individual, as are clients, therefore, several aspects must be considered in order to select the appropriate product for treatment of parasites or the prevention of common or potentially serious parasites. These include:

- Route of administration of the drug—some clients would prefer to administer a medication that resembles a treat rather than apply a topical product. Others may prefer something that remains on the outside of the animal rather than being administered orally. Topical treatment may be particularly important for animals undergoing a food trial or with specific food allergies. Some clients may like or dislike collars based on previous experience. Additionally, injectable options are available for some parasites and might be preferred by the clinician to control compliance.
- Duration of drug activity—some clients may opt for a longer-acting drug than a shorter-acting drug to reduce stressful interactions or to boost adherence.
- Host species—questions to be considered include: is the drug something that is metabolized differently by dogs versus cats? If using a drug not approved for use in dogs and cats, what are the potential adverse effects to be aware of? Have any adverse effects been reported that are breed-specific?
- Host life stage—is the animal young, geriatric, pregnant, lactating, to be used for breeding, or immunocompromised?
- Concurrent medications—some drugs potentiate the activity of others, while others are antagonistic and might reduce the efficacy of one another.
- Resistance profile—has resistance been reported for this parasite/drug combination; if so, how should efficacy be monitored, and what are other treatment options?
- Target parasites in the region—different parasites vary in their distribution and relative prevalence within the United States, so it is important to discuss local risks as well as the potential for travel-acquired parasites with the client.
- Transmission potential—are the parasites in question potential health hazards to other animals of the same species, different species, or even humans?

In this chapter, common antiparasitic drugs available for dogs and cats within the United States are organized in sections by the type of parasites targeted: helminths (nematodes, cestodes, and trematodes), insects, and acari. Extra-label uses of certain products are included provided there is supportive documentation in the literature. The product insert or label should be consulted, and veterinarians should strive to stay up-to-date on primary literature and regulatory changes regarding these commonly used products.

ANTHELMINTICS (TABLES 13.1–13.3)

Many products labeled for use in dogs and cats provide a broad spectrum of activity against common nematode and cestode parasites of pets, either as a treatment or preventive. However, there are a number of nematode parasites, a few cestodes, and most trematodes for which there is no label-approved treatment. Many anthelmintics can be safely used extra-label in dogs and cats. However, due to safety concerns, and because other treatment options are readily available, standard or elevated doses of large animal anthelmintics should not be used in dogs or cats. What follows is a summary of drug classes available in the United States with their labeled indications. Doses are also provided in Tables 13.1–13.3. Drugs are listed alphabetically by drug class (or drug if it is the only utilized drug within a drug class). Discussion is limited to the anthelmintic properties of these drugs; antiarthropod activity is addressed later in this chapter and antiprotozoal activity is discussed in Chapter 12.

TABLE 13.1 Recommended Treatments for Gastrointestinal and Systemic Nematode Parasites of Dogs and Cats[1–14]

Nemadote Parasites	Drugs	Species	Minimum Target Dose	Route	Frequency, Duration
Gastrointestinal Nematodes					
Ancylostoma spp.	Emodepside (+ praziquantel)	C	3 mg/kg	Transdermal	Once
	Fenbendazole	D, C[b]	50 mg/kg	PO	q24h for 3 days
	Febantel (+ pyrantel/praziquantel)	D	10–15 mg/kg	PO	Once
	Ivermectin	C	24 μg/kg	PO	Monthly
	Milbemycin oxime	D	0.5 mg/kg	PO	Monthly
		C	2 mg/kg	PO	Monthly
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly
		C	1 mg/kg	Transdermal	Monthly
		D	0.17 mg/kg	SC	q6 months
		D	0.5 mg/kg	SC	q12 months
	Moxidectin (+ fluralaner)	C	2 mg/kg	Transdermal	q2 months
	Pyrantel pamoate	D, C	5 mg/kg	PO	Once
	Selamectin	C	6 mg/kg	Transdermal	Monthly
Baylisascaris procyonis	Fenbendazole[a]	D	50 mg/kg	PO	q24h for 3 days
	Febantel (+ pyrantel/praziquantel)[a]	D	10–15 mg/kg	PO	Once
	Milbemycin oxime[a]	D	0.5 mg/kg	PO	Monthly
	Moxidectin[a]	D	2.5 mg/kg	Transdermal	Monthly
	Piperazine[a]	D, C	55–110 mg/kg	PO	Once, repeat 10 days later
	Pyrantel pamoate[a]	D	5 mg/kg	PO	Once
Physaloptera spp.	Pyrantel pamoate[a]	D, C	10–15 mg/kg	PO	q 2 weeks, for 3+ treatments
Spirocerca lupi	Doramectin[a]	D	400 μg/kg	PO or SC	q 1–2 weeks for 12 weeks
	Ivermectin[a]	D	400 μg/kg	PO or SC	q 1–2 weeks for 12 weeks
	Milbemycin oxime[a]	D	0.5 mg/kg	PO	Days 0, 7, 28, then monthly
Strongyloides spp.	Fenbendazole[a]	D, C[b]	50 mg/kg	PO	q24h for 5 days, repeat in 4 weeks
	Ivermectin[a]	D, C	200 μg/kg	SC	once and repeat in 2 weeks
	Ivermectin[a]	D, C	200–800 μg/kg	PO	q24h, twice
Toxocara spp.	Emodepside (+ praziquantel)	C	3 mg/kg	Transdermal	Once
	Fenbendazole	D, C[b]	50 mg/kg	PO	q24h for 3 days
	Febantel (+ pyrantel/praziquantel)	D	10–15 mg/kg	PO	Once
	Milbemycin oxime	D	0.5 mg/kg	PO	Monthly
		C	2 mg/kg	PO	Monthly
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly
		C	1 mg/kg	Transdermal	Monthly
	Moxidectin (+ fluralaner)	C	2 mg/kg	Transdermal	q2 months
	Piperazine	D, C	55–110 mg/kg	PO	Once, repeat 10 days later
	Pyrantel pamoate	D, C	5 mg/kg	PO	Once
	Selamectin	C	6 mg/kg	Transdermal	Monthly
Toxascaris leonina	Fenbendazole	D, C[b]	50 mg/kg	PO	q24h for 3 days
	Milbemycin oxime	D	0.5 mg/kg	PO	Monthly
		C	2 mg/kg	PO	Monthly
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly
	Piperazine	D, C	55–110 mg/kg	PO	Once, repeat 10 days later
Trichuris spp.	Fenbendazole	D	50 mg/kg	PO	q24h for 3 days
	Febantel (+ pyrantel/praziquantel)	D	10–15 mg/kg	PO	Once
	Milbemycin oxime	D	0.5 mg/kg	PO	Monthly
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly

TABLE 13.1 Recommended Treatments for Gastrointestinal and Systemic Nematode Parasites of Dogs and Cats[1–14]—cont'd

Nemadote Parasites	Drugs	Species	Minimum Target Dose	Route	Frequency, Duration
Uncinaria stenocephala	Fenbendazole	D, C[b]	50 mg/kg	PO	q24h for 3 days
	Febantel (+ pyrantel/praziquantel)	D	10–15 mg/kg	PO	Once
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly
		D	0.17 mg/kg	SC	q6 months
		D	0.5 mg/kg	SC	q12 months
	Pyrantel pamoate	D, C	5 mg/kg	PO	Once
Systemic Nematodes					
Aelurostrongylus abstrusus	Emodepside (+ praziquantel)[a]	C	3 mg/kg	Transdermal	Once
	Fenbendazole[a]	C[b]	20–50 mg/kg	PO	q24h for 5–15 days
	Ivermectin[a]	C	400 µg/kg	SC	Once and again in 2 weeks
	Moxidectin (+ imidacloprid)[a]	C	1 mg/kg	Transdermal	Monthly
	Selamectin[a]	C	6 mg/kg	Transdermal	Monthly
Crenosoma vulpis	Fenbendazole[a]	D	25–50 mg/kg	PO	q24h for 3–14 days
	Febantel (+ pyrantel/praziquantel)[a]	D	10–15 mg/kg	PO	q24h for 7 days
	Milbemycin oxime[a]	D	0.5 mg/kg	PO	Once
Dioctophyme renale	Surgical removal	D			
Dirofilaria immitis (preventative)	Eprinomectin (+ praziquantel)	C	0.5 mg/kg	Transdermal	Monthly
	Ivermectin	D	6 µg/kg	PO	Monthly
		C	24 µg/kg	PO	Monthly
	Milbemycin oxime	D	0.5 mg/kg	PO	Monthly
		C	2 mg/kg	PO	Monthly
	Moxidectin	D	2.5 mg/kg	Transdermal	Monthly
		C	1 mg/kg	Transdermal	Monthly
		D	0.17 mg/kg	SC	q6 months
		D	24 µg/kg	PO	Monthly
		D	0.5 mg/kg	SC	q12 months
	Selamectin	D, C	6 mg/kg	Transdermal	Monthly
Dirofilaria immitis (adulticide)	Melarsomine dihydrochloride	D	2.5 mg/kg	IM	3 injections total: once and then 2 injections 24 hours apart 1 month later
	Doxycycline[a]	D	10 mg/kg	PO	q12h for 4 weeks
	Minocycline[a]	D	5–10 mg/kg	PO	q12h for 4 weeks
Dirofilaria immitis (microfilaricidal)	Ivermectin[a]	D	6 µg/kg	PO	Monthly or more frequently
		D	50 µg/kg	PO	Once
	Levamisole[a]	D	10 mg/kg	PO	q12h for 14 days
	Milbemycin oxime[a]	D	0.5 mg/kg	PO	Monthly
	Moxidectin[c]	D	2.5 mg/kg	Transdermal	Monthly
		D	0.17 mg/kg	SC	q6 months
		D	0.5 mg/kg	SC	q12 months
		D	0.25 mg/kg	PO	Once
Eucoleus spp.	Fenbendazole[a]	D	50 mg/kg	PO	q24h for 14 days
	Milbemycin oxime[a]	D	2 mg/kg	PO	Once
	Moxidectin[a]	D	2.5 mg/kg	Transdermal	Monthly
Filaroides spp.	Fenbendazole[a]	D	50 mg/kg	PO	q24h for 7–21 days
Pearsonema spp.	Fenbendazole[a]	D,C[b]	50 mg/kg	PO	q24h; several doses may be required

[a]Use for these parasites or parasite stages is extra-label.
[b]Use in this host is extra-label.
[c]Only the transdermal formulation is approved for this use, the other 3 moxidectin formulations are extra-label.
NB: Always check package inserts for specific labeled indications and safety information. In some countries, use may be extra-label for some parasites/parasite stages or for some hosts, even if identified as on-label here.
C, cat; *D*, dog; *IM*, intramuscular injection; *PO*, oral; *SC*, subcutaneous injection.

TABLE 13.2 Available Heartworm Prevention Products for Dogs and Cats in the United States[1]

Macrocyclic Lactone Heartworm Preventives	Additional Actives	Species	Route/Duration
Eprinomectin	+ praziquantel	C	Transdermal, monthly[2]
Ivermectin	+ pyrantel	D	PO, monthly[2]
	+ pyrantel/praziquantel	D	PO, monthly
		D, C	PO, monthly
Milbemycin oxime	+ lufenuron	D	PO, monthly[2]
	+ lufenuron/praziquantel	D	PO, monthly
	+ praziquantel	D	PO, monthly
	+ spinosad	D	PO, monthly
		D, C	PO, monthly
Moxidectin	+ imidacloprid	D, C	Transdermal, monthly[2]
	+ pyrantel/sarolaner	D	PO, monthly
		D	Transdermal, monthly
		D	SC, q6 or q12 months
	+ fluralaner	C	Transdermal q2 months
Selamectin	+ sarolaner	C	Transdermal, monthly[2]
		D, C	Transdermal, monthly

NB: Always check package inserts for specific labeled indications and safety information.
C, cat; *D,* dog; *PO,* oral; *SC,* subcutaneous injection.

Benzimidazoles

Benzimidazoles have broad-spectrum label and extra-label indications. They bind to tubulin molecules within parasites, inhibiting microtubule formation and disrupting cell division. They may also block mitochondrial function by inhibiting fumarate reductase. Metabolism occurs within the liver if it occurs at all, elimination is via the bile.[15]

Fenbendazole

Fenbendazole is approved for use in dogs and is commonly used extra-label in cats. It is available as granules for dogs, and several suspension formulations are available for large animals. Bioavailability is increased when administered with food. Reported adverse effects include anorexia, vomiting, diarrhea, lethargy, and ataxia.[1,15]

Labeled indications for fenbendazole include the treatment of roundworms (*Toxocara canis, Toxascaris leonina*), hookworms (*Ancylostoma caninum, Uncinaria stenocephala*), whipworm (*Trichuris vulpis*), and tapeworm (*Taenia pisiformis*) in dogs when administered at the minimum target dose of 50 mg/kg PO q24h for 3 consecutive days.[1]

When fenbendazole is used in an extra-label manner, efficacy has been demonstrated against the nematodes *Aelurostrongylus abstrusus*, *Ancylostoma tubaeforme*, *Baylisascaris procyonis*, *Crenosoma vulpis*, *Eucoleus* spp., *Filaroides* spp., *Pearsonema* spp., *Strongyloides* spp., *T. leonina*, *Toxocara cati*, and *U. stenocephala* (see Table 13.1). For cestodes, efficacy has been demonstrated for *Mesocestoides* spp. tetrathyridial infection and other *Taenia* spp.; for trematodes, fenbendazole has efficacy against *Heterobilharzia americana, Nanophyetus salmincola*, and *Paragonimus kellicotti*[16–21] (see Table 13.3).

Fenbendazole has a wide margin of safety and is safe to use in pregnant and lactating animals, even for extended durations of time.[15] It is commonly used to mitigate the transmission of hookworm and roundworm infections in dogs from the pregnant bitch to puppies when dosed daily at a minimum target dose of 50 mg/kg, PO q24h, from day 40 of gestation through day 14 of lactation.[22]

Febantel

Febantel is a prodrug which is metabolized to both fenbendazole and oxfendazole within the host. It is not intended for use in pregnant animals, and use in cats is extra-label. Adverse effects include vomiting, diarrhea, transient salivation, and anorexia. Febantel is available as a tablet in combination with pyrantel pamoate and praziquantel.[1,15]

Labeled indications for febantel (in combination with pyrantel pamoate and praziquantel) include the treatment of roundworms (*T. canis, T. leonina*), hookworms (*A. caninum, U. stenocephala*), whipworms (*T. vulpis*), and tapeworms (*Dipylidium caninum, T. pisiformis,* and *Echinococcus* spp.) in dogs when administered at a minimum target dose of 10–15 mg/kg PO once.[1] This product has also been used extra-label for the treatment of *C. vulpis* infections (see Table 13.1).[2]

There is increasing evidence that the canine hookworm, *A. caninum* may be developing resistance to all approved canine anthelmintic classes (benzimidazoles, macrocyclic lactones, and pyrantel pamoate).[23,24] Research is currently focused on resistance biomarkers as well as development of an appropriate alternative treatment strategy. It is important to rule out opportunities for reinfection as a result of "larval leak", whereby parasite stages are released from the musculature or from a fecal-contaminated environment that contains infective hookworm larvae. Should ova be present on fecal flotation approximately 10 to 14 days following anthelmintic administration, adult parasites may not have died from anthelmintic treatment, which may be an indicator of a resistant population. Should ova be absent, the adult population was likely removed, therefore, resistance is unlikely.[23,24]

Emodepside

Emodepside is a cyclic depsipeptide. Cyclic depsipeptides bind to presynaptic latrophilin-like receptors in the pharynx and body wall muscle of nematodes resulting in flaccid paralysis and subsequent worm death.[1] Emodepside is only approved for use in cats in the United States as a transdermal (topical) product in combination with praziquantel.[1] Adverse effects include licking, excessive grooming, hypersalivation, lethargy, agitation, vomiting, diarrhea, eye irritation, respiratory irritation, tremors, ataxia, and erythema or alopecia at the application site. It also may interfere

TABLE 13.3 Recommended Treatments for Gastrointestinal and Systemic Platyhelminth Parasites of Dogs and Cats in the United States[2,16–21,25–27]

Platyhelminth Parasites	Drugs	Species	Minimum Target Dose (mg/kg)	Route	Frequency, Duration
Intestinal Cestodes					
Dipylidium caninum	Epsiprantel	D	5.5	PO	Once
		C	2.75	PO	Once
	Nitazoxanide[a]	D, C	100	PO	Once
	Praziquantel	D, C	5	PO or SC	Once
	Praziquantel (+ emodepside)	C	12	Transdermal	Once
	Praziquantel (+ eprinomectin)	C	10	Transdermal	Monthly
Dibothriocephalus (Diphyllobothrium) spp.	Praziquantel[a]	D, C	25	PO or SC	q24h for 2 days
Echinococcus spp.	Epsiprantel[a]	D	5.5	PO	Once
		C	2.75	PO	Once
	Praziquantel[a]	D, C	5	PO or SC	Once
	Praziquantel[a] (+ emodepside)	C	12	Transdermal	Once
	Praziquantel (+ eprinomectin)	C	10	Transdermal	Monthly
Mesocestoides spp.	Praziquantel[a]	D, C	5	PO or SC	Once
Spirometra spp.	Praziquantel[a]	D, C	25	PO or SC	q24h for 2 days
Taenia spp.	Epsiprantel	D	5.5	PO	Once
		C	2.75	PO	Once
	Fenbendazole	D, C[b]	50	PO	q24h for 3 days
	Nitazoxanide[a]	D, C	100	PO	Once
	Praziquantel[a]	D, C	5	PO or SC	Once
	Praziquantel (+ emodepside)	C	12	Transdermal	Once
	Praziquantel[a] (+ eprinomectin)	C	10	Transdermal	Monthly
Systemic Cestodes					
Dibothriocephalus (Diphyllobothrium) or *Spirometra* spp. (sparganosis)	Praziquantel[a]	D	25	PO or SC	q24h for 2+ days
Mesocestoides spp. (tetrathyridial infection)	Fenbendazole[a]	D	100	PO	q12h for 28 days
Intestinal Trematodes					
Alaria spp.	Praziquantel[a]	D, C	5	PO or SC	Once
Nanophyetus salmincola	Fenbendazole[a]	D	50	PO	q24h for 10–14 days
	Praziquantel[a]	D, C	20–30	PO or SC	Once
Platynosomum fastosum	Praziquantel[a]	C	20	IM	q24h for 3 days
Systemic Trematodes					
Heterobilharzia americana	Fenbendazole[a]	D	50	PO	q24h for 10+ days
	Praziquantel[a]	D	25	PO	q8h for 2+ days
Paragonimus kellicotti	Fenbendazole[a]	D	50	PO	q24h for 10+ days
	Praziquantel[a]	D	25	PO	q8h for 3 days

[a]Use may be extra-label.
[b]Use in this host is extra-label
NB: Always check package inserts for specific labeled indications and safety information. In some countries, use may be extra-label for some parasites/parasite stages or for some hosts, even if identified as on-label here.
C, cat; *D,* dog; *IM,* intramuscular injection; *PO,* oral; *SC,* subcutaneous injection.

with fetal development, therefore, should be used with caution in pregnant animals.[1,15]

Labeled indications (of the combination product with praziquantel) include the treatment of larval and adult stages of *A. tubaeforme* and *T. cati* when dosed at a minimum target dose of 3 mg/kg applied transdermally (topically) once. The combination with 12 mg/kg of praziquantel extends the labeled indications to include *D. caninum* and *Taenia taeniaeformis*.[2] When used extra-label, emodepside is effective for treatment of *A. abstrusus* infections in cats when dosed at the normal 3 mg/kg dose.[3]

Isoquinolones

Isoquinolones attack the parasite neuromuscular junction and the tegument resulting in increased cell membrane permeability to calcium, loss

TABLE 13.4 Recommended Treatments for Insects of Dogs and Cats in the United States[1,28,29]

Insects	Compounds	Species	Route	Frequency
Fleas	Adulticides:			
	Afoxolaner	D	PO	q 4 weeks
	Deltamethrin	D	CO	q 6 months
	Dinotefuran	D, C	TO, SP	q 4 weeks q 2+ weeks
	Fipronil	D, C	TO, SP	q 4 weeks
	Fluralaner	D, C	PO, TD	q 8 or 12 weeks
	Imidacloprid	D, C	TO, CO	q 4 weeks, q 8 months
	Indoxacarb	D, C	TO	q 4 weeks
	Lotilaner	D, C	PO	q 4 weeks
	Nitenpyram	D, C	PO	daily
	Sarolaner	D, C	PO, TD	q 4 weeks
	Selamectin	D, C	TD	q 4 weeks
	Spinetoram	C	TD	q 4 weeks
	Spinosad	D	PO	q 4 weeks
	Insect Growth Regulators:			
	Pyriproxyfen	D, C	TO	q 4 weeks
	S-methoprene	D, C	TO	q 4 weeks
	Insect Development Inhibitor:			
	Lufenuron	D, C	PO, SC	q 4 weeks, q 6 months
Flies	Deltamethrin	D	CO	q 6 months
	Permethrin	D	TO	q 4 weeks
Lice	Dinotefuran	D, C[b]	TO	q4 weeks
	Fipronil	D, C	TO, SP	q4 weeks
	Imidacloprid	D, C	TO	q4 weeks
	Selamectin[a]	D, C	TD	q4 weeks

[a]Use for these parasites is extra-label.
[b]Use in this host is extra-label.
Only compounds approved for use on animals by the EPA or FDA are included. NB: Always check package inserts for specific labeled indications and safety information. In some countries, use may be extra-label for some parasites/parasite stages or for some hosts, even if identified as on-label here.
C, cat; *CO,* collar; *D,* dog; *PO,* oral; *SC,* subcutaneous injection; *SP,* spray; *TD,* transdermal; *TO,* topical spot-on.

of intracellular calcium, and instantaneous contraction and paralysis. The tegument also experiences vacuolization and destruction. Adverse effects include vomiting, especially when given at high doses.[1,15]

Epsiprantel

Following oral administration, systemic absorption of epsiprantel is minimal. Subsequently, it is eliminated unchanged in the feces. Safety in pregnant animals has not been evaluated, but given the poor systemic absorption, safety in pregnant animals is likely.[15] Epsiprantel is available as a tablet with label indications for the treatment of *D. caninum* and *Taenia* spp. infections in dogs and cats (see Table 13.3).[1,16] Extra-label use against additional adult tapeworm species (such as *Echinococcus* spp. and *Mesocestoides* spp.) would be expected at labeled doses.[16]

Praziquantel

Praziquantel is completely absorbed following oral administration and is rapidly distributed, including across the blood-brain barrier. It is metabolized in the liver and predominantly excreted via the kidney. Praziquantel is safe in pregnant animals.[15] Oral, transdermal (topical), and injectable formulations are approved for treatment of common tapeworms, including *D. caninum, Taenia* spp., and/or *Echinococcus* spp. in dogs and/or cats in the United States.[1]

A variety of other praziquantel combination products are also available (in which the dose of praziquantel ranges 5–12 mg/kg as the minimum target dose). These are labeled for treatment of any or all of the following: *D. caninum, Taenia* spp., and/or *Echinococcus* spp. infections.[1] Praziquantel has been used extra-label in the treatment of the following infections: *Alaria* spp., *H. americana*, *Mesocestoides* spp. adults, *N. salmincola*, *P. kellicotti*, *Platynosomum fastosum*, and pseudophyllidean tapeworms (*Dibothriocephalus (Diphyllobothrium)* and *Spirometra* spp.)[2,16–21,25,26] (see Table 13.3). Resistance of *D. caninum* to standard doses of praziquantel has been reported; however, fleas must be completely under control before suspecting resistance is a problem.[30]

Macrocyclic Lactones

The macrocyclic lactones (avermectins and milbemycins) are widely used for prevention of *Dirofilaria immitis* infections (see Table 13.2), but this class of drugs has a broad spectrum of activity against a wide variety of nematodes (see Table 13.1) and arthropods (Table 13.4). Macrocyclic lactones are the by-products of *Streptomyces* spp. bacteria. They act on gamma-aminobutyric acid (GABA) and glutamate-gated chloride channels, which triggers an influx of chloride ions and the hyperpolarization of neurons, with subsequent paralysis and death. Metabolism does not occur and the drugs are excreted in the feces.[15] Adverse effects include vomiting, diarrhea, lethargy, hypersalivation, ataxia, brady/tachycardia, sinus arrhythmia, seizures, blindness, tremors, dehydration, depression, hyperthermia, coma, and death.[1,15] Signs of toxicity have been treated with supportive care and administration of physostigmine (to dogs) and neostigmine (to cats). Lipid emulsion infusion has also been used.[1]

All of the formulations approved for use in dogs are safe in dogs known to have the MDR1/ABCB1-1Δ mutation; however, higher doses should not be used in an extra-label manner, particularly in dog breeds in which this mutation has been more commonly described.[1,31]

Resistant biotypes of *D. immitis* are now circulating in naturally infected dogs, and all available macrocyclic lactone-based heartworm prevention products (with the exception of the feline product that contains eprinomectin) have failed in experimental studies when challenged with a known resistant *D. immitis* biotype. That being said, lack of compliance is still the primary consideration for apparent failure of efficacy of preventive products. Preventive products are still highly effective for prevention of adult heartworm infection and subsequent disease in dogs and cats.[32]

Eprinomectin

Eprinomectin is approved for use in cats in a transdermal (topical) formulation in combination with praziquantel. Eprinomectin is labeled for prevention of heartworm disease caused by *D. immitis*, adult and larval *T. cati* and *A. caninum*, and adult *Ancylostoma braziliense* infections when dosed at a minimum target dose of 0.5 mg/kg transdermally (topically) on a monthly basis in cats. The combination with praziquantel (minimum target dose of 10 mg/kg) extends the labeled indications to cover *D. caninum* and *E. multilocularis*.[1] This product should not be administered orally and has not been evaluated in pregnant animals.[1]

Ivermectin

Ivermectin is approved for use in dogs and cats at a minimum target dose of 6 µg/kg in dogs and 24 µg/kg in cats for the prevention of heartworm disease caused by *D. immitis* when administered PO on a monthly basis.[1] The higher dose in the cat product extends the labeled indications to include *A. tubaeforme*.[1] No teratogenesis was noted in pregnant animals when administered at four times the recommended dose.[15] Elevated doses of large animal formulations of ivermectin should not be used extra-label in dogs or cats. Adverse events consistent with ivermectin toxicity have been reported when the dose is increased above the label recommendation and combined with spinosad.[15,33,34]

Milbemycin Oxime

Milbemycin oxime is approved as a monthly oral tablet for dogs and cats. This drug is also available in combination with other active ingredients, lufenuron with or without praziquantel or spinosad, which can extend the labeled indications to include flea immature stages +/- tapeworms or adult fleas, respectively.[1,15] Milbemycin oxime at a minimum target dose of 0.5 mg/kg PO in dogs and 2 mg/kg PO in cats is indicated for the prevention of heartworm disease, treatment of *Ancylostoma* spp. and *Toxocara* spp. infections in dogs and cats, and *T. leonina* and *T. vulpis* infection in dogs.[1] Milbemycin oxime is safe for use in pregnant animals[1,15] and the oral formulation has been used extra-label for the treatment of *B. procyonis*, *C. vulpis, Demodex* spp., *D. immitis microfilaria, Eucoleus* spp., and *Spirocerca lupi*.[2,5,8,9] Outside the United States, milbemycin oxime has been combined with afoxolaner as a monthly broad-spectrum parasite control product.[35]

Moxidectin

Moxidectin is available in three formulations: sustained-release injection, transdermal (topical), and oral.[1] All three formulations are approved for use as heartworm preventives. The sustained-release injection is also effective against existing hookworm infections.[1] Additional approved indications (please see product labels) for transdermal (topical) moxidectin in dogs include treatment of *D. immitis* circulating microfilariae in heartworm-positive dogs, sarcoptic mange mites, hookworms, ascarids, and whipworms. Imidacloprid has been added to extend the label claim to include fleas as well. There are two approved formulations of transdermal (topical) moxidectin available for cats. In addition to heartworm prevention, the product containing 1 mg/kg of moxidectin (+ imidacloprid) is labeled for ear mites, roundworms, hookworms, and fleas, while the product containing 2 mg/kg of moxidectin (+ fluralaner) is labeled for roundworms, hookworms, fleas, and ticks.[1] Extra-label uses of transdermal moxidectin products include *A. abstrusus* in cats, *B. procyonis* in dogs, several mites in dogs and cats, and *Eucoleus* spp. in dogs.[2,5,9,36–40] Oral moxidectin is available, in combination with pyrantel and sarolaner.[1]

Selamectin

Selamectin is approved as a monthly transdermal (topical) product for dogs and cats and is available alone or, for cats, in combination with sarolaner for added flea and tick control.[1,15] Labeled efficacy (please see product labels) includes prevention of heartworm disease, fleas, and ear mites. In cats, transdermal selamectin is also effective against hookworms and ascarids. In dogs, the label also includes treatment of *Sarcoptes scabiei* and *Dermacentor variabilis*.[1]

Melarsomine Dihydrochloride

Melarsomine dihydrochloride is an organoarsenical compound that inactivates parasite enzyme systems. It is only approved for use in dogs for the treatment of adult *D. immitis* as an IM injection.[2] It should not be given SC or IV. Following injection, it is rapidly absorbed and subsequently rapidly eliminated via the bile and kidneys.[15] Melarsomine dihydrochloride has a narrow therapeutic window and reported adverse effects include injection site reactions, increased liver enzyme activity, cough, gagging, lethargy, anorexia, fever, pulmonary congestion, and vomiting.[1,15] Dimercaprol can be used as an antidote in the case of an overdose. Safety has not been determined in pregnant animals.[15]

Melarsomine dihydrochloride is labeled to kill adult (> approximately 4-month-old) *D. immitis* when given as a series of IM injections. Both a two- and three-injection protocol are approved, however, both the American Heartworm Society and the CAPC recommend the three-injection protocol (2.5 mg/kg IM deep into the epaxial muscles, once on day 0 followed by two injections 24 hours apart 1 month later).[1,41,42] Heartworm treatment is often accompanied by adjunct therapies such as doxycycline or minocycline, glucocorticoids, exercise restriction, heartworm prevention, and a microfilaricidal treatment (if needed) (see Chapter 111).[11,41]

Nitazoxanide

Nitazoxanide is not approved for use in dogs and cats. It is available as tablets or a powder that can be mixed with water.[15] It is effective for treatment of refractory tapeworm infections (*D. caninum* or *Taenia* spp.) when used at a minimum target dose of 100 mg/kg PO once.[27] It is also used extra-label for the treatment of protozoal infections of dogs and cats (see Chapter 12 for more information on nitazoxanide).

Piperazine

Piperazine acts at the neuromuscular junction as a GABA agonist, resulting in worm paralysis. Its spectrum of activity is limited to roundworms. It is rapidly absorbed following oral administration and is excreted through the kidneys. Adverse effects include diarrhea, vomiting, and ataxia. No additional adverse effects have been noted when used in pregnant animals. Piperazine is available as a solution, soluble powder, and tablets.[15] Label indications for this parasiticide include the treatment for *Toxocara* spp. infections in dogs and cats with doses that range from 55 to 110 mg/kg PO.[1]

TABLE 13.5 Recommended Treatments for Ticks and Mites of Dogs and Cats in the United States[1,28,36–40,43,52]

Acari	Compounds	Species	Route	Frequency
Ticks (species)	Afoxolaner (Aa, Dv, Is, Rs)	D	PO	q 4 weeks
	Amitraz (NS)	D	CO	q 3 months
	Cyphenothrin (NS)	D	TO	q 4 weeks
	Deltamethrin (NS)	D	CO	q 6 months
	Etofenprox (NS)	C	TO	q 4 weeks
	Fipronil (NS)	D, C	TO, SP	q 4 weeks
	Flumethrin (NS)	D, C	CO	q 8 months
	Fluralaner (Aa, Dv, Is, Rs)	D	PO, TD	q 8 weeks (Aa), q 12 weeks (Dv, Is, Rs)
	Fluralaner (Dv, Is)	C	TD	q 8 weeks (Dv), q 8 or 12 weeks (Is)
	Isopropyl myristate (NS)	D, C	TO	as needed
	Lotilaner (Aa, Dv, Is, Rs)	D	PO	q 4 weeks
	Lotilaner (Is)	C	PO	q 4 weeks
	Permethrin (NS)	D	TO	q 4 weeks
	Sarolaner (Aa, Am, Dv, Is, Rs)	D	PO	q 4 weeks
	Sarolaner (Am, Dv, Is)	C	TD	q 4 weeks
	Selamectin (Dv)	D	TD	q 4 weeks
Mites (species)	Afoxolaner[a] (Ss, Oc, D)	D	PO	q 4 weeks
	Fipronil (Ss)	D	TO, SP	q 4 weeks
	Fluralaner[a] (Ss, Oc, D)	D, C	PO, TD	q 12 weeks
	Ivermectin (D)	D	PO	daily
	Ivermectin (Oc)	D, C	OT	once, repeat if needed
	Lotilaner[a] (Ss, D)	D	PO	q 4 weeks
	Milbemycin oxime	D	PO	daily
	Milbemycin oxime (Oc)	D, C	OT	once, repeat if needed
	Moxidectin (Ss, Oc, D[a])	D, C	TD	q 4 weeks (q 1–2 weeks for D)
	Sarolaner[a] (Ss, Oc, D)	D, C	PO, TD	q 4 weeks
	Selamectin (Ss, Oc)	D, C	TD	q 4 weeks (q 2 weeks for Ss)

[a]Use for these parasites is extra-label. Only compounds approved for use on animals by the EPA or FDA are included.
NB: Always check package inserts for specific labeled indications and safety information.
Aa, Amblyomma americanum; *C,* cat; *CO,* collar; *D,* dog; *D, Demodex* spp.; *Dv, Dermacentor variabilis; Is, Ixodes scapularis*; *NS,* not specified; *Oc, Otodectes cynotis*; *OT,* otic instillation; *PO,* oral; *Rs, Rhipicephalus sanguineus*; *SP,* spray; *Ss, Sarcoptes scabiei*; *TD,* transdermal; *TO,* topical spot-on.

Pyrantel pamoate

Pyrantel pamoate is a tetrahydropyrimidine that works as a nicotinic agonist at the neuromuscular junction, which results in muscle contraction followed by paralysis. It is poorly absorbed following oral administration, which accounts for its wide margin of safety. This product is safe to use in pregnant animals as well as very young animals. Excretion is mostly as unchanged drug in the feces. Tablets, chewables, and an oral suspension are available formulations for dogs and cats.[15] It is also available as a component of several combination products.[1]

Labeled indications in dogs and/or cats include treatment of *Ancylostoma* spp., *Toxocara* spp., *T. leonina*, and *Uncinaria* spp. infections when dosed at a minimum target dose of 5 mg/kg PO once.[1] An extra-label use includes the treatment of *B. procyonis* infections at the labeled dose of 5 mg/kg PO once in dogs.[5] Treatment for *Physaloptera* spp. in dogs and cats can be achieved using a minimum target dose of 10–15 mg/kg PO every 2 weeks for three or more treatments.[12]

ECTOPARASITICIDES

As for other parasiticides, the list of available products for the treatment of ectoparasites in dogs and cats continues to grow, although the market has recently seen the discontinuation or continued decline in use of some long-standing products used historically.[1,28] As new molecules are identified, the introduction of combination products with broader spectra of activity will likely follow. Documented resistance among fleas and/or ticks has been described for a number of currently approved compounds including carbamates, organophosphates, synthetic pyrethroids, and fipronil.[53–55] Decreased efficacy compared with historical data has also been shown in fleas with selamectin.[56] What follows is an alphabetical listing of drugs and/or drug classes used for the treatment of ectoparasites in dogs and/or cats. Doses are listed in Tables 13.4 and 13.5.

Amitraz

Amitraz is a formamidine which works by inhibition of mixed function oxidases and is an octopamine receptor agonist in arthropods. This results in hyperactivity and detachment of arthropods as well as reduced fecundity, oviposition, and egg hatchability. It functions mostly on acari (mites and ticks) and less so on insects. Adverse effects in dogs include transient sedation, lethargy, pruritus, gastrointestinal stasis and ileus, bradycardia, hypothermia, hypotension, hyperglycemia, hyperexcitability, respiratory depression, mydriasis, shock, disorientation, ataxia, tremors, coma, and seizures. Adverse effects can be offset by using yohimbine and atipamezole. Caution is recommended when using amitraz in diabetic animals as it can contribute to hyperglycemia. Caution is also recommended in pregnant animals. Amitraz is not for use in cats.[15]

Historically, a number of amitraz-based products such as dips and spot-ons were available for use in dogs; however, the only remaining

amitraz product available for use in dogs in the United States is the amitraz 3-month collar for ticks (9%).[28]

Botanicals

Botanicals are molecules with insecticidal properties that are derived from plant materials and include rotenone, limonene, and the pyrethrins.[57–59] Various formulations for dogs and/or cats exist including shampoos, sprays, and dips. Rotenone, available as an ointment, is derived from plant roots and acts to inhibit mitochondrial respiratory enzymes. Limonene is a naturally occurring cyclic terpene derived from citrus fruit. Although reportedly noncarcinogenic with a low oral toxicity, in higher concentrations limonene causes dermal irritation. It is available as a medicated shampoo. Pyrethrin botanicals are derived from the plant *Chrysanthemum cinerariaefolium*. They interfere with neurotransmission by disrupting the transport of sodium and potassium ions, are rapidly biodegradable, and do not possess persistent activity. Pyrethrins are available as dips, shampoos, and sprays.[57–59]

Carbamates and Organophosphates

The carbamates and organophosphates (OPs) were historically used before the advent of newer, safer molecules with equivalent spectra of activity.[58,59] However, these compounds are still available, particularly as over-the-counter products, and therefore, they will be briefly covered here. They inhibit acetylcholinesterase, resulting in accumulation of acetylcholine at the nerve synapse, and overstimulation of the nerves. Carbamate binding to acetylcholinesterase is reversible, while OPs irreversibly bind the enzyme. Adverse effects include salivation, lacrimation, urination, diarrhea, dyspnea, vomiting, muscle fasciculations, weakness, and paralysis. Atropine can be used to reverse these clinical signs. Additionally, slow administration of pralidoxime (2PAM) can help reduce clinical signs associated with OP toxicity.[58,59] Idiosyncratic reactions have been reported in cats, young and thin animals, and sighthounds. These products may be available in spot-on, spray, powder, dip, and collar formulations for dogs and/or cats. Propoxur is a commonly used carbamate, whereas tetrachlorvinphos, coumaphos, diazinon, phosmet, pirimiphos, dichlorvos, and chlorpyrifos are OPs often included in products for pets.[58,59]

Fipronil

Fipronil is a phenylpyrazole insecticide/acaricide which can kill adult fleas, lice, and ticks. Some formulations are also labeled to control sarcoptic mange.[28,59] Fipronil acts on GABA and glutamate-gated chloride channels in the arthropod nervous system and is available in various formulations including sprays (0.29%) and monthly spot-ons (minimum target dose ranging from 6.01% to 9.8%). This drug is safe for use in dogs and cats and in pregnant animals. Adverse effects include irritation at the site of application and hypersensitivity reactions.[28]

Indoxocarb

Indoxocarb is an oxadiazine prodrug insecticide. Once in the mammalian host, it is metabolized and biotransformed into the decarbomethoxylated form which blocks voltage-gated sodium channels.[60] This drug has adulticidal as well as ovacidal and larvacidal properties against fleas.[61] Adverse effects include skin irritation at the site of application, redness, and pruritus. It should not be administered to pregnant animals. Indoxocarb is available as a spot-on formulation for target dogs and cats (minimum target dose of 15 mg/kg).[61,62]

Insect Development Inhibitors and Insect Growth Regulators

Insect development inhibitors (IDIs) and insect growth regulators (IGRs) exert their effects on the immature stages of fleas: eggs, larvae, and/or early pupae.[63] IDIs such as lufenuron interfere with the formation of chitin. IGRs mimic juvenile hormone, which subsequently interferes with the necessary signaling, thus halting proper development of the insect (e.g., methoprene and pyriproxifen).[63] Due to the unique mechanisms of action on insect-specific molecules, adverse effects are not reported in mammals. As many of these compounds are available in combination with other active ingredients, they should be used according to label recommendations when determining if safe in pregnant or young animals. Resistance to these molecules has not yet been reported. Lufenuron is available as a long-acting injectable preparation (minimum target dose of 10 mg/kg) or in combination with oral monthly heartworm prevention products (minimum target dose of 10 mg/kg).[1] It is excreted unchanged in bile. Methoprene is available as a spot-on, spray, collar, or shampoo formulation (minimum target doses ranging from 8.8% to 11.8%).[28] Its longevity is impacted by ultraviolet rays. Pyriproxyfen is available in combination with other insecticides and/or acaricides (minimum target doses ranging from 0.44% to 11.65%).[28]

Isopropyl Myristate

Isopropyl myristate is the ester of isopropyl alcohol and myristic acid. It acts by dissolving the outer wax layer of ticks, which results in uncontrolled desiccation and tick death. It is available as a spray (50%) for dogs and cats to kill ticks. It can be used as often as needed. Adverse effects include dermal and eye irritation[28]. The ester is also commonly found in a variety of human beauty products.

Isoxazolines

The isoxazolines work by selectively binding to and inhibiting the GABA-gated chloride channels. This results in hyperpolarization and generation of inhibitory postsynaptic potentials. Preferential binding to the GABA channels in insects and acari when compared with mammalian GABA channels results in a wide margin of safety. Reported adverse effects are often gastrointestinal or neurological (hypersalivation, weakness, tremor, ataxia, seizures).[43] The FDA has issued a class-wide statement regarding the potential for all of these drugs to elicit neurological adverse effects.[1] Safety in pregnant animals has not been evaluated for all of these products with the exception of fluralaner, which is reportedly safe to use in pregnant animals.[1] Metabolism of these molecules is minimal, and excretion is primarily through the bile.[43]

Isoxazolines have activity against fleas and ticks; however, the number of species of ticks and duration of activity against specific tick species present on the product label varies (see Table 13.5).[1] Isoxazolines also effectively kill (extra-label) several species of mites (see Table 13.5) as well as biting flies, lice, and mosquitoes (see Table 13.4) when administered according to the normal product regimen and dose.[38,40,44–52] Indeed, isoxazolines are becoming accepted as the treatment of choice for demodectic mange in dogs. Afoxolaner is available as a monthly chewable for dogs, dosed at a minimum target dose of 2.5 mg/kg.[1] Fluralaner is available in both chewable or transdermal formulations for dogs (minimum target dose of 25 mg/kg), and transdermal formulations for cats (minimum target dose of 40 mg/kg). Duration of activity is up to 12 weeks.[1] Lotilaner is available as a monthly chewable for dogs and cats, dosed at a minimum target dose of 20 mg/kg for dogs and 6 mg/kg for cats.[1] Sarolaner is available as a monthly chewable tablet for dogs (minimum target dose of 2 mg/kg) and a monthly transdermal formulation for cats (minimum target dose of 1 mg/kg).[1] Isoxazolines are available alone or, increasingly, in combination with macrocyclic lactones or other anthelmintics to provide broader-spectrum parasite control.

Macrocyclic Lactones

In addition to their efficacy as anthelmintics, macrocyclic lactones can be used to treat ectoparasites. Otic formulations of ivermectin (0.01%) and milbemycin (0.1%) oxime are available for the treatment of *Otodectes cynotis* infestations in cats.[28] Transdermal (topical) moxidectin is labeled for *O. cynotis* in cats and *Sarcoptes scabiei* in dogs,[1] and also is effective extra-label for treatment of *Demodex* spp. in dogs when used every 1–2 weeks.[38,64] Transdermal (topical) selamectin is labeled for treatment of flea adults, flea eggs, and *O. cynotis* infestations in dogs and cats; the dog formulation of selamectin is also labeled for treatment of *S. scabiei* and *Dermacentor variabilis* infestations. Selamectin is also effective extra-label against lice, including *Trichodectes canis* in dogs and *Felicola subrostratus* in cats.[29] Although necessary historically when other options were not available, high-dose, extra-label use of large animal macrocyclic lactone products for treatment of small animal ectoparasites (e.g., demodectic mange) may cause toxicity and is not recommended.[15]

Neonicotinoids

Neonicotinoids act on nicotinic acetylcholine receptors in insects.[65] Receptors in mammals and insects are structurally different; therefore, these compounds can be used safely in dogs and cats with little to no adverse effects. Excretion is primarily via the kidneys. Adverse effects include local erythema at the site of application and hyper salivation. These drugs should be used with caution in pregnant animals. Members of the class include dinotefuran, imidacloprid, and nitenpyram which have insecticidal activity against lice and adult fleas, as well as extra-label activity against additional insect species.[15,28,65] Dinotefuran is available as a spray (0.46%) or in combination with other active ingredients in a spot-on formulation (minimum target dose ranges from 4.95% to 22%). Imidacloprid is available as a daily oral medication (minimum target dose of 0.75 mg/kg) or in combination with other medications as a spot-on or collar (8.8%–10%). Nitenpyram is available as a daily oral product dosed at a minimum target dose of 1 mg/kg.

Spinosyns

Spinosyns are formed as a result of fermentation by the actinomycete *Saccharopolyspora spinosa.* They bind to nicotinic acetylcholine receptors in a location that differs from that of the neonicotinoids and to GABA-gated chloride channels. This activity results in hyperexcitation followed by paralysis in the insects.[66] Adverse effects in companion animals include inactivity, vomiting, inappetence, lethargy, and alopecia, erythema, and pruritis at the site of application. Spinosyns should be used with caution in pregnant animals and animals receiving extra-label (high) doses of ivermectin, because they can inhibit P-glycoprotein resulting in ivermectin toxicity. Spinosad is available as a monthly oral product either alone or with another drug in a broad-spectrum heartworm preventive and intestinal parasite control product (minimum target dose of 30 mg/kg). Spinetoram is available as a monthly 11.2% spot-on for use in cats.

Synthetic pyrethroids

In comparison with natural pyrethrins, synthetic pyrethroids are more potent, have a longer duration of action, and are more stable. These work to initially stimulate and then depress nerve cell function in insects and acari, with the end result being paralysis.[59,66] Adverse effects include skin or mucosal irritation, and for some compounds in cats (e.g., high-concentration permethrin), significant adverse effects include hyperexcitability, lethargy, ataxia, vomiting, tremors, seizures, hypersalivation, and death. Synthetic pyrethroids should be used with caution in pregnant animals and some products should be avoided in cats. A number of pyrethroids (most ending in the suffix –thrin) are available in over-the-counter formulations as spot-ons, collars, and shampoos. The most common ones utilized in dogs and/or cats are cyphenothrin, deltamethrin, etofenprox, flumethrin, and permethrin. Cyphenothrin and deltamethrin are fourth-generation synthetic pyrethroids that are available for use in dogs as a monthly spot-on (minimum target dose of 5.2%)[28] and a 6-month collar (minimum target dose of 4%), respectively. Etofenprox, while not a true synthetic pyrethroid, has the same mechanism of action. It is available as a spot-on (minimum target dose of 15%), spray, or shampoo for dogs and cats. Flumethrin is another fourth-generation synthetic pyrethroid that is available for use in dogs and cats as an 8-month collar (minimum target dose of 4.5%).[67,68] Permethrin is a third-generation synthetic pyrethroid that acts on sodium channels as well as chloride and calcium channels. It acts as a contact repellent as well as an insecticide and acaricide and is available in monthly spot-on formulations or sprays. The high concentration (minimum target dose ranges from 36.08% to 44.88%) in the monthly spot-on formulations is toxic to cats; however, the sprays have a lower concentration which can be tolerated by cats.

Synergists

Synergists inactivate mixed function oxidases such that insects are unable to detoxify insecticidal compounds. They are used to enhance the activity of other insecticidal compounds.[66] Commonly used compounds include piperonyl butoxide and N-octyl bicycloheptene dicarboximide (MGK 264) in a variety of formulations.

SECTION 3

Principles of Infection Control

Jane E. Sykes, J. Scott Weese

Infection control has typically been a slowly progressing and reactionary field, with incremental changes implemented based on new threats. While less ideal than a proactive approach, it has still led to major changes in routine infectious disease control measures and approaches in veterinary medicine, aimed at reducing disease risks in both patients and veterinary personnel. The emergence of the COVID-19 pandemic added a new dimension and led veterinary clinics across the globe to rethink their infection control practices in order to optimize safety for personnel, with the added focus of people as sources of veterinary occupational infections and reduction of intra-transmission of pathogens between personnel, not just from patients to personnel. The range of activities implemented or enhanced because of COVID-19, such as enhanced personal protective equipment use, distancing, attention to ventilation, better hand hygiene compliance, and enhanced environmental disinfection, undoubtedly also reduced the risk of hospital-associated infections among veterinary patients. This section addresses control of hospital-associated infections as well as control of infectious diseases in cat and dog populations; Chapter 19 addresses the epidemiology and transmission of zoonotic diseases and ways to reduce the risk of these diseases in immunocompromised people. Specific information on the public health risks of each disease is also provided in pathogen-specific chapters, including more information on equivalent human disorders.

Chapter 20 discusses immunization against infectious diseases. Types of vaccines, vaccine handling and administration, factors that influence the immune response to vaccines, serologic testing as a measure of vaccine efficacy, and adverse effects of vaccination are discussed. In addition, the appendix at the end of this book provides suggested immunization schedules for individual pets and shelter animals. The reader is also referred to chapters in Part II for more detailed information on prevention of specific infectious diseases.

Cleaning and Disinfection

J. Scott Weese

KEY POINTS

- Disinfection is a process that eliminates many or all microbes, but not bacterial spores, from inanimate objects. It is usually accomplished in hospital environments using liquid chemicals such as quaternary ammonium compounds or accelerated hydrogen peroxide. Proper cleaning is an essential step before disinfection to optimize disinfectant activity, and attention to contact time is also critical.
- *Antisepsis* reduces the number of microbes from living tissue and skin. Disinfectants are rarely used for skin antisepsis because they can cause injury to tissues and skin. Chlorhexidine is an example of a commonly used antiseptic.
- *Sanitation* is the reduction in the number of microorganisms on a surface to a safe level.
- *Sterilization* is the complete elimination of all microbes and can be accomplished in the hospital using techniques such as autoclaving.
- *Germicides* are agents that inactivate microorganisms, and include disinfectants, antiseptics, and sanitizers.
- Veterinarians must be aware of the advantages and disadvantages of different disinfectants, antiseptics, and sterilization processes in order to design and implement an optimal infection control program.
- Veterinarians should also be aware of items that represent environmental sources of pathogens and the optimal methods to disinfect those items.
- For detection of hospital bacterial contamination, routine culturing of the environment is not recommended. Fluorescent tagging methods may be useful for demonstration of efficacy of cleaning. In addition, direct observation may also be helpful to identify gaps in protocols and practices. ATP bioluminescence, which detects adenosine 5′-triphosphate (ATP) production by viable microbes in the environment, is a promising tracer to measure hospital contamination with bacteria.

INTRODUCTION

The hospital environment is not sterile, nor is it expected to be so. The environment, medical equipment, and virtually all other external surfaces are contaminated with a range of microbes, many being potential pathogens. The role of the environmental *microbiota*, the vast population of bacteria, viruses, fungi, Archaea, and parasites that exists in every facility, is hard to define; yet it is clear that the environment can be a source of infection of some situations. This risk varies greatly between different pathogens, with site and patient factors also greatly influencing the risk of disease.

Cleaning involves the removal of all visible organic and inorganic material from objects and surfaces through the use of manual or mechanical processes and detergent or enzymatic solutions (Box 14.1). *Sanitation* is the reduction in the number of microorganisms on a surface to a safe level. Sanitizers do not technically disinfect as they are weakly concentrated and have a limited contact time. These products are generally not used in healthcare settings, rather are used in food and water hygiene. *Disinfection* is the process that eliminates many or all microbes, but not bacterial spores, from inanimate objects. Factors that influence the efficacy of disinfection include the type of microorganism present, their number, the amount and type of organic matter present, the presence of biofilms, and the porosity of the surface to be disinfected. Some disinfectants kill spores with prolonged exposure times. These are known as *chemical sterilants*. When chemical sterilants are used at lower concentrations and for shorter contact times, they can inactivate all microbes except large numbers of bacterial spores, and are known as *high-level disinfectants. Low-level disinfectants* inactivate most vegetative bacteria, some fungi, and enveloped viruses, but not bacterial spores. *Intermediate-level disinfectants* inactivate mycobacteria, vegetative bacteria, most viruses, and most fungi.

Antisepsis is the process that reduces the number of microbes from living tissue and skin. Disinfectants are rarely used for skin antisepsis because they can cause injury to tissues and skin. *Germicides* are agents that inactivate microorganisms, and include disinfectants, antiseptics, and sanitizers.

Sterilization refers to complete elimination of all microbes, including bacterial spores, and is accomplished in hospital settings using processes such as pressurized steam, dry heat, ethylene oxide (ETO) gas, or liquid chemicals.

Cleaning, disinfection and sterilization are distinct practices with different goals and approaches. Understanding the differences between these practices is important for designing and implementing a proper environmental control program.

INDICATIONS FOR DISINFECTION AND STERILIZATION

Not all surfaces need to be treated similarly. According to the Spaulding method of classification for human healthcare, items to be sterilized or disinfected can be grouped into *critical, semicritical,* and *noncritical* items.[1] Critical items enter tissue or the vascular system, or are devices through which blood flows. These require sterilization before they can be used. Semicritical items are items that contact mucous membranes or nonintact skin, such as endoscopes. These generally require high-level disinfection. Noncritical items are items that contact intact skin, such as stethoscopes. Noncritical items generally require low-level or

BOX 14.1 Cleaning, Disinfection, and Sterilization Definitions

Sterilization	Complete elimination of all microbes, including bacterial spores. Accomplished in hospital settings using processes such as pressurized steam, dry heat, ethylene oxide gas, or liquid chemicals
Disinfection	Elimination of many or most microbes from an inanimate surface High-level disinfection: inactivation of all microbes except bacterial spores Intermediate-level disinfection: inactivation of mycobacteria, vegetative bacteria, most viruses, and most fungi, but not bacterial spores and many nonenveloped viruses Low-level disinfection: inactivation of most vegetative bacteria, some fungi, and enveloped viruses, but not bacterial spores, mycobacteria, or nonenveloped bacteria
Cleaning	Removal of gross debris through the use of manual or mechanical processes and detergent or enzymatic solutions. This results in removal of 90%–95% of the microbial burden

intermediate-level disinfection. However, it is clear that Spaulding's criteria are not absolute. For example, a fork contacts mucous membranes, yet human hospital cutlery does not undergo high-level disinfection. A food bowl would be a similar example in veterinary medicine. Therefore, these criteria should be used for general guidance, but consideration of the likelihood of contamination, the ability to properly clean and disinfect the item, body surfaces that will be exposed, and health status of patients who will be exposed is required to make final decisions on appropriate cleaning and disinfection practices.

CLEANING, SANITATION, DISINFECTION, AND STERILIZATION

Cleaning

Cleaning is the critical first step of disinfection or sterilization. It typically involves the use of water, combined with detergents or enzymatic agents. The physical aspects of cleaning remove the bulk of pathogens, as well as organic debris, leaving a surface that is more amenable to effective disinfection or sterilization, as these can be significantly impacted by the presence of organic debris. Cleaning also removes microorganisms that are resistant to many disinfectants, such as clostridial spores, nonenveloped viruses, and protozoa. Care should be taken when using high-pressure water sources (e.g., water hose or high-pressure washer) as these likely result in particle aerosolization and creates the potential for transmission and environmental contamination.

Cleaning and disinfection are typically two steps. While some products marketed as "cleaner-disinfectants" are available, efficacy data are sparse. A one-step approach is probably effective with a high-quality disinfectant and a relatively clean surface (e.g., a stainless steel examination table with minimal gross contamination), but it is optimistic to assume effective one-step cleaning and disinfection with moderate or high organic loads or with disinfectants that are readily inactivated by organic debris.

Disinfection

Typically, disinfection involves the use of liquid chemicals such as quaternary ammonium compounds or oxidizing agents. It is important to note that disinfection is a chemical process that can be impacted by the presence of organic debris, the type and level of microbial contamination, the concentration and contact time of the disinfectant, the nature of the item (e.g., porous, cracks, or crevices), and the temperature and pH during the disinfection process.

Disinfectants have variable properties that must be considered when selecting an appropriate product. There can be profound differences in spectrum, contact time, surface compatibility, impacts of organic debris, compatibility with cleaners, safety, environmental impacts, and cost (Table 14.1). These factors must be considered when designing a disinfection program for a facility. Ideally, a single disinfectant is used for most or all applications to reduce the likelihood of user error. However, in some situations, "regular" and "enhanced" disinfection practices may be reasonable. For example, a lower-level disinfectant such as a quaternary ammonium compound might be used routinely based on factors such as infection pressure and cost, with a more effective disinfectant (e.g., bleach, accelerated hydrogen peroxide [AHP]) reserved for pre-defined, higher-risk situations (e.g., puppy with diarrhea where parvovirus is a possibility). Clear documentation of cleaning and disinfection practices, including products, dilution, contact time, and lifespan, is required to reduce the risk of errors.

Glutaraldehyde

Glutaraldehyde is a saturated dialdehyde that is noncorrosive and can be used for high-level disinfection of materials that cannot undergo steam sterilization, such as rubber, plastics, and endoscopic equipment. It is not used as a general environment disinfectant.

Glutaraldehyde has broad-spectrum microbicidal activity. Aqueous solutions require activation by alkalinization to a pH of 7.5 to 8.5 for sporicidal activity to occur. When alkalinized, glutaraldehyde is used at a concentration of 2.4% for adequate periods of time, either chemical sterilization or high-level disinfection occurs, depending on the contact time. Contact times of at least 20 minutes (at or above 20°C) are required for high-level disinfection.

Once activated, 2.4% glutaraldehyde solution retains activity for 14 days, provided inadvertent dilution or excessive gross contamination does not occur. The solution is active in the presence of 2% organic matter. Inadvertent dilution can occur when endoscopes that contain fluid within their channels are immersed in the solution. Test strips are available from the manufacturer to monitor the activity of the solution (but not to attempt to extend the solution's expiration date).

Glutaraldehyde irritates mucous membranes of the respiratory and gastrointestinal tracts, so endoscopes must be rinsed properly after disinfection. It can also cause allergic contact dermatitis, but it is not mutagenic or carcinogenic. The wearing of nitrile rubber or butyl rubber gloves is recommended. Because of its relative expense and toxicity, it is not used to disinfect noncritical surfaces.

Ortho-phthalaldehyde (OPA)

OPA is a high-level disinfectant that contains 0.55% 1,2-benzenedicarboxaldehyde. It has excellent microbicidal, including sporicidal, activity, with a relatively short contact time. With a greater activity than glutaraldehyde, no need for activation, stability over a wide pH range, short contact time (12 minutes at or above 20°C, 5 minutes at 25°C), and lack of mucous membrane irritation, OPA is preferable to glutaraldehyde. While nonirritating, it will stain unprotected skin, and requires protective equipment during handling (gloves, eye and mouth protection, fluid-resistant gown) and adequate rinsing after disinfection. OPA is used for disinfection of equipment such as endoscopes. It is not used as an environmental disinfectant.

TABLE 14.1 Characteristics of Selected Disinfectants

Disinfectant Category	Activity In The Presence Of Organic Matter	Advantages	Disadvantages	Comments
Alcohols	Rapidly inactivated	Fast-acting No residue Relatively nontoxic	Rapid evaporation	Not appropriate for routine environmental disinfection Primarily used as antiseptics
Aldehydes	Good	Broad spectrum Relatively noncorrosive	Highly toxic	Used as an aqueous solution or as a gas (fumigation)
Chlorhexidine	Rapidly inactivated	Nontoxic	Incompatible with anionic detergents	Not appropriate for environmental disinfection Primarily used for antisepsis
Hypochlorites (bleach)	Rapidly inactivated	Broad spectrum, including spores Inexpensive Easy to access Low cost	Inactivated by cationic soaps/detergents and sunlight Frequent application required Corrosive	Commonly used for enhanced disinfection purposes. Corrosive and noxious properties typically preclude routine use.
Accelerated hydrogen peroxide	Good	Broad spectrum, including spores Shorter contact times Environmentally friendly	Cost	Excellent choice for environmental disinfection
Phenolics	Good	Broad spectrum Noncorrosive Stable in storage	Toxic to cats Unpleasant odor Incompatible with cationic or nonionic detergents	Some residual activity after drying. Little reason to use as an environmental disinfectant.
Quaternary ammonium compounds	Moderate	Stable in storage Nonirritating to skin Low toxicity Low cost Effective at high temperatures and pH	Incompatible with anionic detergents	Commonly used but provides relatively low-level disinfection Some residual activity after drying

Peracetic Acid

Peracetic acid belongs to the peroxygen family of compounds. When used at 50°C to 56°C in a specific peracetic acid reprocessing system, 0.2% solutions achieve sterilization in short time periods (30 to 45 minutes). Peracetic acid is active in the presence of organic matter. It is stable but can be corrosive and causes discoloration of endoscopes over time. Peracetic acid concentrates can cause irritation to mucous membranes and are corrosive to the eye and skin, but 0.2% solutions are generally nonirritating.

Potassium Peroxymonosulfate

Potassium peroxymonosulfate is an oxidizing agent that provides broad-spectrum disinfection, including activity against nonenveloped viruses and bacterial spores. Potassium peroxymonosulfate retains some activity in the presence of organic matter. It is corrosive and can cause serious skin and ocular burns at high concentrations, but ready-to-use solutions are nonirritating and less corrosive than bleach. The solution stains fabric and may damage surfaces, particularly metal, over time if rinsing is not performed. It is commonly used as an environmental disinfectant because of its many good properties; however, the potential for surface damage appears to be greater compared with many other disinfectants.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is a potent oxidizer, but standard H_2O_2 is not a good surface disinfectant because of its susceptibility to inactivation. AHP is an H_2O_2 solution that contains surfactants, an acid, and H_2O_2, providing broad-spectrum disinfection, including efficacy against bacterial spores, nonenveloped viruses, and dermatophytes.[2–4] With relatively short contact times and good activity in the presence of moderate organic loads, AHP has gained popularity as a disinfectant among healthcare institutions. Additionally, AHP has low toxicity, is environmentally friendly, and is compatible with most materials, giving it a combination of efficacy and practical use properties that is probably currently unsurpassed.

Sodium Hypochlorite (Bleach)

Hypochlorite is a potent oxidizing agent that provides broad-spectrum activity, including activity against nonenveloped viruses, bacterial spores, and dermatophytes. Household bleach, which contains 5.25% to 6.15% sodium hypochlorite, is readily available but must be diluted prior to use. The concentration of bleach that is used impacts both the required contact time and the level of disinfection. When used at a 1:10 dilution for a 10-minute contact time, household bleach is sporicidal but is irritating and can be highly corrosive to metal surfaces. For most clinical situations, 1:30 to 1:50 dilutions of household bleach provide more than 1000 ppm available chlorine and are effective for intermediate-level disinfection. Sodium hypochlorite is inactivated by organic matter, so cleaning is required before disinfection is performed. Hypochlorite is also light sensitive. Other disadvantages of bleach solutions are bleaching of colored fabric and the release of toxic chlorine gas when they are combined with other disinfectants such as quaternary ammonium compounds. Bleach is most often used for enhanced disinfection, targeting nonenveloped viruses, bacterial spores, or dermatophytes in response to specific cases or outbreaks. However, cost is probably the only benefit of using bleach rather than AHP.

Quaternary Ammonium Compounds

This class of disinfectants contains numerous different compounds, with generally similar activity. They are commonly used in veterinary

clinics but provide relatively low-level disinfection in most situations. Although they are generally fungicidal, bactericidal, and virucidal for enveloped viruses, some bacteria are resistant, and there is little activity against nonenveloped viruses, bacterial spores, or dermatophytes. Some products have claims against nonenveloped viruses, but with higher concentrations and longer contact times. Contact times vary by product, so manufacturer recommendations should be followed; however, 10-minute contact times are often used. Advantages of this class include low cost, high stability, and low toxicity. If used as a primary disinfectant, having a protocol for enhanced disinfection with a more effective disinfectant (e.g., AHP) is needed for situations where resistant organisms are likely to be present (e.g., suspected parvovirus infection).

Phenolics

Phenolics are older disinfectants that are now uncommonly used in clinical environments. They are active against enveloped viruses and bacteria, but they are not sporicidal and have limited activity against fungi and nonenveloped viruses. Their main benefit is better activity in organic debris than some disinfectants, particularly quaternary ammoniums. They irritate skin and mucous membranes, and have the potential to be highly toxic if ingested by cats. Because of these limitations and the availability of other effective disinfectants, there is no indication for their use in veterinary facilities.

Alcohol

Ethyl alcohol and isopropyl alcohol are low-level disinfectants that will kill most bacteria, enveloped viruses, and some fungi. The optimum bactericidal concentration is 60% to 90% (volume/volume) in water. However, they do not destroy bacterial spores or penetrate proteinaceous material and are readily inactivated by organic debris. Therefore, they are not recommended for routine environmental disinfection. Alcohol is occasionally used for low-level disinfection of some patient contact items (e.g., thermometers); however, given the availability of other safe and more effective options, there is little indication to use alcohol for any disinfection procedures. Because alcohol is flammable and dries quickly, it can be difficult to achieve adequate contact times (≥ 1 minute).

Iodophors

Iodine solutions are primarily used as skin antiseptics. Formulations for disinfection are also available, which contain higher concentrations of free iodine than antiseptic preparations. An iodophor is a combination of iodine and a solubilizing agent (e.g., polyvinylpyrrolidone in povidone-iodine), which serves to provide a sustained-release form of iodine. Dilutions of iodophors are more active against microbes than concentrated povidone-iodine, so iodophors must be diluted correctly. Iodophors are bactericidal and virucidal. Their antibacterial activity does not persist for long periods on skin or in tissues, so frequent reapplication is required. Iodophors are relatively nontoxic and nonirritating. They are stable in solution but are inactivated by organic material, and they can stain plastics and, to some extent, tissues. There is no reason to use iodophors for environmental disinfection given the widespread availability of better disinfectants.

Chlorhexidine

Chlorhexidine is a cationic bisbiguanide that disrupts microbial cell membranes and precipitates cell contents. It is used widely for skin antisepsis in veterinary medicine but is a poor environmental disinfectant because of the low-level disinfection that it can achieve and the potential selection for chlorhexidine-resistant bacteria,[5,6] which could impact the efficacy of skin antisepsis and wound care. Anecdotally, outbreaks caused by pathogens with acquired chlorhexidine resistance (e.g., *Pseudomonas*) have been identified in facilities where chlorhexidine was used as a routine environmental disinfectant. As with iodophors, there is no reason to use chlorhexidine for environmental disinfection.

Sterilization

Steam Sterilization

Steam sterilization involves the use of saturated steam under pressure in an autoclave. This is the most effective form of sterilization, is nontoxic and inexpensive, and as a result is the most widely used in healthcare facilities. The use of steam under pressure allows lower temperatures to be used for shorter periods of time when compared with dry heat sterilization (Table 14.2). Cycle times vary depending on the autoclave used and whether items are wrapped or unwrapped, but are generally 30 minutes or less. There are two basic types of autoclaves; gravity displacement autoclaves and high-speed prevacuum sterilizers. Gravity displacement autoclaves admit steam at the top or sides of the autoclave, which displaces air through a drain vent at the bottom of the chamber (Fig. 14.1). High-speed prevacuum sterilizers rapidly pump air out of the sterilizer before steam is admitted. This leads to rapid penetration of steam into all surfaces. As a result, cycle and drying times can be reduced.

Before steam sterilization is performed, instruments should be cleaned thoroughly to remove organic and inorganic material, and then dried. All jointed items should be opened or unlocked, and items should not be crowded in the autoclave so that steam can circulate freely.

Assessment of autoclave efficacy is critical. Chemicals (e.g., indicator tape, indicator strips) are used to monitor temperature or both temperature and time and should be included outside and inside every autoclaved pack.[7] Both internal and external indicators should be used unless the internal indicator is visible through the packaging.[7] The external indicator should be evaluated by the individual removing packs from the autoclave, and the internal indicator should be evaluated by the individual opening the pack at the time of use. Biological indicators, most often consisting of *Geobacillus stearothermophilus* spores,[7] should be used on a regular basis. This is the only method that confirms actual sterilization, and the frequency of testing varies with the frequency of use and the types of items that are autoclaved. Weekly testing is probably appropriate for most veterinary hospitals, but more frequent use may be indicated in busy facilities and consideration should be given to including biological indicators with every load containing implantable devices.[7,8]

Failure of any of these methods to indicate effective sterilization must be immediately investigated. If internal or external indicators fail, the items must not be used and the event investigated. In the event of biological indicator failure (with or without external or internal indicator strip failure), any implantable items must be immediately recalled. Recall of other items is prudent but not considered necessary while the investigation ensues.[8] Three consecutive autoclave runs should be performed with biological indicators, and if any are positive, then all items processed since the last successful biological indicator run should be recalled and reprocessed.[7]

With any possible autoclave failure, an authorized individual should promptly service the autoclave. Biological indicator results should be recorded in an autoclave log to allow for proper tracking of autoclave function. Certified personnel should service autoclaves regularly as part of a preventive maintenance schedule.

Dry Heat Sterilization

Dry heat sterilization, using conditions such as 170°C for 60 minutes, 160°C for 120 minutes, or 150°C for 150 minutes,[9] is reserved for

TABLE 14.2 Recommended Conditions for Heat Sterilization

Sterilization Type	Conditions	Time
Gravity displacement steam	121°C (250°F), 106 kPa (15 lb/in^2)[a]	30 minutes: wrapped items; 20 minutes: unwrapped items
	132°C (270°F), 30 lb/in^2	15 minutes: wrapped items
High-speed prevacuum steam	132°C (270°F), 30 lb/in^2	4 minutes
Dry heat	160°C (320°F)	2 hours at temperature, 3–3.5 hours with cooling
	170°C (340°F)	1 hour at temperature, 2–2.5 hours with cooling

[a]Pressure settings may vary. When possible, follow manufacturer's recommendations.

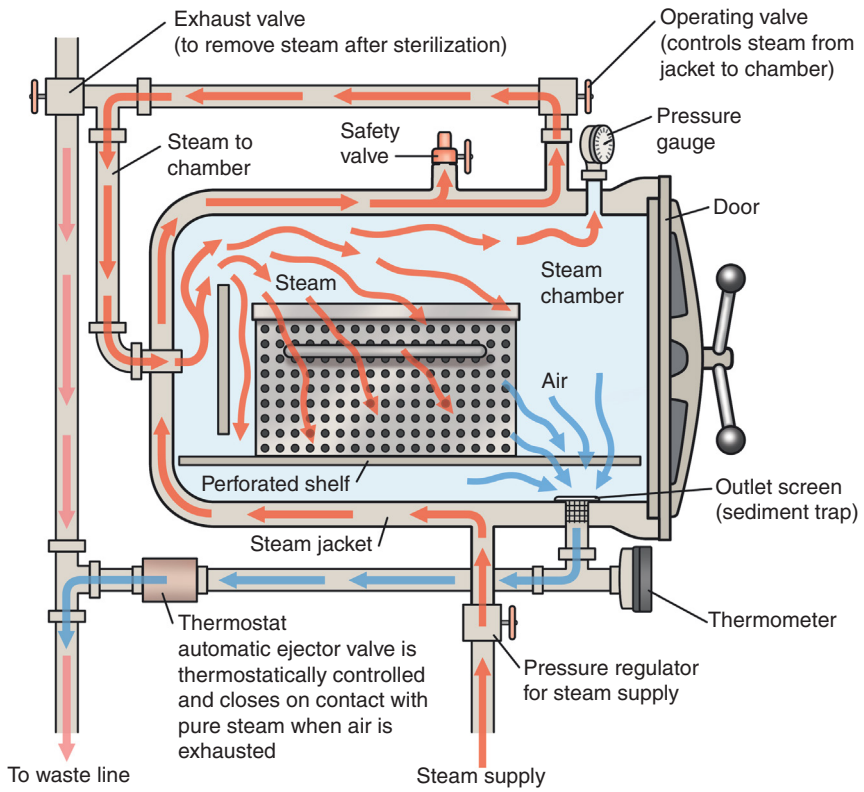

Fig. 14.1 Schematic illustration of gravity displacement sterilization. Steam is admitted at the top or sides of the autoclave, which displaces air through a drain vent at the bottom of the chamber.

materials that might be damaged by moisture or that are impenetrable to moist heat but can tolerate high temperatures. The advantages of lack of corrosive properties and good penetrating power are offset by the long cycle time. This method of sterilization is rarely performed in clinical situations.

Flash Sterilization

Flash sterilization refers to the rapid sterilization of unwrapped instruments and is usually performed as an emergency procedure in an operating room setting when time is insufficient to perform the preferred sterilization of wrapped items. This is most often indicated when an item is inadvertently contaminated during surgery and a sterile replacement is not available. In general, it is performed for 3 minutes at 132°C (270°F) and 27 to 28 lb/in^2. Each instrument must be carefully protected to ensure it does not become recontaminated during transport back to the operating room, usually in a "flash pan." Flash sterilization has occasionally been associated with an increased risk of intraoperative infections and patient injury in humans[10–12] and should not be used for routine purposes or in lieu of stocking an adequate number of surgical instruments or proper scheduling.

Gas Sterilization

ETO gas can be used to sterilize items that cannot withstand steam sterilization. ETO kills microorganisms through alkylation of protein, DNA, and RNA, providing broad-spectrum activity against even hardy organisms like mycobacteria, enveloped viruses, and bacterial spores. As with steam sterilization, a series of factors influence ETO efficacy including gas concentration, temperature, humidity, and time.[9] Typical recommended ranges for these factors are 450–1200 mg/mL, 29°C–65°C, 45%–85%, and 2–5 hours, respectively.[9] Cycle time (2–5 hours plus 8–12 hours of aeration at 50°C–60°C) and cost are disadvantages of this approach, as well as health and safety concerns with this flammable, explosive, and toxic chemical.[9]

Use of H_2O_2 vapor is a relatively new approach that takes advantage of the broad antimicrobial activity of H_2O_2, with the advantages of having no toxic byproducts (as H_2O_2 breaks down to water and oxygen)

TABLE 14.3 Recommended Concentration and Contact Times for Chemical Sterilants

Chemical/Combination	Concentration	Contact Time
Glutaraldehyde	2% or greater	10 hours
Glutaraldehyde + phenol	1.12% + 1.93%, respectively	12 hours
Accelerated hydrogen peroxide	7.5%	6 hours
Hydrogen peroxide + peracetic acid	7.35% + 0.23%, respectively	3 hours
Peracetic acid	0.2% or greater	50 minutes

and a shorter cycle time. H_2O_2 vapor is compatible with a wide range of materials and can effectively penetrate lumens with small internal diameters or long lengths (e.g., 1 mm of greater diameter and 125 mm or shorter length).[13]

As with steam sterilization, biological indicators should be used. *Bacillus* spores are used to assess ETO, while *G. stearothermophilus* spores are recommended for H_2O_2 vapor.[8] Biological indicators should be placed in the most challenging location in an autoclave load, typically in the center of the load.

Liquid Immersion Sterilization

Liquid immersion sterilization ("cold sterilization") involves the use of a variety of chemical sterilants. When used properly, true sterilization can be achieved; however, liquid immersion should be reserved for items that cannot be processed through other methods, as it is generally less effective and more prone to failure. Liquid immersion is likely more dependent on thorough cleaning than other sterilization methods, and is also presumably more prone to processing errors (e.g., improper dilution, inadequate contact time, improper pH, inadequate changing of solutions, and failure to ensure no air pockets are present), highlighting why this method should not be used for items that can be steam processed.

Examples of chemical sterilants with required concentrations and contact times are presented in Table 14.3. The time required to achieve sterilization is typically 3–12 hours,[7] although increasing the temperature can decrease the required time.[13] Manufacturer guidelines for concentration, temperature, and contact time must be followed.

After chemical processing, items typically need to be rinsed before being used on patients. This is a step that creates a risk of contamination if nonsterile water is used or if there is inadvertent contamination from hands, aerosols, or the environment. Care must be taken when handing and rinsing sterilized items. While items can be kept in the solution tray for a short period of time (e.g., for short transportation to the patient, with appropriate protocols to prevent spillage, or while awaiting a procedure), items should not be kept in chemical sterilants for prolonged storage.

"Cold sterile" solutions are often found in veterinary clinics and may contain critical items that come into contact with sterile patient sites. Often, these are used for relatively low-risk procedures such as minor laceration repairs, abscess drainage, or for items such as otoscope tips. Misuse of cold sterile solutions is widespread and bacterial contamination of cold sterile solutions has been identified in veterinary clinics,[14] likely as a result of inadequate pre-cleaning of instruments, inadequate contact time, adding dirty instruments to solutions containing "sterile" instruments, inadequate pH, inadequate changing of solutions, and inadequate dilution. Cold sterile solutions should not be used for surgical instruments or other items that come into contact with sterile sites, regardless of the minor nature of the procedure that will be performed.

Irradiation

Gamma irradiation is commonly used to sterilize disposable medical supplies such as catheters, gloves, syringes, and pharmaceuticals, but is not relevant for in-clinic sterilization.

SPECIFIC CONSIDERATIONS FOR EQUIPMENT CLEANING AND DISINFECTION

Thermometers

Rectal thermometers are at high risk of becoming contaminated with various pathogens. Outbreaks of disease caused by pathogens such as *Salmonella, Enterobacter cloacae,* and enterococci have been reported in humans in association with rectal thermometers, particularly in neonates and sometimes with fatal outcomes.[15–19] Similar reports are not available for veterinary medicine, but there is no reason to think the risk would be lower. The lack of veterinary data may simply reflect failure to identify or publish outbreaks rather than an inherently lower risk.

Human medicine has largely moved away from rectal thermometers, instead using oral or tympanic thermometers. Changes from rectal to tympanic thermometers have been associated with reduced incidence of vancomycin-resistant *Enterococcus* and *Clostridioides difficile* infections.[15] Moving away from rectal thermometers in animals would be ideal, yet practical alternatives are lacking. Tympanic thermometers may not be particularly accurate in animals,[20–22] and taking of oral temperatures is impractical, so rectal thermometers will likely continue to be widely used. Yet, measures can be taken to reduce the risk of pathogen transmission, including dedicating thermometers to individual patients and use of disposable thermometer covers,[23] as well as using proper disinfection practices.[18]

Any practice that involves cleaning and disinfection is accompanied by concerns about ineffective decontamination, either from inadequate protocols or inadequate compliance. Cleaning to remove gross contamination followed by wiping with a disinfectant such as AHP that is able to kill nonenveloped viruses and bacterial spores is the most practical approach, if disposable covers are not used. This is unlikely to completely eliminate pathogens but may be able to adequately reduce contamination to reduce disease risk.

Otoscope Cones

While manufactured as single-use items, otoscope cones are commonly reused in veterinary practices. Because of contact with the ear canal, contamination of otoscope cones is common.[24,25] When one considers the low cost of otoscope cones, it is hard to justify time-consuming disinfection methods. A practical approach would be to discard cones from patients with evidence of infectious disease and disinfect cones used on other patients. There has been limited study of disinfection methods, particularly when applied to naturally contaminated cones that are also contaminated with organic debris (e.g., exudates, ear wax) that might affect disinfection efficacy. Simply scrubbing

or rinsing cones is minimally effective, and contamination can persist despite wiping with disinfectant-containing otoscope cone cleaning solutions.[26] Soaking in 2% chlorhexidine or a quaternary ammonium/EDTA product was shown to be effective with experimentally inoculated cones.[26] It is likely that cleaning to remove any visible debris followed by soaking in commonly used disinfectants would be effective, provided adequate disinfectant concentration and contact times are used, and that solutions are regularly changed. Regardless of the disinfectant used, cones should be rinsed with water prior to use.

Small Portable Medical Equipment

Patient-side medical equipment such as ultrasound machines can easily become contaminated with various pathogens[27] from direct contact with patients, other contaminated items, and hands of veterinary personnel. Specific recommendations are difficult to provide because of the variability in equipment surfaces. However, some basic concepts apply to all.

1. Prevention of contamination: While it is impossible to prevent all contamination, the incidence and degree of contamination can be limited by reducing direct patient contact with equipment as much as possible, using personal protective equipment (e.g., gloves) as indicated and using barriers (e.g., plastic sleeves) for high-risk (or all) cases. For patients that might be harboring a pathogen of particular concern, consideration should be given to whether the procedure is truly needed. Infection control concerns would rarely preclude performing a required diagnostic test, but if a test is not thought to be important, consideration should be given to cancelling or postponing the procedure, particularly if the item cannot be adequately disinfected.
2. Cleaning: Wiping to remove visible debris will greatly reduce any pathogen burden.
3. Disinfection: Specific disinfection approaches will vary with the surface material and characteristics, but wiping with a broadly efficacious environmental disinfect is usually practical and likely effective. Consideration must be given to sensitive equipment (e.g., ultrasound probe heads) and manufacturer guidelines should be consulted with respect to compatibility with different disinfectants.

Ophthalmoscopes and Other Handheld Instruments

Handheld equipment such as ophthalmoscopes and otoscopes are frequently touched and may be infrequently cleaned.[5] The role of these in pathogen transmission is completely unclear and probably limited; however, routine cleaning and disinfection of these (like any common hand contact surface) is indicated. There are no objective guidelines for frequency of cleaning and disinfection, but incorporating these items into a regular (e.g., weekly) schedule is logical, with additional cleaning and disinfection done on an as-needed basis after use on a potentially infectious patient. No disinfection efficacy studies are available, but removal of visible debris followed by wiping with disinfectant is practical. Some items may be more difficult to disinfect based on their design (e.g., many crevices) or surface materials, and those factors (and material compatibility) must be considered when choosing an approach to disinfection.

Clippers and Clipper Blades

As with any item used on multiple patients, clippers and clipper blades pose a potential but unquantified risk. Clippers and blades can be contaminated with the patient's skin microbiota, pathogens from other body sites, environmental bacteria, and opportunistic pathogens from human hands.[28] Risks increase when clippers are used on patients that are more likely to be shedding or contaminated with pathogens (e.g., infected wounds, pyoderma) and in patients or situations where there is an increased risk of disease (e.g., patients with wounds or those that are immunocompromised).

There has been no objective study of methods to disinfect clippers. In most situations, routine disinfection could involve cleaning to remove debris followed by spraying the clipper surface with a good quality environmental disinfectant. If there is concern about contamination with a highly transmissible or otherwise very concerning infectious agent, a more reliable method such as ETO gas or H_2O_2 vapor sterilization could be considered, although data about potential damage to clippers is lacking. Wiping or spraying clippers blades is not likely to be effective. Blades would have to be disassembled to provide adequate contact with disinfectant over the entire surface. Autoclaving blades is a more reliable approach, but requires an adequate supply of clipper blades to ensure that new blades are available whenever contamination may have occurred. Damage to blades from autoclaving is also a concern.

Computer Keyboard and Mouse

These items typically have abundant hand contact and can be contaminated with high microbial burdens.[29–33] With increasing use of electronic medical record systems, greater contact with computers during the course of patient care will increase contamination. Various approaches can be used to reduce the risk and implications of contamination. These include practices to prevent contamination (e.g., hand hygiene prior to using computers, use of keyboard covers) and those to reduce contamination (e.g., wiping with disinfectant wipes).

Phones

Personal or clinic-provided phones are almost ubiquitous in veterinary practice. Given frequent hand contact, contamination of phones and similar small electronic devices (e.g., pagers) is unsurprising and has been well described in both human and veterinary medicine.[34–39] Optimizing phone handling through ensuring hand hygiene is performed prior to phone contact is ideal, but good compliance is unlikely given the high incidence of phone use and the almost-reflexive answering of phones. Education to maximize hand hygiene prior to phone contact is still warranted. Routine disinfection of phones is indicated, although methods that are both effective and nondamaging are not well investigated. Using waterproof phone cases facilitates wiping and spraying with disinfectants, and should be encouraged.

MONITORING EFFICACY OF CLEANING AND DISINFECTION

Bacterial Culture

Routine bacterial culture of the general environment and routine nonsterile items is not recommended.[40] These types of items are not supposed to be sterile, and the relevance of "positive" bacterial cultures is questionable. Finding an opportunistic pathogen on an instrument might mean that it evaded cleaning and disinfection, no attempt was made to clean and disinfect, or that it was contaminated after successful cleaning and disinfection. If those cannot be differentiated, an effective response to the culture result is impossible to develop. Culture should be reserved for targeted situations where a clear action would result from positive versus negative cultures. This could be as part of an outbreak investigation, although environmental cultures are only useful in a small percentage of investigations. Culture could also be used as an educational tool to assess residual contamination after disinfection, but the information that is obtained is limited; there are better tools to assess routine cleaning (see fluorescent tagging below) and post-disinfection environmental cultures are best performed using

Fig. 14.2 Fluorescent tagging indicating lack of cleaning of the space bar of a computer keyboard.

specific laboratory methods that are not available from most diagnostic laboratories.

Fluorescent Tagging

Fluorescent tagging is a cost-effective and easy method for assessment of cleaning, but not disinfection. It involves application of a fluorescent dye that is not visible to the naked eye to various surfaces in a facility.[41] The dye is visible with ultraviolet light, and the "contaminated" sites can be assessed after a predetermined period of time to see if the dye has been removed, an indication of adequate cleaning (Fig. 14.2). When compared with culture, this can be done at very little cost and provide immediate information. Fluorescent tagging can be useful for periodic assessment as well as staff education.

Direct Observation

While typically unstructured and subjective, direct observation of cleaning and disinfection practices can be useful in a veterinary hospital. If done discretely, it allows for assessment of normal activities and potentially identification of gaps in protocols or practices. This can be done by clinicians with little effort, simply by paying attention to cleaning and disinfection practices that are regularly occurring during the course of a day. A more structured approach can be undertaken whereby specific practices or individuals are purposively monitored. However, this is more time consuming and if indiscrete, it can result in bias due to "the Hawthorne effect" (a change in behavior when the observer knows he/she is being observed). In situations where there are specific concerns about a practice or individual, this can be an effective approach. Remote observation can be performed using webcams[42,43] or closed circuit video, but data analysis can be very time consuming and associated with personnel and privacy concerns.

ATP Bioluminescence

More widely used in food production, ATP bioluminescence testing detects adenosine 5′-triphosphate (ATP), which is an excellent indicator of the presence of viable microbes. Various rapid, handheld systems are available to detect and quantify the bacterial burden on an environmental surface. While such testing has been used in healthcare situations,[44] the relevance of test results is currently unknown. As discussed above, general surfaces are not supposed to be sterile, and ATP bioluminescence does not differentiate between potential pathogens and harmless commensals. Readings can also be influenced by various chemicals,[45] some of which might be present on surfaces in a clinic. Currently, it is unclear how (or if) this technology could be applied in veterinary hospitals for infection control purposes.

Prevention of Infectious Diseases in Hospital Environments

Brandy A. Burgess, J. Scott Weese

KEY POINTS

- Healthcare-associated infections (HAIs) increase morbidity, mortality, duration of hospitalization, and cost of care.
- The aim of a hospital infection control program is to reduce the incidence of HAIs in patients, staff, and visitors to a veterinary hospital, and consists of infectious disease control personnel, a written protocol, training, and documentation.
- This chapter describes the key components of an infection control program, which describes practices that minimize transmission of infectious agents such as hand washing, use of protective clothing, cleaning and disinfection, antimicrobial stewardship, appropriate disposal of infectious agents, control of vectors and pests, and surveillance efforts. The protocol can also be used to educate staff about specific transmission precautions for infectious diseases seen within a practice.
- Details on sterilization, disinfection, and antisepsis are covered in Chapter 14.

INTRODUCTION

Optimal patient care cannot be realized without effectively managing risks related to healthcare-associated infections (HAIs).[1] It is well recognized in human healthcare that HAIs result in increased morbidity and mortality as well as increased hospitalization stays among affected patients, and can significantly increase the cost of care.[2] In 2002, there were approximately 4.5 HAIs per 100 human hospital admissions in the United States—accounting for an estimated 5.8% of deaths—representing one of the top 10 causes of deaths in the United States.[3] In human medicine, the Study on the Efficacy of Nosocomial Infection Control (SENIC), conducted in US healthcare facilities (1970–1976) demonstrated that HAI rates could be reduced by as much as 32% if hospitals employed trained infection control personnel, conducted some sort of surveillance, and had a system for reporting results back to stakeholders.[4] While we do not have equivalent data in support of our efforts in veterinary infection control, it is not unreasonable to assume a similar impact on infection rates when these practices are employed.

In veterinary medicine, we are just beginning to gain some perspective on the occurrence of HAIs among patients. Historically, much of the focus has been on epidemic disease as the majority of veterinary teaching hospitals (VTHs) regularly recognize outbreaks of HAIs among patients.[5] These disease epidemics tend to garner attention when they have significant impacts on patient morbidity and mortality.[6] Despite this, it is important to monitor endemic (i.e., baseline) rates of HAIs—the occurrence of which likely impacts a greater number of patients. That being said, data on endemic rates of HAIs among veterinary patients are limited. A single study, using syndromic surveillance, estimated that the endemic rate of HAIs in critical care units at small animal referral hospitals was 16.3% of dogs (95% confidence interval [CI] 14.3–18.5) and 12% of cats (95% CI 9.3–15.5).[7] This study focused on the occurrence of seven different syndromes in critical care patients including intravenous catheter site inflammation, urinary tract inflammation, acute respiratory disorders, gastrointestinal disorders, surgical site inflammation, fever of unknown origin, and bacteremia. It is important to keep in mind that critical care patients are likely to be more susceptible to the development of an HAI due to severe compromise and the invasive nature of their care, and so the rate would be expected to be lower in the general patient population.

Throughout this chapter, the term *infection control* will be used to encompass all practices intended to prevent the introduction and spread of infectious agents within a population. While traditionally, biosecurity (preventing the introduction of an agent into a population) and biocontainment (controlling the spread of an infectious agent after introduction into a population) are different, it is somewhat difficult to make this distinction in a veterinary hospital. By their very nature, clinics treat sick animals that are likely to introduce infectious agents into the hospital population. Therein lies the importance of incorporating infection control strategies into the daily practice of veterinary medicine.

Ethics of Infectious Disease Prevention

As veterinarians, we have ethical obligations laid before us by our oath to protect the individual patient (*relief of animal suffering*), protect the animal population of the present and the future (*protection of animal health and welfare*), and protect people (*promotion of public health*).[8] Incorporation of infection control strategies into the practice of medicine is critical if we are to address these interwoven responsibilities. Although veterinary infection control is in its infancy, there is an emerging minimum standard recognized in veterinary medicine—we must give due effort to infection control—no matter if we are practicing in a hospital, in a shelter, or caring for an individual or population of animals.[9]

Veterinarian's Role in Infectious Disease Prevention

Taking all reasonable precautions to reduce the foreseeable risks associated with infectious disease transmission among personnel and patients, i.e., infection control, is fundamental to provision of excellent patient care. While the majority of VTHs have formalized infection control programs, decidedly fewer small animal hospitals report

having formalized programs.[5,10,11] Infection prevention and control recommendations have been developed by the Canadian Committee on Antibiotic Resistance (CCAR).[12] This guidance document provides specific recommendations for the development of a comprehensive program focusing on recognized best practices for small animal veterinary clinics. The National Association of State and Public Health Veterinarians (NASPHV) has also developed a "model infection control plan for veterinary practices." However, it provides few details and is very limited in scope, focusing mostly on zoonotic disease prevention, an important component of a comprehensive program.[13]

In the United States, veterinarians have both a legal obligation to "furnish to each of his employees employment and a place of employment which are free from recognized hazards that are causing or are likely to cause death or serious physical harm to his employees" [The General Duty Clause of the Occupational Safety and Health Act of 1970, 29 U.S.C. § 654 Sec.5,],[14] as well as a clear responsibility to recommend measures to reduce the risk of zoonotic pathogen transmission and counsel clients and personnel to seek medical attention in the event of zoonotic pathogen exposure.[15] Regulations may vary in other countries, but the essence remains the same. While this is a responsibility that is shared with human physicians, the reality is that neither rarely engages the other in such discussions[16] and understanding of zoonotic disease risks and animal-related infection control measures by physicians tends to be limited. Interestingly, research shows that while physicians believe it to be the responsibility of public health officials and veterinarians, veterinarians believe it to be the responsibility of physicians and public health officials.[17] This often leads to significant gaps, as both relevant groups assume the other is taking the responsibility.

Level of Infectious Disease Prevention

The minimum level of infectious disease prevention is unique to each facility, taking into account the patient population, level of disease risk, the risk aversion of facility stakeholders, and the standards set by the rules and regulations of the state's board of veterinary medicine. Thus, while there are core principles, specific practices within a program will vary.[9]

Disease risk and risk aversion may change over time. Thus, programs must be dynamic and rely upon organized surveillance efforts that provide data upon which to base decisions.[9] For example, during a regional outbreak of canine influenza, it may be prudent to implement additional precautions when caring for dogs with signs of upper respiratory tract disease or those with a travel history to affected regions. Rules and regulations of the region in which the practice is located establish, in part, the minimum standard of practice. For example, the State of Colorado veterinary medicine rules and regulations state that "all veterinarians must maintain a sanitary environment in which they care for patients…they are responsible for ensuring that their work is done in a clean environment and within the standard of care".[18] While this is somewhat vague, there is a clear implication that infection control is an important component in the practice of quality veterinary care. The NASPHV has developed the "compendium of veterinary standard precautions for zoonotic disease prevention in veterinary personnel" which can serve as a valuable resource when determining the level of infectious disease prevention practiced on a daily basis.[19]

Importance of Infectious Disease Prevention

HAIs are commonly linked with outbreaks of disease among hospitalized patients, and zoonotic infections are commonly identified as important occupational hazards among personnel.[5] While outbreaks receive the most attention, the occurrence of endemic disease likely has an impact on a greater number of patients. Infection control programs should be designed with the intention of protecting personnel, patients, and the hospital from foreseeable risks—preventing endemic disease from becoming epidemic disease. In so doing, we can create an environment for the delivery of optimal patient care. Infectious disease prevention in the hospital environment involves protection of: (1) personnel; (2) patients; and (3) the hospital.

1. *Protect personnel*: Veterinarians are occupationally at risk for development of zoonotic infections when compared with members of the general public (i.e., individuals not working with animals).[20] Approximately 61% of > 1,400 human pathogens are considered to be zoonotic, as are an estimated 75% of emerging infectious agents.[21] Veterinarians are exposed to zoonotic pathogens on a daily basis and may be among the first individuals exposed to emerging pathogens. A case example—the majority of zoonotic infections during the 2003 prairie dog-associated monkeypox virus outbreak in Wisconsin (the first reported outbreak outside of Africa) occurred in veterinary staff, who were found to be inconsistently using personal protective equipment (PPE).[22] With this in mind, it is critical to ensure that minimum preventive measures are being used in daily practice. The veterinary standard precautions as outlined by NASPHV is a good reference upon which to base a practice's minimum expectations and standards with respect to the prevention of disease transmission.[19]
2. *Protect patients:* Hospitalization comes with the inherent risk of HAI. Not all infections are preventable—even in hospitals that practice excellent infection control. By their very nature, hospitals congregate many patients from many different households and geographic locations, in various states of immune compromise, many of which may receive invasive treatments or immunosuppressive therapies. This creates a situation where not only are these patients at an increased risk from potential pathogens derived from their own resident flora, but are also at an increased risk for transmission of potential pathogens among patients and personnel. Despite the majority of VTHs accredited by the American Veterinary Medical Association (AVMA) reportedly having a formalized infection control program, 82% have still identified outbreaks of HAIs in a 5-year time span.[5] This undoubtedly represents the tip of the iceberg, as it is likely that endemic rates are higher and impact a greater number of patients. A formalized infection control program should not simply promote the use of recognized best practices, but should strive to educate personnel on the purpose of the program—in other words, the "why"—to encourage program compliance and preventing the endemic from becoming the epidemic.
3. *Protect the hospital:* Infectious disease prevention programs aim to mitigate the baseline transmission risk to prevent its escalation to epidemic levels. We can calculate the direct costs associated with these efforts, both in supplies and personnel time, but it is difficult to truly know the cost of an averted outbreak. Although hospital outbreaks are not uncommon, the costs associated with such an event typically go unreported. Many VTHs report restricting patient admissions (58% of those surveyed) or closing part of the facility (32% of those surveyed) to aid in mitigation efforts.[5] One VTH reported a financial loss of US$4.12 million associated with an outbreak of *Salmonella enterica* serovar Newport that resulted in a partial facility closure.[6] While it is relatively simple to quantify direct losses (i.e., hard costs), indirect losses related to client confidence, emotional stress, lost teaching opportunities, diminished morale of hospital personnel, and poor public relations are more difficult to enumerate. With this in mind, the upfront investment in education and prevention program development and maintenance are essential. While all infectious disease transmission cannot be prevented, strategies can be employed that reduce the baseline transmission risk to an acceptable endemic level.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial stewardship is fundamental to the veterinarians' role in providing optimal patient care as well as safeguarding public health. As antimicrobial resistance (AMR) becomes an increasing animal health concern and use of antimicrobials in animals attracts escalating scrutiny, the need to effectively and logically use antimicrobials is paramount. While emergence of AMR is an inherent risk of antimicrobial use, an array of measures can be implemented to reduce and improve antimicrobial use, ideally with benefits to the patient and the population (both human and animal). The intent of an antimicrobial stewardship program is to improve patient outcomes while minimizing unintended consequences through coordinated efforts advocating the appropriate use (selection, dosing, route, and duration) of antimicrobials. Antimicrobial stewardship is in its infancy in veterinary medicine, with informal use of many strategies but few organized and comprehensive antimicrobial stewardship programs.

AMR can affect the ability to treat individual patients as well as control infectious diseases in animal populations. Many HAIs can be attributed to bacteria resistant to antimicrobials (e.g., *Escherichia coli, Enterococcus* spp., *Acinetobacter baumannii, Staphylococcus pseudintermedius, and Staphylococcus aureus)*.[23–25]

Controlling the emergence of AMR involves both the prevention of selection of resistant microorganisms (i.e., antimicrobial stewardship) and prevention of the spread of resistant organisms (i.e., infection control programs).[26,27] AMR can evolve through the accumulation of chromosomal mutations or the transfer of resistance genes between bacteria from different taxonomic and ecologic groups through mobile genetic elements (e.g., plasmids, transposons, or bacteriophages). Acquired resistance genes can confer resistance to a single antimicrobial, a single antimicrobial class, or a broad group of antimicrobials. Theoretically, all uses of antimicrobial drugs have the potential to select for resistant bacterial populations by providing a survival advantage for resistant bacteria. Genes associated with AMR to one antimicrobial can be linked to resistance genes against other antimicrobials as well as to disinfectants, thereby promoting the development of multidrug-resistant strains that may be more difficult to treat and eliminate from the hospital environment.[28–30]

Risk factors for the emergence of resistance in companion animals are poorly understood. In addition to volume of antimicrobial drug use, other factors likely play a role, including inappropriate dosing regimens (sub-therapeutic dosing, inadequate or excessive duration of therapy) and poor client compliance. There is increasing evidence that AMR in humans may affect pets, and as antimicrobial-resistant pathogens increase in the human population, exposure of pets may be inevitable. This is perhaps best demonstrated with methicillin-resistant *S. aureus* (MRSA)[31,32] but is also a concern with other pathogens such as enterococci and Enterobacterales.

Antimicrobials should be used judiciously.[33] Judicious use implies careful consideration before use and should incorporate the use of adequate doses at correct intervals for appropriate clinical indications, selection of narrow-spectrum antimicrobials specific for the isolated organisms (ideally based on antimicrobial susceptibility testing), selection of antimicrobials against which the isolated organisms are not prone to develop resistance, switching antimicrobials following failure of empiric therapy only after an effective treatment period, restriction of indiscriminate use of antimicrobial drugs (i.e., limit use to ill or at-risk animals and treat only as long as needed to achieve clinical response), and use of topical or local rather than systemic therapy whenever possible.[33]

Antimicrobial stewardship programs apply strategies based on local antimicrobial use and resistance patterns (i.e., facility and/or regionally specific) to reduce and improve use of antimicrobial drugs (Table 15.1). Antimicrobial drugs should be used when there is a reasonable expectation of favorably impacting patient outcomes,[34] and consideration should be given to controlling disease without their use. Not all infections are bacterial in nature, and not all bacterial infections require systemic antimicrobial therapy. Local therapy such as incision and drainage, and the use of local biocides or antimicrobials may be appropriate in some situations. The client's money should be invested in a proper work-up because: (1) early diagnostic intervention to detect diseases that can cause signs suggestive of bacterial infections (e.g., viral infections, immune-mediated or inflammatory conditions, or neoplasia) can eliminate the need for empirical use of antimicrobial drugs,[34] and (2) bacterial infection is almost always secondary to an underlying cause, and resolution of the underlying condition can result in the elimination of secondary bacterial infections without the use of antimicrobial drugs. In addition, failure to resolve the underlying cause only leads to recurrence of bacterial infection after antimicrobial drug therapy is discontinued. Voluntary restrictions on use can be an important component of a stewardship program; however, specific criteria must be provided to guide the "appropriate" use of antimicrobial drugs considered to be "critically important" to public health (e.g., carbapenems). The World Health Organization (WHO) has defined "critically important" antimicrobial drug classes to be classes that: (1) are the only, or are one of limited therapies, to treat serious bacterial infections in humans, and (2) are used to treat infections in people caused by bacteria transmitted from or that may acquire resistance genes from non-human sources.[35] For example, criteria that may need to be met prior to the use of restricted drugs may include: (1) that the infection must be documented based on clinical abnormalities and culture; (2) these drugs should be reserved for infections that are life threatening, not for subclinical infections; (3) resistance to all other reasonable options and susceptibility to the chosen antimicrobial must be documented; (4) infection must be potentially treatable; and (5) the clinician should contact the hospital expert (e.g., infectious disease control officer or a clinical microbiologist) to discuss antimicrobial susceptibility test results, determine whether there are any other viable options, and confirm that a restricted antimicrobial is necessary (see Table 15.1).

While antimicrobial stewardship programs can improve patient outcomes, they should not be relied upon as a primary prevention strategy. Inevitably, microorganisms will be exposed to antimicrobials in veterinary hospitals resulting in patient exposure to resistant bacteria in the hospital environment. Consequently, infection control precautions must be used to reduce the spread of resistant organisms from patient to patient and patients to personnel, and to reduce the likelihood of resistant bacteria becoming established in the hospital environment.

ROUTES OF TRANSMISSION

Transmission of microorganisms can occur via contact (direct or indirect), airborne transmission (aerosol or droplet formation), or be vector borne. Many preventive measures disrupt one or more of these routes of transmission. Transmission can occur among members of the same population (horizontal) or succeeding generations through genetic material (vertical). Spread of an agent to offspring by the placenta, during birth, or in milk is considered to be horizontal transmission. Not all infectious agents are transmissible. For example, systemic mycotic infections originate from soil rather than spreading between individuals.

Reservoirs and Carriers

The *reservoir* of an infectious microorganism is the natural habitat where the agent normally lives and multiplies. For example, *Leptospira*

TABLE 15.1 Key Aspects of an Antimicrobial Stewardship Program[129]

Program team members	Multidisciplinary team	• Infectious disease specialist • Clinical pharmacist with infectious disease training • Clinical microbiologist • Infection control expert • Hospital epidemiologist
Core strategies	Prospective surveillance, intervention, and feedback	• Audit and report use of specific drugs and patient outcomes to stakeholders (e.g., prescribers, administration)

	Antimicrobial restriction	• Restrict use of drugs considered to be "critically important" to public health[35] to approved indications by using:
		  • Formulary restriction, and/or
		  • Preauthorization with justification

	Education	• Provision of foundational knowledge can influence prescribing practices, increase compliance, and improve program buy-in • Combine in-service trainings and e-mail alerts with written guidelines and data from active surveillance (i.e., prospective surveillance and interventions)
Supplemental strategies	Guidelines and clinical pathways	• Evidence-based practice guidelines based on local microbiology and resistance patterns • Implementation should be incorporated with education and reporting use and patient outcomes
	Streamlining and de-escalation of therapy	• Discontinue empirical therapy based on clinical response or culture results, reconsider treatment after 48 hours • Eliminate redundant combination therapy
	Automatic stop orders	• Evidence-based discontinuation of therapy to limit therapy duration (e.g., perioperative prophylaxis automatically discontinued at 2 days unless justification provided for extended therapy)
	Dose optimization	• Base dosing on patient characteristics, causative organism, site of infection, and pharmacokinetics of the antimicrobial drug
	Clinical decision-making computerized support system	• Provide local epidemiological information and its potential impact on courses of therapy • Provide warnings regarding intended therapy based on guidelines and local patterns
Microbiology laboratory	Pathogen identification and susceptibility testing	• Timely and accurate microbial pathogen identification • Susceptibility testing based on Clinical and Laboratory Standards Institute (CLSI) Guidelines • Prioritization of tested antimicrobials • Selective reporting of susceptibility profiles
Determining program impact	Process measures	• Did intervention change antimicrobial use?
	Outcome measures	• Did intervention reduce adverse outcomes (e.g., antimicrobial resistance, adverse drug events)?

(Derived from Dellit TH, Owens RC, McGowan JE Jr, et al. Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America guidelines for developing an institutional program to enhance antimicrobial stewardship. *Clin Infect Dis.* 2007;44:159–177.)

and systemic mycotic agents such as *Histoplasma* and *Cryptococcus* can survive in inanimate reservoirs such as soil and water. Alternatively, agents may exist in animate reservoirs known as *carriers*. Carriers can be clinically or subclinically infected, or they may be latently infected, shedding organisms intermittently in association with reactivation of an infection.

Contact Transmission

Contact transmission can be direct or indirect (vehicle). *Direct contact transmission* involves direct physical contact or close proximity between the reservoir host and the susceptible individual. Venereal transmission of *Brucella canis* between dogs and bite transmission of FIV between cats are examples of direct contact transmission. Direct transmission can be prevented through the use of separation or barrier nursing precautions. *Indirect contact transmission or vehicle transmission* involves the transfer of infectious organisms from the reservoir or carrier to a susceptible host (i.e., animal or person) indirectly by animate or inanimate intermediates known as vehicles or fomites. Indirect transmission depends on the ability of an agent to survive environmental conditions. Common animate fomites are human hands, while common inanimate fomites include stethoscopes, thermometers, doorknobs, keyboards, food dishes, or cages. Canine and feline parvoviruses are often spread via fomites due to the relatively long period of environmental persistence of these viruses. Prevention of indirect transmission may include adherence to rigorous hand hygiene protocols, barrier nursing precautions, or the use of dedicated equipment for infectious disease cases.

Common-source transmission involves simultaneous exposure of a significant number of individuals within a population to a vehicle contaminated by an infectious agent. The vehicles of common-source infections are usually blood products, drugs, food, and water. An example would be a food-source outbreak of *Salmonella* gastroenteritis.

TABLE 15.2 Microorganism Susceptibility to Common Chemical Disinfectants[130]

Susceptibility	Microorganism	Effective Disinfectant Classes
Highly susceptible	Mycoplasmas	Acids, alcohols, aldehydes, alkalis, biguanides, halogens, peroxygens, phenols, QACs
Susceptible	Gram-positive vegetative bacteria	Alcohol, aldehydes, alkalis, biguanides, halogens, peroxygens, some phenols, QACs
	Enveloped viruses	
	Gram-negative vegetative bacteria	
	Fungal spores	Some alcohols, aldehydes, biguanides, halogens, peroxygens, some phenols, some QACs
Resistant	Nonenveloped viruses	Aldehydes, halogens, peroxygens
	Mycobacteria	Alcohol, aldehydes, some alkalis, halogens, some peroxygens, some phenols
Highly resistant	Bacterial endospores	Some acids, aldehydes, halogens (high concentration), peroxygens
	Protozoal oocysts	Ammonium hydroxide, halogens (high concentration), some phenols
Extremely resistant	Prions	Generally resistant to chemical disinfection, sodium hypochlorite (high concentration)

Acids: hydrochloric acid, acetic acid, citric acid; alcohols: ethyl alcohol, isopropyl alcohol; aldehydes: formaldehyde, paraformaldehyde, glutaraldehyde; alkalis: sodium hydroxide, ammonium hydroxide, sodium carbonate; biguanides: chlorhexidine, novalsan, hibistat; halogens: hypochlorite, iodine; peroxygens: hydrogen peroxide, peroxyacetic acid, Virkon, Accel, Rescue; phenolics: TekTrol; quaternary ammonium compounds (QACs): Lysol, Roccal.

Airborne Transmission

Airborne transmission may occur via aerosol transmission or droplet transmission. Respiratory pathogens such as canine influenza virus and *Histoplasma* spp. are commonly spread by this means. *Aerosol transmission* is the spread of very small airborne particles (generally < 100 μm in diameter). Freshly aerosolized particles rarely remain airborne for more than 1 minute unless they are smaller than 5 μm in diameter, at which point they can remain airborne for some time and even travel relatively long distances.[36] Droplet nuclei, which are desiccated aerosolized particles 1–10 μm in diameter, can also be carried alone or on dust particles by air currents for extended periods and distances.[37] Prevention of aerosol transmission often requires isolating the infected animal in its own air space, or at a minimum maintenance of significant separation between patients.

Droplet transmission occurs with larger particles generated during coughing and sneezing or during diagnostic procedures such as draining an abscess, wound irrigation, or performing endoscopy. Droplets generally do not remain airborne for long and typically only travel short distances from the source. Droplets from respiratory, fecal, or genitourinary secretions of dogs and cats generally do not travel farther than 4 or 5 feet unless there are wind currents or particularly forceful coughing, sneezing, or splashing. Separation of patients, use of barrier nursing precautions, and performance of procedures in low-traffic areas can prevent droplet transmission.

Vector-Borne Transmission

Vector-borne transmission involves transmission of infectious agents via invertebrate animals such as flies, fleas, ticks, and mosquitoes. Vectors can transmit through mechanical or biologic means, depending on the infectious agent's ability to multiply or propagate while being carried either externally or internally by the vector. *Mechanical vectors* carry the agent without agent multiplication or propagation. For example, vectors such as flies may transfer organisms externally on their feet or internally within their intestinal tracts. *Biologic vectors* carry an agent that multiplies within the vector before transmission. For example, transmission of the plague bacillus, *Yersinia pestis,* by fleas occurs in this manner. True biologic (developmental or cyclopropagative) transmission by arthropod vectors involves an obligate developmental stage in the life cycle of the vector. Some protozoal pathogens (e.g., *Leishmania*, *Hepatozoon* and *Trypanosoma*) have a developmental life cycle in a vector.

Within a vector, agents can be transmitted transovarially (to successive generations of the vector, e.g., *Rickettsia rickettsii*) or transstadially (during molting from one vector stage to the next, e.g., *Anaplasma phagocytophilum*).

Implementation of vector control programs can reduce vector-borne transmission. Patients should be examined for external parasites and, if found, should be treated to reduce the risk of transmission. If other health concerns preclude treatment, these patients should be segregated from the general hospital population and provided with dedicated grooming equipment.

PREVENTATIVE MEASURES

Cleaning, Disinfection, and Sterilization

Cleaning, sanitation, disinfection, and sterilization are discussed in Chapter 14. Vegetative bacteria are relatively susceptible to most disinfectants; however, resistance to specific disinfectants can be present in certain microorganisms, either inherently or through acquisition of resistance genes. Enveloped viruses are quite susceptible to disinfectants; however, nonenveloped viruses tend to be resistant. Protozoal cysts, mycobacteria, and bacterial spores are highly resistant to disinfection and sanitation (Table 15.2). Prions, the proteinaceous agents that cause transmissible degenerative (spongiform) encephalopathies, are the most resistant infectious agents known.

Hospital Attire

Historically, the "white coat" has symbolized expertise and professionalism. However, white coats also serve to protect the clinician from contaminating their daily attire that may be worn from their homes to work and back again. White coats and neck ties are commonly identified as potential fomites with upwards of 60% of human hospital staff uniforms found to be colonized with potential pathogenic bacteria,[38] including MRSA, on up to 16% of white coats and 32% of neck ties tested.[39] Consequently, attire policies are commonly included in hospital infectious disease prevention programs.

TABLE 15.3 Indications for Hand Hygiene in Veterinary Practice

Hand Washing and Disinfection	Wearing of Latex Gloves
1. At times of arrival or leaving hospital	1. Before wound management
2. Before and after every patient contact	2. Before performing surgical or endoscopic procedures
3. After touching surfaces or objects likely to be contaminated	3. Before placing indwelling catheter
4. After handling patients likely to be colonized with resistant organisms	4. Before handling particularly susceptible patients (e.g., immune compromised, indwelling tubes/catheters)
5. Before preparing food or medications for patients	5. Before handling potential infectious patients
6. After removing gloves	6. Before handling disinfectants
7. After contact with body fluids	7. Handling of patients if you are immune compromised
8. After personal functions (e.g., smoking, sneezing, coughing, nose blowing, use of restroom)	

Hospital Attire in Nonsurgical Areas

Daily attire for hospital personnel in nonsurgical areas should strike a balance between professional appearance with the potential role clothing may play in pathogen transmission. Personnel should be encouraged to wear dedicated hospital attire (clothing and footwear) that is not worn outside of the clinic environment to prevent transportation of pathogens to and from locations outside the hospital. For all hospital personnel, footwear must be safe, protective (i.e., closed-toe), and cleanable (i.e., constructed of a nonporous material). Standard protective outerwear (e.g., white coat) should be neat and clean, with an adequate supply on hand to allow personnel to change at least daily and whenever outerwear becomes contaminated.

Hospital Attire in Surgical Areas

Dedicated attire for hospital personnel in surgical areas is intended to decrease patient exposure to potential pathogens and reduce the risk for surgical site infections. Typically, surgical attire includes scrubs, gowns, caps, masks, gloves, and dedicated footwear/footwear covers. While there are limited data to support these practices, dedicated surgical area footwear has been shown to significantly lower the level of contamination as compared with outdoor footwear,[40] and wearing a cover-gown when leaving the surgical area has been shown to greatly reduce bacterial contamination on surgical scrubs.[41] While the clinical implications of this finding are as yet unrealized, personnel should be encouraged to use either dedicated footwear or shoe covers when in surgical areas, and to wear a cover-gown upon leaving a surgical area or to don clean surgical scrubs prior to re-entry.

Healthcare Laundry

Healthcare laundry is a potential fomite and may include an assorted inventory of textiles such as scrubs and lab coats, surgical towels and drapes, and cage blankets and towels. The goal is to achieve hygienically clean laundry (i.e., laundered items pose a negligible transmission risk to patients and personnel).[42] Laundering reduces microbial contamination through mechanical, thermal, and chemical means. It begins by collecting point-of-use items and, with minimal handling, transportation to a central laundry area. Healthcare laundry may be laundered on-site or sent to a commercial laundry service. If managed on-site, visible debris should be removed before washing. Washing should begin with a rinse, a wash cycle with laundry chemicals and additives, followed by a clean water rinse. Washing with detergent and water temperature of 71.6°F (22°C) achieves a 3 log reduction of microorganisms per cm^2, whereas washing in water temperature of 160°F (71°C) achieves a 5 log reduction.[42] An additional 2 log reduction can be expected with a hot dryer or ironing.[42] Laundered items should be stored to ensure they are not contaminated before use.

Personnel should be encouraged to use dedicated hospital attire that is not worn outside of the hospital environment. Facilities are encouraged to provide a laundry service (on-site or a commercial laundry service) for hospital attire, in particular scrubs and lab coats, to reduce the risk this may pose to the household when taking these items home for laundering. Attire that is taken home for laundering should be transported in a sealed bag and laundered immediately. Personnel should take care to not contaminate themselves or the home environment and practice rigorous hand hygiene after handling contaminated laundry.

Hand Hygiene

One of the most important infection control measures is proper hand hygiene.[19,43–46] Hand contamination increases over time while attending to patients without gloving.[47,48] Use of soap and water or alcohol-based hand sanitizers is critically important to reduce the likelihood for transmission. Hand hygiene should be performed before and after each patient contact and before touching other surfaces or supplies (Table 15.3).

Hand Washing

The mechanical action of hand washing reduces the organic debris and transient microorganisms on the skin, and, with the addition of antimicrobial soap, may inactivate or inhibit the growth of microorganisms (Table 15.4).[19,49] Hand washing should be performed using a biocide-containing hand soap before and after every patient contact, after handling blood or other body fluids, and after the removal of PPE including gloves. Bar soaps should not be used in a healthcare setting and soap containers should be discarded when empty to reduce the potential for creating a reservoir for biocide-resistant bacteria. Wall dispensers should be cleaned and disinfected before refilling. Because frequent hand washing can compromise skin integrity, which increases the risk for bacterial colonization as well as decrease compliance with hand hygiene protocols,[49,50] lotions and moisturizers should also be provided to promote healthy skin. Detailed information on proper hand hygiene is available from the Centers for Disease Control and Prevention (CDC).[45]

Alcohol-Based Hand Sanitizers

Alcohol-based hand sanitizers are a widely available, effective and practical alternative to traditional hand washing.[48] These have rapid and broad-spectrum activity with little risk of emerging resistance. In healthcare settings, the CDC recommends the use of hand sanitizers that contain 60%–95% ethyl or isopropyl alcohol.[51] While hand size impacts total hand coverage, application of 2 mL or 3 mL of product achieves 90% palm or dorsum coverage, respectively.[52] The use of soap and water, rather than an alcohol-based hand sanitizer, is recommended when there is gross contamination with organic debris or when exposure to alcohol-resistant pathogens such as clostridial spores or parvovirus might have occurred.[51] Alcohol-based products can be especially useful when skin is likely to become compromised

TABLE 15.4 Recommended Methods for Hand Hygiene

Method		Description
Hand washing	Removes dirt and some transient bacteria	• Cleaning hands with conventional soap and water
Antiseptic hand washing	Removes and kills transient and some resident bacteria	• Cleaning and disinfecting hands with combination soap and antiseptic solution • Technique: 1) Completely wet hands and wrists in running stream of warm water—keep hands lower than elbows to avoid recontamination 2) Apply soap-antiseptic combination over front and back of hands 3) Rub all surfaces of hands and wrists, interlace fingers, and lather for manufacturers recommended time (15–30 seconds) 4) Thoroughly rinse hands in clear running water 5) Dry hands thoroughly with disposable towel 6) Turn off faucets with towel
Hand sanitizer	Removes and kills transient and some resident bacteria ***Note:*** *Use products containing 60%–95% ethyl or isopropyl alcohol*[51]	• Place hand sanitizer in readily available locations (e.g., kennel side) 1) Dispense 2–3 mL onto hands 2) Rub all hand surfaces for 15 seconds 3) Let disinfectant dry thoroughly before handling objects **Note:** Not effective in the presence of organic debris or for alcohol-resistant pathogens (e.g., clostridial spores, parvovirus)

Hand hygiene in healthcare settings—Hand hygiene guidance[45]		https://www.cdc.gov/handhygiene/providers/guideline.html

due to frequent hand washing or when soap and water are unavailable. Although the cost of alcohol-based hand sanitation can be greater than cost of hand washing, it may bring improved compliance.[53]

Gloves

Glove use is intended to decrease pathogen transmission risk by providing a barrier to protect caregivers and patients. However, gloves are often misused in veterinary settings, potentially leading to greater contamination of people, patients, and the environment. In general, gloving should be considered an adjunct to, and not a replacement for, proper hand hygiene as glove failures are relatively common although typically unrecognized by the wearer.[54,55] Glove use is recommended when personnel expect to contact blood, body fluids, mucous membranes, or nonintact skin.[51] Gloves should be changed and not washed when moving from a contaminated to clean site on a single patient or moving between patients.[51] Additionally, gloves should be removed before touching other surfaces (e.g., countertops, keyboards, phones, or doorknobs) or accessing supplies (e.g., carts, bandage kits, cupboards, and supply rooms). Consideration should be given to double gloving when collecting samples from a patient in isolation or when glove contamination is expected. This will allow the removal of the outer, potentially contaminated, glove before labeling samples or removing PPE.

Hand Hygiene Compliance

While most veterinary personnel believe hand hygiene is important in the prevention of infectious disease transmission and zoonoses,[56,57] overall compliance can be low (14%–20% of hand hygiene opportunities) among small animal practitioners, with lower compliance before patient contacts (3% of opportunities) versus after patient contacts (26%) or between patient contacts (41%–48%).[56,58–60] Practitioner-reported obstacles to compliance include forgetfulness, damage to skin from frequent hand washing, being too busy, and a lack of available hand hygiene supplies.[57,60] There have been conflicting reports on the benefits of hand hygiene awareness campaigns. Signage may improve hand washing technique,[58] and incorporation of an educational component may improve compliance (see Table 15.3).[59]

Barrier Nursing Precautions

"Barrier nursing" precautions (i.e., the use of PPE) are widely used to minimize transmission and to reduce exposure of immunocompromised patients or personnel to potential pathogens. In veterinary settings, this usually includes the use of disposable gowns, gloves, facial protection, and implementation of footwear hygiene (i.e., footwear covers or use of footbaths or footmats). The intent is to create a barrier between "clean" and "dirty" to prevent the contamination of skin or underlying clothing with a potential pathogen from the patient or the environment.[61,62] Use of such precautions is not a panacea. A recent systematic review reported contamination rates from 25% to 100% irrespective of the type of PPE being used.[63] The effective implementation of barrier precautions not only requires a financial investment but an investment in time for proper donning and doffing of PPE and an investment in the education of personnel on the rationale for its use.

Barrier Gowns

Permeable gowns are typically used for general animal care, while impermeable gowns are recommended when splashes are expected (e.g., flushing wounds or draining abscesses). In general, disposable gowns should not be reused even on the same patient. If using washable (i.e., reusable) gowns, they should be appropriately laundered between uses. When donning and doffing gowns, the wearer must only touch the outside of the gown to limit cross-contamination.

Gloves

See the section in this chapter on hand hygiene.

Facial Protection

Face shields or glasses with a mask protect the mucous membranes of the eyes, nose, and mouth from potentially infectious materials. Consideration should be given to their use anytime there may be a splash or a spray hazard (e.g., when flushing wounds or draining abscesses).

Footwear Hygiene

Footwear hygiene includes the use of disposable footwear covers and/or disinfectant footbaths or footmats. Environmental contamination is commonly associated with outbreaks within veterinary hospitals.[64,65] Therefore, it is crucial that footwear be clean before moving to a new environment, either within the hospital or external to the hospital. Footwear should be easily cleaned and there may be additional requirements for safety (e.g., closed-toe shoes). When caring for patients in isolation or those who are immunocompromised, footwear should be able to be disinfected or dedicated to the care of an individual patient (see Footbaths/footmats).

Transmission-Based Precautions

Transmission-based precautions are instituted for patients with confirmed or suspected infections that are known to be transmitted via a particular route—airborne, droplet, or contact.[66]

Airborne precautions prevent the transmission of infectious agents by droplet nuclei. In human medicine, this typically involves isolation in a single-bed, negative-pressure room, barrier nursing precautions, and a high-density respirator (N95) mask. These masks resemble surgical masks but filter 1-μm particles with an efficiency of at least 95%, and must be properly fitted to the individual wearer by trained personnel. Airborne precautions are rarely necessary in hospitals that treat only dogs and cats, but should be considered for animals suspected to have pneumonic plague, tularemia, or a *Mycobacterium tuberculosis* infection.

Droplet precautions are used to prevent transmission by large-particle aerosols. This requires the use of barrier nursing precautions, but does not require a negative-pressure room. Droplet precautions apply to dogs and cats with transmissible respiratory disease. In human medicine, barrier precautions for droplet precautions include facial protection.

Contact precautions are indicated for animals with infections that can be transmitted by direct contact with the patient or through fomite contact (see Barrier Nursing Precautions).

Movement Restrictions, Separation, and Isolation

Managing the flow of traffic and restriction of movement (i.e., separation or isolation) of patients and personnel are important infection control strategies. Efforts should be made to minimize contact between infectious disease suspects and the general hospital population and to minimize their time spent in common areas (e.g., waiting areas or common service areas such as radiology). In general, the flow of patients and personnel should be from clean to dirty areas and from low to high pathogen risk areas. Separation and isolation strategies serve to limit environmental contamination and decrease the likelihood of contact between patients and personnel. The potential infectious disease status of all patients should be considered as early as possible—before arriving at the hospital, based on history, signalment or clinical signs, or during initial examination or hospitalization. The earlier that risks can be identified, the earlier the animal can be separated or isolated and the lower the risk to other patients and personnel. If it is known in advance that an animal with a suspected or known infectious disease is to be seen at the hospital, efforts should be made to admit the patient directly into an examination or isolation room, bypassing the waiting area. Special consideration should be given if a patient is from a shelter or breeding facility, as these are considered high-risk populations.

Separation

Separation is the establishment of hospital areas with differing levels of biosecurity. The degree of separation achieved is dictated by physical and operational limitations of the facility, and may be related to the species (e.g., dogs and cats), age (e.g., adult or neonate), severity of disease (e.g., critical care or elective surgery cases), or type of patient (i.e., inpatient vs. outpatient). Designated hospital areas may include critical care units and isolation units. Equipment and, possibly, personnel should ideally be dedicated to a particular hospital area for patient management. If movement of personnel or equipment is to occur, it should be governed by clearly defined infection control protocols (e.g., use of protective clothing, hand hygiene, and disinfection of equipment between areas).

Isolation

Isolation is a higher level of separation that not only limits contacts but also minimizes personnel and patient traffic in the area. Some facilities may incorporate video monitoring to ensure adequate observation while limiting high-risk contacts. Patients with suspected or confirmed transmissible infectious disease should be evaluated and managed in an area isolated from the main hospital population. In general, patients should be considered for separation and isolation if they have gastrointestinal disease (e.g., diarrhea or enteritis), acute respiratory disease (especially if febrile), abortion/fetal loss, neonatal death or disease, alopecic skin lesions that may represent dermatophytosis or sarcoptic mange, fever with or without other clinical signs, or acute onset neurologic disease. Whether a dedicated isolation facility or just contact precautions are used during hospitalization depends on the regional prevalence of transmissible infections in a specific practice area and the likelihood of one of those infections in the patient under evaluation.

At times, it may be necessary to use common hospital facilities or equipment (e.g., radiology, surgery, and endoscopy) for diagnostics or treatment of an infectious disease case or suspect. Proper communication in advance with veterinary team members located in these common areas about the risks is essential, and every effort should be made to use these areas at the end of the day, with thorough cleaning and disinfection immediately after use.

Footbaths and Footmats

The use of footbaths/footmats is a common strategy employed by VTHs, more so in large animal hospitals than in small animal hospitals.[67] Use of both footbaths and footmats can decrease bacterial counts on footwear.[67–69] However, efficacy depends on frequency of disinfectant replenishment, amount of organic debris on footwear and in the footbath/footmat, the type of disinfectant used, and compliance. Footmats and footbaths also serve as a visual indicator to personnel regarding the risk level of a particular area and may deter foot traffic. When footmats and footbaths are used, care should be taken to instruct personnel on proper use and to mitigate any slip hazard by providing a walk-off mat for surfaces that may become slippery when wet.

Environmental Infection Control

Environmental contamination is commonly associated with epidemic disease in large animal hospitals[6,64,65] and is increasingly recognized as a contributor to outbreaks in companion animal hospitals.[70,71] For some pathogens, the environment is a clear source of infection and a major contributor to disease (e.g., canine parvovirus), but for others, environmental transmission is mainly of concern in specific high-risk environments such as veterinary hospitals, kennels, or shelters (e.g., *Clostridioides difficile*).[70] With this in mind, environmental cleaning and disinfection is a cornerstone of an effective infection control program.

Cleaning and Disinfection

The simple act of scrubbing with a detergent can reduce bacterial load on a concrete surface by 90%.[73] When followed by the application of an appropriate disinfectant (i.e., class, concentration, and contact time),

this can be reduced by an additional 6%.[72] Cleaning should remove all visible organic debris (e.g., feces, urine, nasal exudate, and blood) from surfaces because this can render disinfectants less effective. Many bacteria form biofilms in the environment. These organized bacterial communities produce protective extracellular polymer matrices that promote surface adhesion and protect them from environmental insult (e.g., disinfectants). Environmental biofilms are a source of potential pathogens as well as AMR genes.[73–75] Scrubbing with detergent is required to break up and remove biofilms from cleanable surfaces.

Chemical disinfection is a chemical reaction that is affected by the presence of organic debris as well as conditions such as temperature and UV light (i.e., sunlight). Many commercial products are available for environmental disinfection. When selecting a product, it is important to be cognizant of the major classes of disinfectants, their activity against different pathogens, and conditions that may limit their effectiveness (see Table 14.1). The products used should be registered by governmental agencies such as the US Environmental Protection Agency (EPA), used at label-indicated concentrations and contact times, and all safety precautions recommended by the manufacturer should be followed.

Routine Cleaning and Disinfection

Routine cleaning and disinfection attempts to minimize the burden of potential pathogens in the environment to a level that is inconsequential. Facility-specific protocols should be developed, written down, reviewed at least annually, and made readily accessible to all personnel. Routine cleaning and disinfection should occur regularly in areas used to house and manage all patients—not just areas reserved for suspected or confirmed infectious diseases—as well as personnel areas. While patient examination and treatment areas should be cleaned between each patient, all areas should also have a general daily cleaning with attention to corners, under cabinets, handles, and faucets. Cracks and crevices should be repaired, and dirt floors and porous surfaces (e.g., untreated wood or unsealed concrete) should be avoided as these cannot be effectively disinfected. If porous surfaces cannot be replaced, they can be rendered less porous by painting or sealing the surface.

Enhanced Cleaning

Enhanced cleaning should be completed immediately after use in areas known to have housed patients with suspected or confirmed infectious disease. This may include use of a higher-order disinfectant (e.g., accelerated peroxygen), with attention paid to surfaces that may be easily contaminated but overlooked in general cleaning (e.g., cabinet handles, keyboards, and faucets). Equipment used on such patients should be handled in a manner that minimizes contamination of hospital surfaces and cleaning and disinfection should occur prior to reuse. Aerosol application of disinfectants with appropriate safety measures (including respiratory protection for personnel) can be used as an adjunct to traditional cleaning to manage difficult-to-reach areas such as overhead areas.[76–78]

Common Use Equipment

Level of Disinfection for Patient Care Equipment (Table 15.5).[79]

Critical patient care equipment includes items that may enter a sterile field or the vascular system (e.g., surgical instruments, implants, intravenous catheters). If contaminated, these items carry a high risk for infection. Critical items should either be purchased as sterile or they should be sterilized before use. *Semi-critical patient care equipment* includes items that may contact mucous membranes or nonintact skin (e.g., anesthesia equipment, bronchoscope). These items should have high-level disinfection with chemical disinfectants performed before reuse, with the goal to eliminate all microorganisms except bacterial spores. *Noncritical patient care equipment* includes items that may contact intact skin, but not mucous membranes (e.g., blood pressure cuff). These items should have intermediate- or low-level disinfection with chemical disinfectants performed before reuse, with the goal to eliminate vegetative bacteria and most fungi and viruses. Intermediate-level disinfection is used in the presence of organic debris, while low-level disinfection is typically used in its absence.

Surgical Instruments, Equipment, and Power Tools

While historically cold sterilization has been used in medicine, it should not be used for instrument or implant sterilization when steam or ethylene oxide sterilization is available. With cold sterilization, there is likely greater potential for contamination and incomplete sterilization,[79] and HAIs have also been reported in human medicine associated with reprocessing of reusable medical and surgical instruments.[80] Surgical power tools may present a significant challenge in decontamination. Often having intricate, structurally complex designs, they can accumulate tissue and proteinaceous material which may harbor potential pathogens and disrupt the cleaning and disinfection process.[81,82] All manufacturer decontamination recommendations should be followed to ensure proper sterilization before reuse.

Anesthesia and Nebulizer Equipment

Small animal breathing systems have a tendency to harbor environmental microorganisms of low pathogenicity.[83] Contamination is typically greater in proximal tubing than in more distal tubing and the number of bacteria decreases over time.[83] As such, for routine uses, sterilization is not considered to be necessary. At a minimum, tubing

TABLE 15.5 Recommended Levels of Microbial Disinfection[79]

Level	Expected Effect	When to Use
High	• Elimination of all viruses and vegetative bacteria • Elimination of most bacterial spores and fungi	• Critical patient care equipment (may enter sterile field or vascular system; e.g., surgical instruments, implants, intravenous catheters) • Semi-critical patient care equipment (contact with mucous membranes or nonintact skin; e.g., anesthesia equipment, bronchoscope)
Intermediate	• Elimination of all vegetative bacteria • Elimination of most viruses and fungi	• In the presence of organic debris • Noncritical patient care equipment (contact with intact skin, but not mucous membranes; e.g., blood pressure cuff)
Low	• Elimination of most vegetative bacteria, fungi, enveloped viruses • Equivalent to sanitation	• Used in absence of organic debris • Noncritical patient care equipment (contact with intact skin, but not mucous membranes; e.g., blood pressure cuff)

(Derived from Rutala WA, Weber DJ. Disinfection and sterilization: an overview. *Am J Infect Control.* 2013;41:S2–5.)

should be scrubbed with a detergent to disrupt biofilm and high-level disinfection should be used, as this equipment is considered to be semi-critical. Routine disinfection of breathing systems can be achieved by soaking equipment in an antiseptic (selected due to the potential for contact with mucous membranes) such as chlorhexidine (2% solution) for 15 to 30 minutes, or accelerated hydrogen peroxide, following by thorough rinsing.[84] For nebulizers and humidifiers, flushing hydrogen peroxide (20% by volume in water) through the system with periodic sterilization is recommended. Special consideration should be given to equipment used on patients with suspected or confirmed contagious agents that may require additional measures (i.e., sterilization) before reuse or require disposal.

Endoscopic Equipment

Endoscopic equipment is very complex and intricate, with narrow channels for aspiration, flushing, and equipment passage. As such, endoscopic equipment cannot be sterilized. However, they are semi-critical, so should undergo high-level disinfection. While equipment should be cleaned and disinfected per manufacturers recommendations, a six-step process has been recommended for endoscope reprocessing: (1) pre-cleaning with function control, (2) manual brush cleaning and leak test, (3) rinse, (4) disinfection, (5) final rinse and drying, and (6) safe storage to avoid contamination.[85] Proper cleaning, including use of a brush to scrub channels before disinfection is critical as incomplete cleaning can result in HAIs (e.g., *Pseudomonas*).[86] After cleaning, disinfection can be achieved by soaking in alkaline glutaraldehyde for 10 minutes followed by a sterile water rinse. There are also automated endoscope reprocessing systems that use performic acid,[87] hydrogen peroxide vapor, or other disinfectants. Disinfectants can be corrosive to metal parts and should be thoroughly rinsed from any equipment after the proper contact time has been achieved.

Other Diagnostic Equipment (e.g., Ultrasound, ECG)

While ideally, diagnostic equipment would be dedicated to a particular service or hospital area, this may be impractical due to cost (e.g., ultrasound). Therefore, protocols should be developed to ensure proper cleaning and disinfection before equipment is moved from patient to patient and between hospital areas. Manufacturers' recommendations should be followed when cleaning and disinfecting specialty equipment.

Animal Holding and Housing Areas

General principles of environmental disinfection apply to cage and run cleaning, with removal of organic debris, scrubbing with detergent, rinsing, use of an adequate disinfectant, and provision of an appropriate concentration and contact time as key determinants of success. If high-pressure washing is used (i.e., PSI > 80–100), care should be taken as microorganisms can aerosolize and may result in small surface defects that preclude effective cleaning and disinfection.

Animal Feeding Dishes and Water Bowls

Pet food and water dishes are a recognized reservoir for potential pathogens in the home environment and presumably also in the hospital environment.[88] These items should be properly cleaned and disinfected before reuse. Generally, the use of a dishwasher is preferred to manual washing as higher water temperatures can be achieved that will eliminate many microorganisms, with the exception of bacterial spores.

Waste Management

An important part of effective infection prevention is proper management of medical and infectious waste. The AVMA has published general guidelines to aid veterinary practices in developing waste management programs,[89] which also must be in compliance with federal, state, and local laws.[90] Of particular interest in the United States is the Federal Medical Waste Tracking Act of 1988 (MWTA) which is regulated by the EPA. This act applies to veterinary medical waste that is considered to be a public health hazard. According to the MWTA, waste generators are liable for medical waste from its creation to final disposal, irrespective of the use of a waste management company.

Definitions for medical and infectious waste are provided by state laws and regulations. These definitions typically include information regarding waste infectivity, waste categories (e.g., sharps, tubing, fecal waste), and which facilities are required to comply with these regulations.[89] It is recommended that veterinary hospitals separate medical and infectious waste as it is generated.[89] Medical and infectious waste may include items such as needles, bandages, or bedding contaminated by bodily excretions, such as blood, nasal exudates, urine, or feces, or by tissue removed during medical or surgical treatment. Care should be taken to deter patient access to waste containers, and efforts should be made to reduce the likelihood for vector transmission by insects, rodents, or clinic cats and dogs. Appropriate disposal methods, such as autoclaving and incineration, will depend upon the suspected or confirmed infectious agent as well as local regulations.

Outdoor Elimination or Exercise Areas

Grass and/or dirt exercise and elimination areas are impossible to decontaminate. If possible, outside areas should be designated for use based on the risk for shedding a potential pathogen (e.g., *Salmonella*, *Leptospira*) by creating dedicated space for use by generally healthy patients, immunocompromised patients, and patients with suspected or confirmed transmissible infections. Consideration should be given to installing an outdoor surface such as a concrete pad (heated if it is to be used in a cold climate) that can be cleaned and disinfected after use by a potentially infectious case. If use of a grass/dirt area is unavoidable, "cleaning" should involve removal of all feces, cutting the grass to facilitate sunlight penetration, and "resting" the area (i.e., allowing sufficient time for infectious agent to become inactivated) before use by other patients. Alternatively, dirt can be removed and replaced after use by an infectious disease case.

Handling of Sharps

Sharps handling practices receive considerable attention in human medicine because of the risk of transmission of blood-borne pathogens. Significant injury or illness can follow sharps injuries including transmission of infectious agents and allergic or inflammatory reactions from exposure to medications.

Needle and Sharps Injuries

Needle and sharps injuries are most commonly associated with handling of syringes (64%), suture needles (51%), and scalpel blades (35%).[91] Career estimates for needle stick injury incidence rates range from 83% among veterinarians to 78%–93% among veterinary technicians,[92,93] and annual estimates for needle stick injury incidence rates range from 44% among veterinarians to 46% among veterinary technicians.[92,93] Needle recapping is common in veterinary medicine,[94] and approximately one-third of veterinary personnel report doing so due to a lack of an appropriate container for disposal.[92]

Needle and Sharps Handling Practices

The Compendium of Veterinary Standard Precautions, developed by the NASPHV, recommends that all hospital personnel receive specific training regarding safe sharps handling and risks associated with the handling of sharps. In general, only trained personnel should restrain patients and

needles should not be bent prior to use. Needle caps should never be removed using your mouth and when uncapped, needles should not be passed to another individual nor carried throughout the clinic. If recapping a needle is necessary, the one-handed scoop method should be used—place the cap on a horizontal surface, and while holding a syringe with an attached needle in one hand, use the needle to scoop up the cap without using the other hand, securing the cap by pushing it on a hard surface.[19] To facilitate safe disposal of sharps, approved sharps containers should be placed in all areas used for patient management. To avoid sharps injuries (which can promote transmission of blood-borne zoonotic pathogens), forceps should be used to remove uncapped needles from syringes (or preferably dispose of as a unit) and also to remove scalpel blades from nondisposable scalpel handles (see Waste Management).

Control of Vectors and Rodents

Pest management should be an integrated program that utilizes pesticides, traps, and environmental controls to block access to buildings and create unfavorable environments for pest survival.[19] Environmental controls include sealing of access points, storage of food in sealed containers, elimination of rodent nesting sites, removal of standing water, installation of window screens, and the prompt disposal of waste. Both insects and rodents can serve as biologic or mechanical vectors for dissemination of pathogens. Flies have been shown to carry *Salmonella* as mechanical vectors.[95–97] Clinic cats or dogs can serve as biologic or mechanical vectors for infectious agents as well as be a source of antimicrobial-resistant bacteria.[98,99] Use of a pest control company is strongly encouraged to develop an integrated pest control program that is facility specific.

MONITORING INFECTION CONTROL PROGRAM EFFECTIVENESS

Assessment of an infection control program's efficacy is integral to program effectiveness and promotes compliance. Because infectious diseases emerge and re-emerge, it is imperative to ensure existing protocols are reviewed and updated. Additionally, identifying program limitations may lead to permanent policy change or temporary change to mitigate a transient risk. For example, during a regional outbreak of canine influenza, it may be prudent to implement additional precautions for dogs with upper respiratory signs or those with a travel history to impacted regions.

Surveillance activities can be used to assess program effectiveness and allow early detection of adverse events so that mitigation efforts can be rapidly instituted. Consideration should be given to the surveillance method (i.e., active, passive, syndromic) and type of surveillance (e.g., monitoring patients and/or the environment). Surveillance and monitoring for control of nosocomial infections in veterinary hospitals has been described in detail elsewhere.[100–102]

Surveillance Methods

Surveillance is the systematic collection, analysis, and interpretation of events in a population to enable tailored responses to adverse events or outcomes. A surveillance system has two components: (1) a monitoring system and (2) a critical limit at which a predetermined action will be taken to mitigate a perceived risk. Surveillance data allows for a facility to establish baseline or an expected level of a particular outcome, process, or event. Facility managers can then track this level to detect a deviation from what is normally expected and rapidly instigate corrective actions.

Active Surveillance

Active surveillance is conducted to identify an outcome or indicator of interest, e.g., performing fecal cultures on all dogs fed raw food diets in the home environment. This type of surveillance provides typically high-quality primary data, but is costly both financially and in personnel time. Active surveillance is most commonly used in large veterinary hospitals and may be used for targeted surveillance of high-risk patient groups.

Passive Surveillance

Passive surveillance is the use of information that has been collected for another purpose (e.g., diagnostic laboratory specimens). This type of surveillance is relatively inexpensive and simple to perform, but is considered a secondary data source. As such, there is limited control over the quality of the data. Many hospitals use passive surveillance data to monitor for resistant organisms and resistance patterns.

Syndromic Surveillance

Syndromic surveillance uses nonspecific indicators of disease (e.g., "diarrhea") that are identified before a definitive diagnosis can be determined. This type of surveillance is relatively easy to perform but relies upon formalized definitions to allow for monitoring. Syndromic surveillance can be a useful screening tool to implement enhanced infection control practices and mandatory testing protocols.

Patient Monitoring

Patient monitoring may be active (e.g., performing fecal cultures on all inpatients on admission for *Salmonella*), passive (e.g., summarizing laboratory tests to identify MRSA isolates), or involve observing for a particular syndrome (e.g., fevers in hospitalized patients).

While continuous surveillance can be performed, targeted surveillance of high-risk or high-cost problems is an efficient way to assess program efficacy.[103] It allows for a focused effort on a particular type of patient (e.g., all patients vs. inpatients vs. critical care patients), a specific pathogen (e.g., *Salmonella* or MRSA), or a specific syndrome (e.g., diarrheic or febrile patients). Incorporation of patient monitoring into an infection control program should be facility specific, and reflect the availability of resources and level of risk aversion of stakeholders, previous disease outbreak experiences, and disease prevalence in the area.

Environmental Monitoring

Environmental monitoring allows assessment of program effectiveness through the identification of residual contamination. It also can be instrumental in detecting reservoirs of potential pathogens.[101,104] Considerations are the type of specimens collected, the method of specimen collection, the detection method, laboratory selection, and available resources (both equipment and personnel time). Detection methods must be appropriately validated and optimized for that intended purpose. In general, if environmental testing is to be used, it should be performed regularly to establish a baseline level to which future findings can be compared. It should be remembered that the hospital environment is not expected to be sterile, and the presence of opportunistic pathogens is not unexpected. Environmental surveillance can provide important information during outbreaks, assist evaluation of endemic disease, act as an educational tool for personnel and evaluate the impact of interventions. However, results may be confusing, misleading, and counter-productive if testing is improperly implemented and interpreted.

Multiple methods have been described for environmental sampling including the use of electrostatic wipes or sterile sponges that are cultured for specific microorganisms[104,105] or contact plates (e.g., Rodac plates) to enumerate nonspecific bacterial growth.[106–108] In general, sampling a larger surface area will tend to provide a more representative sample and will likely be a more sensitive method for detection. Focusing sampling efforts on high-traffic areas (e.g., examination areas and common hallways) or on identifying environmentally persistent

pathogens (e.g., *Salmonella*) can decrease costs associated with monitoring, but may provide limited information regarding the scope of the problem. As such, more inclusive follow-up sampling may need to be performed.

Program Compliance

Compliance with infection control protocols is critical to program success, yet it is one of the most challenging aspects of program implementation. Despite veterinarians expressing concern about risks associated with gastrointestinal parasites and bacteria, approximately one-half report "always" washing their hands between patient contacts or before eating, and only one-quarter report using appropriate PPE when evaluating a patient for gastrointestinal disease.[56]

Program compliance stems from creating a "safety culture." A strong safety culture should have norms and rules that explicitly define risks and provide guidelines, it should place safety as a priority and motivate personnel to act accordingly, and it should use reflexivity to understand risk and risk mitigation.[109] In practice, this might include leading by example, development of an education and training program, regular reporting of surveillance efforts, and creation of an infection control committee that will encourage and empower participation in program development and improvement. Personnel should be reminded that the program has been implemented to protect people, patients, and the practice, that it is necessary to provide optimal patient care, and that the program is only as good as those practicing the infection control measures agreed upon by the practice.

SPECIALIZED AREAS OF CONCERN

Healthcare-Associated Infections

HAIs are those that are acquired in a healthcare facility. These may be the result of indigenous microflora or exogenous microorganisms from other sources. Infections incubating at the time of admission to a facility are not classified as HAIs, although this distinction can be difficult to determine. In human healthcare, HAIs increase the duration of hospitalization, patient morbidity and mortality, and the overall cost of care.[2] They are one of the top 10 causes of human deaths in the United States, with an estimated 5.8% of deaths in 2002 being associated with HAIs.[3]

While we lack similar data in veterinary medicine, in 2006, 82% of accredited VTHs surveyed reported outbreaks of HAIs among patients in the previous 5 years and 32% reported zoonotic infections among personnel in the previous 2 years.[5] Among adult dogs and cats admitted to critical care units, approximately 16.3% and 12%, respectively, experienced HAI during hospitalization based on syndromic surveillance conducted at five participating VTHs over a 12-week period.[7] These estimates are derived from critical care patients that generally have systemic illness and thus greater immune compromise than the general patient population, and are more commonly subjected to invasive procedures and placement of indwelling catheters.

Peripheral Intravenous Catheterization

Peripheral intravenous catheterization is commonly associated with insertion site inflammation,[7] and places patients at risk for developing an HAI as it also creates a portal of entry for potential pathogens. Pathogens can gain venous access by migrating down the catheter itself or be introduced through a contaminated catheter tip, hub, or infusates. Catheter-tip culture-positive rates of 25% have been reported among dogs and cats admitted to a critical care unit[110] and 15% among noncritical patients.[111] Bacterial species commonly detected include *Enterobacter* and *Staphylococcus*.[110,111] While it is difficult to determine if catheter tips become contaminated during placement or seeding from another source, it is recommended that the catheter be placed after aseptic preparation of the insertion site—a 1-minute scrub with chlorhexidine followed by an alcohol application.[112,113] Catheter site preparation solutions and materials should be stored in closed containers and should not be refilled. They should be discarded when empty or cleaned and autoclaved before being refilled. Proper hand hygiene should be practiced before contacting the insertion site or placing a catheter. Catheter hub colonization accounts for approximately 70% of catheter-related sepsis in human patients receiving parenteral nutrition.[114] Thus, it has been recommended that the catheter hub be cleaned with alcohol or iodine before use of a sterile needle and syringe to administer medications.[113]

Catheter sites should be checked daily for evidence of thrombophlebitis (e.g., pain, swelling, redness, and discharge).[113] While inflammation itself may not necessitate catheter removal, it increases the risk of infection and can be difficult to distinguish from infection. Consequently, if these signs are observed, the catheter should be promptly removed and the catheter replaced at an alternative site. Aseptic catheter removal is recommended if catheter-tip culture is to follow (which should only be performed if there is evidence of infection at the catheter site): the site should be scrubbed as was done prior to catheter insertion, and the catheter then removed and the tip cut with sterile scissors and placed in a sterile red top tube with a drop of sterile saline to prevent desiccation for submission to the laboratory (avoiding excessive dilution). As a general guideline, a count > 15 CFU suggests a true infection as opposed to mere contamination.[115]

Catheter stabilization reduces the potential for thrombophlebitis. To restrict movement, a small amount of a broad-spectrum antimicrobial ointment should be applied at the point of catheter penetration through the skin and the site should be covered with a sterile occlusive dressing. The date and time of catheter insertion should be recorded. It is recommended that intravenous catheters be removed after 72 hours, although there is little objective data to support this practice. With modern catheter materials, proper placement, and close monitoring, longer-term catheterization is becoming more widely accepted. Catheters made of polytetrafluoroethylene, silicone elastomer, or polyurethane are more resistant to the adherence of microorganisms than are catheters made of polyvinyl chloride or polyethylene.[116] In addition, iodinated alcohol solutions within catheter hubs, chlorhexidine-silver-sulfadiazine or antibacterial-impregnated catheters, and antibacterial-impregnated sponges have been evaluated.[117]

Urinary Catheterization

Urinary catheterization can be associated with urinary tract inflammation[7] and disrupt normal urinary tract defense mechanisms, including normal flow of urine. Urinary catheters permit retrograde migration of commensal organisms that inhabit the prepuce, vagina, and distal urethra into the normally sterile portions of the urinary tract.[118] Prior to urinary catheter placement, external genitalia should be thoroughly cleansed and catheterization performed under aseptic conditions.

Many urinary tract infections (UTIs) occur within the first 3 days of catheterization,[118,119] with the risk for UTI increasing by 27% for every additional day of catheterization.[120] A complicating factor in most veterinary studies is a failure to differentiate subclinical bacteriuria from bacterial cystitis, particularly since treatment of subclinical bacteriuria is not generally recommended.[121] While closed systems are commonly used in human medicine, open systems are frequently used in veterinary medicine (but have been discouraged). Interestingly, the incidence of UTIs was found to be similar among dogs admitted to a

critical care unit when using closed (8.3%) versus open (11.1%) urine collection systems for a median of 2-day duration.[122]

Antimicrobial therapy during catheterization can increase the risk for UTI if in place for more than a few days.[119,120] Therefore, it should be avoided unless there is clinical evidence of bacterial cystitis and/or the patient is deemed to be at high risk for upper UTI. In such cases, treatment should be initiated with the understanding that the goal of treatment is to ameliorate clinical signs, not eliminate infection, and the catheter should be removed as soon as possible.

Aquatic Equipment Used in Physical Therapy

With proper management, aquatic equipment (e.g., whirlpools, water treadmills) poses a low risk for pathogen transmission among patients and personnel. Equipment should be kept clean and free of hair and debris. Water chemistry levels should be checked daily and managed appropriately (chlorine:1–3 parts per million [ppm]; pH: 7.2–7.8; and alkalinity 80–120 ppm).[123]

Patients with a recent history of diarrhea or those with known or suspected resistant infections should be excluded, and patients with visibly soiled haircoats should be brushed and bathed prior to treatment. Facilities should develop protocols in the case of a fecal accident, which may include the use of a filtration system and/or complete removal of water and cleaning and disinfection appropriate for the equipment. The CDC provides recommendations for pool and hot tub owners that may be useful in protocol development.[124]

Immunocompromised Patients and Personnel

Patients and personnel can be immunocompromised as a result of disease (e.g., cancer, diabetes mellitus), medical treatment (e.g., chemotherapeutics), age (i.e., young and old), or pregnancy. While all general recommendations for the prevention of infectious diseases in this chapter are applicable to patients and personnel, particular consideration should be given to the use of barrier precautions to prevent exposure of immunocompromised animals and personnel.

Immunocompromised personnel should discuss any necessary work restrictions and precautions in light of their specific condition with their personal physician and/or an infectious disease doctor. Of particular concern for pregnant veterinary personnel are exposures to toxoplasmosis, lymphocytic choriomeningitis, brucellosis, listeriosis, psittacosis, and Q fever.[19] If possible, veterinary hospitals should establish a relationship with a doctor who is prepared to consult on zoonotic exposures with staff members.

Blood and Blood Component Transfusion Infectious Disease Prevention

Safe blood banking in veterinary medicine relies upon screening of healthy donors using the best available diagnostic tests. The American College of Veterinary Internal Medicine (ACVIM) has published a consensus statement providing guidelines for managing blood donor programs.[125] Blood donor selection should be based on a thorough history, physical examination, and initial clinicopathologic screening (e.g., CBC and biochemistry panel). Suitable donors should then be screened for pathogens that meet at least three of the following criteria: (1) pathogen causes clinical infection in blood recipients; (2) pathogen can be carried subclinically by otherwise healthy-appearing donors; (3) pathogen can be detected using culture or molecular methods in blood; and (4) infection in the recipient may be life threatening or difficult to treat.[125] At a minimum, blood donors should be tested yearly, with more frequent testing for geographically important agents and among animals with exposure to known risk factors (e.g., ticks) for development of infectious disease.[125] The ACVIM consensus statement provides detailed recommendations for specific agents of concern.[125]

Breeding, Boarding, and Shelter Facilities

Many of the general recommendations for the prevention of infectious diseases in this chapter are applicable to breeding, boarding, and shelter facilities. Additional recommendations unique to these facilities are presented in the next three chapters in this book. Many of these facilities have a significant transient population as well as resident animals. Protocols should be developed to reduce the risk to resident animals through separation of transient and resident animals, monitoring for signs of infectious disease, and determining required vaccinations and parasite prevention for all animals. Animals are often stressed on intake, which is exacerbated by high stocking densities, being grouped with unknown animals, and poor nutrition; immune compromise results. High-stocking densities also facilitate infectious disease transmission. Maintenance of separate animal groups, often by species and age, is critical to prevention of infectious disease transmission.

Facility managers need to be cognizant of the maximum capacity for care and strive to maintain populations below this level. The Farm Animal Welfare Council (FAWC) offers guiding principles when managing animal populations that equally apply to dog and cat populations in breeding, boarding, or shelter facilities. In 1979, the FAWC put forward the "Five Freedoms" for animals kept by man: (1) freedom from hunger and thirst; (2) freedom from discomfort; (3) freedom from pain, injury, or disease; (4) freedom to express normal behavior; and (5) freedom from fear and distress. By incorporating these principles into facility management protocols, facility managers are ensuring the health and welfare of the animals, including the prevention of infectious diseases. The Association of Shelter Veterinarians and the American Humane Association have each published detailed guidelines regarding shelter management, standard operating procedures, and standards of care.[126,127] The United States Department of Agriculture–Animal and Plant Health Inspection Service (USDA:APHIS) has published guidance documents for dog kennels and breeding facilities.[128]

Prevention and Management of Infectious Diseases in Multiple-Cat Environments

Miranda Spindel, Jane E. Sykes

KEY POINTS

- Multiple-cat environments are those that contain at least five cats, and include multiple-cat homes, breeding catteries, pet stores, research catteries, shelters, foster or rescue homes, boarding facilities, and feral cat colonies.
- The risk of infectious disease in multiple-cat environments can be reduced by: (1) minimizing individual and population risk factors for infectious disease and (2) movement control.
- Minimizing individual and population risk factors involves attention to overall cat numbers and density, ensuring cats are in stable groups, provision of adequate cage space and hiding areas, use of disposable equipment, proper sanitation that involves use of disinfectants with activity against nonenveloped viruses, attention to air flow and quality, arthropod control, minimizing the ratio of juvenile to adult cats, and ensuring that cats are well nourished and receive preventative treatments for infectious diseases where available. Surveillance programs that allow early detection of increased morbidity and mortality can also reduce risk of infectious diseases.
- Movement control involves segregation of cats into healthy holding, public access, quarantine, and isolation areas. Order of attention to cats should be healthy, quarantined, and then isolated cats.
- Important infectious diseases in multiple-cat populations include infectious respiratory tract disease, GI disease, dermatophytosis, feline retrovirus infections, and FIP. Caregivers in multiple-cat environments should be able to recognize clinical signs associated with these conditions and have an understanding of the approach to their diagnosis, treatment, and prevention as outlined in this chapter. They should also understand the potential for zoonotic transmission of some of the pathogens involved.

INTRODUCTION

Multiple-cat environments are those that contain at least five cats. They include multiple-cat homes, breeding catteries, pet stores, research catteries, shelters, foster or rescue homes, veterinary hospitals, grooming and boarding facilities, and feral cat colonies. The prevalence of infectious disease in multiple-cat environments is often high because it is correlated with animal density and population size, and because resources for disease control may be limited. Many important feline infectious diseases that are common in multiple-cat environments are chronic, difficult to treat, or both. Thus, efficient management and disease prevention are paramount for success in multiple-cat husbandry.

Some degree of exposure to infectious agents is inevitable, given the ubiquitous nature of viruses such as FHV-1 and FCV and the environmental persistence of others such as FPV. Infectious diseases may be transmitted directly by immediate or close contact between reservoir and susceptible hosts, or indirectly through inanimate vehicles (fomites), air, or droplets, or various mechanical or biologic vectors (see Chapter 15). Whether infection becomes important in a multiple-cat setting depends on host, environment, and pathogen attributes.[1] Pathogen attributes include virulence, dose, and route of pathogen inoculation. Virulence is not under the control of the person who manages the feline population, but dose and route of infection can be. Environment and host contributors to infectious diseases also are important targets for minimizing spread of these diseases. This chapter reviews infectious disease management strategies in multiple-cat environments and provides an overview of several major infectious syndromes.

GENERAL MANAGEMENT STRATEGIES

Management of infectious diseases in multiple-cat environments should emphasize good husbandry and preventive medicine. Colony immunity—the resistance of a group of animals to invasion and spread of an infectious agent—should be maximized, as should the *colonization resistance* (CR) of each individual. CR is defined as the innate and acquired capability of an animal to resist infectious disease and includes behaviors (such as avoidance of filth), physical barriers (mucus, epithelium, fur), physical and chemical attributes of the host (low gastric pH, intestinal peristalsis, urine flow, mucociliary escalator), classical immunity, and resident microflora. Animals with impaired CR (e.g., cats infected with FIV, geriatric or immunosuppressed cats, cats receiving antimicrobials) not only are more susceptible to disease but also reduce the overall colony immunity.

Ideally, a preventive management program should be implemented by a team consisting of at least a veterinarian and staff member or volunteer who are familiar with the physical structure of the cats' environment, animal care staff and operations, and other details. Effective management of a multiple-cat environment to decrease risk of infection includes: (1) minimizing population and individual risk factors for infectious disease and (2) movement control, which is the regulation of access to other cats and fomites that could transmit infection.

Minimizing Population and Individual Risk Factors

Risk factors for disease should be systematically evaluated and corrected if possible. Risk factors include environmental factors and

population characteristics. The two most important risk factors in multiple-cat environments are: (1) total cat numbers and (2) density, or the number of cats per unit space. Other intrinsic environmental risk factors include caging strategies, stresses (e.g., dogs, noise, unstable social structures), rate of new cat introduction, sanitation, air flow and quality, healthy cat programs, insect and vermin control, and season and climate. Population risk factors include population age composition, inbreeding status, breeds housed in the group, and presence of concurrent diseases.

Cat Numbers and Density

Cat numbers and density should be kept as low as possible, with an emphasis on minimizing (or properly segregating) the proportion of kittens and immunocompromised cats. If group housing strategies are employed, caging in stable cat groups should allow for some social interactions but not fighting. Cages should provide plenty of opportunities for cats to hide, vertical space, natural light and air, and windows through which cats can look. More detail on optimal group housing can be found elsewhere.[2,3]

Housing

Cages for individual cats should be more than sterile boxes because the increased susceptibility to disease caused by stress outweighs the reduction achievable by ease of cleaning. Environmental enrichment (hiding places, vertical spaces, and things for cats to look at and play with) is very important (Figs. 16.1 and 16.2).[3] Cages should not extend all the way to the ground (bottom cages at least 1 foot off the ground), and sick cats should never be housed above healthy cats. Sick cats with suspected infectious diseases should be in isolation. *All* components of the environment should be disposable or able to be completely cleaned and disinfected. Any potentially nondisposable items should be kept in closed rooms and decontaminated or disposed of when the group of cats has finished with them.

Sanitation

Sanitation is important and often improperly addressed. The main sources of infectious diseases are not cages, but rather the cats, and environmental components that become contaminated and cannot be or are not sanitized, such as carpets and human hands and clothing. Cleanliness is essential in any multiple-cat environment whether the cats are comingled in groups or individually housed. A disinfectant with activity against environmentally resistant microbes such as parvoviruses, calicivirus, and dermatophytes should be in routine use (see Chapter 14 and Table 15.2). For decontamination of *Toxoplasma gondii* and other coccidial oocysts, scalding water or ammonia solutions are required (see Public Health Considerations, Chapters 93 and 104). A protocol that outlines daily, weekly, and monthly routine sanitation procedures should be developed, updated regularly, and posted where it can be visually referenced. Protocols should also exist that cover sanitation procedures to be used during outbreaks of specific infectious diseases.

Air Flow and Quality

Air flow and quality are significant factors in the management of multiple-cat environments, but their importance is overrated. The advantages of increasing air turnover from 10 to 15 changes per minute are not enormous, but the increase in expense is. In general, the greater the population density, the greater the need for increased number of air changes per hour. By far the most efficient way to achieve quality air is to open windows or have indoor-outdoor catteries. Most cats do not need air conditioning as long as they have fresh water, protection from rain, and shade. However, in cold weather, cats need warmth. Optimally, temperature should be maintained at 50°F–80°F and humidity at 30%–70%.[4] Feline respiratory pathogens are not primarily transmitted via aerosol, but it is still important to ensure that air quality is healthy in order to minimize exposure risks and improve the respiratory defenses of the animals. Air ducts and ventilation areas should be cleaned regularly. If uncomfortable environmental conditions exist for humans (e.g., chemical fumes, dust), these should be corrected for the animals as well.

Population Risk Factors

Population risk factors for infectious disease include population age composition, degree of inbreeding, breeds housed, and presence of concurrent diseases. Many of the risk factors that increase the likelihood of endemic or epidemic disease in multiple-cat environments are also factors that increase risks for individual cats. Individual cats are more prone to infectious disease if they are very young, especially if they are colostrum-deprived, or very old; if they are stressed or malnourished; or if they are already incubating an infection. In cats, inbreeding per se is not a risk factor, but being a member of a more susceptible pedigree may be a risk.

Healthy Cat Programs and Vaccinations

Healthy cat programs and arthropod control minimize individual risk factors for infectious disease, maximize colony immunity, and provide a systematic opportunity for cats to be evaluated and either treated or removed from the population if they are not healthy. Routine screening of cats should be performed immediately on intake. Intake examinations should include a complete physical examination, core vaccination, and parasiticide treatment for hookworms and roundworms at minimum. Thereafter, according to the guidelines published by the Association of Shelter Veterinarians (Guidelines for Standards of Care in Animal Shelters),[3] apparently healthy animals that have been in care longer than a month should be weighed and have a body score recorded by trained individuals at least monthly. Veterinary examinations should be performed twice each year or more frequently if problems are identified. Geriatric, ill, or debilitated animals should be examined by a veterinarian for appropriate case management.

Vaccination on entry should be performed for healthy cats and kittens over 4 weeks of age. Because the use of vaccines must be tailored for individual situations, vaccine programs may differ for each multiple-cat environment. Vaccination has four potential disadvantages: (1) some vaccines cause mild disease or transient immunosuppression; (2) parenteral, adjuvanted vaccines have been associated with injection-site sarcoma formation; (3) vaccination can create false-positive serologic and molecular test results; and (4) use of vaccines may lead to a false sense of security that cats are adequately protected and other preventive management practices can be neglected. These disadvantages should be considered when selecting the type of vaccine(s), timing, and route of administration.

Minimally, initial vaccination should be directed at prevention of FPV, FHV-1, FCV and rabies virus infections. Choice of type of vaccine product and route of administration may vary depending on the population. Attenuated live vaccines for FHV-1, FCV, and FPV are preferred in many high-turnover environments such as rescues and shelters due to the rapid onset of immunity they provide. Inactivated virus vaccines must be administered at least twice at 2- to 4-week intervals before effective immunity is produced and thus are inappropriate in populations such as shelters where turnover rates can be rapid. Inactivated vaccines may be advantageous in facilities where vaccine-associated diseases are unacceptable (e.g., in research catteries) or in immunocompromised or pregnant animals. The reader is referred to Chapter 20 for advantages and disadvantages of different vaccine types.

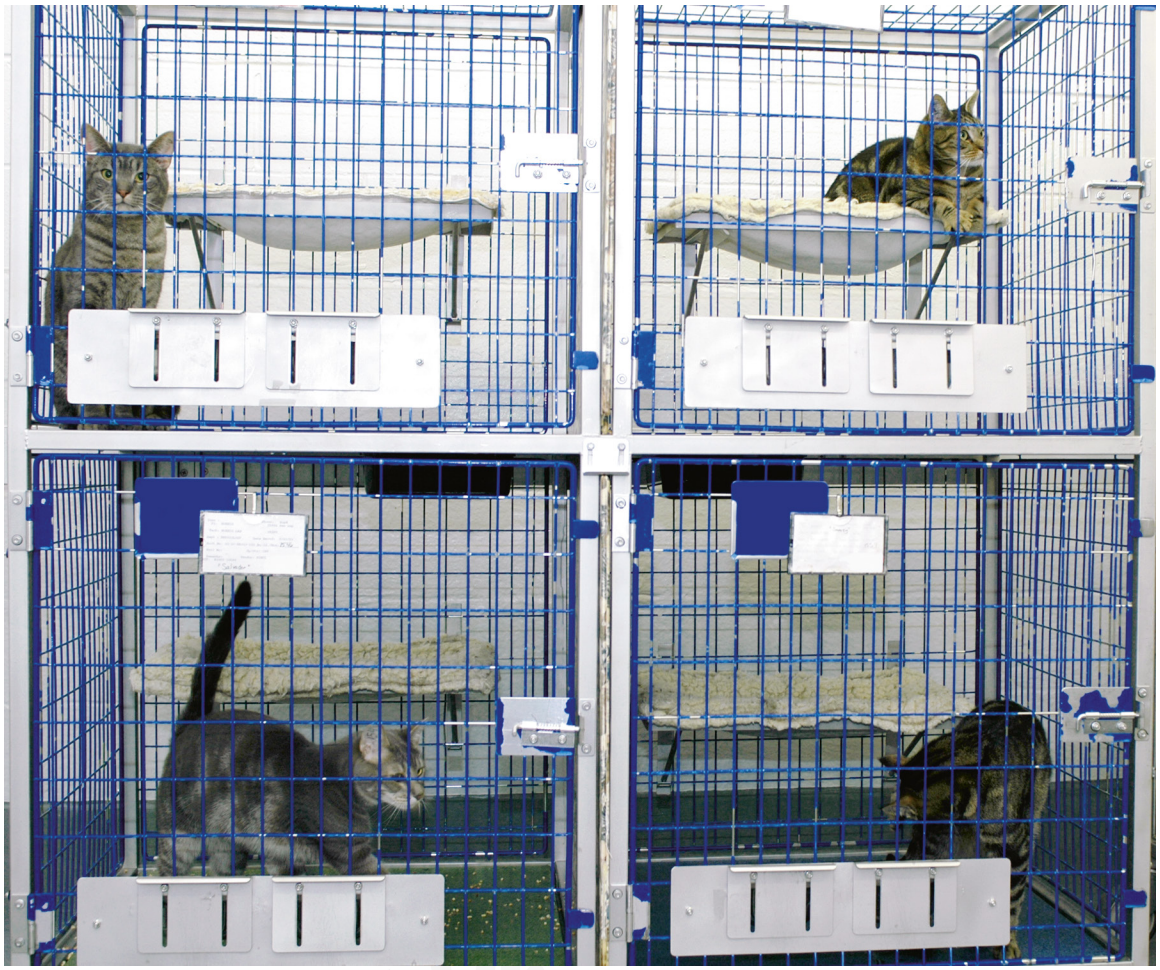

Fig. 16.1 Good husbandry is vital to an effective preventive medicine program.

Fig. 16.2 Hammocks can reduce stress for cats in multiple-cat environments.

The panleukopenia fraction of the intranasal FVRCP vaccine has had questionable efficacy in field settings; therefore, it is not recommended as a sole vaccination for cats and kittens in high-risk environments.

The veterinarian and manager should inspect the animals and premises for arthropods regularly, for which there should be zero tolerance. Fleas and ticks transmit vector-borne diseases and have the potential to contribute to allergic dermatopathies. Cats can be infested with lice, ear mites, and mange mites. If any arthropods are seen during a routine inspection, the entire premises should be cleaned and treated with an approved pesticide, and every cat should receive treatment for ectoparasites. Monthly ectoparasite preventative treatments should be provided if needed to ensure that no cats are infested.

Surveillance for Morbidity and Mortality

It is important to track and to identify causes of mortality and morbidity in a population to better plan and implement infectious disease management programs. Necropsies should be performed after unexplained deaths, especially in shelters, breeding and research catteries, pet stores, and veterinary clinics. When infectious causes are suspected, laboratories should be advised of tentative diagnoses before the necropsy, if possible, and if possible multiple animals should be examined.

Movement Control

All animal facilities should minimally have the ability to separate animals into four physically separate defined areas: (1) healthy holding; (2) public (adoption, sales, etc.); (3) quarantine; and (4) isolation. Flow of human and animal movement and animal separation will depend to a degree on the type of facility and its design.

Healthy holding is typically an area where animals that are newly admitted and apparently healthy are housed. Upon admission, cats should receive healthy-cat care treatments and be observed daily by personnel qualified to perform physical examinations and detect clinical signs of infectious disease. *Quarantine* is a holding area for animals

that may have been or are known to have been exposed to an infectious disease but are not yet showing clinical signs. In some situations, cats may require a quarantine time of days to weeks prior to entering a group to attempt to ensure the group remains free of clinical signs of disease. In high-volume shelters that have multiple-cat group housing, effective quarantine of individual animals can be challenging because new animals are always being admitted to the quarantine area. In such cases, the next best option may be cohort admission. There are different methods for admitting and structuring cohorts to minimize stress and risk of infectious disease. These include grouping by sex, age, and in an all-in/all-out approach where capacity is capped and new animals are not continuously added to a population.

Cats showing signs of infectious disease must be isolated from the general population and from cats that are in quarantine. Isolation spaces should be physically separated, low-traffic areas that are ideally located some distance from healthy cat areas. In some facilities, isolation may not be achievable on-site or may require closing an entire group area. In a small cattery or foster home setting, a cat could be isolated in a bathroom; however, it is difficult for owners to avoid transmitting infectious agents on their clothing, shoes, and skin from a sick cat to other cats. Cats with dermatophytosis, URTD, or diarrhea should ideally be moved to a true isolation ward and the presence of co-infections should be assumed when formulating management. Isolation should be a space that can easily be cleaned and disinfected, with easy entry and exit for staff, a separate air supply if possible, and low traffic. In some situations, isolation may be performed within the same building that general population housing occurs, whereas in others, a veterinary clinic or separate facility may need to be utilized. Population management becomes critical when incidence of infectious disease rises in multiple-cat environments. Facilities and programs must have an understanding of their capacity for care and work within it.

To reduce transmission of infectious agents, a specific order of care should be followed: (1) feed and clean healthy kittens and queens and then healthy cats, (2) feed and clean quarantined cats, and finally, (3) feed and clean isolated cats. In a large facility, isolated cats should be handled by personnel who are not handling the healthy cats. Only if absolutely necessary should a caregiver attend to healthy cats after attending to cats in isolation, and then only if the caregiver has changed clothes and shoes and washed all exposed skin.

IMPORTANT INFECTIOUS SYNDROMES IN MULTIPLE-CAT ENVIRONMENTS

The following section provides an overview of important infectious diseases in multiple-cat environments, with an emphasis on major clinical signs, diagnostic tests, and prevention measures that are relevant in this scenario. The reader is referred to pathogen-specific chapters in this book for more detail on each disease.

Respiratory Tract Disease

Etiologic Agents and Clinical Signs

Respiratory tract disease is the most prevalent and easily recognizable infectious problem in multiple-cat environments, and it is also the most difficult problem to manage.[5] The causative agents of URTD are common, easily transmitted, and cannot be completely prevented through vaccination. In general, minimizing severity and frequency of respiratory outbreaks in a population should be the goal, rather than eliminating disease, which is usually impossible.

FCV and FHV-1 are the most common causes of feline URTD.[6] Bacterial pathogens that contribute to disease include *Bordetella bronchiseptica, Chlamydia felis*, and *Mycoplasma* spp. (see Chapters 34, 35, 49, 55, and 57). The possibility of SARS-CoV2 infection in cats showing signs of respiratory illness should also be considered when exposure to infected humans has occurred (see Chapter 43). Secondary bacterial invaders include *Staphylococcus* spp., *Streptococcus* spp., *Pasteurella multocida,* and *Escherichia coli*. Infrequently, multiple-cat populations may be affected by outbreaks caused by unusual emerging pathogens such as influenza viruses and *Streptococcus equi* subsp. *zooepidemicus*. Respiratory pathogens are highly infectious and are primarily transmitted in ocular, nasal, and oral secretions. Although aerosol transmission can occur, the maximum distance for transmission is 4 feet, based on the average tidal volume of an adult cat. Thus, fomite and direct cat-cat transmission are more important means of transmission in most multiple-cat environments.[7]

FHV-1 is an enveloped DNA virus. Kittens often acquire the infection at a very young age because parturition results in reactivation of shedding by the queen. Later in life, transmission of FHV-1 requires intimate contact between cats. After infection, the virus persists in the trigeminal nerve. Intermittent reactivation results in upper respiratory signs, especially during stressful periods or immunosuppressive events. Disease signs may include conjunctivitis, anterior uveitis, serous ocular discharge with secondary bacterial infection and mucopurulent discharge, or keratitis with or without dendritic ulceration. Ulcerative and necrotizing facial dermatitis has been described in some cats with FHV-1 infection.[8]

FCV is a nonenveloped RNA virus with a high rate of mutation and is antigenically and genetically diverse.[9,10] Respiratory shedding of virus occurs for at least 10 to 14 days and commonly occurs for months in shelters and kittens. FCV infection can cause conjunctivitis and rhinitis with serous ocular discharge, caudal stomatitis, pneumonia, transient fever and limping, and immune-complex polyarthritis and gingivitis. Hypervirulent strains of FCV can cause facial and limb edema, hepatitis, and pancreatitis.[11]

Bordetella bronchiseptica contributes to respiratory tract signs, often in association with respiratory viral infection.[12,13] If it is protected and in a moist environment, *B. bronchiseptica* can survive for weeks. Cats may have mild primary bordetellosis with conjunctivitis and mild oculonasal discharge or develop pneumonia. Occasionally, signs of URTD in cats from multiple-cat environments are caused by *C. felis,* an obligate intracellular bacterial pathogen that survives poorly in the environment. The reservoir for this pathogen is feline conjunctival and genital mucosa. Chlamydiosis is often acquired shortly after weaning and is typically manifested as conjunctivitis. Feline disease attributed to mycoplasmas, which also survive poorly in the environment, include URTD, conjunctivitis, and arthritis. The role of mycoplasmas as primary URTD pathogens in cats has been controversial, given that they commonly are recovered from clinically healthy cats.

Although uncommonly documented in the literature, several agents associated with feline URTD have zoonotic potential. *Bordetella bronchiseptica* has rarely been associated with the disease in immunocompromised individuals.[14] *Chlamydia felis* infection has been documented in one immunocompromised individual with conjunctivitis.[15] Avian influenza H7N2 isolated in an outbreak of feline respiratory disease was also isolated from the veterinarian caring for the cats.[16]

Diagnosis

Although there are clinical signs that are more characteristic of some infections than others, clinical signs overlap and co-infections occur; therefore, specific diagnostic testing is required to identify the causal agents. Gingivostomatitis or extensive oral ulceration are suggestive of FCV infection. Lameness and joint pain suggest infection with *Mycoplasma* spp. or FCV. Cough may suggest *cattery cough (B. bronchiseptica* tracheitis). Keratitis and corneal ulceration suggest FHV-1 infection. Chronic sinusitis, often with turbinate destruction, may

be from infection with either FHV-1 or FCV infection followed by secondary bacterial infection. Fever develops most commonly with FHV-1 or FCV infections.

In general, diagnostic testing should be performed when the results will change therapy or management, when there are increases in prevalence or severity of disease, or when there is a decrease in response to therapies that have previously been effective. In any population, testing a percentage of the population versus one or two representative animals will give a better representation of disease trends because virtually all of the pathogens can be found in clinically healthy cats. Both clinically ill and apparently healthy but exposed populations should ideally be tested. It can also be helpful to test animals who have entered a facility at different times. Before specimens are collected, the diagnostic laboratory should be consulted with for specimen collection and storage information. It is also important to contact the laboratory in advance and notify them if large numbers of specimens are to be submitted. No single test has perfect sensitivity and specificity, and combinations of tests may be required to optimize understanding. PCR is commonly performed for respiratory pathogen diagnosis, and because of its sensitivity, results must always be interpreted in relation to clinical information. Virus isolation and necropsy with histopathology may also be helpful.

Management and Prevention

URTD is best managed in a population by minimizing its severity and prevalence.[1] Infected and exposed cats may have recurring disease, and few multiple-cat populations (except specific pathogen-free research catteries) are free of URTD.

Vaccination. All cats in multiple-cat environments should receive vaccination for FHV-1 and FCV as part of a regular, routine core vaccination program. Because vaccination against panleukopenia is also considered core, these three components are often administered simultaneously. Attenuated live vaccines should be selected over inactivated products, unless there is a risk of pregnancy such as in a breeding facility. Intranasal vaccines can be used in young kittens to overcome maternal antibody, but parenteral vaccination is also required to protect cats from FPV infection. Vaccines for bordetellosis and chlamydiosis are noncore, and recommended for use when documented problems exist in a population. For additional information on vaccination selection and schedules in multiple-cat populations, see the Appendix.

Stress reduction. Every effort should be made to minimize stress as physical, emotional, and environmental stress strongly contributes to development of URTD. Changes in housing, nutrition, human interactions, and length of stay all play a role in optimizing cats' resistance to disease.

Population management. Increased animal density increases the chance of exposure to infectious agents. Additionally, when the number of animals requiring medical care increases, the resources per animal decrease. Sanitation is more difficult, treatment is more time consuming, and quality care is more difficult to provide. Multiple-cat environments with significant URTD may need help to establish clear-cut capacity guidelines in order to break a cycle of progressively worsening URTD.

Sanitation. It is critical that multiple-cat environments have a documented sanitation plan in place. Good sanitation limits pathogen accumulation and minimizes fomite spread. With the exception of FCV, most respiratory agents are very labile in the environment and are easy to inactivate with routine sanitation products and practices. Proper use of a routine disinfectant such as accelerated hydrogen peroxide or potassium peroxymonosulfate will inactivate FCV and all other respiratory pathogens in the environment. Attention must be paid to the role of humans in disease transmission. Animals should be handled, whenever possible, based on age and health status. This means that the youngest and most immunocompromised should be handled before the immunocompromised population. Supplies should be dedicated to specific areas of the facility. Although URTD pathogens are not primarily transmitted via aerosol, it is still important to pay attention to air quality in order to minimize exposure risks and improve respiratory defenses. Optimal temperature is 50°F–80°F, humidity 30%–70%, and air exchange rate 10–15/hour.[2,3] Because few facilities are ideal, it is generally best to focus on how to optimize ventilation. Air ducts and ventilation areas should be cleaned regularly.

Surveillance. Regular physical examinations and good electronic medical records that are maintained from the time of intake can help with early identification of disease. Caregivers need to have the knowledge and training to identify and document important clinical signs, and understand the steps to follow if significant changes are noted. Careful record keeping facilitates monitoring of trends or outbreaks of infectious disease developing in populations that might not be recognized in a large population on a day-to-day basis. Once identified, specific strategies can be implemented to improve animal health and welfare.

Segregation. Cats with URTD should ideally be isolated. Although cats can continue to shed URTD pathogens for weeks to months after clinical recovery, it is not practical in most multiple-cat environments to isolate for this length of time, and subclinical shedding is common in cat populations. Instead, once clinical signs have resolved (when shedding is likely to be greatest) and treatment is completed, cats typically are returned to the healthy areas. If virulent systemic calicivirus infections are suspected, isolation is particularly important. Some facilities may designate "URTD recovery" areas for these cats, but most recognize that respiratory pathogens are ubiquitous in group environments and it is virtually impossible to create a URTD-free zone. Reduction of stress is more critical.

Treatment

Individual cats with URTD should receive nursing care, humidification, and fluids if needed and should be encouraged to eat. Since the majority of infections are viral, antimicrobials should be reserved for inappetent cats that have mucopurulent discharges. Specific antiviral drugs may be valuable to treat severe FHV-1 infection (see Chapters 9 and 34). It is *not* appropriate to treat a whole population of affected cats with antimicrobials because most are infected with viruses, and widespread antimicrobial use adversely affects resident microflora, increases susceptibility to additional infections, and promotes antimicrobial resistance.

Prognosis

Most cats with acute URTD recover within 1 or 2 weeks with supportive care. However, mortality is possible in kittens or immunocompromised patients. Many cats that recover from acute URTD become chronic carriers of FHV-1 and FCV and may experience recurrent clinical signs in the future. Some cats will develop chronic rhinosinusitis.

Gastrointestinal Disease

Etiologic Agents and Clinical Signs

A multitude of bacterial, viral, protozoal, and parasitic agents can cause diarrhea and vomiting, and co-infections are common. Conditions common to multiple-cat environments such as stress, dietary change, intestinal parasitism, and immunocompromise can contribute to clinical signs. The major GI pathogens of concern in multiple-cat environments are FPV, *Salmonella*, *Campylobacter*, *Cystoisospora* and *Cryptosporidium* spp.,

Giardia duodenalis and, *Tritrichomonas blagburni* (see Chapters 30, 62, 65, 104, 103, 101, and 102 respectively). Infections with *T. blagburni* are especially prominent in purebred cats.[17,18] The primary mode of transmission for each of these pathogens is fecal-oral. Clinical signs include anorexia, variable appetite, weight loss or poor body condition, vomiting, large, small or mixed bowel diarrhea, flatulence, weakness, fever, or dehydration. *Salmonella* and *Campylobacter* spp., and some species of *Cryptosporidium* and *Giardia* have the potential to be zoonotic.

FPV is a small nonenveloped DNA virus that causes life-threatening diarrhea, vomiting, and immunosuppression. FPV has prolonged environmental persistence, is resistant to many chemical disinfectants, and is highly contagious.[19] FPV has a tropism for rapidly dividing cells such as epithelial cells of the GI tract, leukocyte precursors in bone marrow, and cerebellar Purkinje cells in neonatal or very young kittens. The incubation period is between 3 days and 2 weeks but is usually 5 to 7 days. Animals younger than 6 months are most likely to develop severe disease, whereas adult animals can have mild disease that is indistinguishable from diarrhea of any other cause. Infection with FPV typically manifests as vomiting and diarrhea that lead to dehydration. Sometimes illness progresses so rapidly that sudden death ensues within hours, and before vomiting and diarrhea develop. Infection is usually accompanied by immunocompromise, which can predispose the animal to bacteremia, shock, and death. Kittens infected in late gestation or in the first 1 to 2 weeks after birth experience damage to the Purkinje cells resulting in poor gross motor control from the cerebellum, although other peripheral nerves and the cerebrum remain intact.

Cats with salmonellosis may be subclinically infected, have diarrhea as the only sign, or be systemically ill. Clinical signs can include vomiting, small, large or mixed bowel diarrhea, and fever. Hematologic values in cats are sometimes suggestive of panleukopenia with neutropenia that has a severe left shift. *Salmonella* endotoxin creates a massive disruption of the host inflammatory mechanisms, resulting in release of acute-phase proteins with fever, vasodilation, increased vascular permeability, thrombosis, hypovolemia, disseminated intravascular coagulation, shock, and death.

Campylobacter spp. are zoonotic gram-negative, motile, curved, rod-shaped bacteria. Infection results in a range of clinical signs from no signs in carriers to severe diarrhea. *Campylobacter upsaliensis* has been associated with outbreaks of hemorrhagic gastroenteritis in populations of dogs and cats and in daycare centers for children.[20–22] Often, diarrhea associated with campylobacteriosis is self-limiting, but mortality can occur in debilitated, dehydrated, or very young animals should extensive nursing care not be feasible.

Diarrhea caused by *Giardia* and *Cryptosporidium* spp. is most severe in young and immunosuppressed animals. *Tritrichomonas blagburni* also tends to affect young adult purebred cats and causes large bowel diarrhea signs. *Cystoisospora* spp. are found very commonly in kittens in small numbers. The number of asexual reproductive cycles appears to be programmed; only two or three occur in any one host individual, and infection is self-limiting. When clinical signs of cystoisosporiasis occur, they typically manifest as profuse, watery diarrhea in kittens.

Diagnosis

As for respiratory pathogens, diagnosis of GI pathogens can be difficult because healthy animals can be infected, so it is difficult to determine the clinical relevance of a positive test result in an individual animal. Exhaustive testing is expensive and difficult, and often fails to identify a specific cause. Testing of multiple healthy and sick animals and comparing the results in each group may help to elucidate the cause.

Diagnostic testing should be performed whenever panleukopenia is suspected, as the consequences of this virus infecting a population can be devastating. Some of the commercially available fecal ELISA assays designed for the detection of parvovirus antigen in canine feces can be used for cats. A CBC may be also informative. False-positive ELISA antigen test results have the potential to occur as a result of recently administered vaccine virus; thus, cats should not be diagnosed with FPV enteritis unless they have appropriate clinical signs or very low blood leukocyte counts. Finally, if any cats die, a necropsy with histopathology should be performed.

While many bacterial and protozoal pathogens present in multiple-cat environments have zoonotic potential, healthy cats with normal stools are not considered human health risks, and testing beyond routine fecal flotation is generally not recommended for cats with normal stools. The AAFP Zoonoses Guidelines committee recommends that laboratory tests to evaluate diarrhea start with a fecal flotation, fecal wet mount examination, rectal cytology, and an acid-fast stain for *Cryptosporidium* spp.[23] Failure to find protozoal cysts on flotation or direct smear does not rule them out as contributing to the diarrhea because these assays have low sensitivity in early infection. *Cryptosporidium* and *Giardia* spp. in feces are more easily detected with ELISA or direct FA (available from commercial laboratories).

Enteropathogenic bacteria can be detected using aerobic, microaerophilic, and anaerobic culture, although it can be difficult to understand the clinical significance of the results. Routine microaerophilic culture on selective agar often is conducted at elevated temperatures (e.g., 42°C) and may fail to yield growth of less thermotolerant strains. Anaerobic culture can be performed on selective media, and immunologic assays can be used to detect *Clostridioides difficile* toxin A. Enteric PCR panels are also available that can detect DNA of a variety of enteric pathogens, which again are best interpreted when applied to multiple affected animals and in conjunction with the results of other diagnostic assays (see Chapters 63 and 64).

Management and Prevention

Surveillance should include regular quantification of the level of GI disease present, including the number of cases in which specific pathogens are identified. Animals can best resist GI infections when they are otherwise healthy and well nourished, not stressed, have intact resident bacterial microflora, and have been appropriately vaccinated. Problems arise in high-density catteries with high turnover of animals, highly susceptible animals, and changes in diet. It should be ensured that kittens receive colostrum. Less frequent but thorough disinfection is preferred to daily cursory disinfection, although spot cleaning should be performed every day. Because many enteropathogens are difficult to inactivate, the environment should be as dry as possible, exposed to UV light, and decontaminated with a disinfectant with activity against nonenveloped viruses. In some facilities, a 14-day intake quarantine is helpful. If the facility has an inadequate amount of space and holding time for a functional quarantine, the next best option is cohort admission.

Treatment

If necessary, empiric treatment of diarrhea may include use of antimicrobials, motility modulators, a bland diet, or anti-inflammatory agents. Antimicrobials can contribute to gut dysbiosis. Drugs to reduce gut motility and diarrhea increase retention time of all luminal contents, including pathogens that can exacerbate the disease. Bismuth subsalicylate should be used carefully in cats because they have very low tolerance for salicylic acid. Even use of bland diets can be counterproductive if cats reject them. Ensuring proper hydration and nutrition should be the focus whenever possible, which may require administration of subcutaneous or intravenous fluids, and tube feeding of inappetent cats.

Dermatophytosis

Etiologic Agents and Clinical Signs

Dermatophytosis (ringworm) is a fungal infection of the hair, nails, and superficial layers of the skin. Dermatophytes most commonly isolated from infected cats are *Microsporum canis*, *Microsporum gypseum*, and *Trichophyton mentagrophytes*. Dermatophytosis poses a significant management issue for multiple-cat environments because it is highly contagious, zoonotic, treatment can be lengthy, and environmental decontamination difficult. Dermatophyte infections tend to be most common in warm, humid environments, and in juvenile animals. Overcrowded conditions are a major risk factor for outbreaks. Early and accurate diagnosis of dermatophytosis in a multiple-cat environment is critical because environmental contamination can rapidly become difficult to contain.

Dermatophytes are divided into anthropophilic, zoophilic, and geophilic species. Anthropophilic species have evolved on humans and only rarely affect animals. Zoophilic species (e.g., *M. canis*) have adapted to animals, but may spread to humans. Geophilic species (e.g., *T. mentagrophytes*) are soil-adapted, and less commonly affect humans than animals. Although there are numerous species of dermatophytes that can affect cats, 90% of dermatophytosis in multiple-cat environments is thought to be due to *M. canis*.[24] For zoophilic species, infective arthrospores develop within the hair or skin, and the most important route of transmission is via direct animal-to-animal contact. For geophilic dermatophyte species, infective arthrospores can be present within the soil.

Dermatophytosis is acquired through contact with infective spores which can persist in the environment for weeks to months. The skin acts as a mechanical barrier, so any type of cutaneous trauma increases an animal's susceptibility to dermatophytosis. Grooming, clipping, or ectoparasites can all result in microabrasions to the skin. Dermatophyte spores can also be transmitted via fomites (e.g. towels, bowls, clippers, kennels) and potentially via airborne modes of transmission if fans or other air circulating devices are in use.

Dermatophyte conidia gain access to keratinized epithelium, then germinate, and mycelia enter cornified strata. As arthroconidia develop in tissue, clinical signs develop because of fungal products such as elastase, collagenase, and keratinase and as a result of allergic responses to the fungi. The incubation period for ringworm is between 4 days and 4 weeks. Infection finally may be resolved by cell-mediated immunity in weeks or months, although some carriers remain chronically infected. Severe or chronic disease prevalence is higher in geriatric cats, those younger than 1 year, Persian cats, cats infected with retroviruses, those that are pregnant or lactating, malnourished, or being given anti-inflammatory drugs, or those that have cancer or are stressed.

Cats with dermatophytosis classically exhibit circular areas of alopecia, broken hairs, crusting, and scaling. However, the clinical appearance is extremely variable. Lesions may be localized to the head or generalized and can vary in severity from minimal crusting and scaling to severely ulcerative, inflammatory lesions. The most common locations include the face, ears, feet, and tail. Subclinical carriage is also widespread. Pruritus may or may not be present. Some cats may present with a miliary dermatitis. Because the clinical signs are so variable, diagnosis should never be based on clinical signs alone. Major differential diagnoses include any disease that causes multifocal areas of alopecia, scale, and crusts, allergies such as atopic dermatitis, external parasites such as fleas and mites, cheyletiellosis, and demodicosis.

Dermatophytosis is also a zoonosis. Disease is most likely to affect very young, old, immunocompromised individuals, although healthy individuals can also become infected.

Diagnosis

Cats in multiple-cat environments can be screened for dermatophytosis using several complementary diagnostic tools: history, visual examination, Wood's lamp examination, PCR, direct examination of fluorescing hairs, and fungal culture. These tools can be used when cats enter a program, and/or when responding to a potential outbreak. It should be known if cats are littermates, from the same environment/home, and littermates or those living in contact with other animals should be treated as infected. A careful visual examination for dermatological issues should be a part of each cat's physical examination. Examination with a Wood's lamp can then be performed on any suspect lesions. In order for a Wood's lamp to be of use, proper technique must be followed with a lamp of sufficient quality (see Chapter 78). Wood's lamps emit long-wave, UVA light (320–400 nm). Infected hairs fluoresce because the fungus in the hair follicle deposits a metabolite on the growing hair shaft. Only *M. canis* produces this metabolite, and this bright apple-green fluorescence is thought to be seen in about 50% of *M. canis*-affected animals. Direct microscopic examination is performed on hairs plucked from the periphery of suspect and/or fluorescing lesions. Hair is cleared of keratin by suspending it in 10% to 20% potassium hydroxide. The slide is then gently heated for 15 to 20 seconds or allowed to stand for 30 minutes at room temperature before being examined. Infected hairs appear swollen and frayed, with loss of normal structure. Arthroconidia and hyphae occasionally can be seen.

Molecular assays are available for detection of dermatophyte DNA. PCR can be especially helpful early in the screening process and when monitoring treatment. However, because PCR is very sensitive, a positive result can be the result of active infection, fomites, or nonviable fungal organisms following successful treatment and fungal culture.[25]

Specimens for fungal culture are collected by plucking hair from the edge of the lesion or running a new toothbrush through the coat. If a toothbrush is used, the brush should be run over the cat's body until hairs are visible in the tines of the brush. If lesions are identified, they should be brushed last to minimize dispersal of spores. Hairs or toothbrush tines are placed onto an appropriate agar such as dermatophyte test medium (DTM) or rapid sporulation medium (RSM) that contain antibacterial and antifungal drugs to discourage growth of contaminants. DTM contains phenol red, which turns red in the presence of alkaline metabolites produced primarily by dermatophytes and a few saprophytes. Bromothymol blue in RSM turns blue-green in the presence of dermatophytes. Plates should be incubated between 27°C and 30°C for up to 3 weeks and should be observed daily for visible fungal mycelia and color change. When candidate dermatophytes are observed, hyphae should be examined under the microscope for the characteristic conidia (most easily seen on RSM) to confirm the diagnosis. This step, which is often skipped, is essential. The morphology and presence of macroconidia and microconidia are essential for confirmation and identification of dermatophytes.

Management and Prevention

Management of dermatophytosis in cat populations requires regular screening as described above in order to promote early recognition of disease and implement a plan for response if an outbreak occurs. Animals with positive culture results and possibly affected or exposed animals should be isolated. Staff members should wear gloves, smocks or coveralls, and boots or shoe covers while working with affected cats. After contact with dermatophyte-infected cats, staff members should not contact healthy cats until they have showered and changed clothes. Affected animals should not be allowed into the main facility until several weeks after clinical recovery and when weekly culture results have been negative for 2 consecutive weeks. Because dermatophyte spores are very hardy in the environment and resistant to many disinfectants,

emphasis should be placed on thorough and repeated environmental decontamination. This is most effective in multiple-cat environments that are designed to be easily sanitized. Food bowls, litter pans, grooming instruments, bedding, and other potential fomites such as toys should be disposable or able to be decontaminated. A 1:10 bleach solution with at least a 10-minute contact time, or accelerated hydrogen peroxide are appropriate disinfectant choices. Washable items can be cleaned in a dishwasher if it has a water temperature of at least 43.3°C (110°F).

Treatment

Although many cats will spontaneously recover from dermatophytosis within months, when dermatophytosis is confirmed in a multiple-cat environment, the risk of outbreak generally leads to initiation of early treatment. Oral antifungal drug therapy in combination with topical treatments are recommended. Topical treatment reduces contamination of the environment and aids in elimination of infection.[25] Clipping, which should be performed *gently* with a number 10 blade, removes infected hairs and therefore reduces environmental contamination, and can be useful for long-haired or matted cats. However, clipping can also introduce infected spores into the environment if not done carefully, so it is not recommended as a routine treatment. Miconazole and lime-sulfur dip (4%) used twice weekly are the most efficacious topical treatments. Many other creams, ointments, and shampoos have disappointing results. Systemic therapy in combination with topical therapy helps to shorten the course of infection because of its activity on fungus within the hair follicles. Itraconazole, fluconazole, and terbinafine are appropriate choices. In multiple-cat environments, it is recommended that treatment continue until two fungal cultures or PCR tests taken 1 week apart are negative.

Retrovirus Infections

Etiologic Agent and Clinical Signs

FeLV and FIV are retroviruses that infect cats worldwide. The prevalence of infection varies greatly depending on age, health, environment, and lifestyle. Despite reduction in prevalence due to vaccination and screening, these viral infections remain a concern where groups of cats are in close contact. In a 2008 study of 18,000 cats, the prevalence of FeLV infection (antigenemia) was 2.3%, and FIV antibodies were detected in 2.5% of cats.[26] A 2017 study of 62,301 cats showed a prevalence of 3.1% for FeLV and 3.6% for FIV.[27] Sick cats and cats allowed outdoor access have a higher prevalence of infection compared with healthy cats. Although some characteristics can be used to predict likelihood of infection (age, sex, health status, and lifestyle), all cats are potentially at risk and it is recommended that each individual cat's status be known. Multiple cat programs should have procedures and policies in place to identify and segregate infected cats from the healthy population, as this is the most effective means of reducing transmission. Neither viruses are currently considered to be zoonotic.

Cats typically acquire FeLV through the oronasal route. Viremic cats shed infectious virus in multiple body fluids, including saliva, nasal secretions, feces and urine, and milk. Examples of activities that allow transmission include grooming, fighting, biting, or transfer during pregnancy or nursing. Transmission through use of shared litterboxes or feeding dishes is possible but less common. FeLV infection is sometimes referred to as "the friendly cat disease" because it can be transmitted by grooming and cohabitating without overt fighting.

In contrast, FIV infection most often affects fighting male cats. The virus is shed in high quantities in saliva, and the primary mode of transmission is through bite wounds. However, transmission has been documented in groups of cats where no fighting has been observed. Sexual transmission and transmission from queen to kitten are uncommon.

Acute FeLV infection is rarely associated with observable clinical signs. There may be transient leukopenia, fever and lethargy, but these signs are generally so mild that they are not noticed by caregivers or are attributed to other causes. Many cats recover from this phase and become regressively infected, without further impact (see Chapter 32). Cats with regressive infections are not viremic; however, FeLV provirus DNA is integrated into the cat's genome and can be detected with DNA-based PCR assays. In cats with progressive infection, the virus replicates in the lymphatic tissues and then the bone marrow. These cats become viremic, and generally develop FeLV-associated diseases. Common clinical signs in cats that develop progressive infection include anemia, opportunistic infections, lymphoma, and gingivitis, and progressively infected cats often succumb to such diseases after several years. When kittens are infected *in utero*, they often do not survive to birth or are stillborn.

FIV infection is often subclinical for years, eventually followed by overt clinical disease in some cats (see Chapter 33). After infection, the cat develops a high viremia followed by host immune-induced significant reductions in circulating virus load. As with FeLV, the acute phase of FIV is transient, nonspecific, and often mild, including fever, reduced appetite, and enlarged lymph nodes. Even though the cat's immune response suppresses viremia, the cat remains infected. Cats then enter the prolonged subclinical period that can last for years. Progressive immune dysfunction during this phase culminates in the chronic phase of illness, sometimes referred to as "feline AIDS" where opportunistic infections, chronic inflammatory disease, oral disease, and a host of secondary conditions occur. Severe URTD, hemotropic *Mycoplasma* infection, and neoplastic disease are common.

Diagnosis

Ideally, all cats should be tested for retrovirus infection because of the consequences of infection and because identification and segregation of infected cats is the most effective method to prevent spread. Testing one cat as a proxy for another or pooling samples from multiple cats for testing is inappropriate. Testing on admission to a program is recommended when group/colony housing is the case. When cats are not comingling, testing on admission is optional but still recommended. Testing is also optional for managed feral colonies in part because neutering reduces fighting which limits transmission. Proper test interpretation is critical. Most FeLV infections are identified by p27 antigen ELISA assays. Most cats and kittens test positive on soluble antigen tests within 28 days of exposure; however, this can vary. When antigen testing is negative and recent exposure is possible (such as on admission), a repeat test should be performed or recommended a minimum of 28 days from the last potential exposure. Kittens may be tested at any time, as there is not a risk of maternal antibody interfering with test results. Some kittens may take weeks to months to test positive if maternal transmission has occurred. A positive ELISA test suggests viremia and true infection for many cats; when prevalence of disease is low, the risk of a false positive increases significantly. This means it is important to confirm positive test results using a different manufacturer's test or an IFA test, which can be performed on blood or bone marrow at any time. A positive IFA indicates a cat that is likely to be persistently infected, whereas cats with positive antigen tests but negative IFA tests may ultimately become regressor cats. If a second antigen test in 30–60 days is still positive, regressive infection is unlikely. PCR assays are positive both in cats with regressive and progressive infections. Cats with discordant results may require repeated testing until the discordance resolves, and should be considered infectious until then.

Cats should be screened for FIV infection using an antibody ELISA. PCR assays are not sensitive enough for screening. Maternal antibodies

can interfere with FIV testing in kittens, but false-positive test results rarely occur at 4 months of age and are very unlikely by 6 months.

Management and Prevention

The decision about how to manage retrovirus-infected cats in multiple-cat environments depends on many factors, including the mission and philosophy of the program, the physical facility, and other resources available. Infected cats can have an excellent quality of life for years; however, they have a contagious, potentially fatal infection and their condition requires appropriate housing and care to prevent transmission and maintain welfare and well-being. Cats that are housed individually pose no transmission risk and this may be an option in some programs. Because even moderately immunosuppressed cats are more susceptible to infection, cats with retrovirus infection can contribute disproportionately to the load of other pathogenic organisms in a multiple-cat environment, thereby increasing risks for other resident cats. In programs where isolation is unrealistic, grouping FeLV-positive cats together and grouping FIV-positive cats together could be considered. This is not ideal, as these cats are immunosuppressed and may transmit a variety of pathogens to each other. It is not recommended to comingle FeLV- or FIV-positive cats with a retrovirus-negative population. Cats must be well nourished, protected from stress and other infectious diseases, and treated for secondary conditions. If the program places cats in homes, either through sale or adoption, new owners should be informed of any positive FeLV/FIV status, the meaning of positive test results, advised to keep cats indoors, and provided with recommendations for care and treatment of these cats. In group environments, the FeLV vaccine can provide protection and is recommended. Because the vaccine requires two doses spaced apart by 2 to 4 weeks for efficacy, use in TNR programs is not advised. Cats should test negative before vaccination, the vaccine should never be considered a replacement for test and segregation as a control strategy, and there is no benefit to vaccinating an already infected cat. In locations where the FIV vaccine remains available, FIV vaccination makes screening difficult because vaccinated cats develop antibodies and therefore have positive ELISA assay results (see Chapter 33). For this reason, the FIV vaccine has not been generally recommended. If ever used, cats should be microchipped and vaccination documented in the medical record in association with the microchip number.

Treatment

Retrovirus-positive cats should receive biannual wellness examinations. A CBC is recommended annually for FIV-infected cats and semi-annually for FeLV-infected cats. Serum biochemistry testing should be performed annually. Spay or neuter is advised for these cats and vaccination decisions are based on individual cats' needs. Inactivated vaccines are generally recommended due to the potential for vaccine-associated disease in an immunocompromised animal. Retrovirus-positive cats should be housed indoors and treated regularly with parasiticides. Studies evaluating antiviral and immunomodulatory drug therapy in cats with retrovirus infections have met with somewhat disappointing results, although the use of oral IFN-α has shown some benefit for cats with stomatitis (see Chapter 33).

Prognosis

It is important to remember that healthy cats that test positive for FeLV may become regressor cats and never develop disease. Even cats that are persistently infected can remain healthy for several years with proper care. Similarly, lifespan may not be negatively impacted by FIV infection, and with supportive care for stomatitis and other secondary infections, even cats with advanced FIV infection can have a good quality of life for many months.

Feline Infectious Peritonitis

Etiology and Clinical Signs

FIP is the disease caused by FCoV, an enveloped RNA virus. Most strains of FCoV have low pathogenicity, and as such either do not cause disease, or just mild enteritis. Transmission of these strains is by the fecal-oral route. In multiple-cat groups, 40% to 60% of the cats shed virus in their feces at any given time, and virtually all cats have positive coronavirus serum antibody test results. Contaminated litterboxes are a major source of infection. However, transmission can also occur indirectly through fecal particles on the fur, and fomites on caregivers' clothing, hands, and sanitation implements.[28]

Low-virulence FCoVs replicate primarily in enterocytes, but also can also be found in other tissues (as a result, the term "feline enteric coronavirus" has been used to describe these strains). Subsequently, most cats eliminate infection. Persistently infected carrier cats predominantly harbor FCoV in their colonic mucosa, facilitating prolonged fecal shedding of virus.[29,30]

A small percentage of cats go on to develop FIP as a result of an interplay between an aberrant immune response and mutation of the virus that allows it to enter macrophages and cause a systemic vasculitis. FIP most commonly develops in 1- to 3-year-old cats from multiple-cat environments and in cats over the age of 12 or in immunocompromised cats, including kittens and retrovirus-positive cats; however, cats of any age and health status can be affected.

Two clinical forms of FIP exist, the effusive ("wet") form and noneffusive ("dry") form, and some cats may initially develop noneffusive disease and progress to effusive disease, or have both forms concurrently. The time between initial exposure and development of FIP varies greatly. Effusive FIP typically progresses more rapidly, over several weeks, with accumulation of moderate- to high-protein effusions in the thorax or abdomen, which leads to dyspnea or abdominal distention. In noneffusive FIP, pyogranulomas develop within a variety of tissues, which can lead to formation of masses and organ failure. Noneffusive FIP may result from a partially successful cell-mediated immune response and signs may not be apparent for months to years. Clinical signs vary depending on the affected organ system and include fever, icterus, ascites, dyspnea, abdominal lymphadenopathy, thickened intestinal loops or abdominal masses, irregular renomegaly, uveitis, and neurologic signs.

Once it develops, FIP is progressive and fatal. Virulent FIP viruses are not shed from the intestinal tract, so FIP is not transmitted from one cat to another. In multiple-cat populations, apparent "outbreaks" of FIP can occur, which are thought to relate to the accumulation of factors that promote virus replication and mutation within individual cats (e.g., genetic susceptibility, concurrent infections, malnourishment, overcrowding, high juvenile to adult cat ratio; see Chapter 31). FCoVs do not infect humans, so there is no risk of zoonotic transmission.

Diagnosis

Obtaining a definitive diagnosis of FIP can be challenging. Clinical signs and laboratory abnormalities are nonspecific. The presence of marked hyperglobulinemia can add support to the diagnosis, and the likelihood of FIP is increased if the characteristic high-protein, low-cellularity effusion is identified. Unfortunately, many cats do not develop these abnormalities. Ultimately, diagnosis is based on a composite of history, signalment, clinical observations, physical examination, laboratory findings, and specific diagnostic testing.

Regardless of the magnitude of the antibody titer, diagnosis of FIP should never be made on the basis of serology alone. Generally, a positive titer result only indicates exposure to a coronavirus, which is more often a low-virulence FCoV strain. Very high (e.g., > 1:3200) titers may be suggestive of FIP in conjunction with consistent clinical signs.

Although some assays are more likely to detect strains with mutations associated with virulence, real-time RT-PCR assays cannot reliably differentiate between low-virulence FCoVs and FIP viruses. Ultimately, the only way to confirm a diagnosis of FIP is to identify coronavirus antigen with immunohistochemical stains in consistent lesions within biopsies or at necropsy. Immunocytochemistry can also be performed on aspirates or cytospins of effusion fluid, but the sensitivity of this method is lower and false-positive results are possible if the technician performing the assay is not adequately experienced.

Management and Prevention

FCoV infections can generally only be eradicated in very small groups of cats (≤ 4 per housing unit). An intranasal vaccine is available, but it has limited efficacy and must be given *before* FCoV exposure, which typically occurs before the age of administration (16 weeks). Prevention of FIP should focus on minimizing overcrowding, fecal contamination, concurrent infections, and the juvenile to adult cat ratio.[31] In breeding catteries, the use of male cats that generate offspring that develop FIP should be avoided for further breeding efforts.

Treatment and Prognosis

Supportive care and use of oral prednisolone at anti-inflammatory doses are currently the mainstay of treatment. In some cats, treatment with prednisolone can lead to complete remissions, but ultimately, weeks to over a year later, disease relapses. There have been encouraging advancements in antiviral drug therapy for FIP (see Chapters 9 and 31), but none of these drugs are commercially available at the time of writing.

Prevention and Management of Infection in Canine Populations

Kate F. Hurley, Stacy Kraus, Jane E. Sykes

KEY POINTS

- Dog populations may be transient or stable. Transient populations have the greatest susceptibility to infectious diseases.
- The key for control of infectious disease in dog populations is ensuring capacity is appropriate and controlling dog movement to limit transmission of disease.
- Other important preventative measures are proper disinfection, reduction of stressors, use of parasite preventatives, vaccination, routine health surveillance, and in animal shelters, active management of length of stay.
- Many pathogens in dog populations have the potential to be transmitted to humans that are in contact with infected dogs. Attention to infection control protocols therefore promotes the health of humans as well as the dog population.

CHARACTERISTICS OF DOG POPULATIONS

Dog populations may be transient or stable. Transient populations are usually associated with veterinary hospitals; grooming and boarding facilities; community animal shelters; communal areas such as dog daycare facilities, dog parks, and dog shows; rescue organizations; retail outlets; suppliers that acquire and condition dogs for resale; and research kennels that do not maintain long-term residents. Relatively stable adult canine populations are found in kennels that support purebred interests (breeding or performance), in those that produce puppies for commercial pet channels, in research kennels that maintain long-term residents, and in multiple-pet households. Characteristics of both stable and transient populations can be noted in many settings including households, shelters, sanctuaries, and breeding and performance kennels.

Regardless of their purpose, all dog populations share general features, including close proximity of residents, some means of confinement, systems for sanitation and husbandry, and some means to deliver preventative and individual animal health care. The type and prevalence of infectious disease that occurs in a population depends on the regional prevalence of an infectious disease and the characteristics of both the facility and the dog population. For example, CPV can persist long-term in some environments if not effectively inactivated or removed. The disease is unlikely to be significant in a population of adult, vaccinated dogs, whereas populations that include naïve puppies are likely to experience a higher incidence of infection and disease. Disease caused by pathogens that survive poorly in the environment, such as those involved in canine infectious respiratory disease complex (CIRDC) (see Chapter 28), is more likely to occur when there are environmental stressors and crowding. Animal shelters offer unique challenges because transient dogs can subclinically be shedding pathogens common to the larger community.

Two extremely important management concepts in population medicine are defining capacity (management of population density) and control of movement of dogs within and among populations (e.g., segregation). Also of importance is proper environmental management of any facility in which a canine population is housed.

Regardless of the type of facility, strong preventative health care is necessary. A comprehensive population infection control program requires planning. Veterinary professionals are essential in the identification of risk factors for disease, to help direct the development of policies and procedures, and in the assessment of effectiveness of these measures.[1] Planned preventative care management is far more efficient and cost-effective compared with purely therapeutic or reactive management to infection outbreaks. In addition, thorough education and training of owners, managers, and staff is critical to successful implementation of a plan.

Zoonoses are of concern in all dog populations, particularly those with a high level of public interaction such as dogs in shelters and pet stores. Specific strategies, including training and availability of personal protective equipment (PPE), should be in place to ensure that staff and public health risks are minimized. Pathogens that have the potential to cause disease in humans in poorly managed environments are listed in Table 17.1.

DISEASE TRANSMISSION

Periodic introduction of disease into canine populations is inevitable, especially in transient populations. The likelihood that disease introduction will lead to transmission within a given population depends on the virulence of the organism introduced, the mechanism of transmission, the immunity of the dog population, and environmental factors that influence level of exposure. In populations where dogs are singly housed, direct transmission is of minimal importance. If dogs have direct contact with one another through open cage panels or are allowed to intermingle during cleaning, the direct route of transmission becomes more significant. The most common method of spread among singly housed dogs is likely to be transmission via contaminated fomites, such as hands, clothing and footwear, equipment, or surfaces. Droplet and aerosol transmission are concerns for canine respiratory pathogens such as CDV and CIVs. Pathogens such as CPV that are not normally airborne can nonetheless be spread by power sprayers or via dust spread by high-power fans. Vector-borne transmission can be an issue in populations where external parasites or biting insects are not controlled.[2]

TABLE 17.1 Examples of Pathogens with the Potential to Cause Disease in Humans in Contact with Dog Populations and Their Mode of Transmission

Pathogen Group	Pathogen Name	Route of Transmission
Viruses	Rabies virus	Bites
Bacteria	*Anaplasma phagocytophilum*	Ticks
	Bartonella spp.[a]	Fleas, needle-stick injuries, ticks?
	Bordetella bronchiseptica	Respiratory: droplets, fomites, close contact with infected dogs
	Brucella canis	Close contact with urinary, respiratory secretions from infected dogs, especially breeding kennels
	Campylobacter spp.	Fecal-oral
	Clostridioides difficile and *Clostridium perfringens* (toxigenic)	Fecal-oral
	Coxiella burnetii	Contact with placental materials
	Leptospira spp.	Contact with urine
	Multidrug-resistant bacteria (e.g., *Staphylococcus* spp., pathogenic *Escherichia coli*)	Contact with skin, urine, feces; infections of preexisting wounds; bites
	Hemotropic *Mycoplasma* spp. (e.g., "*Candidatus* Mycoplasma haematoparvum")[a]	Ticks?
	Pasteurella spp.[a]	Bites, preexisting wound infections
	Salmonella spp.[a]	Fecal-oral
	Streptococcus equi subsp. *zooepidemicus*	Respiratory droplets, other?
	Rickettsia rickettsii and other *Rickettsia* spp.	Ticks
Fungi	Dermatophytes[a]	Direct contact
	Malassezia spp.[a]	Direct contact
Protozoa	*Cryptosporidium* spp.[a]	Fecal-oral
	Giardia spp.	Fecal-oral (some assemblages)
Helminths	*Dipylidium caninum*	Fleas
	Toxocara canis	Fecal-oral
Arthropods	*Sarcoptes scabiei*	Direct contact
	Fleas	Direct contact, environmental
	Ticks (especially *Rhipicephalus sanguineus*)	Direct contact, environmental

[a] Most significant disease in the immunocompromised.

Environmental factors that influence transmission include population density; kennel design; the extent to which populations are segregated effectively; sanitation; and conditions such as ventilation, noise, and humidity.

MANAGEMENT OF POPULATION DENSITY

Maintaining population density within the capacity of the organization and facility is the foundation for a successful infectious disease management program. Crowding is a profound risk factor for transmission of infectious diseases in any population. For example, every day a dog spends in a shelter, they increase their risk of infectious respiratory disease by 3%. A greater burden is placed on air-handling systems, noise tends to increase with more barking dogs present, and the stress associated with crowded conditions will increase susceptibility to disease. If an increase in density is not accompanied by a commensurate increase in staffing, daily care for each animal may be compromised. This can lead to failures in key husbandry practices such as cleaning, monitoring for illness, and prompt isolation of potentially infectious dogs. A vicious cycle can easily ensue as the number of sick dogs increases. Daily treatment will require even more staff time, and individualized care is further jeopardized. The level of infectious pathogens increases in the environment, and spread of infection continues.

To avoid overcrowding, the appropriate capacity of the facility must first be determined. Maximum capacity should be calculated and not exceeded. Ideally, the population should be maintained at no more than 80% of capacity, to allow flexibility for management of dogs with special needs and to prepare for unexpected influxes. Capacity depends on the number of appropriate housing units and available staff time and can vary by subpopulations. For example, capacity for puppies cannot be the same as that for adult dogs, because special housing is required to prevent exposure of puppies to infectious disease. According to the National Animal Care and Control Association,[3] in a shelter situation, 15 minutes per dog is required for minimal daily care and cleaning (9 minutes for cleaning and 6 minutes for feeding). More time will be required to care for animals if the facility design prohibits efficient cleaning. It is more labor intensive if dogs must be removed from their kennels to a holding area that must be disinfected between uses. Optimally, dogs should be housed in a double-sided run where the dog can be moved to one side while the other side is being cleaned (Fig. 17.1). Additional time must also be allocated for medical care, socialization, and other special needs depending on the type of facility and the population in its care. In order to calculate staff capacity of an organization, available total staff time for care is divided by the number of minutes required per dog. For example, in a facility that has one staff member providing 8 hours of care/day for dogs requiring 30 minutes of care each, the staff capacity is 16 dogs. Documenting facility and staff capacities compared to actual average daily animal census on a monthly basis can be helpful for organizations experiencing a great deal of variation in daily population over the course of a year, such as shelters and some boarding facilities (Figs. 17.2 and 17.3).

Fig. 17.1 Double-sided run with a sliding door that separates the two halves. This allows the dog some control over its environment and permits cleaning and care without removing the dog from the run. (From Greene, *Infectious Diseases of the Dog and Cat*, 4e. Figure 96-3, p. 1126.)

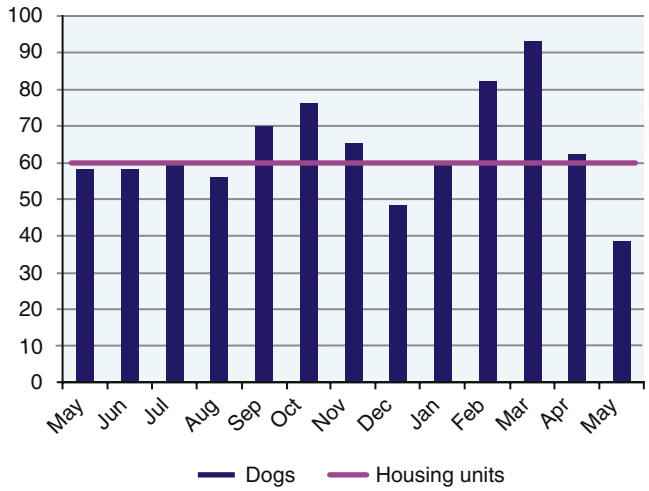

Fig. 17.2 Graph comparing facility capacity to average daily canine population by month over a 1-year period. In this facility, the number of housing units was inadequate for 6 of the 13 months recorded, resulting in chronic overcrowding. (Modified from Greene, *Infectious Diseases of the Dog and Cat*, 4e. Figure 96-1, p. 1125.)

The average daily population for the month is calculated by summing the daily population for each month and dividing by the number of days in that month.

Length of Stay and Pathway Planning

In contrast to some populations in which decreased transience is associated with decreased risk of infectious disease introduction and transmission, increased length of stay (LOS) has been identified as one of the most important risk factors for disease in animal shelters. This is likely due to the relationship between LOS and crowding and its associated risks: for a given number of dogs admitted to a shelter,

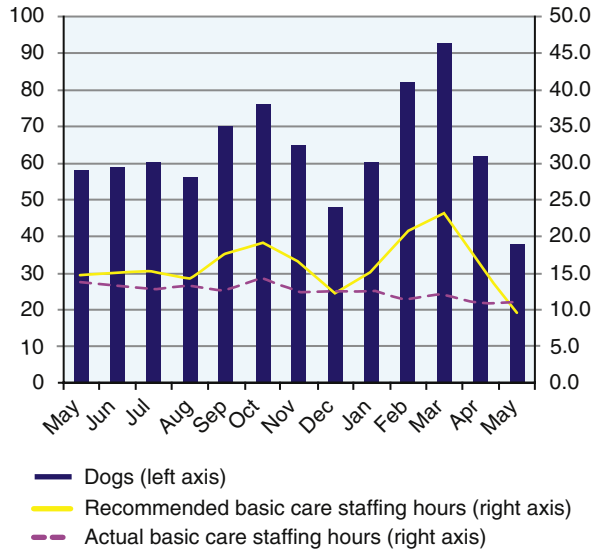

Fig. 17.3 Graph comparing staff capacity (total number of minutes available for care of dogs) with average daily canine population by month over a 1-year period. In this shelter, staffing at times was less than half the level required to provide the recommended minimum 15 minutes of daily care per dog. (Modified from Greene, *Infectious Diseases of the Dog and Cat*, 4e. Figure 96-2, p 1125.)

doubling of the LOS will double the population density on a daily basis. Active management of LOS is therefore a foundation of a successful disease control program in a shelter (or other setting with a fixed capacity and limited control over the rate of new admissions). Ideally, "pathway planning" should begin as soon as an animal is admitted in order to identify the shortest pathway to the best possible outcome for the animal. This can be facilitated by admitting animals that do not need admission on an emergency basis using an appointment system. Needed services such as spay/neuter surgery should be scheduled as soon as possible. Daily population rounds, in addition to identifying health concerns, should include an assessment of any needed actions to help move the dog safely through the system. These could include contacting possible owners or interested parties, marketing the dog for adoption, or evaluating rescue options. Prolonged stray holds often do not assist in increasing return to owner rates and the benefit of these should be carefully weighed against the risks of increased LOS. Ideally, long stray holds should be replaced by active programs to contact owners and reunite dogs with their families. Importantly, rushing to euthanasia or another suboptimal outcome is not a method to manage LOS. Rather, the overall average should be reduced by removing bottlenecks and rapidly identifying barriers, allowing adequate time to care for dogs with more complex needs or requiring a longer shelter stay.

KENNEL DESIGN AND LAYOUT AS IT RELATES TO POPULATION HEALTH

The building layout and defined activity zones will vary based on the mission and function of each facility. Specific zones should be separated and designated by signage to minimize transmission of disease. Some units have a public zone (e.g., veterinary hospitals, boarding and grooming facilities, shelters) that can include an entry area, housing areas, and activity areas. All units should have a restricted zone that includes rooms where animals are received, are held once entering the facility, and are examined for health assessment

and treatment. Some facilities, such as breeding facilities and some shelters, need a physically isolated intake area to hold animals for observation and diagnostic testing before introducing them to the population. Additionally, quarantine areas may be required for isolation of dogs potentially incubating serious infectious diseases, and separate isolation rooms are needed for dogs with signs of disease if treatment is provided in-house. Areas for pregnant bitches, nursing puppies, and weaned puppies should be located away from the general population. Additional detail on segregation is provided later in this chapter, and more information on facility design is available from the resources listed in Box 17.1.[4]

Kennel Type and Size

The minimum size of enclosures depends on factors such as dog breeds housed and duration of housing. Recommendations have been published by the Association of Shelter Veterinarians,[5] the Animal and Plant Health Inspection Service, Department of Agriculture of the United States,[6] and the National Research Council (Box 17.1).[7] Barring medical conditions that require limited movement, enclosures must be of sufficient size to allow dogs to assume normal postures without touching the sides of the enclosure and to urinate and defecate away from feeding and sleeping areas; must accommodate bedding; and must allow for expression of a range of normal behaviors. Size and quality of housing will need to be greater for dogs housed for longer time periods (more than 2 weeks) and for whom no other avenue for exercise, play, and socialization is routinely provided. In production units or shelters, areas for pregnant bitches, nursing bitches, and litters are needed. Space should be adequate for the bitches to separate themselves from the litter. Enclosures should have solid barriers between adjacent enclosures to minimize transmission of pathogens.

Double-sided kennels separated by a guillotine door facilitate cleaning, provide separation of areas for eating or resting versus elimination, facilitate cleaning of enclosures without exposing animals to water or disinfectants, and allow care of aggressive dogs with minimal risk to staff (see Fig. 17.1). Puppies should always be housed in easily sanitized double-sided cages or runs that permit easy and efficient cleaning and care. Doors on kennels or runs should be secure.

Outdoor runs of concrete can be easily cleaned and sanitized. Runs built of gravel, dirt, or grass are challenging to sanitize and may harbor microbes and parasites, especially in warm, humid climates. Daily removal of feces from these areas is essential to limit contamination of the soil, and puppies or dogs with unknown vaccination history should not be exposed to these areas.

Surfaces and Flooring

Buildings should be constructed of materials that can be easily cleaned and disinfected. Concrete facilitates sanitation, provided it is sealed to make the surface impervious. Floor treatments should be coved up the wall of the kennel area and other areas where dogs may walk to facilitate cleaning. Floors should gradually slope to a drainage system to which dogs do not have access.

Play and Socialization Areas

Play and socialization areas can serve different functions in different units. In the shelter environment, these areas can serve to enrich the environment with fresh air and sunshine and to permit dog-human interaction. They can also serve as a place for supervised play between selected dogs. In a breeding establishment or shelter housing puppies, these areas serve as a play area, but also an area to socialize puppies to handling and to different humans. Ideally, separate areas should be dedicated for puppy use. Play areas for puppies should have surfaces that are readily disinfected. Dog parks and dog daycares are areas of dog socialization. In all of these situations, there is potential for ground contamination with enteric pathogens as well as the opportunity for direct transmission of infectious agents when dogs interact with one another. These facilities generally have porous ground surfaces, making sanitation difficult, and reduction of fecal contamination is dependent on owners taking responsibility for cleaning up after their pet.

SEGREGATION OF POPULATIONS

It is generally impractical, and often not desirable, to isolate healthy, compatible dogs from one another during confinement.[8] However, segregation of transient subpopulations is critical for infectious disease control. Less stringent precautions are required for healthy, adult dogs that are currently vaccinated, whereas greater care can be taken when handling vulnerable or infectious individuals.

Characteristics of Effective Segregation

Ideally, separate air supplies should be used for subpopulations, particularly for isolation of dogs with respiratory infections. At minimum, clear visual barriers should delineate physically separate areas stocked with separate equipment and supplies. Color coding of equipment can help ensure that it stays in the designated area. Appropriate PPE should be worn in areas housing puppies, sick dogs, or dogs with unknown or high-risk health histories. This includes long-sleeved tops and long pants or jump suits. Either hands should be thoroughly washed or sanitized before and after entering separate areas, or gloves should be worn and changed between areas. Sanitizer should be available outside each kennel and filled regularly. Gloves should be worn when handling sick dogs, because hand washing is not sufficient to reliably inactivate

all pathogens. Shoe covers or dedicated boots should also be worn in areas housing sick dogs, because foot baths are not sufficient to reliably prevent transmission of disease.[9]

Categories for Segregation

Puppies

Because maternal antibodies may prevent effective immunization until approximately 16 to 20 weeks of age, puppies should always be housed and handled with special attention to infectious disease control. Puppies from different litters should not be cohoused unless both groups have been treated for parasites and there is a very low historical incidence of infectious disease.

Dogs with Unknown Health History

Some vaccines take a week or more to provide full protection, and the incubation period for many infectious diseases is a week or longer. Therefore animals with unknown vaccination or health history should initially be housed in easily sanitized areas and be attended to after the healthy resident dog population. True quarantine for newly admitted or acquired dogs is only viable when additional dogs are not admitted to the population during the quarantine period. This can be used for boarding and breeding facilities and some limited-intake shelters or sanctuaries. However, true quarantine is rarely feasible nor necessary in shelters, and the increased LOS associated with quarantine generally outweighs any benefit of this practice. Instead, newly admitted dogs should be vaccinated immediately upon intake, examined by trained staff, and observed for the first several days of care to monitor for any signs of ill health.

Dogs with Known Exposure to Contagious Pathogens

Dogs with a known history of exposure to CPV, CDV, or other serious contagious pathogens should be assessed for risk of infection based on history, degree of exposure, and antibody titers if appropriate.[10] At-risk dogs should be housed separately for the incubation period of the disease in question (see Dogs with Infectious Disease). If dogs develop illness during the quarantine period, risk assessment must be repeated for remaining dogs and the quarantine period restarted for dogs at risk of new exposure.

Dogs with Infectious Disease

Dogs with known or suspected infectious diseases should be housed in isolation. Ideally, separate isolation housing should be available for dogs with different conditions (e.g., suspected respiratory versus GI infections). At minimum, each dog in an isolation area should be handled with infectious disease precautions (Box 17.2).

Depending on the purpose of the facility, additional categories for segregation may be desirable, including maternity or nursing wards and areas for dogs that are to be rehomed or that require special care or monitoring.

BOX 17.2 Minimum Requirements When Husbanding Dogs in Isolation

1. Care for all healthy, resident animals before entering isolation facility.
2. Don personal protective equipment (PPE: gown or coveralls, gloves, shoe covers, or boots).
3. Avoid wetting animal during cleaning.
4. Examine animal and perform any required treatments.
5. Provide fresh food and clean water.
6. Remove PPE and put disposables in trash or put reusables in laundry.
7. Repeat steps 1 through 6 for each animal in the isolation ward.
8. Do not reenter resident facility.

DISINFECTION, SANITATION, AND PEST CONTROL

One of the cornerstones of prevention and control of disease in populations is a thorough cleaning and disinfection program. It is important that staff have a sound understanding of the major contagious pathogens of dogs, how they are transmitted, the degree to which they persist in the environment, and how they are best inactivated. Posted wall charts can facilitate access to this information. Decontamination of clothing, equipment, and hands as well as surfaces must be systematically addressed.

Effective cleaning and disinfection are dependent on knowing where to disinfect, choosing the right products, and following the essential steps in a disinfection protocol (see Chapter 14).[11] Proper cleaning procedures, including removal of organic material, rinsing before application of disinfectant, and attention to contact times are necessary. The order in which rooms and zones are cleaned and disinfected should proceed from areas housing healthy animals to those housing more vulnerable populations (e.g., puppies or newly admitted dogs) and finally to areas housing sick dogs. If this is not practical for logistical reasons, a change of PPE between areas can serve a similar purpose. Areas accessible to the general public should not be overlooked when developing a plan. Good management procedures, such as traffic patterns; holding, isolation, and quarantine protocols; vector control; washing and sanitation of feed and water bowls; and laundry procedures should be developed and modified when necessary. Education and regular training are key to success.

Pest control can be challenging in animal facilities, and the types of pests may vary with the region. Insects and rodents can contribute to disease outbreaks because they can be mechanical vectors of pathogens or reservoir hosts. All animal waste and spilled animal feed should be frequently removed from floors and feed bins and trash receptacles should be secured shut. Integrated pest management (prevention, nonchemical control when possible, and monitoring) can be effective, although commercial rodent/insect control programs, with careful assessment for safety of any chemical application, may be necessary.

OTHER ENVIRONMENTAL FACTORS

Attention to proper ventilation, humidity, temperature, sound and lighting levels is important to maintain the comfort of animals and caregivers and to reduce disease. Heating, ventilation, and air conditioning (HVAC) systems that share air through the system can serve as a vehicle to circulate pathogens throughout the facility, although other environmental factors such as population density and sanitation can outweigh this risk in most facilities. Separate HVAC systems are ideal and, if strategically placed (e.g., isolation facilities, nursery areas), can help minimize transmission of pathogens. In addition, good HVAC systems remove excessive moisture, dust, irritating gases, and chemical fumes. HVAC systems should not run only based on temperature adjustment, as this may lead to inadequate fresh air exchange during times of year when the temperature is mild. Humidity should be minimized by keeping the animal care areas and dogs as dry as possible. Physical drying of runs helps to keep dogs dry and comfortable and decreases odor and growth of mold and bacteria. Temperature should be maintained within a range that maintains animal comfort.[7] General guidelines are available (e.g., the AVMA recommends a range of 60 to 80°F); however, temperature requirements will vary depending on factors such as age, breed, and medical condition. Daily temperatures should be monitored using a high-low thermometer. Relative humidity should also be checked before husbanding the area. Barking dogs can increase the noise levels above those mandated by the Occupational Safety and Health Administration (see Guidelines for Standards of

Care in Animal Shelters, Box 17.1). Ear-protective devices should be worn to protect staff in these environments. Noise reduction is also advisable to reduce dog and human stress. Good lighting is essential in order to observe and inspect the behavior and physical condition of dogs, as well as for effective cleaning. Natural lighting can benefit both dogs and humans. Controlling the light-dark cycles (12 hours on, 12 hours off) maintains circadian rhythm.[7]

HOST FACTORS

Many pathogens commonly associated with respiratory or GI disease outbreaks can also be isolated from apparently healthy dogs. The likelihood of illness is influenced by the virulence of the pathogen, infective dose, and the host's innate and acquired immunity. Most pathogens also predispose to coinfections because they suppress normal host immune responses or damage host barriers. Immunity can be supported by controlling these coinfections, minimizing stress, and promoting normal behaviors such as self-grooming, eating, drinking, and developing a care routine.

Vaccination

Vaccination can largely prevent certain systemic infectious diseases in canine populations (e.g., parvovirus and canine distemper) and can reduce the frequency and severity of others, such as CIRDC. Vaccination programs should be tailored to the needs of the specific population. For transient kennel populations, such as shelters and boarding facilities, the focus of vaccination is on rapid protection from the limited subset of pathogens most likely to spread in this environment, including CDV, CPV, parainfluenza virus, adenovirus, and *Bordetella bronchiseptica*. Most dogs entering animal shelters may have insufficient titers for protection against CDV and CPV infection.[12] Although some attenuated live vaccines provide a degree of protection within hours to days, ideally vaccines should be given at least a week before entry into a kennel environment to optimize protection (see Chapter 20 and Appendix). If vaccination before entry is not possible, vaccines should be given immediately on admission for all dogs over 4 weeks of age. Inactivated vaccines may not provide protection until 10 to 14 days after a booster vaccine is administered, and for this reason will have limited benefit in highly transient dog populations such as many shelters. For stable kennel populations, infectious disease risk is likely to be lower and vaccination considerations are more similar to those in pet dogs, taking into account the exposure risks particular to the environment and the dog's lifestyle.

Parasite Control

External and internal parasite control is important to support animal health, to prevent contamination of the environment with resistant life cycle stages, to reduce transmission of vector-borne pathogens, and to protect public health. Animals and the environment should be treated as product information dictates to control fleas, ticks, and other external parasites. All animals should be treated with endoparasite preventatives (see Box 17.1)[13] and for heartworm depending on regional and environmental risk of exposure. Treatment for intestinal parasites should ideally be completed before entry into a kennel (e.g., for boarding kennels); otherwise, treatment should be initiated immediately on entry, and animals should be housed in easily cleaned environments until treatment has been completed. Diagnostic testing for internal parasites, when indicated, should ideally be performed at the time of entry to a facility and in the event of disease problems.

Nutrition

For dogs in transient populations such as shelters and boarding kennels, nutritional intake may be compromised by stress, unfamiliar or contaminated food, or competition with kennel mates when dogs are housed in groups. The goal of a feeding program for dogs housed for short periods is to support adequate nutritional intake, avoid anorexia, and prevent diarrhea. Unless the specific diet and amount of food the dog is normally fed are known, a high-quality diet appropriate to the life stage of the animal should be fed initially at the high end of the manufacturer's recommended amount.

Behavioral Wellness/Enrichment

In addition to being a welfare consideration in itself, behavioral wellness programs contribute to infectious disease control by reducing stress and supporting normal self-maintenance behaviors. For all dog populations, infectious disease control must be balanced with enrichment programs. However, LOS is a substantial risk factor for infectious disease in animal shelters, and enrichment can help maintain the behaviors and show dogs in natural settings that can lead to more rapid adoption or other positive outcomes. For dogs that have been vaccinated on intake and observed to be free of signs of infectious disease when monitored for several days, the benefits of out-of-cage enrichment and playgroups generally outweighs the small increased risk of infectious disease transmission. Even for dogs that cannot safely be removed from their runs, training and enrichment can be offered via clicker training, treats, and toys provided by facility staff members.

HEALTH MONITORING

Routine health monitoring of individuals ensures that health problems are promptly identified, treatment is implemented, and infectious disease spread prevented. Monitoring the population as a whole provides a means to evaluate success of husbandry procedures and detect emerging trends in population health. The larger and more transient the population, the more important a formal health monitoring system becomes. However, even for relatively small or stable populations, such as rescue homes, breeding kennels, and sanctuaries, a monitoring system should be established to prevent subtle health problems from being overlooked.

The first component of health monitoring is a thorough physical examination performed on entry to the population. This is important even for facilities admitting dogs in presumed good health. An entry examination documents preexisting conditions, and identifies problems that require treatment or special handling precautions. Results of the examination should be documented and accessible. Provided they remain apparently healthy, dogs in stable populations should be examined at least biannually; more frequent examinations should be performed in populations with higher turnover of animals and caregivers.

For transient populations, "daily rounds" should also be performed during which every animal is visually examined. This should occur before cleaning so that if potentially contagious conditions are identified, steps can be taken to prevent fomite transmission to other dogs in the course of care. Minimum daily observations include a visual assessment of the kennel and dog, including attitude; behavior; presence and character of urine and feces; whether food has been eaten; and any clinical signs such as respiratory, cutaneous, or GI signs. Daily observations should be recorded so patterns of illness can be monitored both for individual dogs and the population as a whole.[14] Example protocols and monitoring sheets can be found at academic shelter medicine sites online (see Box 17.1).[15,16]

In the event of an increase in frequency or severity of signs suggestive of infectious disease, diagnostics should be performed to identify the cause. Specimens should ideally be obtained from 10% to 30% of the population, or at least 5 to 10 acutely affected dogs. The frequency and timing of shedding should be considered when obtaining

specimens for pathogen detection; for instance, the peak shedding period for canine influenza virus precedes clinical signs, so specimens from exposed as well as affected dogs should be tested. If any dog dies or is euthanized with clinical signs of an unidentified illness, necropsy should be considered if an infectious disease is suspected, and is strongly recommended if more than one animal dies with similar signs. At a minimum, specimens should be obtained and held for later testing if further cases are identified.[17] Tissues should be placed in formalin, refrigerated, and frozen so that histopathology, bacterial culture, and nucleic acid amplification assays can be performed if needed. Bacterial culture of specimens held at 4°C for longer than 24 hours is not recommended due to loss of bacterial viability or overgrowth by contaminating bacteria or fungi (see Chapter 3 for more information).

RECORD KEEPING

Thorough medical record keeping is a key component to proper management of dog populations. Each dog should have a record that includes its origin, signalment, history and physical examination including description, and any identification number (e.g., microchip number). Preventative medications should be documented (e.g., anthelmintic used, dose, and route). Details of diagnostic tests performed and their results should be recorded. Reproductive history and findings, including breeding dates, should be recorded for both male and female breeding dogs to assist with prediction of whelping dates and fertility assessments. Reproductive status (intact versus spayed or castrated) should be included. In production units, number of puppies, viability, congenital abnormalities, birth weight, and daily weights should be recorded. Any abnormalities or adverse events following treatment should also be recorded. In small facilities, written records may be kept, but electronic record-keeping systems are commercially available for some types of facilities (e.g., shelters) and can be critical for proper tracking of disease over time.

In addition to the individual record, records to assess the population are also beneficial for health assessment, incidence or prevalence of disease, LOS or animal care days, and other established performance measures based on the facility mission. Tracking current disease rates and comparing them to previous rates can provide incentives for beneficial changes to preventative health protocols. The ability to retrieve valuable information is based on accurate recording of information, and careful assessment.

COMMUNITY HEALTH

Because of the potential for transmission of zoonotic infectious diseases from dog populations to humans, maintaining dog population health is an important component of supporting community health. Although development of a comprehensive infection control plan represents a significant investment of resources, the ultimate return is healthier animals, more successful organizations, and safer communities.

Considerations and Management of Infectious Diseases of Community (Unowned, Free-Roaming) Cats

Linda S. Jacobson

KEY POINTS

- During their lifetimes, community cats can move along the socialization spectrum and between owned and unowned status. They may interact with pet cats, humans, and wildlife. These factors impact infectious disease identification, risk assessment, and control.
- Community cats can carry zoonotic pathogens such as rabies, toxoplasmosis, bartonellosis, and zoonotic helminths.
- Pathogens of particular importance for the cats are retroviral infections, FPV, upper respiratory pathogens, and intestinal parasites.
- Disease prevalence is difficult to ascertain, as most surveys rely on convenience sampling of apparently healthy cats during TNR programs. The magnitude of disease risk to humans and pet cats is likely to be overstated based on pathogen surveys alone, particularly those using antibodies.
- Infectious disease management is focused on high priorities such as vaccination for rabies and other core pathogens. TNR programs offer opportunities for vaccination and parasite control.
- Individuals working with community cats should be vaccinated against rabies, avoid contact with cats that are not anesthetized, and use common-sense precautions such as wearing gloves and frequent hand washing.

INTRODUCTION

Unowned, free-roaming cats occupy a unique ethical, emotional, cultural and ecological niche from which they interface with pet cats, humans, and wildlife. Feral cats are essentially wild, yet are genetically identical to the companions that share our homes, and only a generation from domestication. This has significant implications for pathogen transmission and management.

Domestic cats are classified by ownership status; access to the outdoors; and degree of socialization to, and dependence on, humans.[1] *Feral cats* are unowned, unsocialized, and able to survive independently.[2,3] In urban areas, they often live in groups, or colonies, typically ranging from 2 to 12 members.[4,5] People frequently provide food and shelter for unowned urban cats.[6,7] *Managed colonies* are those whose populations are controlled through surgical sterilization programs, known as TNR.[8] The term *stray* typically refers to socialized cats that have been lost or abandoned. These cats may lose their socialization to humans over time.[2] *Pet cats* are owned and socialized to humans. A substantial proportion have access to the outdoors; this is the norm in many countries and varies according to personal and cultural preferences, rural or urban location, country and climate.[9–11]

Feline subpopulations are not static and cats can move among them during their lifetimes.[2,12] "Feral" cats can therefore be difficult to distinguish from "strays". Further, definitions vary and are used loosely and interchangeably. As a result, *community cat* is now used as an umbrella term for unowned, free-roaming cats, regardless of socialization status.[2,4] This terminology will be used in this chapter. The emphasis is on cats presumed to be feral/unsocialized—by designation or based on having been trapped and sterilized.

Cats are present on every continent except Antarctica, and are the most widespread terrestrial carnivores on earth.[13] Reliable estimates of community cat populations are important for effective management,[9] but are difficult to obtain. The range of published estimates can be so wide as to be almost meaningless—for example, 10 to 120 million for the United States and Canada[9]—and there are no estimates at all for most regions. The interchange among domestic cat subpopulations and the reclusive nature of free-living cats make community cats uniquely difficult to quantify.[9] Feline population dynamics have important implications for disease transmission. Variables include sex, home range, proximity to humans, movement among colonies, and population density.[1,12]

INFECTIOUS DISEASES IN COMMUNITY CATS: GENERAL CONSIDERATIONS

Areas of disagreement between community cat and wildlife advocates include public health concerns; transmission of pathogens to pet cats and other species; public nuisance; predation on wildlife, extinction of native species and disruption of ecosystems; and the welfare of the cats themselves.[8] These disagreements complicate attempts to understand and mitigate infectious disease risks.

The ease of sampling cats during TNR programs has generated a large number of recent pathogen surveys (Tables 18.1–18.6 and Figs. 18.1–18.3). It can be helpful to use a free-living population as a sentinel for emerging disease threats and zoonotic disease risks. However, the connections between pathogen prevalence and disease risk are frequently unclear. Serologic studies reflect previous exposure and may provide little information about clinical illness, reservoir status, or transmission risk. A salient example is *Toxoplasma gondii* infection, for

which antibodies in serum are common but oocysts in feces are rare (see Table 18.5). Surveys of zoonotic pathogens in community cats rarely refer to the prevalence of clinical disease in the human population, or the likelihood of human exposure, in the region. Claims about zoonotic disease risks posed by community cats therefore often remain theoretical and unsupported.

Evolving diagnostic methods and differing methods among studies further complicate interpretation. The increasing use of highly sensitive molecular assays has the potential to significantly increase the perception of disease threats without a true change in prevalence. For example, in one study PCR detected *Bartonella* in 94% of samples, but culture only 35.7%.[14] False-positive results or laboratory error may falsely elevate the apparent prevalence of a pathogen.[15,16] Necropsy studies demonstrate high prevalence of intestinal helminths, particularly cestodes, compared with fecal flotation (see Tables 18.3 and 18.6 and Figure 18.1).

The concept of disease ecology moves beyond detection of antibodies or pathogens in convenience samples, and takes into account co-infections, climate, habitat type, transmission biology, disease vectors, population dynamics, and density (Fig. 18.4).[17,18] Increasingly, anthropogenic climate change and habitat fragmentation are included in attempts to understand disease dynamics.[19] This type of approach

is rare in the community cat literature, possibly because these populations are studied using techniques drawn from clinical veterinary medicine rather than wildlife biology.

Males and older cats often have higher pathogen prevalence in surveys, most likely because of their larger range and greater number of contacts with other animals, while kittens are at higher risk of clinical illness from GI and respiratory pathogens. Prevalence would be expected to vary locally based on expected transmission dynamics (e.g., direct versus vector-borne). However, prevalence patterns did not correlate with population density and caregiver activity in a Korean study.[7]

Altered risk of infection in community cats, compared with their fed and sheltered counterparts, is related to hunting and foraging behaviors; requirements for shelter; antagonistic interactions, particularly among males; and larger home ranges.[20] Malnutrition, parasites, and co-infections may predispose community cats to infection. Dozens of studies include data from both pets and community cats, allowing a cautious assessment of the risks posed by being outdoors and receiving little or no primary health care (see Tables 18.1–18.5).

The extent of morbidity and mortality from infectious diseases is also difficult to assess in free-living populations. Cats that become debilitated often seek hiding places, making it less likely that those dying of disease will be identified[21] or that ill cats will be present when population sampling is performed. Studies of community cat health are typically limited to observation from a distance or examination while anesthetized.[22–25] In the United States, community cats have been reported to be relatively healthy—0.5% were

euthanized for serious health concerns and 0.2% to 0.3% died in care.[4,26,27] However, community kitten mortality is high, with 75% of kittens dying or disappearing before 6 months of age.[21] European studies showed variable proportions (<10% to 58.9%) of adult community cats in poor health, based on body condition score and other criteria.[24,25,28,29] Kittens were more likely to be emaciated than adults (72.7% vs. 45.8%).[22] Observations suggestive of infectious disease were emaciation, anemia, stomatitis, skin conditions, and URTD.[5,24,25,30–32]

Anemia was common in community cats in Italy[25,33] but uncommon elsewhere.[27] There was a significant association between being FIV-antibody positive and reduced red cell count (but not reduced hematocrit), with no significant associations found for FeLV-antigen positive status or seropositivity for *T. gondii*.[25] There was a significant association between testing positive for *Rickettsia* spp. by PCR and ocular disease, but no associations between being PCR positive for other vector-borne pathogens and other variables, including anemia and

thrombocytopenia.[34] The presence of *Cryptococcus*, ear mites, or fleas was not associated with overt clinical disease in most cats assessed.[32,35–37] Subclinical disease is to be expected in free-living populations where some susceptible individuals succumb to disease, directly or indirectly, and others live in equilibrium with infectious agents.[33]

Pathogen prevalence is highly variable among community cat populations (see Tables 18.1–18.5) and can differ markedly among geographic areas, rural and urban cat populations, or even different parts of the same city.[7,38–40] Some pathogens are restricted to certain parts of the world, where they can be very common. For example, high burdens of *Platynosoma* hepatic trematodes, which occur in tropical or subtropical regions, were found in community cats in Brazil[41] and zoonotic fish-borne trematodes are common in Kuwait and Korea.[39,42]

INFECTIOUS DISEASE RISKS TO HUMANS AND OTHER ANIMALS

Zoonotic diseases of concern in community cat populations include rabies, toxoplasmosis, bartonellosis, bite wound infections, toxocariasis, and ancylostomiasis.[43,44] Zoonotic disease risk from community cats should be examined "locally or at least with careful attention to environmental and ecologic conditions,"[27] as these affect cat density, pathogen presence and prevalence, contact with humans and the potential for pathogens to persist in the environment, as well as types and numbers of vectors and intermediate hosts.

There is no compelling evidence that the zoonotic disease risk presented by community cats is high or increasing. Risks may be different in developing countries, for which this type of information is less frequently reported and direct or indirect exposures may differ. However, it is striking that in the face of increasing numbers of TNR programs throughout the world, reports of TNR-related infectious disease outbreaks in humans are lacking. It remains the case, as pointed out more than a decade ago, that "there is concern about the possibility of cats transmitting diseases to humans, but in reviewing the literature there is little information on the actual frequency of zoonotic diseases in which cats can be implicated."[8]

Community cats may not pose a higher risk of zoonotic disease transmission than pet cats (particularly those with access to the outdoors).[1,3,27,45,46] In one study, infection prevalence did not differ between community and pet cats for FIV, FeLV, *Cryptosporidium* spp., *Giardia* spp., or *Toxocara cati*, while community cats had higher seroprevalence for *Bartonella henselae* and *T. gondii*.[27] The potential for direct transmission of pathogens by community cats is limited by their lack of intimate contact with humans and the short duration of contact when it occurs. Of greatest concern may be cats as sources of environmental contamination with pathogens such as *T. cati*, hookworm, and *T. gondii*.

Cat bites account for 5%–25% of reported animal bites.[47–49] The epidemiology differs from dog bites in almost every respect.[48] The majority of cat bites have been from community cats and most are self-reported as provoked.[48,49] In addition to the main concern of rabies transmission, there is a high risk of bacterial infection from cat bites because they tend to result in puncture wounds on the extremities and often transmit *Pasteurella multocida*, a fast-growing infection in humans (see Chapter 75).[47,50]

Cats may pose infectious disease risks to wildlife and vice versa. Some parasites, such as the cat flea (*Ctenocephalides felis*), occur on a large number of wildlife species.[51] Wild felids and domestic cats are susceptible to, or reservoirs for, a variety of shared pathogens.[19,52,53] Exposure of wild felids to domestic cat pathogens may be increasing through habitat fragmentation and compacted range.[52,53] Ingestion of cats may be a route of transmission of FeLV to large predatory felids.[52] In general, however, community cats are concentrated around human settlements and are unlikely to have much contact with nonurban wildlife.[54]

Pathogens can be transmitted among pet cats with access to the outdoors and community cats, among community cat colonies during TNR programs, among cats entering animal shelters, and among geographically separated populations in the case of shelter transport programs.

IMPORTANT INFECTIOUS DISEASES OF COMMUNITY CATS

Rabies

Community cats have been presented as a serious rabies threat in the United States based on the fact that more domestic cats now test positive than dogs.[55] The number of positive cats increased from 192 in 1988, when this shift was first reported,[56] to 270 in 2001,[57] but has remained within a similar range (with some fluctuations) since then.[58] More than 90% of rabies in the United States and Canada is found in wildlife, and > 99% of 50,000 annual rabies deaths in humans

worldwide are estimated to be transmitted by dogs.[58–60] One presumptive and two confirmed human cases of feline-transmitted rabies have been reported in the United States since 1960.[61] Despite low numbers, the potential for rabies in free-roaming cats, low vaccination rates, and sporadic human exposure are continued cause for concern.

Feline Immunodeficiency Virus and Feline Leukemia Virus Infections

Retrovirus prevalence in community cats can be highly variable among studies and regions (see Table 18.1). A large study in the United States and Canada showed significantly higher prevalence among feral and stray cats than among owner-relinquished cats.[62] Adult age, male sex, and illness are associated with higher seroprevalence of FIV, but being an intact versus neutered male is less consistently significant.[28,62–64] In one study, the prevalence of FIV reached 100% in feral male cats older than 4 years.[20] Socially dominant males are most likely to be infected, since transmission is most often associated with fighting.[65] Females may be infected when males bite them on the neck during mating.[65]

Geography and population density affect retrovirus transmission patterns,[66] with a tendency toward higher prevalence in southern regions of Europe and North America, especially for FIV.[28] Urban strays have a promiscuous mating system associated with higher population density, compared with a polygynous system in rural areas.[7,65] This may result in fewer antagonistic interactions among urban cats and could explain why FIV is more prevalent in rural cats.[7,65] FeLV infection prevalence was higher in districts with high caregiver activity;[7] this may be due to higher population density. Most studies do not show a difference between males and females for FeLV antigenemia, and prevalence has not differed between urban and rural habitats.[67]

Feline Panleukopenia Virus and Respiratory Infections

Morbidity and mortality data for FPV, FHV, and FCV infections in community cats are lacking. Given the ubiquity and importance of these infections in domestic cats, they can be presumed to cause significant morbidity and mortality in free-roaming populations and could contribute to high kitten mortality (Fig. 18.5).

Variable proportions of community cats have evidence of exposure to and/or protective antibodies against FPV, FHV, and FCV (see Table 18.1).[7,20,68,69] This can be attributed to natural exposure, with some contribution from vaccination in managed colonies. FPV seroprevalence was higher in community cats than in unvaccinated owned cats, possibly reflecting concentration in areas where environmental virus load was higher.[20] Seroprevalence of this infection was higher in districts with low colony caregiver activity. This was suggested to be related to foraging behavior resulting from lower availability of food. There was an unexpected negative association between FCV seroprevalence and population density.[7]

Community cats with URTD were more likely to test PCR positive for FCV, *Chlamydia felis*, and *Mycoplasma felis* than cats without clinical signs.[70] *Chlamydia felis* was the most prevalent pathogen. A low prevalence of FHV infection was thought to be related to lower population density compared with other groups tested, as well as not having been subjected to the stress of shelter confinement.[70] Shedding of respiratory pathogens at intake to a shelter did not differ between stray and owner-surrendered cats, and in both groups it was ≤ 5% for all organisms other than *M. felis* (>20%).[71] The cumulative risk of developing URTD over time was higher for stray cats.

Toxoplasma gondii Infection

Cats and other felids are reservoirs of infection for *T. gondii* in humans, livestock, and wildlife.[10,27,72–74] Seroprevalence is highly variable in both unowned and owned cats. In studies where the status of the cats was specified, the seroprevalence in feral cats was 9% to 84% (mean, 48.5%) compared with 18% to 85% (mean, 37.2%) for owned cats.[10]

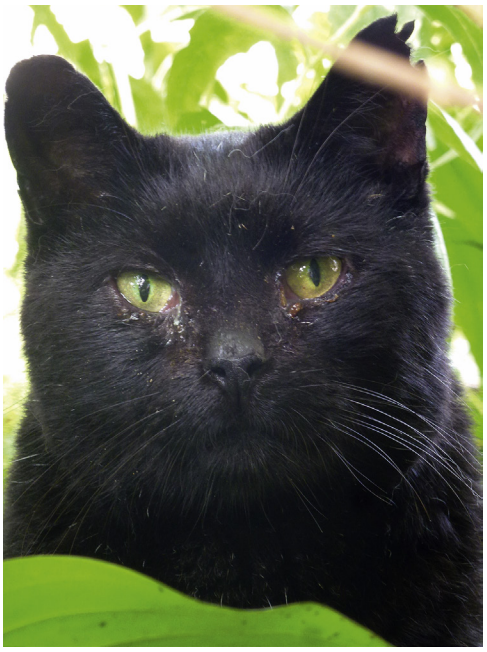

Fig. 18.5 Upper respiratory infections cause morbidity in community cats and are likely to contribute to kitten mortality. (Courtesy Sara Slater, Annex Cat Rescue, Toronto, Canada.)

The seroprevalence for *T. gondii* increases with age due to cumulative risk of exposure over time,[73] and may reflect increased lifespan rather than increased risk. Free-ranging kittens are typically exposed early in life, shed large numbers of oocysts for a short period, then become refractory to infection (see Chapter 93).[75] Oocyst shedding is brief, as reflected by low prevalence in studies using fecal flotation and fecal PCR (see Table 18.5 and Fig. 18.3), and seroprevalence may not correlate well with human infection or environmental contamination. Despite: (1) an increase in the population of cats; (2) increased contact with community cats through TNR and colony caregiving; and (3) high estimated oocyst contamination of the environment,[76] the number of cases of human toxoplasmosis decreased in the United States from 1999 to 2004.[77]

Toxoplasma gondii is more likely to be spread through environmental contamination in urban areas and through ingestion of infected paratenic hosts in rural regions.[7] The density of feral cats is not a reliable predictor of infection risk to native species, as transmission can occur at low cat densities.[17] Feeding commercial food to colonies might reduce infection rates by reducing predation on intermediate hosts.[7,78]

Endoparasite Infestations

Internal parasites, some of which have zoonotic potential, are common in community cats, which serve as an important reservoir through direct contact and environmental contamination.[45,79–82] As with other infections, a clear link between cat population, parasite prevalence, and clinical human infections rarely appears in the literature. Kittens are more likely to be infected, and more likely to carry high parasite burdens, than adults.[83] Co-infections are more common in community cats than in shelter or owned cats and are found in a substantial proportion, and sometimes the majority, of cats[83–86] (see Table 18.3).

Toxocara cati is the most important helminth in community cats (see Table 18.3).[81,83] Human toxocariasis is one of the most

common zoonoses worldwide, but the role of cats is unclear. Interestingly, after pet dogs were banned from Iceland in 1924 (the ban was lifted in 1984), adult humans exposed to cats remained seronegative for *Toxocara*.[87]

Hookworms, which may have zoonotic potential, are found less consistently and the risk varies geographically (see Table 18.3).[81] Whipworms are infrequently reported, although the prevalence of infection is high in some populations. The risk of lungworm (*Aelurostrongylus abstrusus*) infection is higher in community cats due to ingestion of intermediate hosts.[45,88] With some exceptions, *Dirofilaria immitis* is rare or absent in community cat studies,[89–91] but should be considered in highly endemic areas (see Table 18.3).

Cestode infestations are underdiagnosed in fecal surveys due to intermittent shedding of proglottids,[83] and may be a greater source of morbidity in community cats than is appreciated. Prevalence can be very high in necropsy studies (see Table 18.3).[81,92] *Dipylidium caninum* and *Taenia taeniformis* are frequently found, with other cestodes being regionally common.[81] Cats are not currently implicated in transmission of zoonotic cestodes,[93] but surveillance is warranted. Community cats did not carry mature forms of *Echinococcus multilocularis* in a highly endemic area, but eggs have been reported in cat feces elsewhere.[93] *Taenia hydatigena* was common in cats in one study.[38]

Ectoparasite Infestations

Ctenocephalides felis is the most important ectoparasite of community cats, with reported prevalence ranging from 0% to 100% (mean, 32.3%).[51] Most infested cats have no clinical skin disease.[36] Flea infestations can be associated with zoonoses such as flea-borne rickettsiosis[94] and bartonellosis. *Otodectes cynotis* is the only mite of importance in community cats (see Table 18.4),[35,95] and infected cats are frequently clinically normal.[35–37] Tick infestations in cats may be underestimated due to grooming behavior and underdiagnosis of infection by immature stages.[95] However, tick-borne pathogens are rarely identified in community cats and were not associated with anemia or thrombocytopenia.[34,96–98]

Other Infections

The SARS-CoV-2 pandemic prompted initial fears that community cats could become a reservoir for infection for humans and other species. This now appears unlikely, but reasonable precautions should be observed at the community cat–human interface, particularly during TNR clinics.[99,100]

Bartonella, a potentially zoonotic pathogen that is primarily transmitted by fleas, is widespread in the community cat population. Seroprevalence is often higher than PCR-based prevalence (see Table 18.2). Prevalence was significantly higher in urban community cats, disproving a hypothesis that vector-borne disease would be more common in rural areas.[7] Hemotropic mycoplasma infections (see Table 18.1) are more common in male community cats,[101–103] supporting the role of fighting as an important means of transmission (see Chapter 58). Infections are often subclinical and may not be associated with anemia.[33,67] In studies from Europe, warm weather has been associated with increased prevalence.[33,103]

Despite predation on birds and the ability to contract influenza under some circumstances, community cats have not played an important role in the transmission of avian influenza viruses (see Table 18.1).[104,105] However, a large feline outbreak of H7N2 virus infection in a New York shelter, which was associated with a single instance of cat-to-human transmission highlights the need for continued vigilance.[106]

Infections with *Leptospira*, *Toxascaris*, *Cryptosporidium*, *Giardia*, *Leishmania*, *Tritrichomonas*, and *Cryptococcus* spp., and dermatophytes appear to be uncommon in community cats, but for some of these pathogens, studies in different geographic regions are lacking.[24,32,81,107–114]

MANAGEMENT OF INFECTIOUS DISEASES IN COMMUNITY CATS

Rational infectious disease management in community cats requires strategic local decision-making based on clinical disease concerns (for both cats and humans), rather than on pathogen prevalence data alone. Public health records can assist in assessing local zoonotic disease risk.

Population Control

Regardless of attitudes toward community cats, interest groups share the goal of reducing free-roaming populations in order to decrease shelter intake and euthanasia, pathogen transmission, zoonotic disease risk, and predation on birds and wildlife. Community cats contribute disproportionately to feline population growth.[21,23] Reported sterilization rates now range from 0% to 68%, depending on colony management and the socioeconomic status of colony caregivers.[6,7,9,22,26,30,67,115] Sterilization rates for pet cats range from 12% in disadvantaged communities to 80%–98% in communities with access to more resources.[26,30,115–117] Sterilized cats are typically healthier, with improved welfare and increased longevity.[29,118,119] Sterilized cats are also less likely to transmit pathogens that are largely spread through mating and mating-related fighting (e.g., FIV).

The most devastating "disease" of domestic cats is shelter euthanasia. Euthanasia rates are highest for unsocialized cats. Nonlethal population control through TNR has been effective in decreasing shelter intake and reducing euthanasia.[1,4,26,119–121] As numbers decline, shelters can focus on other proactive programs that improve feline welfare. Community kittens can be rescued in greater numbers and socialized community cats can be adopted or transferred.[4,26,115] Colony caregivers play an increasingly important role in controlling disease and improving health and welfare for community cats.[5,22,29,30]

Despite its positive impact, TNR is resource intensive and not universally successful.[119,122] It is most effective in concert with other strategies—animal control policies not to pick up healthy community cats; community engagement and education, particularly around abandonment; targeted (rather than random) TNR; return-to-field; low-cost and pediatric spay/neuter programs for owned cats; universal sterilization before adoption; and supporting the changing culture around the way cats are viewed and valued.

TNR offers the opportunity to assess the health of community cats and provide vaccination, parasite control and additional health care, as practically feasible. It also allows sample collection for disease surveillance. This is likely to become increasingly important as transport programs grow to include more cats, and concerns over importation of infectious diseases grow. In order to mitigate risk, receiving organizations must be cognizant of infectious disease patterns at source locations.

Vaccination

The WHO recommends vaccination rather than population control for reducing transmission of canine rabies,[60] and the 2013 AAFP Advisory Panel recommended that cats in TNR programs receive FVRCP and 3- to 4-year rabies vaccines at the time of surgery.[123] Most community cat programs administer rabies vaccines at TNR.[124] This is an important contribution to public health efforts and helps create a transmission barrier between domestic cats and wildlife. More than 90% of rabid cats in the United States are found in southeastern states, where the raccoon rabies virus variant is endemic.[58] Rabies vaccination at TNR is imperative in such areas.

While rabies boosters should ideally be administered, a single vaccine is likely to provide long-term, or even lifelong, immunity.[60,125–127] A single vaccine at the time of TNR surgery resulted in protective titers against rabies in 98% of cats and protective titers against FPV, FHV, and FCV in the majority.[68]

Among cats with bite wounds and abscesses, 2% of those vaccinated against FeLV tested positive for the disease compared with 14% of unvaccinated cats.[128] The benefit of a single FeLV vaccination in feral cats undergoing TNR is unknown, but this could be considered in high-prevalence populations. Targeting kittens for FeLV vaccination would be most cost-effective, given the higher susceptibility of this age group to infection.

Parasite Control

Parasite control is high in the needs hierarchy, from both welfare and public health perspectives. Younger cats excrete more fecal eggs than adults[82] and are more severely affected clinically. This should be a target group for parasite control. Reducing parasite burdens, even transiently, is likely to be beneficial. Because unsocialized cats should only be handled after they are anesthetized, treatment is limited to topical and injectable products. The value of a single treatment for adults at TNR is questionable. Providing deworming treatment at colony feeding stations could lead to parasite resistance because of sporadic and potentially subtherapeutic treatment in a high-burden environment. Compared with untreated community cats, communally housed shelter cats with outdoor access and sporadic deworming had 49.5% prevalence of intestinal parasites compared with 77.3% in untreated community cats.[84] This suggests a limited benefit of sporadic deworming.

It must be accepted that some zoonotic parasites such as roundworms and hookworms cannot be controlled, similar to the case for wildlife species. Therefore, risk mitigation procedures to reduce human exposure should be in place in regions in which humans are at higher risk and for those working closely with community cats.

Control of Retrovirus Infections

Sterilization is expected to reduce retrovirus transmission through prevention of reproduction and decreased inter-cat aggression.[128] However, despite the growth in TNR, there was no overall decline in feline retrovirus prevalence in the United States in the decade to 2010.[62,63] This may be related to variable and often low sterilization rates. Subsequent large-scale surveys, reflecting TNR programs over the past decade, will be of great interest. Retrovirus infection prevalence decreased over time when strategies included sterilization, removal of positive cats, and vaccination against FeLV.[28,119] The effect of sterilization on prevalence was not examined separately.

The ethics of euthanasia of healthy cats that test positive for retroviruses are questionable.[28] False-positive test results are common when disease prevalence is low, and confirmatory tests are impractical in TNR settings. Testing healthy free-roaming cats for these diseases is not currently recommended, as removing them from the population is unlikely to significantly impact population prevalence, and resources are better directed to sterilization and vaccination.[2,154] Removal of positive cats from colonies might also affect colony social dynamics in ways that could influence pathogen transmission.

Education and Safety Precautions

Safe handling of community cats is essential to prevent injury, infection, and euthanasia for suspected rabies in the event of bite incidents. In their natural environment, unsocialized cats are wary of humans and will seek to hide or escape if approached. However, unsocialized cats are likely to bite defensively in fear when handled, such as when animal control personnel attempt to capture a cat by hand or place a cat in a carrier for transportation. Anyone who works with community cats should receive rabies vaccines. Gloves, and preferably gauntlets, should be worn when handling these cats. Many communities and shelters are now familiar with humane trapping methods, and information about safe and humane trapping and handling is readily available.[129]

Education initiatives must include those that relate to appropriate hand hygiene when community cats are handled or when exposed to their environment; avoidance of unessential handling of free-roaming cats; encouragement of pet owners to keep their pets indoors and provide adequate preventive care; and sterilization of pet cats.

Companion Animal Zoonoses in Immunocompromised and Other High-Risk Human Populations

Jason W. Stull

KEY POINTS

- Immunodeficiencies are common in people and may be congenital or acquired. It is estimated that up to 20% of the North American population and approximately 60% of North American households have some degree of immunosuppression.
- Up to 60% of households own pets, most commonly dogs or cats. Pet ownership may predispose high-risk people to zoonotic diseases. In addition, high-risk people often experience more severe disease, a longer duration of symptoms, or more severe or unexpected complications when compared with others. In general, the mental and physical benefits of pet ownership outweigh the risks, so education of pet owners to reduce the risks is important.
- Veterinarians play a key role in educating the public about ways to reduce the risk of zoonotic diseases, and should provide both written and verbal communications on this topic to pet owners. This should be documented in the medical record.
- Over 250 organisms are known to cause zoonotic infections, with over 70 of these involving companion animals. The most common zoonotic pathogens, their mode of transmission, clinical signs in humans, and prevention methods are reviewed in this chapter.

OVERVIEW OF HUMAN IMMUNODEFICIENCY SYNDROMES

Immunodeficiencies are frequently identified in people and result from numerous physiologic and pathologic processes (Box 19.1). Immune system defects generally increase the risk of infectious disease. Immunodeficiencies are categorized as congenital or acquired. Congenital immunodeficiencies, resulting from genetic disorders, increase susceptibility to infectious disease, depending on the type and penetrance of the defect.[1] One or more arms of the immune system (e.g., B cells, T cells) may be affected. Alternatively, immunodeficiencies are acquired, resulting from nongenetic factors, such as extremes of age (i.e., less than 5 years of age, greater than 65 years of age), pregnancy, or an immunocompromised state. Transplants (i.e., bone marrow and solid organ), infectious diseases (e.g., HIV infection), metabolic diseases (e.g., diabetes mellitus), splenectomy, cancers, and treatment with immunosuppressive drugs or chemotherapeutics most commonly contribute to an immunocompromised state.[2] The term "high-risk" is often used to denote individuals who have one or more congenital or acquired immunodeficiencies.

The mechanism of immunodeficiency varies with the cause of the immunodeficiency. Examples of mechanisms include incomplete immune development (children), waning immune response (elderly), temporary hormone-induced suppression (pregnancy), or specific abnormalities that result from congenital or acquired immunodeficiencies (e.g., metabolic derangements that result in inhibition of lymphocyte maturation and function).[3–5] Specific immune deficiency syndromes may increase risk for particular pathogens (e.g., neonates and invasive salmonellosis); however, this area is poorly understood.[6] Concurrent factors, such as other illnesses, burns, or indwelling tubes, catheters, or implants, increase the risk of infection by loss of natural barriers to infectious agents. Additionally, children and some individuals with developmental disabilities may have suboptimal hygiene practices or higher-risk contacts that further increase risk.[7]

It is estimated that 1 in 500 individuals in the United States is born with a defect in one or more components of the immune system.[5] More than 1.2 million people in the United States are infected with HIV, and approximately 10% do not know they are infected.[8] Each year approximately 50,000 people in the United States receive solid organ or bone marrow transplants.[9] There are approximately 25,000 splenectomies performed each year in the United States[10] in addition to the thousands of functionally hyposplenic patients, all of whom are considered at increased risk for infectious disease. In addition, there are many individuals with other underlying conditions that have less pronounced but still significant effects on the immune system, such as diabetes mellitus, renal disease, and cirrhosis. Pregnant women also have varying degrees of immunodeficiency; it is estimated that 2% of the population of the United States is pregnant at any given time.[11] Taken together, up to 20% of the North American population has some degree of immunosuppression (i.e., considered high-risk) with an even greater proportion of households having at least one high-risk individual (estimated as 59% of households in one study).[12,13]

PREVALENCE AND ADVANTAGES OF PET OWNERSHIP

Up to 60% of households with high-risk people in North America[12,14,15] and elsewhere[16] have pets. Dogs and cats are the most common pets residing in households with high-risk people, but other species (e.g., reptiles, birds, exotics, rodents) are also reported.[14,16] Additionally, pets are often acquired by high-risk individuals or households with a high-risk family member. In one study, 20% of households with

BOX 19.1 Factors Associated with Immunocompromise in Humans

Age	Fetuses, infants, preschoolers (less than 5 years of age), older adults (greater than 65 years of age)
Health Issues	Hospitalization, concurrent illness, autoimmune disease, organ transplantation, AIDS, diabetes mellitus, Cushing's syndrome, chronic renal failure, pregnancy, burns, leukopenia, cancer, congenital immunodeficiencies, hepatic cirrhosis, malnutrition, splenectomy, splenic dysfunction, myelosuppression, other reasons for immunocompromise
Therapeutic Agents	Cancer chemotherapy, immunosuppressive drug therapy, antimicrobial drugs
Medical Instrumentation and Procedures	Catheters, indwelling tubes, synthetic implants, splenectomy

children diagnosed with cancer acquired a new pet after their child was diagnosed.[14]

The mental and physical benefits that companion animals provide are great, and the risk for acquiring infections from pets is overall low. However, high-risk individuals are at greater risk for pet-associated infections than others, knowledge of disease risks is generally poor, and such individuals often engage in practices that put them or household members at increased risk for infections.[7,12,14] Helping the public and health professionals recognize both health benefits and risks associated with pets, as well as providing specific recommendations for precautions while handling and caring for pets can reduce risk of infection. The information in this chapter emphasizes zoonoses that are more commonly identified in high-risk individuals. However, because zoonoses can affect immunocompetent people, many of the principles pertain to anyone with pets.

RISKS OF COMPANION ANIMAL-ASSOCIATED ZOONOSES IN HUMANS

Zoonoses are infectious diseases that are naturally transmitted from living animals to humans.[17] High-risk people who own pets are at greater risk of contracting zoonotic diseases than those without pets (Box 19.2). In addition, high-risk people often experience more severe disease, a longer duration of symptoms, or more severe or unexpected complications than others.[18,19] For example, individuals infected with HIV are at 20–100 times greater risk of *Salmonella* bacteremia than those without HIV infection[18]; individuals with hematological malignancy are at 8 times the risk of *Salmonella* gastroenteritis and 2 times the risk of *Campylobacter* gastroenteritis than those without malignancy[19]; alcoholics, asplenic individuals, and immunocompromised individuals are at risk for severe (often fatal) *Capnocytophaga canimorsus* infection following dog/cat licks or bites[20]; and *Bordetella bronchiseptica* can cause severe illness in immunocompromised individuals,[21] while others rarely experience disease.

Despite the increased disease risk, to date, few studies have determined what proportion of human disease is attributable to contact with pets. For instance, it is estimated that 14% of all human illness caused by enteric pathogen groups is attributable to direct or indirect animal contact[22]; it is likely that pets are responsible for a relatively small component of this. In a separate study, cats or dogs were estimated to be responsible for 26% of all reported zoonotic human enteric infections for which contact with animals or their environment was the likely mode of transmission.[23] The true scope of pet-associated disease remains unknown partly due to a relative absence of reportable pet-associated pathogens (in people and animals) and complicating factors such as multiple non-pet exposure sources and subclinical shedding by pets.[24] This results in challenges relating to risk communication and decision-making, especially when attempting to weigh disease risks against benefits of pet ownership.

Given the high frequency of pet exposure and low reported pet-associated disease incidence, overall, pet-associated disease incidence is suspected to be low.[12,25–27] However, this should not negate awareness of important and severe disease in high-risk individuals.

People can acquire pet-associated zoonoses through numerous routes (see Box 19.2). Organisms can be acquired through contact with the skin and mucous membranes (e.g., bites, scratches, direct or indirect contact with animal saliva, urine and other body fluids), ingestion of animal fecal material, and inhalation of aerosols or droplets. Vector-borne pathogens can be transmitted from dogs and cats to humans when vectors feed on co-habitating humans. In some cases, dogs and cats bring vectors that are already infected with an organism closer to people. Many zoonoses have multiple routes of infection, so identification of a zoonotic pathogen in a pet-owning person does not necessarily indicate pet-related transmission.

BOX 19.2 Mechanisms of Transmission of Zoonotic Infections

Zoonoses (dogs and cats to humans)	Bite, saliva, scratch, or close physical contact	Rabies, tularemia, pasteurellosis, *Capnocytophaga* infection, bartonellosis, dermatophytosis, *Malassezia pachydermatis* infection, sporotrichosis
	Droplet	Bordetellosis, plague, tularemia, coxiellosis, rhodococcosis
	Fecal-oral	Campylobacteriosis, yersiniosis, salmonellosis, toxoplasmosis, cryptosporidiosis, giardiasis, ancylostomiasis, toxocariasis
	Urine or genital secretions	*Escherichia coli* infections (pathogenic strains including ExPEC), canine brucellosis, leptospirosis, coxiellosis
Shared Vector-Acquired Zoonoses	Tick or flea vector	Ehrlichiosis, Rocky Mountain spotted fever, *Rickettsia felis* infection, borreliosis, plague, tularemia, bartonellosis, dipylidiasis
Sapronoses (environmentally acquired)	Inhalation or cutaneous inoculation	Anthrax, listeriosis, *Mycobacterium avium*–complex infection, blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis, aspergillosis, pneumocystosis, microsporidiosis
Anthroponoses (humans to dogs and cats)		Group A streptococcal infections, *Streptococcus pneumoniae* infection, methicillin-resistant *Staphylococcus aureus* infections, *Clostridioides difficile* infection, *Mycobacterium tuberculosis* infection, *Entamoeba histolytica* infection, SARS-CoV-2 infection (COVID-19)

Some pathogens are maintained in nature by replication of the organism in soil or water, on vegetation, or in decaying carcasses or animal excreta and can infect both humans and animals (*sapronoses*). For these pathogens, both humans and animals can acquire infections in a similar manner but independently of each other; in most cases, infected animals do not represent a direct infection risk for people (see Box 19.2). Instead, when animals get these infections, they act as sentinels for the risk of human infection in the region. Some zoonotic pathogens are maintained in humans (*anthroponoses*). Some of these infections can affect animals such as dogs and cats that may then transmit the infection to other animals or people, but this is not the most likely route of human infection.

Barriers to Prevention of Pet-Associated Zoonotic Diseases

One of the barriers to prevention of pet-associated zoonotic disease is low knowledge of these disease risks among the public and other healthcare professionals, which includes those at an increased risk for disease.[12,14] This may partly result from limited education of high-risk pet owners on the topic.[12,14,15] In one study, 94% of surveyed physicians in the United States stated they never or rarely initiated discussions about zoonoses with patients with HIV infection or AIDS.[28] Few veterinary (58%) and human medical (4%) practices make educational materials on zoonotic diseases available to clients or patients.[28,29] This is unfortunate, as several studies suggest that high-risk individuals are open to educational opportunities from healthcare providers and veterinary personnel.[12,14]

In order to provide targeted education and recommendations to clients with high-risk household members, veterinarians must be aware of the presence of high-risk household members or others that frequently contact household pets. As an additional barrier, veterinarians infrequently gather this information from clients.[14,28,30] Evidence suggests that many clients are comfortable providing veterinary personnel with human healthcare information to assist in determining the high-risk status of household members; yet if veterinary personnel do not ask, many clients will not provide this information.[14]

Perhaps one of the largest challenges is that the subject of pet-associated zoonoses falls at the intersection of veterinary and human medicine. In order to effectively address this area, multiple disciplines (e.g., human healthcare, veterinary healthcare) need to communicate. Unfortunately, evaluations of this area document poor interdisciplinary communication.[28,30,31] In one study, 100% of physicians and 97% of veterinarians in the United States claimed to never or rarely contact individuals of the other profession when looking for advice on zoonotic disease risks or cases.[28] Without a strong collaborative approach among healthcare disciplines, pet contact recommendations coming from a single healthcare group may be overly conservative or lacking due to limited knowledge of the area.

Although veterinarians generally are better prepared than human family practitioners to answer questions about animal diseases and human risks, patients, especially those who are immunocompromised, may not view them as the primary providers of this information.[14] Paradoxically, physicians seem to be uncomfortable discussing zoonotic diseases with their clients and view the veterinarian as playing a more important role in this service. In surveys of medical and veterinary professionals, physicians felt that public health officials and veterinarians should be responsible for this task.[32] When questioned about educating clients on the risk of zoonotic diseases, a much greater percentage of veterinarians felt comfortable with this task than did physicians.[30]

Veterinarians can be an important source of information about health risks of pet ownership and precautionary measures for high-risk people so that they can safely keep their pets. The latest guidelines from a number of public health and infectious disease organizations recommend that rather than give up their pets, immunocompromised people take simple precautions to prevent infection (see Recommendations).[3,13,25,33–38] A number of resources are available for clients or other healthcare professionals that provide a balanced view of health risks and benefits of pet ownership (Box 19.3).

Veterinarians can demonstrate their willingness and expertise to provide advice and guidance for zoonosis prevention by having signs or brochures in their waiting rooms, posting information on their website or similar social media channels, and actively engaging clients in the topic through client and patient intake questionnaires. Offering regional talks on pet care, zoonoses, and prevention may be particularly valued by the public. It is important to recognize that human health information may fall under country-specific privacy laws. In the United States, the Health Insurance Portability and Accountability Act (HIPAA) states that information about a person's health status is considered confidential and protected.[39] Therefore, veterinary staff need to ensure that any human health information obtained (e.g., client health status, immunocompromising conditions in household members or those frequently spending time with the client's pets) is adequately protected when recorded.[40] Often this is best achieved in veterinary medicine by keeping all written human health information general, including medical record notes and questions and responses contained in patient intake questionnaires. Additionally, a signed consent from clients is advisable when specific human health information is recorded or clients authorize veterinary team members to discuss their protected health information with a physician. Example disclosure forms are available.[40]

OCCUPATIONAL AND ENVIRONMENTAL FACTORS THAT INCREASE RISK OF ZOONOSES

Veterinarians, animal health workers, and those working or training in settings with high animal contact (e.g., pet shops, shelters) may be at greater risk for zoonoses.[41–43] During their careers, approximately two-thirds of veterinarians report a major animal-related injury that results in lost work or hospitalization.[44,45] In two studies, 28% and 47% of veterinarians in the United States reported development of a zoonotic infection during the course of their veterinary work.[29,46] Zoonoses most frequently reported included dermatophytosis, bartonellosis, and cat and dog bite infections. Similar risks exist for other veterinary personnel and students.[43,47] Within-clinic zoonotic transmission of pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Salmonella* has also been reported.[48–50] Suboptimal use of personal protective equipment may be partly responsible for the increased zoonotic disease risk in the veterinary profession.[51]

LEGAL IMPLICATIONS OF ZOONOSES FOR VETERINARIANS

Veterinarians have an inherent responsibility to advise pet owners on their risk of contracting zoonoses.[52,53] The use of both written (e.g., brochures, website materials) and verbal approaches are useful. It is important to clearly document all oral and written communications regarding these topics in the medical record, including whether a client declines veterinary advice. Veterinarians must advise clients to seek human healthcare advice when they suspect a zoonotic infection has occurred or is likely to occur. Veterinarians must also report zoonotic diseases where public health laws dictate, and must also protect their

BOX 19.3 Resources for High-Risk Pet Owners, Veterinary Personnel, and Healthcare Workers

Level	Resource	Comments On Audience/Content
International	World Organization for Animal Health (www.oie.int)	Association responsible for improving animal health worldwide

employees through education on preventative measures. For information on prevention measures, consult the Recommendations section in this chapter and the *Compendium of Veterinary Standard Precautions for Zoonotic Disease Prevention in Veterinary Personnel,* published by the National Association of State Public Health Veterinarians online and in print.[54]

BENEFITS OF PET OWNERSHIP

Risks of zoonotic infection need to be balanced against the mental and physical health benefits of pet contact, especially for those who are ill or at increased risk of infections.[55,56] The emotional bond between owners and animals can be as important to the owner as human relationships and provides similar psychological benefits.[57] In many cases, pets are considered family members. Positive health outcomes including reduction in stress, depression, systemic blood pressure, and favorable lipid profiles have been associated with animal interaction.[56–59] Benefits have also been documented in the healthcare setting with reductions in pain and improved morale reported among those participating in animal-assisted therapy.[55]

Benefits from pet contact have been equally observed among individuals at high risk of pet-associated infections.[57–59] Children brought up with companion animals often have better social skills, self-esteem, and empathy than children without pets.[60] In adults and the elderly, studies have documented an association between pets and reduced risk of cardiovascular disease and improved psychological and physical well-being.[61] Health benefits are also well documented in individuals who are immunocompromised. Although illness and disability often alienate individuals from their family, friends, and acquaintances, pets provide continued and unconditional companionship and help their owners overcome the deleterious effects of loneliness.[62]

Given the many argued health benefits of pet ownership and contact, it may be more detrimental to the well-being of immunocompromised people to lose their pet companions than to risk acquiring a zoonotic infection. However, such people should understand the health risks and, perhaps most importantly, be aware of measures that

can be taken to reduce infection risks while maintaining the strong bond with pets.

SPECIFIC DISEASE INFORMATION FOR HIGH-RISK INDIVIDUALS

More than 250 organisms are known to cause zoonotic infections, with over 70 of these involving companion animals (see Box 19.2). Given the growing molecular and epidemiologic evidence of the interspecies exchange of pathogens, such as MDR bacteria, this number is likely to increase.[63] Of these, only a subset is of greatest importance for high-risk people due to the severity of infection and overall frequency of infections (Table 19.1). Most of these zoonoses are more likely to be acquired from sources other than dogs and cats (e.g., the environment, other animal hosts, or people). Nevertheless, pet ownership does pose a risk to immunocompromised people and should be considered. Further, many are readily preventable, so client awareness and education is important. The reader is referred to respective chapters elsewhere in this book for additional information on each infection.

Bartonellosis

Bartonella spp. are small, fastidious, gram-negative, arthropod-borne, intracellular bacilli. The genus includes numerous species, 13 of which are believed or known to be associated with human disease.[64] Cats and dogs serve as reservoirs for infection of people.[64] Domestic cats serve as the primary reservoir for *Bartonella henselae* and *Bartonella clarridgeiae,* which cause cat scratch disease (CSD) and potentially life-threatening infections in humans.

CSD most commonly occurs from a cat scratch or cat bite, as claws and teeth can become contaminated with feces from infected fleas, or through direct flea bites.[64] Bartonellosis often manifests as subacute solitary or regional lymphadenomegaly and fever in immunocompetent people. More severe disease, such as bacteremia, endocarditis, neuroretinitis, and proliferative lesions on the skin, liver, or spleen can occur in high-risk patients (Fig. 19.1). Children (especially those aged 5–9 years) appear to be at greatest risk of CSD.[65]

Flea control is essential for reducing the spread of *Bartonella* spp. infection among cats, dogs, and humans. Additionally, attention to proper training and handling of cats and dogs to reduce bites and scratches is critical for households with high-risk people. Bite and scratch avoidance is particularly important for animals most likely to be infected (e.g., kittens, feral cats, outdoor cats, cats with fleas). Declawing is not a recommended strategy to reduce zoonotic infection; however, nails can be clipped to reduce the chance of their lacerating the skin. Keeping cats indoors can reduce risk of infection and is recommended in high-risk households. Guidelines aimed at reducing infections in HIV-infected persons recommend these individuals only acquire cats greater than 1 year of age that are in good health, reduce bites and scratches (in part by avoiding rough play), maintain flea control, promptly wash bites and scratches, and prevent cats from licking wounds.[66] It is reasonable to extend these recommendations beyond those with HIV infections to all high-risk households.

Bordetella bronchiseptica Infection

Bordetella bronchiseptica is a gram-negative coccobacillus commonly found in the respiratory tracts of many mammals, including cats and dogs, and is well known as a contributor to canine infectious respiratory disease complex. Humans are unusual hosts for this agent; exposure to infectious dogs or cats, or the attenuated live intranasal vaccine has been implicated in human infection, although proof that the vaccine causes human infection is lacking.[67,68] In immunocompetent people, *B. bronchiseptica* has been occasionally associated with mild upper respiratory tract infections.[67] In immunocompromised individuals, infection remains rare, however disease may be moderate to severe in affected individuals with sinusitis, tracheobronchitis, pneumonia, bacteremia, endocarditis, peritonitis, and meningitis. People with cystic fibrosis may be especially vulnerable to severe infection.[21,69–73]

Although bordetellosis is uncommon, it has been recommended that severely immunocompromised people, their pets, or both avoid contact with animals in animal shelters, dog kennels, catteries, or animal shows, where the infection is more prevalent or respiratory disease has been observed in animals. If necessary, vaccination of an immunocompromised person's pets can be considered to help control the spread of an outbreak of infection, preferably with the inactivated vaccine.[68]

Brucellosis

Humans most often become infected with *Brucella canis* through contact with the organism in canine genital secretions or from laboratory culture. Dogs may shed the organism in urine, saliva, and respiratory secretions; however, fluids from these routes generally have fewer organisms than genital secretions and are of lower risk for human infection. Infections in people are rarely reported; however, this may be a combination of low occurrence, unapparent clinical disease, and missed cases due to challenges in organism detection and limited testing.[74] Of the reported human cases, high-risk individuals are often involved. Immunocompromised patients (e.g., infected with HIV, cirrhosis) have been infected with *B. canis* as a result of contact with household dogs, resulting in bacteremia, fever, endocarditis, and peritonitis.[75–78] Several clinical *B. canis* infections in young children have been reported following contact with puppies.[79,80]

Individuals with infected dogs should be counseled on potential zoonotic disease risks; local public and agriculture health regulations may dictate the approach to *B. canis*-positive dogs.[81] In all circumstances, infected dogs should be neutered to help reduce the public health risk should they be kept as pets. Hygiene practices (e.g., hand washing, use of protective outerwear) should be carefully observed around aborting bitches. High-risk individuals should avoid contact with dogs with known or suspected brucellosis (such as dogs from breeding kennels that have had abortions or reproductive failure). The zoonotic risk of a neutered animal is low, but concerns about keeping an infected animal in the household with a high-risk person may be valid. Households with high-risk members should prevent unrestricted outdoor access of dogs, especially if contact with other dogs, notably strays, is likely.

Campylobacteriosis

Campylobacteriosis is caused by a microaerophilic group of gram-negative, curved, motile rods that are commensal flora of animals. Fecal-oral, foodborne, and waterborne modes of transmission are the principal avenues for human infection. *Campylobacter* spp. are frequently isolated from dogs and cats (especially younger than 1 year of age) recently acquired from pet stores, kennels, animal shelters, or pounds. Puppies and kittens with diarrhea have been most commonly associated with human infections.[82] Signs of infection in humans are intense abdominal discomfort, bloody diarrhea, fever, tenesmus, and fecal leukocytosis. Immunocompromised and young individuals are at the greatest risk for infection and severe disease. Immunosuppressed individuals with AIDS develop recurrent diarrhea, dehydration, and bacteremia. Dog-associated *Campylobacter* transmission to people has been well documented, including a large national (USA) outbreak of MDR *Campylobacter jejuni*, involving over 100 human cases (24% hospitalized) linked to puppy exposure.[83–87] Young children who live with a puppy are perhaps at greatest risk for infection.[83]

TABLE 19.1 Predominant Disease Manifestations of Dog and Cat Zoonoses of Importance for High-Risk People

Pathogen (Chapter)	Disease	Signs in Dogs and Cats	Signs in Immunocompetent Human Hosts	Predisposing Conditions	Signs in Immunocompromised Hosts
Viral					
Cowpox virus (38)	Cowpox	Usually in cats, rare in dogs: solitary crusted skin lesion on head, neck, or thoracic limbs to disseminated skin lesions with secondary bacterial infections, abscesses, fever, inappetence, lethargy, oculonasal discharge, diarrhea, and death	Usually mild, with a crusted skin lesion, sometimes with fever, headache, and nausea. Rarely more severe with large painful skin lesions with systemic illness requiring hospitalization and prolonged recovery	Atopic eczema, alcoholism, and drug abuse	Increased risk for severe form
Bacterial					
Bartonella spp. (70)	Cat scratch disease	Usually subclinical	Regional lymphadenopathy	HIV-AIDS, liver or kidney transplant, abnormal cardiac valve	Bacillary angiomatosis, peliosis hepatis, endocarditis
Bordetella bronchiseptica (55)	Bordetellosis	Cough	Pertussis-like syndrome	Malignancy, AIDS, malnutrition, chronic renal failure	Pneumonia, pleural effusion, sepsis, peritonitis
Campylobacter (65)	Campylobacteriosis	Diarrhea, especially in young animals	Abdominal discomfort, large-bowel diarrhea, fever	Young (<5 years old), HIV-AIDS	Recurrent diarrhea, dehydration, bacteremia
Capnocytophaga (75)	None	Subclinical	Wound infections	Asplenia/hyposplenia, alcoholism, elderly	Sepsis, pneumonia, soft tissue infection
Clostridioides difficile (64)	CDAD	Subclinical or diarrhea	Antibacterial-associated diarrhea, nosocomial diarrhea	Advanced age, long healthcare facility stays, gastrointestinal surgery, chemotherapy, organ transplantation	Similar to immunocompetent, but at increased risk for CDAD and have a poorer prognosis
Coxiella burnetii (48)	Q fever	Typically subclinical	Asymptomatic or mild flu-like illness, occasionally hepatitis, pneumonia, myocarditis, pericarditis, encephalitis	Previous cardiac valvulopathy, chronic steroid therapy, solid organ transplants, alcoholism, cirrhosis	Pneumonia, endocarditis, osteomyelitis, and chronic hepatitis; for pregnant women, spontaneous abortion, intrauterine growth retardation, premature delivery, fetal death
Escherichia coli (63)	Traveler's diarrhea	Enteric forms (especially neonatal kittens and puppies): vomiting, diarrhea, dehydration, anorexia, lethargy, weakness and death. Extraintestinal forms: UTI, emphysematous cystitis, severe acute hemorrhagic pneumonia	Enteric forms: severe acute diarrhea sometimes complicated by hemolytic uremic syndrome. Extraintestinal forms: UTI, sepsis, pneumonia, meningitis, and various multiorgan infections and abscesses	HIV-AIDS, cancer, leukemia, aplastic anemia, chemotherapy, glucocorticoids, diabetes mellitus, transplant patients, liver disease, autoimmune disease, malnutrition, alcoholism	Increased risk for both enteric and extraintestinal forms
Francisella tularensis (74)	Tularemia, rabbit fever, deer-fly fever	Subclinical to fever, lymphadenomegaly, draining wounds	Ulceroglandular or glandular illness	Older age, alcoholism, diabetes mellitus, transplantation, AIDS	Prolonged infection or death
Pasteurella spp. (75)	Pasteurellosis	Subclinical	Local cellulitis	Cirrhosis of liver and other chronic liver diseases, solid organ malignancies, glucocorticoid use, diabetes mellitus, prosthetic joints	Bacteremia or sepsis, endocarditis, osteomyelitis, pneumonia, endophthalmitis
Salmonella spp. (62)	Salmonellosis	Diarrhea or subclinical infections to bacteremia with osteomyelitis, meningitis, pneumonia, fever, and abortion	Usually self-limiting gastroenteritis with mucoid diarrhea and hematochezia	AIDS, age (<5 years old, elderly), diabetes mellitus, renal disease with dialysis, prosthetic heart valves, aplastic anemia, chemotherapy, malignancy	Refractory or life-threatening diarrhea; extraintestinal illness with absence of diarrhea including bacteremia, sepsis, meningitis, osteomyelitis, endocarditis

Continued

TABLE 19.1 Predominant Disease Manifestations of Dog and Cat Zoonoses of Importance for High-Risk People—cont'd

Fungal					
Dermatophytes; *Microsporum canis, Trichophyton* spp. (78)	Ringworm	Subclinical or lesions with circular alopecia, scaling, erythema, pruritis, hyperpigmentation, claw infections	Circular alopecia, scaling, crusting	Age (premature infants), HIV-AIDS, immunosuppressive medications with organ transplantation, autoimmune diseases	Same as immunocompetent, atypical signs, (e.g., disseminated cutaneous infections)
Malassezia pachydermatis (79)	*Malassezia* dermatitis	Normal skin flora in healthy animals. Can become pathogenic with skin inflammation, chronic glucocorticoid therapy, endocrine disorders, immunocompromise. Clinically presents as otitis externa, seborrheic skin with possible alopecia, lichenification, crusting, scaling, and pigmentation	Not normally found on human skin, asymptomatic	Age (infants in neonatal ICUs)	Bacteremia, UTIs, meningitis
Parasitic					
Cryptosporidium parvum, Cryptosporidium canis, Cryptosporidium felis (103)	Cryptosporidiosis	Subclinical in immunocompetent adult dogs and cats. Diarrhea, especially in young animals, kittens with FeLV or FIV infection, or immunocompromised dogs (e.g., CPV, CDV, intestinal lymphoma)	Diarrhea, abdominal cramps, nausea, vomiting	HIV-AIDS, malnutrition in children, organ transplantation, hyper IgM syndrome, cancers, chemotherapy	Prolonged intractable diarrhea, extraintestinal infection of the biliary and respiratory tracts
Giardia duodenalis (101)	Giardiasis	Subclinical or diarrhea, soft, light-colored, frothy, mucoid stools, flatulence, failure to thrive	Watery, foul-smelling diarrhea with flatus, abdominal distention	Malnutrition and chronic diarrhea in infants and children, nephrotic syndrome or lymphoma, age (older adults), AIDS and other immunodeficiencies; agammaglobulinemia, gastric surgeries, and reduced gastric acid	Prolonged diarrhea (more refractory to therapy)
Strongyloides stercoralis (116)	Strongyloidiasis	Subclinical; occasionally diarrhea, pneumonia, dermatitis in puppies	Subclinical, rash, diarrhea, abdominal pain	Immunosuppressive drugs, hematologic malignancy, human T-cell lymphotropic virus-1 (HTLV-1) infection	Abdominal pain, vomiting, diarrhea, intestinal obstruction, peritonitis, cough, hemoptysis, meningitis
Toxocara canis, Toxocara cati (112)	Toxocariasis	Subclinical; occasionally failure to gain weight, abdominal distension, respiratory signs in juveniles; enteritis in adults	Asymptomatic	Youth (less than 6 years of age for visceral larval migrans; mean age of 8–16 years for ocular larval migrans)	Visceral larval migrans (cough, fever, seizures), ocular larval migrans (unilateral vision loss, strabismus, chorioretinal granuloma, retinal detachment)
Toxoplasma gondii (93)	Toxoplasmosis	Subclinical, occasional diarrhea in kittens	Asymptomatic, self-limiting lymphadenopathy, chorioretinitis	Pregnancy (unborn fetus), HIV-AIDS, chemotherapy, cancer, especially bone marrow or organ transplantation, long-term glucocorticoid use	CNS complications (focal neurologic deficits, cognitive dysfunction, altered mental status); in pregnant women spontaneous abortion, prematurity or stillbirth; in neonates fever, microcephaly, hydrocephalus, hepatosplenomegaly, jaundice, seizures, chorioretinitis

AIDS, acquired immunodeficiency syndrome; *CDAD, Clostridioides difficile*–associated diarrhea; *CDV*, canine distemper virus; *CNS*, central nervous system; *CPV*, canine parvovirus; *CSD*, cat scratch disease; *FeLV*, feline leukemia virus; *FIV*, feline immunodeficiency virus; *GI*, gastrointestinal; *HIV*, human immunodeficiency virus; *ICU*, intensive care unit.

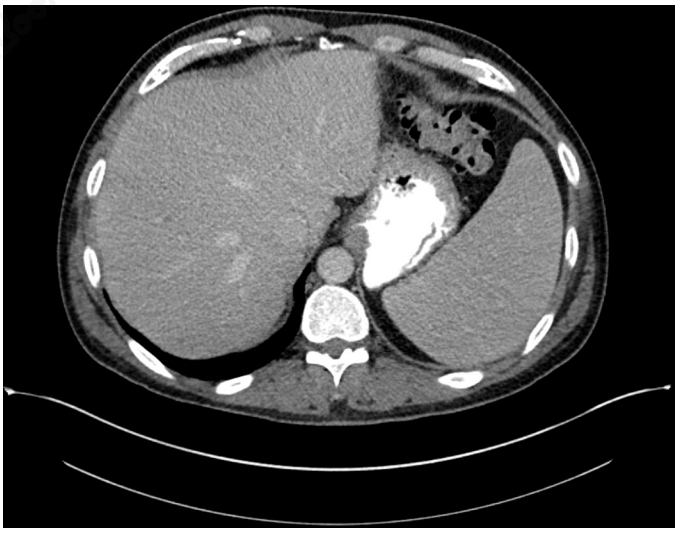

Fig. 19.1 Bartonellosis-associated hepatosplenomegaly (CT image) in a person with AIDS admitted for prolonged fever. The patient lived with many flea-infested cats and reported a recent cat scratch. (Photograph courtesy of Shandra Day and Shu-Hua Wang, Columbus, Ohio, USA.)

Preventative measures among high-risk people include avoidance of animals with diarrhea and adoption of pets younger than 1 year of age or from pet stores, kennels, or shelters. Washing hands after handling pets or their feces, and especially before eating is the most important precaution.

Capnocytophaga Infection

Capnocytophaga canimorsus is a gram-negative, rod-shaped organism that is found in the oral flora of dogs, cats, and other animals.[20] Transmission of *Capnocytophaga* is most commonly from a dog bite, although other types of contact with dogs or cats can also result in transmission.[88,89] Specific serovars of *C. canimorsus* appear to be linked with human infection.[90] In one review, a history of a cat or dog bite was present in 89% of 28 cases.[91] In the remaining cases, contact with salivary secretions on mucosal or broken skin surfaces may have been involved in transmission. Cats and dogs should not be allowed to lick a person's open cuts or wounds or have contact with medical devices, such as peritoneal dialysis equipment.[92] The clinical manifestations of *Capnocytophaga* infection in people range from cellulitis to fulminant sepsis. Although the condition is considered rare, it is likely that the infection is under-reported because the organism is difficult to culture by routine methods. Most cases in people are associated with an underlying immune disorder or a similar immunocompromising condition (e.g., alcoholism). Individuals with splenectomy are at increased risk, but other conditions can render a patient functionally asplenic or hyposplenic, such as sickle cell disease, alcoholism, and cirrhosis. Signs of infection are acute severe cellulitis and bacteremia, which may develop within 24 to 48 hours after the bite. The mortality associated with this organism is often at or greater than 20%. For those who survive, neurological sequelae are common.[89,93] Prevention involves bite and scratch avoidance and prompt treatment (e.g., washing with soap and water, antimicrobials as indicated). All individuals, especially high-risk people, should be advised to consult with a physician as soon as possible following an animal bite or severe scratch. Prophylactic antimicrobials are often administered to high-risk individuals in these situations. Pets should never be permitted to lick or otherwise have contact with wounds, ulcers, or skin lesions.

Clostridioides difficile Infection

Clostridioides difficile (previously *Clostridium difficile*) is a rod-shaped, gram-positive, anaerobic, spore-forming bacterium. Pathogenic strains can produce toxin A, an enterotoxin, and toxic B, a cytotoxin. *Clostridioides difficile* is an important cause of antimicrobial-associated diarrhea in humans, with an estimated 223,900 *C. difficile* infection (CDI)-related hospitalizations and at least 12,800 deaths each year in the United States.[94] Individuals at increased risk for CDI include those with recent antimicrobial use, hospitalized patients, the elderly, those receiving PPIs, and individuals with underlying immunosuppressive disease or chronic illnesses.[95]

The role of *C. difficile* as a pathogen in dogs and cats is controversial. Reports of animals as confirmed sources of infection for humans are lacking. However, dogs and cats can develop infection and shed the organism, with isolates often indistinguishable from those found in people.[96] Therapy dogs visiting human hospitals frequently (58/102; 58%) had positive culture results for *C. difficile* with 71% of the isolates being toxigenic strains.[97] Dogs became colonized with *C. difficile* (in addition to MRSA) during visits to the human hospital. The risk of acquisition is higher in dogs that lick patients or accept treats during visits.[98] In one study, residing with a pet was a risk factor for *C. difficile* colonization of immunocompromised individuals, and the organism was found to contaminate the environment of affected households.[99] In a study of dogs and cats owned by patients with CDI, probable transmission between the patient and pet was documented in 3/14 (21%) of the contacts.[100]

As with other potentially zoonotic enteric infections, avoidance of contact with feces or fecal-contaminated surfaces, use of gloves when cleaning up pet feces, frequent hand washing, and prompt diagnosis and treatment of animals that develop diarrhea are important precautions for high-risk individuals. Animal exposure to infected people and contaminated fomites, especially in healthcare facilities, should be avoided if possible.

Cowpox Virus Infection

Cowpox infection is a disease currently confined to Eurasia and is caused by a virus of the genus *Orthopoxvirus*. Cats acquire the pathogen from contact with infected rodents.[101] Cat-to-human transmission, often acquired through an abrasion in the skin, is the most common cause of human infection.[102] Cowpox infection in healthy individuals is often clinically mild, with the development of one to several pox lesions, nausea, pyrexia, and headaches.[102] In severe cases, often associated with immune suppression or preexisting skin disease, infection can cause large, painful skin lesions and systemic illness that can require hospitalization and even result in death (Fig. 19.2).[103] The use of simple hygiene practices, such as hand washing and use of gloves, reduction of cat-rodent contact in regions where the virus is present, and bite and scratch avoidance are recommended to avoid transmission.[101,103,104]

Coxiellosis

Q fever (coxiellosis) is caused by *Coxiella burnetii,* a small, gram-negative, obligately intracellular bacterial pathogen. Illness in humans due to Q fever can be acute or chronic. In the immunocompetent host, most acute infections are either asymptomatic or a self-limiting, febrile illness. Occasionally, granulomatous hepatitis, pneumonia, myocarditis, pericarditis, or encephalitis can occur, with an increased risk of these manifestations in high-risk individuals.[105–107] Endocarditis is the most frequent manifestation of chronic Q fever, with patients with existing valvulopathy at particularly increased risk.[108] Other features of chronic infections include infections of aneurysms and vascular grafts, osteomyelitis, and chronic hepatitis.[105] Individuals with solid organ transplants, alcoholic cirrhosis, or on chronic steroid therapy are also at increased risk for developing chronic Q fever.[105] Pregnant women deserve special mention because both the fetus and mother are at risk. Pregnant women can develop systemic disease or endocarditis,

Fig. 19.2 Severe diffuse skin lesions of cowpox infection in a person with preexisting eczema. (Photograph courtesy Richard Lawn, Stafford, UK, letter to the editor of *Veterinary Record,* May 15, 2010, page 631, volume 166.)

Fig. 19.3 Dermatophytosis (*Microsporum canis*) lesions on forearms of child with recent history of contact with a dog with dermatophytosis. (Photograph courtesy of Nordau Kanigsberg, Ottawa, Ontario, Canada.)

while spontaneous abortion, intrauterine growth retardation, premature delivery, or fetal death can also occur.[109] Dormant *C. burnetii* can reactivate during subsequent pregnancies.

The primary reservoirs for human Q fever infection are cattle, goats, and sheep, but cats can be an important reservoir of Q fever in the urban setting.[110,111] Dogs are a less frequent source.[112] Infection in animals is usually not clinically apparent. Infected animals contaminate the environment by excretion of the organisms in placental tissues and in their milk. Parturient cats have been linked to human outbreaks of Q fever.[113] Raw meat has been implicated in the transmission of *C. burnetii* to cats and people.[114]

High-risk individuals described in this section should avoid contact with placental tissues of animals, periparturient animals, and newborn animals. Because coxiellosis has developed in humans exposed to parturient cats, protective gloves and outerwear, including masks and protective eyewear, should be worn by all individuals performing procedures in which there is contact with the genital tissues or secretions of parturient or aborting animals.

Cryptosporidiosis

Cryptosporidiosis is an intestinal infection caused by *Cryptosporidium* spp., ubiquitous, coccidian parasites of vertebrates. *Cryptosporidium parvum* is the least host-specific species, and infects people and many animal species including dogs and cats. *Cryptosporidium canis* and *Cryptosporidium felis* are predominant species in dogs and cats, respectively. Although these two species do not commonly infect humans,[115] they have been known to infect immunocompromised individuals, so are considered zoonotic.[116,117]

Cryptosporidium oocysts are infective as soon as they are shed in the feces, and the infective dose is very low, making direct transmission possible by any potential fecal-oral route, such as through contact with contaminated fur, soil, hands, clothing, or water. The oocysts are highly resistant to chemical and biological destruction, and remain infectious in cool, moist conditions for many months. They can survive in freshwater and saltwater and in chemically treated swimming pool water.

Immunocompetent human patients can be asymptomatic, but they may also experience a range of symptoms, including diarrhea, cramps, nausea, vomiting, and fever that typically lasts for 5 to 10 days. Cryptosporidiosis appears to be very common in individuals with certain immunocompromising conditions (e.g., estimated pooled global prevalence of 14% in HIV-infected people).[118] Immunocompromised individuals (e.g., HIV-AIDS, malnourished children, transplant recipients, hyper IgM syndrome, hematologic neoplasia, and cancer patients on chemotherapy) are at risk for severe, intractable disease that may be fatal.[119–121] Ownership of dogs and cats as pets has not been shown to increase the risk of cryptosporidiosis in immunocompetent persons.[122] In one study of people infected with HIV with and without cryptosporidiosis, pets were not a major risk factor for infection.[123]

Caution is advised when any *Cryptosporidium* species are found in a pet dog or cat. High-risk individuals should be particularly careful to avoid fecal contact, especially when the animal has diarrhea. Disposable gloves should be worn if contact with feces is unavoidable; hands should be immediately washed after glove removal. High-risk owners should seek veterinary advice promptly if their pets develop diarrhea. Stray animals or pets with diarrhea should not be adopted by high-risk individuals.

Dermatophytosis

Dermatophytosis in pets is most commonly caused by the zoophilic fungi *Microsporum canis, Microsporum gypseum,* and *Trichophyton* spp., and cats and dogs can serve as carriers. *Microsporum canis* is the most commonly implicated organism, especially in cats. Humans can acquire dermatophyte infections through contact with clinically affected or healthy animals or humans as well as contaminated fomites, such as household surfaces, bedding, and clothing. Classic skin lesions in humans consist of circular alopecia, scaling, crusting, and ulceration (Fig. 19.3).

Immunocompromised individuals can develop signs similar to those in immunocompetent patients or can have atypical signs such as adult tinea capitis (infection of the scalp involving the skin and hair), nail infections, or disseminated cutaneous infections.[124,125] Severe zoonotic dermatophytosis has been reported in humans with AIDS, systemic lupus erythematosus, and transplant patients on immunosuppressive medication.[126–129] One outbreak occurred in a neonatal intensive care unit (ICU) among premature infants with low birth weight and multiple medical problems.[130] A nurse who worked in the

unit had acquired a cat and subsequently developed a recurrent clinical *M. canis* infection. The cat was taken to a veterinary dermatologist, who made the diagnosis of *M. canis* infection. The nurse was taken off duty and underwent treatment, and the unit instituted strict enhanced cleaning and disinfection procedures. This case underscores the importance of good communication among veterinarians, their clients, and their clients' physicians to help prevent or respond to infections, in this case dermatophytosis, where an animal might be involved.[131] Other outbreaks among neonates in hospitals have also been reported.[132,133]

Prevention of pet-associated zoonotic dermatophytosis involves avoidance of contact with infected animals, use of barriers (e.g., gloves) when handling infected animals, effective therapy of infected animals, and cleaning and disinfection of contaminated living spaces. Immunocompromised pet owners should seek veterinary care early should their pets develop skin lesions. Given the increased likelihood of infection, colonization, or contamination of shelter animals, such animals are not ideally suited for households with immunocompromised individuals. If such clients choose to acquire a pet from a shelter, temporary housing of the animal in a separate location for several weeks to ensure they are healthy and not incubating pathogens is recommended.

Escherichia coli Infections

Escherichia coli are gram-negative, rod-shaped bacteria that belong to the resident flora of the intestinal tract of humans and animals and are ubiquitous in the environment. The pathogenicity of individual strains varies depending on pathogen virulence factors and their interplay with host immunity.

In humans, diarrhea caused by virulent pathotypes can be acute, severe, watery, mucoid, bloody, or persistent and possibly complicated by hemolytic uremic syndrome. Extraintestinal pathogenic *E. coli* (ExPEC) is the most common cause of UTIs in people and can cause a variety of other infections, such as sepsis, pneumonia, and arthritis. High-risk individuals are at increased risk of infection and severe disease.[134]

Human-, dog- and cat-derived *E. coli* strains share similar resistance patterns, genotypes, and virulence factors, which suggests the possibility of zoonotic transmission.[135,136] Transmission of enterohemorrhagic *E. coli* (0157) from a dog to a sick child was implicated in one report. Two family dogs and cattle on a farm were colonized with the same strain as the child. No contact between the cattle and child was reported, but close contact between the dogs and child had occurred.[137]

Humans are most often infected as a result of consumption of contaminated food or exposure to other humans with diarrhea, and confirmed transmission from dogs and cats has not been reported. However, humans, dogs, and cats can share pathogenic types of *E. coli*. Because high-risk individuals are at increased risk for clinical illness and complications, these individuals should practice a high level of hygiene to reduce fecal-oral transmission. This includes frequent hand washing after animal fecal exposure, frequent removal and disposal of pets' feces, preferably by an immunocompetent individual, ensuring pets remain clean of urine and fecal material, and ensuring that sick pets are promptly seen by a veterinarian for early diagnosis and treatment. Raw or inadequately cooked diets, especially with meat or poultry ingredients, and unpasteurized dairy products are known potential sources of *E. coli* and should not be fed to pets who come into contact with high-risk people.

Giardiasis

The cause of giardiasis is *Giardia duodenalis*, a ubiquitous, extracellular protozoan found in the intestinal tracts of vertebrate animals and humans. *Giardia duodenalis* has been categorized into seven genetic assemblages (A–G), each adapted to a specific range of hosts. Humans can be infected with assemblages A1, A2, and B. Dogs can be infected with assemblages A1, B, C, and D. Cats can be infected with assemblages A1 and F. Rarely, dog- and cat-specific assemblages infect people.[138]

Giardiasis is reported most frequently in young children.[139] The primary sign in immunocompetent humans is watery, foul-smelling diarrhea with flatus and abdominal distention. Asymptomatic shedding can occur and is usually self-limiting. Patients with immunodeficiencies, such as common variable immunodeficiency and X-linked agammaglobulinemia, a history of gastric surgery, reduced gastric acid, and lymphoma have increased risk of infection and are often more difficult to treat.[140] AIDS patients are not at increased risk of infection, but can be refractory to treatment, with development of chronic diarrhea and malabsorption.[33]

Zoonotic transmission from dogs and cats is most likely to result from direct fecal contamination.[141] Because assemblage determination is not currently practical in a clinical setting, any infected dog or cat should be considered a potential source of infection for humans. Dogs and cats younger than 6 months of age and those with diarrhea are most commonly shedding *Giardia* and should be avoided as pets by high-risk people.[142] Off-leash park practices have been associated with an increased risk for *Giardia* shedding in dogs, therefore should also be avoided by such individuals.[143] Infected humans are of equal or greater concern as a potential source of infection to high-risk individuals and should generally be the first line of consideration when investigating illness in a person or instituting prevention measures. High-risk people should avoid contact with animal fecal material; if contact is required, gloves should be worm and hands washed immediately afterward.

Leptospirosis

Leptospirosis is caused by several serovars of the spirochete *Leptospira interrogans* that can infect dogs, cats, and a wide variety of other animals. Spirochetes are shed in the urine into water or moist environments. Humans become infected by contact of their mucous membranes, cuts, or skin abrasions with contaminated water or urine. The clinical signs of leptospirosis in people can vary widely from an inapparent influenza-like illness to a severe fatal disease with hepatic and renal failure as well as hemorrhagic pneumonia.

Infected dogs have been reported as the source of infection for people, although such reports are poorly documented in the literature.[144] Precautions for high-risk people include limiting exposure of pets by keeping cats indoors and dogs in a fenced yard or on a leash when outdoors, promptly seeking diagnosis and treatment for illness in pets, and vaccinating dogs against leptospirosis. Shortly after treatment with appropriate antimicrobial drugs (i.e., 48 hours), the urine of infected dogs is no longer likely to be infectious; therefore, prompt recognition and treatment is critical in reducing zoonotic risk.[144]

Malassezia pachydermatis Infection

Malassezia pachydermatis is a ubiquitous, lipophilic, commensal yeast found on the skin and mucocutaneous areas of animals, including dogs and cats. This yeast species most frequently colonizes dogs, whereas cats are colonized by this and other *Malassezia* species. *Malassezia* can be transmitted to humans through direct contact. One study[145] suggested that humans become contaminated with *M. pachydermatis* while contacting dogs with or without dermatitis. In this study, PCR detected *M. pachydermatis* on approximately 93% of the human participants. Although *M. pachydermatis* can colonize humans exposed to pets, clinical manifestations are most common in infants and immunocompromised adults.[146]

Malassezia pachydermatis is not a normal skin commensal in humans; however, humans can harbor it subclinically. *Malassezia pachydermatis* was identified as a cause of nosocomial infection in 15 infants in a hospital ICU.[147] It was isolated from the blood, urinary tract, CSF, tracheal aspirates, skin, and an intravenous catheter tip from affected infants. The source of infection was not certain, but it was considered likely that the infection was transmitted by healthcare workers infected by their pet dogs at home. All 15 isolates from the infants, the hands of one nurse, and skin of three of the healthcare workers' pet dogs that were sampled had matching genotypes of *M. pachydermatis* isolates. Improving hand washing stopped the spread of this infection cluster.[147]

Multidrug-Resistant Bacterial Infections

An estimated 2.8 million people annually in the United States develop MDR bacterial infections and at least 35,000 people die as a direct result of these infections.[94] The level of evidence for transmission between pets and people varies with the bacterial species. It is currently thought that many of these MDR bacteria are predominantly human pathogens, with people serving as the main reservoir, but that household pets can become colonized or infected, thus serving as a secondary source for human infection.

Methicillin-Resistant Staphylococcal Infections

Staphylococcus aureus is a human-adapted commensal that causes opportunistic infections. *Staphylococcus aureus* can also infect other animal species, including dogs and cats. MRSA has become an important public health concern due to its antimicrobial resistance to beta-lactam antimicrobials, and often to additional antimicrobial classes. MRSA is usually harbored by humans in their nasal passages, notably healthcare workers including veterinarians, who may develop infections or remain colonized for extended periods and inadvertently transmit the pathogen to others. Transfer of MRSA can also occur between humans and animals.[63] Although transfer can be bidirectional, humans are the most important source of MRSA for dogs or cats in human hospital, veterinary hospital, and community settings.[63,98,148,149] For example, dogs that visited human healthcare facilities were at five times the risk of acquiring MRSA than dogs involved in other interventions.[98]

In contrast, *Staphylococcus pseudintermedius* is the most common commensal of the skin of dogs. Reports of this organism causing infection and disease in humans are rare, but anecdotally increasing, and in some instances, isolates from diseased humans have been methicillin-resistant (MRSP), making therapy difficult.[150]

Judicious use of antimicrobials by veterinarians and physicians and strict infection control practices, especially hand hygiene, can help reduce the chance of MRSA and MRSP infections spreading among animal health workers in veterinary practices as well as to pet owners. High-risk individuals who live with dogs or cats that are known to be infected or colonized with MRSP or MRSA should perform hand hygiene immediately after pet contact and avoid contact with any infected sites on the animal.

Other Multidrug-Resistant Infections

Extended-spectrum beta-lactamases (ESBLs) are plasmid-mediated enzymes that hydrolyze beta-lactams and critical third-generation cephalosporins used to treat resistant bacterial infections in humans, thus inactivating a wide range of antimicrobials. ESBL-producing members of the order Enterobacterales (e.g., *E. coli*, *Klebsiella pneumoniae*, *Salmonella*) have become a focus of public health due to an increased frequency of human infections with these organisms, treatment challenges, and extension of infections into both hospital and community settings. Clinical manifestations are similar to those for nonresistant organisms, including UTI, bacteremia, splenic abscess, and sepsis. Although less

Fig. 19.4 Radiograph showing osteomyelitis (presumed *Pasteurella*) of the finger following a cat bite in a 4-month-old child. (Photograph courtesy of Jason Brophy, Ottawa, Ontario, Canada.)

widespread than in humans, ESBL-producing Enterobacterales have now been identified in dogs and cats.[151,152] Pet ownership has been documented as a risk factor for ESBL colonization in people.[153] Further, identical pulse field gel electrophoresis (PFGE) profiles of ESBL *E. coli* were detected in 9.5% (4/42) of isolate pairs from dogs and owners.[135] Resistance to other important antimicrobial classes (e.g., carbapenem, colistin) has recently been identified in companion animals.[154–157] Transmission of these organisms between people and their pets is possible and represents an important public health concern.[157]

Pasteurellosis

Pasteurella multocida is a gram-negative coccobacillus that colonizes the oral cavities of cats and dogs. *Pasteurella multocida* is a leading cause of animal bite wound infections in both immunocompetent and high-risk individuals. Like immunocompetent individuals, high-risk individuals also develop local soft tissue infections but are predisposed to develop more invasive, systemic infections, including sepsis, pneumonia, osteomyelitis, endocarditis, and meningitis (Fig. 19.4). Human infants less than 1 month of age who are exposed to dogs or cats appear to have a high risk for severe disease, with predisposition to meningitis.[158] In infants, most cases involve nontraumatic contact between the child and pet (e.g., licking or sniffing).[158] Nonbite exposures (e.g., scratches or lick contamination of mucous membranes, open wounds, or surgical sites) are also reported in adults, especially those at high risk for pet-associated infections.[159,160] Cirrhosis of the liver is one of the most common predisposing conditions associated with severe *Pasteurella* infections in adults,[161] but other predisposing conditions such as neoplasia, organ transplantation, recent joint implants, and polycystic kidney disease have been reported.[159,160] The elderly may also be predisposed to complications and death following *Pasteurella* infection, with an 8% fatality proportion in one study.[162] Severe *Pasteurella* peritonitis among individuals undergoing peritoneal dialysis who own

pets (notably cats) has been reported, drawing attention to the need of educating patients on strict hygiene measures and avoiding pet contact with the dialysis equipment (especially in bag exchange areas).[163,164] The urgency of seeking treatment is illustrated by a case report of a 64-year-old man with cirrhosis who developed sepsis after a cat bite. Although he did seek medical care, it was 48 hours after the bite, and he died within 72 hours of the bite.[165]

Prevention measures focus on bite and scratch avoidance and prompt wound treatment. Pets should never be permitted to lick or otherwise have contact with wounds, surgery sites, dialysis or similar healthcare equipment, or skin lesions or be permitted to lick faces or ears of high-risk people.

Salmonellosis

Salmonella spp., a gram-negative, facultative anaerobic, rod-shaped bacterial species, infects mammals, birds, reptiles, amphibians, fish, and invertebrates. Exposure to contaminated food, such as meat and eggs, account for most human infections. The most well-known pet-related exposures have occurred with reptiles (notably turtles) and amphibians, in part due to their high frequency of subclinical carriage.[166,167] Healthy dogs and cats that live in low-stress environments are unlikely to be colonized with *Salmonella*; however, some factors increase colonization prevalence. Animals that are more likely to shed *Salmonella* include cats that have access to the outdoors and prey on wild birds,[131] young, debilitated, stressed, or immunocompromised dogs and cats[168] and those fed raw food diets containing meat or poultry, both commercial and homemade.[169,170] In one study, risk factors for *Salmonella* colonization in dogs were contact with livestock; treatment with a probiotic in the past 30 days; consumption of a commercial or homemade raw food diet, raw meat and eggs, or a homemade cooked diet; or the presence of more than one dog in a household.[171] Pets generally shed *Salmonella* in feces, although bacteriuria has been reported and potentially poses a human health risk.[172]

Salmonella-infected dogs and cats are usually subclinically infected or have acute diarrhea, but severe disease can occur. Symptoms in humans vary from a self-limiting gastroenteritis to bacteremia, fever, septic arthritis, abscesses, endocarditis, meningitis, or pneumonia. Immunocompromised people, young children, and older adults are predisposed to clinical illness. In addition to enteritis, high-risk individuals often suffer from extraintestinal infections (e.g., endocarditis, bacteremia, and sepsis).[173,174] People infected with HIV are at 20–100 times greater risk of *Salmonella* bacteremia than those without HIV infection.[18]

Animals that reside with high-risk individuals should only be fed canned or dry commercial food or well-cooked homemade food. Any dairy or animal-based (egg, meat) products or treats should be cooked or (high-pressure) pasteurized. If raw or undercooked products are fed, care should be taken to reduce cross-contamination during food preparation or feeding, and high-risk individuals should not have contact with animal feces. The use of stainless steel bowls for feeding, which are easier to disinfect, and gloves during feces clean-up are advised. Hands should be washed immediately after contact with animal feces, whether or not gloves are worn. Cats should be kept indoors.

Reptile-associated salmonellosis in high-risk individuals is often severe and can lead to bacteremia and meningitis, which can be fatal. High-risk people should avoid contact with reptiles, amphibians, exotic species (e.g., hedgehogs), rodents, young chicks, and ducklings and should exercise caution when visiting petting zoos or farms.[175–178]

Strongyloidiasis

Strongyloides stercoralis, sometimes referred to as the human threadworm, is a nematode found in the tropics, subtropics, and limited foci within the United States and Europe.[179] Humans are the principle hosts, although dogs (and rarely cats) can be infected and potentially serve as a source for human infection.[180] Young puppies, especially those housed in groups, are most likely to be infected.[181,182] Humans generally become infected with *S. stercoralis* from penetration of the skin by infective larvae in the soil.

In immunocompetent humans, most strongyloidiasis infections are asymptomatic. Occasionally, a localized, pruritic rash starting at the site of larval penetration occurs. Signs may progress to diarrhea and abdominal pain, with chronic infections leading to pruritis around the anus and perineum.[183] Immunocompromised individuals are at increased risk for severe, complicated strongyloidiasis, including hyperinfection and disseminated strongyloidiasis syndromes. The greatest risk factor for severe infection is high-dose glucocorticoid use, although other immunocompromising conditions including neoplasia and human T-cell lymphotropic virus-1 infection also increase disease risk.[179,184,185] In cases of severe strongyloidiasis, gastrointestinal symptoms are common, including abdominal pain, nausea, vomiting, diarrhea, and ileus, which can lead to intestinal obstruction. Ulceration of the intestinal mucosa can produce hemorrhage, peritonitis, and sepsis. Cough, hemoptysis, respiratory difficulties, and meningitis can result from migrating larvae.[183] High mortality (approaching 100%) is associated with untreated disseminated strongyloidiasis, and even with treatment mortality may exceed 25%.[179]

Dogs and cats likely have a minimal role in human strongyloidiasis. There is limited existing evidence of zoonotic transmission. In one study, an individual who worked in a dog colony was diagnosed with strongyloidiasis, and dogs in the facility were subsequently shown to be shedding *S. stercoralis* in their feces.[182] Individuals (especially those who are immunocompromised) who work closely with large groups of young dogs, such as breeding kennel and pet store workers, are likely those at any reasonable zoonotic risk for *S. stercoralis*. In these situations, measures to reduce individuals' exposure to dog feces will reduce any dog-associated *S. stercoralis* risk.

Toxocariasis

Toxocara canis and *Toxocara cati* are roundworms (ascarids) of the dog and cat, respectively. Nonembryonated eggs are passed in feces by dogs and cats into the environment where they become infective after several weeks. Humans become infected through consumption of infective eggs (e.g., contaminated soil, tissues of infected animals such as cattle and birds, contaminated fruits, and vegetables).[186] Human infections occur wherever there are dogs and cats. Given the time required for eggs to become infective, direct exposure with infected dogs and cats is of limited transmission potential, although there is some concern for contaminated dog/cat hair to serve as a source of human infection.[187] Contamination of the outdoor environment is common in many regions, and infective eggs are able to survive for extended periods under extreme climatic conditions leading to high levels of contamination and risk of human exposure.[188]

Although exposure to *Toxocara* spp. and subsequent antibody development is common, clinical disease is generally rare.[189] Adults do not typically develop clinical disease, while children, especially those with a history of pica or living in unsanitary conditions, appear to be at the greatest risk for toxocariasis.[189,190] VLM, where infective *Toxocara* spp. larvae migrate throughout the tissues of the infected person, may present as cough, fever, headache, wheezing, and seizures. Children under 6 years of age are most frequently diagnosed with VLM.[189] Ocular larval migrans (OLM), where infective larvae migrate into the eye, often presents as unilateral vision loss or strabismus with endophthalmitis, retinitis, chorioretinal granuloma, or retinal detachment. Children diagnosed with OLM are generally older than those diagnosed with VLM.[186,189]

Proper deworming of cats and dogs (especially of puppies, kittens, bitches, and nursing dams) is important to reduce environmental contamination and zoonotic risk.[191] Given the required time for eggs to become infective, prompt removal of feces further reduces zoonotic risks. As human infection relies on consumption of infective eggs, hand washing especially following contact with high-risk material (e.g., puppy/kitten environments, soil) and prohibiting pica are critical to human disease prevention.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan found worldwide. Although cats are the definitive hosts for the organism, humans can acquire infection through consumption of raw or undercooked meat, from vertical transmission to the fetus during pregnancy, and from soil contaminated with cat feces.[192] Although toxoplasmosis can be acquired by ingestion of oocysts shed by infected cats, infection in humans living in industrialized countries is usually caused by ingestion of undercooked meats, especially goat, mutton, or pork.[193]

In immunocompetent humans, *T. gondii* infection is often asymptomatic, whereas in others a self-limiting lymphadenopathy or mild influenza-like illness develops. In contrast, immunosuppressed individuals may develop serious illness with encephalitis, pneumonitis, or myocarditis. The unborn fetus, individuals with HIV-AIDS, or those on chemotherapy are at particular high risk for complications.

Congenital human toxoplasmosis is typically the result of an acute asymptomatic infection in the mother, and the risk of transmission to the fetus is dependent on the stage of pregnancy. The chance of transmission to the fetus is approximately 25% if the mother is exposed in the first trimester, 55% in the second trimester, and 65% in the third.[194] If the mother is infected early in pregnancy, spontaneous abortion, premature delivery, or stillbirth may result. Features seen in infants born to women infected later in pregnancy include fever, microcephaly, hydrocephalus, hepatosplenomegaly, jaundice, seizures, and chorioretinitis. Some infants are asymptomatic at birth and develop complications months, or even years, later. Results from a combination of serologic tests are needed to accurately determine whether a pregnant female or her fetus is infected.

Immunocompromised individuals, notably those with HIV-AIDS and cancer, are at approximately twice the risk of *T. gondii* infection compared with immunocompetent individuals.[195] Toxoplasmosis affects approximately 10% of AIDS patients and is thought to be responsible for at least 30% of CNS complications.[196] CNS involvement may result in focal neurologic deficits, cognitive dysfunction, and altered mental status in patients in late stages of HIV infection.[196] Individuals with cancer, particularly with bone marrow cancer, or those who receive organ transplantation or long-term glucocorticoid therapy are vulnerable to infection. Importantly, most cases of CNS toxoplasmosis are a result of reactivation of latent infections (often acquired through consumption of undercooked meat) rather than recent exposure.

The overall risk of becoming infected by cats in the urban household is low when compared with other modes of exposure (e.g., soil, food).[192,197] Oocysts must sporulate to be infectious, a process that takes 1 to 5 days. Because feces do not generally remain on the fur, direct contact with cats is an unlikely source of infection. Because of their environmental resistance, oocysts can enter the freshwater and marine water supplies and cause disease in humans or animals that ingest contaminated water or invertebrates harboring these organisms. Outbreaks have been associated with contamination of municipal water supplies by oocysts from feral or wild felids.[195–201]

Immunosuppressed people should wear gloves and wash their hands after contact with soil or raw meat. Cat litter boxes should be changed daily, preferably by an immunocompetent person. Hands should be washed after changing the litter box, gardening, or after other contact with the soil. All raw fruits and vegetables should be washed well before consumption, and raw meats should not contact foods that are to be eaten raw or cutting boards used to prepare them. Sandboxes should be covered when not in use.

In order to reduce exposure, cats of immunocompromised people should be kept inside and fed only commercial diets or well-cooked home-prepared diets. Patients do not have to part with their cats or have them tested for toxoplasmosis, either serologically or by fecal examination. However, cats that have serologic positive test results are likely protected from oocyst shedding because shedding is transient and generally occurs only after initial exposure. Despite the infrequency of cat-associated toxoplasmosis, many physicians, including obstetrician-gynecologists, still focus on cat litter disposal measures and overlook other potential sources of food ingestion or environmental exposure.[202] Veterinarians should be prepared to discuss this important topic with misinformed clients and healthcare professionals.

Tularemia

Francisella tularensis is an intracellular, highly pleomorphic, gram-negative coccobacillus, which is endemic in many regions of the world. The organism is typically found in lagomorphs (rabbits and hares), rodents, and arthropods. *Francisella tularensis* is transmissible to humans in infectious doses as low as 10 to 50 bacteria when inhaled. Both immunocompetent and immunocompromised people are affected; the clinical presentation ranges from cutaneous ulcers to pneumonia and rarely death. Individuals with advanced age, alcohol abuse, diabetes mellitus, organ transplantation, and AIDS are more likely to have severe infection.[203–205]

Although most human cases occur following arthropod bites and contaminated aerosols (e.g., aerosols generated by mowing over infected rabbit carcasses), more than 70 human cases of tularemia acquired from cats and dogs have been reported.[206–208] Both clinically healthy and sick cats and dogs can transmit tularemia; some cases involved a bite, but in others, casual contact was the only exposure.[207] Transmission to humans is likely due to the presence of organisms in an animal's mouth or claws.

Prevention of tularemia is primarily through reduction of the risk of tick and other arthropod bites to people and pets. Individuals such as hunters who handle potentially infected animals should wear gloves to prevent the introduction of the organism through cuts or abrasions, and game meat should be cooked. To prevent aerosol exposure, dead animals should be removed from grassy areas before mowing. Control of arthropod vectors, prevention of hunting by cats and dogs (e.g., by keeping cats indoors, control of dogs when outdoors), and prevention of cat bites and scratches in areas where tularemia is endemic are the primary means of reducing the infection risk from pets.

Vector-Borne Infections

Numerous arthropods transmit infections to people (e.g., RMSF, ehrlichiosis, Lyme borreliosis). The mammalian reservoirs of these infections are often wildlife species, and dogs and cats are not a direct source of infections for humans. Instead, they act as sentinels for infection, or they bring the shared vectors closer to humans. Sufficient duration of tick attachment is important in the successful transmission of many of these diseases. Therefore, good ectoparasite control for humans and pets can help to reduce the threat of infection.

Other Zoonoses

Numerous other pathogens have been identified as or suspected to be transmitted from cats or dogs to people (see Box 19.2). To date, these

other pet-associated infections have not been documented with any greater frequency in high-risk individuals than in the general population; however, this area is currently under continued investigation. New zoonotic pathogens emerge and the epidemiology of existing zoonotic pathogens evolve, highlighting the importance of continued surveillance, research, and education in this rapidly changing and complex field. As an example, in 2020 the SARS-CoV-2 virus rapidly spread throughout the world resulting in the COVID-19 pandemic. While suspected to be of animal origin, COVID-19 spread predominately human-to-human. Yet, infection and illness in household pets was documented (transmitted from infectious people, anthroponoses) underscoring the close connection between human and pet infectious diseases. The references at the end of this chapter and the Public Health Considerations sections in other chapters in this book provide a more extensive review of all companion animal-associated zoonoses.

RECOMMENDATIONS ON ANIMAL OWNERSHIP AND CONTACT FOR HIGH-RISK INDIVIDUALS

Recommendations for animal ownership and contact have been established for patients in high-risk groups (see Box 19.3).[3,13,25,33–38] Guidelines are also available for animal-assisted interventions in healthcare facilities[209,210] and animals housed or visiting schools and other public settings.[176] Recommendations target common exposure routes and disease risk and severity. Human and veterinary healthcare providers should provide advice in a manner that is sensitive to the possible psychological benefits of pet ownership. It is rarely necessary for a high-risk individual to part with pets. In most cases, handling pets does not pose more risk for high-risk individuals than contact with other people or the environment. However, simple measures can further reduce the risk of pet-associated zoonoses. Many factors that increase the propensity of animals to carry pathogens (exposure to pathogens through food/water, other domestic animals, wildlife or the environment) are modifiable. Further, owners can often institute routines that reduce the chance of exposure to a pathogen from their companion animals.

Pet Selection

Because infectious diseases, including zoonoses, are more prevalent in puppies or kittens, when acquiring a new pet, households with high-risk individuals should seek mature, healthy dogs or cats with a known history from established vendors. Stray animals or animals being housed in areas of high population density, such as humane shelters, pet-breeding facilities, pounds, puppy or kitten mills, or crowded pet stores, are more likely to harbor pathogens. High-risk individuals should avoid contact with dogs and cats less than 6 months of age. Contact with, or purchase of reptiles, amphibians, rodents, exotic species (e.g., hedgehogs), and young poultry (e.g., chicks) should be avoided. Any newly acquired pet should be examined by a veterinarian before being introduced to a household, especially one with high-risk individuals. In some cases, individuals may wish to wait to acquire a new pet, such as if an individual's immunocompromised state is transient or variable until immune suppression is stable.

Personal Hygiene

High-risk people should perform hand hygiene (wash their hands with soap and water or use alcohol-based hand sanitizer) frequently, and always after handling pets or pet excretions. Hand hygiene is especially important before touching mucous membranes or other vulnerable sites—this includes before eating, smoking, performing dental hygiene, and having contact with medical devices and corrective lenses. Any bites or scratches from animals should be promptly washed. Given the increased risk for infections, high-risk individuals should promptly consult with their healthcare provider regarding the need for antimicrobial prophylaxis following bites or scratches. Pets should be strictly prohibited from licking open wounds, broken skin, mucous membranes (i.e., face licking), or medical devices such as intravascular catheters. Saliva should be washed from hands or open wounds. Rubber gloves should be worn by high-risk individuals when oral medication is given to pets, or someone else should assume these responsibilities. Bite wounds are probably the most common health risk faced by high-risk individuals. Pets that are aggressive in behavior or play should not be kept by households with high-risk people, and such households should take concerted efforts to reduce development of such behaviors through early training. Children should be taught not to startle feeding or sleeping animals.

Handling of Excrement

High-risk people should reduce contact with pet feces and animal-derived pet treats by use of gloves or a plastic bag, or another immunocompetent household member should perform these tasks. Hands should be washed after gloves are removed. Diarrheic stools are particularly challenging to remove without becoming exposed to enteropathogens. Animals with diarrhea should be bathed as needed. If contact cannot be avoided, high-risk individuals should wear rubber gloves during cleaning of diarrheic or other stools and use household bleach (5.25% sodium hypochlorite solution) at a dilution of 1 ounce per quart of water (1750 ppm) and 10 minutes of contact time for disinfection. Similar precautions can be recommended for handling other body fluids, including blood, urine, and saliva.

Daily cleaning of feline litter boxes can prevent *Toxoplasma* infection. Feline litter boxes should not be placed in food preparation areas and should be cleaned by a nonpregnant, immunocompetent adult. Creation of litter box dust can be avoided by using bag liners and dust-free litter. Although the litter box should be emptied outdoors or in well-ventilated areas to prevent inhalation, litter should be directed to a landfill and not placed directly into the environment. Cats should be prevented from jumping on kitchen counters or dining tables.

Dogs should be discouraged from coprophagia or drinking from the toilet. Within communities, animals should be restricted from defecating in child play areas, including playgrounds. Parks should have well-marked, designated areas for pets, playground sandboxes should be kept covered when not in use, and owners should promptly pick up and properly dispose of their pets' excrement. Children should be closely observed in certain environments to avoid pica, and should be taught (and observed) to effectively wash their hands, especially after playing in soil or having higher-risk contact with animals or the environment.

Care of Pets Owned by High-Risk Individuals

Pets in households with high-risk individuals should receive routine vaccinations and routine screening and prevention for endoparasites and ectoparasites based on history and lifestyle. Pets should be neutered to decrease roaming tendencies and behavioral problems. Serologic testing for FeLV and FIV is recommended for cats. Although FeLV and FIV pose no chance of infecting humans, infected cats are more susceptible to other infectious diseases, including zoonoses. Yearly physical examinations are important to maintain the health of the pet. Veterinary attention should be sought immediately for any pet that develops illness. Pets should be bathed regularly if needed, and the haircoat should be brushed regularly and matted fur removed. Claws should be trimmed on a regular basis to reduce the chance of scratch injuries, but declawing of cats is not indicated. Routine visual

inspection for ticks and fleas is indicated based on the area and lifestyle of the pet. For ticks, pets should be checked daily or immediately after leaving tick-infested areas. Any attached ticks should be removed with gloves, a tick removal device, or tweezers, and hands should be washed after removal. Ticks should not be removed or crushed with bare, exposed hands.

Only canned or dry commercial food or well-cooked home-prepared food should be fed to pets in households with high-risk individuals. Dairy or animal-based (egg, meat) products or treats should be cooked or (high-pressure) pasteurized. Pets should be fed in a designated nonkitchen area to reduce opportunities for cross-contamination between pet food, human food, and common human-touch surfaces near eating locations. Pets should be prevented from coprophagia, scavenging, hunting, and feeding on carrion or garbage. They may need to be leashed or confined, or be supervised outdoors. Cats should be kept indoors or bells placed on their collars to scare prey and other wildlife. Access to outside surface water or toilet bowl water should be restricted.

Additional Recommendations for High-Risk Workers in Veterinary Clinics and Other High Animal-Contact Settings

High-risk workers in veterinary clinics and other animal-contact settings should discuss any necessary work restrictions and precautions with their physician. In general, high-risk individuals in these settings should avoid handling animals with suspected or known zoonotic diseases. Such individuals should strictly follow infection control principles, including hand hygiene and use of personal protective equipment (e.g., single use gloves, gowns). Based on the level of immunosuppression, routine glove use should be considered when handling all animals; however, strict hand hygiene after every patient contact and immediately after glove removal is most important. Gloves should always be worn when having contact with animal fluids, wounds, or feces (e.g., when performing a complete physical examination). Prevention of animal bites, scratches, and sharps injuries is important. Training for all staff on pet-associated zoonotic disease risks and prevention within and outside the veterinary clinic should be required and documented. Staff knowledge on this topic should be periodically assessed.

Animals in Human Healthcare Facilities

Dogs and cats are frequently permitted to enter human healthcare facilities and interact with human patients.[210–212] Zoonotic disease protocols at facilities are often lacking, or those responsible for the animals may have limited understanding of zoonotic diseases and prevention measures.[213] Zoonotic disease outbreaks associated with animals in healthcare have been described.[85,210] Guidelines are available to reduce the risk of zoonotic disease transmission in healthcare environments.[209,210,214] These recommendations incorporate recommendations for households with high-risk members, with a few important additions. In healthcare facilities, only dogs (not cats) should be used for animal-assisted activities. Dogs should be at least 1 year (ideally 2 years) of age, kept on leash at all times, have passed a temperament evaluation specific for the encountered conditions, should be healthy (i.e., without history of vomiting or diarrhea within the past week and no known or suspected communicable diseases), and not been fed in the past 90 days raw or dehydrated foods or treats of animal origin (excluding those high-pressure pasteurized or γ-irradiated). Hand hygiene should occur and be stressed before and after every animal contact. The reader is referred to specific guidelines for additional information such as required training for handlers, restricted areas within healthcare facilities, and recommendations for other animal groups, such as service animals, research animals, and personal pet visitation.[210]

Immunization

Jane E. Sykes

KEY POINTS

- Active immunization can partially or completely protect dogs and cats from severe consequences of infection with a variety of different pathogens, and in some cases it reduces shedding of these pathogens.
- Vaccines contain attenuated live microorganisms, inactivated microorganisms, or portions of these organisms. They also contain preservatives and may contain adjuvants.
- Failure of immunization can occur with improper storage or administration of vaccines, a large challenge dose, host factors such as concurrent infections or disease, and interference by maternal antibody.
- Other adverse effects of vaccine administration are uncommon to rare but include hypersensitivity reactions, disease induced by live attenuated vaccine organisms, and injection-site sarcomas in cats.
- The decision to administer a vaccine should be based on discussion of risks and benefits between the veterinarian and pet owner. This should be documented in the medical record.
- Guidelines for vaccine selection and administration have been published by a number of veterinary bodies, such as the AAFP, AAHA, AVMA, and WSAVA; suggestions can also be found in the Appendix.

INTRODUCTION

Immunization refers to artificial induction of immunity or protection from infectious disease and may be *active* or *passive*. In contrast, *vaccination* is the administration of an antigenic product. It follows that not all vaccinations are associated with successful immunization. *Active immunization* involves administration of vaccines that stimulate CMI or humoral immunity, or both, to a specific pathogen. Sometimes active immunization can also enhance nonspecific immunity, leading to reduction in disease caused by nontarget pathogens. *Passive immunization* refers to the administration of antibodies in order to provide temporary protection from disease and can occur through acquisition of MDA transplacentally in colostrum or milk; or treatment with preparations that contain specific or nonspecific immunoglobulins (see Chapter 9, Antiviral Chemotherapy and Immunomodulatory Drugs, and Chapter 21, for post-exposure prophylaxis for rabies.). Readers are referred to advanced immunology texts for detailed descriptions of the physiology of active and passive immunity.[1]

The goal of immunization is to generate a protective immune response of prolonged duration against a specific infectious disease, with minimal adverse effects. Because of the potential for adverse effects, vaccination should be performed only if there is a risk for significant morbidity or mortality from an infectious disease. Since the 1950s, a large number of vaccines for dogs and cats have been developed and marketed worldwide, and more are in development. Nevertheless, it is estimated that even in developed countries such as the United States, only 30% to 50% of dogs are properly immunized, and possibly an even smaller proportion of cats.[2,3] Appropriate vaccination of a larger proportion of the pet population may assist in reduction of the prevalence of infectious diseases through the induction of herd immunity (although the concept of herd immunity has been controversial following the COVID-19 pandemic). Protection of 70% of the population can be effective in reducing the prevalence of diseases when communicability is low, such as with rabies. However, with diseases such as CPV enteritis, where the virus is resistant and large quantities of virus are shed, the percentage of protection may need to be much higher to prevent outbreaks.

With the appearance of injection-site sarcomas (ISSs) in cats and increased recognition of leptospirosis in small-breed dogs, increased emphasis has been placed on vaccine safety. Three-yearly vaccination protocols for some vaccines have been recommended, with administration of other vaccines based on exposure risk. Manufacturers have also worked to purify vaccines and minimize adjuvant content without compromising vaccine efficacy. Vaccines have had a profound influence in the control of infectious disease, and for many vaccines the benefits of vaccination outweigh the risks. The massive injection of resources into vaccine research as a result of the COVID-19 pandemic has accelerated the design and production of safer yet highly efficacious vaccines for humans, and this will undoubtedly impact the nature of companion animal vaccines in the future.

VACCINE COMPOSITION AND TYPES OF VACCINES

A vaccine is a suspension of attenuated live or inactivated microorganisms, or parts thereof, that is administered to induce immunity. Currently available vaccines are primarily for bacterial or viral diseases, because the relatively small number of surface antigens on viruses and bacteria makes immunoprophylaxis more successful when compared with protozoal, fungal, or parasitic diseases. In addition to protective antigens, vaccines may contain preservatives and stabilizers as well as specific antimicrobials to preserve the antigen and inhibit bacterial and fungal growth within the vaccine. Some vaccines also contain an *adjuvant* to enhance the immune response to the antigen. Adjuvants increase the uptake of antigen by antigen-presenting cells, activate and mature antigen-presenting cells, induce production of immunoregulatory cytokines, activate inflammasomes, and induce local inflammation and cellular recruitment.[4,5] The most widely used adjuvants are particulate delivery system adjuvants, such as those that contain aluminum salt precipitates including aluminum hydroxide (Table 20.1).[4] Alum adjuvants are thought to activate the innate immune system after being detected by nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), and they preferentially stimulate Th2 responses.

TABLE 20.1 Types of Adjuvants

Category	Adjuvant Example
Delivery Systems	Aluminum salts
Mineral salts	Calcium phosphate
Lipid particles	Incomplete Freund's adjuvant
Microparticles	PLA (polylactic acid), PLG (poly[lactide-coglycolide])
Immune Potentiators	Muramyl dipeptide
	Lipopolysaccharide
	Imidazoquinolones (e.g., imiquimod)
	Saponins

Modified from Apostolico Jde S, Lunardelli VA, Coirada FC, et al. Adjuvants: classification, modus operandi, and licensing. *J Immunol Res.* 2016;2016:1459394.

Other adjuvants include immune potentiators such as saponin, which is present in a canine *Leishmania* vaccine. Immune potentiators activate innate immune responses by activating pattern recognition receptors (PRRs), including Toll-like receptors, NLRs, and the retinoic acid-inducible gene-I-like receptors (RLRs), which are expressed by immune cells. With an improved understanding of the mechanism of action of different adjuvants, it is possible to manipulate immune responses to vaccines by using different combinations of adjuvants.

Attenuated live vaccines (or modified live vaccines) contain microorganisms that are artificially manipulated so as to negate or greatly reduce their virulence, or are field strains of low virulence. Repeated passage through cell culture is the most common means of attenuation, but it can also be achieved through artificial manipulation of a pathogen's genome. Because they replicate in the host, organisms in attenuated live vaccines usually stimulate an immune response that most closely mimics the protection that results from natural infection. Vaccination with attenuated live CPV and CDV vaccines in the absence of MDA can result in protective immune responses within 3 days of a single injection, which may be followed by immunity that lasts many years, if not for life.[6–8] Partial immunity after vaccination with attenuated live CDV and FPV vaccines can occur within hours.[3,9,10] In addition, vaccine organisms that are shed can serve to immunize other animals in a population. However, the potential for reversion to virulence or vaccine-induced disease exists. Vaccine-induced disease is most likely to occur in highly immunosuppressed animals, including neonates less than 4 weeks of age. Attenuated live vaccines also have the potential to cause some immunosuppression in their own right,[11,12] or they may shift the balance from Th1 to Th2 immune responses.[13] Rarely, this can lead to clinical disease. For example, an outbreak of salmonellosis was reported in cats after use of a high-titer attenuated live FPV vaccine.[14] Very rarely, contamination of attenuated live vaccines has occurred with other potentially pathogenic microorganisms present within cell cultures used to propagate the vaccine. Bluetongue virus grew undetected in one commercial release of canine vaccine in the early 1990s, and caused abortions, cardiac failure, and respiratory distress in pregnant bitches vaccinated in the last trimester of gestation.[15] A more contemporary example is the detection of the feline endogenous retrovirus RD-114 in cell lines used to produce vaccines for dogs and cats in Japan and the United Kingdom.[16] This virus is capable of infecting canine cell lines and concern has been raised about its potential to cause immunosuppression or neoplastic disease, should it adapt to dogs.

Generally speaking, *inactivated vaccines* are less effective than attenuated vaccines, because replication in the host does not occur. They produce weaker immune responses of shorter duration, and more frequent booster immunizations may be required. With the exception of rabies, two initial doses of vaccine 3 to 4 weeks apart are essential to produce an effective immune response, and if more than 6 weeks elapses between these doses, it has been recommended that the series should be repeated.[2,17] Full protection may not develop until 2 to 3 weeks after the last dose. Beyond the initial vaccination series, it is not clear whether lapsed annual boosters require the series to be restarted. This is not always considered necessary for human immunization[18] but has been suggested for dogs when more than 2 or 3 years elapse between boosters.[17] Inactivated vaccines often (but not always) contain adjuvant as well as a large infectious dose to improve immunogenicity. The immune response to inactivated vaccines is often of shorter duration than the immune response to attenuated live vaccines. Inactivated vaccines are safer than attenuated live vaccines for use during pregnancy and in very young or debilitated animals, although it is possible that systemic allergic reactions could still jeopardize pregnancy. Although bacterins have traditionally been associated with a greater likelihood of allergic reactions than attenuated live vaccines, newer inactivated vaccines are safer and have reaction rates that more closely approach those of live attenuated vaccines.[19] The maximum duration of immunity (DOI) that is induced by commercially available bacterins for dogs and cats remains largely unknown, partly because challenge studies that evaluate long-term DOI are prohibitively expensive. Recent studies looking at the DOI for canine leptospirosis vaccines demonstrate protection that lasts at least 12 months,[20,21] with one study demonstrating reduction in leptospiremia and leptospiruria in dogs challenged 15 months after vaccination.[20] Some inactivated virus vaccines have been shown to have DOIs in excess of 7 years in cats.[22] Caution is required when extrapolation is made from the DOI for one product to that for a similar product from a different manufacturer, because it may not be equivalent. Although bacterins usually do not protect all animals from infection, they may prevent clinical illness. In some cases, natural infection of vaccinated animals serves to further boost the immune response, and this can influence DOI in the field. The advantages and disadvantages of attenuated live and inactivated vaccines are shown in Table 20.2.

Subunit vaccines contain specific structural components of a microbe that stimulate a protective immune response, together with adjuvant. They contain reduced amounts of foreign protein, which minimizes the potential for hypersensitivity reactions.

Recombinant DNA vaccines are created through manipulation of the DNA of a pathogen in the laboratory, with the negation of pathogen virulence. Sometimes this also can allow diagnostic tests to differentiate naturally infected from vaccinated animals (DIVA), because of differences in the antibody response evoked by the vaccine. There are several different types of recombinant DNA vaccines:

1. Recombinant subunit vaccines. These are produced by cloning one or more genes for a protective antigen into an expression vector, such as in *Escherichia coli.* The protein expressed by the bacteria is then purified and used in the vaccine (Fig. 20.1A). An example of a recombinant subunit vaccine is the Lyme recombinant OspA vaccine (Recombitek Lyme, Boehringer Ingelheim) and the Lyme recombinant OspA/chimeric OspC vaccine (Vanguard CrLyme, Zoetis) (see Chapter 69). Recombinant subunit protein vaccines have a DOI similar to that of inactivated whole-agent vaccines.
2. Deletion mutant vaccines. These are produced by deleting virulence genes from a pathogen while protective antigens are left in place. There are currently no such vaccines commercially available for dogs and cats, but their development has been described for FHV-1[23] and FCoV.[24]
3. Vectored vaccines. These are produced by inserting genes for one or more protective antigens into the genome of a virus. The virus replicates in the host and expresses the antigens but is nonpathogenic

TABLE 20.2 Comparison of Conventional Whole-Agent Attenuated Live and Inactivated Vaccines

	Attenuated Live	Noninfectious/Inactivated
Advantages	Rapid onset of immunity Sustained immunity after single dose May immunize others in populations Improved breakthrough of maternal antibody interference Improved stimulation of cell-mediated immunity Can administer via the mucosal route Lower risk of hypersensitivity reactions	Safe, even in immunocompromised and pregnant animals Do not interfere with development of immunity from other vaccines Stable in storage
Disadvantages	Potential for reversion to virulence Virulence in the immunocompromised Contraindicated in pregnancy May cause immune suppression Can interfere with development of immunity if administered within days to 2 weeks of another vaccine Less stable in storage Potential for vaccine contamination	Slow onset of immunity Multiple boosters required Often highly adjuvanted, with greater potential for adverse effects Reduced degree of protection compared with attenuated live vaccines Poor breakthrough of maternal antibody interference Restricted to parenteral use
Indications	Routine vaccination Outbreaks Production of mucosal immunity	Pregnancy (when needed) Immunocompromised animals Attenuated live options not available
Availability	Canine parvovirus enteritis (P) Canine adenovirus infection (P, IN, PO) Canine distemper (P) Canine parainfluenza (P, IN, PO) Feline panleukopenia (P, IN) Feline herpesvirus infection (P, IN) Feline calicivirus infection (P, IN) Feline infectious peritonitis (IN) *Bordetella bronchiseptica* (IN; D, C) (PO; D) *Chlamydia felis* (P)	Rabies (D, C) Canine influenza (H3N8, H3N2) Canine coronavirus enteritis *Babesia canis* Leptospirosis Lyme borreliosis *Bordetella bronchiseptica* (D) Feline panleukopenia virus Feline calicivirus Feline herpesvirus-1 Feline leukemia virus Feline immunodeficiency virus *Chlamydia felis*

C, cats; *D*, dogs; *IN*, intranasal; *P*, parenteral; *PO*, oral.

(Fig. 20.1B). Vaccines can be engineered to protein epitopes that are important for the agent's attachment, replication, development, or spread within the host. Multiple genes can be inserted, including those for cytokines such as IL-2, which can enhance the immune response to the simultaneously generated immunogenic proteins. One potential problem with genetically engineered vector vaccines is that the host can mount an immune response to the vector. For example, a recombinant vaccinia virus expressing FeLV gp70 envelope protein was not successful in producing antiviral antibodies in cats.[25] Instead, inoculated cats developed neutralizing antibody against the vaccinia virus. Currently available vectored vaccines for dogs and cats use canarypox virus as a vector, and include vaccines for rabies, CDV, and FeLV infection (Purevax FeLV, Boehringer Ingelheim; Recombitek Canine Distemper, Boehringer Ingelheim; Purevax Feline Rabies, Boehringer Ingelheim). Commercially available oral rabies vaccines with poxviruses as vectors have also been used to protect wildlife. Other vectors have also been used experimentally to create dog and cat vaccines, such as CAdV[26] and myxoma virus.[27]

4. DNA vaccines. These consist of naked DNA that encodes the antigens required for protective immunity. The DNA is injected directly to the animal intramuscularly using an inoculation system. The DNA is then taken up by host cells and translated into antigen. Both humoral and cell-mediated immune responses are produced, but inefficient uptake, concerns about modification of the host genome, and limited studies showing efficacy are disadvantages.[28] Formulations with nanoparticles, cationic lipids, protein polymers, or biodegradable microspheres allow for oral or intranasal delivery and result in significant production of secretory IgA production at mucosal sites. DNA vaccines are stable, resisting extremes in temperature, making their storage and preservation more practical and less expensive. Although they have been developed and tested experimentally, DNA vaccines are not available commercially for use in dogs and cats.
5. mRNA vaccines. mRNA vaccines are a relatively new type of vaccine that have entered widespread use following the COVID-19 pandemic (Moderna and Pfizer vaccines). mRNA vaccines are created in the laboratory from a linear DNA template using a phage RNA polymerase. They offer many advantages over other vaccine types; they are noninfectious and do not integrate into other nucleic acid molecules, so insertional mutagenesis is not of concern; they are degraded by normal host physiological processes; there is also no chance of an immune response to a vector virus; and they have inherent immunostimulatory activity, so can be nonadjuvanted. They elicit strong humoral and cellular immune responses. The instability of mRNA has been a limiting factor, however technological advancements have led to manipulations in mRNA composition and reagents that facilitate uptake of mRNA, protect it from being degraded, and prolong the immune response. The manufacture of mRNA vaccines also has the potential to be highly scalable, inexpensive and rapid. Based on

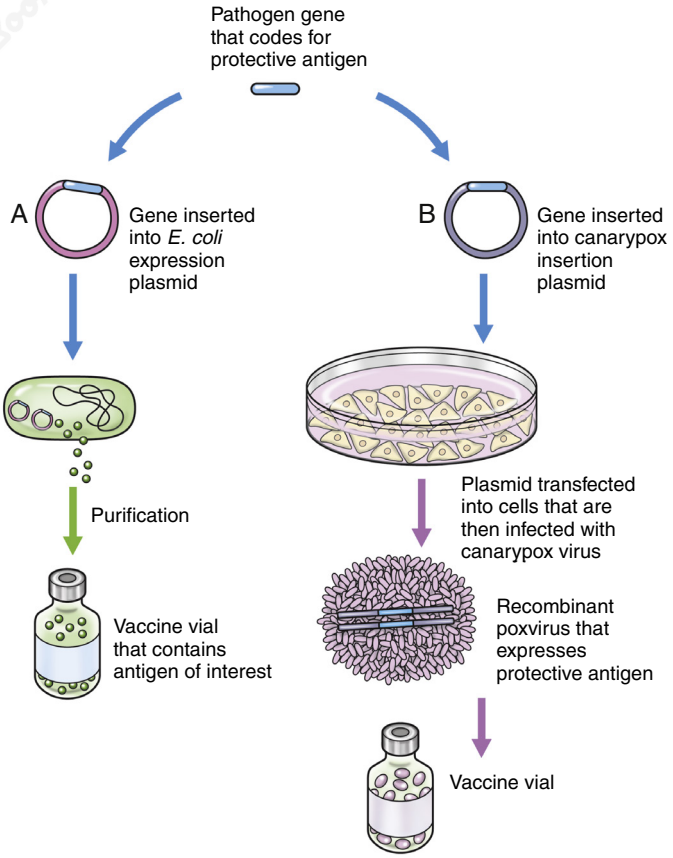

Fig. 20.1 Examples of recombinant DNA vaccines. (A) Recombinant subunit vaccine. The gene of interest is inserted into an expression vector such as a plasmid taken up by *Escherichia coli*, which subsequently produces large amounts of an immunogenic protein. This is purified and used in the vaccine. (B) Vectored vaccine. The gene or genes of interest are inserted into a canarypox or vaccinia vector, which is then inoculated into an animal. Replication of the vector within the host is followed by expression of the immunogenic protein. (From Sykes JE. *Canine and Feline Infectious Diseases*. 1st ed. Elsevier; 2014.)

the success of COVID-19 mRNA vaccines in terms of safety and efficacy, the appearance of mRNA vaccines for prevention of companion animal infectious diseases in the future is likely.

VACCINE STORAGE, HANDLING, AND ADMINISTRATION

Vaccines should be stored and administered according to label recommendations, which generally means refrigeration at 4°C (39.2°F). Inactivation of vaccines can occur if they are inadvertently frozen or heated to excessive temperatures, exposed to excessive amounts of light, or used beyond their expiration date. Hands should be washed before preparation and administration of the vaccine. Lyophilized products should be reconstituted with the proper diluent, and different vaccines should not be mixed in the same syringe or vial. Reconstituted products should be used immediately after reconstitution. Although it has been recommended that attenuated live vaccines be discarded if more than 1 hour has lapsed since reconstitution,[17] no published reports exist of the viability of vaccine organisms over time after reconstitution or of the ability of stored, reconstituted vaccine to elicit an immune response. In particular, the immunogenicity of distemper virus vaccines may be compromised if vaccines are improperly stored and handled, given the poor ability of this virus to survive in the environment. Vaccines should only be used in the animal species for which they are labeled, or serious adverse effects or failure of immunization can occur.

To reduce the likelihood of an adverse reaction, the number of vaccines administered should be minimized to core vaccines and those required based on risk assessment.[2] If vaccines for multiple different pathogens are to be administered simultaneously, they should be injected at distant sites, or, if possible, a combination vaccine should be used. Simultaneous vaccination for more than one pathogen does not appear to interfere with immune responses to each component of the vaccine,[29–31] and vaccine manufacturers must demonstrate that the protection that occurs for a specific pathogen after vaccination with a combination product equals the protection that occurs when a vaccine for only that pathogen is given (known as *interference testing*). The results of multiple studies have shown lack of interference with immunity in dogs and cats when antigens are used in combination.[32–35] In contrast, successive parenteral administration of different attenuated live vaccines at 3 to 14 day intervals has the potential to interfere with immune responses. An interval of 4 weeks is preferred for human patients.[18,36] Inactivated vaccines do not produce interference in this way.[18] Although anesthesia and surgery do not appear to interfere with immune responses to vaccination,[37] if possible, administration of vaccines to animals that are under anesthesia should be avoided because adverse reactions may be difficult or impossible to recognize in this situation. It is not necessary to re-administer an intranasal vaccine if the animal coughs or sneezes after administration.

The site and route of administration, product, serial number, expiry date, results of any serologic tests, and individual who administered the vaccine should be recorded for each vaccine administered. It has also been recommended that the date for the next vaccination be noted on the vaccination certificate, and that there be documentation that relevant information was provided to the client and that the client authorized vaccination. Veterinarians are expected to educate their clients about infectious disease risks for their pets, to inform clients of the risks and benefits of particular vaccines, and to handle and administer products in accordance with the manufacturer's guidelines and commonly accepted standards of practice.

COMPONENTS OF THE IMMUNE RESPONSE

The immune response is divided into innate and adaptive immune responses. The innate immune response is nonspecific and acts as an immediate line of defense against an infection. Components of the innate immune response consist of natural killer cells, which recognize host cells that are infected by viruses; complement, which is activated by bacterial cell wall components; and phagocytes, such as macrophages and dendritic cells. The adaptive immune response develops over several days and involves presentation of antigen by dendritic cells in association with the major histocompatibility complex and stimulation of B- and T-cell responses, together with the formation of memory B cells. The nature of the innate response influences the subsequent adaptive response. Cells of the innate immune system possess PRRs that can recognize patterns that are characteristic for various pathogens (PAMPs), including Toll-like receptors and NLRs. PAMPs are under investigation for use as adjuvants in human and animal vaccines in order to create improved T-cell immune responses.[38,39]

DETERMINANTS OF IMMUNOGENICITY

All vaccines that are available for dogs and cats induce CMI with induction of immunologic memory and a booster effect on repeat administration. Although the presence of antibody correlates with protection for some pathogens, such as CDV and CPV, a lack of antibody does not infer a lack of protection, because of the presence of CMI, which is more difficult to measure.

Vaccines rarely protect all vaccinated individuals from infection and disease. In particular, vaccines for canine and feline respiratory pathogens do not prevent disease but can reduce the prevalence and severity of disease as well as reduce the number of organisms shed. Limited immunity following vaccination is especially likely for infections for which immunity after natural infection is partial or short-lived.

The ability of a vaccine to induce an immune response depends not only on the target pathogen, vaccine composition, and route of administration but also on host factors such as age, nutrition, pregnancy status, stress, concurrent infections, and immune status, including the presence or absence of passively acquired antibody (Box 20.1). Some of these factors may also influence vaccine safety. Some animals may have an impaired ability to respond to vaccination. These dogs have been termed *nonresponders*.[2,40] This situation is probably rare if efficacious vaccines are used and booster vaccines are administered. Young dogs less than 1 year of age, have a significantly reduced response to vaccination with rabies virus vaccines when compared with adult dogs.[41] Small-breed dogs have a greater serologic response to rabies vaccines than large-breed dogs.[42] Administration of vaccines to febrile animals, animals with other infectious diseases, or animals with moderate to severe illness should be avoided if possible until 2 to 3 weeks after recovery has occurred, because the immune response to the vaccine may be suboptimal.

Failure of immunization can result from an inadequate dose of antigen. Thus, division of a single vaccine dose for administration to a larger number of dogs and cats, small-breed dogs as opposed to large-breed dogs, or young kittens as opposed to older kittens, may lead to failure of immunization. Veterinarians should not split vaccine doses because this shifts the liability from the vaccine manufacturer to the veterinarian if vaccine failure occurs. Immunization can also fail in the face of an overwhelming challenge dose.

The route of administration can influence the type of immune response generated. Subcutaneous administration is associated primarily with an IgG response, and rarely induces high levels of secretory IgA antibodies. In contrast, intranasal administration results in an IgA and, to a lesser extent, an IgG response. Immunogenicity and safety may be compromised when a vaccine is administered using the incorrect route.

In young animals, the presence of MDA inhibits endogenous IgG production through negative feedback mechanisms. The presence of MDA may also neutralize vaccine antigens and interfere with effective immunization. In dogs, a small proportion of MDA (approximately 10%) is acquired transplacentally and protects puppies that are deprived of colostrum for a short time after birth. In contrast, feline neonates appear to be born without transplacentally acquired antibodies.[43] IgM has been detected in some kittens at birth, likely as a result of perinatal production of IgM, because IgM is too large to cross the placental barrier.[43] Most MDA in dogs is acquired from colostrum, and to a lesser extent, from milk (Table 20.3). In dogs, colostral/milk IgG, IgA, and IgM concentrations are >120-fold, >110-fold, and >10-fold that of serum, respectively, and the IgG concentration in mammary secretions decreases to that of serum within the first 4 weeks of lactation. In contrast, in one study in cats, colostral IgG was only twofold higher than in serum, and IgA and IgM concentrations were actually lower.[43] The absorption of colostral antibodies occurs in the duodenum and jejunum via membrane Fc receptors on the intestinal epithelium that facilitate transport of IgG into the systemic circulation. The process is maximal within 24 hours of birth but also occurs to a limited degree throughout the remainder of the nursing period. The amount of antibody absorbed is also inversely proportional to the size of the litter. Once absorbed, the immunoglobulin from colostrum can give the neonate a titer that can equal or exceed that of the dam in some instances. Over time, the MDA declines at a characteristic half-life that is specific for each disease-producing agent (Table 20.4).[44–56] Antibody class is also important with respect to titer loss. Overall in kittens, the half-lives of maternally derived IgG and IgA in one study were 4.4 and 1.9 days, respectively, whereas in dogs, half-lives were 10 and 4–5 days, respectively. Maternally derived IgG in kittens was lowest at around 3 to 4 weeks of age, and serum IgG and IgA increased dramatically at 5 to 7 weeks of age. These results suggested that kittens may be susceptible to infectious diseases at about 1 month of age, perhaps as much as 2 weeks earlier than puppies.[43]

Despite these findings, it is important to recognize that there is considerable individual variation, with some animals maintaining high concentrations of maternal antibody for months. The persistent presence of MDA is one of the most common reasons for vaccine failure in dogs and cats. Any MDA titer against CPV has the potential to interfere with immunization. The amount of MDA in a puppy or

BOX 20.1 Factors That Can Affect Immune Responses to Vaccines

- Target pathogen (e.g., respiratory versus systemic pathogen)
- Vaccine composition (e.g., inadequate adjuvant)
- Route of administration
- Young age
- Breed/genetic factors
- Nutrition
- Pregnancy status
- Concurrent moderate to severe illness
- Fever
- Immunosuppressive drugs
- Presence of maternal antibody
- Improper vaccine storage and administration
- Vaccination with an attenuated live viral vaccine within last 3 days to 2 weeks
- Inadequate time allowed for immunization before exposure to field organisms

TABLE 20.3 Relative Proportions of Maternally Derived Antibody Obtained Transplacentally Versus from Colostrum for Selected Canine Infectious Diseases

	SERUM TITER OF NEONATE		
	% of Dam's Titer		% of Neonate's Titer
Disease	Presuckle	Postsuckle	Obtained in Utero/ Obtained from Colostrum
Canine distemper	3	77	4/96
Infectious canine hepatitis	NR	92	NR/NR
Canine parvoviral infection	5.7	60	10/90

NR, not reported.

TABLE 20.4 Half-Life of Maternally Derived Immunoglobulins in Neonatal Dogs and Cats

Pathogen	Half-Life (Days)	Usual Duration of Protection (Weeks)[a]
Canine distemper virus[47]	8.4	9–12
Canine parvovirus[49,50]	9.7	10–14
Canine adenovirus-1[44]	8.4	9–12
Feline panleukopenia virus[52]	9.5	8–14
Feline leukemia virus[53]	15.0	6–8
Feline herpesvirus-1[45,46,51]	18.5	6–8
Feline calicivirus[48,54]	15.0	10–14
Feline coronavirus[56]	7.0	4–6
Feline immunodeficiency virus[55]	12.5	12

[a]The duration of maternal antibody protection usually corresponds to the interval over which vaccines are ineffective.
Modified from Greene CE, Levy JK. Immunoprophylaxis. In: Greene CE, ed. *Infectious Diseases of the Dog and Cat*. 4th ed. Philadelphia: Elsevier; 2011.

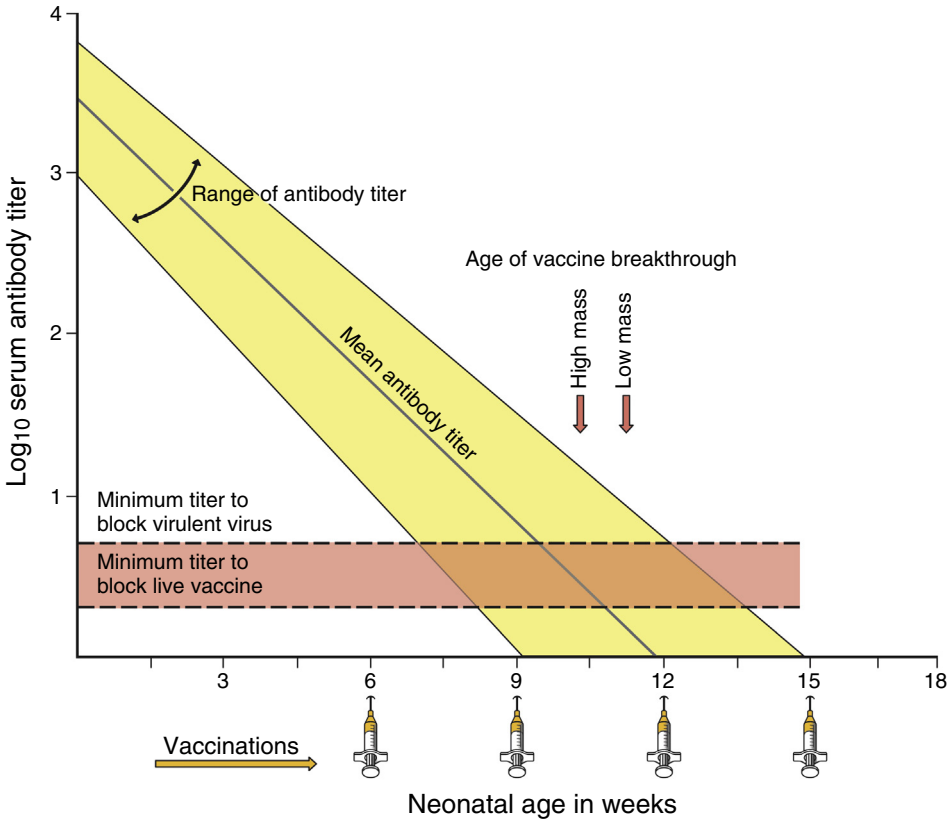

Fig. 20.2 Influence of maternally derived antibody (MDA) on immunization. Puppies and kittens acquire variable amounts of MDA transplacentally and through colostrum after birth. This binds to vaccine antigens and inhibits the immune response. A series of vaccines are administered to maximize the chance of inducing an immune response as MDA concentrations decline. The *window of susceptibility* is the period of time when MDA concentrations are high enough to interfere with immunization, but not sufficient to prevent natural infection. High antigen mass vaccines provide protection earlier than low mass vaccines. (From Greene CE, Schultz RD. Immunoprophylaxis. In: Greene CE, ed. *Infectious Diseases of the Dog and Cat*. 3rd ed. St Louis, MO: Saunders; 2006.)

kitten at any one point in time cannot be predicted because it varies depending on the titer of the dam and the amount of colostrum ingested after birth. As a result, a *series* of vaccinations, given every 2 to 4 weeks through 16 to 18 weeks of age, have been administered to puppies and kittens in order to increase the chance that successful immunization will occur soon after the decline of MDA titers to sufficiently low concentrations (Fig. 20.2). Nevertheless, a window always exists when MDA concentrations are high enough to interfere with immunization, but not sufficient to prevent natural infection. This window is known as the *window of susceptibility* or the *window of vulnerability*. The WSAVA has recommended that the vaccination typically given at 1 year of age instead be administered at 6 months of age, as the purpose of this booster was to ensure effective vaccination of animals that still had maternal antibody at the end of the vaccination series.

TABLE 20.5 Manufacturer's Claims for Vaccine Efficacy and Safety

Claim	Comment
Prevention of Infection	Products able to prevent all colonization or replication of the challenge organism in a vaccinated animal
Prevention of Disease	Products shown to be highly effective in preventing clinical disease in vaccinated animals. The 95% confidence interval estimate of efficacy must be at least 80%.
Aid in Disease Prevention	Products shown to prevent disease by a clinically significant amount which is usually less than that required to support a claim of disease prevention.
Aid in Disease Control	Products that alleviate disease severity, reduce disease duration, or delay disease onset.

The use of recombinant vector vaccines can overcome the interference by MDA, although the extent to which this applies in animals that have passive immunity to the vector virus (i.e., immunity transferred from a dam that was immunized with a recombinant vector vaccine) requires clarification. Because replication of the vector is aborted, the immune response to the vector itself may be reduced. As a result, passive transfer of neutralizing antibody titers to the vector may not occur. Mucosal vaccines can also provide greater protection in the face of MDA because the mucosal immune system matures shortly after birth.[57,58]

Whenever possible, animals should be isolated until sufficient time has elapsed for proper immunization. For most parenteral and mucosal vaccines, this is 1 week (and at the absolute minimum, 3 days) after inoculation. Vaccine failure can also occur in animals that are incubating the disease for which vaccination is performed at the time of vaccination.

VACCINE EFFICACY AND CHALLENGE STUDIES

The gold standard methodology for determination of vaccine efficacy is to expose vaccinated and unvaccinated animals to the same challenge dose and measure the severity of clinical disease that follows. These challenge studies are performed in SPF animals under laboratory conditions, which may not represent the genetic variation seen in some breed lines or field conditions.

Vaccine efficacy is often expressed in terms of *preventable or prevented fraction* (Table 20.5), which is the proportion of vaccinated animals that do not develop a disease after challenge compared with those unvaccinated animals that do develop the disease.

The formula is calculated as follows:

$$\text{Prevented fraction} = \frac{\text{Prevalence (\%) of disease in nonvaccinates} - \text{Prevalence (\%) in vaccinates}}{\text{Prevalence (\%) in nonvaccinates}}$$

It can also be expressed as mitigatable fraction (proportion with reduction in severity of clinical signs). Other claims include reduction of pathogen shedding, prevention of a specific clinical sign, or prevention of mortality. The level or degree of protection claim can therefore be limited.

After vaccine efficacy is determined in laboratory animals, a vaccine is subjected to field trials by a limited number of veterinarians before they are released for general use. Many products are initially marketed without complete knowledge of DOI or adverse effects. Manufacturers are receptive to reports of complications encountered by veterinarians and, in turn, keep the veterinary profession informed of continuing efficacy studies and potential complications.

Duration of Immunity

The DOI is important in determining the timing for booster vaccinations, and is determined by challenging animals with an infectious agent at variable periods of time after vaccination. With the exception of rabies vaccines, DOI of many marketed vaccines sold in the United States is not available because most challenges are performed several weeks after immunization. Vaccine manufacturers in the United States are not required to demonstrate longer DOI for already-licensed antigens. However, USDA guidelines do require DOI challenge studies for vaccines containing "newer" agents (i.e., those for which biologics were developed after ca. 2000), those likely to have shorter DOIs, and rabies virus vaccines.[59] The level of protection that must be demonstrated for long-term studies is generally less stringent than that for challenge studies obtained a few weeks after the primary vaccination series. Studies have shown DOIs of at least 3 years[60,61] and 4.75 years[6] for attenuated live CPV, CDV, and CAdV-2 vaccines. An inactivated canine rabies vaccine was shown to have a DOI of a minimum of 3 years, with clinical signs developing in 28 (88%) of 32 vaccinated dogs and 30 (97%) of 31 unvaccinated dogs.[62] Minimum DOIs of at least 1 year have been established for *Borrelia burgdorferi*,[63–65] *Leptospira*,[66–68] and intranasal *Bordetella bronchiseptica* vaccines in dogs,[69,70] although the latter two vaccines typically reduce infection and shedding but do not eliminate it altogether.

Laboratory kittens vaccinated with an inactivated vaccine against FHV-1, FCV, and FPV were protected against challenge with FPV 7 years after the initial series.[22] Protection against FHV-1 and FCV was only partial because these challenged cats developed respiratory signs of varying severity.[22,71] However, immunization lessened the severity of respiratory disease on subsequent challenge. Cats vaccinated with a nonadjuvanted inactivated bivalent FCV vaccine that contained attenuated live FHV-1, FPV, and *Chlamydia felis* had reduction in clinical signs but not shedding following challenge with a heterologous FCV strain and subsequently FHV-1.[72] The degree of protection against feline respiratory viruses following challenge 2 to 4 weeks after vaccination with inactivated or attenuated live vaccines has been similar,[73] although there is some evidence of slight waning of immunity in the period between 4 weeks and 1 year after vaccination, possibly to a greater extent for FHV-1 infection.[73–75] These studies do not take into account the natural boostering effect of field exposure for cats that contact other cats. Cats that are kept in indoor-only households following vaccination with no exposure to other cats may be at greatest risk of contracting severe disease when exposure ultimately occurs years later. This exposure could occur at a veterinary clinic if adequate precautions are not taken during examination (handwashing and proper disinfection of fomites in the examination room). Alternatively, the stress of visiting a veterinary clinic could lead to reactivation of latent FHV-1 infection in these cats.

A 2-year DOI study was conducted for an inactivated FeLV vaccine in which kittens were vaccinated at 8 and 11 weeks of age, then challenged 2 years after vaccination.[76] Persistent viremia developed in all of the 11 control cats but only 2 of 12 vaccinated cats. In another study, cats received one of four commercially available vaccines at 15 to 16 and 18 to 19 weeks of age, and a fifth group of cats served as unvaccinated control cats.[77] Four months following their final of two vaccinations, the cats were challenged with virulent FeLV, and the incidence of persistent viremia was determined. Two of the vaccines had a measured prevented fraction of 100%, whereas the other two had a fraction of 57% and 29%, respectively.

More information on vaccine efficacy and DOI can be found in chapters in this book relating to specific infectious diseases for which vaccines are available. Vaccines produced by different manufacturers, for the same antigen, may not necessarily have equal efficacy or DOI, because they may contain different adjuvants, strains, and organism titers.

MEASUREMENT OF THE IMMUNE RESPONSE

For some infections, such as rabies, CDV, CPV, and FPV, the presence of detectable circulating antibodies after MDA has waned (i.e., from age 20 weeks) correlates with protection. Thus, serologic assays such as hemagglutination-inhibition (for detection of CPV antibodies) and virus neutralization (for CDV, CAdV-1, CPV, and FPV) have been used in dogs and cats to decide whether vaccination is necessary, and also as a predictor of long-term DOI. Serologic testing has also been used to clear pets for travel; for example, immunity to rabies virus can be predicted using the rapid fluorescent focus inhibition test (a modified virus neutralization method) or fluorescent antibody virus neutralization (see Chapter 21), although protective serum antibody titers are generally not accepted as an alternative to vaccination where there is a legal requirement for vaccination against rabies.

Although positive antibody titers are associated with protection from some infections, an animal with no titer may still be resistant to challenge because of CMI, which is not measured. Conversely, an animal with a positive antibody titer has the potential to develop disease after challenge, possibly because of overwhelming exposure, immune suppression, or emergence of variant strains. Infections where the presence of detectable circulating antibodies does not correlate with protection include leptospirosis; respiratory and gastrointestinal viral and bacterial infections (where mucosal secretory IgA correlates better with protection); and chronic, persistent infections such as leishmaniosis, FIV infection, FIP virus infection, bartonellosis, and babesiosis. For *B. burgdorferi* infections, the presence of detectable antibodies to the conserved outer surface protein OspA present in vaccines can correlate with protection, because this neutralizes the pathogen within the tick during ingestion of a blood meal (see Chapter 69). However, the presence of other anti-*Borrelia* antibodies may not imply protection because reinfection with new strains can occur and the spirochete can persist in the face of the host immune response. Accurate and reliable rapid POC assays for measurement of antibody responses in dogs and cats are now available, although they still remain more expensive than vaccination. Assays are available for CDV, CPV, CAdV-1 and FPV (VacciCheck, Spectrum Labs, AZ/Biogal, Galed Labs, Kibbutz Galed, Israel; TiterCHEK CDV/CPV, Zoetis, NJ, USA). These have reduced the problems associated with variability of results among different laboratories, and insufficient validation of some assays. Measurement of antibody titers may be considered for animals that have had previous adverse responses to vaccination, particularly susceptible breeds (e.g., Rottweilers and CPV infection). The WSAVA has suggested that puppies could be tested at least 4 weeks after the final puppy vaccine to decide whether further vaccination for CDV or CPV is necessary; if the titer is positive, the next booster would not be required for 3 years.[2] Negative titers should prompt additional vaccination for these puppies.

Rapid POC serologic assays have also been used to make decisions regarding isolation or euthanasia in shelter situations, through identification of immune animals.[78] In the face of an outbreak, incoming seronegative animals can be vaccinated and fostered before returning them to the shelter. Unfortunately, it is not always possible to know if positive titers represent recent infection, and animals that test positive may still shed virus and pose a risk to other animals. In young puppies and kittens, positive results may represent persistent MDA or the presence of active immunity, and MDA does not have the same ability to protect against infection. POC serologic assays can also be used to decide whether pregnant animals are susceptible in a shelter environment and thus minimize adverse reactions to attenuated live vaccines in this group of animals (see Appendix). A study that evaluated the performance of one ELISA assay (TiterCHEK CPV/CDV) found that for CPV antibodies, the sensitivity and specificity of the assay was 92% and 94%, respectively, when compared with hemagglutination inhibition; and for CDV, it was 76% and 92%, respectively, when compared with serum neutralization.[79]

EFFECT OF AGE AND IMMUNOSUPPRESSION ON IMMUNE RESPONSES

Age-related declines in the immune response to vaccination can be a concern for the timing and frequency of booster vaccination for older dogs and cats.[80] However, geriatric dogs and cats rarely die of vaccine-preventable infectious diseases, even when not vaccinated for many years.[8] Compared with mice and humans, relatively little is known about the effect of age on the immune system of dogs and cats. No difference in the concentration of serum IgG was found between young and aged German shepherd dogs.[81] Compared with most Labrador retriever age groups, older members have decreased lymphocyte stimulation responsiveness to mitogens and increased percentages of their lymphocytes as total T cells, but a decreased percentage of CD4+ cells.[82,83] In dogs of various breeds, 32 young (3.15 ± 0.8 years) and 33 old dogs (12.1 ± 1.3 years) were vaccinated against CDV, CPV, and rabies.[84] No differences between old and young dogs were noted in postvaccination titers against any of the viruses. Results of one study were that senior cats had higher serum IgA and IgM but lower leukocyte counts and lower absolute values of T cells, B cells, and natural killer cells compared with young adult cats.[85]

Administration of glucocorticoids, even at immunosuppressive doses, has been shown to not interfere with the immune response to vaccination. In one study, unvaccinated 13-week-old puppies were treated with prednisolone at 1 or 10 mg/kg q12h for a week, q24h for a second week, then q48h for a third week, then vaccinated for CDV and challenged 3 days later. Although the prednisolone-treated puppies had decreased lymphocyte responsiveness, all vaccinated puppies were resistant to challenge. However, dogs treated with methotrexate and antithymocyte serum developed vaccine-induced distemper after CDV vaccination.[86] In another study, there was no difference in rabies antibody titers following vaccination in dogs treated with dexamethasone (0.25 mg/kg) and untreated dogs.[87]

ADVERSE REACTIONS TO VACCINES

A vaccine is needed if an infectious disease causes significant morbidity and mortality. Vaccines should prevent more disease than they cause. In order to produce protective immunity, a vaccine *must* stimulate a reaction in an animal, both at the site of injection and systemically. This may cause clinical signs. Ideally, the signs are mild and either unnoticeable or acceptable to the pet owner. In rare situations, adverse reactions are severe enough to threaten a pet's life. Sometimes, enhanced efficacy leads to a reduction in vaccine safety. Veterinarians are encouraged to report adverse reactions to vaccines to a technical service veterinarian employed for this purpose by the vaccine manufacturer. In some countries, the drug company then reports details of the adverse reaction to drug regulatory authorities. In the United Kingdom, the Veterinary Medicines Directorate has been evaluating adverse vaccine reactions since 1985, and the absolute number of adverse reactions to different vaccine types were published for dogs and cats until 2013.[88–96] The number of reports increased slightly over this period, but these broad numerator data represent a variety of factors, potentially affected by increased reporting, increased reports of perceived (rather than true) adverse reactions, more widespread vaccination, an increase in pet ownership, and so on, rather than a true increase in adverse events. An understanding of the true nature and

Fig. 20.3 Facial edema and hyperemia in a 4-month-old intact male Chihuahua mix after vaccination with a bacterin vaccine. (Courtesy Dr. Stephen D. White, University of California, Davis Veterinary Dermatology Service.)

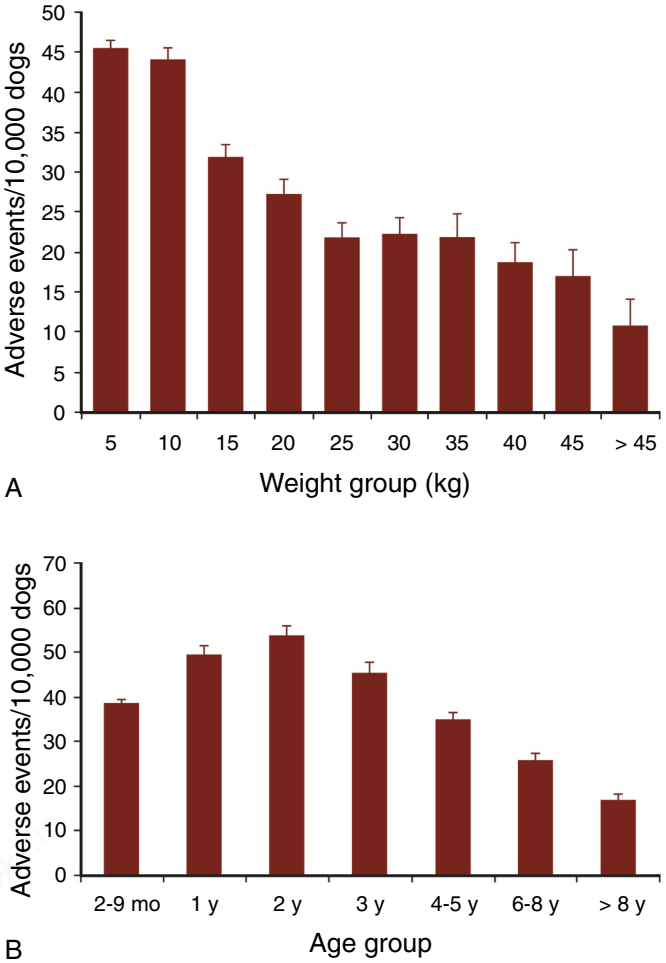

Fig. 20.4 Correlation between (A) body weight and (B) age and the occurrence of vaccine-associated adverse effects within 3 days of vaccination in dogs. (From Moore GE, Guptill LF, Ward MP, et al. Adverse events diagnosed within three days of vaccine administration in dogs. *J Am Vet Med Assoc.* 2005;227(7):1102–1108.)

incidence of adverse effects associated with vaccination requires much more detailed information, and has also been hampered by underreporting and variable delays between vaccination and the inconsistent appearance of potential, more chronic systemic adverse effects.[97] In addition, correlation of adverse reactions to vaccine administration in young animals may be difficult because of the uniform and frequent administration of vaccines to this group. For example, it has been difficult to prove a connection between vaccination for distemper and development of hypertrophic osteopathy in Weimaraner dogs. Nevertheless, it has been suggested that lines of Weimaraners that develop this problem following vaccination with attenuated live vaccines be vaccinated instead with recombinant canarypox CDV vaccines.[98] Despite claims of many antivaccination advocates, epidemiologic analysis has not revealed any correlation between vaccination within the last 3 months and ill health in dogs.[99] Of interest, analysis of survey responses from 2261 veterinarians from the United States and Canada in early 2020 identified a positive correlation between the existence of organized antivaccination movements against mandatory vaccination of children in the community and the number of clients resistant to pet vaccination.[100]

Immune-Mediated Vaccine Reactions

Type I Hypersensitivity Reactions

Type I hypersensitivity reactions occur when allergens cross-link IgE molecules that are bound to receptors on mast cells and basophils and trigger degranulation. Clinical signs of type I hypersensitivity responses that occur after vaccine administration include facial or periorbital edema, urticaria, cutaneous hyperemia, generalized pruritus, salivation, hypotensive shock, tachypnea, vomiting, diarrhea, collapse, and even death (Fig. 20.3). Vomiting and respiratory distress are common in cats. These signs generally occur within 24 hours of vaccine administration; anaphylaxis usually begins within minutes. The estimated incidence of anaphylaxis after vaccination of dogs and cats is 1 in 5,000 to 1 in 50,000 and depends on the vaccines used. One retrospective study evaluated 1.23 million dogs and nearly 0.5 million cats from more than 300 Banfield hospitals in the United States in 2002 through 2005. In this study, vaccine-associated adverse effects that were listed as vaccine reactions, allergic reactions, anaphylaxis, urticaria, and/or cardiac arrest were documented within 3 days of vaccine administration in 38.2 per 10,000 dogs and 47.4 per 10,000 cats.[30,101] Reactions coded as "allergic" or "anaphylaxis" were reported in approximately 1 in 785 dogs and 1 in 1,200 cats. Reactions coded as anaphylaxis constituted only 5% of these reactions. Death occurred in 1 in 400,000 dogs and 1 in 125,000 cats that received vaccines, and all 3 dogs and 1 of the 4 cats that died received four or more doses of a vaccine (i.e., more than one vaccine product administered simultaneously). Most reactions in dogs (73%) occurred on the day the vaccine was administered (day 0), 19% occurred on day 1, 6% on day 2, and 3% on day 3. Data from the UK Veterinary Products Committee report indicated anaphylaxis in 1 in 385,000 vaccinated dogs and 1 in 555,000 cats.[40]

Vaccines that contain large amounts of adjuvant, certain preservatives, or inactivated bacteria with proinflammatory outer surface components are more likely to cause reactions. Proteins present in fetal calf serum and stabilizers such as gelatin within the vaccine may also be responsible for allergic reactions.[102] In the Banfield study, the risk of reactions increased with the number of vaccine doses (i.e., volume of vaccine in milliliters) administered per office visit.[30] Small-breed dogs, such as miniature dachshunds, pugs, Boston terriers, miniature pinschers, and Chihuahuas, were more susceptible to development of acute vaccine reactions, and the risk of a vaccine-related adverse event increased as body weight decreased. The risk of vaccine-related adverse events was four times greater in dogs that weighed 5 kg or less than in those that weighed more than 45 kg (Fig. 20.4). Adverse events increased in frequency with age up until 2 years in dogs and 1 year in cats, after which the frequency progressively declined to rates lower

than that observed in animals less than 1 year of age (see Fig. 20.4). The decrease in frequency with older age may have occurred because of owners' unwillingness to have their pets vaccinated if a previous reaction occurred. Sexually intact dogs were less likely to develop adverse reactions than neutered dogs, but the opposite was true for cats.[22,34] Female cats were more likely to exhibit reactions than male cats. Because there is some evidence that vaccination can increase allergen-specific IgG and IgE in allergic dogs,[103] it has been suggested that atopic dogs receive booster vaccinations during nonallergenic seasons or disease-free intervals.[99]

The treatment of choice for anaphylaxis is epinephrine, together with other supportive treatments such as intravenous fluids and supplemental oxygen if necessary (Box 20.2). Antihistamines (e.g., diphenhydramine, IV or IM) and glucocorticoids (e.g., IV methylprednisolone sodium succinate) can be administered to dogs with less severe reactions. Vaccination should be avoided in animals with a history of severe reactions, although legal requirements for rabies vaccination may need to be considered in some geographic locations. Treatment with an antihistamine 20 to 30 minutes before vaccination could be considered in animals with a history of milder reactions. These animals should also be monitored closely in the hospital for several hours after vaccine administration. It has been suggested that in the future, commercial production of low-dose vaccines for small-breed dogs might be more appropriate, given their increased risk of reactions and more marked serologic responses to vaccination.[104] Preparations are currently available that are half the volume of previous preparations (0.5 mL instead of 1 mL), but the amount of vaccine antigen and adjuvant remains unchanged.

BOX 20.2 Considerations for Treatment of Anaphylaxis

Place intravenous catheter
Epinephrine (adrenaline): Initially, 0.01 mg/kg of a 1:1000 dilution IV; repeat every 5 to 15 minutes as needed to a maximum of 0.3 mg in patients < 40 kg and 0.5 mg in patients > 40 kg.
Isotonic crystalloid 40–50 mL/kg (D) or 20–30 mL/kg (C) by IV infusion over 10 minutes; consider further resuscitation up to a total of 90 mL/kg (D) or 50 mL/kg (C).
Supplemental oxygen
Diphenhydramine 2 mg/kg IM or IV (D, C)[a]
Methylprednisolone sodium succinate 2–6 mg/kg IV (D, C)[a]

[a] Not a substitute for epinephrine and intravenous fluids.
C, cats; *D,* dogs; *IM,* intramuscular; *IV,* intravenous.

Other Hypersensitivity Reactions, Including Autoimmune Disease

Type II hypersensitivity reactions occur when IgG and IgM bind to cell surface antigens and fix complement, with target cell lysis or removal of target cells by macrophages within reticuloendothelial tissues. Inactivated bacterial vaccines are most likely to serve as a nonspecific trigger because of the immune-enhancing effects of adjuvants and bacterial cell walls. Another potential mechanism is molecular mimicry, where vaccine antigens mimic host antigens, resulting in immunologic cross-reactivity against certain host tissues. Concerns have been raised that vaccination may predispose certain genetically susceptible individuals to immune-mediated cytopenias, although as in human medicine, studies of dogs and cats to date have failed to conclusively document vaccines as causes of these and other chronic diseases.[36,100] Immune-mediated hemolytic anemia was suspected to occur following parvovirus vaccination, possibly due to the hemagglutinating properties of the virus and the high antigen mass in some of these vaccines,[105] but a later retrospective case-control study found no association.[106] Transient thrombocytopenia can occur after vaccination in some dogs.[107] In one study, dogs developed antithyroglobulin antibodies after vaccination, although this was not associated with development of hypothyroidism.[108] Cats that are vaccinated with CRFK cell-derived vaccines develop antibodies against the CRFK proteins alpha-enolase and annexin A2.[109] Whether production of these antibodies has clinical significance remains to be determined.

Type III hypersensitivity reactions are characterized by immune-complex deposition in tissues and may be a consequence of immunization with certain vaccines. For example, anterior uveitis and subclinical

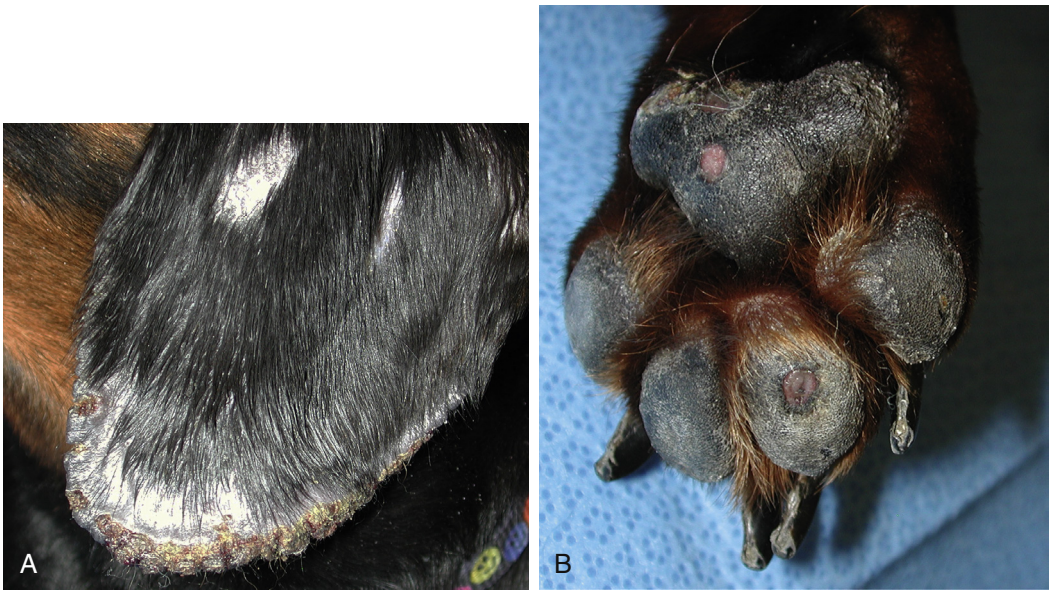

Fig. 20.5 Ischemic dermatopathy suspected to be associated with rabies virus vaccination that involved (A) the pinnae and (B) footpads of a 1-year-old male dachshund. The rabies vaccine was administered several months before the onset of signs. (Courtesy Dr. Stephen D. White, University of California, Davis Veterinary Dermatology Service.)

nephritis developed in 0.4% of dogs receiving CAdV-1 vaccine. This vaccine was replaced by CAdV-2 vaccines, which do not produce these lesions. A cutaneous vasculitis has been described after vaccination of dogs and cats with rabies virus vaccines ("rabies vaccine-induced vasculitis")[110–112] (Fig. 20.5). This can occur at the site of vaccine administration, and in some animals, a multifocal ischemic dermatopathy and myopathy that affects sites such as the pinnal margins, periocular areas, tail tip, and paw pads has been reported to occur 1 to 5 months after the appearance of the initial skin lesion.[112] The multifocal dermatopathy and myopathy has been reported to resolve after treatment with pentoxifylline and vitamin E. Additional evidence is required to strengthen the association between the multifocal condition and rabies vaccination. Similarly, concerns have been raised about a possible temporal association between vaccination and immune-mediated polyarthritis in some dogs,[113] but this association remains unproven. Immune-mediated polyradiculoneuritis, a type IV hypersensitivity reaction (delayed-type hypersensitivity), occurred after vaccination of dogs with suckling-mouse brain-derived inactivated rabies vaccines, which are no longer available.[114] Subsequent re-exposure resulted in more severe and prolonged paralysis. Granuloma formation at the site of vaccine administration also represents a type IV hypersensitivity reaction.

Despite the lack of conclusive evidence for an association between vaccination with currently available vaccines and autoimmune disease, it is possible that vaccination may be associated with dysregulation of the immune response in predisposed individuals. Therefore, vaccination is often withheld if not absolutely necessary in dogs and cats with a history of autoimmune disease. Serum titers could also be assessed to gauge the need for specific immunization in these animals.

Vaccine Organism-Induced Disease

Disease occasionally results from replication of microorganisms present in a vaccine, although severe disease is uncommon with currently available vaccines. Fever and lethargy are the most common adverse effects of vaccination and result from cytokine production in response to the vaccine. These are transient and usually resolve within 1 to 2 days.

In the past, the use of attenuated rabies virus vaccines resulted in ascending paralytic disease in a proportion of cats and dogs. This led to a change to inactivated, adjuvanted rabies vaccines. Administration of attenuated parvovirus vaccines (parenteral or intranasal) to pregnant cats and dogs can lead to cerebellar disease in the fetus, and these vaccines have the potential to cause severe disease if shed vaccine virus infects colostrum-deprived neonates that are less than 2 weeks of age.[2] A febrile lameness syndrome rarely can occur in young kittens vaccinated with certain FCV vaccines.[115,116] This usually develops 7 to 21 days after vaccination and resolves within 7 days with supportive care. Some CDV vaccines have been associated with postvaccinal distemper in young puppies.[117] As a result, vaccination with live attenuated CDV, CPV, and FPV (cats) vaccines should be avoided when possible in pregnant animals, puppies and kittens less than 6 weeks of age, and animals receiving potent anticancer chemotherapy drugs. Some CDV vaccine strains, such as Rockborn-like strains, are more virulent than others, and these may cause postvaccinal distemper in young puppies or severely immunocompromised dogs, and continue to circulate and contribute to distemper in the dog population.[118] The safest attenuated live CDV vaccines contain the Onderstepoort strain. Vaccination of certain exotic pet, zoo, and wildlife species, such as ferrets, with any attenuated live CDV vaccine for dogs can also lead to postvaccinal distemper.[119,120] For animals with chronic immunocompromise, the use of inactivated vaccines has been recommended if immunization is deemed necessary. However, inactivated vaccines may have reduced efficacy in immunocompromised animals compared with healthy animals.

The use of mucosal (e.g., intranasal) vaccines for respiratory pathogens in dogs and cats can be followed by development of mild to moderate, transient upper respiratory tract signs. There have been concerns that mucosal *B. bronchiseptica* vaccines may cause respiratory disease in immunosuppressed humans who inhale the vaccine directly during administration or who contact vaccine organisms that are subsequently shed by the vaccinated dog,[121,122] but definitive proof of this is still required (see Chapter 55). Inadvertent parenteral administration of the avirulent live intranasal *B. bronchiseptica* vaccine to dogs can lead to local injection-site reactions and, occasionally, fatal hepatic necrosis.[123] Inadvertent parenteral administration of mucosal *B. bronchiseptica* vaccines should be treated with subcutaneous fluids at the site of administration and an oral antibiotic likely to be effective against *B. bronchiseptica*, such as doxycycline. The ASPCA Poison Control Center also recommends injection of a gentamicin sulfate solution into the affected area (2 to 4 mg/kg gentamicin sulfate in 10 to 30 mL of saline).[3] Doxycycline treatment could be continued for 5 to 7 days. Dogs that develop hepatic necrosis may need more aggressive supportive care.

Local Cutaneous Reactions and Injection-Site Sarcomas

Local cutaneous reactions are common adverse effects of vaccination, especially in cats, and include pain, swelling, irritation, and abscess formation. In dogs, focal alopecia or discoloration of the haircoat at the vaccination site can also occur (Fig. 20.6). Inactivated vaccines that contain adjuvant have been most commonly incriminated. Focal cutaneous granulomas and sometimes permanent focal alopecia have been most commonly reported after inactivated rabies vaccine administration to breeds such as Maltese terriers and bichon frisé.

In the late 1980s, an increase in inflammatory injection-site reactions at the sites of rabies vaccine administration were noted in canine and feline biopsy specimens sent to the University of Pennsylvania. Shortly thereafter, sarcomas were observed at these sites in cats in the United States, with a 25% increase each year from 1987 to 1991 (Fig. 20.7).[124] This followed: (1) the change from attenuated live to inactivated rabies vaccines, (2) increased use of rabies vaccines in cats, and (3) the introduction of FeLV vaccines. The national incidence of sarcoma

Fig. 20.6 A 2-year-old female toy poodle/Maltese terrier mix that developed focal alopecia at the site of vaccination followed by regrowth of hair with an altered color and texture. (Courtesy Nicole Pierce, University of California, Davis, Class of 2013.)

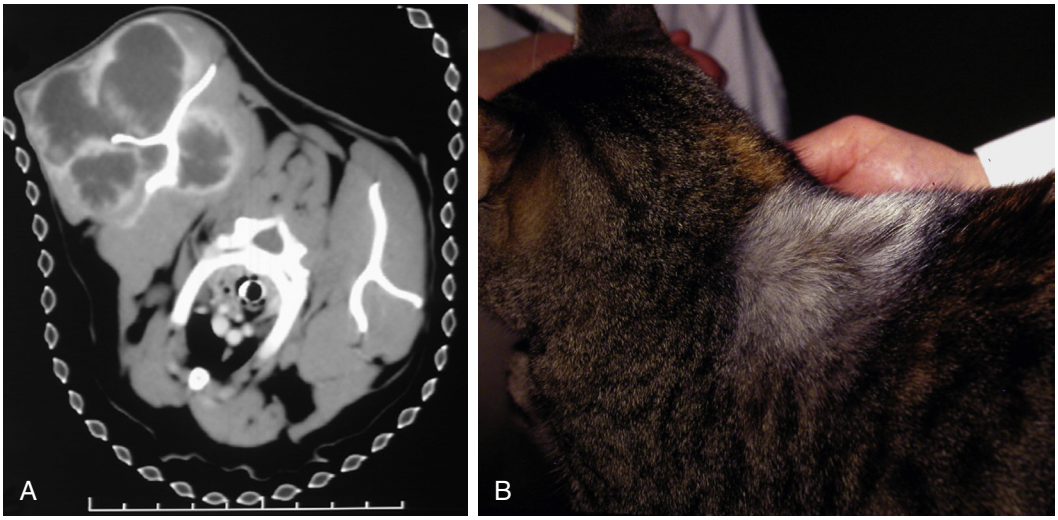

Fig. 20.7 (A) Computed tomographic image of an injection-site sarcoma over the scapula of a 12-year-old male neutered domestic shorthair cat. (B) Discoloration of the haircoat after radiation therapy.

formation is estimated to be 0.6 to 2 sarcomas per 10,000 cats that are vaccinated.[125,126] In contrast, in the United Kingdom, it was 0.21 per 10,000 vaccine doses sold between 1995 and 1999[126] and 1 per 5,000 to 12,500 vaccination visits in 2013.[127] The interval between tumor development and the last rabies vaccine typically ranges from 2 months to 10 years. Most tumors are fibrosarcomas, but other types of sarcomas can also occur. The term feline ISS is preferred to vaccine-associated sarcoma because the sarcomas have arisen at sites where other medications, including long-acting glucocorticoids, meloxicam, and intralesional cisplatin, have been injected.[128,129] The FDA also lists injection-site neoplasms as reported adverse effects following cefovecin injection. In addition, sarcomas have been identified at the site of a deep, nonabsorbable suture[130]; a retained abdominal surgical sponge[131]; microchip implantation[132,133]; and an indwelling port for subcutaneous fluids administration.[134] Feline ISSs differ histologically and are more aggressive in behavior than sarcomas at other sites. They are characterized by perivascular infiltration of lymphocytes and macrophages at the tumor periphery, a central area of necrosis and infiltration by tumor cells. The rate of metastasis has been estimated at 10%–28%,[135,136] with the most common site of metastasis being the lung.[137]

Although development of ISSs is clearly linked to administration of FeLV, rabies, and other vaccines, development of sarcomas is not related to the use of specific brands or types of vaccine within an antigen class (with the exception of recombinant vaccines, which have been associated with a decreased risk of ISS[138]), reuse of syringes, needle gauge, use and shaking of multidose vials, or concomitant viral infection.[139] There is also a lack of evidence that aluminum-containing vaccines are associated with a higher risk of sarcoma development than aluminum-free vaccines. There has been concern that adjuvant stimulates an intense inflammatory response that predisposes to sarcoma formation. One study showed that inactivated vaccines were approximately 10 times more likely to be associated with ISSs when administered at the pelvic limb site than nonadjuvanted recombinant vaccines.[138] An *in vitro* study that involved exposure of feline fibroblasts to aluminum chloride salts promoted cell cycle progression and cell growth, suggesting that aluminum alone may be capable of tumorigenesis in the absence of inflammation.[140] A study from Switzerland suggested that a decline in the incidence of feline ISSs may have followed introduction of a nonadjuvanted FeLV vaccine.[141]

Nevertheless, neither attenuated live, recombinant, nor inactivated vaccines are risk-free, and the connection between adjuvants and ISSs remains controversial.[142] There is some evidence that administration of cold vaccine may also be more likely to be associated with sarcoma formation, but this also requires verification.[139] To date, no oncogenic viruses have been identified in association with the sarcomas despite searches for FeLV, FIV, feline sarcoma virus, FFV, polyomavirus, and papillomaviruses.[143–147]

Treatment of ISSs involves aggressive surgical resection together with full-course radiation therapy because of the high incidence of recurrence. Radiation therapy may be delivered preoperatively, targeting the entire tumor plus a 3- to 5-cm margin, or postoperatively.[148] Median times to reported recurrence are 2 months to > 16 months, and recurrence may be manifested as multiple new tumors that develop along the surgical scar site. Advanced imaging using CT or MRI is necessary to determine the full extent of the tumor before surgery. In assessing tumor size, one study showed that CT is more accurate than physical examination, especially for larger tumors.[149] Possible adverse effects of radiation include mild to moderate cutaneous burns, hypopigmentation of the hair in the field (see Fig. 20.7B), and damage to the spinal cord, lungs, and kidneys within the field, although the last is rare. Use of computer-based radiation treatment plans and linear accelerators that incorporate imaging technology can help to reduce the size of the radiation field. In one study, the median survival time for cats treated with postsurgical curative radiation therapy was 43 months.[150] Most of these cats had clean margins after surgical resection of the tumor. In contrast, the median survival times for cats treated with coarse fractionated radiation therapy was 24 months. These cats generally had macroscopic disease or dirty margins. Postoperative brachytherapy using iridium-192 implants has also been used, with a median disease-specific survival time of 1242 days; local failure rate was still 55% and distant failure rate was 14% due to lung metastasis.[151] Adjuvant chemotherapy with carboplatin, single-agent doxorubicin, or epirubicin also has been associated with improved outcome in some studies.[150,152] *In vitro* sensitivity of ISS cells to carboplatin has been demonstrated.[153] Administration of toceranib to affected cats did not appear to result in clinical response in one study.[154] Administration of a recombinant canarypox vector expressing IL-2 at the tumor site commencing just before brachytherapy and continuing on day 7, 14, 21, 35 and 49 in 71 cats with ISSs resulted in a significantly longer time to relapse (> 730 days) when compared with surgery and radiation therapy alone (287 days).[155] This product was approved by the European Medicines Agency in 2013 (Oncept IL-2, Boehringer Ingelheim Vetmedica GmbH) and was conditionally licensed by the USDA in 2015 to delay postsurgical recurrence of feline fibrosarcoma in adult cats with stage I disease.

In order to prevent death from sarcoma formation in cats, a task force, the Vaccine-Associated Feline Sarcoma Task Force (VAFSTF) in North America recommended that rabies vaccines be administered as distally as possible on the right pelvic limb, and leukemia vaccines be administered as distally as possible on the left pelvic limb ("rabies right, leukemia left"). Care should be taken not to administer the vaccine too proximally or in the flank region, because tumors in these locations cannot be resected as effectively.[156] Vaccination of the cat in a crouched position may result in inadvertent administration into a more proximal location. The AAFP suggested that other core vaccines should be administered below the right elbow.[126] These recommendations were not adopted by the WSAVA, which suggested that vaccination sites be rotated from year to year.[2] The tail has also been used.[157] Both groups recommended that the interscapular region be avoided because vaccine constituents can pool in this region and contribute to a chronic inflammatory response. In addition, both groups recommended that the sites of administration and the product and batch number be documented to facilitate the reporting of adverse events. Excessive administration of vaccines to cats should be minimized. Owners should be advised to monitor injection sites for 3 months after vaccines are administered. The AAFP recommends performance of an incisional biopsy if a mass: (1) persists for 3 months or longer after injection; (2) becomes larger than 2 cm in diameter; or (3) continues to increase in size 1 month after injection (the "3-2-1 rule").[126]

In accordance with the VAFSTF recommendations, the anatomic location, shape, and size of masses that develop at injection sites should be documented, and an incisional or tru-cut biopsy performed. Fine-needle aspiration and excisional biopsy are not recommended because excisional biopsy is unlikely to be sufficient treatment should a sarcoma be present. If the mass is malignant, routine laboratory tests and thoracic radiography should be performed, together with CT or MRI of the mass if client finances allow. A veterinary oncologist should be consulted, and if possible, referral to a specialist surgeon or oncologist is recommended. Wide excision that includes at least a 3-cm margin (and preferably 5-cm margin) is necessary, together with one fascial plane beneath the mass,[158] and the entire piece of tissue excised should be submitted for histopathology and evaluation of surgical margins. Additional treatment, such as radiation therapy, chemotherapy, and immunotherapy (where available) can improve outcome. Cats should be reevaluated at 3-month intervals for at least 1 year after surgery.

Interference with Diagnostic Test Results

Vaccination has the potential to interfere with the results of assays that detect the antibody response to infection or assays that detect components of a pathogen itself.

Interference with antibody test results can be specific for the target pathogen or nonspecific. Nonspecific interference results from cross-reactivity between antibodies to vaccine components (such as albumin) and the reagents used in serodiagnostic tests, but it is rarely a problem. More commonly, specific interference occurs, resulting in false-positive test results for the infection targeted by the diagnostic test. This especially problematic if: (1) vaccination does not completely protect against infection, (2) the results of antibody tests are required for diagnosis, and (3) infection is chronic and persistent, and so identification of recent natural infection through seroconversion is usually not possible. For example, the inactivated FIV vaccine that is still available in some countries (Fel-O-Vax FIV, Boehringer Ingelheim) does not provide 100% protection, but vaccinated cats develop antibodies to the vaccine virus. These antibodies are detected by some ELISA and Western blot immunoassays used for diagnosis of FIV infection. In the absence of a history of vaccination, and in kittens older than 6 months of age, positive antibody test results for FIV indicate active infection.[159] PCR can be used to detect FIV infection in infected cats that have a history of vaccination with FIV vaccines, but PCR can occasionally be negative in cats with active infection, so a negative PCR result does not rule out natural infection with FIV. Vaccine interference with serodiagnosis can occur after vaccination of dogs for influenza or leptospirosis, but because both of these diseases are acute, seroconversion can be used for diagnosis of recent infection in vaccinated dogs. Some serologic assays differentiate between vaccinated and naturally infected animals (DIVA). Although not designed with that intent, the Antigen Rapid and Witness (Zoetis) generally only test positive for antibodies to FIV in truly infected cats, and are negative in uninfected cats that have been previously vaccinated. Serologic assays that detect the C6 antigen of *B. burgdorferi* do not detect antibodies that result from immunization with Lyme vaccines. The development of recombinant vaccines that stimulate a pattern of antibody responses that differ from those that result from natural infection can help to overcome issues related to differentiation of naturally infected and vaccinated animals.

Interference with the results of assays *that detect the pathogen itself (as opposed to the antibody response)* occurs after vaccination with attenuated live vaccine organisms that are shed by animals after vaccination. For example, cats may test positive using ELISA assays for FPV antigen after vaccination with attenuated live FPV vaccines, although for some assays, the rate at which this occurs is very low.[160] PCR tests can be positive for days to several weeks after vaccination with attenuated live vaccines.[161,162] In some cases, sequence analysis of the PCR product can sometimes allow differentiation between vaccine and field strains, but this is currently performed only on a research basis.[163] Rapid PCR assays have also been designed that differentiate between vaccine and field strains of some pathogens, such as CDV or *B. bronchiseptica*.[164,165] Quantification of organism numbers present in a specimen through the use of real-time PCR assays (e.g., for CDV) may shed light on whether natural infection (high organism load) or vaccination (low organism load) has occurred.

VACCINE SELECTION

The advantages and disadvantages of vaccines and vaccine combinations that are currently available on the market are provided in the relevant sections of this book for each infection entitled "Immunity and Vaccination." Suggested vaccination schedules for individual pets and shelter animals that are based on recommendations provided by the AAHA, the AAFP, the International Society of Feline Medicine (ISFM), and WSAVA are summarized in tables in the Appendix.[2,17,126,166–173]

To facilitate vaccine selection, vaccines for dogs and cats have been divided by various task forces into core vaccines, noncore vaccines, and those that are generally not recommended.

Core vaccines are recommended for all animals with an unknown vaccination history. The diseases involved have significant morbidity and mortality and are widely distributed, and in general, vaccination results in good protection from disease. All shelter animals should be vaccinated with core vaccines before entry to a shelter or at the time of entry if immunization ahead of time is not possible. Canine core vaccines include vaccines for CPV, CDV, CAdV, and rabies for countries where rabies is endemic. The leptospirosis vaccine also has been recommended as a core vaccine by the BSAVA[174] and some academic veterinary hospitals. The core feline vaccines are those for FHV-1, FCV, FPV, and rabies.

Noncore vaccines are optional vaccines that should be considered in light of exposure risk, that is, based on geographic distribution and the lifestyle of the pet. Vaccines considered as noncore vaccines for dogs are CPIV, CIV, *B. bronchiseptica, Leptospira* spp. (core in some statements), and *B. burgdorferi*. Optional or noncore vaccines for cats include FeLV, FIV, *C. felis,* and *B. bronchiseptica* vaccines.

Several other vaccines for infectious diseases are currently available on the market. For dogs, these are vaccines for CCoV, FIP, and rattlesnake envenomation. The reports of the AVMA and the AAHA canine vaccine task force, as well as the WSAVA guidelines, have listed the CoV vaccine as not generally recommended. Reasons for listing vaccines as not generally recommended are that "the diseases are either of little clinical significance or respond readily to treatment," evidence for efficacy of these vaccines is minimal, and they may "produce adverse events with limited benefit." Two studies examined outcomes following rattlesnake vaccination with the *Crotalus atrox* vaccine. One study used a mouse model and demonstrated improved survival following challenge with western diamondback venom, but not with northern Pacific or southern Pacific rattlesnake venom.[175] One retrospective study included 15 dogs that had received the rattlesnake vaccine and 256 dogs that had not received the vaccine. No significant difference was found between canine snakebite severity scores and a history of having received the vaccine.[176] Of concern, anaphylactic shock was reported in two dogs that had been previously vaccinated with the *C. atrox* vaccine following first-time envenomation, the authors hypothesizing that the vaccine was the initial inciting trigger.[177] For cats, the intranasal FIP vaccine is not generally recommended by the AAFP or the WSAVA because most cats are infected with FCoV before the age for initial vaccination (16 weeks), and the vaccine contains a CoV type that differs from the type that causes most infections (see Chapter 31).

VACCINATION OF EXOTIC CARNIVORES

Many nondomestic carnivores are vaccinated for diseases of dogs and cats with commercially available canine and feline vaccines. Unless absolutely necessary, attenuated live products should not be used in exotic species because they may cause clinical illness, and the potential always exists for reversion of the attenuated strain to virulence in a foreign host. Inactivated and recombinant vaccines should be used only after safety and efficacy have been demonstrated in the specific exotic species. Oral recombinant-vectored rabies vaccines have been used to control rabies in wildlife. The recombinant canarypox virus-vectored CDV vaccine has been proven safe and effective in ferrets and has been recommended to protect other captive wildlife species that are susceptible to distemper.[178,179] Recommendations for vaccination of captive wild canids and felids can be found elsewhere.[179]

Vaccination of wolf hybrids and Bengal cat hybrids has been controversial because they are considered wildlife, and efficacy of canine and feline vaccines in these species has not been proven. Vaccinating these animals creates legal and ethical issues for veterinarians and public health officials. In jurisdictions where these animals are not legal pets, they should not be vaccinated; however, veterinarians can decide to vaccinate in areas where ownership is allowed. The owner should be provided with written notice as part of informed consent that efficacy of vaccines is not proven in these animals.

VACCINATION REQUIREMENTS FOR TRANSPORT OF ANIMALS

Interstate shipment of animals with infectious diseases or those that have recently been exposed to infectious diseases is prohibited within the United States. Each state has established guidelines that generally include a physical examination and current rabies vaccination. Information about pet travel is available online in the current regulations of the USDA,[180] Department of Agriculture in Canada,[181] Department of Agriculture and Natural Resources in Australia,[182] Department of Environment, Food and Rural Affairs in the United Kingdom,[183] and similar bureaus in other countries. Worldwide travel regulations are also available at http://www.pettravel.com/passportnew.cfm.

In the European Economic Community, animals can move between member countries provided they show no signs of disease, are identified by tattoo or implanted microchip, are vaccinated using a WHO-approved vaccine certified by an official veterinarian, and are accompanied by an animal passport clearly identifying the individual.

For information regarding serologic testing and proof of rabies immunization for transport of animals, see Chapter 21.

PART II

Specific Infectious Diseases and Their Etiologic Agents

Introduction to Part II

The remainder of this book is devoted to information on major infectious diseases of dogs and cats and the pathogens involved. The first 5 sections cover viral, bacterial, fungal, protozoal, and parasitic diseases, and the last section covers clinical problems associated with different body systems. For most infectious diseases, information on each disease is organized in a standard format: Etiologic Agent and Epidemiology, Clinical Features (including clinical signs and their pathogenesis, and physical examination findings), Diagnosis (laboratory findings, imaging findings, specific diagnostic assays, and pathologic findings), Treatment and Prognosis (including tables with drug doses), Immunity and Vaccination, Prevention, and Public Health Aspects. Whenever possible, a case example has been provided to illustrate how the principles discussed in the chapter can be applied to clinical cases. Since the last edition, in addition to the case examples, a key points section at the start of the chapter summarizes the most important information about each disease, illustrations have been updated, and a series of suggested readings has been added. Some pathogens that were previously described as part of a complex (e.g., canine infectious respiratory disease complex) now are described in separate chapters, because our understanding of these pathogens has increased. Multiple infections of public health importance are covered, such as SARS-CoV-2 infections in dogs and cats, leptospirosis, zoonotic vector-borne bacterial diseases such as Lyme disease and rickettsioses, bite and scratch wound infections; sporotrichosis, toxoplasmosis, leishmaniosis, toxocariasis, ticks, fleas, and multidrug resistant bacterial infections. That is just to name a few. Choose your favorite bug! However, I would recommend those who suffer from nightmares refrain from reading parasite chapters at bedtime…

SECTION 1

Viral Diseases

Jane E. Sykes

Our knowledge of viral diseases has expanded considerably in recent years with the advent of nucleic acid–based approaches to diagnosis, including application of rapid whole genome sequencing platforms. New viruses have been discovered, such as canine pneumovirus (Chapter 28), *Felis catus* gammaherpesvirus (Chapter 34), and several papillomaviruses (Chapter 40). The availability of sensitive, quantitative nucleic acid amplification tests has changed our understanding of the pathogenesis of diseases such as feline leukemia virus infection (Chapter 32), which has also led us to rethink our approach to diagnosis. Antiviral drugs such as famciclovir and remdesivir promise improved treatment outcomes for cats with feline infectious peritonitis (Chapter 31) and feline herpesvirus infections (Chapter 34). The appearance of new influenza virus variants (Chapter 25) and SARS-CoV-2 (Chapter 43) has highlighted the susceptibility of cats and dogs to emerging viral infections as well as the importance of the human-animal bond. However, diseases such as rabies (Chapter 21) also continue to be a threat to public health, and veterinary efforts to control these diseases in dogs and cats worldwide remain critical.

21

Rabies

Bruno B. Chomel, Jane E. Sykes

KEY POINTS

- First Described: Circa the second millennium BC, Mesopotamia.[1]
- Cause: Rabies virus (family *Rhabdoviridae*, genus *Lyssavirus*).
- Primary Mode of Transmission: Biting, with inoculation of saliva containing the virus.
- Affected Hosts: All warm-blooded animals. Main reservoir hosts include foxes, coyotes, jackals, dogs, wolves, raccoons, raccoon-dogs, skunks, mongooses, ferret-badgers, and a wide range of bat species. Accidental hosts (depending on the virus strains that infect them) include cats, cattle, sheep, goats, horses, ferrets, primates, and woodchucks.
- Geographic Distribution: Classic (genotype 1) rabies is found worldwide, except for Australia, New Zealand, Iceland, the United Kingdom, Japan, most of western Europe, Fiji, Hawaii, and Guam. However, bat-borne lyssaviruses are present in some of these countries (Australia, western Europe including the United Kingdom).
- Major Clinical Signs: Variable fever, lethargy, behavioral changes, pupillary dilation, ataxia, lower motor neuron paresis or paralysis (including of the muscles of mastication), vestibular signs (including a head tilt), dysphagia, dysphonia, tremors, seizures, ptyalism.
- Differential Diagnoses: Distemper virus infection; Aujeszky's disease (pseudorabies in dogs and cats), West Nile virus infection; equine encephalitis virus infection; bacterial, protozoal, or fungal meningoencephalitis; toxins such as strychnine; CNS trauma; spinal neoplasia; granulomatous meningoencephalitis.
- Public Health Significance: Rabies is a deadly zoonosis and domestic dogs remain the main source of human infection worldwide, accounting for more than 95% of human cases. In the United States, most human rabies is associated with bat contact.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Rabies is a deadly, zoonotic, neurologic disease caused by a bullet-shaped, enveloped, single-stranded RNA virus that belongs to the genus *Lyssavirus* (from Lyssa, the Greek goddess of madness, rage, and frenzy) (Fig. 21.1). The viral genome encodes five structural proteins: a nucleocapsid (N) protein, a phosphoprotein (P), a matrix (M) protein, a glycoprotein (G), and an RNA-dependent RNA polymerase (L). The virus is fragile in the environment, and readily inactivated by a variety of disinfectants, soaps, ultraviolet light, and heat. It can survive up to 3 to 4 days in carcasses at 20°C, and longer with refrigeration.[2,3] Freezing tissues at temperatures less than –20°C may prolong survival of the virus for years. However, freezing samples in a household-type freezer with subsequent defrosting cycles will destroy the virus for subsequent detection.

Currently, the lyssaviruses are classified into 16 species (Table 21.1).[4,5] The major rabies species are assigned to genotypes 1 through 7. Classic rabies virus belongs to genotype 1. The remaining lyssavirus genotypes primarily infect bats and less frequently cause fatal human encephalitis, which is clinically indistinguishable from classic rabies.[6] Thus, although Australia, New Zealand, Iceland, the United Kingdom, Japan, most of western Europe, Fiji, Hawaii, and Guam are designated terrestrial rabies-free, lyssaviruses that infect bats capable of causing fatal encephalitis in humans exist in some of these regions, such as Australia or western Europe including the United Kingdom (Fig. 21.2). Suspected spillover of European bat lyssavirus to domestic cats and sheep in Europe has been described. North, Central, and South America are unique because both terrestrial mammals and bats are only infected with genotype 1. The remaining information in this chapter pertains only to genotype 1 rabies virus infections.

Infection with rabies virus most commonly occurs as a result of inoculation of virus-containing saliva into a bite wound, in the large majority of the cases after a dog bite. Other routes of transmission reported in species other than dogs and cats are rare and include corneal or solid-organ transplantation in human patients[7]; aerosol transmission, such as that occurring within caves containing large numbers of bats[8,9]; transmission after ingestion of infected tissues[9,10]; and butchering of infected dogs.[11]

All warm-blooded animals are susceptible to rabies, although dogs, wild carnivores, and bats are considered the main natural reservoirs of rabies virus. Main reservoir hosts include foxes, coyotes, jackals, dogs, wolves, raccoons, raccoon-dogs, skunks, mongooses, ferret-badgers, and a wide range of bat species. Accidental hosts (depending on the rabies virus strains that infect them) include cats, cattle, sheep, goats, horses, ferrets, primates, and woodchucks. Marsupials, including opossums, have a lower degree of susceptibility. Some bird species can be experimentally infected but do not develop clinical signs and are unlikely hosts.[12] Rabies in a domestic fowl that had been bitten by a dog was described in India.[13]

Not every bite from a rabid animal leads to rabies virus infection, and infection may not always culminate in death, unless clinical signs develop. Factors influencing the outcome after a bite from a rabid animal include the proximity of the bite site to the CNS, the degree of innervation of the bite site, the age of the host (young animals are more susceptible), the amount of virus inoculated, and the neuroinvasiveness of the rabies virus variant involved. If left untreated, up to 60% of humans bitten by a rabid dog on the head or neck develop rabies compared with up to 40% of those bitten on the hand and 10% of those bitten on the trunk or leg.[14]

Rabies viruses that circulate within a certain geographic region are adapted to specific dominant reservoir hosts. Examples in the United States are bat rabies virus variants and raccoon or skunk rabies virus variants. All rabies virus variants can infect and cause disease in animals other than their reservoir hosts (spillover hosts). The possibility of a subclinical carrier state, especially in bats, has been suggested based on the detection of rabies virus antibody and, rarely, the virus itself in some reservoir host species that are not showing signs of illness.[6] The recognition of dogs that survived rabies in Ethiopia has raised concern about subclinical carriage in dogs.[15]

Owing to mandatory vaccination and control programs, domestic animal rabies in the United States has decreased in prevalence, whereas wildlife rabies has increased (Fig. 21.3). The dog rabies virus variant was considered eradicated from the United States at the beginning of the 21st century. Currently, cats are more commonly reported with rabies in the United States (about 300 cases/year) than dogs (fewer than 100 cases/year), most likely reflecting rabies vaccination practices and pet behavior, as pet cats are more likely to roam (Fig. 21.4A). No feline rabies virus variant has been described. In developed countries, the geographic distribution of feline and canine rabies follows that of regions where wildlife rabies is endemic. Most cats and dogs are infected with the rabies virus variant that is associated with the major wildlife reservoir host in their respective geographic location (Fig. 21.4B). In the United States, rabid cats are most often reported from the northeastern, mid-Atlantic, and south-Atlantic states, with lesser numbers from the north and south central states. The eastern distribution of feline rabies follows the distribution of raccoon rabies.[16,17] Rarely, cats are infected from bats. Rabies in dogs and cats is most commonly reported from the north central, south central, and Atlantic states (see Fig. 21.4A). In the four contiguous US states, dogs are mainly infected with rabies virus variants from raccoons or skunks. Because of the long incubation period, infected dogs have also been imported into the United States from other countries where canine rabies variants are endemic.[18,19] In Europe, the major wildlife reservoir species have been foxes and raccoon dogs, and in South Africa, jackals and mongooses predominate. In Western Europe, fox rabies has largely been eliminated as a result of mass vaccination campaigns. Spillover occurs from wildlife reservoir hosts to domestic animal species, which subsequently contact humans. Nevertheless, the vast majority of human cases in North America result from contact with infected bats, which are present in all states except Hawaii (see Public Health Aspects). Rabies in rodents and lagomorphs is rare, possibly because they are always killed by the bite of a rabid animal. In the United States, most reports have been from woodchucks in raccoon rabies endemic areas.[20] A few cases of rabies in pet ferrets, rabbits, and a pet guinea pig have been described.[21]

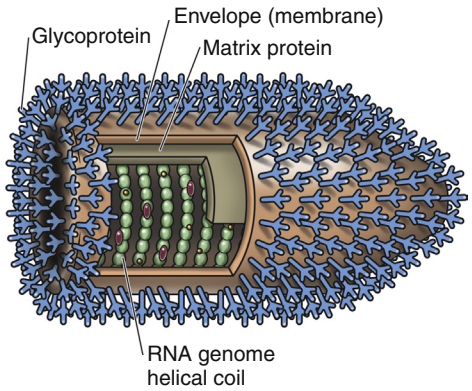

Fig. 21.1 Structure of a rabies virus virion.

Although rabies occurs in cats and dogs of any age, it is most frequently reported in young dogs and cats, with a median age of 1 year for both cats and dogs in one study; 75% of animals were 3 years of age or younger.[22] Rabies can occur in puppies and kittens that have not yet reached the age at which routine rabies vaccination is approved, which is an emerging issue as a result of illegal importation of pet dogs from countries where dog rabies is endemic. Male dogs may be slightly more predisposed, and most dogs and cats with rabies have not been neutered and live in rural environments, frequently being unrestrained

TABLE 21.1 Current Taxonomy of Lyssaviruses

Species (Genotype)	Potential Vector/Reservoir	Geographic Distribution
Rabies virus (1)	Carnivores (worldwide); bats (Americas)	Worldwide (with the exception of several islands)
Lagos bat virus (2)	Fruit (frugivorous) bats (*Megachiroptera)*	Africa
Mokola virus (3)	Unknown	Sub-Saharan Africa
Duvenhage virus (4)	Insectivorous bats	Southern Africa
European bat lyssavirus 1 (5)	Insectivorous bats (*Eptesicus serotinus*)	Europe
European bat lyssavirus 2 (6)	Insectivorous bats (*Myotis* spp.)	Europe
Australian bat lyssavirus (7)	Frugivorous and insectivorous bats (*Megachiroptera*/*Microchiroptera)*	Australia
Aravan virus	Insectivorous bats (*Myotis* spp.)	Central Asia
Khujand virus	Insectivorous bats (*Myotis* spp.)	Central Asia
Irkut virus	Insectivorous bats (*Myotis* spp.)	East Siberia
West Caucasian bat virus	Insectivorous bats (*Miniopterus* spp.)	Caucasian region
Shimoni bat virus	*Hipposideros commersoni*	East Africa
Bokeloh bat lyssavirus	Insectivorous bats (*Myotis* spp.)	Europe
Ikoma virus	Unknown	Africa
Gannoruwa bat lyssavirus	Unknown	Asia
Lleida bat lyssavirus	Insectivorous bats (*Miniopterus* spp.)	Europe (Spain)
Taiwan bat lyssavirus	Insectivorous bats	Taiwan

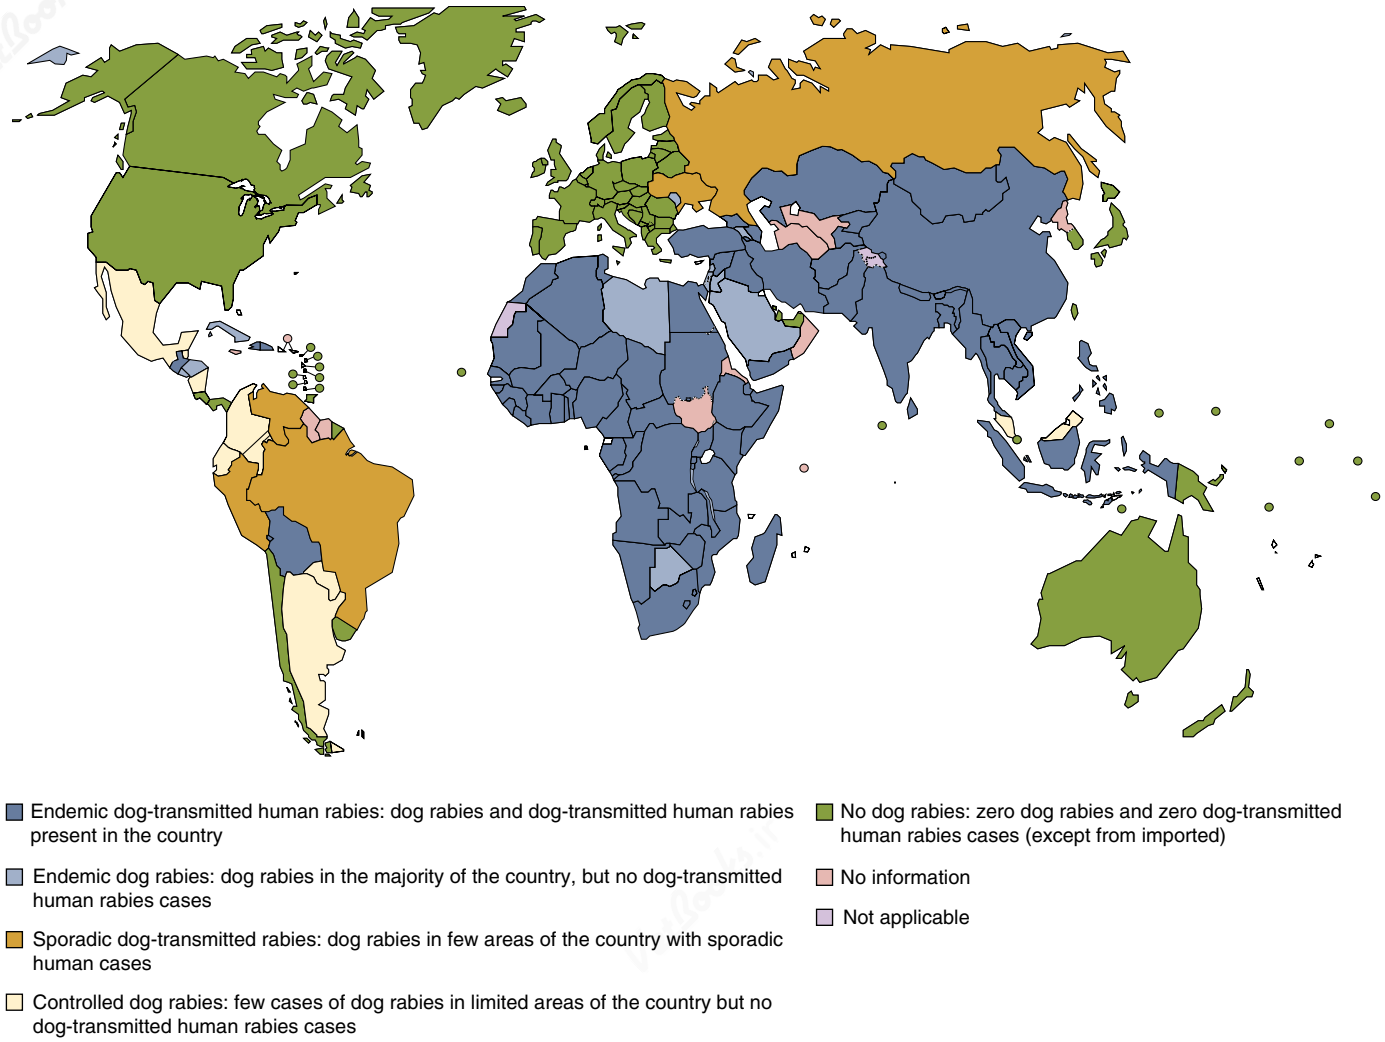

Fig. 21.2 Endemicity of dog rabies and dog-transmitted human rabies, 2016. (From the World Health Organization, Weekly Epidemiological Record No 7.© WHO 2017. All rights reserved © OMS 2017.)

at night.[16,22] In the United States, some degree of seasonality occurs for rabies in dogs and cats, which correlates with seasonal increases in rabid raccoons and skunks.[16,22] For the majority of cats and dogs with rabies, a history of known contact with wild animals or a wound is lacking.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After inoculation into the subcutaneous tissues and muscle, rabies virus replicates locally within muscle cells, with the nicotinic acetylcholine receptor on the postsynaptic muscle membrane being the main receptor for the virus.[23] It is thought to bud into the synaptic cleft, and then attach to peripheral nerve endings, in part using the neuronal cell adhesion molecule (NCAM) and p75NTR as receptors. Local replication around the bite site can continue for months before the virus exclusively enters peripheral motor nerve endings. It is no longer thought that sensory and autonomic nerves are involved.[23] The virus then travels in a retrograde fashion up nerve axons at a rate of 3 mm/hour, with virus replication and assembly occurring within the neuronal cell body, followed by transport to and budding from another synapse.[9] Once the virus is within the CNS, there is massive viral replication within neurons (Fig. 21.5), but without histopathologic evidence of damage to those neurons. The spinal cord, medulla oblongata, periaqueductal gray matter, limbic system, and cerebellum are particularly affected. The virus also moves outwards from the CNS in somatic and autonomic nerves and is deposited in a variety of tissues, including cardiac and skeletal muscle, the eye, the kidney, pancreas, nerves around hair follicles, and the salivary glands. Production of new virions through budding from the plasma membranes occurs primarily within the salivary glands, which results in the shedding of virus that can be transmitted to other hosts. Thus, the presence of virus in the saliva indicates that the CNS has been infected. In some animals, death occurs before the saliva becomes infected. Virus is shed by some dogs for up to 13 days before the onset of clinical signs, but more often the period of virus shedding before onset of clinical signs in dogs and cats is 1 to 5 days.[24]

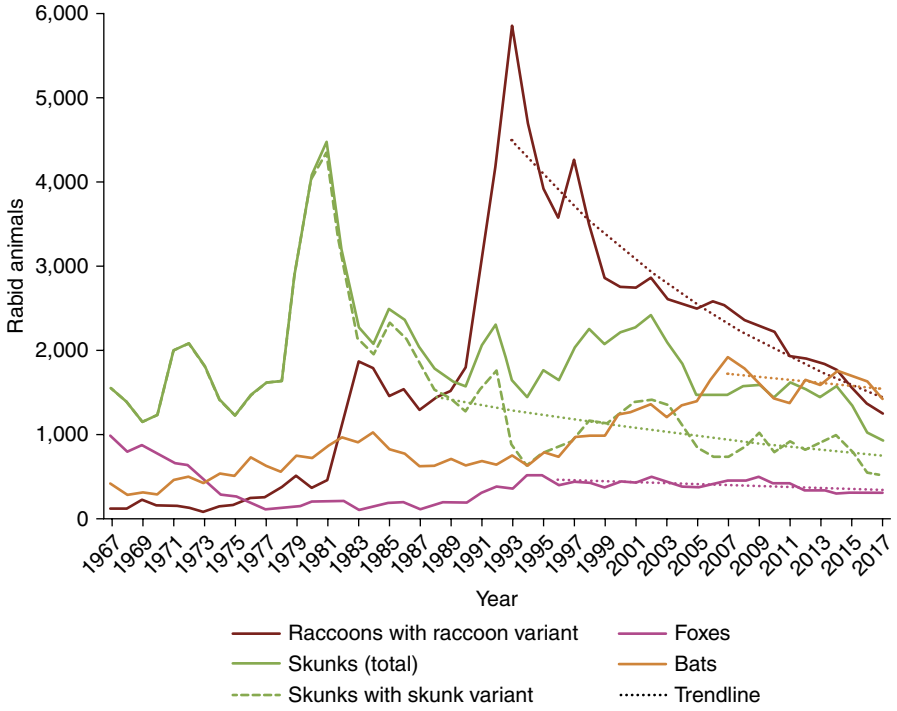

Fig. 21.3 Cases of rabies among wildlife in the United States, by year and species, 1966 to 2017. (From Ma X, Monroe BP, Cleaton JM, et al. Rabies surveillance in the United States during 2017. *J Am Vet Med Assoc.* 2018;253:1555–1568.)

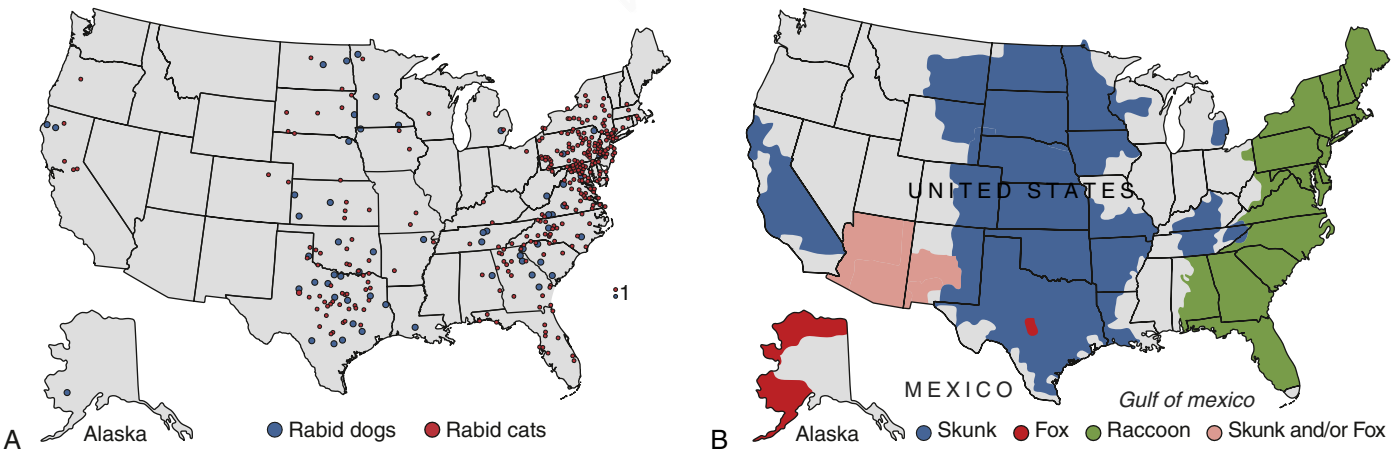

Fig. 21.4 (A) Reported cases of rabies that involve cats and dogs, by county, during 2017. Note the overlap with the distribution of wildlife reservoir hosts in B. (B) Approximate distribution of major rabies virus variants among mesocarnivores in the United States from 2013 through 2020. As a result of oral rabies vaccination programs, infection with the Texas gray fox rabies virus variant has not been reported from Texas since 2013 (central red region in Texas). Also, in California, skunk rabies virus variant infections between 2016 and 2020 have been limited to central California. (A and B modified from Ma X, Monroe BP, Cleaton JM, et al. Rabies surveillance in the United States during 2017. *J Am Vet Med Assoc.* 2018;253:1555–1568 and Ma X, Bonaparte S, Toro M, et al. Rabies surveillance in the United States during 2020. *J Am Vet Med Assoc.* 2022; May 5:1–9.)

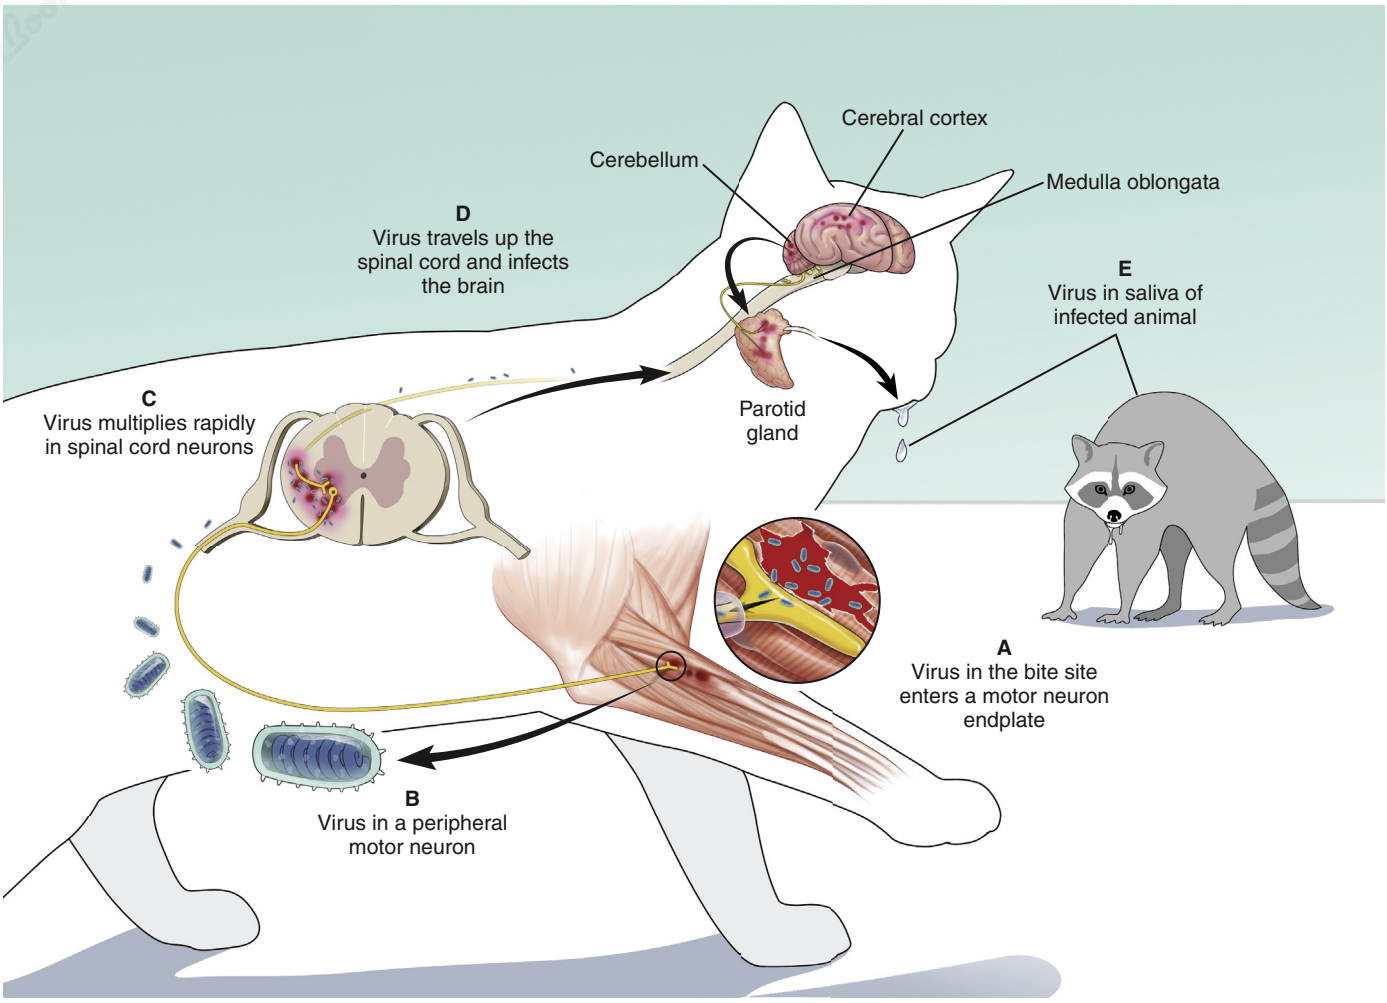

Fig. 21.5 A, Rabies virus enters peripheral nerves, or may replicate in myocytes and spread to motor nerve endings. B, Retrograde intra-axonal (centripetal) spread to the central nervous system occurs in peripheral motor nerves. C, Virus replicates in spinal cord neurons and spreads rapidly throughout the nervous system, causing progressive lower motor neuron paralysis. D, Virus enters the brain, causing cranial nerve deficits and behavioral changes. E, Virus spreads centrifugally in peripheral and cranial nerves, from which it enters the salivary glands and saliva and other tissues.

Although uncommon, infection by routes other than by bite is possible. After ingestion, the virus can infect cells of the oral mucosa, taste buds, pulmonary system (by aspiration), and intestinal mucosa. From these sites, virus migrates up branches of the cranial nerves and spreads to the brainstem.

The precise mechanism by which rabies virus causes fatal disease remains unknown. Clinical signs probably result from impaired neuronal function due to alteration of neuronal networks,[9,23] and occur after an incubation period that ranges from just over a week to 6 months or more. Most dogs and cats develop disease 1 to 2 months after exposure. In general, the closer the bite site is to the CNS, the shorter the incubation period. The incubation period is also influenced by the host species, age, degree of innervation of the bite site, neuroinvasiveness of the rabies virus variant, and the amount of virus inoculated. Although 90% of humans develop disease within 6 months of exposure, incubation periods of 6 years or more have been reported.[25–27]

The clinical presentations of rabies virus infection have been divided into excitatory ("furious") and paralytic ("dumb") forms. Three phases have been described in the progression of the disease, the prodromal, furious, and paralytic phases, but the stages are variable and may overlap, and signs may be atypical (Table 21.2). Infrequently, there is a history of a wound, or wounds are still present at the time neurologic signs occur. Unfortunately, rabies is infrequently suspected as the possible diagnosis at the time rabid animals are examined by veterinarians.[16,22]

When it occurs, the *prodromal phase* lasts 2 to 3 days in dogs and 1 to 2 days in cats, and is characterized by a variable fever, licking or chewing at the bite site, and behavioral changes. Dogs and cats may become lethargic, anorexic, apprehensive, restless, or reclusive, and vomiting may occur.[16] Some animals become more docile or affectionate. Pupillary dilation, sometimes with decreased pupillary light reflexes, may occur. The *furious phase* occurs in approximately two thirds of affected cats and dogs[28] and lasts 0 to 7 days. Clinical signs result from forebrain involvement and include irritability, anxiousness or excitability, hyperesthesia, hypersalivation, vocalization, roaming, and aggression (Fig. 21.6). Affected animals may try to eat foreign objects, which may become lodged within the GI tract, or they may attack their surroundings or moving objects. Some animals develop prolapse of

the nictitans, ataxia, vestibular signs, abnormal sexual behaviors, and grand mal seizures. Tremors; staring, or a wild, spooky, or blank look in the eyes; increased vocalization; and compulsive running can occur in cats, which also often develop aggressive behavior.[16,22,29] The *paralytic phase* develops 1 to 10 days after the onset of clinical signs and is characterized by flaccid paralysis, which is ascending and often initially involves the bitten extremity. Neurologic examination reveals flaccid paralysis with absent segmental reflexes. Laryngeal paralysis may lead to a change in the sound or pitch of a dog's bark or cat's meow. Hypersalivation results from paralysis of the pharyngeal muscles, and a "dropped jaw" can occur as a result of masticatory muscle paralysis, especially in dogs, which may appear to owners as if they are choking.

If euthanasia is not performed, coma and death usually occurs within a week of the onset of signs, with a few animals dying as long as 10 days after the onset of illness. Death is associated with multiorgan failure, especially cardiac and respiratory failure. Recovery from rabies is extremely rare. Experimentally, some dogs have recovered from clinical rabies days to months after being infected with certain rabies virus strains.[30,31]

TABLE 21.2 Major Clinical Findings in 183 Cats and 119 Dogs with Rabies in the United States

Sign	Percentage of Cats	Percentage of Dogs
Aggression	55	31
Ataxia	30	49
Irritability	34	23
Anorexia	22	38
Lethargy	20	37
Hypersalivation	14	41
Dysphagia	10	30
Lameness	18	16
Limb paralysis	17	29
Jaw paralysis	3	29
Dysphonia	16	9
Hyperesthesia	10	17
Seizures	8	14
Fever	3	14

From Eng TR, Fishbein DB. Epidemiologic factors, clinical findings, and vaccination status of rabies in cats and dogs in the United States in 1988. National Study Group on Rabies. *J Am Vet Med Assoc.* 1990;197:201–209.

DIAGNOSIS

Rabies should be suspected in dogs and cats evaluated for sudden onset of behavioral changes and flaccid paralysis, especially in rabies-endemic regions, or in animals imported from rabies-endemic countries. Although a particularly high degree of suspicion is warranted for animals that lack a vaccination history for rabies, the disease has been reported in partially and completely vaccinated dogs and cats,[16,22,29] so a history of rabies vaccination should not be used to dismiss suspicion for rabies.

Laboratory Abnormalities

No specific or characteristic hematologic or biochemical changes have been reported in dogs and cats with rabies. Mild anemia was reported in one dog.[32] Analysis of the CSF may be unremarkable or show an increase in CSF protein concentration and mild to marked CSF pleocytosis. Small lymphocytes account for most of the differential cell count.[32]

Electromyography in one dog revealed abnormalities consistent with impaired neuromuscular transmission, including moderate fibrillations, positive sharp waves, and an absent M wave.[32] Changes suggestive of denervation have also been described in humans with rabies.[33]

Diagnostic Imaging

Magnetic Resonance Imaging Findings

Findings on MRI in dogs with rabies have included hyperintense lesions on T2-weighted images, especially in the midbrain, thalamus, and basal

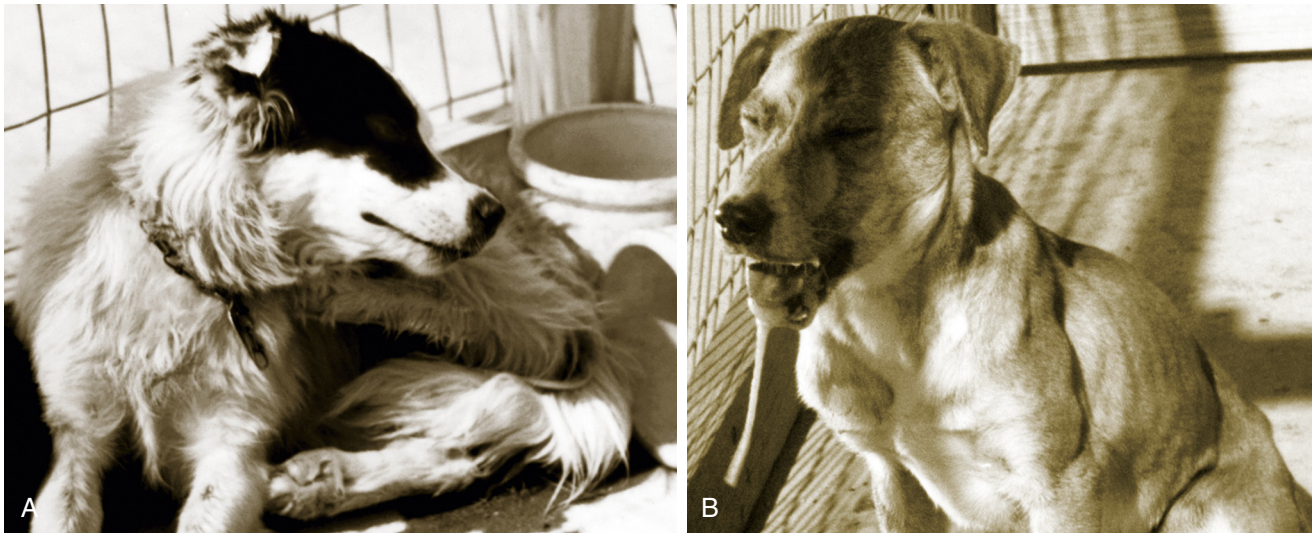

Fig. 21.6 (A) Dog with paralytic stage of rabies in sternal recumbency with torticollis. (B) Dog with rabies. Note open jaw and visible tongue with excessive salivary secretions resulting from the inability to swallow. (Courtesy CDC, Atlanta, USA.)

ganglia, that do not enhance with contrast.[34] In human patients with rabies, no significant abnormalities may be present on MRI, or MRI may show hyperintensities on T2-weighted images, especially in association with the gray matter. Lesions are frequently described in the medulla, pons, basal ganglia, and thalamus and reflect concentrations of rabies virus antigen.[35] Contrast enhancement can be present in comatose human patients but is usually not detected early in the course of illness. CT commonly does not reveal lesions in humans with rabies.

Microbiologic Testing

Diagnostic assays for rabies in dogs and cats are listed in Table 21.3.

Direct Fluorescent Antibody Testing and Immunohistochemistry

Rabies virus diagnosis is generally based on direct fluorescent antibody (DFA) staining for virus on impression smears of brain tissue obtained at necropsy. This is rapid, sensitive, and economic and is performed only in qualified laboratories that have been approved by local or state public health departments. In the United States, a national standardized protocol for rabies testing is published by the CDC.[36] False-negative results with DFA staining are rare when compared with mouse inoculation testing,[37] and all animals with virus in their saliva test positive. A direct rapid IHC test is also available, which has a similar sensitivity and specificity and does not require a fluorescence microscope.[38]

If rabies is suspected, the animal should be handled with extreme caution (see Prevention). Humane euthanasia should be performed, and the entire head should be submitted as soon as possible to public health authorities, so as not to delay postexposure prophylaxis measures for exposed individuals (see Public Health Aspects). Opening the skull using a saw generates aerosols and is not recommended. Although not optimal, if the head is not available, the spinal cord can be submitted. Tissues should be refrigerated and not frozen for optimal test sensitivity. Approved shipping containers should be used, which must be labeled with appropriate warnings.

Antemortem, DFA testing has been used to detect rabies virus in corneal touch impressions and frozen skin biopsy sections from the nuchal area in humans[39,40] or the region of the whiskers in dogs and cats. The sensitivity of this method is as low as 25%, and it should not be used for clinical diagnosis in dogs and cats suspected to have rabies. DFA staining has also been used for detection of rabies virus antigen in extracranial tissues at necropsy, including the tongue, salivary glands, adrenal glands, pancreas, GI tract, and myocardium.[41,42]

Serologic Diagnosis

Serologic tests for rabies virus antibodies are often negative in affected animals, as a result of immune evasion by the virus during the incubation period and possibly also virus-induced immunosuppression after the onset of clinical signs. If seroconversion occurs, it is typically late in the course of illness. Prior vaccination for rabies may result in confusing results. Determination of acute and convalescent titers on serum and determination of CSF antibody titers can aid in the diagnosis of human rabies.[40] In dogs and cats, serologic testing is most commonly used to document proof of prior vaccination, which is required for importation into rabies-free countries. It is not suitable for determining the need for booster vaccinations.[43]

Serologic methods include virus neutralization assays and ELISA assays.[44] The gold standard of rabies serology is the rapid fluorescent focus inhibition test (RFFIT), a virus neutralization assay, which assesses the ability of antibodies to prevent viral replication in cell culture. The fluorescent antibody virus neutralization (FAVN) test has been accepted as an alternative for determining titers in animals before importation. A minimum titer of 0.5 U/mL is required before importation to rabies-free countries is permitted.

Virus Isolation and Mouse Inoculation

Rabies virus can be isolated in a variety of cell culture lines, although isolation may be less sensitive than nucleic acid–based detection methods.[45] Virus isolation and inoculation of mice with tissue from affected patients can be used to confirm rabies virus infection by public health authorities when DFA testing of brain tissue is negative.

TABLE 21.3 Diagnostic Assays Available for Rabies in Dogs and Cats

Assay	Specimen Type	Target	Performance
Direct fluorescent antibody staining or immunohistochemistry	Brain, spinal cord, skin biopsies (latter not recommended in animals), other extracranial tissues	Rabies virus N (nucleocapsid) protein	High sensitivity and specificity on the brain tissue; because a single negative result does not rule out rabies, confirmatory tests such as mouse inoculation or RT-PCR is required for specimens testing negative. Sensitivity when used on extracranial tissues is relatively low.
Serology	Serum or CSF	Antirabies virus antibodies	Virus neutralization assays are the gold standard for serology, although ELISA assays are also available. Rarely useful for diagnosis of rabies, as the antibody response is delayed and so titers are often negative. Titers often determined before importation of animals into rabies-free countries.
Histopathology	Brain, spinal cord	Intracytoplasmic eosinophilic inclusions (Negri bodies)	Detection of Negri bodies has low sensitivity and is currently rarely used as a diagnostic test
RT-PCR	Brain, spinal cord, saliva, CSF, extracranial tissues	Rabies virus RNA	Rapid (within hours), has the potential to be very sensitive and specific; can be used to identify rabies genotypes and strains.

RT-PCR, real-time polymerase chain reaction; *CSF,* cerebrospinal fluid.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Nucleic acid detection techniques are increasingly employed to detect rabies virus in tissues and may ultimately replace techniques such as isolation and histopathology.[46] RT-PCR assays have been used to rapidly detect the RNA of rabies virus and other lyssaviruses in dogs, cats, and humans and, when used on brain tissue, are sensitive and specific, the results correlating with those of DFA testing.[47–49] RT-PCR can be used to detect virus in a decomposing tissue, when the results of other assays might be negative.[50,51] Genetic analysis of resultant PCR products can also be used to identify lyssavirus genotypes and rabies virus variants (see Table 21.1).[52] For antemortem diagnosis in human patients, saliva is more likely to test positive than CSF. A nuchal biopsy specimen can also be tested.[53] The same appears to be true in dogs and cats, although again, attempts to make an antemortem diagnosis of rabies are not recommended in animals.[54] The sensitivity of RT-PCR for detection of rabies virus in the saliva of rabid dogs was 87%, so a negative result does not rule out a diagnosis of rabies.

Pathologic Findings

Gross Pathologic Findings

Gross lesions are generally absent in the CNS of dogs and cats with rabies. Lesions consistent with a previous wound or traumatic event may be present elsewhere on the body.

Histopathologic Findings

Rabies virus infection results in a remarkably mild, nonsuppurative polioencephalomyelitis. Changes include mild neuronal degeneration and neuronophagia, which may be followed by neuronal necrosis.[32] Lymphoplasmacytic perivascular cuffing and focal microglial hyperplasia are frequently described. The longer the duration of illness, the more pronounced the nonsuppurative inflammatory response. Sometimes, a spongiform encephalopathy with vacuolization in the gray matter is present.[21] In some animals, eosinophilic intracytoplasmic viral inclusion bodies (Negri bodies) are identified (Fig. 21.7). Negri bodies are considered a hallmark of rabies virus infection and are most commonly seen in tissues such as the pons, thalamus, hypothalamus, and hippocampus. They are generally only seen once neurologic signs have developed, and only in about 50% of animals that test positive using DFA testing. Inclusions that resemble Negri bodies have been described in the brain of cats and ruminants without rabies, and so the potential for confusion and a false-positive diagnosis of rabies exists.[55]

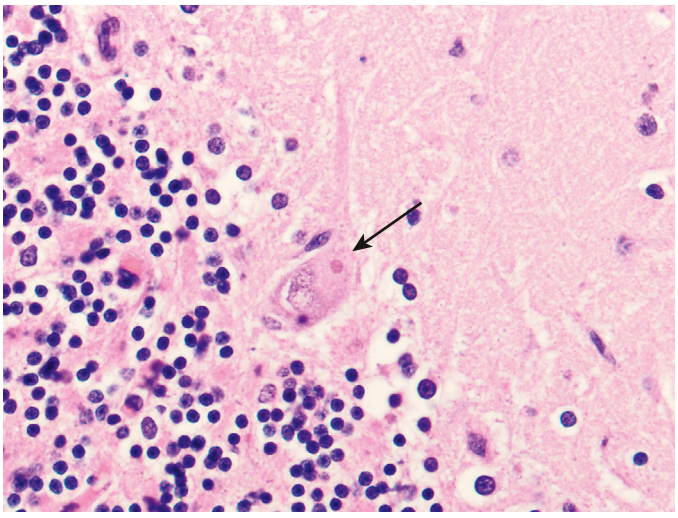

Fig. 21.7 Negri body *(arrow)* in a neuron within the central nervous system (hematoxylin and eosin stain, ×400). (From Kumar V, Abbas AK, Aster JC. *Robbins & Cotran Pathologic Basis of Disease*. 10th ed. Philadelphia, PA: Elsevier; 2021.)

TREATMENT AND PROGNOSIS

Immediate euthanasia and testing of dogs and cats suspected to have clinical signs of rabies is recommended. Once clinical signs have developed, rabies is almost always fatal and very few humans have survived. Most have been children, and several of those individuals had been vaccinated for rabies before the onset of illness. In all individuals, moderate to severe neurologic sequelae persisted. A 17-year-old girl in Texas survived clinical rabies without the need for intensive care.[56] Although a controversial treatment, after treatment with induced coma (the "Milwaukee protocol"), an 8-year old girl survived rabies that may have been acquired after a scratch from a stray cat.[57] Rarely, dogs inoculated experimentally with certain canine rabies virus variants have recovered from rabies encephalitis, sometimes with intermittent shedding of rabies virus in saliva after recovery.[31]

IMMUNITY AND VACCINATION

In most cases of human rabies, no immune response is detectable at 7 to 10 days after the onset of clinical signs. Rabies virus may evade immune recognition through rabies virus phosphoprotein-induced disruption of IFN signaling, as well as inhibition of apoptosis and destruction of invading T cells.[23,58] This may explain the relative lack of an inflammatory response within the CNS.

Currently available vaccines for cats and dogs contain inactivated virus or are canarypox-vectored recombinant rabies (cats) vaccines. Attenuated live rabies vaccines are no longer available in the United States because of their association with occasional postvaccinal rabies encephalitis in dogs and cats.[59] Vaccinia poxvirus-vectored glycoprotein recombinant vaccines are only used for wildlife vaccination.

In the United States, all dogs and cats should be vaccinated for rabies at 3 or 4 months of age (depending on local regulations), with a booster dose 1 year later, then every 3 years with approved inactivated vaccines, or annually with recombinant vaccines (see Chapter 20). It has been recommended that rabies vaccines be administered as distally as possible in the right pelvic limb, to allow better understanding of which vaccines are associated with sarcoma formation and to permit complete removal of sarcomas by amputation should they develop.[60,61] Canine rabies vaccination is required by law within most of the United States, and vaccines must be administered only by (or under the direct supervision of) a veterinarian.[62] Effective vaccination of at least 70% of the dog population is required to prevent rabies epizootics.[63] Owners who fail to comply with state or local requirements should be reported to the public health authorities.

Although rare, rabies has been reported in vaccinated animals, especially when vaccinations are not up to date.[29] Dogs and cats less than 1 year of age are not considered immunized until 28 days after the initial vaccination.[62] Because of a rapid anamnestic response, an animal is considered fully vaccinated immediately after booster vaccination.

The use of inactivated rabies virus vaccines in cats has been associated with formation of injection-site sarcomas.[64,65] More commonly, rabies virus vaccination is associated with pain at the injection site, lameness, transient fever, and local cutaneous reactions, such as alopecia, focal cutaneous vasculitis, and focal granulomas.[66] A more generalized ischemic skin disease characterized by variable alopecia, crusting, erosions, and ulcers on the pinnal margins, periocular areas, tail tip, and paw pads has been described that occurs several months after rabies virus vaccination of dogs and begins with a lesion at the site of vaccination (see Chapter 20).[67]

Oral vaccinia-vectored recombinant rabies vaccines, which express the rabies virus glycoprotein, have been used in Europe and subsequently North America to control the spread of rabies in wild animals

such as foxes, raccoons, and coyotes.[68] Canine and feline rabies vaccines are not approved for use in wild animals, which include wild animal hybrids such as wolf hybrids and Savannah cats. Wolf hybrids and Savannah cats are considered unvaccinated when decisions must be made regarding quarantine and euthanasia (Table 21.4).

PREVENTION

Prevention of rabies is dependent on widespread education of the public regarding the need to vaccinate dogs and cats for rabies, and the risks of wildlife contact. Control of stray dogs and cats and wild animal vaccination programs also help to prevent the disease. Ownership and importation of wild animals and hybrids is discouraged; in July 2021, the CDC issued a ban on the importation of dogs from rabies-endemic countries (113 countries in total). Puppies and kittens that have not yet reached the age for rabies vaccination should be kept away from wildlife.

According to US regulations, unvaccinated dogs and cats that have been exposed to a rabid animal should be euthanized immediately or vaccinated and placed in strict isolation, without direct contact with people or other animals, for 6 months.[62] If the biting animal is a wild animal that is unavailable for testing, the biting animal is presumed to be rabid.

For dogs and cats that are overdue for a booster vaccination, there are two possible outcomes: (1) if the animals have appropriate documentation of having received a USDA-licensed rabies vaccine at least once previously, they should immediately receive veterinary medical care for assessment, wound cleansing, and booster vaccination. The animal should be kept under the owner's control and observed for 45 days; and (2) if appropriate documentation is lacking, they should immediately receive veterinary medical care for assessment and wound cleansing, and local public health authorities should be consulted.[62]

Dogs and cats that are currently vaccinated should be revaccinated immediately (within 48 hours), kept under the owner's control, and observed for 45 days. Any illness in isolated or confined animals should be reported to local public health officials. If clinical signs suggestive of rabies develop, euthanasia and rabies testing should be performed. Ferrets that are overdue for a booster vaccination should be evaluated on a case-by-case basis.

Animals suspected to have rabies should be isolated from other animals and humans and handled with extreme caution, using heavy leather gloves, catch poles, and cages for restraint. Care should be taken not to allow people's skin to come into contact with salivary secretions. Signs that warn of the possibility of rabies should be placed on the cages of animals that are hospitalized for any period of time. If the risk of rabies is low, the animal should be confined and observed for 10 days. The clinician in charge should keep a list of all in-contact personnel during that period, and procedures should be minimized. High-risk rabies suspects should be confined in isolation using an established hospital protocol. Marked improvement in an animal's condition that occurs during a 10-day period is not consistent with a diagnosis of rabies. All specimens submitted to the laboratory should be labeled with warning labels.

TABLE 21.4 Procedures Required by Public Health Officials for Prevention of Rabies According to the Compendium of Animal Rabies Prevention and Control[42]

Situation	Rabies Vaccination History	Procedure	Rationale
Dog or cat exposed[a] to a rabid wild animal or wild animal that is unavailable for testing	Unvaccinated, dog or cat	Euthanize immediately or place in strict isolation for 6 months. Administer rabies vaccine on isolation or up to 28 days before release.	The quarantine period is based on the known incubation period for rabies. Animals that develop signs consistent with rabies during quarantine should be euthanized and tested for rabies.
	Not up to date with booster vaccinations (no proof of prior vaccination for dogs or cats). Not up to date for ferrets.	Contact public health authorities who decide procedures (revaccination or euthanasia) based on biting species, local prevalence of rabies, timing of previous vaccinations.	
	Vaccinated, dog or cat Or not up-to-date with booster vaccinations, but proof of prior vaccination.	Revaccinate, and keep under owner's control and observation for 45 days.	
Human bitten by a healthy dog or cat	Any	Confine animal and observe daily for 10 days; report illness that develops immediately to public health authorities. If signs of rabies develop, euthanize and test for rabies. Vaccination should not be performed until after the isolation period is complete.	Dogs and cats shedding rabies virus within the saliva will develop illness and die within the 10-day quarantine period.
Human bitten by a stray or unwanted dog or cat		Euthanize biting animal immediately and submit for rabies testing.	
Human bitten by a known rabid animal	Vaccinated, human	Vaccinate (1 mL) on day 0 and day 3 intramuscularly, in the upper deltoid muscle.	
	Unvaccinated, human	Postexposure prophylaxis: injection of human rabies immune globulin infiltrated at the bite site, followed by vaccination (1 mL) on days 0, 3, 7 and 14 (and 28 only for immunocompromised persons)	

[a]Exposure for rabies constitutes introduction of the virus into bite wounds, open cuts in skin, or onto mucous membranes from saliva or other potentially infectious material such as neural tissue.

PUBLIC HEALTH ASPECTS

Each year, more than 50,000 people die from rabies worldwide. Approximately half of those numbers occur in India alone, and it has been estimated that 3 billion people continue to be at risk of rabies virus infection in more than 100 countries.[69] A large proportion of these people are children who have been attacked by rabid dogs. In the United States, human deaths due to rabies have decreased from more than 100 per year in the early 20th century to 2–3 per year.[70] Most humans in the United States are infected as a result of contact with insectivorous bats, which often appear injured or are behaving abnormally (including flying during the day), and, depending on the bat species, around 5% to 40% of dead or ill bats submitted for testing have rabies.[71,72] Seemingly insignificant contact with tiny bats, particularly the eastern pipistrelle and silver-haired bats, is reported in many human rabies cases (cryptic bat rabies). Despite the high prevalence of raccoon rabies in the eastern United States, only three human deaths (including one organ recipient) associated with a raccoon rabies variant have been reported.[71,72]

Prodromal signs of rabies in humans include malaise, fever, and pain, itching, or paresthesia at the site of the bite. People with furious rabies become nervous and hyperexcitable, after which signs of hydrophobia, aerophobia, confusion, and aggression develop. Autonomic signs such as hypersalivation, vomiting, miosis or mydriasis, excessive sweating, and priapism may occur. Paralytic rabies can be confused with Guillain-Barré syndrome.[40]

Sick domestic and wild animals that bite humans in regions where rabies is endemic and that subsequently die should be tested for rabies without delay. Prompt and aggressive treatment of wounds including irrigation under pressure with 20% aqueous soap solution, and application of a greater than 50% ethanol solution or povidone-iodine, can dramatically reduce the risk of contracting rabies after a bite.

The chain of events that must occur after a dog or cat bites a human are listed in Table 21.4 and depend on whether the animal is owned or stray, and on the animal's vaccination status.[62] Public health authorities must be notified when potential exposure occurs and make the final decision as to how these animals are handled.

Postexposure prophylaxis (PEP) is administered to humans after a bite from a known or suspected rabid animal. In the United States, it consists of an injection of human rabies immune globulin (H-RIG), ideally with at least half of the whole dose in the region of a bite site as soon as possible within the first 7 days of the bite, followed by a 4-dose vaccination regimen by the IM route on days 0, 3, 7 and 14 (and 28 in immunocompromised individuals) in the upper deltoid muscle with 1 mL of vaccine.[73] Fewer than 5 humans develop rabies each year in the United States, but PEP is given to 20,000 to 40,000 people each year, with on average 50 people receiving PEP for each rabies case investigated.

Depending on the risk, certain individuals may receive prophylactic vaccines against rabies. These individuals include veterinarians, veterinary students and staff, dog catchers, rabies researchers, rabies diagnosticians, wildlife workers, and travelers visiting rabies-enzootic regions. After exposure to a rabid animal, administration of immunoglobulin to these individuals is not necessary. Instead, rabies vaccine boosters are given immediately and 3 days later. The major vaccine in use in the United States is the human diploid cell vaccine (HDCV), although in developing countries, access to this vaccine is limited. Among animal workers, antibody titers are generally checked every 2 years, with administration of a booster dose if necessary.

Canine Distemper Virus Infection

Jane E. Sykes, Marc Vandevelde

KEY POINTS

- First Described: 1905, Henri Carré, France.[1]
- Cause: CDV (family *Paramyxoviridae,* subfamily *Paramyxovirinae,* genus *Morbillivirus*).
- Affected Hosts: Dogs and other Canidae such as coyotes, foxes, and wolves; Procyonidae (raccoons, pandas); Mustelidae (ferrets, mink, skunks, otters); non-human primates. Large wild Felidae can also be affected.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Oronasal contact with virus in secretions or excretions, droplet nuclei, and large-particle aerosol transmission.
- Major Clinical Signs: Fever, lethargy, inappetence, vomiting, diarrhea, dehydration, tachypnea, cough, conjunctivitis, neurologic signs, footpad and nasal planum hyperkeratosis.
- Differential Diagnoses: Canine parvovirus infection, other infectious causes of gastroenteritis, other causes of canine infectious respiratory disease, rabies, parasitic GI and respiratory disease, toxins such as lead and ethylene glycol, GI foreign body, dietary indiscretion, protozoal meningoencephalitis, systemic fungal infections such as cryptococcosis, portosystemic shunting with hepatic encephalopathy.
- Human Health Significance: CDV has been used as a model to study measles virus infection. The white matter lesions in the brain are considered to be a model for multiple sclerosis. There is some evidence that it may be involved in the pathogenesis of Paget's disease, a chronic, focal skeletal disorder of the elderly. Distemper outbreaks in primates raise concern about zoonotic potential of CDV.

ETIOLOGY AND EPIDEMIOLOGY

Canine distemper is an important disease of domestic dogs and wild animals worldwide. It is caused by CDV, an enveloped, pleomorphic negative-stranded RNA virus that belongs to the genus *Morbillivirus* (family *Paramyxoviridae*). CDV is closely related to the human measles virus and rinderpest virus and has been used as a model to study the pathogenesis of measles virus infections. The outer envelope of CDV contains hemagglutinin (H) and fusion (F) proteins, which are important in cellular attachment and entry (Fig. 22.1). Infection of dogs can lead to a severe, multisystemic disease that primarily affects the GI, respiratory, and neurologic systems (Fig. 22.2).

The host species spectrum of CDV is unusually wide. It includes terrestrial as well as aquatic mammals and affects the orders Carnivora (in 12 families that include Canidae, Mustelidae, Procyonidae, and Felidae), Rodentia (four families), Primates (two families), Artiodactyla (three families), and Proboscidea (one family).[2] Ferrets also are highly susceptible to distemper, but domestic cats are not affected. Virus shed by wildlife species such as raccoons can infect domestic dogs, but virus that is shed by dogs may also be a significant threat to wildlife populations, with catastrophic outbreaks of disease and high mortality rates.[3,4] A high prevalence of anti-CDV antibodies was detected in coyotes, red foxes, and gray foxes from Pennsylvania, USA, which raised concerns about the degree of spillover occurring between domestic dog and wild canid populations.[5] In domestic dogs with signs of infectious upper respiratory disease ("kennel cough"), distemper is an important differential diagnosis, and distemper can also mimic CPV enteritis. In fact, dual infections with CDV and CPV are probably underrecognized. Despite minor genetic variation, CDV isolates are serologically homogeneous. However, various strains differ in their pathogenicity, which may affect the severity and extent or type of clinical disease. Certain isolates, such as Snyder Hill, A75/17, and R252 strains, are highly virulent and neurotropic. The Snyder Hill strain causes polioencephalomyelitis, whereas the latter two strains cause demyelination. Other strains vary in their ability to cause CNS lesions. Properties of proteins coded by the N- and M-genes also affect viral persistence[6] and the ability to cause CNS disease.

Worldwide, a growing number of geographic lineages (also referred to as genotypes or clades) of CDV exist based on sequence analysis of the H-gene: Asia-1, Asia-2, Asia-4, India-1/Asia-5, America-1, America-2, Europe-1/South America-1, Europe-2 (Europe wildlife), South America-2, South America-3, Arctic, Rockborn-like, Africa-1, and Africa-2.[7] In the United States, vaccine strains belong to the America-1 lineage, whereas most field strains belong to the America-2 lineage. Strains that belong to the Europe-2 and Europe-3 lineages have also been detected in North American dogs.[1,8–10] In 2021, additional lineages were detected in wildlife in Ontario, Canada (Canada-1)[11] and red pandas in China.[12] Whether strains contained in CDV vaccines provide adequate protection against all wild-type viruses that currently circulate has been controversial. For example, one recent case series described CNS lesions associated with CDV infection in 4 vaccinated dogs, 2 of which were found to be infected with South American wild-type strains not included in the vaccine.[13] However, most disease in vaccinated dogs likely reflects failure of adequate vaccination, rather than lack of strain cross-reactivity.

Contact among recently infected (subclinical or diseased) animals maintains the virus in a population, and the birth of puppies helps provide a susceptible population for infection. Dogs that are not properly vaccinated can become infected after stress, immunosuppression, or contact with diseased individuals. Based on results of serosurveys, the infection rate is considered to be higher than the disease rate,[14] which reflects a certain degree of natural and vaccine-induced immunity in the general dog population. Many susceptible dogs can become subclinically infected but eliminate the virus without showing signs of illness. Although most recovered dogs clear the virus completely, some may harbor virus in their CNS.

The prevalence rate of spontaneous distemper in cosmopolitan dogs is greatest between 3 and 6 months of age, correlating with the loss of MDAs in puppies after weaning. In contrast, in susceptible, isolated populations of dogs, the disease is severe and widespread, affecting all ages. Increased susceptibility among breeds has been suspected but not proven.

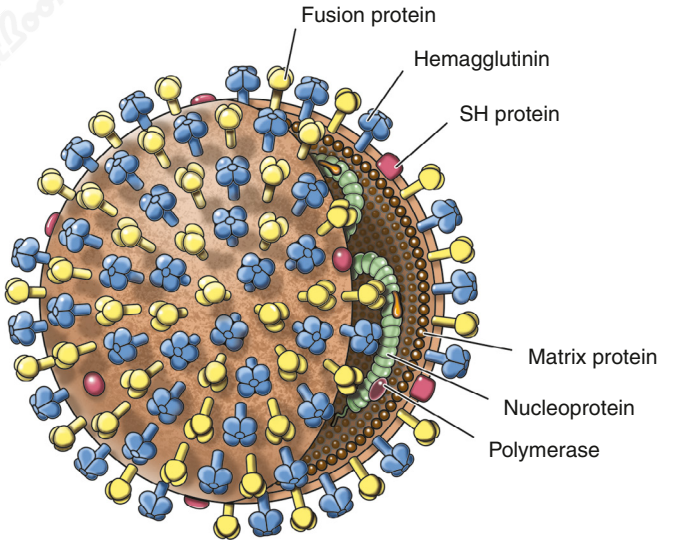

Fig. 22.1 Structure of CDV. The outer envelope contains hemagglutinin (H) and fusion (F) proteins, which are connected to the nucleocapsid by a matrix (M) protein, which is the most abundant protein in the virion. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

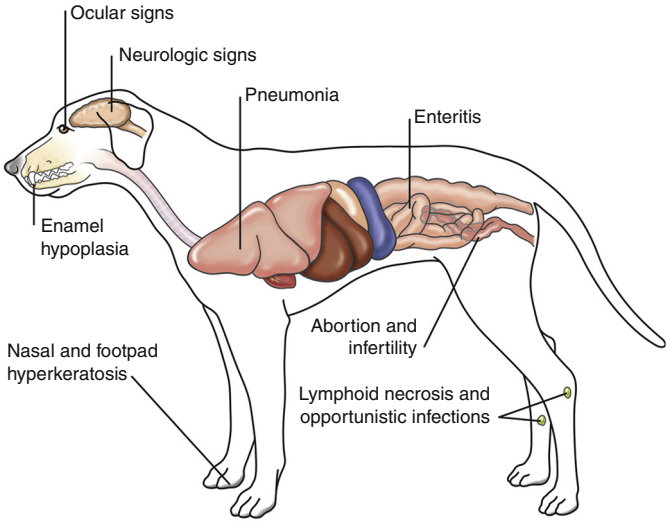

Fig. 22.2 Anatomic sites targeted by CDV infection. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Brachycephalic dogs have been reported to have a lower prevalence of disease, mortality, and sequelae compared with dolichocephalic breeds. Although vaccination has reduced the incidence of the disease, distemper still remains important where large numbers of young dogs with inadequate immunity are housed together, such as in kennels, large breeding facilities, and shelter environments. Puppies that have lost their maternal antibody are predisposed in regions where vaccination is performed, but occasionally disease occurs in older, vaccinated dogs.[15–17] Distemper also occurs in regions where vaccination of dogs is not performed or is poorly timed. As an enveloped virus, CDV is susceptible in the environment (surviving less than 1 day at room temperature) and is readily inactivated by heat, drying, and disinfectants; thus, contact between infected dogs is important to maintain transmission of the virus.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

CDV is highly contagious and is spread through droplet nuclei and large-particle aerosol transmission. Dogs are generally exposed to CDV through contact with infected oronasal secretions, which may be shed by subclinically or clinically affected dogs. The virus initially infects monocytes within lymphoid tissue in the upper respiratory tract and tonsils and is subsequently disseminated via the lymphatics and blood to the entire reticuloendothelial system (Fig. 22.3). Within 24 hours PI, CDV multiplies in tissue macrophages and spreads in these cells via local lymphatics to tonsils and bronchial lymph nodes.[18] By days 4 to 6 PI, virus multiplication occurs within lymphoid follicles in the spleen, the gut-associated lymphatic tissue of the lamina propria of the stomach and small intestines, the mesenteric lymph nodes, and Kupffer cells in the liver. The viral hemagglutinin binds to a molecule on the surface of host cells known as the signaling lymphocytic activation molecule (SLAM, also known in humans as CD150). SLAM is a membrane glycoprotein of the immunoglobulin superfamily. It is important for cell entry by CDV as well as other morbilliviruses and is a key molecule in the pathogenesis of disease.[19] SLAM is expressed by immature thymocytes, activated lymphocytes, macrophages, and dendritic cells. Direct viral destruction of a significant proportion of the lymphocyte population, and especially CD4+ T cells, occurs within the blood, tonsils, thymus, spleen, lymph nodes, bone marrow, mucosa-associated lymphoid tissue, and hepatic Kupffer cells (Fig. 22.4).[20–22] Massive destruction of lymphocytes results in an initial lymphopenia and transient fever, which occurs a few days after infection. Acute CDV infection causes lymphocytic apoptosis, T-cell depletion, and long-lasting immunosuppression.[22–24] Prenatal and neonatal distemper infections can result in immunodeficiency in surviving puppies and can make concurrent infections with other viruses such as parvovirus, bacteria such as *Clostridium piliforme*, or protozoa such as *Neospora caninum* more severe.[25,26]

Further spread of CDV to epithelial and CNS tissues on days 8 to 9 PI probably occurs hematogenously as a cell-associated and plasma-phase viremia using the nectin 4 receptor[27] and its intensity depends on the dog's humoral and cell-mediated immune status. By day 14 PI, animals with adequate CDV antibody titers and cell-mediated cytotoxicity clear the virus from most tissues early on and show no clinical signs of illness. Recovery from CDV infection is associated with long-term immunity and cessation of viral shedding. Dogs with intermediate levels of cell-mediated immune responsiveness with delayed antibody titers by days 9 to 14 PI experience viral spread to their epithelial tissues. Clinical signs that develop may eventually resolve as antibody titer increases and virus is cleared from most body tissues.

By days 9 to 14 PI, in dogs with poor immune status, there is spread of virus to many tissues, including skin, exocrine and endocrine glands, and epithelium of the GI, respiratory, and genitourinary tracts. Clinical signs of disease in these dogs are usually dramatic and severe, and virus usually persists in their tissues until death. A frequent site of persistence is the skin, notably the foot pads ("hard pad disease") associated with hyperkeratosis and parakeratosis with vesicle, pustule, and inclusion body formation.[28] Virus entering the footpad epithelium during the viremic period causes proliferation of basal keratinocytes, resulting in the observed hyperkeratosis; however, neither the virus nor its nucleic acid appears to persist indefinitely.[29–31] Cytokine expression is upregulated in virus-infected footpad epidermal cells.[32,33] Alteration in the viral H protein gene sequence has been associated with this viral adaptation.[34]

Neuroinvasion occurs when viremia is of sufficient magnitude, which depends on the quality of the systemic immune response mounted by the host. In dogs, free or lymphocyte-associated virus can enter the brain by crossing the blood-brain barrier or the CSF via the choroid plexus, where it spreads to periventricular and subpial structures explaining the distribution of the ensuing lesions.[35] At least in

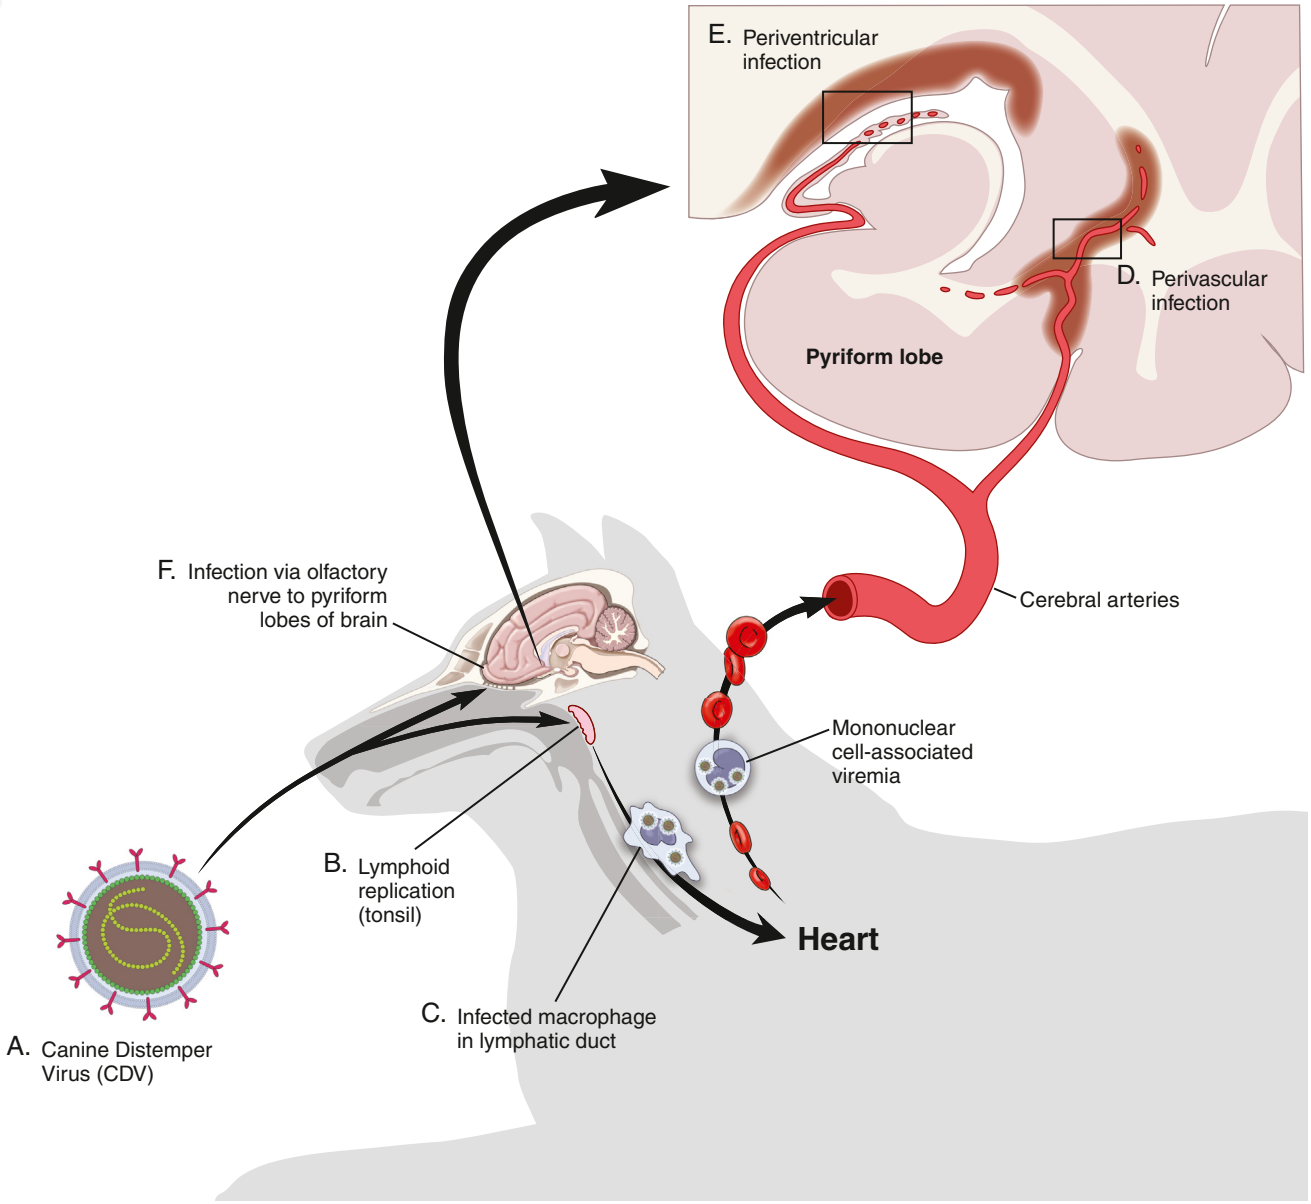

Fig. 22.3 Pathogenesis of distemper virus infection. *A,* CDV enters the respiratory tract via aerosols and colonizes the local lymphoid tissues such as the tonsils. *B,* Primary viral replication occurs in the tonsils, retropharyngeal nodes, bronchial lymph nodes, and GI lymphoid tissue. *C,* From these sites of primary replication, mononuclear cell-associated viremia occurs. *D,* Virus enters the CNS via the cerebral circulation and is deposited in the perivascular spaces of fine blood vessels. *E,* Alternatively, virus enters the vessels of the choroid plexus and eventually the CSF and ventricular system. *F,* As an uncommon phenomenon in dogs, CDV can travel from the nasal passage, through the cribiform plate and anterograde via the olfactory nerve to the olfactory bulb and CNS. There it localizes, predominantly in the pyriform lobes of the cerebral cortex.

ferrets, CDV can spread from the olfactory mucosa through the olfactory bulb and nerve to the brain. It is possible that selective polioencephalomalacia of rhinencephalic structures (including the pyriform and temporal lobes) in young puppies may result from olfactory invasion by CDV.[36]

The type of lesion produced and the course of infection within the CNS depend on numerous factors, including the age and immunocompetence of the host at the time of exposure, the neurotropic and immunosuppressive properties of the virus, and the time after infection at which lesions are examined. Gray matter lesions are the result of neuronal infection and necrosis and can lead to polioencephalomalacia. However, neuronal infection can also occur with minimal evidence of cytolysis and accumulation of viral inclusion bodies. Demyelination occurs in the white matter following productive viral replication in microglial and astroglial cells (Fig. 22.5). In oligodendrocytes, which produce myelin, infection is restricted to viral transcription without translation, which likely leads to metabolic dysfunction and degeneration of oligodendroglial cells. The end result is demyelination via a downregulation of myelin gene expression.[35] Other studies suggest that demyelination may be secondary to axonal damage.[37]

Because of immunosuppression, classical signs of inflammation are lacking in acute lesions, but there is a marked increase in CD8+ T cells throughout the CNS in dogs with acute distemper in response to the presence of the CDV nucleocapsid protein and increased Il-8

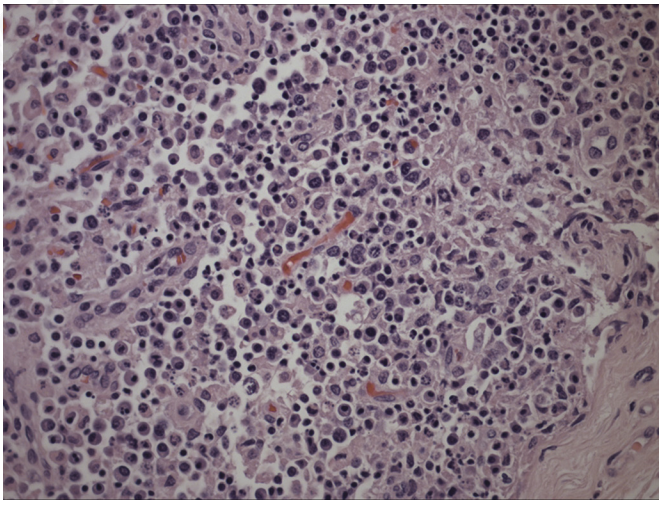

Fig. 22.4 Lymph node histopathology of a 5-month-old German shepherd mix with distemper. The dog had been adopted from a shelter and subsequently developed neurologic signs, diarrhea, and pneumonia. There is marked lymphoid necrosis. Hematoxylin and eosin stain. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

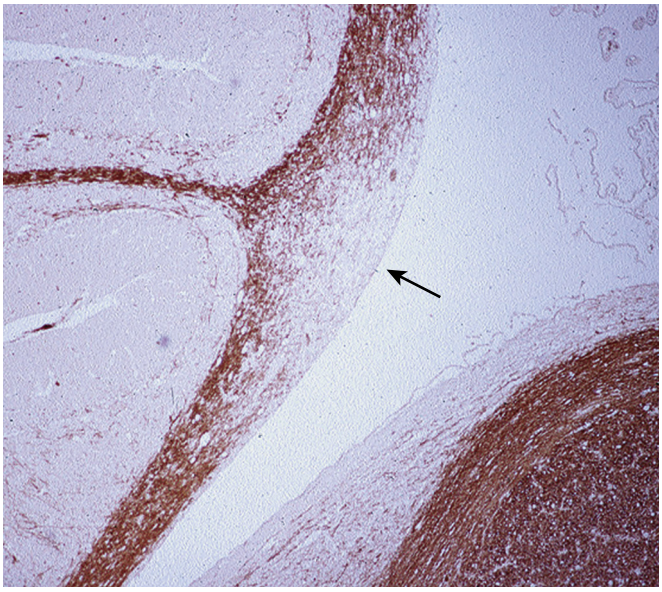

Fig. 22.5 Histopathology showing acute noninflammatory demyelination, with loss of myelin staining *(arrow)*. There is minimal inflammation in these lesions, which are typical for dogs with poor anti-CDV immunity (myelin-basic protein immunostain ×20).

activity.[38,39] Diffuse MHCII upregulation has also been recognized,[40] which may result from elevated levels of IFN-γ; this is frequently seen in viral infections in general.[41] Besides upregulation of MHC molecules, microglial cells in distemper exhibit enhanced secretion of reactive oxygen radicals.[42] Proinflammatory cytokines are upregulated in distemper lesions, whereas anti-inflammatory cytokines remain unchanged.[43] In the subacute to chronic stage of CDV encephalitis, perivascular mononuclear cell infiltrations develop (Fig. 22.6) because these animals are recovering from lymphoid depletion throughout the body, and they have a significant increase in T- and B-lymphocyte populations. These cells induce a strong humoral immune response, and increased intrathecal virus-neutralizing antibodies are present.[44,45] Antibodies to CDV appear to interact with infected macrophages in CNS lesions, causing their activation with the release of reactive oxygen radicals. This activity can lead to further destruction of oligodendroglial cells and myelin through an "innocent bystander" mechanism.[46,47] Thus, the reaction of the immune system, not viral interference, is the pathogenic mechanism for demyelination in this phase. If viral spread through the CNS has been extensive by the time the host immune system responds to the virus, widespread damage occurs with a fatal outcome. Some animals may recover because CDV is completely cleared from the inflammatory lesions. Frequently, CDV persists in the brain,[48] and keeps driving the inflammatory response and collateral white matter damage, which results in a chronic progressive or rarely a chronic relapsing disease. Persistence is related to noncytolytic cell-to-cell spread of viral nucleocapsids. By the time the infection is detected by the immune system, with an associated inflammatory response, CDV has already spread further to an area remote from the inflammatory focus. Thus, CDV "outruns" the immune system by rapidly spreading through the astroglial network using an as-yet unknown glial receptor. "Old dog encephalitis" is an exceedingly rare, poorly characterized form of distemper, manifested as a chronic progressive demyelinating panencephalitis similar to subacute sclerosing panencephalitis, a measles virus–induced disease in children. The term "old dog encephalitis" is a misnomer, because affected dogs are not necessarily old. Virus has been detected within the brains of these dogs with immunohistochemistry and RT-PCR assays.[25]

CDV is shed in all secretions and excretions from as early as day 5 after infection, before the onset of clinical signs. Shedding of virus can continue for as long as 3 to 4 months, but usually resolves after 1 to 2 weeks.

The clinical signs of distemper in dogs vary dramatically and are highly dependent on virus strain and the age and immune status of the host, as well as concurrent infections with other viruses and bacteria. Many dogs experience subclinical infection, whereas others exhibit rapidly progressive infection followed by death. The incubation period ranges from 3 to 6 days. Respiratory or GI tract signs may be indistinguishable from those caused by other respiratory or enteric viruses and bacteria, or signs may be so mild that they go unnoticed by the owner. Dogs with respiratory involvement may exhibit fever, bilateral serous and nasal ocular discharges, conjunctivitis, and a nonproductive cough. Secondary bacterial infection, which occurs unhindered as a result of virus-induced immunosuppression, can lead to the development of mucopurulent nasal and ocular discharges and bacterial bronchopneumonia, with tachypnea, productive cough, lethargy, and decreased appetite. Viral destruction of the GI tract epithelium can result in inappetence, vomiting, diarrhea, electrolyte abnormalities, and dehydration. Dogs that mount an intermediate or delayed immune response may recover from acute illness but fail to eliminate the virus completely, which leads to a spectrum of more chronic disease manifestations, which often involve the uvea, lymphoid organs, footpads, and especially the CNS. Opportunistic infections can also develop in these dogs, whereas dogs developing nasal and digital hyperkeratosis usually have various neurologic complications.

Neurologic manifestations usually begin 1 to 3 weeks after recovery from systemic illness; however, no way is known to predict which dogs will develop neurologic disorders. Neurologic signs can also coincide with multisystemic illness, or less commonly, they can occur weeks to months later. Neurologic signs frequently develop in the presence of nonexistent or very mild extraneural signs.[49] Neurologic signs, whether acute or chronic, are typically progressive. Chronic relapsing neurologic deterioration with an intermittent recovery and a later, superimposed acute episode of neurologic dysfunction can occur. Neurologic complications of canine distemper are the most significant factors affecting prognosis and recovery from infection. Neurologic signs vary according to the area of the CNS involved. Hyperesthesia

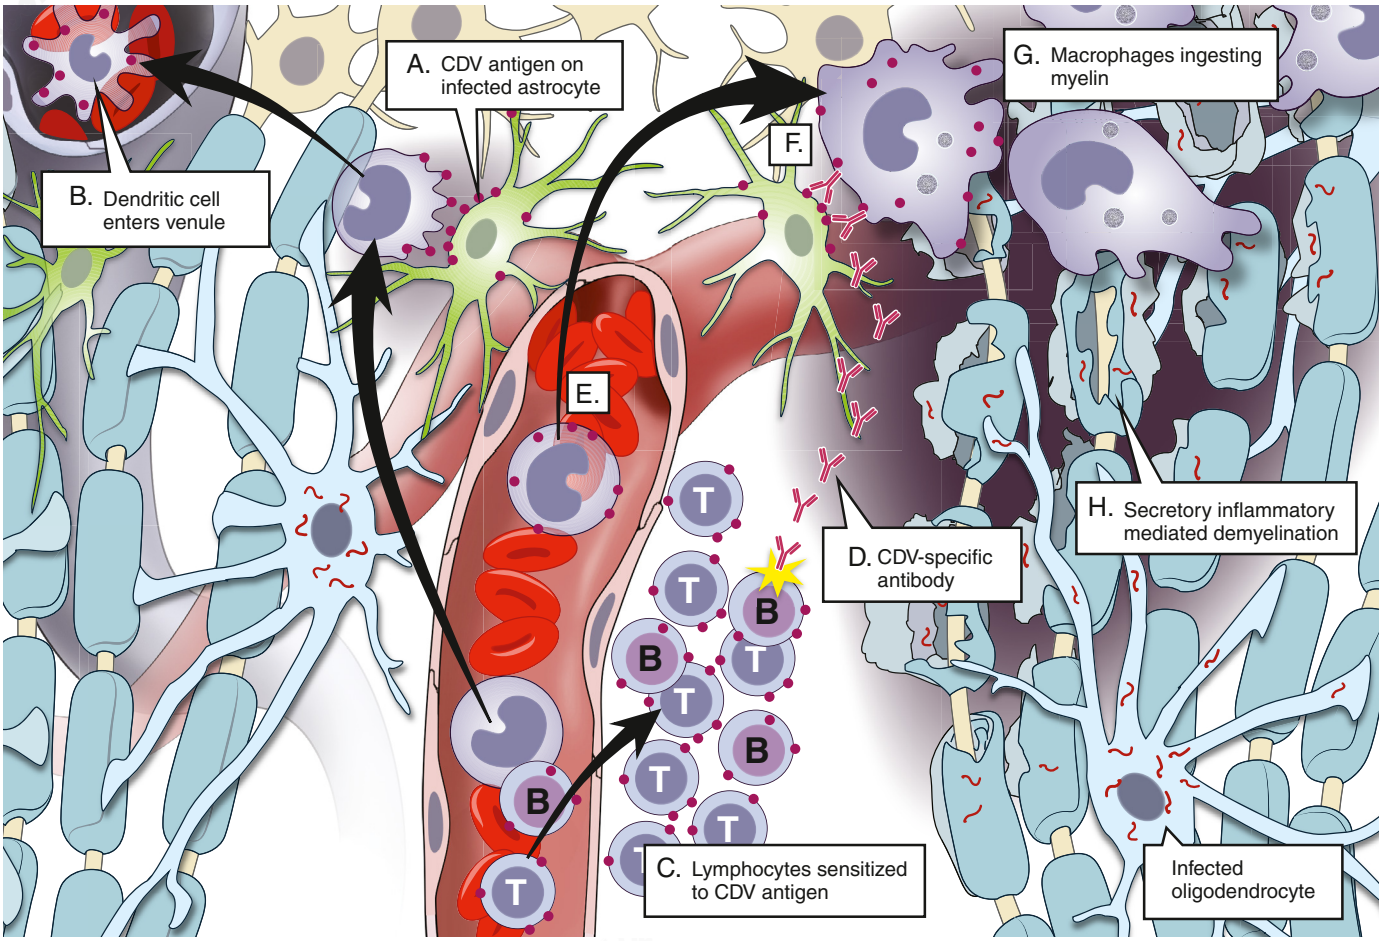

Fig. 22.6 Chronic perivascular cuffing with demyelination. For periods after viral infection, low quantities of unenveloped viral nucleocapsids remain in astrocytes with minimal cellular inflammatory response. Virus may also be found in oligodendrogliocytes and some neurons as untranslated viral RNA. ***A,*** CDV antigens are expressed on the surface of astrocytes. Signaling lymphocyte activation molecule (SLAM) on the surface of immune cells such as dendritic cells interacts with this viral antigen. ***B,*** Macrophages activated by the viral interaction transform to dendritic cells and emigrate from the CNS via venules and enter the systemic circulation, traveling to lymph nodes. There they present antigen to T cells and cause CDV-specific activation of other immunocytes. ***C,*** Lymphocytes, now sensitized to CDV antigens, enter the CNS via the blood vessel as a result of immune recruitment. Perivascular cuffing occurs with antigen-directed B cells and $CD8^+$ and $CD4^+$ T cells. ***D,*** B cells synthesize and release CDV-specific antibody. ***E,*** Similarly, sensitized mononuclear cells enter the perivascular space of the CNS with increased expression of cytokines (interleukin [IL]-6, IL-8, IL-12, and tumor necrosis factor-α) as a heightened immune response against the virus. ***F,*** CDV-specific antibody from the B cells that has become bound to surface antigen of infected astrocytes attracts activated monocyte/macrophages, displaying increased major histocompatibility complex class II and SLAM molecule expression. These bind to the Fc portion of this bound antibody, triggering antibody-dependent, cell-mediated cytotoxicity. In this process, activated macrophages secrete "highly active molecules" (e.g., matrix metalloproteinases, their associated inhibitors, and reactive oxygen radicals). These radiate into surrounding tissue, further damaging the blood-brain barrier, myelin, and other cellular elements in a "bystander" mechanism. ***G,*** Myelin unraveling and fragmentation occur as a result of the inflammation and necrosis. ***H,*** Macrophages ingest degenerating myelin and necrotic debris as a part of the clean-up process.

and cervical or paraspinal rigidity can be found in some dogs as a result of meningeal inflammation. Seizures, cerebellar and vestibular signs, paraparesis or tetraparesis with sensory ataxia, and myoclonus are common. Seizures can be of any type, depending on the region of the forebrain that is damaged by the virus. Myoclonus, the involuntary twitching of muscles in a forceful simultaneous contraction, can be present without other neurologic signs. The rhythmic flexor-extensor contractions of myoclonus can be present while a dog is awake, although they more commonly occur during sleep. Although considered specific for CDV infection, myoclonus can also be seen in other paramyxovirus infections of dogs and cats and, less commonly, in other inflammatory conditions of the CNS.[50] Ocular signs of persistent CDV infection include uveitis, chorioretinitis, keratoconjunctivitis sicca (KCS), keratitis, and optic neuritis, which may be associated with blindness. KCS is thought to result from damage to the lacrimal gland by CDV.[22] It may be transient or permanent, and can lead to keratitis and corneal ulceration. The virus itself can also infect the corneal epithelial and stromal cells. Young puppies infected with CDV before the eruption of permanent dentition can have severe damage to the enamel, dentin, or roots of their teeth. Enamel or dentin can show

an irregular appearance in addition to partial eruption, oligodontia, or impaction of teeth. Enamel hypoplasia with or without neurologic signs may be an incidental finding in an older dog and is relatively pathognomonic for prior infection with CDV (Fig. 22.7). Infection of the skin can lead to a vesicular and pustular dermatitis, although this is uncommonly recognized. Persistent infection of the footpad and nasal planum epithelium leads to hyperkeratosis in these regions (Fig. 22.8). Myocarditis has been rarely described in puppies, with evidence of viral inclusions in cardiomyocytes at necropsy.[51]

Immunosuppression results from lymphopenia, necrosis of hematopoietic cells in the bone marrow, and dendritic cell malfunction. Lymphocyte apoptosis also occurs independent of viral infection of lymphocytes. The viral V protein allows CDV to replicate rapidly in T cells and is critical in CDV-mediated immunosuppression. This protein almost completely antagonizes IFN-α, TNF-α, IL-6, IFN-γ, and IL-2 in the acute phase of infection.[22] Finally, the nucleocapsid (N) protein

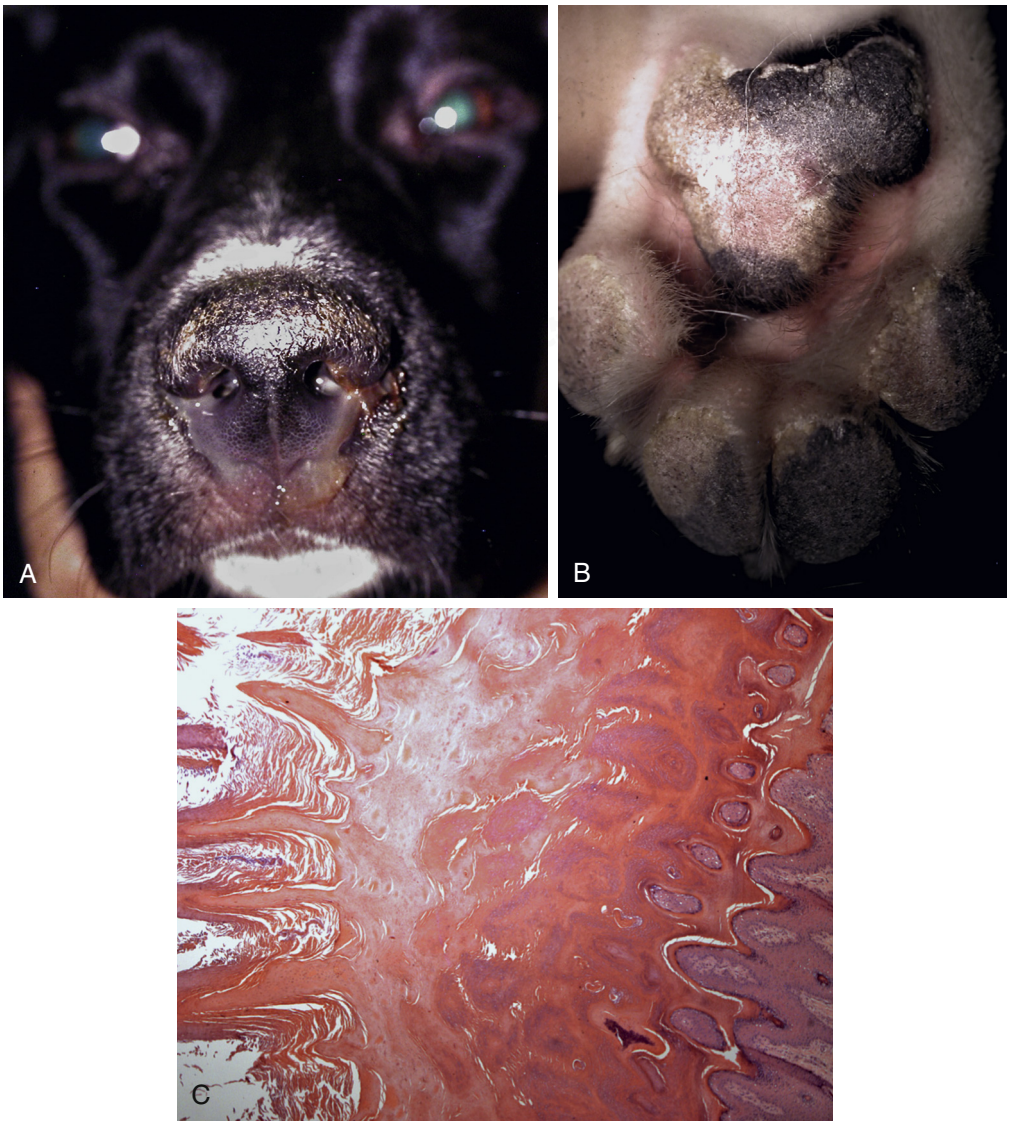

Fig. 22.8 Nasal planum (A) and footpad (B) hyperkeratosis induced by CDV infection in a 4-month-old border collie mix with conjunctivitis, mucopurulent nasal and ocular discharge, and myoclonus. Blepharospasm is also present. (C) Histopathology of the footpad of a 1-year-old German shepherd mix with distemper. Marked hyperkeratosis is evident. Hematoxylin and eosin stain, 40× magnification. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

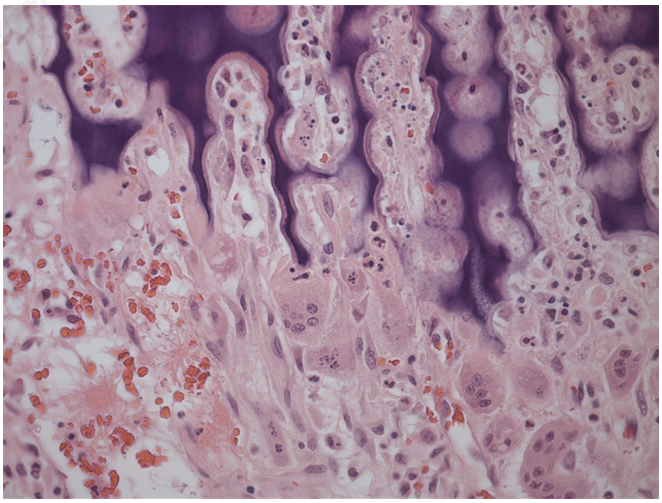

Fig. 22.9 Severe, neutrophilic osteomyelitis with submetaphyseal osteonecrosis and extensive bony resorption in a 4-month-old intact male Labrador retriever mix with distemper. The dog was seen for lethargy, mild diarrhea, fever, and reluctance to stand; joint pain was detected on physical examination. Direct IFA on urine sediment was positive for CDV, but a conjunctival scrape tested negative with direct IFA. Necropsy also revealed pneumonia with intracytoplasmic and intranuclear viral inclusions. Hematoxylin and eosin stain. (From Sykes JE. *Canine and Feline Infectious Diseases.* Elsevier; 2014.)

of morbilliviruses binds to the CD32 (Fc-γ) receptor on B cells, which results in impaired differentiation of B cells into plasma cells.[52] When the virus binds this receptor on dendritic cells, impaired antigen presentation by dendritic cells results, which disrupts T-cell function. The most common secondary infections in distemper are secondary bacterial infections that contribute to bronchopneumonia. *Bordetella bronchiseptica* is a common copathogen. Dogs may be diagnosed with bordetellosis in the early stages of distemper, and the underlying CDV infection may be overlooked. Other opportunistic infections that have been identified in dogs with distemper include toxoplasmosis,[53] salmonellosis,[54], nocardiosis,[55,56] and generalized demodecosis. Infection with *Pneumocystis carinii* was associated with CDV infection in a mink,[57] and concurrent neosporosis and canine distemper was reported in a raccoon.[58]

Uncommonly, CDV infection has been associated with metaphyseal bone lesions in young dogs as a result of infection of osteoclasts, osteoblasts, and osteocytes.[59] Infected cells undergo degeneration and necrosis, and metaphyseal osteosclerosis occurs (Fig. 22.9). This may lead to pain and lameness. CDV RNA has also been detected in bone cells of dogs with hypertrophic osteodystrophy, and CDV may play a role in this disease.[60] It has been shown that CDV surface proteins promote osteoclast formation.[61]

Finally, transplacental infections with CDV may be associated with infertility, stillbirth, or abortion and with neurologic signs in puppies that are less than 4 to 6 weeks of age.

Physical Examination Findings

Physical examination findings in dogs with distemper depend on the severity and chronicity of the disease, but include fever (occasionally up to 106°F or 41.1°C), conjunctivitis, serous to mucopurulent ocular and nasal discharges, blepharospasm and photophobia, tonsillar enlargement and hyperemia, tachypnea, and increased lung sounds (see Fig. 22.8). Cough may occur during the examination. Dehydration may also be present, especially in dogs with GI and severe neurologic signs. Rarely, a measles-like cutaneous rash or pustular dermatitis is evident.

Dogs with chronic disease can be thin or emaciated and show hyperkeratosis of the nasal planum and footpads. Puppies with hyperkeratosis, also known as "hardpad," have thickened, crusty footpads that resemble those of adult dogs (see Fig. 22.8). Myoclonus (involuntary twitching of isolated muscle groups) is common and, when mild, is most readily detected when affected puppies are at rest. Other neurologic signs include obtundation, seizures, tremors, opisthotonos, tetraparesis, paraparesis, delayed placing reactions, ataxia, and, less commonly, behavioral abnormalities, compulsive pacing, and vestibular signs such as a head tilt, nystagmus, strabismus, and circling.[15] Progressive lower motor neuron signs and hyperesthesia were described in one 4-month-old dog in association with a focal cervical spinal cord lesion on MRI.[62] Focal seizures may be localized to the head and jaw, with accompanying foamy hypersalivation ("chewing gum" seizures). Vocalization and apparent blindness can also occur. In addition to conjunctivitis and ocular discharge, an ophthalmologic examination may reveal corneal edema, corneal ulceration, aqueous flare, chorioretinitis, uveitis, or optic neuritis. Markedly decreased Schirmer tear test results and positive fluorescein tests may be present.[63] Optic neuritis appears as a large, pale, fluffy, optic disc with no physiologic depression. Rarely, lameness may be observed.

Dogs that have recovered from CDV infection may have evidence of dental abnormalities and enamel hypoplasia (see Fig. 22.7); healed chorioretinitis lesions, which appear as hyperreflective circular lesions ("gold medallion lesions"); keratoconjunctivitis sicca; or residual neurologic signs, especially myoclonus.

DIAGNOSIS

Practical diagnosis of canine distemper is primarily based on clinical suspicion. A characteristic history of a 3- to 6-month-old unvaccinated puppy with a compatible illness supports the diagnosis. Establishment of a diagnosis of distemper is most easily accomplished in dogs that have the full spectrum of clinical abnormalities, and especially when myoclonus is present, because there are few other diseases that cause this array of clinical signs. In dogs with isolated respiratory, GI, or neurologic signs, antemortem diagnosis is more challenging because these signs are less specific, laboratory diagnostic assays can be insensitive, and the presence of attenuated live vaccine virus can lead to false-positive results. A combination of laboratory tests may be required to establish the diagnosis, and the finding of a negative result for any assay does not rule out distemper. Sensitivity for detection of CDV using assays that detect virus may also be increased by testing of multiple specimens from different anatomic locations, such as various combinations of blood, urine, conjunctival smears, and CSF. In dogs with respiratory signs, the presence of conjunctivitis, blepharospasm, and ocular discharge should raise suspicion for distemper. Distemper should always be considered as a diagnosis in young dogs with neurologic signs, whether or not respiratory or GI signs are present. Finally, clinicians should maintain a high suspicion for the presence of concurrent infections such as parvoviral enteritis, concurrent respiratory viral infection, or bordetellosis.

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs with acute distemper most commonly reveals mild anemia and an absolute lymphopenia caused by lymphoid depletion. This frequently persists in very young dogs with rapidly progressive systemic or neurologic signs. The lymphocyte count may also be normal, especially in more chronic distemper. Thrombocytopenia (as low as 30,000 cells/μL) and regenerative anemia have been found in experimentally infected neonates (aged less than 3 weeks) but have not been consistently recognized in older or spontaneously infected dogs

TABLE 22.1 Complete Blood Count Findings at Admission in 50 Dogs Diagnosed with Distemper at the UC Davis VMTH

Test	Reference Range	Percent Below the Reference Range	Percent Within the Reference Range	Percent Above the Reference Range	Range for Dogs with Distemper
Hematocrit (%)	40–55	80	20	0	17–53

(Table 22.1). Neutropenia, monocytopenia, can occur, and occasionally these are severe. Neutrophilia with a left shift and toxic neutrophils may be present.

Serum Biochemical Tests

Abnormalities on the serum biochemistry panel in dogs with distemper are nonspecific and include electrolyte changes that occur with vomiting and diarrhea such as hyponatremia, hypokalemia, and hypochloridemia (Table 22.2). Hypoalbuminemia and associated hypocalcemia are also common. Mild increases in liver enzyme activities occur in some dogs, which may reflect hypoxia or secondary infections that occur as a result of translocation of intestinal bacteria.

Urinalysis

No specific urinalysis findings are reported in dogs with distemper.

CSF Analysis

Abnormalities of the CSF are detectable in dogs with neurologic signs of distemper; however, dogs with acute noninflammatory demyelinating encephalomyelitis may have normal CSF analysis results. Increases in protein (more than 25 mg/dL) and cell count (more than 10 cells/μL with a predominance of lymphocytes) are characteristic of subacute to more chronic, inflammatory forms of CDV encephalomyelitis.[15] Increased anti-CDV antibody (see section on serology) in CSF could be definitive evidence of distemper encephalitis because antibody is locally produced. An antibody ratio can help identify the effect of nonspecific leakage of distemper-specific IgG into the CSF from serum by dividing the concentration of distemper-specific IgG in CSF by that of IgG in serum and comparing the result with a corresponding CSF-serum antibody ratio for another infectious agent such as CAdV or CPV. If the ratio for CDV is higher than that for CAdV or CPV, then *de novo* local production of CSF antibody caused by CNS infection with distemper is expected. Alternatives are to compare the CDV-specific CSF-serum ratio with the ratio of IgG or albumin in CSF and serum.[64] In acute CNS infections, some mononuclear cells may contain large (15 to 10 μm), oval homogenous eosinophilic intracytoplasmic inclusions.[21] More effective is direct FA on cytospin preparations of CSF cells (see following text).

Diagnostic Imaging

Plain Radiography

When present, abnormalities on thoracic radiography in dogs with distemper include pulmonary interstitial to alveolar infiltrates and consolidation compatible with bronchopneumonia, especially in the cranial and ventral lung lobes.

Magnetic Resonance Imaging

Dogs with distemper encephalomyelitis can have normal MRI findings. Hyperintense lesions and loss of contrast between gray and white matter in the cerebellum and/or the brainstem have been described in T2-weighted images, which correspond to demyelination on histopathology.[65] Multifocal T2 and fluid-attenuated inversion recovery (FLAIR) hyperintensities can occur in other locations in the brain, and there may be mild meningeal contrast enhancement (Fig. 22.10).

Microbiologic Tests

Microbiologic tests for CDV infection are shown in Table 22.3.

Virus Isolation

Growth in pulmonary macrophages or lymphocytes was once considered an essential feature of virulent CDV isolates, whereas isolation of virulent CDV has been difficult in routine cell cultures. Currently, dog lymphocyte cultures,[66] marmoset lymphoid cell line (B95a),[66] and, probably most effective, SLAM transfected Vero cell lines[22] are routinely used. Cultures are monitored for giant cell (syncytia) formation, a characteristic cytopathic effect of CDV or by immunofluorescence. Because of defective viral replication, specimens from dogs with chronic or vaccine-induced encephalitis may not yield successful

TABLE 22.3 Diagnostic Assays Available for Distemper in Dogs

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival and nasal swabs, blood, urine, transtracheal wash specimens, necropsy specimens	CDV	False negatives can occur in specimens that contain low numbers of virus particles. Attenuated live vaccine virus may also be isolated. Not widely offered for routine diagnostic purposes
Direct immunostaining (such as direct fluorescent antibody)	Smears made from conjunctival scrapings, urine sediment, respiratory lavage specimens, impression smears of tissue specimens	CDV antigen	False negatives can occur in specimens that contain low numbers of virus particles. False positives can occur if nonspecific fluorescence is incorrectly interpreted as a positive result. Possibility of false positives after recent vaccination with attenuated live CDV vaccines
Distemper ELISA antigen assay	See Virus isolation	CDV antigen	Inexpensive and rapid. Sensitivity and specificity in naturally infected dogs have not been well established. False positives can occur for weeks after vaccination with attenuated live CDV vaccines
RT-PCR	See Virus isolation	CDV RNA	Sensitivity and specificity can vary depending on assay design. Testing specimens from multiple anatomic sites or combining PCR assays with other diagnostic tests for CDV improves sensitivity. Attenuated live vaccine virus may be detected for days to weeks after vaccination. Because of the high sensitivity of some assays, the significance of a positive result in relation to disease may be difficult to interpret; quantitative assays may help distinguish between natural infection (high virus load) and vaccination (low virus load). False-negative results can occur when virus levels are low or as a result of degradation of viral nucleic acid during specimen transport
Serology (IgG and IgM ELISA; SN)	Serum and/or CSF	Antibodies against CDV antigens	Acute and convalescent sera are required for diagnosis of acute distemper, so diagnosis is retrospective. False positives can occur with recent CDV vaccination
Histopathology	Usually necropsy specimens, but also skin biopsies (such as footpad biopsies)	Eosinophilic intracytoplasmic and intranuclear inclusions; CDV antigen with immunostaining or CDV RNA with *in situ* hybridization	If available, *in situ* hybridization may be most sensitive for detection of virus in tissues

SN, serum neutralization.

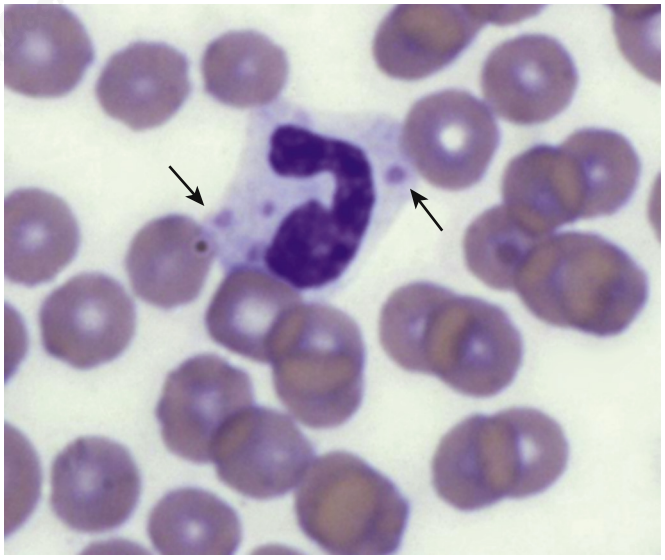

Fig. 22.11 Intracytoplasmic inclusions *(arrows)* in a circulating leukocyte of a 4-month-old border collie mix with distemper. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

cultures. Wild-type virus must be distinguished from vaccine virus in dogs that have been recently vaccinated with attenuated live vaccines.

Cytologic Demonstration of CDV Inclusions

Intracytoplasmic viral inclusions can occasionally be seen in circulating blood cells of affected dogs, especially early in infection (although they also can be seen in chronic infections) (Fig. 22.11). Inclusions may also be visible in the cytoplasm of conjunctival epithelial cells. Epithelial cells can be scraped from the conjunctiva using a curette after application of a topical ophthalmic local anesthetic preparation. The cells are smeared onto a glass slide, stained with a Romanowsky or Wright-Leishman stain, and examined with light microscopy. Unfortunately, this has low sensitivity for diagnosis of distemper.[67] Intracytoplasmic distemper inclusions can be detected in the early phase of disease by examination of stained peripheral blood films, in low numbers in circulating lymphocytes, and with even less frequency in monocytes, neutrophils, and erythrocytes. Wright-Leishman-stained inclusions in lymphocytes are large (up to 3 μm), single, oval, gray structures, whereas erythrocytic inclusions (which are most numerous in polychromatophilic cells) are round and eccentrically placed and appear light blue. The sizes of erythrocytic inclusions are between those of metarubricyte nuclei and Howell-Jolly bodies. Buffy coat and bone marrow examination can improve the chances of detecting inclusions. Electron microscopy has confirmed that these inclusions consist of paramyxovirus-like nucleocapsids.

Immunostaining for CDV Antigen

Direct immunostaining of cells in conjunctival scrapings, CSF, or blood films is helpful in acute phases of illness. In chronic cases, it may be less rewarding because antibody coating or elimination of viral antigen may yield negative results. Immunostaining is more sensitive than identification of CDV inclusions with routine stains,[67] but false negatives still occur when low quantities of virus are present in the specimen.

Direct IFA techniques are often used in practice to detect CDV antigen in a variety of cell types, including conjunctival epithelial cells, leukocytes in a buffy coat smear, urine sediment, CSF cells (Fig. 22.12A), bone marrow, or tissues obtained at necropsy (Fig. 22.12B). Enzyme-antibody labelling can also be used (Fig. 22.12C).

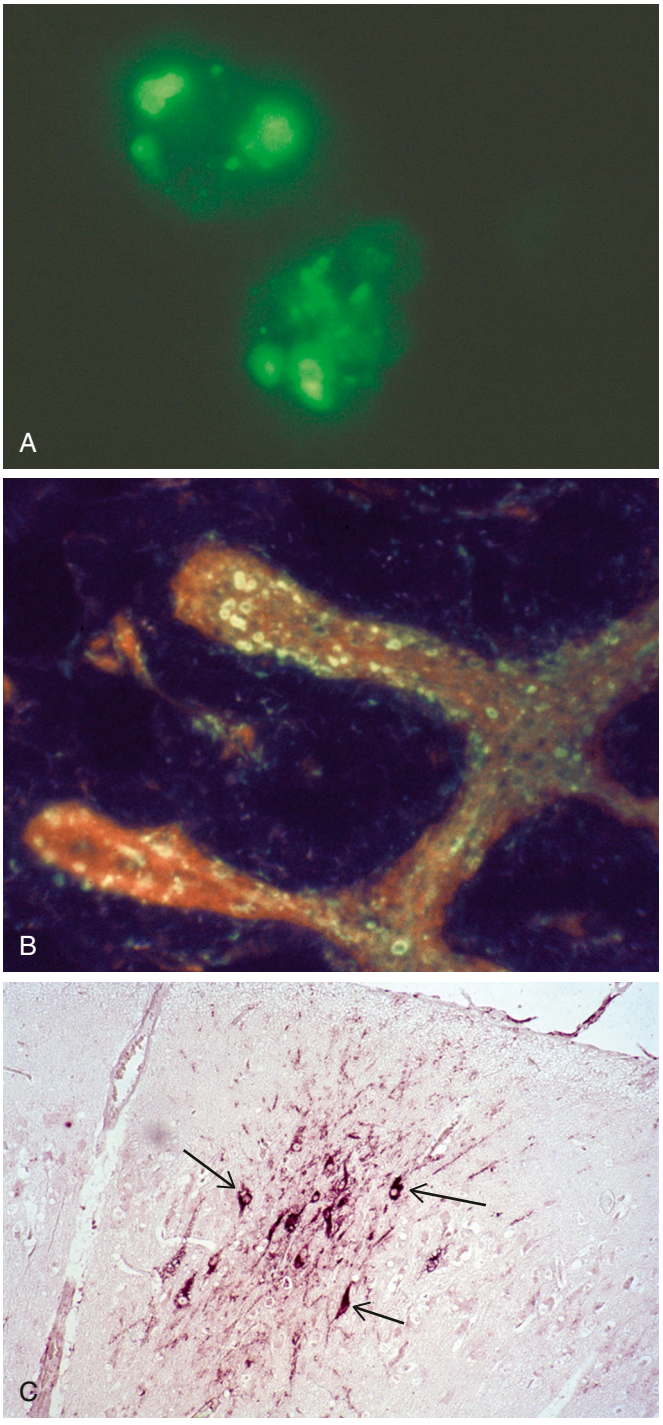

Fig. 22.12 (A) Immunofluorescent staining of CDV antigen in CSF cells (×1000). (B) Immunofluorescence highlighting CDV in a footpad biopsy. (C) Histopathology showing CDV RNA in neurons of cerebral cortex as detected using in situ hybridization *(arrows)*.

Transient false-positive results might occur after vaccination with attenuated live vaccines, so the results must be interpreted with caution in recently vaccinated dogs. False positives also have the potential to occur if nonspecific fluorescence is interpreted as a positive result by inexperienced laboratory technicians. Smears should be made on precleaned slides, air-dried thoroughly, and preferably fixed in acetone for 5 minutes before transport to the laboratory. At the laboratory, they are stained directly or indirectly with fluorescein or enzyme-conjugated CDV antibody.

Positive staining in conjunctival and genital epithelium is usually detected only within the first 3 weeks PI, when systemic illness is apparent. Virus also disappears in these tissues after the first 1 to 2 weeks of clinical illness (21 to 28 days PI) as antibody titers rise in association with clinical recovery. Virus can be detected for longer periods in epithelial cells and macrophages from the lower respiratory tract, and transtracheal washings can be obtained accordingly for diagnosis. Virus also persists for at least 60 days in the skin, uveal tissue, footpad, and CNS. In a series of clinically diagnosed cases of distemper, good correlation between direct FA and PCR was found.[67] Positive direct FA also correlated well with viral isolation.[8] Further research is required to understand the prevalence of and influence of vaccination on false-positive direct IFA results for diagnosis of distemper.

Antigen Detection ELISA Assays

ELISA assays that detect CDV antigen in serum (see Table 22.3) are available commercially as in-practice kits in some countries, but large well-controlled studies on their effectiveness are scant. Low sensitivity and false positives in dogs that were naturally infected with distemper were found in early assays.[68] Newer techniques such as lateral flow (immunochromatography) assay had improved sensitivity equivalent to that of an RT-PCR assay when applied to conjunctival swab specimens, but sensitivity was 90% and 86% when the assay was applied to blood lymphocytes and nasal swab specimens from dogs with distemper.[69] Sandwich-dot ELISA for the detection of CDV in clinically affected dogs showed an excellent correlation with direct electron microscopic demonstration of CDV.[70]

Molecular Diagnosis Using Nucleic Acid–Based Testing

The most sensitive laboratory technique for detection of CDV is the RT-PCR. A positive PCR result is indicative of infection, although not always associated with clinical illness. False-negative PCR results can occur if the virus is present in low concentrations at the site from which specimens are collected, or as a result of improper sample handling and extraction procedures or degradation of viral RNA during specimen collection and transport to the laboratory. In outbreak situations, collection of specimens from multiple dogs (at least 5 to 10) may increase the chance of positive test results.[71] Quantitative PCR is very sensitive and correlates well with viral isolation in experimentally infected dogs.[72] PCR also correlates very well with immunohistochemistry for CDV.[73]

RT-PCR assays are offered by a number of commercial veterinary diagnostic laboratories for diagnosis of distemper, sometimes as part of a panel that includes assays for other canine respiratory pathogens (see Chapter 124). Most assays detect a portion of the N protein gene. RT-PCR can be performed on whole blood, buffy coat, skin biopsies, conjunctival scrapings, urine, CSF, transtracheal washes, nasal and oropharyngeal swabs, and a variety of other tissues collected at necropsy (e.g., lung, small intestine, stomach, kidney, brain, bladder, lymphoid tissues). In one study of a limited number of experimentally infected dogs, conjunctival swabs were superior to whole blood, nasal flushes, and urine for PCR diagnosis of CDV infection,[74] whereas another study of naturally infected dogs showed highest viral loads in blood, followed by conjunctival swabs, and then urine.[75] At the time of writing, several POC PCR assays have been developed for detection of CDV. With further clinical validation and refinement, these assays have the potential to facilitate rapid and accurate diagnosis in veterinary clinics, shelters, and other poor-resource environments.[76,77]

RT-PCR is more sensitive than direct FA, but false positives may be more likely to occur after vaccination with attenuated live virus vaccines (not the recombinant vaccine), because most RT-PCR assays that are currently available for routine diagnostic purposes do not distinguish between vaccine and wild-type strains. Assays have been developed that differentiate between field and vaccine strains of CDV, but these are not commercially available.[78] Quantitation of RT-PCR results has been used to differentiate between shedding of attenuated vaccine virus (low viral load) from natural infection (high viral load) (e.g., Canine Distemper Quant RealPCR Test, IDEXX Laboratories, Portland, ME).[79] False-positive test results should not occur after use of *recombinant* CDV vaccines. A sensitive nested RT-PCR followed by an MspI restriction enzyme digestion step enabled to differentiate CDV field and vaccine strains using restriction fragment length polymorphism (RFLP) analysis.[80] More research is needed to clarify the influence of vaccination on the results of RT-PCR for distemper. The diagnosis is strengthened when positive PCR assay results are combined with positive results of other assays such as direct IFA.

Serologic Diagnosis

Neutralizing anti-CDV antibodies directed against the membrane proteins (H and F) of the virus appear 10 to 20 days PI, and can persist for the life of a recovered animal. They can be measured in the laboratory using serum neutralization (SN) assays (see Chapter 2), which is the gold standard against which other techniques are evaluated. Indirect FA testing has also been used to measure postvaccination titers, and results are comparable to those of SN.[81] ELISA assays are simpler and can be performed more rapidly, and these currently have similar sensitivity and specificity as SN.[82] Although sometimes less specific, whole-virus ELISA has been used to detect serum IgG and IgM antibodies to CDV. Increased specificity has been achieved using recombinant N protein–based ELISA in dogs.[83–86] Antibody to N and P proteins may appear 6 to 8 days PI when measured by ELISA. An ELISA based on CDV-H, which may be more relevant to assess protection, has also been developed.[87] Use of serology for diagnosis of distemper is complicated by the confounding effect of vaccination. This is especially true in shelter environments where all dogs are vaccinated on intake. High IgG titers are ambiguous and can indicate either past or present infection with CDV or past vaccination against CDV. Nevertheless, a fourfold rise in titer over a 2- to 4-week period supports recent infection. Acute and convalescent sera should be submitted to the same laboratory, because inter-laboratory variation in assay results occurs. Dogs with delayed-onset CDV encephalomyelitis have high levels of antibody in the CSF when compared with serum,[88] but should still be interpreted with caution. Increased titers of serum IgM-neutralizing antibody can be measured in dogs that survive the acute phase of infection and usually disappear by 3 months. Dogs that fail to develop significant titers of IgM or IgG post inoculation eventually die or have to be euthanized because of severe clinical illness.[89] High serum IgM titers have been more accurate in detecting acute clinical distemper cases (81%) compared with chronic progressive inflammatory encephalitis (60%). Transient IgM increases to CDV NP can also be seen for up to 3 weeks after first, but not after second, immunization with CDV vaccine.[84]

The results of serologic tests can be used to assess the need for vaccination, and also to determine which dogs are protected and therefore of low risk for development of disease and to some extent, virus shedding in outbreak situations. SN titers of at least 1:16 to 1:20 correlate with protection after vaccination. Titers of 1:100 or more correlate with protection in puppies that have received maternal antibodies.[90] One study showed a high (95%) prevalence of positive titers (≥ 10) using SN in 97 healthy client-owned adult dogs, and no appreciable increase in titers after vaccination.[91] Age less than 2 years was associated with lack of pre-vaccination antibodies. As a result, the authors suggested routine testing may be more appropriate than regular vaccination in adult dogs. Because of the presence of CMI, negative serologic results

do not imply lack of protection. POC ELISA assays are also available for semiquantitative measurement of antibodies to CDV. One assay in this respect (Synbiotics TiterCHEK CDV/CPV, now offered by Zoetis) had a sensitivity of 76% and a specificity of 92% compared with SN when performed as a POC assay.[92] The low sensitivity would tend to overestimate the need for vaccination, which is preferable to an assay with low specificity, which might result in unnecessary exposure of a susceptible dog to infected dogs. In a 2021 study that evaluated the sensitivity and specificity of 4 POC tests available in Europe (ImmunoComb Canine VacciCheck, Biogal; TiterCHEK CDV-CPV, Zoetis; FASTest CDV-CPV Ab, Megacor; CanTi Check, Fassisi) using SN as the gold standard, specificity was high in 40 SPF dogs but poor for all assays in 176 dogs with acute or chronic illness. Sensitivity varied from 40 to 100%.[93]

Pathologic Findings

Gross Pathologic Findings

In addition to physical examination abnormalities described earlier, gross pathologic findings in canine distemper include thymic atrophy, pulmonary congestion and consolidation, liquid intestinal contents, and lymph node congestion and enlargement. Less common findings are mild pleural, pericardial, and/or peritoneal effusion and, uncommonly, visceral congestion and ecchymotic hemorrhages and meningeal congestion. In some dogs, gross necropsy abnormalities are minimal. Concurrent external and intestinal parasitic infections may also be identified.

Histopathologic Findings

Multifocal demyelinating lesions are pathognomonic for CDV infection (Fig. 22.13). Acute noninflammatory lesions include disseminated gray matter lesions with neuronal infection and degeneration and, characteristically, demyelination with spongy vacuolation of white matter and reactive gliosis. In surviving animals, patchy areas of demyelination are replaced by hypertrophic astrocytes and macrophages that are ingesting myelin. The most severe white matter changes in the CNS can be found in the lateral cerebellar peduncles, the dorsolateral medulla adjacent to the fourth ventricle, the deep cerebellar white matter, the optic nerves and tracts, and the spinal cord.[94] In one study of 17 dogs submitted for necropsy, the lumbosacral, thoracolumbar, cervical, and cervicothoracic regions were affected in 13, 11, 9, and 9 dogs, respectively.[95] Lesions in the lateral and dorsal funiculi were most common, and white matter lesions consisted of demyelination (17 dogs), astrocytosis (17), microgliosis (17), gemistocytes (11), and non-suppurative inflammation (10). Gray matter lesions included gliosis (8), non-suppurative inflammation (7), and malacia (5). Intracytoplasmic or intranuclear inclusions can be found

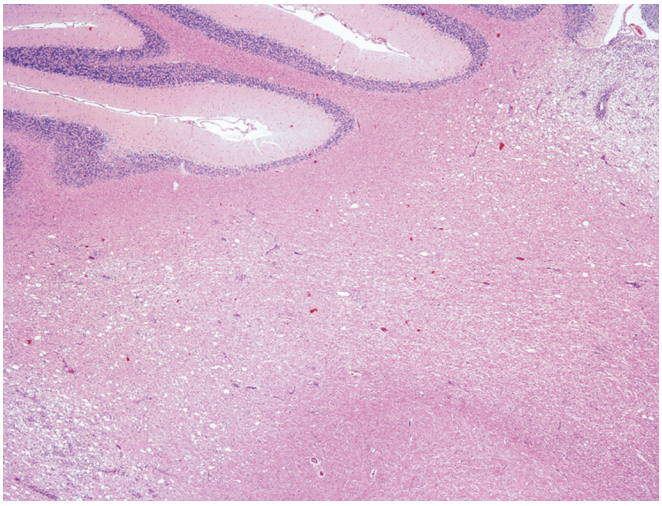

Fig. 22.13 Inflammatory demyelinating lesions (upper right and lower left corner) in cerebellar white matter. Hematoxylin and eosin stain.

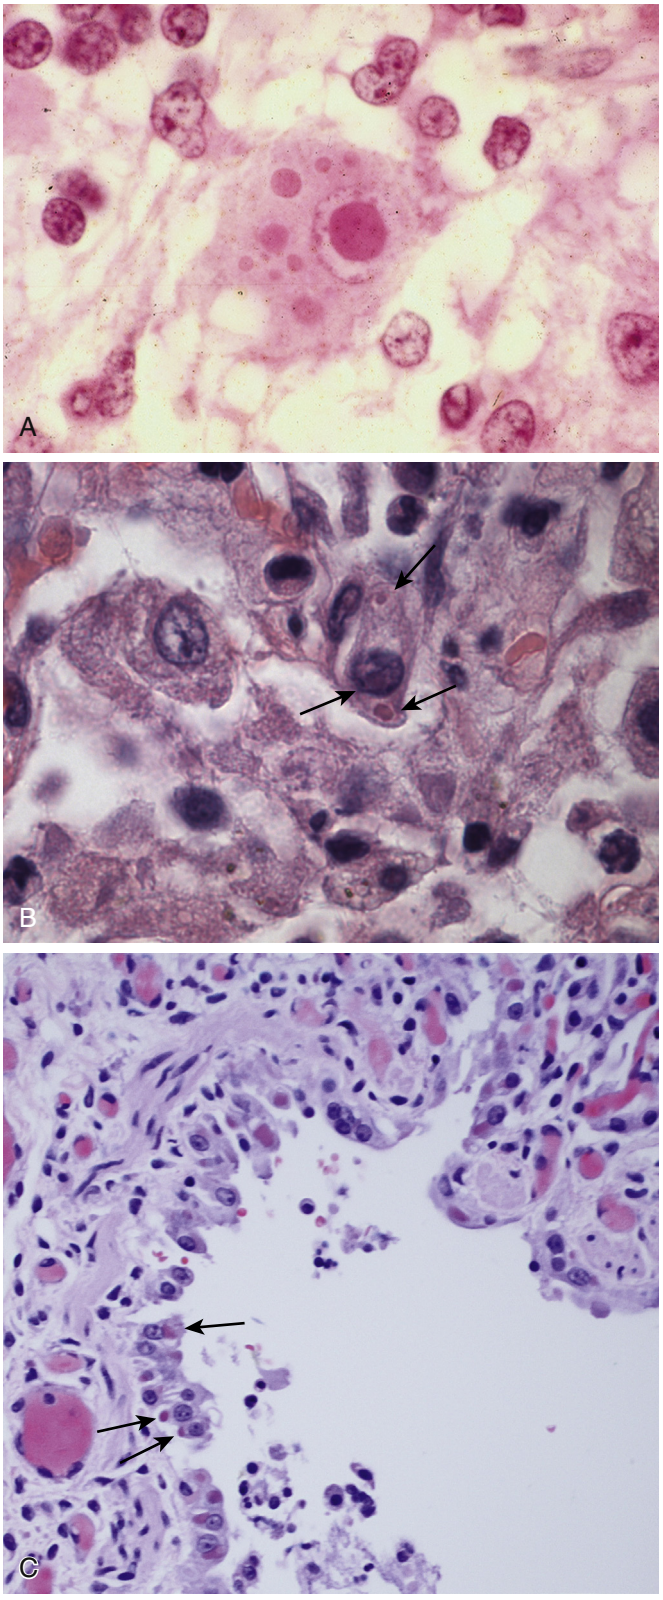

Fig. 22.14 (A) Neuron with multiple intracytoplasmic and intranuclear inclusion bodies in the cerebellum of a dog with distemper. Hematoxylin and eosin stain, 1000× oil magnification. (B) Eosinophilic intracytoplasmic and intranuclear viral inclusions *(arrows)* in the lung of the dog from Figure 22.4. Hematoxylin and eosin stain, 1000× oil magnification. (C) Bronchial epithelium from a dog infected with CDV. Intracytoplasmic inclusions are abundant *(arrows)*. Hematoxylin and eosin stain. (B, from Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014. C, courtesy of Dr. Patricia Pesavento, University of California, Davis Veterinary Anatomic Pathology service.)

predominantly in astrocytes and neurons (Fig. 22.14). Chronic lesions are characterized by widespread perivascular lymphoplasmacytic infiltration, particularly in areas of demyelination. Demyelinating lesions can be more widespread and severe than lesions in dogs with acute encephalitis. Lesions of vaccine-induced distemper are typically those of a necrotizing polioencephalitis of the caudal brainstem with preference for the ventral pontine nuclei. Inclusions can be found in the nucleus or cytoplasm of astrocytes and neurons. Infection of the lungs leads to a lymphocytic and histiocytic interstitial pneumonia with proliferation of the alveolar epithelium; neutrophilic bronchopneumonia occurs as a result of secondary bacterial infection. There is often widespread lymphoid depletion and necrosis in all reticuloendothelial tissues (see Fig. 22.4), although lymphoid hyperplasia may be observed in dogs with chronic distemper. Epithelial cell necrosis may be present in the dental ameloblast layer, trachea, and bladder mucosa.

The diagnosis of CDV infection is supported by the presence of multifocal demyelination and eosinophilic intracytoplasmic or intranuclear inclusion bodies, which are 1 to 5 μm in diameter and occur in a variety of cell types, but especially in neurons, astrocytes, microglial cells, conjunctival epithelial cells, bladder epithelium, footpad epithelium, and sometimes lymphocytes (see Fig. 22.14). Less commonly, syncytia may be identified, such as in lymph nodes, lung, and brain. Confirmation of the presence of CDV in tissues can be established with the use of immunostaining, *in situ* hybridization, or RT-PCR (Fig. 22.15).

TREATMENT AND PROGNOSIS

When required, the mainstay of treatment for CDV infection is supportive care. No specific antiviral drug is available for treatment of CDV infection in living animals. R ribavirin,[96] 5-ethynyl-1-β-D-ribofuranos ylimidazole-4-carboxamide (EICAR),[97] 6-methylmercaptopurine riboside,[98] caffeic acid,[99] various flavonoids,[98] and others all have anti-CDV activity but have only been tested *in vitro*. In view of the central role of membrane fusion in CDV pathogenesis,[100] fusion inhibitors would potentially be powerful antiviral drugs. High effectiveness of such drugs has been proven *in vitro* but they have not yet been tested *in vivo*.[101,102] Likewise, treatment of distemper with type 1 IFNs largely remains theoretical.[103,104] The old paradigm of treating distemper with hyperimmune sera was rekindled by an immunotherapy with porcine anti-CDV antibodies which decreased mortality in puppies with natural CDV infection.[105] The basic problem remains that CDV persists inside cells and immunoglobulins do not penetrate the blood-brain barrier.

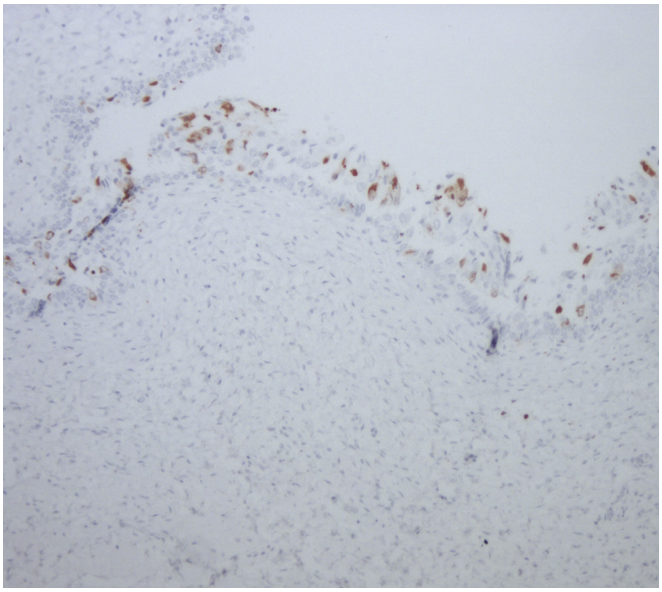

Fig. 22.15 Immunohistochemistry that shows CDV antigen (brown staining) in bladder transitional epithelial cells from a 2-year-old male neutered Australian cattle dog infected with CDV that had been recently adopted from a shelter and developed cough, ataxia, blindness, and seizures. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Dogs with mild respiratory or GI distemper may recover spontaneously without treatment. Dogs with severe respiratory and GI disease may require hospitalization and treatment with IV fluids, antimicrobial drugs for secondary bacterial pneumonia, oxygen supplementation, nebulization, and coupage. Ideally, these dogs should be housed in isolation, although in many veterinary hospitals, isolation may not permit treatment with oxygen and adequate monitoring. Under these circumstances, dogs could be housed under strict barrier precautions where oxygen and critical care can be provided. When possible, collection of a respiratory lavage specimen for culture and susceptibility is recommended for dogs with secondary bacterial pneumonia. When this is not possible, the use of antimicrobial drugs likely to be effective against *Bordetella bronchiseptica* (such as doxycycline) is recommended (see Chapter 55). Dogs with severe bronchopneumonia may require treatment with parenteral broad-spectrum antimicrobial drug combinations, such as ampicillin and a fluoroquinolone. Other supportive treatments include enteral nutrition, artificial tears for dogs with KCS, and antiemetics. Parenteral nutrition should be used only if absolutely necessary, because of the immunosuppression that occurs with CDV infection and possibility of nosocomial infections. Vitamin A supplementation before experimental infection reduced morbidity and mortality associated with CDV infection in ferrets,[106] but its usefulness as a treatment for canine distemper requires further investigation. Administration of daily oral vitamin A for 2 days to children younger than 2 years of age with measles reduces the risk of mortality and pneumonia-specific mortality, and because levels of serum retinol in children with severe measles are typically low, vitamin A treatment for these children is recommended by the American Association of Pediatrics.[107] Ascorbic acid has also been advocated as a treatment for distemper in dogs, but its efficacy remains unproven.[90]

Owners of dogs with respiratory and GI illness should be warned that CNS signs have the potential to develop weeks to even months after apparent recovery. Unfortunately, the development of CNS signs is unpredictable. When neurologic signs occur, they rarely resolve and may be progressive. Seizures, myoclonus, or optic neuritis are three neurologic manifestations in dogs that can be tolerated by many owners. As with myoclonus in humans, treatment can lessen the severity of the muscle contractions but rarely eliminates it.[108] Botulinum toxin appeared to have a beneficial effect on myoclonus in one clinical distemper case.[109] Recommendations have been made to administer anticonvulsants after the onset of systemic disease but before the development of seizures. No evidence shows that anticonvulsants prevent entry of the virus into the CNS; however, they can suppress irritable foci from causing seizures, which may prevent seizure circuits from becoming established. Information on seizure treatment in dogs can be found elsewhere.[110] Glucocorticoid therapy to reduce inflammation or CNS edema may have variable success for control of the blindness or papillary dilation from optic neuritis or other neurologic signs associated with vaccine-induced or chronic inflammatory forms of encephalitis. Any other oxygen radical scavenger could theoretically be beneficial in view of the neuropathogenesis of distemper.[35]

IMMUNITY AND VACCINATION

Immunity to CDV requires antibodies as well as cell-mediated immunity. Recovery from natural infection provides lifelong immunity. Distemper can be effectively prevented through immunization with attenuated live or recombinant vaccines. Inactivated vaccines do not provide sufficient protection and are not available in the United

States. In contrast, proper vaccination with attenuated live vaccines can provide long-lasting (at least 3 to 5 years), sterile immunity.[111] Attenuated live vaccines should be given to pet puppies every 3 to 4 weeks, commencing no earlier than 6 weeks of age. Maternal antibodies are usually absent by 12 to 14 weeks of age, and so the last vaccine should be given no sooner than 16 weeks of age (consider extension to 16 to 20 weeks in breeding kennels and shelters).[111] Ideally, pups should be isolated for at least 7 to 10 days after the last vaccine is administered (see Appendix). For dogs older than 16 weeks of age that are brought to the veterinarian for their first vaccination, two doses of vaccine should be given 3 to 4 weeks apart, although a single dose may provide protection. A booster is recommended by AAHA at 1 year and then no earlier than every 3 years thereafter.[111] The WSAVA recommends administration of the 1-year booster at 6 months.[112] For shelter dogs, vaccination should be performed as soon as possible before entry into the shelter. A single vaccine given even hours before entry can provide protection from severe disease.[113,114] Infection can still occur, but disease severity is lessened.

Although generally safe and effective when used according to label recommendations, attenuated live CDV vaccine virus can cause encephalitis when administered to immunocompromised dogs and puppies less than 6 weeks of age, and severe disease can occur in susceptible species such as ferrets and certain wildlife species. Administration of attenuated live CDV vaccines to dams immediately after whelping has been associated with the development of encephalitis in the puppies, and it was suggested that vaccine virus shed by the dam may cause disease in the pups.[115] Postvaccinal encephalitis usually occurs 3 to 20 days after vaccination and has been associated with certain batches of vaccines that contain the Rockborn strain.[116] Neurologic signs such as ataxia may be reversible in some dogs. Seizures may be progressive and irreversible. Some distemper vaccines available on the market still contain the Rockborn strain, and Rockborn-like viruses have been isolated from dogs with distemper, which may represent residual virulence of vaccine virus or circulation of vaccine-derived Rockborn-like viruses in the dog population.[117] Attenuated live CDV vaccines have been incriminated as a cause of hypertrophic osteodystrophy, especially in young Weimaraner dogs,[90,118] but there is a paucity of published evidence that supports the association.

A canarypox-vectored recombinant vaccine that expresses the H and F glycoproteins of CDV is also available for prevention of canine distemper (Boehringer Ingelheim). This vaccine induces a 3-year duration of immunity, protects dogs from severe disease when administered hours before shelter admission, can protect puppies from virulent CDV infection in the face of maternal antibody, and can be used in pregnant bitches and puppies as young as 4 weeks of age in the face of an outbreak or in heavily contaminated environments.[112,119] The recombinant vaccine has replaced the use of canine measles vaccines, which were previously used to overcome maternal antibody in the face of distemper outbreaks. Whether the recombinant vaccine overcomes maternal antibody that is directed against the canarypox-vectored vaccine virus as effectively as it overcomes maternal antibody against the attenuated CDV vaccine virus requires further evaluation. Further study of the relative efficacy of the recombinant and attenuated live vaccines in heavily contaminated environments such as shelters is also required. The canarypox-vectored recombinant vaccine is also the vaccine of choice for ferrets, and a specific ferret vaccine is available (Purevax Ferret Distemper, Boehringer Ingelheim).

Vaccine strains of CDV, such as Onderstepoort, Snyder Hill, and Lederle, belong to the America-1 lineage, but field strains that circulate in North America belong primarily to the America-2 lineage. Concern has been raised that these vaccines may not adequately protect against infection with field strains, but cross-neutralization studies suggest that antigenic differences are not sufficient to warrant changes in the current vaccines. The development of distemper in vaccinated dogs may reflect failure of vaccine efficacy as a result of the improper administration of vaccines, improperly timed vaccination series, or the use of vaccines that have been stored and handled inappropriately. The last is especially important for CDV vaccines because attenuated live vaccine virus is so labile. Vaccines should be stored in a refrigerator that maintains an internal temperature of 0°C to 4°C and reconstituted with the proper diluent immediately (within 1 hour) before administration. It has been recommended that vaccine held for longer than 1 hour after reconstitution be discarded.[111] A second dose should be given if some of the vaccine is found on the haircoat after administration.

PREVENTION

Properly timed vaccination is the key to prevention of CDV infection. Puppies with declining maternal antibody titers should be kept away from other dogs until the vaccination series is complete. In shelter situations, dogs with signs of respiratory or GI disease should be held well away from other dogs (at least 25 feet has been suggested[71]) and handled only after apparently healthy dogs have been cared for. Puppies should always be separated from adult dogs using equipment designated only for that area, and overcrowding should be prevented. Quarantine for CDV is difficult because the incubation period for development of neurologic signs may be as long as 6 weeks. Wildlife species such as raccoons can also shed CDV and were suspected as a source of infection in an outbreak that occurred in a Chicago shelter, when raccoons and dogs were co-transported in the back of a vehicle.[71] Routine cleaning and disinfection of contaminated surfaces readily eliminates virus in the environment. Proper nutrition may also help to prevent disease due to CDV. Isolated vitamin A deficiency is a major risk factor for severe measles and death in humans and distemper in ferrets. Retinoids interfere with replication of measles virus *in vitro* through a type I IFN-dependent mechanism.[120] The impact of nutritional status on disease due to CDV requires further investigation.

PUBLIC HEALTH ASPECTS

Because of close relationship between measles virus and CDV and the observation of multiple CD outbreaks in primates, it has been speculated that CDV could potentially adapt to humans. A number of experimental *in vitro* studies support this speculation, but there is no evidence *in vivo*; these are reviewed elsewhere.[121] It is likely that measles virus immunity would also protect against CDV. Both CDV and measles virus have played a controversial role in Paget's disease of bone, a common skeletal disorder characterized by focal abnormalities of increased bone turnover, which is associated with bone pain, deformity, and pathologic fractures.[122] Paget's disease most often occurs in the elderly, men are more likely to be affected than women, and the overall prevalence of the disease has decreased in many geographic locations.[123] Genetic factors clearly play a role in the disease, but in some studies, the RNA of paramyxoviruses that include CDV has been detected within lesions.[124] Other studies have failed to detect the nucleic acid of CDV in lesions, and contamination has been suggested as a reason for positive test results.[122] However, CDV has been shown to infect and replicate in human osteoclast precursors, further raising concern about the possibility of zoonotic transmission of CDV.[125]

CASE EXAMPLE

Signalment

"Molly", a 1.5-year-old female spayed golden retriever from Sacramento, CA.

History

Molly was evaluated for a 1-month-long history of abnormal behavior that included stumbling, failure to catch balls, and loss of interest in activity. She also had a 1-year history of seizures, which were thought to be due to idiopathic epilepsy and which were treated with phenobarbital (4 mg/kg PO q12h) and potassium bromide (17 mg/kg PO q12h). This was associated with a decrease in seizure frequency. Two weeks after the onset of abnormal behavior, Molly was taken to a local veterinary clinic. A serum phenobarbital concentration at that time was 50 μg/mL (therapeutic range, 10 to 40 μg/mL). The phenobarbital dose was decreased (1.4 mg/kg PO q24h), but Molly began circling to the left, head pressing, pacing, and vocalizing. She also stopped responding to the owners when they called her name, and two episodes of vomiting were noted. In the week before evaluation, Molly refused to eat dry food, but ate canned dog food. Her thirst had decreased and she was voluntarily urinating in the house. A serum phenobarbital concentration was repeated 2 days before she was evaluated and was 13 μg/mL. Molly had been vaccinated regularly (CDV, CPV, CAdV-2, and parainfluenza) and received monthly flea, tick, and heartworm prophylaxis.

Current Medications

Phenobarbital (1.4 mg/kg PO q24h); potassium bromide (17 mg/kg PO q12h).

Physical Examination

Body weight: 23.2 kg

General: Obtunded but hydrated. T = 101.7°F (38.7°C), HR = 60 beats/min, RR = 36 breaths/min, mucous membranes pink, CRT = 1 s.

Integument, eyes, ears, nose, and throat: No clinically significant abnormalities were identified. A full ophthalmologic examination was also unremarkable.

Musculoskeletal: Body condition score was 5/9. Molly was ambulatory on all four limbs.

Cardiovascular, respiratory, GI, and urogenital systems: No clinically significant findings were identified. All peripheral lymph nodes were normal sized. Average systolic blood pressure (10 measurements) was 120 mm Hg.

Neurologic Examination

Mentation: Obtunded and not responsive to verbal and most tactile stimuli; head pressing.

Gait/posture: Compulsive circling and leaning to the left was present.

Cranial nerves: No clinically significant abnormalities were identified.

Postural reactions: Placing reactions were absent in the left thoracic and left and right pelvic limbs.

Segmental reflexes: Diminished biceps and withdrawal reflexes were present, left thoracic limb only.

Panniculus: No abnormalities detected.

Spinal palpation: Pain was elicited in several regions along the spine. Resisted cervical ventroflexion.

Neuroanatomic localization: Diffuse cerebral or thalamic disease; C6 to T2 myelopathy.

Laboratory Findings

CBC: HCT 37.9% (40–55%), MCV 68 fL (65–75 fL), MCHC 35.4 g/dL (33–36 g/dL), WBC 7510 cells/μL (6000–13,000 cells/μL), neutrophils 4859 cells/μL (3000–10,500 cells/μL), lymphocytes 2155 cells/μL (1000–4000 cells/μL), monocytes 338 cells/μL (150–1200 cells/μL), 427,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 141 mmol/L (145–154 mmol/L), potassium 4.4 mmol/L (4.1–5.3 mmol/L), chloride 109 mmol/L (105–116 mmol/L), bicarbonate 21 mmol/L (16–26 mmol/L), phosphorus 3.9 mg/dL (3.0–6.2 mg/dL), calcium 12.2 mg/dL (9.9–11.4 mg/dL), BUN 6 mg/dL (8–31 mg/dL), creatinine 0.6 mg/dL (0.5–1.6 mg/dL), glucose 109 mg/dL (70–118 mg/dL), total protein 6.1 g/dL (5.4–7.4 g/dL), albumin 2.7 g/dL (2.9–4.2 g/dL), globulin 3.4 g/dL (2.3–4.4 g/dL), ALT 132 U/L (19–67 U/L), AST 62 U/L (21–54 U/L), ALP 155 U/L (15–127 U/L), CK 399 U/L (46–320 U/L), GGT 10 U/L (0–6 U/L), cholesterol 291 mg/dL (135–345 mg/dL), total bilirubin 0.2 mg/dL (0–0.4 mg/dL).

Serum ionized calcium: 1.39 mmol/L.

Urinalysis: SpG 1.014; pH 7.0, few amorphous crystals. No other abnormalities detected.

Serum bromide concentration: 1.1 mg/mL (therapeutic range, 1.0–2.0 mg/mL).

Serum phenobarbital concentration: 1.4 μg/mL (result rechecked, therapeutic range, 15–40 μg/mL).

Serum bile acids: Pre-meal, 14 μmol/L (reference range, 0–12 μmol/L); post-meal, 16 μmol/L (reference range, 0–16 μmol/L).

Imaging Findings

Thoracic radiographs: No clinically significant abnormalities were present.

Spinal radiographs: Disc space narrowing was present between the sixth and seventh cervical vertebrae and to a greater extent between the seventh cervical and first thoracic vertebrae.

Abdominal ultrasound: No significant lesions were identified.

MRI: Precontrast: Multiple small regions of hyperintensity were noted on dual echo and FLAIR sequences, one of which was in the left thalamus along the third ventricle and another diffusely along the lateral aspect of the right thalamus. There was a linear region of hyperintensity along the right parietal and temporal lobes. On T1-weighted postcontrast images, a small focus of contrast enhancement was noted in the ventral aspect of the right thalamus in the region of hyperintensity on the precontrast fluid-weighted sequences. Impressions: Multifocal, relatively non–contrast-enhancing lesions in the cerebrum and thalamus suggestive of cerebral edema, encephalitis, or small infarcts.

Electroencephalography: No abnormalities were detected.

CSF Analysis

	Lumbar	Cisternal
Protein (mg/dL)	31	21
Total RBC (cells/μL)	111	2
Total nucleated cells (cells/μL)	1	3
Neutrophils (%)	0	0
Small mononuclear cells (%)	92	80
Large mononuclear cells (%)	8	20
Microscopic evaluation	Mild to moderate lymphocytic reactivity	Marginal mononuclear (lymphocytic) pleocytosis

Treatment and Outcome

Molly was hospitalized for a week during the diagnostic workup and treated with IV fluids and potassium bromide (35 mg/kg PO q12h). She became progressively more obtunded and showed additional neurologic signs of circling to the right and positional horizontal nystagmus with a fast phase to the right. The narrowed disc spaces were thought to represent intervertebral disc disease, and granulomatous meningoencephalitis was suspected. Potassium bromide was discontinued, and treatment with phenobarbital (5 mg/kg PO q12h), reinstituted. Dexamethasone was administered (0.2 mg/kg, IV q24h), but there was minimal improvement, and euthanasia was elected.

Continued

CASE EXAMPLE—cont'd

Necropsy Findings

Brain, cerebrum: Severe, generalized, chronic neuronal loss, axonal necrosis, and myelin degeneration with abundant eosinophilic inclusion bodies and canine distemper antigen (immunohistochemistry).

Brain and spinal cord (C1 to T7), corticospinal tracts: Severe, diffuse axonal necrosis and myelin degeneration.

Brain, cerebrum, and meninges: Generalized, lymphoplasmacytic, perivascular cuffing.

Tonsil, lymph nodes (mandibular, mesenteric, thoracic): Mild, multifocal lymphopolysis with intranuclear and intracytoplasmic eosinophilic inclusion bodies and canine distemper antigen.

Diagnosis

Chronic distemper encephalitis with demyelination ("old dog encephalitis").

Comments

Distemper was not suspected in this dog because of the dog's older age and history of vaccination. Initial infection may have occurred before vaccination was complete, vaccination may have been improperly performed, or the dog may have been a vaccine nonresponder, which is believed to occur rarely. The previous diagnosis of epilepsy further complicated the identification of distemper as an underlying cause. This case example highlights the importance of including distemper on the differential diagnosis list for young adult dogs with neurologic signs, because of the chronic course of disease that can occasionally occur. Additional laboratory tests that might or might not have been helpful for diagnosis of distemper in this dog include comparison of serum antibody titers to CDV in the CSF and serum, and RT-PCR for CDV on CSF. Neurologic signs were progressive in this dog and largely unresponsive to anticonvulsant drugs, and so the prognosis was extremely poor.

Infectious Canine Hepatitis and Feline Adenovirus Infection

Nicola Decaro

KEY POINTS

- First Described: Infectious canine hepatitis (ICH) was first described in 1947 in Sweden (Rubarth)[1]; CAdV-1 was first isolated in chick embryos in 1951.[2] An adenovirus was first isolated from a cat in 1999 and was further characterized in 2019.[3]
- Cause: Canine adenovirus-1 and feline adenovirus 1 (family *Adenoviridae*, genus *Mastadenovirus*, species *Canine mastadenovirus A*).
- Affected Hosts: Dogs, coyotes, foxes, wolves, bears, skunks (CAdV-1); domestic cats (FAdV-1).
- Geographic Distribution: Worldwide (CAdV-1); the distribution of FAdV-1 is unclear, but antibodies have been detected in cats in Europe and North America.
- Mode of Transmission: Direct contact with infected saliva, feces and urine, and contaminated fomites.
- Major Clinical Signs in Dogs: Fever, lethargy, inappetence, vomiting, hemorrhagic diarrhea, abdominal pain, dehydration, conjunctivitis, petechial hemorrhages, tachypnea, cough, corneal edema ("blue eye"), icterus or neurologic signs. The spectrum of clinical signs in cats requires further study, but disseminated infection has been described.
- Differential Diagnoses (ICH): Other systemic viral diseases such as parvoviral enteritis and canine distemper, enteric viral and bacterial infections, hepatotoxicosis (e.g., mushrooms), dicumarol poisoning, Rocky Mountain spotted fever, GI foreign body, dietary indiscretion, leptospirosis, portosystemic shunting with hepatic encephalopathy, disseminated fungal infections (especially systemic candidiasis), systemic protozoal infections (especially sarcocystosis, toxoplasmosis, or African trypanosomiasis), hemic neoplasia (especially lymphoma).
- Human Health Significance: CAdV-1 does not infect humans. FAdV-1 is related to human adenovirus-1 but the zoonotic significance of this virus is unknown.

CANINE ADENOVIRUS INFECTION

ETIOLOGY AND EPIDEMIOLOGY

Infectious canine hepatitis (ICH) is an uncommonly recognized disease of dogs that is caused by CAdV-1, a nonenveloped, icosahedral double-stranded DNA virus that is antigenically related to CAdV-2 (see Chapter 28) (Fig. 23.1). As with other adenoviruses, CAdV-1 is highly resistant to environmental inactivation, surviving disinfection with various chemicals such as chloroform, ether, acid, and formalin, and is stable when exposed to certain frequencies of ultraviolet radiation. The virus survives for days at room temperature on soiled fomites and remains viable for months at temperatures below 4°C. Inactivation of CAdV-1 occurs after 5 minutes at 50°C to 60°C, which makes steam cleaning a plausible means of disinfection. Chemical disinfection has also been successful when iodine, phenol, and sodium hydroxide are used; however, all are potentially caustic.[4]

There are 50 different species within the genus *Mastadenovirus*, and within these species, there are many different adenovirus types; for example, 7 human adenovirus species (designated *Human mastadenovirus A* though *G*) including 85 different types have been described.[3] Disease caused by CAdV-1 (now referred to as *Canine mastadenovirus A* by the International Committee on Taxonomy of Viruses) was first observed in farmed red foxes (*Vulpes vulpes*) and consequently named epizootic fox encephalitis due to the neurological disorders observed in the affected animals.[5] ICH was reported in dogs a few years later and based on the similar clinical course and pathology, Carl Sven Rubarth suggested a common etiology for the two diseases,[1] which were subsequently known as Rubarth's disease. The etiological agent, CAdV-1, was isolated a decade later[2] and attenuated through passages on canine and swine cell lines to produce vaccines. In 1961, another adenovirus of dogs, CAdV-2, was isolated from dogs with laryngotracheitis or tracheobronchitis.[6] ICH has been reported in free-ranging foxes and other wild carnivores belonging to the families *Canidae*, *Ursidae*, *Procyonidae*, and *Mustelidae*. A fatal infection was reported in an otter (*Lutra lutra*).[7] In addition to these carnivores, serum antibodies have also been detected in marine mammals including walruses (*Odobenus rosmarus*) and sea lions (*Eumetopias jubatus*).[8-10] The high prevalence of naturally occurring serum neutralizing antibodies in the unvaccinated feral and wildlife dog population suggests that subclinical infection is widespread.[11-14]

ICH has been described worldwide and most commonly occurs in dogs that are less than 1 year of age, but it was frequently reported in adult dogs before widespread vaccination for ICH was introduced. CAdV-1 has been isolated from all body tissues and secretions of dogs during the acute stages of the disease. By 10 to 14 days post inoculation (PI), using traditional methods the virus can be found only in the kidneys and is excreted in the urine for at least 6 to 9 months. However, molecular tools have proved that CAdV-1 viremia and shedding can last for several weeks. Aerosol transmission of the virus via the urine is unlikely, given that susceptible dogs housed 6 inches apart from virus shedders do not become infected. Viral spread can occur by contact with fomites, including feeding utensils and hands.[4]

The strong antigenic relationship between CAdV-1 and CAdV-2 is clinically important, because parenteral vaccines that contain CAdV-2 protect against infection with CAdV-1 and vice versa. After the introduction of CAdV vaccines, ICH largely disappeared, but over the past decade it has reemerged in dogs and wildlife, with published reports of disease from Italy, France, Switzerland, UK, Brazil, Australia, and the United States.[14-27] Disease in Europe has been associated with puppy trading from kennels in eastern European countries and possibly spillover of virus circulating

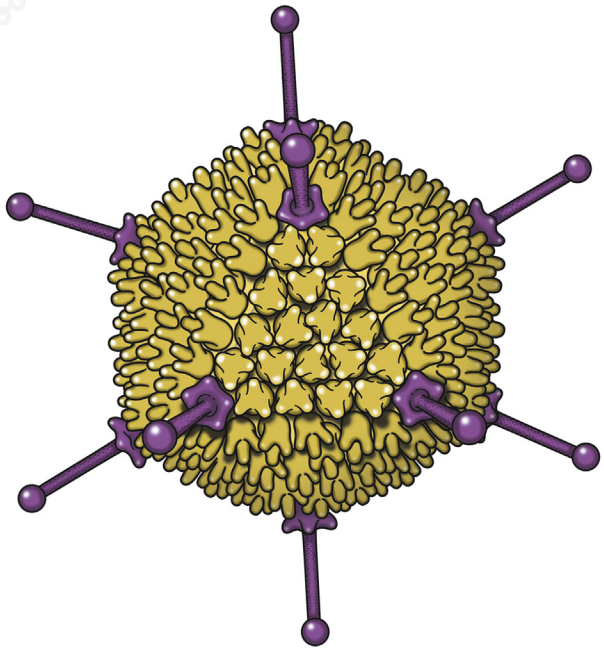

Fig. 23.1 Structure of canine adenovirus. The virus is a non-enveloped, icosahedral virus with fibers *(purple)* that radiate outwards from the virion.

in wildlife.[28] In Italy, three outbreaks occurred in shelters and the others involved purebred puppies imported from Hungary a few days before the onset of clinical signs. Several of the dogs were coinfected with other viruses, such as CDV, CPV, or CCoV.[18] Encephalopathy due to CAdV-1 infection was described in nine 5-week-old Labrador retriever puppies from Arkansas in the United States, all of which belonged to the same litter.[17] The litter was from an unvaccinated bitch. Mixed infections with CAdV-1, CAdV-2, CDV, CPV, and *Neospora caninum* were reported in puppies in Brazil,[29] and a coinfection with CAdV-1 and *Pasteurella pneumotropica* was documented in Italy in a 2-month-old male German shepherd with fever, lethargy, and cachexia.[21] These case descriptions confirm that CAdV-1 continues to circulate in the dog population and can result in severe disease in young dogs when vaccination does not occur, is improperly timed, and stress, coinfections and overcrowded conditions prevail. In addition, it is possible that emergence of new strains, such as through viral recombination, may be associated with reduced efficacy of vaccination. A recombinant CAdV-1 strain that has some genetic characteristics of CAdV-2 was reported to cause acute and fatal disease in a 6-month-old rottweiler and an 11-week-old poodle mix from South Australia in 2013.[26] Both dogs had received vaccines for CAdV-2, although the age of these dogs when the last vaccine in the series was given was not reported, so it is possible they were vaccinated in the face of persistent MDA. Rarely, CAdV-2 infection has been associated with neurologic signs in dogs.[30]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

CAdV-1 is shed in saliva, feces, and urine, and transmission occurs through direct dog-to-dog contact or contact with contaminated fomites such as hands, utensils, and clothing. Ectoparasites such as fleas and ticks are also potential mechanical vectors.[28,31]. Airborne transmission does not appear to be important. After natural oronasal exposure, the virus initially localizes in the tonsils (Fig. 23.2), where it spreads to regional lymph nodes and lymphatics before reaching the blood through the thoracic duct. Using virus isolation to detect the virus, viremia lasts 4 to 8 days PI, whereas using molecular assays, CAdV-1 can be detected for several weeks in the blood.[32] Viremia results in rapid dissemination of the virus to other tissues and body secretions, including saliva, urine, and feces. The duration of viral shedding is variable, but urinary shedding has the potential to last 6 to 9 months. Hepatic parenchymal cells and vascular endothelial cells of many tissues, including the CNS, are prime targets of viral localization and injury. Initial cellular injury of the liver, kidney, and eye is associated with cytotoxic effects of the virus. A sufficient antibody response by day 7 PI clears the virus from the blood and liver and restricts the extent of hepatic damage. Widespread centrilobular to panlobular hepatic necrosis is often fatal in experimentally infected dogs, which may be accompanied by a persistently low virus neutralization antibody titer (less than 1:4). Acute hepatic necrosis can be self-limiting and centrilobularly restricted such that hepatic regeneration occurs in dogs that survive this phase of the disease. Dogs that demonstrate a partial neutralizing antibody titer (> 1:16, but < 1:500) by day 4 or 5 PI may develop chronic active hepatitis and hepatic fibrosis. Persistent hepatic inflammation continues, possibly as a result of chronic latent hepatic infection. Dogs immune to parenteral challenge with CAdV-1 are still susceptible to respiratory disease via aerosolized viral particles.[4]

Both virulent and attenuated live strains of CAdV-1 produce renal lesions. As detected by immunofluorescence and ultrastructural evaluation, virus initially localizes in the glomerular endothelium in the viremic phase of disease and produces glomerular injury. An increase in neutralizing antibody at approximately 7 days PI is associated with the glomerular deposition of circulating immune complexes (CICs) and transient proteinuria. Glomerular lesions contain deposits of viral antigen, immunoglobulin (Ig)G, IgM, and C3.[4,33,34] CAdV-1 is not detected in the glomerulus after 14 days PI; however, it persists in renal tubular epithelium. Tubular localization of the virus is primarily associated with viruria, and only a transient proteinuria occurs. A mild focal interstitial nephritis is found in recovered dogs. However, in contrast to liver disease, there is a lack of evidence that chronic progressive renal disease results from infection by CAdV-1.[4]

Clinical complications of ocular localization of CAdV-1 occur in approximately 20% of naturally infected dogs and in less than 1% of dogs after vaccination with attenuated live CAdV-1 vaccines. The development of ocular lesions begins during viremia, which develops 4 to 6 days PI. The virus enters the aqueous humor from the blood and replicates in corneal endothelial cells. Severe anterior uveitis and corneal edema develop 7 to 14 days PI, a period corresponding to an increase in neutralizing antibody titer (Fig. 23.3). Deposition of CICs with complement fixation results in chemotaxis of inflammatory cells into the anterior chamber and extensive corneal endothelial damage. Disruption of the intact corneal endothelium, which serves to pump fluid from the cornea into the anterior chamber, results in corneal stromal edema. Uveitis and edema are usually self-limiting unless additional complications or massive endothelial destruction occurs. Clearing of corneal edema coincides with endothelial regeneration and restoration of the hydrostatic gradient between the corneal stroma and aqueous humor. Recovery of the eye is usually apparent by 21 days PI. If the inflammatory changes are severe enough to block the filtration angle, increased intraocular pressure can result in glaucoma and hydrophthalmos.[4]

Complications are often associated with the pathogenesis of ICH. DIC, a frequent complication, begins in the early viremic phase of the disease and can be triggered by endothelial cell damage, with widespread activation of coagulation, or hepatic malfunction, with decreased clearance of activated clotting factors. Decreased hepatic synthesis of clotting factors in the face of excessive consumption compounds the bleeding defect. Although the cause of death in ICH is uncertain, the liver is a primary site of viral injury. Hepatic insufficiency and hepatic encephalopathy can result in a semicomatose state and death. Some dogs die so suddenly that liver damage with clinical evidence of hepatic failure does not have time to occur. Death in these

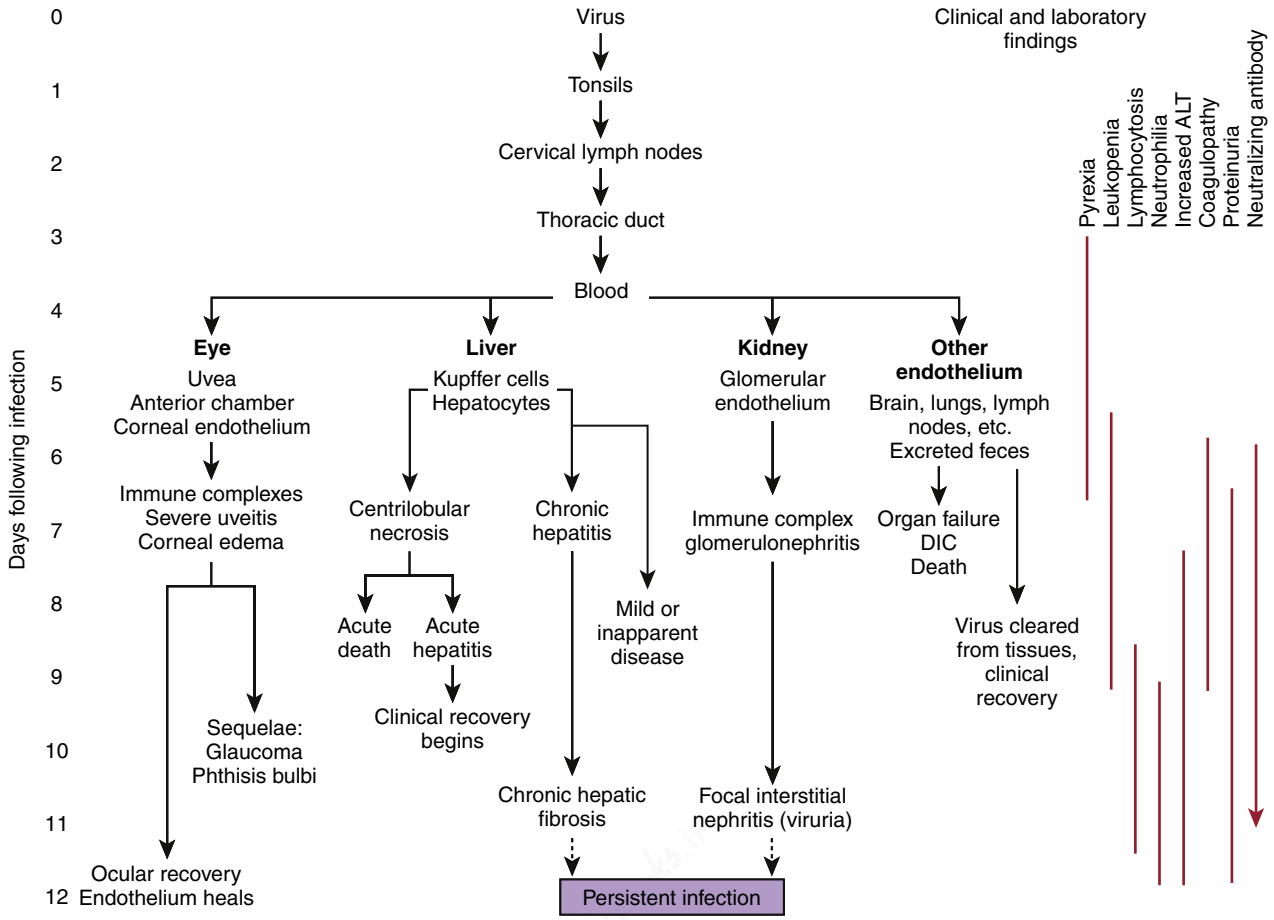

Fig 23.2 Pathogenesis of CAdV-1 infection.

dogs can result from damage to the brain, lungs, and other vital parenchymal organs or from the development of DIC.[4]

The incubation period in dogs is of 4 to 6 days after ingestion of infectious material and 6 to 9 days after direct contact with infected dogs.[23,24] Coinfections with CCoV, CDV, or CPV can exacerbate the disease, increasing mortality.[22,35-38]

ICH is most frequently recognized in dogs younger than 1 year, although unvaccinated dogs of all ages can be affected. Many infected dogs probably show no signs of illness.[4,28,31] Three overlapping disease syndromes have been described. The first is peracute disease with circulatory collapse, coma, and death after a brief illness that lasts less than 24 to 48 hours. The second, more commonly described syndrome is acute disease, which is associated with high morbidity and reported mortality rates of around 10% to 30%.[4] Dogs with acute disease either recover or die within a 2-week period. The third is a more chronic form that occurs in dogs with partial immunity, with death due to hepatic failure weeks (subacute disease) or months (chronic infection) after initial infection.[39]

Clinical signs in dogs that survive the acute viremic period include vomiting, abdominal pain, and diarrhea with or without evidence of hemorrhage. In the early phase of infection, fever (103° F to 106°F [39.4°C to 41.1°C]), tachycardia, and tachypnea may occur. Fever may be transient or biphasic. Tonsillitis, usually associated with pharyngitis and laryngitis, is common. Cough and increased breath sounds may be present in dogs with pneumonia. Cervical lymphadenomegaly can occur with subcutaneous edema of the head, neck, and dependent portions of the trunk. Abdominal pain and hepatomegaly are usually apparent. There may be widespread petechial and ecchymotic hemorrhages, epistaxis, and bleeding from venipuncture sites. Icterus is uncommon in acute ICH, but it is found in some dogs that survive the acute fulminant phase of the disease. Abdominal distention is caused by accumulation of serosanguineous fluid or hemorrhage. CNS signs, including lethargy, disorientation, seizures, or coma, can develop at any time after infection. In foxes and rarely in domestic dog pups, CNS signs can be seen in the absence of other systemic manifestations.[17] The development of neurologic signs may also represent hepatic encephalopathy, intracranial thrombosis or hemorrhage, or, as occurred in one outbreak, concurrent infection with CDV.[18]

Mildly affected dogs may recover after the initial febrile phase. Clinical signs of these uncomplicated cases of ICH frequently last 5 to 7 days before improvement. Persistent signs may be found in dogs with a concurrent viral infection such as canine distemper or in dogs that develop chronic hepatitis. More severe or additional clinical signs occur in dogs that are coinfected with other pathogens.[18,19,21,22,36-38]

Glomerulonephritis usually occurs about 1 to 2 weeks after the acute signs resolve. Infection of the glomerular endothelium is followed by a persistent tubular infection, interstitial nephritis, and viruria, but chronic renal failure has not been described.[33,34] Corneal edema and anterior uveitis usually occur when clinical recovery begins and may be the only clinical abnormalities seen in some dogs. Dogs with corneal edema show blepharospasm, photophobia, and serous ocular discharge. Corneal edema usually begins at the limbus and spreads centrally (Fig. 23.4). Ocular pain, present during the early stages of infection, usually subsides once edema is diffuse. However, pain may return with the development of glaucoma or corneal ulceration and

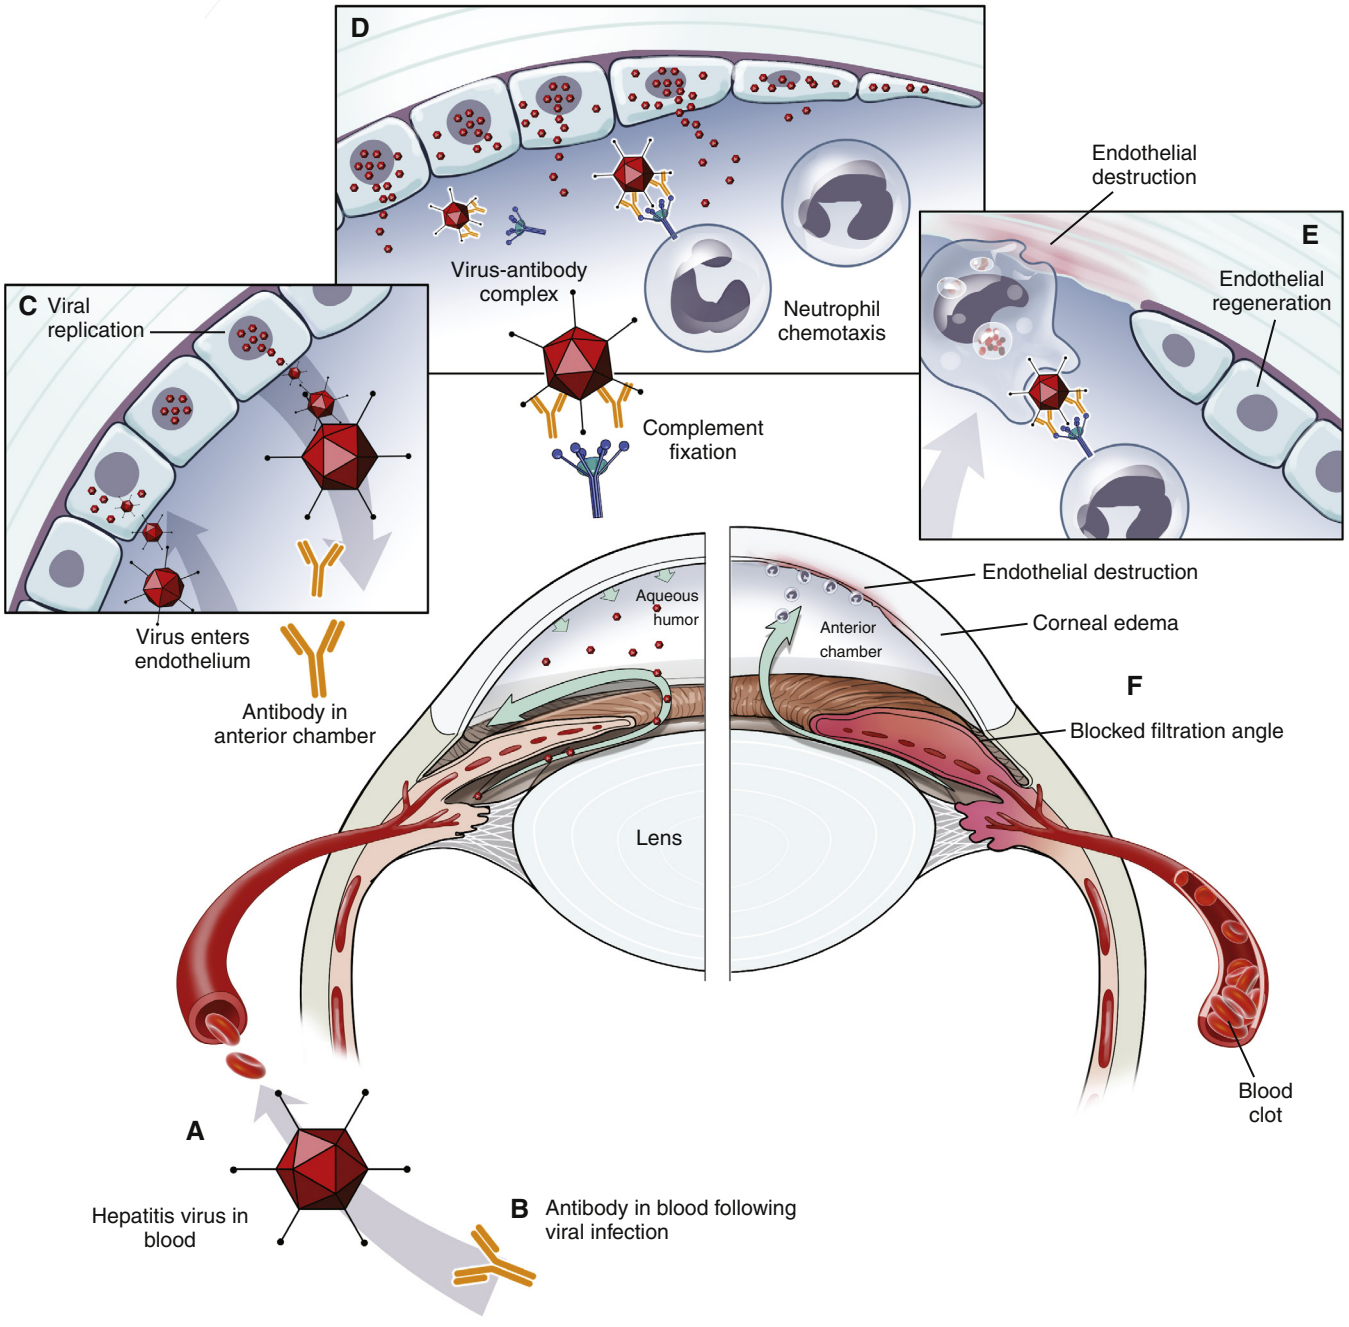

Fig. 23.3 Sequential pathogenesis of CAdV-1 infection in the eye. A, During the viremic period, CAdV-1 enters the eye via the uveal tract, localizing in vascular endothelial cells of the choroid and causing mild uveitis. Virus also enters the aqueous humor and localizes in the corneal endothelial cells. B, A CAdV-1-specific antibody response reaches the eye via the uveal tract and enters the aqueous humor in the presence of virus. C, Virus is free in the aqueous and endothelial cells and there is viral-antibody complex formation and intranuclear inclusion body formation. D, There is complement fixation on virus-immune complexes free and in endothelial cells to chemotaxis of neutrophils. More severe uveitis and corneal endothelial injury occurs. E, Corneal endothelial cell loss allows aqueous to enter the cornea causing corneal edema (blue eye). After mononuclear phagocytes remove virus-immune complexes, and inflammation subsides, corneal endothelium regenerates. F, Uveal inflammation may lead to blockage of the filtration angle and subsequent glaucoma.

perforation. Occasionally, corneal edema fails to resolve for months and may be associated with complications such as glaucoma.[40] In older literature, the Afghan hound was reportedly susceptible to this complication.[41]

In experimental infections with CAdV-1, chronic hepatitis with extensive fibrosis was observed in some dogs that recovered from acute illness, with survival for up to 8 months.[39] The virus could not be found in hepatic lesions from these dogs. Attempts to detect CAdV-1 in the liver of other dogs with chronic active hepatitis using PCR assays have to date been unrewarding.[42-44]

Physical Examination Findings

Physical examination findings in dogs with acute ICH vary, but can include lethargy, dehydration, fever (up to 106°F or 41°C), mild to severe congestion and enlargement of the tonsils, pallor, conjunctivitis, peripheral lymphadenopathy, tachypnea, increased breath sounds, and tachycardia. In some reports, serous to mucopurulent ocular and nasal discharge have been observed, but these may have resulted from coinfections with other respiratory viruses.[28] Abdominal palpation may reveal hepatomegaly, splenomegaly, or abdominal pain. Icterus is uncommon but can occur in dogs with a more prolonged course of disease. Peripheral edema that involves the head, neck, and ventral abdomen has been described.[44] Puppies with CAdV-1 encephalitis may show circling, vocalization, head pressing, ataxia, and blindness.[17] Coagulopathies may be manifested as cutaneous or mucosal petechial hemorrhages, epistaxis, or prolonged bleeding from venipuncture sites.

Ocular complications occur in at least 20% of affected dogs. Unilateral or, less commonly, bilateral corneal edema may be observed, which initially develops at the limbus and is occasionally associated with blepharospasm, photophobia, and a serous ocular discharge.[40] Unilateral involvement may progress to bilateral involvement over several days. Using a slit lamp, the cornea is markedly thickened, and there is episcleral and ciliary injection. Uveitis may also be apparent. Corneal ulceration and increased intraocular pressure has also been described in dogs with corneal edema, the latter of which may result in blindness.[40]

Fig. 23.4 Young adult dog with corneal edema from an Italian shelter outbreak of CAdV-1 infection. (Dr. Nicola Decaro, Department of Veterinary Medicine, University of Bari, Italy.)

DIAGNOSIS

ICH should be suspected in any dog less than 1 year of age that has a questionable vaccination history and signs of fever, respiratory, GI, and hepatic disease, and certainly in any young dog that develops corneal edema. Diagnosis is easily achieved at necropsy when characteristic intranuclear inclusion bodies are seen in tissues, but the sensitivity and specificity of this finding is unknown. Inclusion bodies may be seen on impression smears of liver biopsies or tissue obtained at necropsy. Antemortem diagnosis is challenging owing to the lack of commercially available assays and the disease may be underdiagnosed (Table 23.1). Serologic (antibody) assays are available, but they provide only a retrospective diagnosis, and interpretation of these assays may be a challenge when there is a history of vaccination or active circulation of CAdV-2.[31]

Laboratory Abnormalities

Complete Blood Count

Findings reported on the CBC in dogs with ICH are variable and include leukopenia, anemia, normoblastosis, and moderate to severe thrombocytopenia. Leukopenia (< 2000 cells/μL) occurs early in the course of infection and may be profound. Initially there is lymphopenia, then progressive neutropenia until death.[45] Bandemia and toxic changes may also be present. Occasionally leukocytosis is observed.[37] Leukocytosis and lymphocytosis may occur as part of the recovery process.

TABLE 23.1 Diagnostic Assays Available for Infectious Canine Hepatitis

Assay	Specimen Type	Target	Performance
Histopathology	Usually necropsy specimens, but also liver biopsy	Hepatic necrosis with intranuclear inclusions; CAdV-1 antigen with immunohistochemistry	True sensitivity and specificity of inclusion visualization unknown. Liver biopsy may not be feasible because of coagulopathies
PCR and real-time PCR	EDTA-blood; rectal, conjunctival, and nasal swabs; urine; tissues collected at necropsy	CAdV-1 DNA	Sensitivity and specificity may vary depending on assay design. Assays discriminating between CAdV-1 and CAdV-2 are available. The significance of a positive result from urine may be difficult to interpret due to subclinical shedding. False-negative results may occur as a result of PCR assay inhibition by components of feces
Virus isolation	All body secretions, tissues	CAdV-1	Sensitive, but generally only available as a research tool. No discrimination between CAdV-1 and CAdV-2

Serum Biochemical Tests

Changes on the serum biochemistry profile include increased activity of serum ALT (sometimes >1000 U/L), AST, and ALP; hyperbilirubinemia; hypoglycemia; and hypoalbuminemia.[46] The degree of increased activities of serum transaminases and ALP depends on the time of sampling and the magnitude of hepatic necrosis. These enzyme increases continue until day 14 PI, after which they decline, although they may persist or recur in dogs that develop chronic hepatitis. Of diagnostic importance, the increase in ALT activity, a measure of hepatocellular necrosis, is often disproportionately higher than the increase in serum bilirubin. This disparity, which is typical for ICH and differentiates it from most other causes of widespread hepatic necrosis, results from the predominant centrilobular nature of the necrosis. In contrast, the periportal, peripheral lobular regions are spared. Serum protein alterations, detectable only on serum electrophoresis, are a transient increase in α2-globulin by 7 days PI and by a delayed increase in γ-globulin, which peaks 21 days PI.[4]

Measures of hepatic function, such as serum ammonia or bile acid concentrations, can be increased during the acute course of ICH or later in dogs that develop hepatic fibrosis. Similarly, hypoglycemia may be found in dogs in the terminal phases of the disease. Determination of serum ammonia concentration may facilitate diagnosis of hepatic encephalopathy in dogs with neurologic signs.

Urinalysis

The urinalysis of dogs with ICH may reveal proteinuria, hyaline and granular cylindruria, hematuria, and bilirubinuria. Proteinuria (primarily albuminuria) is a reflection of the renal damage caused by the virus and can usually be detected on random urinalysis because the concentration is greater than 50 mg/dL. The increase in glomerular permeability can result from localization of the virus in the glomerulus in the initial stages of infection. Alternatively, as the disease progresses, glomeruli become damaged by CICs or as an effect of DIC.[4]

Coagulation Profile

In addition to thrombocytopenia, coagulation abnormalities reported in ICH reflect the presence of DIC and hepatic failure and include prolonged PT, markedly prolonged APTT (to 6 to 7 times control values), decreased factor VIII activity, hypofibrinogenemia, and increased fibrinogen degradation product concentrations. Platelet function assays have shown reduced platelet adhesion.[45]

Diagnostic Imaging

Findings on plain radiography and abdominal sonography in dogs with ICH have not been reported. Possible findings on plain radiography are a normal to slightly enlarged liver, and poor detail as a result of abdominal effusion or young age.

Microbiologic Tests

Virus Isolation

CAdV-1 can be readily isolated in a variety of cell types, such as Madin-Darby canine kidney (MDCK) cells.[8,9] In dogs with acute illness, any body fluid or tissue is likely to contain sufficient virus for isolation. The optimal necropsy specimens are kidney, lung, and lymphoid tissues; liver is rich in arginase, which inhibits virus isolation in cell culture.[46] Viral growth in cells is manifested as cell rounding, cluster formation, and detachment. Immunofluorescence (IF) can detect viral antigens in infected cell cultures and in acetone-fixed tissue sections or smears. As a consequence of viral replication, intranuclear inclusion bodies may be evident within cells after staining with H&E.[17,18,31] However, virus isolation, even if followed by detection of viral antigens, is not able to distinguish between infection with CAdV-1 and CAdV-2. This is important since CAdV-2 can be sporadically isolated from organs and feces of either vaccinated or acutely infected dogs, while CAdV-1 can be often detected in the respiratory secretions, trachea, and lungs.[31] In addition, virus isolation is not widely offered by commercial veterinary diagnostic laboratories.

Serologic Diagnosis

Serologic tests are available for detection of IgG and IgM against CAdV-1, which include ELISA assays, hemagglutination inhibition, and serum neutralization. However, due to cross-reactivity with CAdV-2, diagnosis of ICH cannot rely only on serological testing. In addition, dogs with acute disease may die before they develop antibodies to the virus.[39] For dogs that recover from illness, a recent history of vaccination may complicate interpretation of acute and convalescent phase serology. In the absence of a vaccination history, a fourfold rise in titer over a 2- to 3-week period together with compatible clinical signs is supportive of the diagnosis of ICH. Titers that follow natural infection may be higher than those that follow vaccination. Rapid serological tests, based on the ELISA technology, are available for determination of postvaccination antibodies.

Molecular Diagnosis

Due to the antigenic relatedness of the two CAdV types, distinction between CAdV-1 and CAdV-2 requires molecular testing. PCR amplification followed by restriction fragment length polymorphism analysis (see Chapters 6 and 7) using the endonucleases *Pst*I and *Hpa*II generates differential patterns.[48] Endpoint (conventional) PCR assays for rapid detection of CAdV-1 in clinical specimens such as nasal, rectal, and ocular swabs and blood, as well as tissue obtained at necropsy, have been described. These include assays that differentiate between CAdV-1 and CAdV-2 (Fig. 23.5).[23] Because of the rarity of the disease, the clinical sensitivity and specificity of these assays are not well understood. A SYBR® Green real-time PCR assay has been introduced for CAdV detection and differentiation.[49] A duplex real-time PCR assay based on the TaqMan technology for simultaneous detection and characterization of CAdV-1 and CAdV-2 was developed by using a single primer pair and virus-specific probes.[45,50] This assay was highly sensitive (at least 1 to 2 logs more than endpoint PCR) and showed a good linearity over a range of nine orders of magnitude, which allows a precise calculation of DNA load in samples that contain widely varying amounts of virus.

The results of PCR assays on urine may be more difficult to interpret than those for other specimens, because of the potential for chronic shedding from this site in the absence of clinical signs. Assays that specifically detect CAdV-1 differentiate between virulent CAdV-1 virus and vaccine virus, because vaccines for ICH all contain only CAdV-2.

Pathologic Findings

Gross Pathologic Findings

Findings on necropsy or biopsy examination of tissues from dogs can usually confirm a diagnosis of ICH. Dogs that die during the acute phase of the disease are often in good body condition, with edema and hemorrhage of superficial lymph nodes and cervical subcutaneous tissue. Icterus is mild or not usually apparent. The abdominal cavity may contain fluid that varies from clear to bright red in color. Petechial and ecchymotic hemorrhages are often present on serosal surfaces. The liver is enlarged, dark, and mottled in appearance, and a prominent fibrinous exudate is usually found on the liver surface and in the interlobar fissures (Fig. 23.6). Typically, the gallbladder is thickened and edematous and has a bluish-white opaque appearance. Fibrin can be deposited on other abdominal serosal surfaces, giving them a ground-glass appearance. Intraluminal GI hemorrhage is a frequent finding. The spleen is enlarged and bulges on the cut surface.

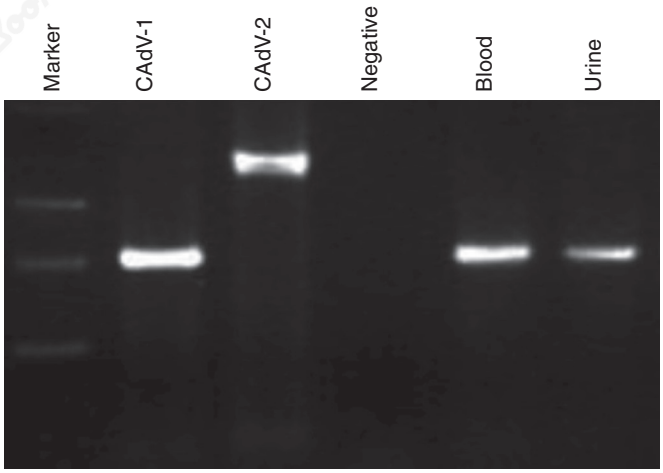

Fig. 23.5 PCR assay for detection of CAdV-1 and CAdV-2. Lane 1, molecular weight marker. Lane 2, positive control for CAdV-1 (508 base pair [bp] product). Lane 3, positive control for CAdV-2 (1030 bp). Lane 4, negative control (rectal swab from a dog negative for CAdV-1/CAdV-2). Lanes 5 and 6, clinical specimens positive for CAdV-1 (EDTA-blood and urine collected from the case example 2 weeks after initial examination).

Fig. 23.6 Infectious canine hepatitis, hepatic necrosis, liver, dog. The liver from dogs with infectious canine hepatitis can be slightly enlarged and friable with a blotchy yellow discoloration. Sometimes fibrin is evident on the capsular surface. Note the petechiae on the serosal surface of the intestines caused by vascular damage. (Courtesy Dr. M.D. McGavin, College of Veterinary Medicine, University of Tennessee. In Zachary JF, McGavin MD. *Pathologic Basis of Veterinary Disease*, 5th ed. St. Louis, MO: Mosby; 2012.)

Variable gross lesions in other organs include multifocal hemorrhagic renal cortical infarcts. The lungs have multiple, patchy, gray-to-red areas of consolidation. Hemorrhagic and edematous bronchial lymph nodes are found. Scattered hemorrhages, present on coronal section of the brain, are primarily located in the midbrain and caudal brainstem. Ocular lesions, when present, are characterized by corneal opacification and clouding of the aqueous humor.

In dogs with chronic disease, the liver may be small, firm, and nodular. The kidneys may be studded with multiple white foci (0.5 cm diameter) that extend from the renal pelvis to the outer cortex. Ocular sequelae from the acute disease can include either glaucoma or phthisis bulbi.[4]

Histopathologic Findings

Histopathologic examination of the liver of dogs that die of acute hepatitis usually reveals widespread centrilobular to panlobular necrosis. In dogs with mild hepatocellular necrosis, the margin between necrotic and viable hepatocytes is sharply defined within the liver lobule. Preservation of the underlying support stroma allows for eventual hepatic regeneration. Only in severe cases does coagulation necrosis of entire hepatic lobules prevent regeneration. Neutrophilic and mononuclear cell infiltrates are associated with the removal of underlying necrotic tissue. Bile pigment rarely accumulates in most cases because of the transient nature of hepatocellular necrosis and the frequent lack of peripheral lobular involvement of portal regions. Intranuclear inclusions are initially found in Kupffer's cells and later in viable hepatic parenchymal cells. Subacute to chronic hepatic disease is marked by sporadic foci of necrosis with neutrophilic, mononuclear, and plasma cell infiltration and is found in dogs with partial immunity that survive initial stages of infection.

Historically, CAdV-1 has been observed with direct fluorescent antibody in hepatocytes of recovered dogs with chronic hepatic inflammation. PCR and histochemical staining of tissues have been used to examine for CAdV-1 in the livers of dogs with naturally occurring ICH, chronic hepatitis, and hepatic fibrosis.[44] Although the dogs with known ICH have had positive test results, CAdV-1 has not been detected in studies that used PCR on liver specimens from dogs with idiopathic acute or chronic hepatitis.[43]

Widespread histologic alterations occur in other organs as a result of endothelial injury caused by the virus. The gallbladder has marked subserosal edema, but the epithelium remains intact. Viral inclusions are initially found in the renal glomeruli but are later found in renal tubular vascular endothelium. Focal interstitial accumulations of neutrophils and mononuclear cells are found in the renal cortex and medulla. These mild changes often progress to focal interstitial fibrosis.[51] Lymphoid organs, including the lymph nodes, tonsils, and spleen, are congested with neutrophilic and mononuclear cell infiltrates. Lymphoid follicles are dispersed with central areas of necrotic foci. Intranuclear inclusions can be found in vascular endothelial cells and histiocytes. The lungs have thickened alveoli with septal cell and peribronchial lymphoid accumulations. Alveoli in consolidated areas are filled with an exudate consisting of erythrocytes, fibrin, and fluid. Mucosal and submucosal edema with focal subserosal hemorrhage is found in the intestinal tract. Widespread vascular degeneration and tissue hemorrhage and necrosis are associated with the presence of intravascular fibrin thrombi.

Swollen, desquamated endothelial cells in meningeal vessels often contain intranuclear inclusions. Mononuclear cuffing is present around small vessels throughout the parenchyma of the CNS.[17] Mild endothelial proliferation and mononuclear perivascular infiltration persist for at least 3 weeks after clinical recovery.

Ocular changes are characterized by granulomatous iridocyclitis with corneal endothelial disruption and corneal edema. Iridial and ciliary vessels are congested with inflammatory cells that are also present in the iris and filtration angle.

The inclusion bodies seen in ICH have been classified as Cowdry type A or B. They are often multiple basophilic inclusions and are present in both ectodermal and mesodermal tissues. Their relative abundance in the liver makes this the optimal tissue for impression smears obtained by biopsy or at necropsy (Fig. 23.7). Initial hypertrophy of the cell nucleus is followed by peripheral margination of the chromatin network and nucleolus, which forms a central, dark-staining nuclear remnant surrounded by a halo of chromatin. The initial inclusions are acidophilic but become basophilic as the chromatin marginates. Care must be taken to distinguish inclusions from faintly staining hepatocyte nucleoli.[4,31]

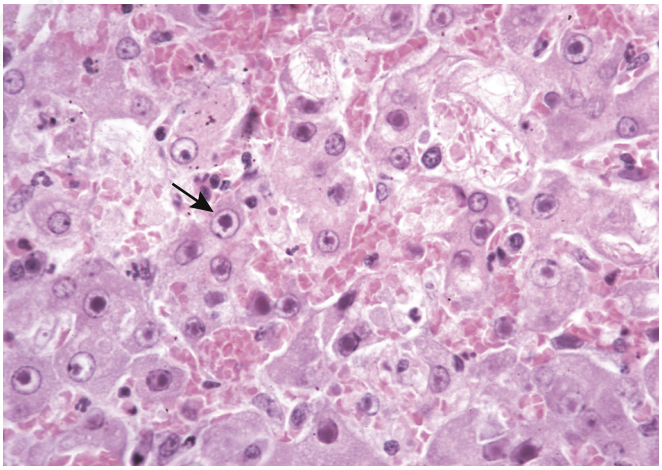

Fig. 23.7 Infection of hepatocytes and endothelial cells with CAdV-1 produces characteristic basophilic intranuclear inclusions surrounded by a clear zone that separates them from the marginated chromatin *(arrow)*. H&E stain. (Courtesy Dr. W. Crowell, College of Veterinary Medicine, The University of Georgia and Noah's Archive, College of Veterinary Medicine, The University of Georgia. In Zachary JF, McGavin M. *Pathologic Basis of Veterinary Disease*, 5th ed. St. Louis, MO: Mosby; 2012.)

TREATMENT AND PROGNOSIS

Supportive Care

Clinical management of dogs that develop ICH is primarily supportive. In the absence of complicating factors, clinical recovery and hepatocellular regeneration can occur with centrilobular necrosis. It may be difficult to determine whether neurologic signs are related to hepatic encephalopathy or viral encephalitis. Measurement of blood glucose or ammonia concentrations may be helpful.

Immediate placement of an indwelling intravenous catheter is required for severely affected dogs; however, because of coagulopathy, care must be taken to minimize hemorrhage. Fluid therapy with a polyionic isotonic fluid such as Ringer's solution can correct losses from vomiting and diarrhea. Replacement of clotting factors and platelets through administration of fresh plasma or whole blood may be necessary in conjunction with anticoagulant therapy in dogs with coagulopathies.

In comatose dogs, possible hypoglycemia should be addressed by administration of 50% glucose (0.5 mL/kg, IV, over 5 minutes). Hypoglycemia is likely to recur if continuous infusion of hypertonic glucose is not maintained. Hypertonic glucose infusion should be continued at a rate not greater than 0.5 to 0.9 g/kg per hour. Treatment of hepatic encephalopathy is directed at reducing protein catabolism by colonic bacteria and ammonia resorption in the renal tubules. Ammonia production can be reduced by administering restricted protein diets and management of GI hemorrhage. Evacuation of the colon by administration of warm water enemas may also retard ammonia absorption. Nonabsorbable oral antibacterials such as neomycin have been advocated to reduce ammonia-producing bacteria in the intestine, but their effectiveness is questionable. Acidification of the colonic contents can also be achieved by feeding oral lactulose to nonvomiting animals. Renal resorption of ammonia can be reduced by administration of parenteral or oral potassium and correction of metabolic alkalosis.

Other medications that may be indicated include antiemetics, antacids, sucralfate, whole blood or plasma transfusions, and colloids such as hetastarch. The use of parenteral broad-spectrum antimicrobial drugs should be considered for dogs with hemorrhagic gastroenteritis that may develop bacteremia as a result of bacterial translocation. After fluorescein staining has shown no evidence of corneal ulceration, dogs with severe corneal edema and uveitis should be treated with topical ophthalmic preparations that contain glucocorticoids and atropine to prevent development of glaucoma.

Prognosis depends on the severity of disease, which reflects the immune status of the affected dog and possibly the virus strain. There is a possibility that recovered dogs may develop chronic hepatitis or chronic glomerulonephritis, but the extent to which this truly occurs is unknown.

IMMUNITY AND VACCINATION

Immunity to natural infection with CAdV-1 is probably lifelong. Effective vaccines have been available and widely used as part of core vaccine programs for dogs for many years. Immunity after immunization with attenuated live vaccines lasts at least 3 years and probably longer, up to 9 years according to challenge and serological studies.[52] Early vaccines, which contained CAdV-1, were associated with the development of corneal edema and glomerulonephritis in a small percentage (<1%) of immunized dogs. Replacement of attenuated live CAdV-1 with CAdV-2 occurred after 1980 and eliminated this complication.[53] These vaccines have the potential to cause transient respiratory signs and tonsillitis in dogs if accidental inhalation occurs, so care should be taken not to aerosolize the vaccine during administration. MDA persists until puppies are 12 to 16 weeks of age and interferes with immunization when virus neutralization titers are high. Vaccines should be administered every 3 to 4 weeks from 6 weeks of age, with the last vaccine given no earlier than 16 weeks of age (see Appendix). After completing the puppy series at 16 weeks or older and vaccinating again at 26 or 52 weeks of age, revaccination need not be done more often than every 3 years. In the absence of MDA, attenuated live vaccines protect against ICH as early as 5 days after vaccination. Revaccination can be avoided, especially in immunocompromised dogs or dogs with a history of postvaccination reactions in the presence of specific antibodies, which can be easily determined by commercially available serological assays.[54] The presence of serum antibody, regardless of titer, in an actively immunized dog over the age of 20 weeks is correlated with protection.[55] Vaccine virus may be shed from the respiratory tract by dogs after vaccination, which has the potential to immunize other dogs as well.

Although extensive vaccination has greatly reduced the incidence of CAdV-1 infection, reemergence of ICH in western Europe has been associated to parallel trading of pups with uncertain sanitary status from the eastern European countries. Currently, there are few data on the molecular epidemiology of CAdV-1, but it is commonly accepted that vaccine breaks occur very rarely with CAdV-2 vaccines, since the viruses are genetically stable. Accordingly, CAdV-1 infection in vaccinated dogs has been associated with MDA interference in the early life of the pups rather than the emergence of variants genetically distant from the prototype strains contained in commercially available vaccines.[18]

PREVENTION

The best means of prevention of ICH is proper vaccination. Additional control measures that could be considered in locations where outbreaks occur, such as in shelters, include proper disinfection, isolation, and prevention of overcrowding and other coinfections, which may worsen disease. Because contact with wild animal species such as coyotes, wolves, and foxes that might be shedding the virus may also be a

source of infection for dogs, exclusion of these species from interactions with domestic dogs may also serve to prevent the disease.

PUBLIC HEALTH ASPECTS

In humans, species C adenoviruses are considered to be the most clinically significant adenovirus species, as they can become latent in an episomal form in immune cells and reactivate in immunocompromised patients.[3] There is currently no evidence that CAdV-1 infects humans. However, there is some evidence that adenoviruses that infect cats may have the capability of infecting humans (see Feline Adenovirus Infection).

FELINE ADENOVIRUS INFECTION

In cats, clinical disease caused by adenovirus infection is most likely to occur in immunocompromised animals.[56,57] In studies of cats in Hungary, Scotland, the Netherlands, the Czech Republic, and the United States, serologic findings indicated adenovirus exposure in 15%, 10%, 20%, 25%, and 26% of cats, respectively.[3,58,59] However, the clinical findings of disseminated adenovirus infection have only been described in detail in one cat.[60,61] Inclusion body hepatitis in a black panther was suggestive of adenovirus infection; however, the causative agent could not be confirmed by electron microscopy or through virus isolation.[62]

The cat with disseminated adenovirus infection was an 8-year-old, spayed female, domestic shorthair cat. Physical examination findings included mental obtundation and oral mucosal petechiae. Abnormal hematologic findings included leukopenia (2100 cells/μL) and thrombocytopenia (73,000/μL). There was no apparent response to treatment with IV lactated Ringer's solution, dexamethasone, and vitamin K, and the cat died 4 hours after initial examination. At necropsy, the abdominal cavity and pericardial sac were filled with serous fluid. Serosal and mucosal surfaces of the small and large intestines were diffusely dark red with scattered serosal petechiae, and there was dark red fluid intestinal contents. The liver and kidneys were enlarged, and the liver had an accentuated lobular pattern. Abdominal fluid tested positive for FeLV p27 antigen and was negative for FIV antibody. An adenovirus particle was identified by electron micrography of intestinal contents. Histologically, there was moderate lymphoid depletion and peripheral hemorrhage in lymphoid tissue. Endothelial cells were detached from intramyocardial arteries (Fig. 23.8). Nuclei of these sloughed cells were large and pleomorphic, and many contained intranuclear inclusion bodies. Multiple round eosinophilic inclusions were present in some nuclei, with amphophilic granular inclusions filling other nuclei. Some nuclei were almost filled with well-delineated basophilic inclusions, with margination of the small amount of surrounding chromatin (Fig. 23.8, *inset*). Some nuclei had indistinct borders, resulting in a "smudge cell" appearance. The cytoplasm of sloughed endothelial cells was eosinophilic.

Throughout the GI tract, there was diffuse submucosal edema. Diffuse superficial necrotizing and hemorrhagic enteritis was present in the small intestine. Necrosis was more severe in the ileum, with full-thickness mucosal necrosis over Peyer's patches. Sections of colon were comparably affected, with particularly severe mucosal necrosis overlying areas of submucosal lymphoid tissue. Submucosal and mesenteric blood vessels at all levels of the GI tract had endothelial lesions as described in the heart. Similar vascular lesions were seen in small hepatic arteries, pulmonary arteries, trachea, thymic remnant, urinary bladder, thyroid gland, adrenal gland, bone marrow, spleen, lymph node, and kidney.

Electron microscopic examination of detached endothelial cells revealed intranuclear viral particles measuring approximately 65 nm in diameter (Fig. 23.9). Some of these particles were icosahedral, with dense central cores. In some areas, viral particles formed loose crystalline arrays.

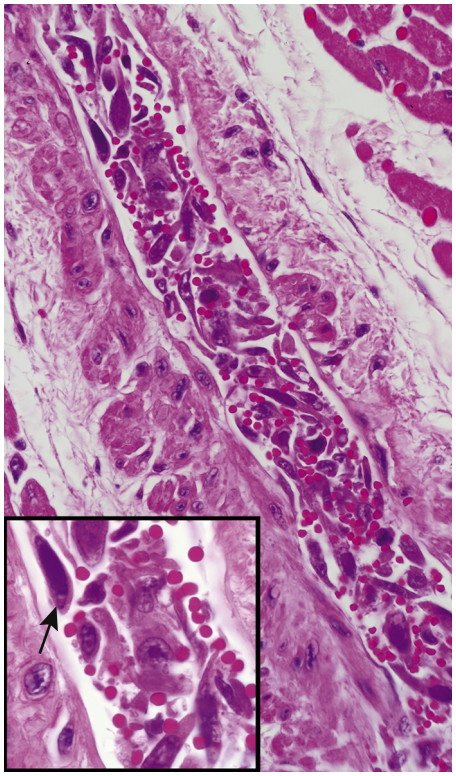

Fig. 23.8 Photomicrograph of an intramyocardial artery from a cat with disseminated adenovirus infection. Endothelial cells are sloughing. Spindle-shaped cells within the arterial lumen have large, pleomorphic nuclei, some with inclusion bodies (H&E stain, ×400). **Inset,** Nucleus containing an inclusion body (*arrow*; H&E stain, ×1000). (Courtesy Frances A. Kennedy, Michigan State University, East Lansing, MI.)

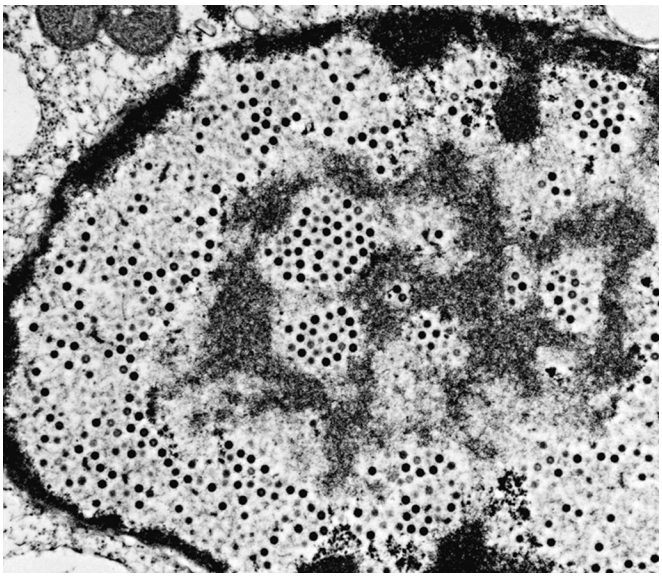

Fig. 23.9 Electron micrograph of an endothelial cell from a cat with disseminated adenovirus infection. There are intranuclear viral particles. Moderate autolytic change is responsible for disruption of adenoviral arrays (×17,900). (From Kennedy FA, Mullaney TP. Disseminated adenovirus infection in a cat. *J Vet Diagn Invest.* 1993;5:273-276.)

Because adenoviruses are generally considered to be relatively host-specific,[1] healthy horses, dogs, and one goat on the property

were unlikely sources of infection for this cat. Other cats on the property were also apparently healthy. It is possible that FeLV-associated immunocompromise predisposed this cat to disseminated adenovirus infection. Leukopenia may have been a consequence of FeLV infection, terminal endotoxemia, or both. Thrombocytopenia was most likely consequent to consumption secondary to vascular lesions.

Results of serologic studies in cats, measuring serum antibody to feline adenovirus, have indicated that persistent subclinical adenovirus infection exists in the feline population. Risk factors for seroreactivity are age and the presence of respiratory or GI signs.[63] However, to date, only one case of adenovirus infection in a cat has been confirmed using molecular methods.[3,59] The affected cat had transient hepatic failure, and the results of serologic testing supported the possibility of adenovirus infection. Adenovirus hexon capsid nucleic acid was detected in two rectal swabs taken 1 year apart and a pharyngeal swab taken at the second time point. This finding suggests that, in addition to persistent subclinical infections, chronic shedding of adenovirus may be possible in cats.

Feline adenovirus is not considered to cause disease in humans, although there are few reports that describe the possibility of interspecies transmission. In one report of a 1-year-old girl with gastroenteritis, a fecal specimen from the child was positive for an adenovirus strain that exhibited a high degree of homology to a feline adenovirus.[12] No cats were kept in the household. A feline adenovirus isolate was also described that could replicate in both monkey Vero cells and human HeLa cells.[11] In a large epidemiological survey for adenoviruses in humans in Brazil, a nasopharyngeal aspirate of a child contained a strain that had a hexon gene sequence with 100% nucleotide identity to feline isolates.[13] Most recently, the adenovirus isolated from a rectal swab from the cat with hepatitis in the late 1990s was shown to replicate in human and feline cell lines, exhibited serologic cross-reactivity with human adenoviruses, and had high sequence homology to species C human adenoviruses.[3,59] It was proposed that the virus be named FeAdV-1.[3] In contrast, the cat with disseminated disease and FeLV infection was infected with an adenovirus that was distinct from human adenoviruses,[64] which currently remains unnamed.

CASE EXAMPLE

Signalment
"Pablo," 2-year-old male American pit bull terrier from Bari, Italy.

History
Pablo lived indoors but contacted other dogs at a building site, to which he was occasionally brought. Pablo was unvaccinated, and was fed commercial dry food. The owner reported a 2-day history of inappetence, lethargy, and respiratory distress before taking Pablo to a veterinary clinic. As a puppy, Pablo had severe gastroenteritis of unknown etiology.

Physical Examination
Body weight: 23.3 kg.

General: Lethargic, not fully responsive, with evidence of respiratory distress. Temperature = 103.1°F (39.4°C), HR = 70 beats/min, RR = 48 breaths/min, mucous membranes slightly pale, CRT = 2 s.

Integument, eyes, ears, nose, and throat: Mild tonsillitis.

Musculoskeletal: Ambulatory on all four limbs. No clinically significant abnormalities.

Cardiovascular, respiratory, gastrointestinal, and urogenital systems: Increased breath sounds diffusely. Tense abdomen, with severe cranial abdominal pain. Moderate peripheral lymphadenopathy, mainly involving the retropharyngeal lymph nodes. Prepucial edema and hemorrhages were observed.

Laboratory Findings
CBC: HCT 36.3% (37–55%)MCV 73.2 fL (60–77 fL), MCHC 38.2 g/dL (30–37.5 g/dL), WBC 13,510 cells/μL (5500–16,900 cells/μL), neutrophils 11,440 cells/μL (2000–12,000 cells/μL), lymphocytes 1112 cells/μL (500–4900 cells/μL), monocytes 65 cells/μL (30–2000 cells/μL), platelets 27,000/μL (175,000–500,000 platelets/μL)

Serum chemistry profile: BUN 13 mg/dL (7–27 mg/dL), creatinine 1.0 mg/dL (0.5–1.8 mg/dL), glucose 89 mg/dL (74–143 mg/dL), total protein 4.6 g/dL (5.5–7.5 g/dL), albumin 2.01 g/dL (2.5–4.0 g/dL), globulin 2.6 g/dL (1.8–3.9 g/dL), ALT 698 U/L (10–100 U/L), AST 700 U/L (0–50 U/L), ALP 155 U/L (23–212 U/L), creatine kinase 458 U/L (10–200 U/L), GGT 0 U/L (0–7 U/L), cholesterol 201 mg/dL (110–320 mg/dL), total bilirubin 0.1 mg/dL (0–0.9 mg/dL)

Serum protein electrophoresis: There was a slight reduction of the albumin fraction (43.6%, reference range 45.0–55.0%) and an increase in the α2-globulin fraction (18.2%, normal range 8.0–14.0%). The albumin/globulin ratio was 0.77.

Urinalysis: SpG 1.033; pH 6.5, 1+ protein, 1+ bilirubin, 1+ hemoprotein, no glucose, no WBC, rare RBC, 2+ epithelial cells, few granular casts.

Imaging Findings
Thoracic radiographs: The cardiovascular and pulmonary structures appeared within normal limits. Pulmonary interstitial and alveolar infiltration were evident along with a moderate pleural effusion.

Abdominal ultrasound: A moderate abdominal effusion was present. Spleen, liver, and gallbladder walls were enlarged and hypoechoic. Multiple enlarged, hypoechoic mesenteric, and splenic lymph nodes were observed.

Fecal Examination
Fecal flotation and sedimentation: Negative for parasites.

Molecular Assays
EDTA-blood, fecal, and nasal swab specimens were submitted for molecular detection of canine parvovirus, coronavirus, adenoviruses, and distemper virus using PCR-based assays. All specimens tested positive for CAdV-1.

Diagnosis
Infectious canine hepatitis.

Treatment
Supportive care was provided with IV fluids, oxygen supplementation, and anti-inflammatory drugs; S-adenosylmethionine (20 mg/kg PO q24h) was also administered.

Follow-up
At a recheck 2 weeks later, there was marked clinical improvement. The dog was fully responsive, energetic, with slight pallor of the mucus membranes and a temperature of 100.9°F (38.3°C). Thoracic auscultation and abdominal palpation were unremarkable, and preputial hemorrhages had resolved. There was persistent generalized lymphadenopathy. Liver enzyme activities were normal. A CBC showed anemia (HCT 27.3%), leukocytosis (WBC 29120 cells/μL), neutrophilia (23,160 cells/μL), monocytosis (4280 cells/μL), and thrombocytosis (660,000 platelets/μL). Urinalysis findings were unremarkable. Blood-EDTA and urine samples tested still positive for CAdV-1 by endpoint PCR see (Fig. 23.5).

Comments
The clinical course of ICH in this dog was atypical since there was no overt gastroenteric involvement. This was likely due to the age of the affected animal since it is well known that the pathogenic potential of CAdV-1 is higher in young pups than in adult dogs. The detection of the viral DNA 2 weeks after the dog was first examined is in agreement with the long-term viremia and shedding observed for CAdV-1. Canine Herpesvirus Infection

Autumn P. Davidson, Jane E. Sykes, Margret L. Casal

KEY POINTS

- Cause: CHV-1 (*Canid alphaherpesvirus 1*), genus *Varicellovirus,* subfamily *Alphaherpesvirinae,* family *Herpesviridae*, a cytocidal species-specific alphaherpesvirus. An Epstein-Barr (EBV)-like gamma herpesvirus has been described in dogs with unclear clinical significance (described separately below).
- First Described: New York, United States, 1965.[1]
- Affected Hosts: CHV-1 only infects domestic and wild Canidae. Specific receptors on the canine cell surface have been identified that contribute to this specificity.
- Geographic Distribution: The distribution of CHV-1 is worldwide. Serosurveys of wild canid populations indicate a ubiquitous exposure. The seroprevalence in domestic dogs ranges from 15% to as high as 100% in some kennels. A higher seroprevalence exists in kenneled dogs or colony dogs than in household pets.
- Route of Transmission: Direct contact with mucosal secretions from the respiratory or genital tracts of infected canids.
- Major Clinical Signs: Abortion is the main sign of CHV-1 infection in bitches. Adult dogs may show URTD and keratitis. Neonates infected with CHV-1 may develop inappetence, failure to thrive, vocalization, tachypnea, diarrhea, neurologic signs, abdominal pain, nasal discharge, weight loss, mucosal petechiation, and death.
- Differential Diagnoses: For CHV-1, major differential diagnoses are bacterial sepsis and infections with other viruses such as CDV and CPV-2.
- Human Health Significance: CHV-1 does not infect humans.

CANINE HERPESVIRUS-1

ETIOLOGIC AGENT AND EPIDEMIOLOGY

CHV-1 is a double-stranded DNA enveloped virus that belongs to the family *Herpesviridae* (Fig. 24.1). Infections with the virus have been reported from the United States, Canada, Australia, Japan, England, and Germany. The virus has a genome that is approximately 125 kb long, and to date, whole genome sequence information suggests that isolates worldwide may be genetically very similar.[2,3] CHV-1 was first recognized in the mid-1960s in association with a fatal disease in puppies.[1] It is commonly blamed for acute neonatal puppy death or failure to thrive, sometimes termed the "fading puppy syndrome." When confirmed as a cause of disease, untreated CHV-1 infection in neonates can cause high (up to 100%) mortality among littermates. There is serologic evidence of widespread exposure of domestic dogs to CHV-1 worldwide, with seroprevalences ranging from 15% to as high as 100% in some kennels. A higher seroprevalence exists in kenneled dogs or dogs from colonies than in household pets. Serosurveys of wild canid populations indicate a ubiquitous exposure.[2,4–9]

Alphaherpesviruses are cytocidal, causing tissue necrosis and localized mucosal or generalized systemic infection, most often in young or immunosuppressed animals. The replication of CHV-1 is similar to that of other alphaherpesviruses. Synthesis of viral DNA and nucleocapsids occurs within the host cell nucleus, with the viral envelope being acquired at the nuclear membrane. The virus is transported through the endoplasmic reticulum and Golgi apparatus to the cell surface and released, although most of the virus remains intracellular. CHV-1 is temperature sensitive and prefers to replicate at temperatures less than 37°C. As an enveloped virus, CHV-1 is not stable in the environment and is readily inactivated by standard disinfectants and by heat above 40°C.[10] It is maintained in nature by persistence in its canine host and direct spread from infected animals.

CHV-1 persists in the ganglionic and lymphoid tissues of the oronasal and genital mucosae. Replication and shedding occurs at mucosal surfaces where temperatures are cooler. Recovery from CHV-1 disease is believed to be associated with lifelong latent infection of the neural ganglia. Periodic reactivation of shedding can occur following immunosuppression, such as that induced by pregnancy, transportation, overcrowding, or immunosuppressive drug therapy. Factors that predispose neonatal pups to generalized infection are hypothermia during the first 2–3 weeks of life and a lack of natural immunity if the dam is unexposed.[7,10] CHV-1 infection has not been reported in cats; CHV-1 shares only 51% genetic homology with FHV-1.[11]

CLINICAL FEATURES

Pathogenesis and Clinical Signs in Adult Dogs

Respiratory infection

Transmission of CHV-1 occurs through direct contact with mucosal secretions from the respiratory or genital tracts of infected animals. The incubation period is 6 to 10 days. The virus replicates in the epithelial cells of the oronasal and pharyngeal mucosa, the genital tract, and the regional lymphatics. CHV-1 is one of the viral etiologies of CIRD complex. In a temporal study in shelter dogs, CHV-1 was found in 9.6% of BAL and 12.8% of transtracheal wash specimens from necropsied dogs with endemic respiratory illness.[12] Compared with other incriminated pathogens for which the dogs had received vaccination, CHV-1–associated illness in this report was usually more severe, and its isolation rate was usually highest 3 to 4 weeks after the dog's introduction into the kennel. Signs associated with upper respiratory infection with CHV-1 can also be mild and transient. Healthy adult dogs

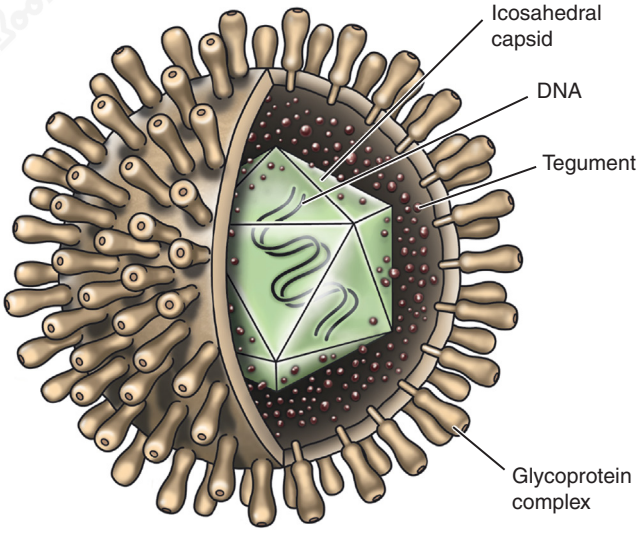

Fig. 24.1 Schematic structure of a herpesvirus. Herpesviruses are large, enveloped DNA viruses. The DNA is contained within an icosahedral capsid.

of either gender can develop mild upper respiratory signs (sneezing, serous oculonasal discharge, keratitis) for a few days but are otherwise usually clinically unaffected. The inherent immunity in a given breed of dog or in an individual dog likely plays an important role in protection against herpesvirus infections.

Genital infection

Infection with CHV-1 can cause genital infections and visible lesions in adult dogs. Primary genital infections in older bitches are characterized by lymphofollicular lesions, variable degrees of vaginal hyperemia, and occasionally petechial or ecchymotic submucosal hemorrhage (Fig. 24.2). No discomfort or vaginal discharge is noted in affected pregnant bitches, even in those that had abortions or stillbirths. Vesicular lesions have been noted during the onset of proestrus and regress during anestrus. Male dogs, with similar lesions over the base of the penis and preputial reflection, may have a preputial discharge. However, these lesions are nonspecific and not pathognomonic for CHV-1 infection. Occasionally herpesviruses have been isolated from papulovesicular lesions of the canine genital tract; such lesions may be recurrent episodes in previously infected bitches. Genital localization of the virus in bitches may be a means of venereal transmission of the virus, but it is most important as a source of infection for pups at birth. Spread of CHV-1 from seropositive males to susceptible females at the time of breeding does not appear to be a significant mode of transmission, although such a mechanism is believed to occur. Application of PCR assays has shown persistence of the virus in the lumbosacral ganglion, with presumed recrudescence and mucosal replication with subsequent shedding by the genital mucosae. Localized genital or respiratory infections and viral shedding can occur in the presence of circulating antibodies.[10]

Ocular infection

CHV-1 can be detected in conjunctival or corneal swab specimens from adult dogs. Because the prevalence of infection in apparently healthy dogs is high, associating positive test results with disease is difficult. However, CHV-1 is more prevalent in conjunctival swab specimens from dogs with conjunctivitis versus those without. Furthermore, CHV-1 has been found in dogs with naturally occurring dendritic corneal ulcerations that are considered pathognomonic lesions in other species. The development of dendritic keratitis was described in a dog with keratoconjunctivitis sicca that was treated with topical immunosuppressive drugs (cyclosporine and tacrolimus).[13] Conjunctivitis

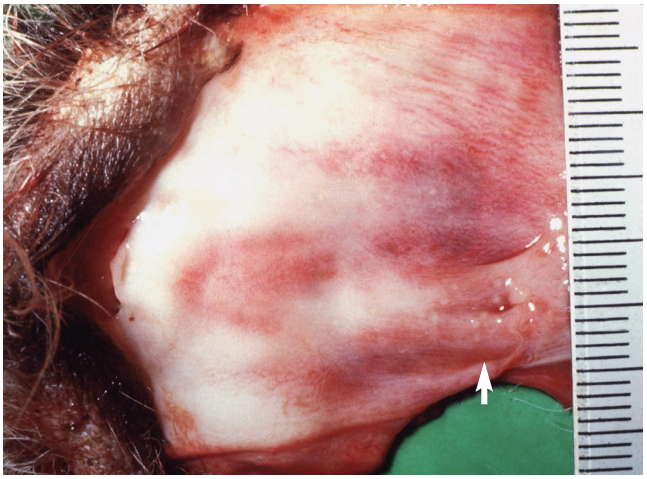

Fig. 24.2 Vaginitis associated with CHV-1 infection. *Arrow* points to a vesicular lesion. (Courtesy Akira Hashimoto, Hokkaido University, Sapporo, Japan.)

and ulcerative and nonulcerative keratitis were identified in an outbreak of ocular disease in a closed domestic dog colony; CHV-1 was incriminated as the cause by PCR and viral culture. Furthermore, experimental topical ocular inoculation of dogs produced a self-limiting ocular infection manifested by conjunctivitis and followed by latency. Infection, characterized by conjunctivitis, keratitis, and viral reshedding, was reactivated 8 months later by systemic administration of immunosuppressive doses of glucocorticoids. Topical ocular application of glucocorticoids was not associated with recrudescence of infection.[14–17]

Systemic disease

A fatal multisystemic infection by CHV-1 was reported in a 9-year-old spayed female bichon frisé with no evidence of underlying immunosuppression.[18] The dog was evaluated with clinical signs of vomiting and diarrhea, which were rapidly followed by death. At necropsy, there was multifocal necrosis with intranuclear inclusion bodies in the liver, adrenal glands, and small intestinal tract.

Pathogenesis and Clinical Signs in Fetuses and Neonates

In utero infection

Although neonatal infection usually is acquired at or soon after birth, transplacental transmission can also occur. Death of neonatal puppies younger than 1 week as a result of infection probably indicates *in utero* infection. The recently infected brood bitch generally shows no clinical signs. The effects of transplacental infection with CHV-1 depend on the stage of gestation at which infection occurs (Fig. 24.3). Resorption (apparent infertility) and abortion of stillborn or weak pups with no clinical signs in the dam have been reported. Although some puppies can survive such *in utero* infections and appear normal after delivery by cesarean section, others harbor the virus inapparently in their tissues. However, most pups develop systemic herpesvirus infection within 9 days of birth.[10]

Systemic neonatal infection

Transmission of CHV-1 can occur subsequent to close contact with infectious vaginal fluids during whelping or with vulvar or oronasal secretions in the postpartum period. Exposure of a naïve bitch to CHV-1 during the last 3 weeks of gestation results either in late-term abortion of a litter, or neonatal disease or death within the first few weeks of life, because inadequate periparturient maternal antibodies exist to allow passive immunity to be acquired by the neonates.

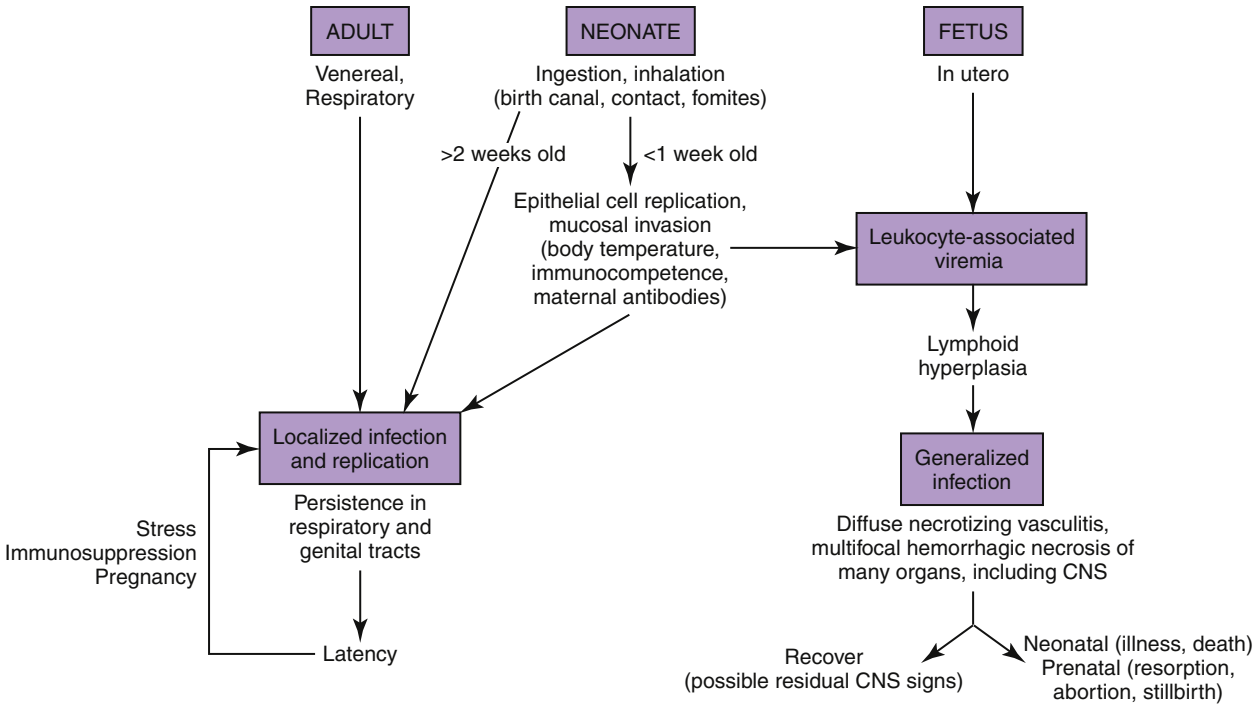

Fig. 24.3 Pathogenesis of canine herpesvirus-1 infection.

Puppies born to a naïve bitch may also become infected as a result of contact with other dogs in the home or kennel that shed virus. Neonatal CHV-1 infection is usually associated with an acute and fatal illness, primarily between 1 and 3 weeks of age. Immunity acquired from the dam appears to be important in the survival of infected neonates, as those suckling seropositive bitches can become subclinically infected while shedding virus from the oropharynx. The existence of maternal antibodies or immune lymphocytes acquired from milk may explain why naturally infected pregnant bitches that give birth to diseased puppies subsequently give birth to healthy litters. Serum antibody titers in previously infected pregnant bitches may also suppress viremia and spread of infection to the fetus.

CHV-1 replicates in the epithelial cells of the neonatal oronasal and pharyngeal mucosa, the genital tract, and the regional lymphatics. Replication and spread of the virus are facilitated by the presence of a low body temperature (33°C–35°C), which is present in oral and genital mucous membranes and in canine neonates. Temperature regulation of the newborn pup is not developed until 2 to 3 weeks of age, and neonatal rectal temperature is usually 1°C to 1.5°C (2°F to 3°F) lower than that of the adult dog. In addition to having a reduced capacity for temperature regulation, neonatal pups are incapable of an adequate febrile response. Cell-mediated immune functions are also suppressed at temperatures lower than 39°C, rendering hypothermic pups more susceptible to CHV-1 infection. The virus then enters the bloodstream by way of macrophages. Cell-associated viremia develops within 3 to 4 days of inoculation. Virus localization in the mononuclear phagocytic cells of the lymph nodes and spleen results in lymphoid hyperplasia and necrosis. Progressive multifocal hemorrhagic necrosis occurs in several organs; the highest concentrations of virus are found in the adrenal glands, kidneys, lungs, spleen, and liver. Lesions may be related to the vasculitis and marked thrombocytopenia that occurs during infection. Thrombocytopenia can result from DIC associated with widespread vascular endothelial damage and tissue necrosis. Ganglioneuritis of the trigeminal nerve is a frequent lesion in puppies infected by oronasal exposure. Meningoencephalitis can also occur in neonatal puppies,[19] but CNS signs are not always apparent. Puppies usually die from systemic illness before neurologic signs appear.

Clinical signs in the neonate are not specific and include incessant vocalization, poor nursing effort (with weight loss), diarrhea, and serous to hemorrhagic nasal discharge. Despite the muscular activity associated with crying, restlessness, and shivering, no increase in body temperature typically occurs. Neonates lose consciousness and may have opisthotonos and seizures just before death. Rectal temperatures become subnormal terminally, typically within 24 to 48 hours after the onset of clinical illness.

Some neonates develop mild clinical disease and subsequently recover. Ocular involvement was described in one recovering puppy.[20] Animals that survive systemic infection may develop persistent neurologic signs; normal survivors have also been reported.[21] Persistent shedding of CHV-1 for several weeks after recovery has been documented in recovering puppies.[20] Older (> 3 to 5 weeks of age) puppies exposed to CHV-1 may develop subclinical infection, or the course of disease may be less severe as a result of their ability to mount a febrile response. Latent infection also may develop.

Physical Examination Findings

Physical examination findings in dogs with URTD associated with CHV-1 infection may include cough and/or serous to mucopurulent ocular and nasal discharge. Genital infections in bitches may be manifested as lymphofollicular or papulovesicular lesions, vaginal hyperemia, and occasionally petechial or ecchymotic submucosal hemorrhage (see Fig. 24.2). Vesicular lesions have been noted during the onset of proestrus and regress during anestrus. Male dogs can also develop vesicular lesions over the base of the penis and preputial reflection, which are sometimes accompanied by preputial discharge. Dogs with ocular infections due to CHV-1 can show signs of blepharitis, conjunctivitis, ulcerative and nonulcerative keratitis, dendritic ulceration, and serous to mucopurulent ocular discharge.

CHV-1–infected neonates may have petechiation of the mucous membranes and an erythematous rash with papules or vesicles and subcutaneous edema of the ventral abdominal and inguinal region. Vesicles may be present in the vulva and vagina of female puppies, the prepuce of males, and the buccal cavity. An increased respiratory effort with tachypnea and vocalization is common. Abdominal distension

and pain upon abdominal palpation occurs. Normal orientation and localization toward the dam is lacking, and the suckle reflex can be diminished.

DIAGNOSIS

Diagnosis of ocular, respiratory, and reproductive infection by CHV-1 in adult dogs usually involves application of NAATs to clinical specimens, but again there may be challenges distinguishing between positive tests due to latency or subclinical exposure and those associated with disease.

Antemortem diagnosis of CHV-1 infection in neonates can be challenging. Necropsy of at least one deceased littermate for diagnostic testing is usually required. A timely diagnosis facilitates correct therapeutic decisions and directs proper kennel management.

Laboratory Abnormalities

Hematologic and biochemical abnormalities in dogs with herpesvirus infections are nonspecific, but marked thrombocytopenia can be observed in neonatal puppies. A marked increase in the activity of serum ALT can be found in infected neonates.

Microbiologic Tests

Virus Isolation

CHV-1 can be isolated from several parenchymal organs of puppies that have died of acute systemic infection but is most commonly isolated from the adrenal glands, kidneys, lungs, spleen, lymph nodes, and liver. In animals that have recovered or are older, growth of CHV-1 is usually restricted to the oral mucosa, upper respiratory tract, and external genitalia. As noted, recrudescence of virus shedding may be provoked by administration of immunosuppressive doses of glucocorticoids and may also be precipitated by stressful situations, such as the introduction of unfamiliar dogs into a kennel. CHV-1 grows only in cultured cells of canine origin, primarily in dog kidney cells at an optimal temperature range of 35°C to 37°C. CHV-1 produces Cowdry type A intranuclear inclusions, which can be difficult to demonstrate and are most readily identified in tissues that have been fixed in Bouin's solution. FA techniques, electron microscopy, and PCR can be used to detect CHV in cell cultures. Diagnosis by virus isolation takes several days.[10]

Serologic Diagnosis

Antibody titers to CHV-1 are usually determined using virus neutralization assays. Neutralizing antibodies increase after infection and remain high for only 1 to 2 months; low titers may be detected for at least 2 years. Seropositivity indicates exposure, not necessarily active infection, although viral persistence and latent infection might be presumed. Serologic tests are not standardized, resulting in variation in results among laboratories. The main application of serologic diagnostic assays is in outbreak investigations, and acute and convalescent serologic testing may be required to document recent infections.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Tissues obtained at necropsy, ocular or genital swabs, or respiratory lavage specimens (for dogs with respiratory disease) can be submitted for rapid molecular diagnosis using CHV-1–specific PCR assays. Nucleic acid detection has been evaluated in suspected cases of spontaneous CHV-1 infection and is the most reliable means of detecting latent infection in older animals. Nested PCR and *in situ* hybridization have been used to detect virus in formalin-fixed, paraffin-embedded tissues from naturally infected puppies.[22,23] In one study, real-time PCR was used to detect the shedding of CHV-1 in nasal and ocular secretions of puppies that recovered from systemic CHV-1 infection; other puppies in the litter died and CHV-1 was detected in the kidney, liver, lung and brain tissue.[20] Viral nucleic acid has been found within nuclei adjacent to and within hemorrhagic lesions in pups. Many epithelial cells, neurons, fibrocytes, cardiac myocytes, and hepatocytes contain virus. Nucleic acid testing for CHV-1 is offered by some university and commercial laboratories; clinicians should be aware of availability and turnaround time. Unfortunately, false-negative results have been observed from different laboratories or with different sampling methodologies and reduced viral load during latency; false-positive results can occur because of the high prevalence of clinically healthy dogs that are carriers of the virus.

Pathologic Findings

Gross Pathologic Findings

Gross changes in the kidneys at necropsy of pups infected with CHV-1 include multifocal petechial to ecchymotic subcapsular hemorrhages. The pleural surfaces may be mottled pink and red due to coagulation necrosis (Fig. 24.4A–D). Multifocal random acute necrosis of other organs, including the liver, pancreas, intestine, and adrenal glands, may also be apparent. Lesions may resemble those of bacterial sepsis.

Histopathologic Findings

Histopathology can be used to confirm CHV-1 infection in neonates but may be unrewarding if the timing of specimen collection is not optimal. Characteristic viral intranuclear inclusion bodies can be difficult to find. Histopathologic evaluation commonly reveals severe nephrosis (proximal renal tubular epithelial necrosis and renal pelvic epithelial apoptosis with swollen vesicular nuclei); diffuse severe hepatic congestion and inflammation with vacuolar hepatopathy (neutrophilic, histiocytic, and lymphocytic infiltration with apoptosis); acute severe necrotizing bronchointerstitial pneumonia with pulmonary edema and hemorrhage (terminal bronchiolar hemorrhage and edema with fibrin accumulation, macrophage infiltration, necrosis, and alveolar disruption); and thymic, lymph node, and splenic lympholysis (severe diffuse cortical lympholysis with sinus congestion). Findings on examination of the CNS include multifocal glial nodules, cerebellar cortical necrosis, and meningeal inflammation, although the inflammatory reaction may be minimal. Depending on the stage of cellular infection and method of fixation, basophilic or acidophilic inclusions may be noted, but they are less commonly identified than those found in other herpesvirus infections. Inclusions are more readily seen in the nasal epithelium or kidney than in areas of widespread necrosis, such as the lung or liver.[10] *In situ* hybridization has been used to document the location of CHV-1 DNA in the brain of affected neonates and showed nucleic acid in the granule neurons of the cerebellum, meningeal, and parenchymal endothelial cells, and randomly distributed neurons.[19]

TREATMENT AND PROGNOSIS

Respiratory and Ocular Infections

Treatment of respiratory infections typically requires only supportive care. Ocular disease caused by CHV-1 has been treated with topical idoxuridine, trifluridine, and cidofovir(see Chapter 9). Treatment with 0.5% cidofovir twice daily for 14 days decreased shedding but was associated with worsening of ocular signs, so it is not recommended.[24] Treatment of experimentally infected dogs with topical trifluridine six times daily for 2 days and then four times daily for 12 days led to reduction in clinical signs and viral shedding when compared with a placebo group, without evidence of toxicity.[25] In dogs that were experimentally infected with CHV-1, the application of topical ophthalmic 0.15% ganciclovir gel (one drop five times daily for 7 days, then one drop three times daily for 7 days) was effective in reducing clinical disease scores when compared with an untreated control group and was well tolerated.[13]

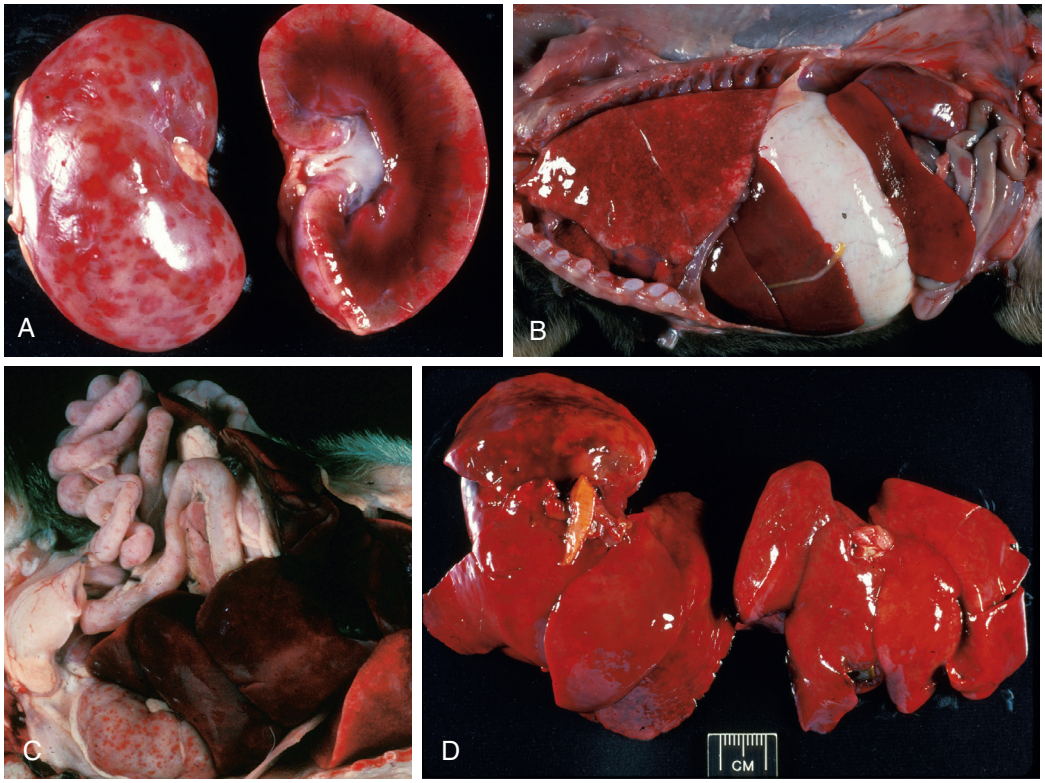

Fig. 24.4 (A) Kidneys from 12-day-old mastiff puppy from a litter of 17 puppies, 14 of which died. CHV-1 was isolated from the puppy. Gross changes include subcapsular hemorrhagic foci typical of (but not pathognomonic for) herpetic nephritis. On cut section, white and red cortical streaks are evident; a hemorrhagic medulla is evident. (B) Multifocal pink and red pleural mottling in the puppy described in A. Serosanguinous pleural fluid was present. Histopathology identified multiple areas of pulmonary necrosis and bronchopneumonia. (C) Small-intestinal serosal petechiation in the same puppy. Histopathology identified enterocyte necrosis consistent with CHV-1 infection. (D) Liver of the same puppy showing uniform firmness and diffuse mottle with rounded edges. Histopathology identified scattered multiple foci of acute hepatic coagulation necrosis; eosinophilic intranuclear inclusions typical of herpesviral inclusions were seen within viable hepatocytes. (Images courtesy JR Peauroi.)

Neonatal Infections

Treatment of puppies with CHV-1 infection is often unrewarding and rarely effective due the rapid progression of fulminant clinical signs. Residual cardiac and neurologic damage may occur in recovered animals. This possibility must be discussed with owners before considering antiviral treatment of an infected litter. Treatment of affected puppies with immune serum from seroconverted dams has been described but is typically ineffective. In some cases, mortality can be reduced during an outbreak by treating puppies with 1 to 2 mL of immune sera given intraperitoneally. Immune sera can be obtained by pooling sera from bitches that had recently given birth to litters of puppies that died of CHV-1 infection. Only one dose is required because of the short susceptibility period. This seems to reduce mortality, but its success depends on the presence of adequate levels of serum antibodies and administration of the sera *before* full development of systemic disease. If neurologic signs have already developed, they will likely persist.[10] Under experimental conditions in which body temperatures were elevated artificially *before* exposure to virus, puppies had reduced mortality, less severe clinical signs, and minimal pathologic changes. At elevated temperatures, viral growth in tissues was restricted compared with growth in conventionally reared pups. Pretreatment by raising ambient temperature could be considered for exposed but as yet unaffected puppies in a litter.[10]

An incompletely developed immune system and inadequate thermoregulation during the first days of life means neonates are vulnerable to systemic infection (by both bacterial and viral pathogens). The umbilicus of neonates should be treated with tincture of iodine immediately after birth to reduce contamination and prevent bacterial ascent into the peritoneal cavity (omphalitis-peritonitis). Neonatal bacterial peritonitis with bacteremia can cause rapid neonatal death if not recognized and treated promptly. Factors that predispose puppies to bacteremia and sepsis include endometritis in the bitch, a prolonged delivery/dystocia, feeding of replacement formulas, the use of ampicillin, stress, low birth weight (<350 g), and hypothermia with body temperatures less than 35.5°C (95°F). Bacterial organisms most frequently associated with bacteremia are *Escherichia coli*, streptococci, staphylococci, and *Klebsiella* spp. Commonly, a decrease in weight gain, failure to suckle, hematuria, persistent diarrhea, unusual vocalization, abdominal distention and pain, and sloughing of the extremities indicate sepsis. These signs are similar to those encountered with CHV-1 infection. Prompt therapy with broad-spectrum, bactericidal antibiotics; optimal nutrition via supported nursing, tube feeding, or bottle feeding; maintenance of body temperature; and appropriate fluid replacement are indicated. The third-generation cephalosporin ceftiofur sodium is an appropriate choice for treatment of neonatal sepsis.

Failure of a pup with the tentative diagnosis of neonatal sepsis to respond to antibacterial drug treatment should prompt consideration of CHV-1 infection. Specific antiviral therapy, if instituted in a timely manner, may reduce mortality from CHV-1 (see Chapter 9). Treatment of systemic CHV-1 infection with antiviral drugs such as 5-iodo-2-deoxyuridine has been unsuccessful, and few studies have

been performed on newer antiviral agents that are effective for treatment of localized and CNS herpes simplex virus (HSV) infections in humans and laboratory animals. In one study, two 15-day-old pups died of CHV-1 infection. Five littermates were given a course of vidarabine as soon as the cause of the deaths was identified, and they all survived. The surviving pups had high (>1:64) neutralizing antibody titers 2 months later, indicating that they had been infected.[26] Vidarabine (cidofovir) is only available as a compounded ophthalmic solution. Acyclovir has activity against HSV (Table 24.1). Its use in dogs has not been well studied; one case report exists describing survival of 4 litter mates following confirmation of CHV-1 in 2 deceased 25-day-old puppies.[21] Valacyclovir, an acyclovir prodrug, increases bioavailability in humans to 50%. The efficacy of famciclovir, a prodrug for penciclovir, for treatment of CHV-1 infection requires further study, but the pharmacokinetics of famciclovir in dogs resembles that in humans; much lower doses may be required when compared with cats. Bovine lactoferrin, an iron-binding antimicrobial component of milk, has been reported to inhibit CHV in vitro experimentally. Lactoferrin is commercially available as a component of a topical product (Zymox) for dermatological application; its use on neonatal oronasal mucosa has been suggested if CHV exposure is suspected.[27]

IMMUNITY AND VACCINATION

Minimal transplacental transfer of immunity occurs in the dog. Adequate ingestion of colostrum must occur immediately postpartum for puppies to acquire passive immunity. The transmission of protective passive immunity (placental or colostral antibodies) to puppies depends on the prior existence of adequate serum maternal antibodies. Therefore, breeding bitches with exposure to CHV-1 earlier in life have the best opportunity to seroconvert and develop protective antibodies. This commonly occurs in kennels or at crowded canine events such as dog shows and trials. Documentation of an antibody titer to CHV-1 generally indicates the presence of adequate maternal antibodies.

Unexposed bitches must be strictly isolated from potential exposure during gestation and for at least 6 weeks postpartum to prevent acquisition and transmission of the virus to the fetus or neonates. Subsequent litters of the infected pregnant or postpartum bitch are usually normal because of acquisition of maternal antibodies; however, reactivation of maternal viral infection with stress, pregnancy, and immunosuppressive drugs has been reported.[28,29]

Because CHV-1 infects pups *in utero* or as neonates, active immunization can be considered only in the dam. Development of vaccines for CHV-1 has been hampered by the poor immunogenicity characteristic of the herpesviral vaccines developed for other species, such as FHV-1 vaccines. Immunization with a commercially inactivated vaccine in Europe resulted in fourfold increases in virus neutralization titers in most vaccinated dogs, but did not appear to provide long-term protection.[10] A lyophilized, inactivated, purified CHV-1 strain F205 vaccine prepared with enriched glycoproteins was used to vaccinate SPF bitches 10 days postcoitus and 6 weeks later near the end of gestation. The near-term booster was used to enhance the short-lived humoral response. As analyzed by PCR, 100% of pups born to these bitches were protected against clinical illness when challenged oronasally with CHV-1 at 3 days of age; in most instances (93.5% of 31 pups) they were also protected against viral infection. In contrast, a majority of challenged control pups (81% of 31 pups) died of generalized CHV disease between 6 and 14 days after challenge.[30] The vaccinated bitches and litters were kenneled with the control bitches and litters. A subunit vaccine using this inactivated strain is licensed for use in some European countries (Eurican Herpes 205, Boehringer Ingelheim, Germany). Revaccination with two doses of the vaccine is recommended at each pregnancy. In one study, adult dogs with experimentally induced latent CHV-1 infection were vaccinated and then treated with glucocorticoids in order to reactivate infection and disease. Vaccination did not prevent disease or viral shedding, but was associated with reduced clinical scores within a 2-week period after vaccination, and improved long-term (34 weeks) immune responses to the virus.[31] The vaccine is not currently available in the United States. Vaccination of naïve bitches before whelping makes sense; the effect of this vaccination on litters from previously seroconverted bitches needs to be demonstrated in a controlled study.

PREVENTION

On a practical basis, eradication of CHV-1 from a kennel is impossible. Screening for infected animals also is impractical, and owners should be advised that subsequent litters from an affected bitch have a very low risk of developing clinical illness. Accordingly, cesarean delivery or artificial insemination is not justified to reduce spread of infection. Artificial insemination could be used when a male that is known or suspected to be infected is bred to a primiparous naïve bitch, but the benefit of such a practice has not been studied.

As a preventive practice, care should be taken to ensure that the environmental temperature of newborn puppies is kept warm with heated whelping boxes, heat lamps, or other warming devices that do not cause excessive dehydration. Mild to absent clinical signs are

TABLE 24.1 Treatment for Canine Herpesvirus Infections

Drug	Dose	Route	Interval	Duration	Indication
Acyclovir[a]	10 mg/kg (0.01 mg/g)	Oral	q6h	5–7 days	Neonatal infections[b]
Famciclovir (feline)	90 mg/kg	Oral	q12h		Ocular infections
Lactoferrin (oral solution in spray form)		Swab oral mucosa	q12h		Suggested preventative approach in exposed puppies, evidence unclear
Trifluridine solution (1%)	One drop	Topical ophthalmic	Six times daily for 2 days, then four times daily for 12 days	14 days	Ocular infections
Ganciclovir gel (0.15%)	One drop	Topical ophthalmic	Five times daily for 7 days, then three times daily for 7 days	14 days	Ocular infections

[a]Available as 200-mg capsules. Contents of capsule are added to 10 mL of warm water. The powder does not dissolve; however, each pup receives 0.5 mL (10 mg) of the suspension orally every 6 hours. Famciclovir may be a safer and more efficacious choice for systemic treatment (see Chapter 9).
[b]Because of the small size of neonates, fluids or plasma therapy may have to be given intraperitoneally, intraosseously, or subcutaneously rather than the preferred intravenous route. Additional warming of the animals is essential.

common in dogs that have recovered from CHV-1 infection, with occasional rhinitis, vaginitis, or balanoposthitis. Viral shedding for 1 week generally ensues with introduction of new dogs in a kennel (stress), during concurrent illnesses, or in a dog with drug-induced immunosuppression. Such dogs can act as reservoirs of infection for neonates and should be separated from new litters. Clinically affected puppies shed large quantities of virus in their secretions for 2 to 3 weeks after recovery. Virus persists for only short periods in respiratory or vaginal secretions, so its spread is most common through immediate direct contact with infected animals or through fomites. CHV-1 outbreaks causing reproductive problems are most likely in large, open commercial breeding operations. Private breeders have the best success in avoiding exposure of naïve bitches and their offspring by operating a closed kennel during breeding.

PUBLIC HEALTH ASPECTS

In general, herpesviruses are very host specific, and CHV-1 is not known to infect humans.

CANINE GAMMAHERPESVIRUS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Gammaherpesviruses belong to the subfamily *Gammaherpesvirinae*. In humans, the primary gammaherpesviruses of disease significance are Epstein-Barr virus (EBV) (human gammaherpesvirus 4) and Kaposi's sarcoma-associated herpesvirus (human gammaherpesvirus 8). EBV is the cause of infectious mononucleosis and has been associated with a variety of lymphoproliferative disorders, nonlymphoid malignancies, and autoimmune conditions. Kaposi's sarcoma-associated herpesvirus causes nodular mass lesions in the skin, lymph nodes, and sometimes other organs.

Gammaherpesviruses can latently infect lymphocytes and cause lytic infections of epithelial cells and fibroblasts. Only a few studies have examined the prevalence and importance of gammaherpesvirus infections in dogs by examining blood and tissues for either gammaherpesviral, EBV or EBV-like particles, DNA, RNA, or antibodies.[32–40] Serologic evidence exists that dogs are exposed to gammaherpesviruses, and there is preliminary evidence of an EBV-like herpesvirus within B cells in dogs with malignancies.[34] Other studies suggest that gammaherpesviruses do not cause malignancies in dogs.[37,39]

In Taiwanese dogs, antibodies against EBV-specific polymerase, EBV-encoded DNA binding protein and EBV-specific thymidine kinase proteins were present in 10, 15, and 32 of 36 dogs tested, respectively.[32] When the presence of EBV-like DNA was investigated in both serum and WBC of 21 of these dogs, all serum samples were negative, but 15 WBC samples were positive for a partial EBV sequence using molecular testing. Serum antibodies were not present in all dogs with positive EBV-like viral DNA in their WBCs suggesting that latent infections may be possible in dogs.[32] Gammaherpesviruses have been detected in other carnivores, namely the lion (*Panthera leo*) and the spotted hyena (*Crocuta crocuta*) (the latter being more closely related to the dog) using PCR detection of both gammaherpesvirus-specific polymerase and glycoprotein B genes.[33] Another study aimed to determine the prevalence of EBV infection in dogs in the United Kingdom (n = 112) and the United States (n = 104) using serology and PCR to detect EBV in various tissue specimens.[36] An IFA demonstrated serum antibodies against EBV or EBV-like viruses in about a third of the British dogs and two thirds of the American dogs. All blood samples, lymphoma specimens, and all but one tonsil specimens were negative by PCR for EBV DNA. A study from Italy examined the prevalence of gammaherpesvirus infection in blood donor dogs. All nested PCRs performed to detect viral DNA in 54 dogs were negative.[35] However, as in other studies, the number of animals sampled was relatively small.

EBV is implicated as a contributor to idiopathic pulmonary fibrosis in humans, multinodular pulmonary fibrosis in horses, and pulmonary fibrosis in an experimental mouse model by causing epithelial injury.[40] There has been interest in a possible association between gammaherpesvirus infection and canine idiopathic pulmonary fibrosis (CIPF) in the West Highland white terrier.[38] Blood and lung specimens were obtained from affected and control dogs and tested for the presence of alpha-, beta-, and gamma-herpesviral DNA encoding a highly conserved region of a polymerase gene (*DOPL*) by PCR. None of the samples were positive.[38] However, the DNA was extracted from paraffin-embedded lung tissue, which often yields low-quality DNA.

More importantly, EBV in humans is associated with epithelial and hematological malignancies. This raises the question whether EBV or EBV-like gammaherpesvirus could be associated with malignancies in dogs. Two studies were unable to detect gammaherpesviral particles using a specific and degenerate PCRs in tissues and blood of dogs with lymphoma despite the presence of serum antibodies against EBV.[36,39] In another study, DNA was extracted from paraffin-embedded canine mammary tumors to study the relationship between EBV infections and malignancies.[37] Only one of 47 specimens examined was positive by nested PCR for the presence of viral DNA. EBV-like viral DNA and RNA as well as latent membrane protein-1 were detected in malignant lymph nodes from dogs with lymphoma.[34] Adding weight to evidence for a possible association between this infection and malignancy was the finding that the highest serum antibody titers were found in those dogs with B-cell lymphoma.[34]

Further studies will be needed to determine the pathogenicity of EBV, EBV-like, or other gammaherpesviruses in dogs and their association with canine malignancies. Currently, antibody titers and molecular assays for the detection of gammaherpesvirus infections are only performed in specialized laboratories.[35] Should a gammaherpesvirus be established as a cause or contributor to some types of lymphoma in dogs, treatment of lymphoma in dogs using chemotherapy alone may need to be reevaluated. In human patients with EBV infections, treatments such as adoptive immunotherapy (with EBV-specific cytotoxic T cells) have been used with some success, but use of antiviral drugs has been met with limited success.[41]

CASE EXAMPLE

Signalment

Two, 25-day-old female Labrador retriever puppies from a litter of eight whelped at a guide dog kennel in San Rafael, California.

History

Whelping was directly observed and occurred without incident; the pups showed normal weight gain (checked twice daily) and behavior until the last 24 hours. The litter nursed from birth, and the dam was normal. The dam was housed in a private home until a week prepartum, then was kenneled in the whelping facility with five other bitches in separate runs. Four days previously, the litter was vaccinated with an intranasal *Bordetella bronchiseptica* vaccine and dewormed with pyrantel pamoate according to routine preventative healthcare practice.

Current Medications

None.

Continued

CASE EXAMPLE—cont'd

Physical Examination

Physical examination of both puppies revealed hypothermia (rectal temperature 36.3°C [97°F] and 36.0°C [97°F], respectively), tachypnea, a markedly tense abdomen, and continuous vocalization.

Differential Diagnosis

Bacterial sepsis (*Escherichia coli, Streptococcus, Staphylococcus,* and *Klebsiella* most commonly), infections with CHV-1, *Bordetella bronchiseptica*, CAdV-2, CPIV, *Brucella canis*, CDV, *Neospora caninum, Toxoplasma gondii.*

Laboratory Findings

Fecal Examination: Negative for parasites or ova.

Necropsy Findings

Despite supportive care (exogenous warming, supplemental feeding with artificial bitch's milk [Esbilac Pet Ag, Inc.], subcutaneous lactated Ringer's solution, and ceftiofur sodium [2.5 mg/kg SC q12h]), the puppies died within 12 hours and then underwent necropsy examination. Tissues collected for histopathologic evaluation included kidney, liver, lung, thymus, mesenteric lymph node, and spleen.

Because of gross findings of hemorrhagic foci in the lungs and kidneys, renal tissue was submitted for a CHV-1–specific PCR assay. The PCR assay confirmed the presence of CHV-1 DNA in the renal tissue. Gross (foci of hemorrhage in the lungs and kidneys) and histopathologic evaluations of the deceased puppies were typical of CHV-1 but were not confirmatory because of the similarity of findings to those of neonatal bacterial sepsis. The presence of intranuclear inclusion bodies were suspected in macrophages from the lung of one puppy. Aerobic bacterial culture of the peritoneal cavity was negative for bacterial growth.

Diagnosis

Neonatal CHV-1 infection.

Treatment

Poor weight gain and vocalization were reported in two additional puppies. The primary differential diagnoses included neonatal bacteremia and CHV-1 infection. Because of the lack of response to therapy for bacterial infection in the two deceased puppies, the remaining six puppies were treated with acyclovir suspension (20 mg/kg PO q6h) for 7 days, and exogenous warming adequate to raise the rectal temperature to just above 37.7°C (100°F). Therapy was initiated the day before the PCR assay confirmed infection with CHV-1.

All six treated puppies survived and were successfully weaned between 5 and 6 weeks of age. All were placed in private homes and had uneventful subsequent health histories and normal behavior. Physical examinations including complete fundic evaluations were performed at 12 to 14 months of age and were normal in all. Two of the dogs have become active guide dogs for the blind, and one is an assistance dog for the hearing impaired. All remain physically normal at more than 26 months of age.

Comments

The epizootiology of this outbreak suggests that the puppies were born from a naïve bitch and exposed to CHV-1 from another carrier dog at days 14 to 17 after birth. Two of eight (25%) succumbed to the disease; two of the remaining six showed early clinical signs, after which antiviral therapy was initiated for all dogs.

Influenza Virus Infections

Thomas W. Vahlenkamp, Jane E. Sykes

KEY POINTS

- Cause: In recent years, several influenza viruses have been transmitted from human (H1N1, H3N2), avian (H3N2, H7N2, H5N1, H5N6), or equine (H3N8) origin to dogs and cats. The transmitted avian influenza viruses (H5N1, H5N6) also included highly pathogenic viruses causing severe disease. Only CIVs H3N8 and H3N2 have exhibited sustained transmission within dog populations. The distinct differences in receptor preference among influenza viruses of different species cause a rather inefficient transmission of influenza viruses among different hosts.
- First Description: CIV H3N8 was first described in 2004 (Florida, USA) in the racing greyhound population.[1] CIV H3N2 emerged in 2006 in South Korea and China and spread to the USA in 2015.[2]
- Geographic Distribution: Worldwide with regional accumulation of cases.
- Mode of Transmission: Aerosol transmission or close contact, sometimes fomites.
- Major Clinical Signs: Mild respiratory disease, including frequent cough and fever, although infection of the lungs and more severe disease and death occur on occasion and are probably associated with mixed infections by other viruses or bacteria.
- Differential Diagnoses: Other viruses that cause similar signs are CAdV, parainfluenza virus, CRCoV, CHV, canine pneumovirus, and possibly reoviruses. In cats, FCV, FHV-1, and SARS-CoV-2 are other viruses that should be on the differential diagnosis list. Bacterial causes of upper respiratory tract disease such as *Bordetella bronchiseptica* and in cats, *Chlamydia felis,* must also be considered.
- Human Health Significance: The infections of dogs and cats with influenza viruses of different origins, including human, avian, and equine, along with the history of close contact of the companion animals with infected humans, birds, or horses in most of the reported cases have raised the concern that companion animals may act as host species contributing to the adaptation of avian viruses in mammals as well as a potential reservoir of mammalian influenza viruses to humans.

ETIOLOGY AND EPIDEMIOLOGY

Influenza viruses are in the family *Orthomyxoviridae*, and are negative-sense, single-stranded, RNA viruses that infect a variety of mammals and birds. Aquatic birds are generally subclinically infected reservoirs. Mammals, both domestic (swine, horses, dogs, ferrets) and nondomestic (mink, aquatic), poultry, and humans inadvertently can become infected with individual viral strains that spread among the various hosts.[3] Almost every winter, two genera of influenza viruses—influenza A and B—produce episodic outbreaks of an acute self-limiting febrile illness in susceptible humans. Influenza B and C are mainly human pathogens and are only rarely seen in animals. Influenza A viruses have the widest host species range and greatest mutability, and can rapidly evolve into new genetic subtypes.

Subtypes of influenza A viruses are specified by the antigenic nature of two surface glycoproteins (hemagglutinin [H1-H18] and neuraminidase [N1-N11]) (Table 25.1). Influenza viruses continuously evolve through point mutations in their nucleic acid that lead to a gradual "drift" in their genome, which encodes surface proteins. The immune response selects for new virus strains by allowing those strains that can escape the antibody-mediated response to replicate. This process results in continuous emergence of new strains every influenza season. In avian species, waterfowl are often the subclinical reservoir for influenza A viruses, whereas chickens and turkeys may develop disease after infection. The viruses are shed in the feces of aquatic birds and contaminate the environment where other hosts may become exposed. Influenza viruses in mammals primarily spread through the transfer of virus-containing respiratory secretions via aerosolized particles (smaller than 10 μm) from an infected to a susceptible individual. Fomite transmission through contact with contaminated surfaces or common usage items can also occur. Influenza A viruses cause generally mild respiratory disease or reduced egg production in avian hosts; however, mutations in strains with hemagglutinins of subtype H5 or H7 can sometimes result in highly pathogenic avian influenza virus (HPAIV) strains that can cause significant mortality in birds.

TABLE 25.1 Influenza A Virus Subtypes Identified in Dogs and Cats with Naturally Occurring Respiratory Disease

Species	Host Origin	Subtype	Location
Dog	Human	Pandemic H1N1/09	China, USA (NY), Mexico
	Avian	H3N2 CIV	South Korea, China, USA
		H3N1 CIV	South Korea
		H5N1	Thailand
		H5N2	China
	Equine	H3N8 CIV	USA
Cat	Human	Pandemic H1N1/09	USA, Italy, Canada
	Avian	H7N2 (LPAIV)	USA (NY)
		H5N1 (HPAIV)	Thailand, Europe
		H5N6 (HPAIV)	Asia, Europe, Africa

HPAIV, highly pathogenic avian influenza virus; *LPAIV,* low pathogenic avian influenza virus.

The genome of influenza viruses consists of eight different segments which allow for extensive reassortment of individual or multiple genome segments during coinfection of a single host species with two different influenza viruses (see Fig. 7.6). This drives evolution of influenza viruses in avian species and in mammals. For example, pigs can become simultaneously infected with both human and avian strains because the different sialic acid receptors in the respiratory epithelium allow simultaneous entry of swine, human, and avian influenza virus strains. Within the porcine host, novel influenza virus A strains can originate in a sudden and dramatic fashion, through antigenic "shift" from genetic reassortment. The genome segments of the progeny viruses may be derived from different species. Pigs are, therefore, believed to serve as a "mixing vessel" with regard to this genetic reassortment. If genetic recombination occurs, a new human influenza virus strain may arise with the ability to spread readily from swine back to people, but with a markedly different antigenic composition from the original infecting human strain. An antigenically distinct new strain may evolve to which the human population has no immunity.[4] Viruses that are naturally circulating in pig populations can occasionally also cause influenza in people who are occupationally exposed. Historically, these viruses are not transmitted efficiently among humans.[5] This also applies to virulent avian influenza virus strains that can occasionally spread directly to people, but causing only limited spread. Meat from poultry or swine does not pose a risk for human infections when it is properly cooked.

Most contemporary human infections have been associated with either influenza B viruses or the H1N1 and H3N2 subtypes of influenza A. Fever, myalgia, and signs of upper or lower respiratory tract infections are the most common manifestations in people. Mortality is the result of pulmonary complications. Dogs and cats, living in close proximity to their owners, may occasionally become infected during human influenza A outbreaks. Furthermore, dogs or cats coming in close proximity to birds, swine, or horses or eating uncooked meat by-products from these animals may contract these infections. Several influenza A subtypes have been detected in dogs and cats, with sustained transmission only documented for H3N8 and H3N2 viruses in dogs (Fig. 25.1).[6] Currently only H3N2 appears to be circulating in the dog population, with an active outbreak in Los Angeles, California, at the time of writing.

As enveloped viruses, influenza viruses are relatively susceptible to environmental influences. Their survival is prolonged by colder temperatures and moist conditions. Common disinfectants and warm environmental temperatures with low humidity are most effective in their inactivation. In the absence of organic material, most common disinfectants (1% sodium hypochlorite, quaternary ammonium compounds and 70% ethanol, aldehydes, and lipid solvents) inactivate the virus after 10 minutes' contact time. At pH 7.0, chlorine concentrations typically used in drinking water are sufficient to inactivate the avian virus after times of exposure as brief as 1 minute.[7] Ionizing radiation and acid (pH 2.0) are also virucidal. In the absence of disinfection, survival in moist conditions is not greater than 30 minutes at 56°C (133° F), a few hours at 55°C (132°F), several days at room temperature of 22°C (71°F), and at least a month when frozen. At room temperatures canine virus isolates survive on surfaces, clothing, or hands for 48, 24, or 12 hours, respectively.

INFLUENZA VIRUS INFECTIONS OF HUMAN ORIGIN

Experimental intranasal or intravenous infections of dogs with human influenza virus A,[8-11] B,[10,11] and C[12-15] types have provided convincing evidence that these viruses can replicate in dogs. However, clinical signs in infected animals have either been absent or consisted of a mild conjunctivitis, serous nasal discharge, and variable fever. With respect to natural infections, serologic responses to influenza A virus have been observed in dogs during human disease outbreaks.[16-19] Limited data, based on virus isolation from respiratory secretions, document sporadic natural transmission and subclinical infection of dogs with *human* H3N2 influenza A viruses[18,20-23] and type C viruses.[12,13] There is, however, no evidence for sustained transmissions of human influenza viruses in dogs. Species barriers may be too tight for natural transmission to occur[24] despite the fact that human influenza viruses readily replicate in Madin-Darby canine kidney (MDCK) cells.

Antibodies have been detected in the blood of healthy cats using HI against H3N2 influenza viruses.[10,16,18,25,26] No antibodies against subtypes H1, H2, and H4 through H8 were detected.[26] As human epidemics with influenza H3N2 viruses occurred in the countries of investigation, it might be that the cats had been exposed to this particular virus. Cats have also been experimentally infected with human (H3N2), avian (H7N3), and seal (H7N7) influenza viruses.[10,18,25,27] After infection, cats developed antibodies, sometimes even shed virus, but never showed clinical signs. In some studies, human influenza virus H3N2, H2N2, and influenza B virus infections could also be transmitted among experimental cats that were housed together. These earlier studies suggested that cats and dogs might represent yet another host for various influenza viruses in nature.[27]

Pandemic Influenza H1N1 Virus Infections

Before its spread to dogs and cats, the pandemic influenza A/H1N1/09 virus was only known to infect humans, pigs, horses, and birds. In dogs, the first detection of influenza A/H1N1/09 was reported from China. Two of 52 samples from sick dogs tested positive for the virus.

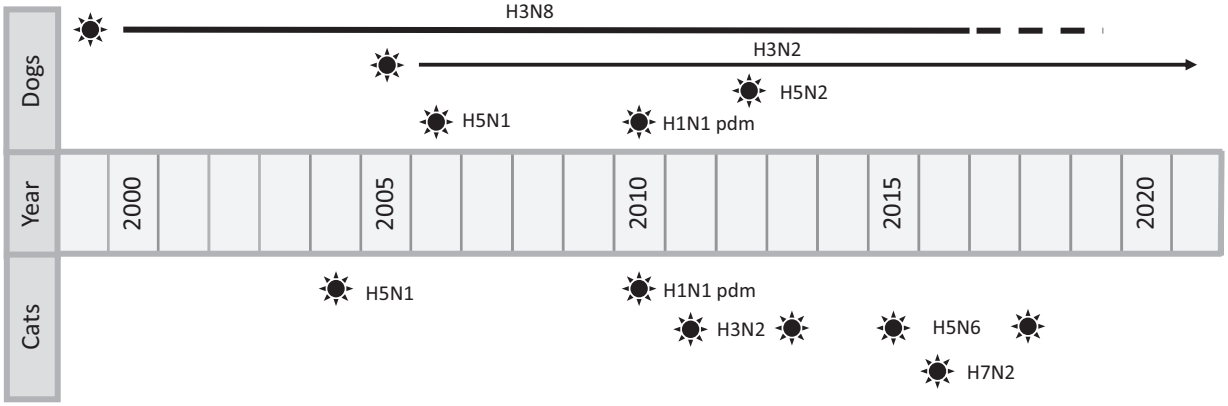

Fig. 25.1 Timeline of influenza virus infections from 1999–2021 in dogs and cats. H3N8 and H3N2 virus infections have been sustained in dog populations over several years with a recent case decline and possible disappearance of H3N8.

The viruses in the dogs had genomes that were 99% homologous to those of viruses from human H1N1 flu cases, confirming that the dogs were infected. In New York, a 13-year-old dog with respiratory illness associated with lethargy, cough, anorexia, and fever had radiographic evidence of pneumonia. The dog improved after therapy with fluids, antibacterials, and nebulization and was discharged from the hospital after 48 hours. Molecular testing confirmed that the dog was infected with the pandemic H1N1 virus.

In separate incidents, two cats from Iowa and Utah, one cat from California, and two cats from Oregon[28] developed respiratory signs after family members in the household suffered from influenza illness. One of the Iowa cats developed respiratory illness within 6 days after onset of respiratory disease in human family members.[29] The cat was afebrile and dehydrated on physical examination. Bilateral multifocal caudodorsal alveolar densities were observed on thoracic radiography (Fig. 25.2). Cytologic examination of bronchoalveolar wash specimens revealed foamy macrophages, nondegenerate neutrophils, and small lymphocytes. All of the cats had had serum antibody reactive to the pandemic influenza virus A/H1N1/09. The cats and their owners recovered, and there was no evidence that the cats transmitted the virus to humans. RT-PCR results targeting the influenza H1N1 virus were positive in one cat.[29] However, results are often negative, perhaps relating to the low rate and transient nature of viral shedding in heterologous hosts. In cats that died of H1N1 infections, severe necrotizing bronchointerstitial pneumonia has been found with virus present throughout tissues in the lower respiratory tract.[28]

Serological screening of domestic dogs and cats between 2011 and 2014 from animal shelters in 19 provinces of Thailand revealed only few exposed animals.[30] In total 932 sera from dogs and 79 cat sera were investigated. Six canine and one feline serum specimens were seroreactive to the pandemic H1N1 virus. At the same time, serosurveys conducted in Europe and Asia using ELISA revealed influenza-specific antibodies in the sera of domestic cats at low prevalence (1.5–2.5%).[31,32] In contrast, serosurveys conducted in Japan and the United States using HI assays for pandemic H1N1 virus revealed a prevalence exceeding 30% in domestic cats.[33] Antibody prevalences to human seasonal influenza H1N1 and H3N2 viruses in the cat sera investigated were 10.9 and 17.6%, respectively. It is also possible that variation in the sensitivity of different assays has contributed to the observed differences.

Because the degree of shedding of influenza A H1N1 virus by dogs and cats is low, there appears to be low risk of infecting more susceptible human hosts. Even swine infected with the A/H1N1/09 strain harbor it in tissues for no longer than 3 days after exposure.[34] Influenza H1N1 virus RT-PCR tests can be used for diagnosis.

Public Health Aspects

Because of the close association of pets with humans, concern has been raised that dogs and cats may be important in the spread or maintenance of influenza infection in people. Many reports exist of the presence in dogs and cats of antibodies against human influenza virus strains. Influenza infection that jumps between different species is often a self-limiting spread and is not efficiently transmitted between in-contact animals. No evidence suggests that the virus replicates sufficiently to spread from infected pets to humans. Because of their potential infection on a clinical or subclinical basis, dogs and cats may be useful as sentinel hosts for surveillance of influenza virus infections.[35]

INFLUENZA VIRUS INFECTIONS OF AVIAN ORIGIN

All influenza H and N subtypes can be found in varying combinations in different aquatic birds, which represent the natural reservoir of all influenza viruses. In aquatic birds, influenza virus infections are usually of low pathogenicity and not associated with clinical signs. Viral replication is mainly restricted to the GI tract and transmission of the infection

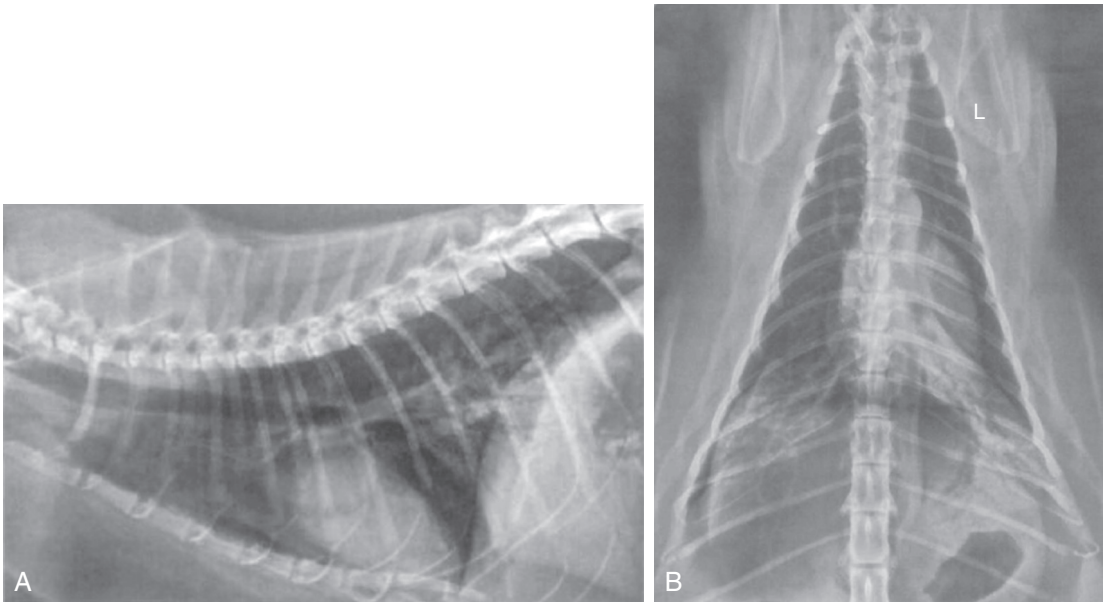

Fig. 25.2 Radiographs of the thorax of a cat with confirmed influenza A pandemic (H1N1) 2009 virus infection. (A) Right lateral view; (B) Dorsoventral view. Asymmetric soft-tissue opacities are evident in the right and left caudal lung lobes. An alveolar pattern, composed of air bronchograms with border-effaced (indistinct) adjacent pulmonary vessels, is most pronounced in the left caudal lobe *(L)*. A small gas lucency in the pleural space appears in the right caudal and dorsal thoracic cavity. An endotracheal tube is visible at the thoracic inlet on the lateral view in this moderately obese cat. (From Sponseller BA, Strait E, Jergens A, et al. Influenza A pandemic (H1N1) 2009 virus infection in domestic cat. *Emerg Infect Dis*. 2010;16:534-537.)

is facilitated by the cloacal-oral route. Avian influenza viruses subtype H5 and H7 are exceptional in that they can mutate at the hemagglutinin cleavage site, which leads to systemic spread and replication of the virus in the infected avian host. Therefore, avian influenza viruses subtype H5 and H7 are divided into low-pathogenic avian influenza viruses (LPAIVs) and HPAIVs based on their biological nature. In contrast to LPAIV infections, infections with HPAIVs are associated with diverse clinical signs in waterbirds and severe clinical signs in domestic poultry. Some of these viruses also acquire a broadened host spectrum.[3,36]

Avian influenza viruses preferentially infect cells that harbor a 2′-3′ sialic acid receptor linkage, whereas human influenza viruses infect cells that harbor a 2′-6′ sialic acid receptor linkage. This difference in receptor preference among these viruses is the reason for inefficient transmission of avian influenza viruses to mammalian hosts. Nevertheless, occasional virus transmissions to dogs and cats can occur.

Influenza H3N2 Virus Infections

CIV H3N2 was first recognized in South Korea and China in 2006, and likely arose from transfer of an avian influenza virus in 2005. The virus caused an outbreak of respiratory disease in South Korea in dogs at three veterinary clinics and one kennel.[2] All but one of the dogs at the clinics died. Infection with a closely related strain was found in southern China.[37] The virus then circulated throughout Korea and both northern and southern China, which was associated with some genetic drift. Clinical signs in affected dogs included fever, sneezing with nasal discharge, cough, and anorexia. The dogs had signs of severe pulmonary lesions at necropsy. In experimentally infected dogs, H3N2 is shed for up to 6 days after the onset of illness. Unlike the highly pathogenic avian-origin H5N1 strains, which produce respiratory and systemic illness, the avian-lineage H3N2 isolate, which adapted to spread among dogs, produced mild upper respiratory tract disease, including frequent cough and fever. However, infection of the lungs and more severe disease and death occur on occasion and are probably associated with mixed infections by other viruses or bacteria.[38]

In Asia, the virus has been most widespread among dogs in kennels and meat dog farms and markets. Given that live poultry markets in Asia have been identified as a major source of influenza viruses that spill over to infect new hosts, close physical contact between birds and dogs in these host-dense environments might have facilitated the emergence of the virus in dogs.[39] H3N2 influenza virus was introduced into the Chicago area in the United States from Asia in 2015, and has since caused widespread outbreaks of disease in dogs.[40] Despite local control measures, the virus continued circulating among dogs in and around Chicago and then appeared in southeastern states, for example, Georgia and North Carolina, although secondary outbreaks appear to have ended within a few months.[39] Continued infections in the Chicago area occurred, this time without evidence of secondary outbreaks. Multiple introductions of H3N2 influenza virus from Asia have re-seeded disease within the United States in different locations, with an active shelter outbreak in southern California at the time of writing (August 2021). Influenza H3N2 virus appears to have a relatively broad host range, infecting ferrets, guinea pigs, and cats after experimental challenge. Natural spillover of the virus from dogs to cats has been documented in South Korea and the United States, but those outbreaks were largely confined to the shelter populations where they emerged, and the viruses do not appear to undergo prolonged transmission in household cats, despite high level of viral shedding. Experimental inoculation of Korean or USA H3N2 strains into pigs resulted in poor replication, so infection of pigs from dogs appears to be unlikely, even though pigs are a common host of other H3N2 influenza viruses.

Dogs vaccinated with two doses of an inactivated adjuvanted H3N2 virus vaccine were protected against challenge infection with the avian-lineage canine influenza isolate.[41] In the USA, both monovalent and bivalent inactivated vaccines are available for prevention of CIV H3N8 and H3N2 infections. Two doses (2 to 4 weeks apart) are required to achieve protection, which limits their efficacy when used at entry in shelter and boarding environments.

Public Health Aspects

Human influenza H1N1 (pandemic and seasonal) and H3N2 viruses appear to be able to occasionally infect dogs. Although none of these infections is known to have resulted in major onward transmission among dogs, this might provide the opportunity for human influenza viruses to reassort with CIVs through natural coinfections in dogs. In the last decade, novel reassorted CIVs (H3N1, H3N2) have emerged in South Korea.[42,43] No transfers of either CIV subtype to humans have been documented. Nevertheless, the potential of dogs to act as virus mixing vessels or as sources of zoonotic infections exists.

Influenza H7N2 Virus Infections

In 2016 an outbreak of influenza H7N2 virus occurred in cats at several animal care shelters in the United States (New York, Pennsylvania). The first outbreak was detected in three facilities of the municipal animal shelter system in New York City. Transmission of the virus to an attending veterinary staff member warranted the use of additional precautions measures. By the end of the outbreak approximately 500 cats had been tested positive for this virus and retrospective serological analyses supported the existence of two human infections during this outbreak.[44] Sequence analysis revealed that the virus was phylogenetically related to a North American lineage low-pathogenic avian influenza H7N2 virus circulating in live poultry markets during 1996 and 2005.[45] While it is unknown how the index cat was exposed to the influenza H7N2 virus, the high rate of transmission among cats and concern about a possible zoonotic transmission mandated quarantine precautions. Person-to-person transmission was not observed, although the influenza H7N2 virus obviously is capable of eliciting mild illness in humans. Airborne transmission and/or direct contact with fomites of infected cats most probably contribute to the efficient transmission of the virus between cats and also to the transmission from cats to humans.[46] Therefore continued surveillance and transmission-based precautions are necessary during the treatment and care of influenza H7N2 virus–infected cats.

Highly Pathogenic Influenza H5N1 Virus Infections

HPAIV of subtype H5N1 originated in China in 1996 and spread to other countries in Southeast Asia until 2003. The viruses, continuously shaped by several reassortment events and by antigenic drift, established endemic infections, driven by subclinically infected duck populations in this area. An incursion of HPAIV H5N1 of the phylogenetic cluster 2.2 ("Qinghai lineage") into the wild bird population of northwestern China in 2005 marked the beginning of an unprecedented virus spread to other Asian regions, Europe, and Africa within a single year. Apart from causing severe clinical signs in gallinaceous bird populations, HPAIV H5N1 also exhibited a potential to infect mammals including humans. Next to humans, naturally infected mammal species were members of the order Carnivora (Canidae, Felidae, Mustelidae, and Viverridae).[47-50]

In dogs and cats, a fatal infection of a dog that ingested HPAIV H5N1–infected chicken carcasses was reported in Thailand in 2006.[51] Several outbreaks of HPAIV H5N1 infection have been reported in felids under natural conditions. The first outbreak was in 2003, when two tigers and two leopards died in a zoo in Suphanburi, Thailand after developing high fever and respiratory distress.[52] Shortly after, a clouded leopard died in a zoo in Chonburi, Thailand, from infection with influenza

H5N1. One month later, a tiger at the same zoo was found to be infected but recovered.[53] During an outbreak in a tiger zoo in Sriracha, Thailand, a total of 147 tigers died or were euthanized.[54] The first evidence that domestic cats were at risk of infection with HPAIV H5N1 was in 2004, when 3 domestic cats from a household in Thailand, in which 14 cats had died, testing positive for influenza H5N1.[53] The virus was also detected in a domestic cat in Thailand that had died following development of fever, dyspnea, seizures, and ataxia.[55]

Experimental inoculation of dogs with HPAIV H5N1 results in severe clinical illness.[56] Experimental infections using HPAIV H5N1 confirmed that cats can develop severe clinical signs after infection[24,57] or after ingestion of infected chicken.[24] The first cases of HPAIV H5N1 infection in domestic cats in Europe were detected during the outbreak of avian influenza on the German Isle of Rügen in February 2006, during which three free-roaming cats found dead were harboring the virus.[48] At approximately the same time, three cats that did not show clinical signs tested positive by RT-PCR for influenza virus H5N1 in an animal shelter in Graz, Austria, after an infected swan had been brought to the shelter.[58]

Phylogenetic analysis of the HPAIV H5N1 viruses from the dog and a cat from Thailand revealed that the virus was highly similar to the avian influenza virus circulating in poultry at the same time.[59] No genetic reassortment event was necessary for the transmission of the virus to the dog. In central Thailand, about 25% of 629 village dogs had positive test results for H5-specific antibodies.[60] It remains to be verified whether increased numbers of dogs with antibody-positive test results can be found in areas with a high prevalence of HPAIV infections in poultry or wild birds. In order to evaluate the potential of dogs to spread H5N1 influenza virus to humans, inoculation studies were performed with two different HPAIV H5N1 strains.[8,9] Short-term virus shedding from the nasal cavity was observed inconsistently and only with low titers. All of the inoculated dogs developed antibodies. Transmission of infection to in-contact dogs and cats was not observed.[8] Therefore, although dogs are susceptible to HPAIV H5N1, no evidence has been obtained for a major role of dogs in the spread of this virus.

As in dogs, infections of felids with HPAIV H5N1 have been documented in areas with HPAIV H5N1 infections in poultry or wild birds in the surrounding area.[29,52,58] Phylogenetic analyses have shown that viral isolates from cats and tigers are highly similar to the avian virus circulating in poultry at the same time, indicating that no genetic reassortment events with mammalian influenza viruses had occurred. Several point mutations have been identified that are associated with higher virulence in mammals; however, none of them seem to be essential for the infection in felids.[52,59,61,62] Sporadic fatal disease due to HPAIV H5N1 infection in domestic cats, leopards, and tigers received considerable public attention.[63] Infections in felids were reported in Asia (China, Thailand, Vietnam, Indonesia, Iraq) and Europe (Austria, Germany). The presence of antibodies and clinical evidence of HPAIV H5N1 infections in different species of wildcats (e.g., Asiatic golden cat, clouded leopard) have been reported from Cambodia.[64]

Despite the described sporadic HPAIV H5N1 cases in felids, the prevalence of infection among pet cats in European countries seems to be low. A study conducted in Germany included 171 cats having outdoor access in areas in which infected birds had been found at the time of investigation. Neither virus excretion nor antibodies were detected among the cats.[65] In Milan, Italy, there was no evidence of antibodies to HPAIV H5N1 in cats.[66] Because no outbreaks of avian influenza had occurred in the sampling area at that time, the likelihood of finding antibody-positive cats was most probably low. Because the tests performed in these studies are able to detect antibodies against all influenza A viruses, the investigations also confirmed that cats are not prone to infections with the seasonal influenza viruses circulating in humans. In contrast to these investigations, 8 (7%) of 111 feral cats tested in an unpublished study of the National Institute of Animal Health in Bangkok and 20% of 500 cats tested in Indonesia[67] had antibodies to influenza A H5N1. It is possible that cats are more susceptible to virus strains circulating in Asia compared with European virus strains, and thus, more cats become infected in Asia. Within HPAIV H5N1, at least two genetically and antigenically distinct lineages (clades 1 and 2) exist with different geographic distributions in Asia. Clade 1 was isolated mainly in Vietnam and Thailand, whereas clade 2 was found mainly in China and Indonesia. From there, the "Qinghai-like" sublineage spread to the Middle East, Europe, and Africa and separated into three different subclusters.[61,68] All Asian cases reported in felids were caused by infections with clade 1 viruses. The outbreak in domestic cats in Iraq and the fatal cases in Germany were caused by Qinghai-like clade 2 viruses. Therefore, cats seem to be susceptible to different circulating H5N1 virus strains.[61] It seems likely that the difference in prevalence among cats is caused by higher risk of exposure to the virus in Asia. Compared with the situation in Asia, only a relatively small number of wild birds and poultry farms were affected in Europe. Additionally, cats included in the European studies were pet cats, which were fed by their owners and thus would probably have been exposed to the virus only during bird hunting.

Pathogenesis

Infection of felids occurs mostly through direct contact with infected birds, particularly through ingestion of infected poultry.[24,52,54,55] Both inhalation and ingestion seem to be potential routes of virus entry.[24,69,70] The virus spreads to the lower respiratory tract, where it can cause severe pneumonia.[48,52,55] In the lungs, influenza H5N1 viruses in cats attach predominantly to type II pneumocytes and alveolar macrophages.[71] The predominant involvement of the lower respiratory tract and the inability of the virus to attach to cells of the upper respiratory tract may be a reason why cats excrete virus at relatively low concentrations.[24,71] Experimentally infected cats develop a significant rise in body temperature from day 1 PI, lethargy, protrusion of the nictitating membrane, conjunctivitis, and respiratory distress by day 2 PI. Unlike other influenza viruses, which usually have restricted replication in the mammalian respiratory tract, HPAIV H5N1 infection in cats leads to viremia and systemic infection. Severe necrosis and inflammation in many organs occur, with a fatal disease outcome. This has also been shown after experimental intratracheal and oculonasopharyngeal infection.[24,57,70] Virus can be detected in pharyngeal, nasal, and rectal swabs as well as urine specimens. Viral shedding starts between days 1 and 3 PI and lasts up to 7 days PI.[24,70] Ingestion of infected birds can be a route of transmission to cats under natural conditions.[24] Horizontal transmission through both the respiratory and gastrointestinal routes has been demonstrated in experimental infections[24] and was also assumed under natural conditions in the Sriracha tiger zoo outbreak in Thailand.[54]

Clinical Features

The incubation period appears to vary depending on the route of infection and is shorter after direct experimental infection through respiratory and oral routes (1 to 2 days) than after cat-to-cat transmission (5 days).[70,72] Clinical signs described in affected felids include fever, lethargy, dyspnea, conjunctivitis, and protrusion of the third eyelid.[24,52,54,55] Neurologic signs result from cerebral and cerebellar congestion and nonsuppurative meningoencephalitis accompanied by vasculitis.[54,55] Diarrhea, as described in affected poultry and also in humans infected with HPAIV H5N1,[73,74] has not been observed in affected cats. Sudden death may occur in cats as soon as 2 days after the onset of clinical signs.[54,55]

Infection of cats with HPAIV H5N1 also can result in subclinical infection. Three cats housed in an animal shelter in Austria shed virus after contact with an infected swan, and two cats developed antibodies to influenza H5N1 virus, but none developed clinical signs.[58]

Experimentally, the development of clinical signs is dose-dependent. Infection with a high viral dose results in virus shedding and fatal disease. When cats are exposed to a moderate dose, they do not develop clinical signs but seroconvert and shed only small amounts of virus. Cats exposed to a low dose of virus do not become infected.[57]

Laboratory abnormalities described in tigers include severe leukopenia and thrombocytopenia and increased activities of serum ALT and AST.[54] Markedly increased liver enzyme activities also have been found in diseased domestic cats.[48]

Diagnosis

Influenza should be considered as a diagnosis in cats that develop respiratory disease with outdoor access in regions with sporadic or endemic outbreaks of influenza virus H5N1 in birds. Because of the systemic replication of the virus in diseased dogs and cats, detection is possible not only in pharyngeal, nasal, and rectal swabs but also in fecal and urine specimens, organ tissues, and pleural fluid.[69,70,75] Pharyngeal swabs are convenient to obtain and will also detect subclinically infected cats.[57,58] Swabs should be placed in a sterile tube with a few drops of saline. Bacterial transport medium should not be used. Influenza virus RNA can be identified by RT-PCR with primers specific for the matrix (M) gene. A subtype-specific RT-PCR can then be used to identify involved hemagglutinin and neuraminidase genes.[48,52] Viral isolation can be performed by inoculation of swab suspensions into embryonated hen eggs or in cell cultures (e.g., MDCK) and be identified subsequently by RT-PCR or HI assays.[51,55,70] Immunohistochemistry can be used to detect influenza virus antigen in affected organs.[55,70] In-clinic tests designed to screen cats for infection are not commercially available. All tests that have been studied lacked the sensitivity to produce reliable results in specimens derived from experimentally infected cats.[65]

Antibodies to influenza viruses in serum specimens can be detected using viral neutralization assays within 3 weeks after infection.[57] HI assays and a commercially available, species-independent competitive ELISA assay based on the nucleoprotein are more sensitive for the detection of antibodies against influenza viruses. Both tests are able to detect antibodies within 2 weeks PI and may be used for serosurveillance studies.[57,58,76]

Treatment

Not much is known about the efficacy of antiviral treatment in cats infected with HPAIV H5N1. The neuraminidase inhibitor oseltamivir (Tamiflu, Roche, Nutley, NJ) has good antiviral activity against HPAIV H5N1 *in vitro*[77] and in experimentally infected mice and ferrets,[78,79] and is recommended for treatment and prophylaxis of HPAIV H5N1 infection in humans.[80] However, treatment with oseltamivir (75 mg/60 kg q12h) failed to protect tigers from infection and disease during the outbreak in the Sriracha zoo in 2004. This might be due to differences between humans and felids in drug pharmacokinetics and host metabolism.[54,62] Sequence analysis of the virus obtained from the treated tigers excluded the possibility that drug-resistant mutants had emerged.[62]

The prognosis for infected cats in the field is unclear. Subclinical infections are possible, but all domestic cats that developed clinical signs to date have died or had to be euthanized.

Prevention

Although sustained transmission of HPAIV H5N1 in cats in Asia and Europe has not occurred, the number of countries reporting these infections demonstrate that the transmissions are not exceptional single events but rather expected if the exposure or the infection pressure in the environment is high enough. The role of cats in the adaptation of HPAIV H5N1 to mammals remains to be elucidated and, therefore, vaccination regimens have been discussed. So far, however, no licensed influenza vaccine for cats is available.

An inactivated, adjuvanted heterologous whole-virus vaccine based on an LPAIV of subtype H5N6 protected cats even against a lethal high-dose challenge HPAIV H5N1 infection.[57] Vaccination induced high HPAIV H5N1 cross-reacting HI antibody titers before challenge. Vaccinated cats did not develop any clinical signs and showed a significant reduction in viral excretion.[57] Other experimental studies have used fowlpox virus expressing avian influenza virus H5 derived from an H5N8 influenza virus,[42] H5 from a H5N1 influenza virus,[81] or a canine adenovirus expressing H5 of a recent tiger isolate as a vaccine vector.[82] These vector-based vaccines have never been tested in challenge experiments. However, a recombinant vaccine with a canarypox vector producing the hemagglutinin protein protected cats against challenge with two HPAIV H5N1 isolates from humans.[29]

Public Health Aspects

Although dogs and cats are susceptible to infection with HPAIV H5N1, there is no evidence they play a major role in spread of this virus. There have been no reports of humans contracting the infection from diseased dogs or cats. However, preventative measures must be taken to minimize the risk of virus transmission to humans when cats or dogs are suspected to be infected with HPAIV H5N1. All natural infections in cats and dogs have been connected directly to the occurrence of HPAIV H5N1 in birds. Therefore, contact of dogs and cats with infected birds must be avoided. It has been advised to keep cats indoors in areas where HPAIV outbreaks occur. Cats should also not be fed uncooked poultry meat. If animals are suspected to be infected or infection is confirmed, they should be isolated and the number of contacts with them should be minimized. Personnel handling infected animals should wear protective clothing (gloves, face masks, etc.). Fractious cats should be sedated for handling. Proper quarantine, hygiene, and disinfection are important.

Transmission of infection from infected cats to dogs and from infected dogs to cats has been investigated experimentally with contact conditions similar to those common in pet households.[8] Cats and dogs had close contact and shared water and food bowls. At least under these conditions, no transmission occurred. Therefore, the risk of trans-species transmission of HPAIV H5N1 infections between dogs and cats seems to be low.

Highly Pathogenic Influenza H5N6 Virus Infections

The avian influenza H5N1 virus was the first influenza virus identified with a polybasic cleavage site in its haemagglutinin (therefore displaying a highly pathogenic phenotype) and that could infect cats. In recent years, another HPAIV (subtype H5N6) spread among poultry across Asia, Europe, and Africa. In China, HPAIV H5N6 emerged in 2013 and spread to Southeast Asia. In 2014, the first human H5N6 infection was reported in China. Analysis of fecal specimens from wild birds and one lung specimen from a dead domestic cat collected in areas with close proximity to the residence of the infected human revealed that some of the wild birds and also the cat died due to a H5N6 infection.[83] This was the first case of fatal H5N6 avian influenza virus infection in a domestic cat. Subsequent analyses during HPAIV H5N6 outbreaks in poultry and wild birds in South Korea in 2016 revealed three additional infected cats.[84] The cats displayed acute salivation, lethargy, and seizures, and died within 4 days of illness onset despite antimicrobial drug treatment. Virus isolated at necropsy from the three cats were similar to HPAIV H5N6 isolated in chicken farms nearby. Necropsy findings included bloody nasal discharge, severe pulmonary congestion and edema, splenomegaly, and necrotic lesions and influenza virus antigens in multiple visceral organs. It seems likely that the neurotropism of the virus was a key factor contributing to the sudden death of the animals.[84] Epidemiological investigations showed that the cats might have been infected by ingestion of (or contact with) infected wild birds, although the virus was not isolated from wild birds

around the area at this time. Sequence analyses of H5N6 viruses isolated from cats in China in 2016 showed continued antigenic drift and antigenic shift. Analyzed influenza H5N6 viruses harbored individual genome segments from three different (H5N6, H9N2, H7N9) viruses.[85] This confirmed a continued evolution of the co-circulating avian influenza viruses in China. Due to the large distribution of H5N6 virus infections in birds and the few documented infections in cats, the probability of H5N6 virus transmission to cats can be assumed to be low. Nevertheless, avian influenza virus surveillance will be needed for mammals, including cats, during regional H5N6 outbreaks. Irrespective of and before the occurrence of HPAIV H5N1 and H5N6 infections in dogs, canine infection with LPAIV H5N2 was reported in China.[86]

INFLUENZA VIRUS INFECTIONS OF EQUINE ORIGIN

Clinically apparent influenza virus infection associated with sustained transmission in dogs occurred in the United States in Florida as early as 1999, when a strain of H3N8 equine influenza virus circulating in horses adaptively evolved via genetic mutation–induced alterations in the hemagglutinin protein and infected racing greyhounds.[1,87] The virus was first isolated during an outbreak of respiratory disease in dogs in 2004, and homologous isolates were found in greyhounds and other breeds in Florida and other states thereafter.[88] The spread of infection appeared to be sporadic and involve the integration of infected dogs into populations of susceptible dogs.

Canine Influenza H3N8 Virus Infections

The influenza H3N8 virus isolate from the Florida outbreak was determined to be a host-adapted CIV; it readily replicated in dogs and spread in a sporadic fashion throughout the United States. The virus has the entire genome of the equine virus with minor modifications in the hemagglutinin portion of the genome[88-90] resulting in five amino acid substitutions. Sequential examination of the canine isolates has revealed minor genetic alterations with the continuing trend of mutations typical of influenza viruses.[91] This modified H3N8 virus readily replicates and spreads between dogs[92] but does not establish a productive infection in horses.[75,93,94] The adapted CIV also does not replicate in avian species such as domestic chickens, turkeys, or ducks.[95]

Epidemiology

Retrospective antibody detection studies with genetic documentation in the United Kingdom and Australia between 2002 and 2007 have substantiated independent novel infections of dogs with equine H3N8 strains that were in direct or indirect contact with horses.[88,96-100] These represent individual episodes of exposure of dogs to infected horses, with limited replication and spread in dogs, rather than independent mutational adaptations to infect dogs. Horizontal spread among affected dogs in these outbreaks has not been demonstrated. In the United States, the virus that emerged in Florida spread widely for several years. Interconnected networks of dense susceptible host populations found in dog shelters and kennels probably enabled the long-term maintenance of the virus. The virus has subsequently become increasingly confined to areas in the northeastern United States.[39] Since 2016, influenza H3N8 virus has only been rarely identified in the USA,[40] and at the time of writing, the virus appears to be extinct.

In one experimental study, dogs cohoused with horses that were infected with an equine H3N8 isolate also became infected. However, although virus was found in the nasal passages of affected dogs, horizontal spread of the virus among dogs was not confirmed.[101] Similar findings were made in one natural outbreak where affected dogs were in direct contact with, or in the immediate vicinity of, infected horses.[99] However, dogs in that study did not become infected if their only exposure was to owners having contact with infected horses. Furthermore, infected dogs from that study were transported and kept with other dogs in urban locations, and no further spread of infection to contact dogs was found. Cross-species transmission of influenza virus from horses to dogs increases the concern for future respiratory infection outbreaks in dogs exposed to horses or possible new adaptations of the equine virus to preferentially infect dogs.

Pathogenesis

Experimental inoculation of the canine-adapted Florida virus isolate back into horses produced a milder illness in horses than that caused by the parental equine strain.[102] Mice can also be experimentally infected and develop respiratory tract inflammation.[103] Experimental intratracheal and intranasal inoculation of the laboratory-isolated virus into dogs produced fever (above 39° C [102.2° F]) for 2 days without signs of respiratory illness.[1] In other studies, intranasally infected 14- to 15-week-old antibody-negative pups developed respiratory signs and lung lesions with demonstrated viral replication and seroconversion.[104] These lesions were also found in further studies where adult dogs were infected by intranasal and intratracheal virus inoculation.[103] Although respiratory airway and lymph node inflammation is prominent, pulmonary involvement to the point of consolidation is uncommon in experimentally infected dogs.[88,103] Viral replication and shedding was greatest during the early incubation period, which lasted 2 to 4 days, and rapidly declined thereafter; lower-level shedding lasted up to 7 to 10 days. Shedding of CIV is of lower magnitude and shorter duration than that observed for influenza virus infections of other species. However, even subclinically infected dogs still shed virus, although at lower levels than more severely affected dogs.

Clinical Features

Subclinical infections can be documented by seroconversion without illness in dogs. However, after introduction of the virus into facilities with susceptible dogs, the severity of infection and prevalence of infection may be suddenly noticeably greater than with other causes of CIRD. The longer naïve dogs entering an endemic shelter reside, the more likely they are to become infected.[105] Clinical signs of affected dogs in the first identified outbreaks ranged from fever, tachypnea, and mucopurulent nasal discharge to self-limiting cough (10 to 14 days). As the infection has spread and vaccination has been implemented, the severity of signs and proportion of severely ill dogs has been reduced in those kennels. The most severe and persistent respiratory manifestations are associated with the development of pneumonia, which can be confirmed by thoracic radiography. Leukocytosis with a left shift may be found with evaluation of the hematologic parameters in dogs with pneumonia. Recovery occurs in a majority of infected dogs; a minority dies peracutely, and death is associated at necropsy with pulmonary, mediastinal, and pleural hemorrhages.[1,87,103] Infections in greyhound kennels have had the greatest severity of respiratory complications including pneumonia, which may relate to concurrent infection with group C streptococci and other bacteria.[87,103] Histologic changes included tracheitis, bronchitis, and suppurative bronchopneumonia (Fig. 25.3). Subsequent to these outbreaks, dogs that have had no history of respiratory illness may have high antibody titers against these viruses, indicating rapid spread of infection with subclinical illness in many dogs and to many other kennels, shelter facilities, and individual pets.

Diagnosis

Signs of CIV infection are similar to those caused by other agents of CIRD. Specific testing, although not always indicated in the clinical situation, should be performed to confirm the cause of illness. This is sometimes important in large outbreaks when causes must be confirmed to aid in control measures. A variety of tests can confirm the viral cause. For serum antibody determination, which is often the most reliable method, acute and convalescent samples should be taken within the first 7 days of illness

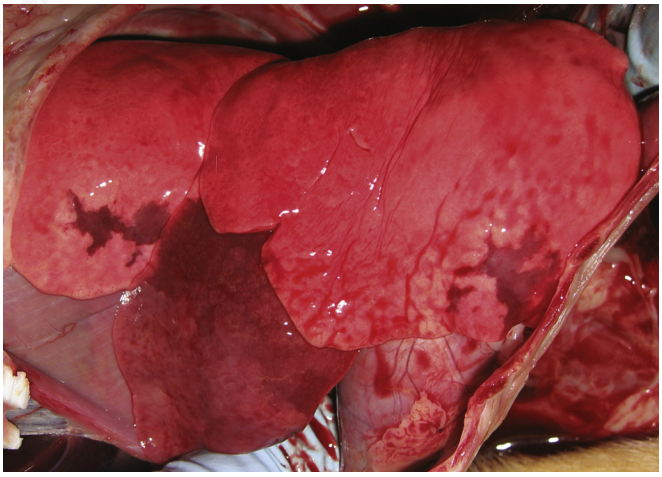

Fig. 25.3 Canine influenza virus–induced lung lesions in a young dog, 3 days after experimental exposure. Pulmonary congestion and consolidation and petechial hemorrhages are visible. (Courtesy Merck (MSD) Animal Health.)

and again 14 days later. Fourfold change in the antibody titer is indicative of active infection. Single positive titer determinations or lack of demonstration of a significant change in the titer only confirms exposure. Virus-specific antibody titers can be measured using HI and microneutralization assays.[1,88,106] The second method is the detection of virus, isolated from nasal (best) or pharyngeal (lower yield) swabs during the first 4 days of infection. Although tracheal or pulmonary washings may be superior, they involve additional cost and risk for collection from clinical patients. Virus can be cultivated in MDCK cells or embryonated eggs.[88] Specific antisera and RT-PCR can be used to identify the influenza virus subtype. RT-PCR can also be used directly from clinical specimens, preferably nasal swabs; however, as with viral isolation, results are usually only positive in the first 4 days of illness. Using immunohistochemical staining or in situ hybridization, virus can be detected throughout the respiratory tract in association with the inflammatory lesions. Pulmonary tissue should be submitted for culture, RT-PCR, or pathologic evaluation from dogs that die.

Clinical signs of this infection are similar to that caused by group C streptococci (*Streptococcus equi* subsp. *zooepidemicus*), which can cause outbreaks of acute, often fatal respiratory illness in many host species including kenneled dogs.

Treatment

Therapy with broad-spectrum antibacterials can reduce the severity of illness related to secondary bacterial infection and pneumonic complications; however, it does not offer a practical means of preventing virus spread and will not shorten the disease course in animals without significant secondary bacterial infections. Use of specific anti-influenza virus drugs, such as oseltamivir, is not recommended because their efficacy has not been investigated. Hospitalization, which is often required for severely affected animals, requires isolation and symptomatic therapy with parenteral fluids to maintain hydration. Recovery is generally within 2 to 3 weeks, although it can be longer in dogs that develop pneumonia.

Prevention

In experimental studies, recombinant-vectored H3 vaccines have increased virus-specific serum antibody concentrations in dogs and protected them against experimental challenge.[76,107] Vaccines against the infection in horses are commercially available. In dogs, vaccines are licensed in individual countries. An inactivated equine influenza virus vaccine was evaluated before availability of a canine influenza vaccine but did not provide protection.[88] A commercially available subcutaneous, adjuvanted, inactivated CIV H3N8 vaccine protected pups challenged 13 days after the second vaccination.[108] The severity of clinical signs, pathologic lesions, and magnitude of viral shedding were lower in vaccinated pups than in animals of the control group. HI antibody titers increased more dramatically after exposure to virulent challenge virus in vaccinated as compared to control pups. The vaccine is given as two 1-mL doses 2 to 4 weeks apart. It is recommended for dogs that have a lifestyle conducive to exposure to this virus and other respiratory tract infections. Dogs that are group-housed, in facilities with a high turnover of animals (e.g., animal shelters), or in densely populated communities with high viral prevalence are at greatest risk. Dogs in contact with horses might also be vaccinated; however, the cross-protection provided by the canine vaccine against the equine virus strains requires additional study. Those in individual households are least likely to contract infection. Pups should be at least 6 weeks old for the first injection. Annual vaccination is recommended. Because of the limited level and duration of shedding of influenza virus by infected dogs, the geographic spread of infection has been gradual and sporadic. Implementation of vaccination programs for dogs will help to control further spread of this virus.

Preventative measures should be exercised to prevent cross-species infection of influenza viruses where they are known to exist.[109] As influenza in horses is restricted to the respiratory tract and does not cause a systemic infection, viral transmission from horses to dogs through feeding raw horse meat is rather unlikely, although this feeding practice is common in management of certain sporting or working breeds such as greyhounds.

Public Health Aspects

Although human influenza virus strains occasionally infect dogs and cats, there is no evidence that the canine influenza H3N8 virus can be spread from dogs to people.[110] Nevertheless, immunocompromised humans should generally avoid direct contact with animals having respiratory illness. Veterinarians should report concurrent human and animal respiratory outbreaks because of the rare chance that the human- or canine-adapted viruses may have changed species affinity with the risk of subsequent spread. There is no evidence that CIV infects other animals such as cats. Therapeutic and preventative measures should be used in management of ill dogs to minimize the spread of infection.

Canine Parainfluenza Virus Infection

John A. Ellis

KEY POINTS

- Cause: CPIV is a paramyxovirus that is related to parainfluenza viruses and mumps virus in humans (family *Paramyxoviridae*, genus *Rubulavirus*).
- First Described: CPIV was first isolated from dogs with acute URTD in 1967.
- Affected Hosts: Canids. Experimental infections in rodents, cats, and ferrets have been reported, but are a questionable clinical significance.
- Geographic Distribution: Worldwide.
- Route of Transmission: Aerosol, direct contact, fomites.
- Major Clinical Signs: Nonspecific signs of URTD comprising harsh or honking cough, serous nasal discharge, conjunctivitis, and fever (uncomplicated disease). May predispose to lower respiratory tract disease (bronchitis, pneumonia) that is usually associated with secondary bacterial infections, such as *Bordetella bronchiseptica* infections. CPIV has also been rarely associated with neurologic and enteric diseases in dogs.
- Differential Diagnoses: Other causes of acute infectious URTD including, CAdV, CIV, CRCoV, CHV, *B. bronchiseptica*, and possibly reoviruses and canine pneumovirus. Less frequently, other causes of upper and lower respiratory diseases such as airway collapse, fungal or protozoal pneumonia, respiratory tract neoplasia, airway foreign bodies, chronic bronchitis, parasitic infections (such as *Filaroides, Oslerus, Capillaria, Paragonimus, Dirofilaria*), aspiration bronchopneumonia, left-sided congestive heart failure.
- Human Health Significance: None documented; clinical CPIV infections are limited to canids.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

CPIV has a long, complicated history. It has been called Simian virus 5 (SV5), parainfluenza virus 5, canine parainfluenza 2, or, simply, CPIV.[1] It was first found in cultures of rhesus and cynomolgus monkey kidney cells in 1956[2] which led to a still somewhat unresolved controversy concerning its infectivity and pathogenicity in laboratory rodents and in humans.[1] CPIV was first isolated from dogs with respiratory disease in 1967.[3]

CPIV is in the genus *Rubulavirus* of the subfamily *Paramyxovirinae*, order *Mononegavirales,* of the family *Paramyxoviridae*.[4] Other important rubulaviruses that are distantly genetically and antigenically related to CPIV are human parainfluenza virus types 2 and 4 (HPIV-2 and HPIV-4, respectively) and mumps virus.[1,4] Parainfluenza viruses are spherical to pleomorphic and consist of a nucleocapsid that is surrounded by a lipid envelope.[1,4] CPIV has a single-stranded, nonsegmented, negative-sense RNA genome made up of approximately 15,000 nucleotides comprising seven genes that encode for eight proteins. The nucleocapsid or ribonucleoprotein (RNP) core of the virus includes the N or nucleoprotein, the phosphoprotein (P), and large (L) proteins. The matrix or M protein is the most abundant viral protein in an infected cell. It is located on the inner face of the forming envelope, and is essential in the assembly, budding, and release of progeny virions.[1,4] Hemagglutinin-neuraminidase (HN) and fusion (F) glycoproteins are found on spikes in the envelope; they mediate attachment to, and penetration of, the host cell, respectively, and are targets for protective antibody responses.[4] There are two other small nonstructural proteins: the small hydrophobic or SH protein that modulates apoptosis or "programmed cell death" in infected cells; and the V protein that affects interferon biology, the cell cycle, and apoptosis.[4] The RNA-dependent RNA polymerase is a nonstructural protein that is essential for the transcription of viral mRNA and replication of genomic RNA.

Like other single-stranded RNA viruses, CPIV exists as a diverse population of related viruses, or "quasispecies", rather than a single "species." Currently, there is little known about genomic and antigenic differences among CPIVs isolated from dogs, mostly because only a small number of field isolates have been examined.[1,5] Such differences could be related to virulence, and, potentially, to vaccine efficacy. Direct sequencing of CPIV isolates from one outbreak of respiratory disease in kennelled dogs revealed 100% sequence identity in PCR products amplified from two tracheal specimens, and these did not differ from the CPIV vaccine isolate.[6] Unfortunately, these products were from the N protein gene, which is highly conserved and probably unlikely to reveal differences among isolates.[4] Application of panels of monoclonal antibodies has revealed only minor differences in the HN, F, and P proteins among CPIV isolates.[1]

Infection and disease associated with CPIV are most prevalent in situations where dogs are commingled and crowded, such as during boarding, thereby enhancing the potential of droplet transmission (aerosol) of the virus.[1,7–13] CPIV spreads rapidly under these conditions and a large percentage of dogs can rapidly become infected. Certainly, based on what is known about human parainfluenza virus infections in environments such as hospitals and nurseries, fomites are likely important in transmission of CPIV.[4] In addition, the physiological sequelae of stress that accompany commingling situations are likely an important co-factor in CPIV infection, but are unexamined. Climate and seasonal weather variation in transmission and prevalence of infection are also likely to be important unexplored variables in CPIV in dogs.

Numerous historical and recent serological surveys and identification of CPIV in CIRD cases from many countries on several continents indicate a worldwide and widespread prevalence of CPIV infection.[1,7–13] The incidence of CPIV infection in outbreaks varies, as does the incidence of co-infections. Respiratory disease is generally more severe when co-infections are present.[1] There is less known about the prevalence of CPIV in household dogs, but it is probably much lower. A 2015 study documented CPIV in 3.2% of dogs without clinical signs of respiratory disease that were examined at animal shelters, providing an insight into the prevalence of subclinical infections.[14]

An area of controversy in the epidemiology of CPIV infections has been the host range of CPIV. Summarizing numerous studies, available data indicate that canids are the primary or only target species for clinical CPIV infections.[1] This includes wild canids, notably coyotes and foxes. Among other canids, CPIV-associated clinical disease has only been documented in ferrets, and that was only by experimental infection. CPIV seropositivity has been detected in some wild mustelids. Domestic cats have been experimentally infected with CPIV, but no disease resulted. Their possible role as reservoirs for dogs has not been completely excluded. Beyond carnivores, notably in laboratory rodents, the preponderance of evidence indicates that CPIV infections are restricted or abortive. Mice and hamsters can be infected, that is, CPIV can be recovered after "infection", but no disease or lesions result. The ability of CPIV to infect primates is more complicated and somewhat unresolved. Taken together, data indicate that CPIV is unlikely to be of clinical concern in immunocompetent humans. However, its zoonotic potential should probably not be completely discounted in immunosuppressed individuals, approximately 40% of whom own pets in the United States.[15]

CLINICAL SIGNS AND THEIR PATHOGENESIS

CPIV can cause a variety of clinical signs of variable severity including a dry, harsh, hacking cough for 2 to 6 days, several days of pyrexia, nasal discharge, pharyngitis, and tonsillitis.[1] Importantly, these signs are not specific for CPIV infection, and there are often co-infecting pathogens. This makes a clinical etiologic diagnosis difficult.

Since most dogs with uncomplicated CPIV infections recover, there is little documentation of lesions associated with CPIV infection in natural outbreaks. Available data indicate that the main CPIV-associated lesion is histologic tracheobronchitis that is similar to parainfluenza virus infections in other species.[1,4] There is necrosis of tracheal and bronchiolar epithelial cells and sometimes hyperplasia of mucosal epithelium (Fig. 26.1). This is accompanied by infiltration of the epithelium and lamina propria by a mixed population and inflammatory cells. Purulent exudate may be visible in the airways. These changes can lead to disruption of mucociliary function of ciliated epithelia, which can predispose infected animals to secondary bacterial pneumonia. Local inflammation and congestion in the olfactory mucosa can also result in a loss of sense of smell.[16]

Studies in children and puppies suggest that parainfluenza virus infections, especially when combined with other common respiratory pathogens, can have a lifelong impact on hyper-responsiveness in airways. Although there has been no recent work on this phenomenon in dogs, available data suggest that CPIV infection can have pulmonary physiologic and chronic inflammatory effects beyond those normally attributed to acute viral infection.[1,4]

Naturally occurring, uncomplicated, CPIV infections in dogs are usually self-limiting and restricted to the respiratory tract, primarily the upper respiratory tract. However, there have been a few reports of systemic infection, which have included involvement of the CNS and the GI tract. CPIV was isolated from an ataxic paretic puppy with encephalitis with hydrocephalus, and from a puppy with acute hemorrhagic enteritis.[1] Certainly, other paramyxoviruses with broader target cell tropisms, notably CDV, cause systemic disease in dogs, but involvement of CPIV in disease outside the respiratory tract is a rare event that may be attributable to viral strain differences.

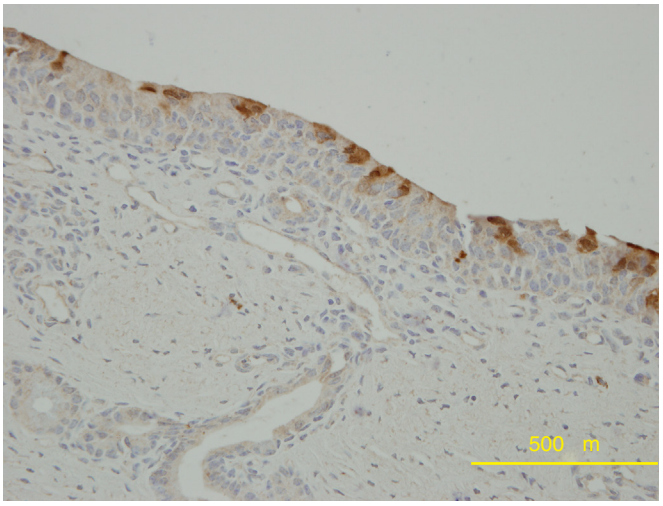

Fig. 26.1 Tracheitis in a calf with bovine parainfluenza virus-3 (BPIV-3) infection. Note numerous ciliated epithelial cells containing brown-staining viral antigens and associated mixed population of inflammatory cells in the epithelial layer and lamina propria.

DIAGNOSIS

As with CIRD pathogens in general, the most definitive antemortem diagnosis of CPIV infection involves detection of the virus in nasal secretions (Table 26.1).[1,4] Historically, this was done with cell culture. From a practical standpoint, use of polyester-tipped swabs are preferred for isolation.[1] CPIV readily grows in a variety of cell types from different host species origins.[1] The use of primary canine cells may improve the sensitivity of detection of field isolates. CPEs in inoculated cell cultures include intracytoplasmic inclusion bodies and syncytium formation, which varies among isolates, and hemadsorption with guinea pig erythrocytes.[1,4] Immunofluorescence (IF) staining is usually used to confirm CPIV infection. CPIV is relatively labile in storage and transport. Failure to account for this can result in false-negative results in isolation. Rapid diagnosis of CPIV can also be attempted by direct IFA staining of cells in smears of nasal swabs. Traditional culture methods have mostly been replaced by PCR detection. Usually these are multiplex PCR assays in the form of a "respiratory panel" that has the capability to detect multiple pathogens simultaneously.[8–13,17] These highly sensitive and specific tests are now in common usage and are available from commercial diagnostic laboratories in many countries. Two important caveats in their use are the timing of specimen collection (> 6–7 days after infection) and recent intranasal (IN) vaccination. Collection of specimens more than 6–7 days after infection risks a high likelihood of negative test results (due to the brief period of virus shedding). Collection of specimens within 3 weeks of IN vaccination is likely to lead to false-positive test results.

In an outbreak situation, serology can be a useful diagnostic approach, especially if dogs have been affected for more than a week. Acute and convalescent serum samples, optimally collected 10–14 days apart, should be used. Hemagglutination-inhibition, virus neutralization tests, or now, more frequently, ELISA tests can be used to measure CPIV-specific antibodies.[1] Factors to consider when using serological testing include the overall endemicity of infection, persistence of maternal antibodies, and routine vaccination, all of which can result in dogs having antibodies to CPIV in the absence of recent exposure. Such dogs may not have anamnestic antibody responses following infection.[1] Despite some limitations, serology using stored paired

TABLE 26.1 Diagnostic Assays Available for Parainfluenza Virus Infections in Dogs

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival, nasal and caudal pharyngeal swabs, transtracheal and bronchoalveolar wash specimens, airway and lung specimens collected at necropsy	Virus	False negatives can occur in specimens that contain no or low numbers of virus particles. Attenuated live virus may also be isolated. May take several days and requires specialized techniques and expertise.
RT-PCR	See above	Parainfluenza virus RNA	Sensitivity and specificity may vary depending on assay design. Sensitivity may be low because of brief shedding. Attenuated live vaccine virus may be detected after mucosal vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of degradation of viral nucleic acid during specimen transport.
Serology	Serum	Antibodies against parainfluenza virus (hemagglutination-inhibition, virus neutralization tests, ELISA)	Interpretation complicated by previous vaccination and exposure. May be useful when the exposed population is naïve and unvaccinated. Acute and convalescent sera required for diagnosis.
Histopathology	Necropsy specimens	Immunostaining	Can be used for diagnosis at necropsy. Immunostaining and/or PCR is required to definitively identify the presence of parainfluenza virus

serum samples may be the only approach to document CPIV infection in outbreak situations when virus detection attempts are not undertaken or fail to yield positive results. The presence of tracheobronchitis or bronchiolytic lesions in dogs that die of respiratory disease is suggestive of CPIV infection. CPIV infection in these cases can be documented using immunohistochemical staining[18]; however, if an affected dog has been sick for more than a week and has secondary bacterial pneumonia, CPIV may no longer be detectable in the lesions.

TREATMENT AND PROGNOSIS

As with most other acute respiratory virus infections, there is no specific therapy for CPIV infections other than supportive care. For most infections, disease is self-limiting. At the population level, control of CIRD including CPIV infection by vaccination alone is often inadequate, especially in high-density dog populations; therefore, attention to environmental co-factors is important. In a kennel or boarding facility, routine cleaning with one of the various commercially available disinfectants is recommended; because CPIV is an enveloped virus, it is susceptible to most disinfectants as well as desiccation. It is also important to clean or remove sources of fomites, which are probably an underappreciated means of transmission.[1,4] Adequate ventilation is also critical in reducing the airborne transmission of CPIV and other CIRD pathogens. Furthermore, 12 to 20 air exchanges per hour and maintenance of facilities at a relative humidity between 50% and 65% with ambient temperature between can 21°C and 23.8°C has been recommended. At the first signs of respiratory disease, infected animals should be isolated if possible. Once an outbreak has occurred, depopulation of the entire facility for up to 2 weeks may be necessary. Minimally, this should preclude exposure via shedding of CPIV by subclinically infected and recovering animals.

IMMUNITY AND VACCINATION

Vaccines for CPIV have been available since the late 1970s, when both IN and parenteral vaccines were developed.[1] Current CPIV vaccines are combination vaccines containing one or more respiratory or systemic pathogens, available for either parenteral or IN administration. Vaccine efficacy has been tested primarily in experimental infections. A limitation of experimental infection models is the usually mild or no disease that results from infection with attenuated CPIV strains that have been propagated in culture in the laboratory, often resulting in a less than robust test of vaccine-stimulated immunity. Nevertheless, both mucosal and parenteral vaccines, when administered properly, optimally at least 10 to 14 days before exposure, can confer clinical immunity as defined by reduced clinical disease and reduced viral shedding.[1] Although CPIV can be a component of core vaccines that are administered every 3 years, vaccination for CPIV and *Bordetella bronchiseptica* should be performed annually for dogs at risk. Therefore, different products must be used for vaccination in the second and third years of each cycle. The ability of IN CPIV-containing vaccines to stimulate rapidly induced local innate immunity and their potential use prior to commingling, or in outbreak situations has not been examined. Although somewhat controversial, both mucosal and systemic antibody responses are correlates of immunity; however, currently, the antibody response to CPIV in vaccinated dogs remains poorly characterized. Moreover, there is virtually nothing known about CMI in CPIV infections, although it is likely to be important, as in other respiratory paramyxoviral infections. Although not formally tested, it is likely that maternal antibodies interfere with priming of CPIV immunity by parenteral vaccination of puppies, as is the case with CDV, which may favor the use of an IN vaccine as a first dose. The comparative utility of IN and injectable CPIV vaccines in boosting of primed immune responses has not been examined. Beyond measuring antibody titers over time, there is very little known about the duration of clinical immunity conferred by vaccination or recovery from infection; it is probably shorter than the persistence of any detectable antibody. Despite gaps in the knowledge, priming through mucosal vaccination early in puppyhood, followed by boosting parenterally when maternal antibodies have decayed at 2–3 months of age, may be the most efficacious approach to immunoprophylaxis.[19]

Canine Respiratory Coronavirus Infection

Canio Buonavoglia, Jane E. Sykes

KEY POINTS

- Causes: CRCoV belongs to the genus *Betacoronavirus* of the *Coronaviridae* family. It was thought to arise from bovine coronavirus (BoCoV) through a cross-species transmission event, as suspected for the closely related human coronavirus OC43 (HCoV-OC43).[1] Viruses of the *Betacoronavirus* genus are typically responsible for either respiratory or enteric disease. Enteric CCoV is a different coronavirus that belongs to the genus *Alphacoronavirus*.
- First Described: CRCoV was first reported in 2003 in a group of dogs newly introduced in a rehoming facility in the United Kingdom where enzootic respiratory disease was reported despite regular vaccination. The earliest report has been ascribed to an old sample collected in Canada in 1996 based on a retrospective study,[2] but earlier circulation cannot be ruled out.
- Affected Hosts: Natural infection with CRCoV has been reported only in dogs, supported by Koch's postulates by experimental infection.[3] Similarly, CCoV only causes disease in canids. However, in 2021 a recombinant CCoV was identified in humans with respiratory illness in Malaysia.
- Geographic Distribution: Both CRCoV and CCoV have been found worldwide. Serologic studies and molecular surveys have detected CRCoV in Europe, the United States and Canada, Japan, Korea, China and New Zealand, demonstrating a global distribution of CRCoV with various prevalence rates.
- Route of Transmission: CRCoV is a highly infectious pathogen with respiratory tropism. Oronasal transmission due to shedding of viral particles through respiratory secretions is considered preferential. In addition, CRCoV has been detected in the feces from naturally infected dogs,[4–6] thus suggesting a possible fecal-oral transmission, although this was not confirmed experimentally.[3]
- Major Clinical Signs: Like CCoV, CRCoV often causes subclinical infections. When disease occurs, CRCoV infection is associated with mild respiratory signs including nasal discharge, sneezing, and cough, which have been documented in natural and experimental infections. CRCoV is a significant contributor to the CIRD complex, predisposing dogs to secondary infections and more severe clinical signs. Occasionally, CRCoV has been detected in dogs with nonrespiratory disease, although whether this virus was responsible for the observed signs was unclear since other pathogens were also detected.[4] A hypervirulent strain of CCoV, known as pantropic CoV, can also infect the respiratory tract, but most affected dogs have shown GI and neurologic signs, in association with leukopenia.
- Differential Diagnoses: Differential diagnosis for CRCoV infection includes infection by other CIRD-associated pathogens, such as CAdV-2, CPIV, CHV-1, *Bordetella bronchiseptica*, *Mycoplasma cynos*, and *Streptococcus equi* subsp. *zooepidemicus*, together with influenza viruses, canine pneumovirus (CPnV), pantropic CCoV, and mammalian reovirus (MRV).
- Treatment and Prevention: For CRCoV, no specific treatment has been tested yet and, to date, vaccines are not available. Vaccines available for prevention of CCoV infection do not protect against CRCoV infection.
- Human Health Significance: There are no reports of disease caused by CRCoV in humans or animals other than dogs.[7] Nonetheless, animal CoVs are regarded as a potential threat by the scientific community, chiefly after the emergence of SARS CoVs and Middle East Respiratory Syndrome (MERS), since potential cross-species transmission may occur from animals to humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

CRCoV belongs to the family *Coronaviridae* (order *Nidovirales,* subfamily *Coronavirinae*) that consists of pleomorphic virions of 80 to 120 nm in diameter, containing a positive-sense single-stranded RNA genome of the largest size among all RNA viruses. Due to the envelope, coronaviruses are susceptible in the environment and easily inactivated by commercial disinfectants and detergents. They are more likely to survive in the environment at cooler temperatures. Comparative analysis of coronavirus genomes shows an exceptional plasticity and a marked ability to evolve, generating new strains, genotypes, and serotypes, as a result of a high mutation rate, recombination events, and occasionally of interspecies transmission.[8] Phylogenetically, coronaviruses are classified into four genera, *Alpha-*, *Beta-*, *Gamma-*, and *Deltacoronavirus*, and several species. CRCoV is grouped with bovine coronavirus (BoCoV) and human coronavirus (HCoV) OC43 within the *Betacoronavirus-1* group, which is also defined as bovine-like compared with SARS-CoV-1 and SARS-CoV-2 that are referred to as *Betacoronavirus-2*.[9,10] With a few exceptions, CCoV mainly includes strains with enteric tropism and that belong to the genus *Alphacoronavirus-1*, closely related to FCoV, porcine transmissible gastroenteritis virus (TGEV), HCoV-229E, and HCoV-NL63.[11] All coronaviruses display a similar genome organization with five genes arranged in a conserved order. Two thirds of the genome comprises the replicase gene, which encodes for two overlapping open reading frames, ORF1a and ORF1b, which work as replication/transcription complex.[12] Downstream of the ORF1 gene there are four genes encoding for the structural proteins S, E, M, and N. The spike (S) glycoprotein mediates viral attachment to specific cell receptors driving host cell type binding and is the main inducer of virus-neutralizing antibodies. The E protein drives the assembly of the viral envelope, but is not essential for virus propagation. The membrane (M) protein constitutes the most abundant structural component. Finally, the nucleocapsid (N) protein is complexed with viral RNA, which shapes the core structure of the viral particles.[12] In addition, each coronavirus possesses group-specific accessory genes that are dispensable for viral replication *in vitro* but, as a rule, are maintained in field strains driving

virus-host interactions and increasing virulence in natural hosts.[13] CRCoV possesses the canonic genome organization of the genus *Betacoronavirus*, with an additional accessory gene encoding for a surface hemagglutinin-esterase protein (HE)[14] and three accessory genes encoding for nonstructural proteins (*nsp*) that are scattered in the genome, namely ORF 2a, 4a, and 4b.[15] Since its first detection in 2003 in dogs from a rehoming center in the United Kingdom where enzootic respiratory disease was identified, CRCoV was clearly distinguished from CCoV by its molecular and pathologic features.[15,16] Serologic investigations have demonstrated that CRCoV is widespread. The highest seroprevalences to CRCoV have been found in Canada (59.1%) and the United States (54.7%), with lower prevalences from the United Kingdom (36.2%), Ireland (30.3%),[17] Italy (32.1%),[4] and New Zealand (29%).[18] Furthermore, circulation of CRCoV in Asia also has been reported, although with lower seroprevalences in Japan (17.8%)[19] and Korea (12.8%).[20] Due to the antigenic similarities between CRCoV and BoCoV, the bovine virus has often been used as antigen for CRCoV serologic surveys. Importantly, it has been shown experimentally that BoCoV can infect dogs, causing subclinical infection and seroconversion.[19] It is possible that dogs, chiefly in rural areas, have antibodies due to exposure to bovine viruses rather than CRCoV, which should be taken into account when interpreting the results of serologic investigations. Worldwide, at the time of writing, more than 25 dogs have been reported with evidence of natural infection by SARS-CoV-2 (the cause of COVID-19 in humans),[21,22] but most dogs have had no clinical signs and the extent to which this virus can cause disease in dogs remains unclear. Clinical signs and viral shedding did not occur in dogs that seroconverted following experimental infection.[23] Infection of pet dogs has followed exposure to infected humans, and there is currently no evidence of dog-to-human transmission (see Chapter 43 for detailed information on COVID-19 and animals).

Almost all the dogs tested on entry to the shelter in the United Kingdom where CRCoV was first detected seroconverted after 3 weeks, drastically increasing the seroprevalence from 30% to 99%.[16] Similarly, a high incidence of seroconversion has been described in Canada.[24] This indicates that the virus is highly contagious, spreading rapidly in groups of susceptible dogs. Increased prevalence is reported in high-density environments and dogs housed in shelters or kennels, especially after 2–3 weeks of residence in those environments. Dogs older than 6 months are also at increased risk for exposure.[17]

Molecular surveys using PCR have confirmed the circulation of CRCoV in dogs from several countries, with prevalences of 17.5% in the United Kingdom,[16] 7.2% in Italy,[25] 5% in Finland,[26] 9.8% in Germany,[27] and 2.1% in Japan.[5] Interestingly, CRCoV is uncommonly detected in healthy dogs, with 1.8% positive animals in the United States,[28] 0% in Germany,[27] and 4% in Austria.[29] Molecular characterization has identified several CRCoV strains, which suggests genetic diversification, possibly related to geographic patterns of evolution. Whether the observed genetic diversity also implies changes in the biologic features and/or virulence of the various strains requires further investigation.[15,30]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

CRCoV has been primarily associated with respiratory disease. The multifactorial etiology of CIRD hinders a clear understanding of the pathogenesis of CRCoV infection, as synergic mechanisms with other respiratory pathogens impact the clinical course of the infection. Viral transmission mainly occurs via the oronasal route, through respiratory droplets propagated either directly or indirectly. In experimentally infected dogs, viral shedding from the oropharynx was detected at 4 and 6 days PI and lasted for 8–10 days. Sentinel dogs in close contact with inoculated dogs displayed the same shedding pattern.[3] Early shedding of viral particles from day 2 PI may be responsible for the rapid spread observed under natural conditions.[16] Histopathologic evaluation with IHC reveals CRCoV antigen in respiratory columnar epithelial cells within the trachea, bronchi, and major bronchioles.[2,31] Viral antigen has also been detected in ciliated epithelial and goblet cells within the trachea during experimental infections, with visible accumulations in cytoplasmatic vacuoles and on the luminal surface.[31] Replication of CRCoV in these locations negatively impacts ciliary function, interferes with antiviral defense provided by activation of the IFN-JAK/STAT signal transduction pathway within infected cells, and downregulates the expression of proinflammatory cytokines, such as IL-1β, IL-6, TNF-α, and chemokines, such as IL-8.[31] This predisposes to invasion and colonization by other viral and bacterial pathogens (Fig. 27.1).

CRCoV RNA also has been identified in the stools of infected dogs, suggesting a possible additional route of transmission. Attempts to re-isolate CRCoV from enteric samples of dogs actively shedding the virus at the oropharyngeal level were not successful, so it is possible that CRCoV may pass through the canine enteric tract mechanically without intestinal replication.[3] Further investigation is required to determine conclusively whether enteric shedding of the virus can play a role in transmission of CRCoV among dogs. Although CRCoV tropism seems to be restricted mainly to respiratory tissues, the virus has been occasionally detected in dogs with nonrespiratory signs, although co-infection with other pathogens may have been responsible for the observed clinical signs.[4,5] Therefore, a dual enteric-respiratory tropism is possible, as observed for BoCoV,[32] although the ability of the virus to replicate in the GI tract has not yet been demonstrated.

Mild respiratory signs such as nasal discharge, sneezing, and dry cough are the main clinical signs in dogs infected by CRCoV. Loss of appetite, lethargy, or weight loss and other nonspecific signs of illness could be observed when other CIRD-associated pathogens are also involved. This could explain the prolonged duration or the increased severity of the disease observed in some cases. CRCoV seems to be associated primarily with early-stage signs of CIRD, operating as a "quick-hit" respiratory pathogen, and creates conditions that promote more severe secondary infections when other environmental and medical-related factors are favorable. Whilst it is not clear if CRCoV should be considered a primary pathogen of CIRD, a role in the development of this disease complex has been confirmed repeatedly. Accordingly, CRCoV should be always included in the diagnostic algorithms when acute respiratory disease is reported.

Physical Examination Findings

CRCoV infection can result in nonspecific respiratory signs that include serous to mucopurulent ocular and nasal discharge, sneezing, and a dry cough. In dogs with tracheitis, cough may be easily elicited on manipulation of the trachea. To date, there is no evidence of severe disease associated with CRCoV infection. Fever, loss of appetite, and lethargy are rarely reported, and are mostly related to co-infections with other pathogens.[4] Lower respiratory tract signs may appear when secondary bacterial infections complicate the clinical course.

DIAGNOSIS

Laboratory Abnormalities

Information on CBC and serum chemistry profile findings during CRCoV infection is limited. Dogs infected experimentally with CRCoV show some CBC abnormalities.[3] Significant lymphocytosis was observed between days 6 and 14 PI. In addition, transient neutropenia was observed in a significant number of dogs. Some dogs have developed a mild bandemia and toxic changes within leukocytes. Usually, coronavirus infections trigger abnormalities in lymphocyte subsets, interfering with the immune function of the host in a manner that is specifically related with the viral tropism.[33] For betacoronaviruses, transient neutropenia has been reported for SARS CoVs[34,35] and BoCoV.[36] Whether CRCoV is able to modulate the immune system is unknown.

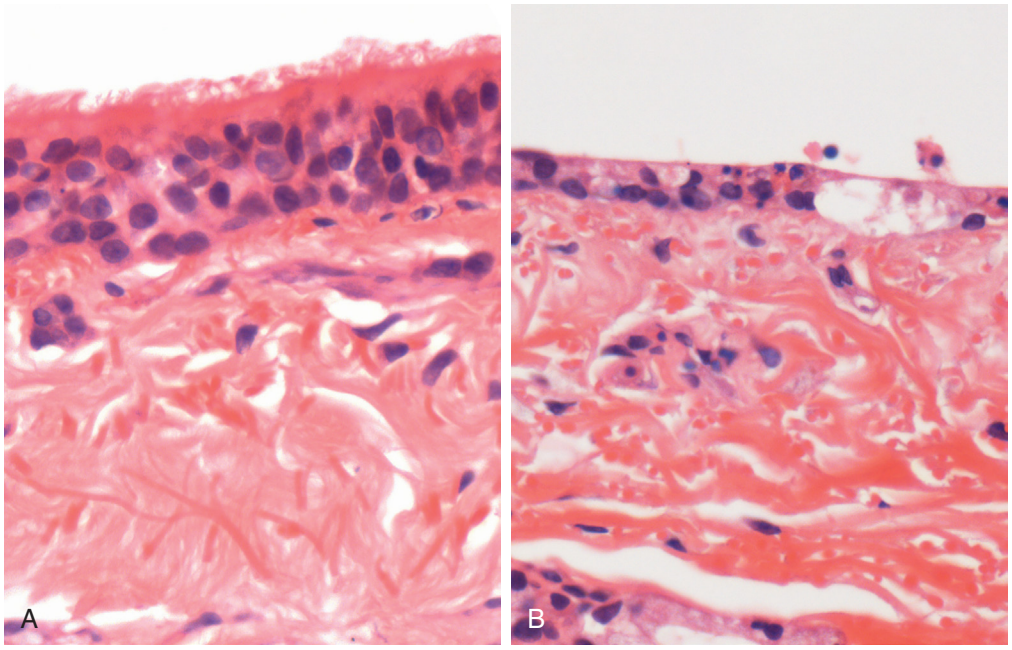

Fig. 27.1 Effect of canine respiratory coronavirus (CRCoV) infection on ciliated respiratory epithelial cells. (A) Respiratory epithelium immediately before inoculation with CRCoV. (B) The same cells 48 hours after inoculation with CRCoV. There is marked loss of cilia, thinning of the epithelium with individual cell necrosis, and sloughed necrotic cells on the surface. There are also occasional large vacuoles within the epithelium, which likely represent foci of cell loss secondary to viral replication. (Courtesy Dr. Simon Priestnall and Professor Joe Brownlie, Royal Veterinary College, UK.)

Microbiologic Tests

As observed for all the etiologic agents suspected to play a role in CIRD, clinical signs are generic and if sought, a definitive diagnosis of CRCoV infection must rely on specific microbiologic tests (Table 27.1). History of recent exposure to other dogs, rapid spread of the disease in a high population density environment, and short clinical course of the disease may support a diagnosis of CIRD, but these do not provide clues to the cause(s) of disease.

Virus Isolation and Molecular Diagnosis

Virus isolation for CRCoV can be difficult because some CRCoV strains are not adapted to grow *in vitro*. Virus propagation on human rectal tumor cell line HRT-18[37] can be successful. The supernatant of infected cell cultures agglutinates chicken erythrocytes at 4°C and mouse erythrocytes at room temperature, although this technique is not sensitive and is difficult to standardize.

In contrast, molecular-based methods are sensitive and specific tools for diagnosis of CRCoV infection. A quantitative real-time RT-PCR assay specific for detection of CRCoV has been developed,[6] and some commercial veterinary diagnostic laboratories offer respiratory PCR panels that include detection of CRCoV.

Specimens suitable for analysis can be collected from the nasal and oral cavities, the oropharynx and nasopharynx. Nasal and tracheal washes and lung lavage fluids from infected animals are expected to yield positive results.[3,6,38] At necropsy, nasal and palatine tonsils, trachea, bronchial lymph nodes, and lung tissues can be collected. Due to the limited period of viral shedding, negative results can occur when specimen collection occurs late after the onset of the clinical signs.

Serologic Testing

Serologic tests may provide information on the prevalence of exposure to CRCoV in dogs but are not recommended for diagnosis. Rapid seroconversion occurs in high density populations. Commercial kits are not available on the market, and either ELISA tests based on BoCoV antigen[4,16] or serum neutralization assays are used.[5] Because the HE protein of betacoronaviruses can agglutinate chicken and mouse erythrocytes, HI has been investigated for detection of antibodies to CRCoV. However, it appears to be poorly specific and sensitive, and not recommended for diagnosis.[4] An ELISA based on CRCoV antigen yielded results comparable to BoCoV-based ELISA assays.[17] IFA has been proposed as the gold standard for serologic testing based on comparative evaluation of sensitivity and specificity.

TABLE 27.1 Diagnostic Assays for Canine Respiratory Coronavirus Infections

Assay	Specimen Type	Target	Significance
Virus isolation (HRT-18 cells)	Nasal or oral swabs, respiratory lavage specimens	CRCoV	Poorly sensitive, difficult to perform.
RT-PCR	Nasal or oral swabs, respiratory lavage specimens	CRCoV RNA	Rapid, sensitive, and specific. Positive results do not imply disease causation because the virus can be found in healthy dogs.
Serology (ELISA, HI, or IFA)	Serum	Antibodies	Positive results reflect exposure. Acute and convalescent titers are required to document recent infection in association with respiratory signs. Assays based on HI have poor sensitivity and specificity and are not recommended.

CRCoV, canine respiratory coronavirus; *ELISA,* enzyme-linked immunosorbent assay; *HI,* hemagglutination-inhibition; *IFA,* immunofluorescent antibody; *RT-PCR,* reverse transcriptase-polymerase chain reaction.

IHC on paraffin-embedded formalin-fixed tissues[2] or CRCoV-inoculated tracheal tissue culture[3] is useful for detection of CRCoV antigen using a cross-reactive antiserum raised against BoCoV, as the two viruses share high genetic and antigenic similarity in the spike gene/protein.

Pathologic Findings

Gross Pathologic Findings

Gross lesions suggestive of inflammation have been observed only in the nares and trachea of experimentally CRCoV-infected dogs at necropsy.[3] The clinical relevance of these findings is unclear because such changes can also be found in healthy dogs.

Histopathologic Findings

On histopathology, dogs infected with CRCoV exhibit remarkable alteration of the ciliated columnar epithelium of the trachea and bronchioles. There is loss or damage of cilia, deficiency of goblet cells, and infiltration of inflammatory cells within the epithelium with proteinaceous material on the luminal surface.[3] Lymphoid aggregates have occasionally been observed in the lungs close to airways or blood vessels. An *in vitro* model using an air-interface system of tracheal tissues demonstrated that CRCoV may impair ciliary function and alter mucus secretion by goblet cells.[6] In addition, infection may lead to functional alteration of antiviral mechanisms, with significant reduction in the expression of proinflammatory cytokines and chemokines. CRCoV antigen can be found in columnar epithelial cells, goblet cells, and in multifocal aggregates dispersed on the luminal surface.[3,6] The same pattern was observed in specimens from two naturally infected dogs with bronchitis and suppurative bronchiolitis collected during an outbreak of distemper in a shelter.[2]

TREATMENT AND PROGNOSIS

There are no specific antiviral drugs available for treatment of dogs for CRCoV infection. However, CRCoV rarely causes complicated or severe disease. Treatment consists of supportive care for respiratory disease (see Chapter 28).

IMMUNITY AND VACCINATION

Vaccines are not available for prevention of CRCoV infection. Vaccines for CCoV are not expected to protect against CRCoV infection (or SARS-CoV-2 infection) because of the low antigenic relationships among the viruses.[17,36,39] Current guidelines for vaccination of dogs do not recommend vaccination because they have not been shown to protect effectively against pathogenic strains of CCoV.[40] CRCoV elicits a humoral immune response with seroconversion within 14 to 21 days PI in both natural and experimental infections.[3,37] The duration of CRCoV-induced immunity has not been evaluated yet, and it is not clear whether dogs with specific immunity are protected against reinfection or disease. In a serologic study of kennelled dogs, seropositivity was statistically associated with protection from respiratory signs, although 50% of seropositive dogs still developed signs. Serum neutralization tests have demonstrated a high degree of antigenic similarity among strains circulating in geographically distinct locations, which increases the likelihood that any vaccine developed in the future might cross-protect against strains that circulate worldwide.[3]

PREVENTION

Prevention involves reducing stress, control of co-infections with vaccination where available, and limiting transmission through proper infection control protocols. These aspects are particularly relevant in high-density environments, such as shelters, rehoming centers, and breeding kennels, where CIRD can impact significantly. Vaccination of dogs against other CIRD pathogens may reduce, but not completely prevent, respiratory disease in kennels. Antimicrobials can be used to treat opportunistic bacterial infections, but they should be reserved for dogs with complicated disease associated with mucopurulent ocular and nasal discharges. Basic precautions for disease prevention and management in shelters should be aimed at reducing the opportunities of exposure to viruses by: (1) limiting contact among animals, (2) prevention of overcrowding, (3) use of quarantine for dogs before their introduction in the shelter, and (4) use of appropriate disinfectants (see Chapter 17).

PUBLIC HEALTH ASPECTS

CRCoV appears to be a variant of BoCoV.[41] Whether the virus originated directly from BoCoV or from a common ancestor is not clear, although the two viruses are highly similar genetically and antigenically.[9] Dogs can be experimentally infected with an enteric BoCoV and SARS-CoV-2, with subclinical seroconversion.[19,23] Unlike other coronaviruses, BoCoV and SARS-CoV-2 seem to easily cross host species barriers.[42] Coronaviruses genetically and/or antigenically similar to BoCoV have been detected in water buffalo,[43] several deer species,[44] alpacas,[45] waterbuck,[46] and giraffe.[47] Furthermore, the virulent BoCoV enteric strain DB2 can cause mild diarrhea in avian hosts under experimental conditions.[48] BoCoV-like viruses have also been identified from humans.[49] The human enteric CoV strain 4408, which is genetically and antigenically closely related to BoCoV, was identified from a child with acute diarrhea. At the time of writing, natural infections with SARS-CoV-2 have been reported in a variety of host species, including domestic cats, dogs, hamsters, ferrets, mink, otters, white-tailed deer, and multiple captive wild felids (see Chapter 43).[21,22] Hamsters, rhesus macaques, rabbits, white-tailed deer, and ferrets have been infected experimentally.[50] Interspecies transmission and recombination are common events for coronaviruses, and several novel human coronaviruses, including SARS-CoV-2, have emerged in recent years from animal coronaviruses.[8] In a serologic survey of immunocompetent adult humans conducted in the United States before the 2019 pandemic, CRCoV-specific antibodies were not identified.[7] However, in 2021, a cluster of infections with CCoV-HuPn-2018, a coronavirus related to CCoV and a FCoV was recognized in children with respiratory illness in 2017–2018 from Malaysia.[51] The clinical significance and epidemiology of this coronavirus requires further investigation. Monitoring the circulation and diversity of animal coronaviruses is pivotal for readily identifying potential zoonotic risks and developing adequate strategies of prevention and control.

CASE EXAMPLE

Signalment

"Bruce," a 6-month-old intact male English bulldog puppy.

History

Bruce was acquired at 10 weeks of age from a breeder, and at that time the owner noticed stertorous breathing. Approximately 1 month later, Bruce developed signs of nasal discharge and cough. Bruce was examined at a local veterinary clinic at that time. Radiographic findings were suggestive of localized pneumonia. Treatment with clavulanic acid-amoxicillin for 10 days was associated with clinical improvement, but 3 days after the antimicrobials were discontinued, the signs returned. Reinstitution of antimicrobial treatment for 1 week again led to resolution of clinical signs. When the signs returned for a third time, they were more severe. Radiographs showed evidence of a hypoplastic trachea and a diffuse alveolar pattern, with the left lung fields more severely affected than the right. A CBC showed leukocytosis (21,430 cells/μL) due to neutrophilia (17,940 cells/μL). Serum chemistry profile was unremarkable. Bruce was hospitalized and treated with IV fluids, clavulanic acid-amoxicillin, enrofloxacin, and nebulization. This led to rapid clinical improvement, and after discharge from the hospital, antimicrobials were continued. The owner was also instructed to hand-feed meatballs to reduce the risk of aspiration of food. Approximately 5 weeks before evaluation at the UC Davis VMTH, Bruce played with another puppy that was diagnosed the following day with "kennel cough." A day later, Bruce began making retching sounds with increased respiratory effort, although these improved after 24 hours. Mucopurulent nasal discharge appeared 7 days after contacting the puppy. Since that time, the owner reported that Bruce had exhibited a deep nonproductive cough that was most apparent throughout the night, and cough was often worse after eating and drinking.

Current Medications

None

Other Medical History

Bruce had been properly vaccinated with an attenuated live CDV, CPV2, CAdV-2, and CPIV-3 vaccine. There are no other dogs in the household, only three adult cats, but Bruce frequently plays with other puppies. Bruce always had a good appetite and was fed canned commercial dog food. There has been no increased thirst or urination. Intermittent vomiting has been noticed since Bruce was acquired.

Physical Examination

Body weight: 11.0 kg

General: Bright, alert, responsive, hydrated. Temperature = 101.3°F, HR = 150 beats/minute, normal RR, mucous membranes pink, CRT = 2 seconds.

Integument: Clean haircoat. No evidence of ectoparasites. Moist dermatitis between skin folds.

Eyes, ears, nose, and throat: Severe epiphora, conjunctivitis, and mild scleral injection OU. Bilateral mucopurulent nasal discharge with normal airflow. Severe prognathism.

Musculoskeletal: BCS 4/9. Ambulatory, well-muscled.

Cardiovascular: Strong and bilaterally synchronous femoral pulses. No murmurs or arrhythmias on auscultation.

Respiratory: Increased upper airway sounds. Multiple episodes of nonproductive, deep, "honking" coughs (5–10 per episode) during examination. No abnormal findings on lung auscultation.

GI: No evidence of abdominal pain or other abnormalities on palpation. Small bladder noted.

Genitourinary: Single descended testicle. No other abnormalities detected.

Rectal examination: Unremarkable.

Lymph nodes: All within normal limits.

Laboratory Findings

CBC: HCT 37.5% (40%–55%), MCV 69.3 fL (65–75 fL), MCHC 33.1 g/dL (33–36 g/dL), WBC 15,690 cells/μL (6,000–13,000 cells/μL), neutrophils 11,265 cells/μL (3,000–10,500 cells/μL), lymphocytes 2,918 cells/μL (1,000–4,000 cells/μL), monocytes 1,098 cells/μL (150–1,200 cells/μL), platelets 430,000/μL (150,000–400,000 /μL).

Imaging Findings

Thoracic radiographs: There is a moderate bronchial pattern excessive for the patient's age. The cardiac silhouette and pulmonary vasculature appear within normal limits. There is a small amount of gas and fluid within the esophagus on the lateral projections. Within the viewable abdomen, abdominal serosal detail is adequate for the patient's age. The stomach has a small amount of gas. The gastric rugae are mildly prominent. There is a hemivertebra in the mid-thoracic vertebral column.

Neck: The soft palate is moderately to markedly thickened. There is increased opacity over the region of the larynx. The trachea is narrowed and appears to have a thick wall. The trachea-to-thoracic inlet ratio is 8.5%. The tympanic bullae are small and have thick walls.

Impressions: Brachycephalic syndrome. Hypoplastic trachea with suspected tracheitis. Hypoplastic bullae and vertebral anomaly consistent with the breed.

Microbiologic Testing

Respiratory real-time PCR panel: PCR positive for CRCoV and *Streptococcus equi* subsp. *zooepidemicus* on pooled nasal and ocular swabs. PCR negative for influenza virus (H3N8), CDV, CPIV, CAdV-2, CHV-1, and *Bordetella bronchiseptica*.

Diagnosis

Brachycephalic airway syndrome (BAS). Infection with CRCoV and *Streptococcus equi* subsp. *zooepidemicus*. Cryptorchidism.

Treatment

Treatment with enrofloxacin and amoxicillin-clavulanic acid was reinstituted, together with 0.1% dexamethasone ophthalmic drops for the conjunctivitis (OU q12h). The owner was also instructed to feed Bruce in an upright position to reduce the likelihood of aspiration. Clinical improvement occurred, with the cough limited to the night time, but signs again worsened when the antibiotics were discontinued. Three weeks after the initial examination, an esophagram was performed which identified a sliding hiatal hernia. Bronchoscopy and bronchoalveolar lavage (BAL) were performed. Airway examination revealed an elongated soft palate and everted laryngeal saccules. Bronchoscopy showed a markedly hypoplastic trachea with moderate mucus accumulation. All airways were mildly edematous with mild mucus and mild stenosis. The BAL showed moderate neutrophilic inflammation (40% neutrophils, 53% macrophages, 400 cells//μL) with some intracellular bacterial rods and occasional diplococci. Aerobic bacterial culture yielded moderate numbers of *B. bronchiseptica* and very small numbers of *Mycoplasma* spp. The *Bordetella* isolate was susceptible to amoxicillin-clavulanic acid, enrofloxacin, and doxycycline. A respiratory real-time PCR panel on BAL solution was negative for all pathogens. Two days after bronchoscopy, Bruce was anesthetized again. The soft palate and everted laryngeal saccules were resected, and a routine prescrotal closed castration was performed on the left testicle and the right retained testicle was removed via the same incision. Bruce recovered uneventfully and was discharged the following day with instructions to administer omeprazole and sucralfate, and to continue elevated feeding. Doxycycline (5 mg/kg PO q12h for 4 weeks) was prescribed for treatment of bordetellosis. Subsequently, his clinical signs improved markedly and there was no recurrence of clinical signs after antimicrobials were discontinued.

Comments

Bruce was infected with multiple respiratory pathogens including CRCoV, likely as a result of contact with other dogs. Some of his respiratory signs and conjunctivitis may have been caused by these organisms, and some may have resulted from aspiration pneumonia secondary to a hiatal hernia and BAS. It is possible that BAS predisposed Bruce to persistent infections with these organisms due to impaired host defenses. Interestingly, bacterial pneumonia was associated with a *Bordetella* and *Mycoplasma* infection, as confirmed by cytology and culture of BAL fluid. Although *Bordetella* was detected using culture, real-time PCR for *Bordetella* was negative, demonstrating the need for application of multiple types of microbiologic tests in some cases. Because resolution of BAS can reduce intrathoracic pressure and decrease herniation, surgical correction of the hiatal hernia was not performed. After 4 months, a repeat esophagram showed some evidence of persistent hiatal herniation and gastroesophageal reflux. However, because clinical signs were controlled, the owner was instructed just to monitor for any worsening of clinical signs that might trigger the need for surgery.

Miscellaneous and Emerging Canine Respiratory Viral Infections

Simon L. Priestnall, Jane E. Sykes

KEY POINTS

- First Described: Respiratory disease in dogs was first described in 1961 in Canada (due to CAdV-2).[1] With the exception of SARS-CoV-2, the most newly recognized virus, canine hepacivirus, was described in the United States in 2011.[2]
- Proposed Causes: CAdV, CIV (and other influenza viruses), CPIV, CRCoV, CHV, canine pneumovirus, possibly reoviruses, bocaviruses, and canine hepacivirus.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Aerosol transmission or close contact, sometimes fomites.
- Major Clinical Signs: Harsh or honking cough, serous nasal discharge, conjunctivitis, fever (uncomplicated disease). Fever, lethargy, inappetence, tachypnea, productive cough, mucopurulent nasal and ocular discharge, rarely death (complicated disease).
- Differential Diagnoses: Upper and lower respiratory diseases such as airway collapse, bordetellosis, *Streptococcus equi* subsp. *zooepidemicus* infection or other bacterial pneumonia, fungal or protozoal pneumonia, respiratory tract neoplasia, airway foreign bodies, chronic bronchitis, eosinophilic bronchopneumopathy or granulomatosis, parasitic infections (such as *Filaroides, Oslerus, Capillaria, Paragonimus, Dirofilaria*), aspiration bronchopneumonia, left-sided congestive heart failure.
- Human Health Significance: Viruses that cause CIRD generally are not considered zoonotic. However, the emergence of human influenza virus infections in dogs, particularly in eastern Asia, is a growing concern. At the time of writing, it remains unclear whether dogs can be a source of human infection with SARS-CoV-2.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Canine viral respiratory disease is a widespread problem where large numbers of dogs are housed indoors together, such as in shelters, commercial dog colonies, and breeding facilities. The longer dogs are housed in a shelter situation, the greater the risk that respiratory illness will occur.[3] In shelter environments, CIRD, previously referred to as "kennel cough" or canine infectious tracheobronchitis, delays the placement of dogs in homes and can result in unmanageable costs related to treatment, quarantine, and isolation. CIRD occasionally occurs in owned dogs after a period of contact with large numbers of other dogs at dog parks, dog sporting events, or dog behavior classes. It can also occur after dogs (or dog owners) visit veterinary hospitals, boarding facilities, or pet daycare centers.

With the widespread clinical application of molecular diagnostic assays, it is increasingly apparent that the number of viruses that can infect the canine respiratory tract is much larger than previously thought. This has led to exciting new discoveries in the field of CIRD, and our knowledge of the pathogens involved continues to expand. Co-infections with multiple viruses and bacteria such as *Mycoplasma* spp., *Bordetella bronchiseptica*, and *Streptococcus equi* subspecies *zooepidemicus* are common and contribute to an increased severity of disease.[4–8] Younger age has also been associated with increased severity of disease.[5]

Viruses confirmed as causing or contributing to CIRD include CHV-1 (see Chapter 24), CAdV-2 (see Chapter 23), CDV (see Chapter 22), CPIV (see Chapter 26), CRCoV (see Chapter 27), and CIV (see Chapter 25). There is evidence that infection with canine pneumovirus (CPnV) may also be associated with respiratory disease.[4] CAdV-1 may also play a role when vaccination is not performed or when it is performed improperly.[7] CAdV-1 is discussed in more detail in Chapter 23 and will not be discussed further here. The extent to which SARS-CoV-2 causes respiratory disease in dogs is not clear; most infected dogs have shown no signs. Infections of dogs and cats with SARS-CoV-2 are covered in Chapter 43. The major bacterial causes of CIRD are covered in Chapters 50, 55 and 57.

Although most of the canine respiratory viruses have a worldwide distribution, their relative prevalence varies from year to year and between geographic locations. Even within a state or city, predominant pathogens may differ from one shelter and boarding kennel to another.

CDV, CHV-1, CPIV, CRCoV, CPnV, and CIV are enveloped viruses, so they survive poorly in the environment and are susceptible to a variety of disinfectants. Despite this, contact with virus that persists in the environment may be important for transmission in densely housed populations of dogs. CAdV-2 is a nonenveloped virus and has the potential to survive several weeks on fomites. Shedding times vary depending on the pathogen (Table 28.1). Diagnostic tests for respiratory viral pathogens are summarized in Table 28.2.

CANINE RESPIRATORY VIRUSES WITH ESTABLISHED PATHOGENICITY

Canine Herpesvirus-1

The extent to which CHV-1 plays a role in respiratory disease in dogs has been debated.[9] Experimental infections of dogs can result in rhinitis or signs of tracheobronchitis, and intraocular infection results in conjunctivitis and keratitis (Case Example and Fig. 28.1).[10–13] There is

TABLE 28.1 Major Viral Causes of Transmissible Respiratory Disease in Dogs

Organism	Incubation Period (Days)[a]	Shedding Period[a]	Environmental Survival
Canine adenovirus-1	4 to 9	6 to 9 months	Weeks to months
Canine adenovirus-2	3 to 6	1 to 2 weeks	Weeks to months
Canine distemper virus	3 to 6, longer for neurological signs	Weeks to months	Hours
Canine herpesvirus-1	6 to 10; may be longer with stress-induced reactivation	Unknown	Hours
Canine influenza virus	2 to 4	7 to 10 days (H3N8); H3N2 up to 21 days	Hours
Canine parainfluenza virus	3 to 10	8 to 10 days	Hours
Canine respiratory coronavirus	Probably days	6 to 8 days	Hours
Canine pneumovirus	Unknown	Unknown	Hours

[a]Incubation and shedding periods are approximate and may differ when co-infections or immunosuppression operate.

TABLE 28.2 Diagnostic Assays Available for Respiratory Viruses in Dogs

Assay	Specimen Type	Target	Performance
Virus isolation	Conjunctival, nasal and caudal pharyngeal swabs, transtracheal and bronchoalveolar lavage specimens, airway and lung specimens collected at necropsy	Virus	False negatives can occur in specimens that contain no or low numbers of virus particles. Attenuated live virus may also be isolated. May take several days and requires specialized techniques and expertise.
RT-PCR	See above	Viral RNA	Sensitivity and specificity may vary depending on assay design. Sensitivity may be low because of brief shedding for some viruses. Assays may not be available for all viruses or may not detect all virus strains. Testing specimens from multiple different anatomic sites, or combining PCR with other diagnostic tests can increase sensitivity. Attenuated live vaccine virus may be detected after vaccination. Because of subclinical shedding, the significance of a positive result may be difficult to interpret. False-negative results may occur as a result of degradation of viral nucleic acid during specimen transport.
Serology	Serum	Antibodies against respiratory viral antigens	Interpretation complicated by previous vaccination and exposure. May be useful when the exposed population is naïve and unvaccinated for the virus of interest. Acute and convalescent sera required for diagnosis.
Histopathology	Necropsy specimens	Viral inclusions; immunostaining	Can be used for diagnosis at necropsy. Detection of inclusions has low sensitivity and immunostaining and/or PCR is required to definitively identify the infecting virus

RT-PCR, reverse transcriptase-polymerase chain reaction.

evidence of widespread exposure to CHV-1 in dogs worldwide,[9] and a substantial proportion of the dog population may be latently infected. Like other herpesviruses, CHV-1 becomes latent in neurologic tissues, with precipitation of virus shedding by stress. Consistent with the time delay required for reactivation after stress, CHV-1 was most frequently detected 3 to 4 weeks after dogs were introduced to a rehoming center, whereas CRCoV and CPIV were most frequently detected in the first and second week. Dogs infected with CHV-1 were more likely to have severe respiratory disease, although severe respiratory disease itself might predispose dogs to the shedding of CHV-1.[9] Infection with CHV-1 was reported in association with fatal hepatic necrosis in an adult dog that lacked any evidence of immunosuppression.[14] More recently, CHV-1 has been associated with fatal pneumonia in four previously clinically healthy (nonimmunosuppressed) dogs in the United States[15] (Fig. 28.2); thus, the role of this virus as a primary respiratory pathogen in adult dogs may need to be further investigated. For more information on CHV-1 infections, the reader is referred to Chapter 24.

Canine Adenovirus-2

Adenoviruses are icosahedral DNA viruses that infect a variety of animal species. CAdV-2 is found worldwide and primarily infects the respiratory tract of dogs. Rarely, it has been implicated as a cause of enteritis in dogs, and it was found in the brains of puppies with neurologic signs.[16] The virus replicates in nonciliated bronchiolar epithelial cells; epithelial cells of the nasal mucosa, pharynx, and tonsillar crypts; mucous cells in the trachea and bronchi; and type 2 alveolar epithelial cells. CAdV-2 can also be isolated from retropharyngeal and bronchial lymph nodes as well as epithelial cells of the intestinal tract. Shedding typically ceases 1 to 2 weeks after initial infection. For more information on CAdV infections, the reader is referred to Chapter 23.

Canine Influenza Viruses
