Successful treatment of anaerobic infections may require medical and, on many occasions, surgical interventions combined with appropriate antimicrobial therapy. Antimicrobial therapy without surgical drainage is usually unsuccessful. Abscesses or pus-filled cavities have poor blood supply, and drainage allows for entrance of newly exuded fluids containing the antimicrobial agent. Furthermore, few antibacterial drugs work effectively in the presence of accumulated pus. Because anaerobic infections are often polymicrobial, antimicrobial therapy of infectious processes with an anaerobic component should focus on the anaerobic and the presumed aerobic components. In dogs and cats, the most commonly isolated aerobes are enterics (*E. coli*), *Pasteurella*, and *Staphylococcus pseudintermedius*.[5,26]

Anaerobic bacteria are inherently resistant to certain antibacterials (e.g., the aminoglycosides and the second-generation quinolones), although extended-spectrum (third- and fourth-generation) quinolones, such as pradofloxacin, have a reasonable activity against anaerobes at generally used therapeutic dosages.[74,75] Although there are reports of an increase in the prevalence of antimicrobial resistance in anaerobes isolated from humans, the use of empiric agents in veterinary medicine is still recommended.[26] The prevalence of resistance to β-lactams and fluoroquinolones is high among *Bacteroides* spp., but it is also observed in other anaerobes of the gram-negative group.[27,72,74]

The most active antimicrobials against anaerobes are metronidazole, amoxicillin-clavulanate, chloramphenicol, and clindamycin (Table 54.8). Numerous β-lactamase inhibitor combinations such as ampicillin-sulbactam, ticarcillin-clavulanate (if available), and piperacillin-tazobactam have been shown to be very active against human anaerobic isolates but have not been tested on veterinary isolates.[26,27,70] Factors such as tissue penetration should be considered

TABLE 54.8 Suggested Antimicrobial Drugs for Treatment of Anaerobic Bacterial Infections in Dogs or Cats[a]

Drug	Dose (mg/kg)	Interval (Hours)	Route
Amoxicillin-clavulanate potassium	12.5–25	12	PO
Ampicillin-sulbactam	10–20	8	IV, IM
Metronidazole	15 15	12 12 (dogs), 24 (cats)	IV PO
Clindamycin hydrochloride, clindamycin phosphate[b]	11 10	12 (dogs), 24 (cats) 12	PO IV, IM
Chloramphenicol, chloramphenicol sodium succinate	40–50 (dogs), 12.5–20 (cats)	6–8 (dogs), 12 (cats)	PO, IV, IM[c]
Pradofloxacin	3–5 (dogs), 5–10 (cats)	24	PO[d]

[a]The concurrent presence of aerobes should also be considered when selecting antimicrobial drugs.
[b]For intravenous administration, dilute 1:10 in 0.9% saline and administer over 30–60 minutes.
[c]See Chapter 10 for warnings about chloramphenicol use.
[d]In countries where available.

when selecting antimicrobial drugs, and the concurrent presence of aerobic bacteria must also be taken into account. A combination of a β-lactam/β-lactamase inhibitor drug or clindamycin and a drug with activity against gram-negative bacteria, such as a fluoroquinolone or an aminoglycoside, could be a reasonable choice for initial treatment of serious infections whilst awaiting the results of susceptibility testing for aerobic bacteria when mixed aerobic-anaerobic infections are suspected.

There are few studies published that report antimicrobial susceptibility data from veterinary anaerobe isolates. In the United States, a veterinary diagnostic laboratory reported that a few isolates were resistant against antimicrobials tested by the gradient strip method (amoxicillin-clavulanic [1/145], ampicillin [7/77], chloramphenicol [4/242], clindamycin [12/158], metronidazole [10/247] and penicillin [54/243]).[26] Collected unpublished data from anaerobes tested in 10 veterinary diagnostic laboratories shows that these bacteria were susceptible to most antimicrobial agents, with the exception of *B. fragilis*.

Strains of the *netF*-producing type A *C. perfringens* (which has been associated with necrotizing enteritis in neonatal foals and necrotizing and hemorrhagic enteritis in dogs) showed susceptibility to 12 antimicrobial agents, including all β-lactams tested (such as penicillin G and ampicillin), clindamycin, chloramphenicol, and metronidazole. However, these isolates consistently displayed a reduced susceptibility or resistance to tetracycline.[76]

Drugs in the broad-spectrum carbapenem group such as imipenem, meropenem, and ertapenem have been very effective in anaerobic infections associated with mixed aerobic populations. However, empiric use of these agents in veterinary medicine is not routinely recommended based on antimicrobial stewardship concepts. Although anaerobes may be susceptible to trimethoprim-sulfonamides *in vitro*, inhibitors (mainly thymidine) are found *in vivo* that make this drug combination an unpredictable treatment for anaerobic microorganism infections.[77] The response to tetracyclines is unpredictable as well.[4]

PREVENTION

Prevention of anaerobic bacterial infections involves management or prevention of underlying conditions that predispose to these infections (see Clinical Features). Vaccines for prevention of anaerobic bacterial infections are not available. An inactivated, whole cell vaccine preparation *Porphyromonas denticanis, P. gulae,* and *Porphyromonas salivosa* was available for several years for prevention of periodontal disease in dogs, but was withdrawn from the market due to apparent lack of efficacy when its conditional license expired.

PUBLIC HEALTH ASPECTS

It is estimated that 250,000 human bites, 400,000 cat bites, and 4.5 million dog bites occur in the United States each year in both adults and children.[18] Although most of the wounds resulting from animal bites contain aerobic microorganisms, approximately one third contain anaerobes. All are thought to be members of the normal oral cavity microbiota of dogs and cats. The most common anaerobes belong to the same genera as the anaerobes found in disease processes in dogs and cats.[18,78] Some members of the oral microbiota of dogs and cats produce serious disease in immunocompromised individuals and those that are asplenic or have liver disease (see Chapter 75).

Clostridioides difficile is an important cause of disease in humans and it has been found in food-producing animals and retail meats. *Clostridioides difficile* ribotypes in animals are associated with human infections; however, prevalence and spore numbers were low.[79–82] No association between *C. difficile* fecal carriage and raw meat consumption was noted in dogs[81]; however, other enteric pathogens such as *Salmonella* were detected.[83] *Clostridium perfringens* can be transmitted to people on contaminated foods from production animals. No data exist concerning the communicability of *C. perfringens* from dogs and cats to people. However, because it appears that this microorganism can be acquired from contaminated environments, it seems likely, but unproven, that *C. perfringens* from any source can infect dogs, cats, or people. Whether resulting disease depends on a trigger event remains undetermined (see Chapter 64).

CASE EXAMPLE

Signalment

"Cocoa," a 4-month-old intact female Labrador retriever from Gonzales, CA.

History

Cocoa was brought to the University of California, Davis, William R. Pritchard Veterinary Medical Teaching Hospital for evaluation of a history of seizures. Approximately 6 weeks before referral, the dog was seen for redness and protrusion of the left eye (exophthalmos). She was treated with amoxicillin-clavulanic acid for 1 week, and the left ocular exophthalmos resolved, but subsequently protrusion of the right eye was noted. A second 1-week course of amoxicillin-clavulanic acid was instituted, and the exophthalmos again resolved. One month later, Cocoa appeared painful on opening her mouth. She was treated with cephalexin and meloxicam with no apparent improvement. Two days later she was inappetent. When the owners offered her food by hand, she ate, became ataxic, fell over, her thoracic limbs stiffened, and foamy saliva was noted around her mouth. She was taken to an emergency clinic and she vomited in the car. At the emergency clinic, she had three generalized seizures that were treated with diazepam. She was also treated with enrofloxacin (5 mg/kg, IV, once).

CASE EXAMPLE—cont'd

Cocoa's diet normally consisted of commercial dog food and she had been vaccinated for distemper, hepatitis, parvovirus at 8 and 12 weeks of age. There had been no coughing, sneezing, diarrhea, exposure to ticks or toxins, trauma, or travel outside California.

Physical Examination

Body weight: 15.3 kg.

General: Quiet but alert and responsive. Hydrated. T = 102.8°F (39.3°C), pulse = 110 beats/minute, panting, mucous membranes pink, CRT = 1 second.

Eyes, ears, nose, and throat: No clinically significant abnormalities were noted. No evidence of pain on opening the mouth provided neck movement was prevented.

Integument: No abnormalities detected.

Musculoskeletal, cardiovascular, GI, genitourinary systems, and peripheral lymph nodes: No clinically significant findings.

Neurologic examination: Mild obtundation noted. The dog held her head down and was reluctant to move her neck. There was moderate to marked ataxia that involved all four limbs, with the pelvic limbs most severely affected, and the right pelvic and thoracic limbs more severely affected than the left. Cranial nerve examination revealed only a decreased corneal reflex on the right side. Conscious proprioceptive deficits were noted in all four limbs, with the right limbs more severely affected. There was severe pain on palpation of the cervical spine and moderate pain on palpation of the lumbosacral spine. Based on the neurologic examination, multifocal CNS lesions were suspected.

Laboratory Findings

CBC: HCT 34.4% (40%–55%), MCV 64.9 fL (65–75 fL), MCHC 34.9 g/dL (33–36 g/dL), reticulocytes 22,000 cells/μL (7,000–65,000 cells/μL), WBC 17,780 cells/μL (6,000–13,000 cells/μL), neutrophils 12,979 cells/μL (3,000–10,500 cells/μL), band neutrophils 533 cells/μL, lymphocytes 3,023 cells/μL (1,000–4,000 cells/μL), monocytes 1,245 cells/μL (150–1,200 cells/μL), platelets 392,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 143 mmol/L (145–154 mmol/L), potassium 4.6 mmol/L (3.6–5.3 mmol/L), chloride 102 mmol/L (108–118 mmol/L), bicarbonate 23 mmol/L (16–26 mmol/L), phosphorus 6.9 mg/dL (3.0–6.2 mg/dL), calcium 11.1 mg/dL (9.7–11.5 mg/dL), BUN 7 mg/dL (5–21 mg/dL), creatinine 0.4 mg/dL (0.3–1.2 mg/dL), glucose 95 mg/dL (64–123 mg/dL), total protein 6.1 g/dL (5.4–7.6 g/dL), albumin 2.8 g/dL (3.0–4.4 g/dL), globulin 3.3 g/dL (1.8–3.9 g/dL), ALT 35 U/L (19–67 U/L), AST 52 U/L (19–42 U/L), ALP 103 U/L (21–170 U/L), creatine kinase 556 U/L (51–399 U/L), GGT 4 U/L (0–6 U/L), cholesterol 262 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.013; pH 6.5, negative for protein, glucose, ketones, bilirubin, hemoprotein, WBC, RBC, casts, and bacteria.

Imaging Findings

Thoracic radiographs: Cardiopulmonary structures were within normal limits.

Abdominal ultrasound: The gastric wall was mildly thickened with bright, echogenic speckles within the muscularis layer. The submucosa of the stomach was echogenic. Impressions: Changes associated with the stomach were suggestive of gastritis. The remainder of the abdominal ultrasound was unremarkable.

Spinal radiographs: Open physes were present within the vertebral column. No abnormalities were identified.

Brain MRI: In the pre-contrast brain study, a flattened, fusiform structure was identified in the dorsal part of the foramen magnum that caused moderate dorsoventral compression of the spinal cord (Fig. 54.7). This structure was hypointense to brain but hyperintense to CSF on the T1-weighted images and moderately hyperintense on dual echo and fluid-attenuated inversion recovery (FLAIR) images. The post-contrast brain study showed diffuse meningeal enhancement that involved the spinal cord and brain with the most prominent enhancement noted along the ventral brainstem and left cerebral hemisphere. The contrast enhancement pattern was consistent with meningitis. There was a discrete rim of enhancement surrounding the aforementioned fusiform structure, which gave it a cystic appearance. This structure appeared to be extradural in location. The structure in the foramen magnum had partial fluid characteristics, but was not consistent with pure fluid, and in light of the meningeal enhancement, was thought to most likely represent an abscess.

Analysis of CSF (Lumbar CSF)

CSF protein: 726 mg/dL (reference range, < 25 mg/dL)

Total RBCs: 5 cells/μL (reference range, 0 cells/μL)

Total nucleated cells: 7,500 cells/μL (reference range, < 2 cells/μL)

Differential: 88% neutrophils, 12% large mononuclear cells

Microscopic evaluation: The specimen was highly cellular and contained a large number of nondegenerate neutrophils. A few pyknotic forms were noted. Lower numbers of monocytoid cells, large reactive lymphocytes, and rare eosinophils also were observed. Interpretation: Marked neutrophilic pleocytosis (purulent inflammation).

Cytologic Analysis of CSF (Cisternal)

A direct smear of cisternal CSF was examined and found to contain disrupted cells and mildly to moderately degenerate neutrophils. These were admixed with low numbers of monocytoid cells and intermediate-sized reactive lymphocytes. Rare neutrophils were observed with intracellular rod-shaped bacteria. Few free rod-shaped bacteria were noted in the background.

Microbiologic Testing

Aerobic urine culture: No growth was detected.

Aerobic and anaerobic blood cultures: No growth was detected.

Aerobic and anaerobic CSF culture: Small numbers of *B. fragilis*, positive for β-lactamase production.

Diagnosis

Bacteroides fragilis meningitis with extradural abscess formation.

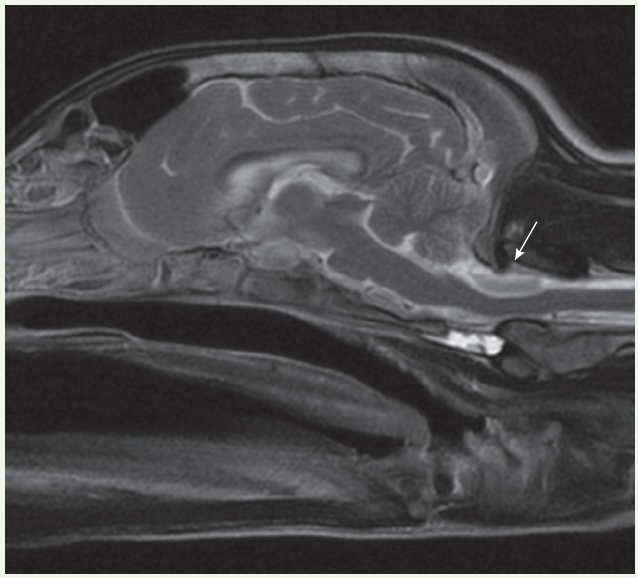

Fig. 54.7 Post-contrast brain magnetic resonance image (MRI) of a 4-month-old intact female Labrador retriever with *Bacteroides fragilis* meningitis and an epidural abscess located in the dorsal part of the foramen magnum. There is a flattened, fusiform structure in the dorsal part of the foramen magnum associated with moderate dorsoventral compression of the spinal cord *(arrow)*. Diffuse meningeal enhancement and a discrete rim of enhancement surrounding the fusiform structure are present.

Continued

CASE EXAMPLE—cont'd

Treatment and Outcome

Cocoa was treated with ticarcillin (50 mg/kg, IV, q6h), metronidazole (10 mg/kg, IV, q8h), and IV crystalloids (LRS with 20 mEq/L KCl at 50 mL/h, IV). The following day her mentation improved and she became more willing to move. On day 3 after starting antibiotics, treatment was changed to clavulanic acid-amoxicillin (16 mg/kg, PO, q8h) and metronidazole (16 mg/kg, PO, q12h). On day 4, Cocoa was less ataxic and had normal conscious proprioception, but had a seizure while on a walk outside. The seizure lasted 45 seconds and was manifested by jaw chomping and defecation, but Cocoa did not fall over or lose consciousness. Potassium bromide (40 mg/kg, PO, q8h for 4 days, then 40 mg/kg, PO, q24h) was added to the treatment regimen and Cocoa was discharged from the hospital.

At a recheck 3 weeks later, Cocoa's owners reported that she had shown steady clinical improvement and for the last week she had been acting like a normal puppy. There had been no seizures. She received her final series of vaccines 1 week ago. No abnormalities could be detected on full neurologic examination. A CBC showed persistent mild nonregenerative anemia (HCT 34.8%), 5,253 neutrophils/μL, and 228 band neutrophils/μL. A repeat MRI showed a marked decrease in the diffuse meningeal enhancement and marked reduction in the size of the cystic structure, although there was persistent mild spinal cord compression. Analysis of CSF revealed a CSF protein concentration of 37 mg/dL, < 1 RBC/μL, 24 nucleated cells/μL, with 12% neutrophils, 51% small mononuclear cells, and 37% large mononuclear cells. Microscopic examination revealed a heterogenous population of lymphocytes that included small mature lymphocytes, larger reactive lymphocytes, and many plasmacytoid lymphocytes along with mature plasma cells and moderately vacuolated macrophages. A few nondegenerate neutrophils were present. Antimicrobial drug treatment was continued and a recheck was recommended in 3 months, but the dog was subsequently lost to follow-up.

Comments

The history of exophthalmos increased suspicion for an anaerobic bacterial infection of the CNS in this dog; therefore, anaerobic culture of the CSF and blood was performed. Given the young age of this dog, a migrating foreign body was suspected. The history, together with the distribution of lesions in the CNS and the lack of lesions elsewhere, suggested direct extension of the infection from the retrobulbar location to the meninges, rather than hematogenous spread of infection. Because the dog was treated with antibiotics before culture was performed, the concurrent presence of other facultative organisms or other anaerobic species may have been obscured. The identification of β-lactamase production by the *B. fragilis* isolate was not surprising because of the high (> 90%) prevalence of β-lactamase production by this species. *B. fragilis* is also known for its propensity to form abscesses.

Bordetellosis

Krystle L. Reagan

KEY POINTS

- First Described: In 1911 (*Bacillus bronchicanis*).[1] The genus *Bordetella* was named after Bordet who first described *Bordetella pertussis*.[2]
- Cause: *Bordetella bronchiseptica*, an aerobic gram-negative motile coccobacillus (family Alcaligenaceae).
- Affected Hosts: Dogs, cats, wild carnivores, pigs, horses, rabbits, rodents, turkey, humans. Dogs and cats share the same strains.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Aerosol, contact with contaminated fomites and water sources.
- Major Clinical Signs: Sneezing, serous to mucopurulent nasal discharge, harsh or honking cough (especially dogs). Dogs and cats with bronchopneumonia can develop fever, lethargy, inappetence, tachypnea, productive cough, and mucopurulent nasal and ocular discharge.
- Differential Diagnoses: Upper and lower respiratory diseases such as dynamic airway disease, viral respiratory infections, fungal pneumonia, protozoal pneumonia, respiratory tract neoplasia, airway foreign bodies, chronic bronchitis, eosinophilic bronchopneumopathy or granulomatosis, parasitic infections (such as *Filaroides, Oslerus, Capillaria, Paragonimus, Dirofilaria*), bronchopneumonias secondary to conditions such as laryngeal paralysis or ciliary dyskinesia, left-sided congestive heart failure.
- Human Health Significance: *Bordetella bronchiseptica* is closely related to *B. pertussis* and *Bordetella parapertussis*, which cause whooping cough in humans. Uncommonly, it has been associated with respiratory disease in humans and rarely systemic infections such as peritonitis, bacteremia, and meningitis. It primarily causes disease in the immunocompromised. Contact with dogs and cats has been associated with human infections, but host specificity may also be strain related.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Bordetella spp. are small, pleomorphic, gram-negative coccobacilli. There are at least nine different bacterial species in the genus *Bordetella* (Table 55.1).[3] The only species known to cause disease in dogs and cats is *Bordetella bronchiseptica,* but *B. bronchiseptica* is closely related to *Bordetella pertussis* and *Bordetella parapertussis,* which cause pertussis (whooping cough) in humans. *Bordetella* species possess fimbriae (pili), and *B. bronchiseptica* is motile by means of flagella, which is composed of flagellin. Other species in the genus do not express flagellin. Genetic studies have shown that there is wide genetic diversity among *B. bronchiseptica* isolates, whereas *B. pertussis* is relatively well conserved. There is evidence that *B. pertussis* evolved from a distinct, human-associated lineage of *B. bronchiseptica,*[4] and it has been recommended that *B. bronchiseptica, B. pertussis,* and *B. parapertussis* be reclassified as subspecies of the "*B. bronchiseptica* cluster."[5] *Bordetella pertussis* has been shown to be able to colonize puppies in the absence of clinical signs of respiratory disease.[6]

Worldwide, *B. bronchiseptica* is an important and prevalent cause of respiratory disease in dogs and cats; it also infects and causes respiratory illness in many different animal species including wild carnivores, pigs, rabbits, and occasionally horses, other herbivores, rodents, turkeys, and humans. There are a large number of different strains of *B. bronchiseptica* that vary in virulence and host specificity. Results of molecular typing efforts have shown that strains that infect dogs can be passed to cats and vice versa.[7–9] The whole genome of *B. bronchiseptica* has been sequenced.[10] Its genome is larger than that of its close relatives, and it possesses several plasmids, some of which mediate antimicrobial drug resistance.[11]

Like viral respiratory infections, bordetellosis is especially prevalent in dogs and cats in shelters, pet stores, boarding facilities, and other situations where large numbers of potentially stressed animals may have been in close contact with one another. Infections with *B. bronchiseptica* frequently occur in concert with respiratory viral and/or *Mycoplasma* spp. infections (see Chapters 26, 28, and 57).[12,13]

Unlike *B. pertussis* and *B. parapertussis*, *B. bronchiseptica* can persist in the environment for at least 10 days and can grow in natural water sources.[14] *Bordetella bronchiseptica* is susceptible to most disinfectants, including accelerated hydrogen peroxide or chlorhexidine cleaners.[15]

The prevalence of *B. bronchiseptica* infections in group-housed animals, including shelters, varies from group to group, even in the same geographic region. For example, between 2009 and 2016, the prevalence of detection of *B. bronchiseptica* in European dogs with respiratory disease varied from 3.3% to 78.7%.[16] *Bordetella bronchiseptica* can be isolated from apparently healthy cats and cats with respiratory disease, but is more likely to be isolated from cats with respiratory disease.[17] In one European study that included 1,748 cats from private multiple-cat households, shelters, and breeding catteries, the more cats in the group, the greater the chance that *B. bronchiseptica* would be detected.[18] In rescue shelters, increased seroprevalence has been associated with poor hygiene.[18] In a study of 742 cats in the United Kingdom, *B. bronchiseptica* was isolated from 0% of pet cats, 19.5% of cats from rescue shelters, and 13.5% of cats from research colonies.[19] *Bordetella bronchiseptica* was cultured from 3.1% of 614 cats from four shelters in Louisiana,[20] 5.1% of nasal swabs from 59 cats with acute respiratory disease in Colorado,[21] 2.4% of pharyngeal swabs from 250 cats at intake in a Canadian shelter,[22] and none of 22 cats with respiratory disease in a shelter in California.[23] However, the prevalence of infection was nearly 50% in nasal swabs from 40 cats with rhinitis from a shelter in Colorado.[24] Similarly, a high prevalence (26%) of infection was detected with a PCR assay in 100 cats with upper respiratory disease from central Italy.[25]

TABLE 55.1 Species That Belong to the Genus *Bordetella*

Species	Host(s)	Disease
Bordetella bronchiseptica	Dogs, cats, pigs, horses, rabbits, rodents, sheep, seals, humans	Rhinitis, tracheobronchitis, bronchopneumonia
Bordetella pertussis	Humans	Whooping cough
Bordetella parapertussis	Humans, sheep	Whooping cough (humans); ovine-adapted strains cause respiratory disease in sheep
Bordetella holmesii	Humans	Upper respiratory tract disease, bacteremia
Bordetella trematum	Humans	Otitis media and wound infections
Bordetella avium	Poultry (especially turkeys)	Rhinotracheitis
Bordetella hinzii	Turkeys, rabbits, rarely humans	Turkey, rabbit upper respiratory disease
Bordetella petrii	Environment, rarely humans	None, osteomyelitis
Bordetella ansorpii	Humans	Bacteremia, skin infection

In a case review from the eastern United States, *B. bronchiseptica* was isolated from 49% of 65 pet dogs under 1 year of age with radiographic and microbiologic evidence of bacterial bronchopneumonia. Most of these dogs had originated from breeders (40%) or pet stores (41%), and only 8% were from shelters. Dogs infected with *B. bronchiseptica* were younger (7–35 weeks of age), had been owned for a shorter period of time (median, 18 days), were more likely to have originated from a pet store, and were less likely to have originated from a breeder than dogs with pneumonia caused by other organisms.[26] *Bordetella bronchiseptica* was detected using PCR in 9% of respiratory specimens from client-owned dogs with and without respiratory tract disease that were submitted to the Athens Veterinary Diagnostic Laboratory (Athens, GA, USA). The prevalence of infection was significantly higher in the colder months than in the summer, in contrast to the other respiratory pathogens detected, and was more likely to be detected in dogs less than 12 months of age.[27] Of 2,054 specimens submitted to IDEXX laboratories for PCR detection of respiratory testing in 2020, 15% were positive for *B. bronchiseptica*, the most frequently detected pathogen after *Mycoplasma cynos*.[28] In a study of dogs with respiratory disease from the United Kingdom, *B. bronchiseptica* was detected in 14.5% of 1,602 respiratory specimens submitted to four different laboratories from 2016 to 2019.[29]

Bordetella bronchiseptica was isolated from dogs with respiratory disease as well as from healthy dogs in a rehoming kennel in the United Kingdom.[30] Of 138 dogs with acute upper respiratory tract disease or dogs that were directly exposed to dogs with respiratory signs from Italy, eight (10.3%) of the acutely ill dogs were positive using PCR for *B. bronchiseptica* versus one (1.3%) of the healthy exposed dogs.[31] Additionally, when a cohort of dogs with acute respiratory signs were assessed by PCR for *B. bronchiseptica,* it was found that 78% (48/61) of sick dogs were PCR positive, whereas 45.6% (41/90) of clinically healthy control dogs were positive.[12] In another study, *B. bronchiseptica* DNA was detected using PCR in 19.5% of apparently healthy dogs on entry to a shelter.[32]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Transmission of *B. bronchiseptica* occurs primarily by the airborne route, but contact with contaminated fomites and water sources may also be important. The organism is highly contagious. Much of what is known about *B. bronchiseptica* pathogenesis is based on studies of infections in host species other than the dog or cat. *Bordetella bronchiseptica* is inhaled, adheres to respiratory cilia, evades the immune system, and secretes toxins that damage the respiratory epithelium (Figs. 55.1 and 55.2).

Adhesion of virulent strains of *B. bronchiseptica* to respiratory cilia occurs by means of fimbrial adhesins (FIM), a filamentous hemagglutinin (FHA), pertactin, and cell wall LPS. *Bordetella* colonization factor A (BcfA) is another outer membrane protein that appears to be important for tracheal colonization by *B. bronchiseptica*.[33] *Bordetella bronchiseptica* possesses genes that encode for pertussis toxin, an important adhesin in *B. pertussis*.[34] These genes are not expressed *in vitro*, but there is some evidence for pertussis toxin expression *in vivo*.[35]

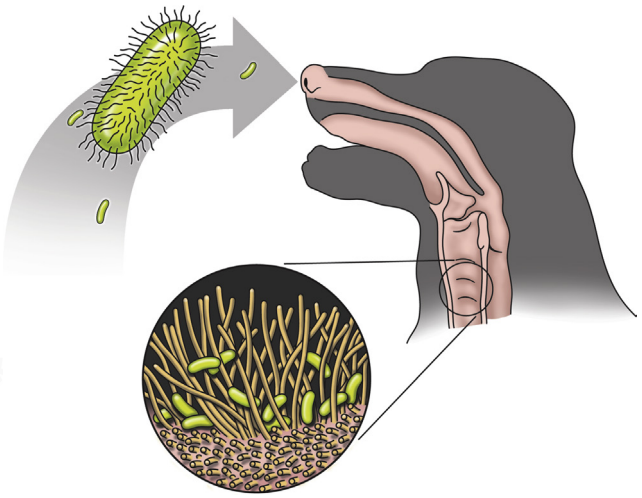

Fig. 55.1 *Bordetella bronchiseptica* infection. *Bordetella bronchiseptica* is inhaled, adheres to respiratory cilia by means of fimbrial adhesins, evades the immune system, and secretes a variety of toxins that damage the respiratory epithelium.

Evasion of host defenses is mediated by the organism's outer capsular (O) antigens, adenylate cyclase toxin, type III secretion systems, and pertactin. The capsule and O antigen protect it from phagocytosis and destruction by complement. Adenylate cyclase toxin catalyzes the conversion of ATP to cAMP, which inhibits the migration and activation of phagocytes and T cells. Pertactin allows the organism to resist neutrophil-mediated clearance.[36] A type III secretion system was recently described with an *in vitro* model showing that it may prevent phagocytosis by macrophage and induces cellular necrosis.[37] A type VI secretion system also appears to play a key role in persistence of *B. bronchiseptica*.[38] Other virulence determinants present in the outer membrane include LPS and the Brk protein (*B*ordetella *r*esistance to *k*illing), which allow the organism to resist complement-mediated destruction. At least two other important exotoxins damage respiratory epithelial cells and cells of the immune system, and incite cytokine production: tracheal cytotoxin (TCT) and dermonecrotic toxin (DNT). TLR4 has been shown to play an important role in the innate immune response against *B. bronchiseptica*.[39] The flagellin of *B. bronchiseptica* has been shown to be a potent proinflammatory factor, and can signal through TLR5.[40]

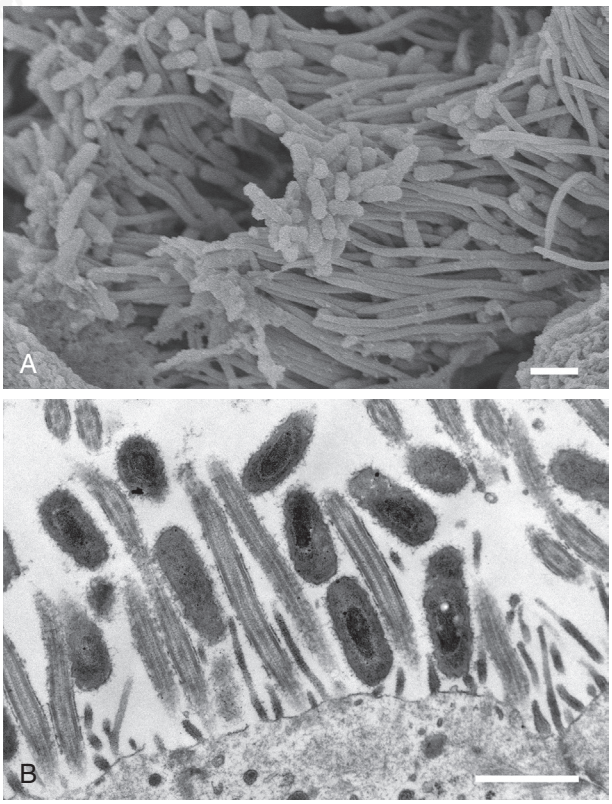

Fig. 55.2 (A) Scanning and (B) transmission electron microscopic images of *Bordetella bronchiseptica* in puppies that died from bronchopneumonia. Numerous piliated bacteria are seen adherent to cilia. (From Chambers JK, Matsumoto I, Shibahara T, et al. *J Comp Pathol.* 2019;167:41–45.)

The inflammation and altered cell function that occur as a result of *B. bronchiseptica* infection lead to increased fluid and mucus secretion, and impairment in host innate immune defenses predisposes to opportunistic viral and bacterial infections. Clinical signs vary in severity and may reflect factors such as the bacterial strain involved, host immunity, and the presence of co-infections. The incubation period ranges from 2 to 10 days. Rhinitis and tracheobronchitis may be associated with serous to mucopurulent nasal discharge, sneezing, stertor, and, especially in dogs, a persistent, often paroxysmal harsh cough. In some dogs, development of bronchopneumonia leads to fever, productive cough, lethargy, and decreased appetite. Bronchopneumonia may be due to *B. bronchiseptica* itself or it may result from co-infection with other respiratory pathogens, such as CDV. An outbreak of fatal *B. bronchiseptica* bronchopneumonia was described in 22 newborn puppies at a breeding facility in Japan; tests for other respiratory pathogens were negative.[41] In cats, infection is significantly associated with sneezing, and cough is uncommon.[19] Cats with pneumonia may develop tachypnea, cyanosis, and death.

Shedding of *B. bronchiseptica* by both dogs and cats can continue intermittently for at least a month and sometimes several months after infection. Evasion of the immune system through survival inside phagocytes may explain the persistent infection that occurs. In contrast, *B. pertussis* is rapidly destroyed by macrophages.[42]

Physical Examination Findings

On physical examination, dogs with uncomplicated bordetellosis are bright, alert, and active with a paroxysmal cough that can occur throughout the examination. The cough is often easily elicited on tracheal or laryngeal palpation. Conjunctivitis and serous to mucopurulent ocular and nasal discharge may be present in affected dogs and cats (Fig. 55.3). Dogs and cats with complicated *Bordetella* bronchopneumonia may be pyrexic, lethargic, and tachypneic with increased respiratory effort.

Fig. 55.3 Kitten with *Bordetella bronchiseptica* conjunctivitis and bronchopneumonia. The kitten was tachypneic and had mucopurulent ocular discharge.

There may also be increased lung sounds and/or referred upper airway noises on thoracic auscultation, and mucopurulent nasal discharge.

DIAGNOSIS

Laboratory Abnormalities

There are no specific laboratory abnormalities in uncomplicated bordetellosis. Usually the CBC is normal. Dogs with bronchopneumonia can also have a normal CBC,[26] or a mild to moderate neutrophilia, bandemia, and toxic neutrophils may be present. Cytologic examination of transtracheal lavage (TTL) or bronchoalveolar lavage (BAL) specimens may reveal a suppurative or mixed exudate, and sometimes intracellular and extracellular coccobacilli are visible (Fig. 55.4).

Diagnostic Imaging

Plain Radiography

Plain thoracic radiographs in dogs with uncomplicated bordetellosis may be unremarkable or show a mild diffuse interstitial or bronchointerstitial pattern. *Bordetella* bronchopneumonia may be characterized by development of peribronchial and alveolar infiltrates and lobar consolidation.

Microbiologic Tests

The main assays used for diagnosis of bordetellosis in dogs and cats are aerobic bacterial culture and PCR assays, which can be performed on nasal or oropharyngeal swabs, TTL or BAL specimens, or respiratory tract tissue collected at necropsy (Table 55.2). In some studies, *B. bronchiseptica* has been detected in nasal but not oropharyngeal swabs, but in other studies, the use of oropharyngeal swabs was more sensitive. Collection of swab specimens from the nasal cavity or posterior nasopharynx is preferred for diagnosis of pertussis in humans because these regions have ciliated epithelial cells, for which *B. pertussis* has affinity.[43] False-negative results occur when organism numbers in secretions are low, and depending on the sensitivity of the PCR assay used and the viability of the bacteria in the specimen, culture may be positive when PCR is negative and vice versa. Although the detection of *B. bronchiseptica* in TTL or BAL specimens is diagnostic for bordetellosis, it may be more difficult to interpret the significance of a positive culture or PCR assay result from nasal or oropharyngeal swabs, especially among group-housed dogs and cats when the background prevalence of infection is high. Co-infections with viral

respiratory pathogens should always be considered when *B. bronchiseptica* is detected, as well as the presence of other comorbidities that suppress the innate or adaptive immune system that could predispose to bordetellosis (e.g., ciliary dyskinesia or brachycephalic obstructive syndrome in dogs, retroviral infections in cats).

Cytology

In 20 of 24 dogs that were diagnosed with bordetellosis in one study, organisms adherent to respiratory epithelial cilia were noted on cytologic examination of bronchoalveolar lavage fluid (BALF) or bronchial brush fluid (BBF).[44] The identification of bacteria on cytologic examination aided rapid diagnosis and was more sensitive than bacterial culture of BALF. Nevertheless, definitive identification of the bacteria using PCR or culture is still recommended to rule out the presence of other coccobacilli.

Bacterial Culture

Bordetella bronchiseptica can usually be isolated on routine aerobic bacterial culture media, such as MacConkey agar and blood agar.

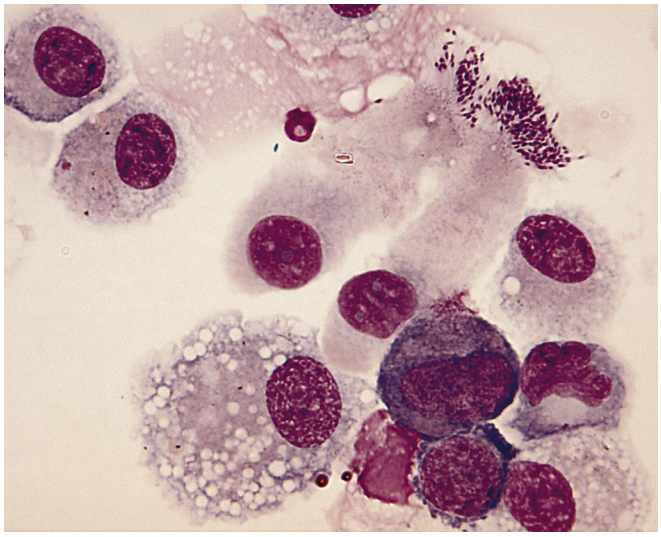

Fig. 55.4 Bronchoalveolar lavage cytology from a dog infected with *Bordetella bronchiseptica*. Numerous coccobacilli are adhered to the cilia of columnar epithelial cells. Wright stain, 1000× oil magnification. (Courtesy of Michael Scott, Michigan State University. In: Raskin RE, Meyer D, eds. *Canine and Feline Cytology: A Color Atlas and Interpretative Guide*. 2nd ed. St. Louis, MO: Saunders; 2010.)

Charcoal-based medium that is supplemented with cephalexin is preferred for isolation of *B. pertussis*, which is more fastidious. For *B. bronchiseptica*, use of methicillin or oxacillin in selective media can prevent overgrowth by contaminating microflora.[5] The laboratory should be informed when bordetellosis is on the differential diagnosis list. In one study, *B. bronchiseptica* was isolated from cats using nasal swabs but not oropharyngeal swabs.[21] The use of Dacron, rayon, or calcium alginate swabs is preferred for culture of *B. pertussis*, because growth is inhibited when cotton swabs are used.[43] Unlike PCR assays, successful detection of *B. bronchiseptica* using culture allows susceptibility testing, which assists in rational antimicrobial drug selection. It is also important to keep in mind that *B. bronchiseptica* can be detected in healthy animals, so its identification in specimens from a single animal does not imply disease causation.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Sensitive and specific real-time PCR assays that detect *B. bronchiseptica* DNA have been described,[18,45] and assays are available through several commercial veterinary diagnostic laboratories. Some laboratories offer panels that also detect other respiratory pathogens, which can be useful for detection of co-infections. In cats, PCR was able to detect *B. bronchiseptica* DNA from conjunctival, nasal, and oropharyngeal swabs using a real-time PCR assay.[17]

As with culture, negative results can occur when organism numbers are low in the specimen, or when there has been recent antimicrobial drug use; however, PCR assays may be more likely to be positive than culture in these situations. Positive PCR assay results can occur for at least 4 weeks after intranasal vaccination.[46,47] A conventional PCR assay that differentiates between field strains and one vaccine strain of *B. bronchiseptica* has been described,[46] but commercially available real-time assays that distinguish between field and vaccine strains are needed. As for culture, the detection of *B. bronchiseptica* using PCR, especially in an individual animal, does not imply disease causation because the organism can be found in healthy animals.

Serologic Diagnosis

Antibodies to *B. bronchiseptica* can be detected using bacterial agglutination or recombinant or whole-cell ELISA assays, but serology is of limited use for diagnosis because of the high prevalence of antibodies in the dog and cat population and the influence of vaccination, which is routinely performed on entry to most shelters. Serology has primarily been used to study the epidemiology of infection and to examine immune responses as they relate to vaccination.

TABLE 55.2 Diagnostic Assays Available for Bordetellosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Aerobic bacterial culture	Nasal and oropharyngeal swabs, transtracheal and bronchoalveolar lavage specimens, airway and lung specimens collected at necropsy	*B. bronchiseptica*	False negatives can occur when specimens contain no or low numbers of organisms, or after antimicrobial treatment. Allows subsequent susceptibility testing. The clinical significance of positive culture results from nasal and oropharyngeal swab specimens may be difficult to interpret.
PCR assays	See Aerobic bacterial culture	*B. bronchiseptica* DNA	Sensitivity and specificity can vary depending on assay design. False negatives can occur when specimens contain no or low numbers of organisms, or after antimicrobial treatment. Testing specimens from multiple different anatomic sites or combining PCR assays with other diagnostic tests can increase sensitivity. Avirulent live vaccine organisms may be detected for several weeks after intranasal vaccination. Because of subclinical shedding, the clinical significance of a positive result may be difficult to interpret.
Serology	Serum	Antibodies against *Bordetella* antigens	Interpretation complicated by previous vaccination and widespread exposure.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with uncomplicated bordetellosis are usually minimal. There may be an accumulation of mucopurulent exudate in the airways. In more severely affected patients with *B. bronchiseptica* bronchopneumonia, lesions have been noted most commonly in the cranial and middle lung lobes, but consolidation may be diffuse (Fig. 55.5A). Fibrinous pleural fluid has also been reported in severely affected cats.[48]

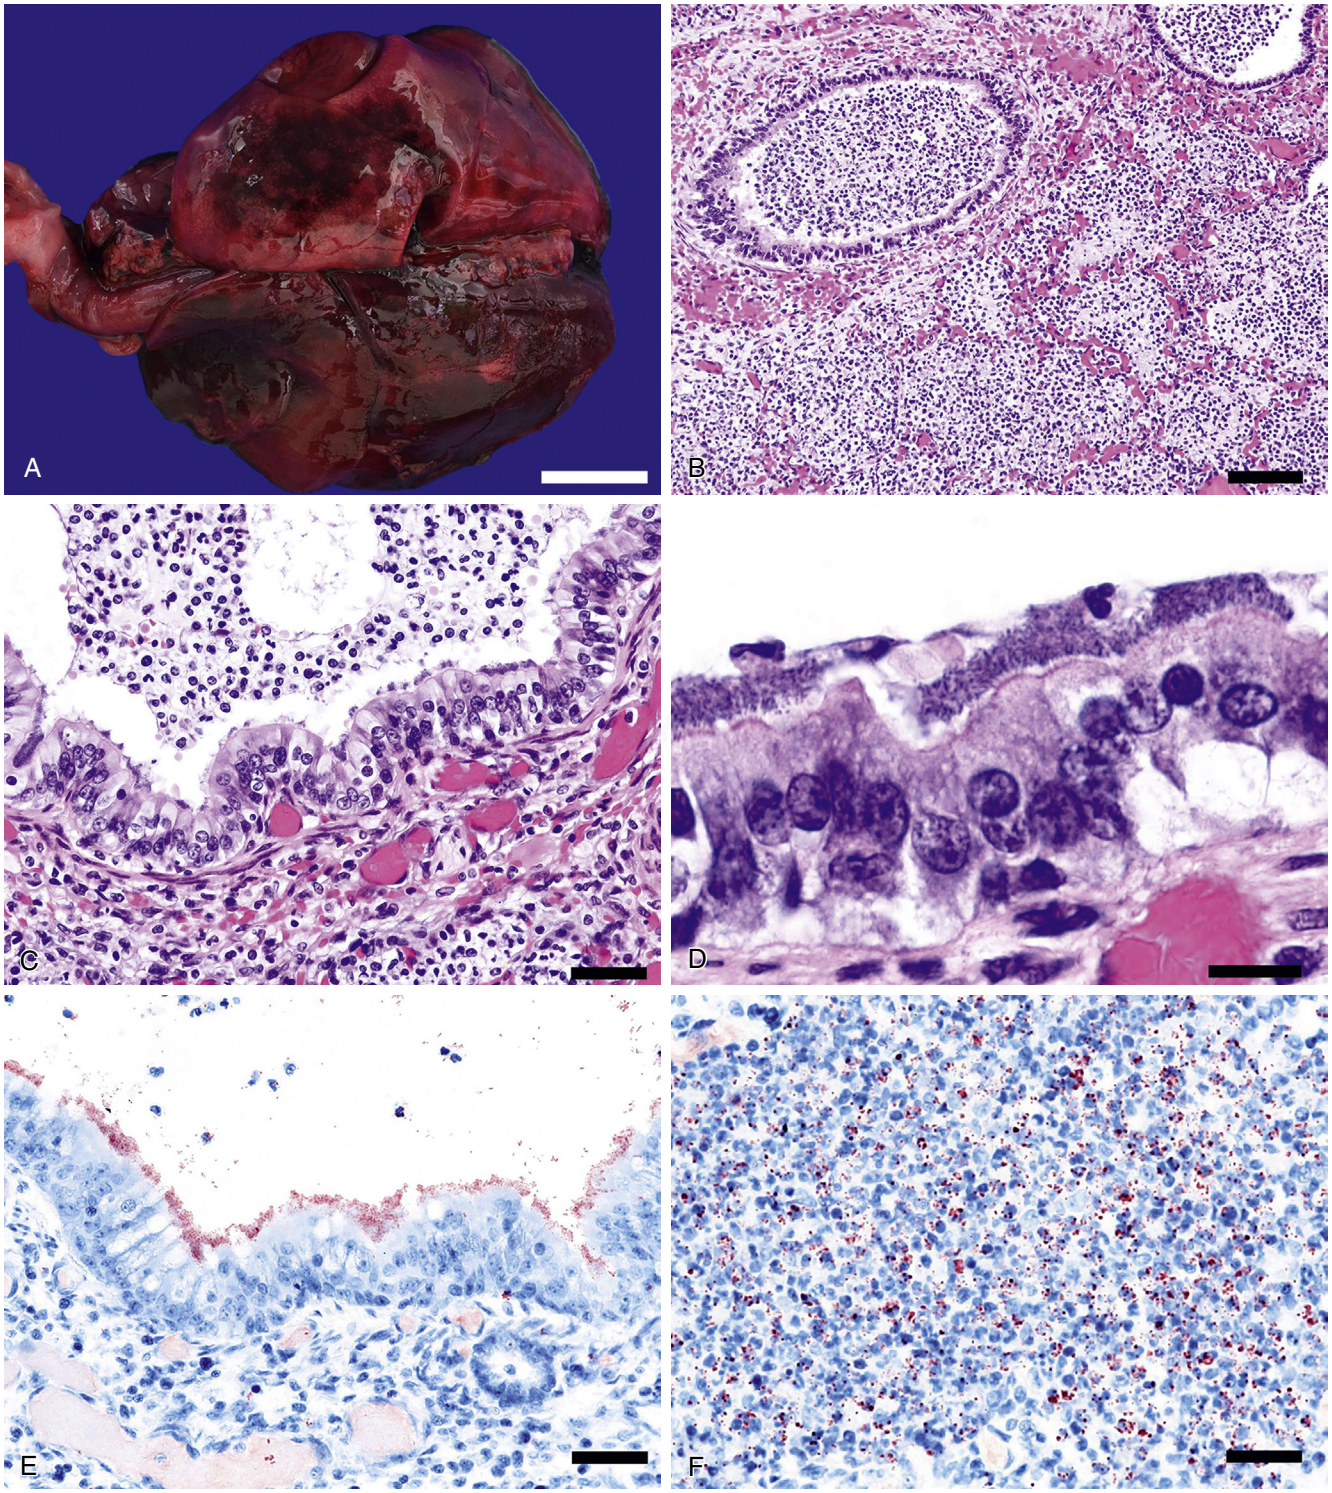

Fig. 55.5 Pathologic findings of *Bordetella bronchiseptica* bronchopneumonia. (A) Diffuse lung congestion. Bar, 1 cm. (B) Severe neutrophilic bronchitis. Bar, 200 μm. (C and D) Basophilic bacteria on the surface of bronchial epithelial cells. Bar, 50 μm (C) 20 μm (D). (E and F) Immunohistochemical staining for *B. bronchiseptica* antigen. Bacteria on the surface of bronchial epithelium, the cytoplasm of inflammatory cells in the bronchus, and bacteria in alveoli stain brown. Bar, 50 μm. (From Chambers JK, Matsumoto I, Shibahara T, et al. An outbreak of fatal *Bordetella bronchiseptica* bronchopneumonia in puppies. *J Comp Pathol.* 2019;167:41–45.)

Histopathologic Findings

Microscopic findings in dogs or cats with bordetellosis consist of a suppurative inflammatory response that is usually confined to the ciliated portions of the respiratory tract (Fig. 55.5B). Cilia are mostly intact, but regional bronchial epithelial necrosis may be present. Mild lymphoid hyperplasia may be present. Depending on the stage and severity of infection, aggregates of bacteria may be observed in association with the cilia (Fig. 55.5C and D).[48,49] IHC can be used to identify bacteria as *B. bronchiseptica* (Fig. 55.5E and F).

TREATMENT AND PROGNOSIS

Antimicrobial Treatment

Bordetella bronchiseptica isolates from dogs and cats have the propensity to exhibit multidrug resistance (i.e., resistance to three or more antimicrobial drug classes). Resistance to amoxicillin and trimethoprim-sulfamethoxazole is common. Widespread resistance to third-generation cephalosporins (cefovecin) has also been documented.[13] Many infections are mild or self-limiting, and so antimicrobial drug treatment should be reserved for animals with confirmed *B. bronchiseptica* infection that have persistent clinical signs (>7 to 10 days) or those with more severe clinical signs and radiographic abnormalities that suggest bronchopneumonia. Young kittens and puppies (<6 to 8 weeks of age) are candidates for early initiation of treatment because disease in neonates may progress rapidly to pneumonia and death. Treatment should be based, whenever possible, on the results of culture and susceptibility testing. When susceptibility results are not available, or when they are pending and bordetellosis is strongly suspected, the initial drug of choice is doxycycline. There is poor susceptibility of *B. bronchiseptica* to penicillins and first-generation cephalosporins, and beta-lactamase production is commonly present.[50,51] At the time of writing, doxycycline resistance is uncommon among isolates from dogs and cats,[52–55] and doxycycline effectively penetrates the lung tissue. Unfortunately, doxycycline is not the best choice for other secondary bacterial pneumonias because it is bacteriostatic, and parenteral doxycycline can be expensive and difficult to administer. This reinforces the need for culture whenever feasible in animals with evidence of pneumonia. Bacterial shedding may continue despite resolution of clinical signs, so affected dogs and cats should remain in isolation from other animals whenever possible for at least 2 months after treatment.

Rarely, treatment with systemic antimicrobial drugs fails to resolve clinical signs of bordetellosis, and the organism persists despite documented susceptibility to the antimicrobial drug selected. In this situation, the use of nebulized aminoglycosides has been suggested. In one retrospective study of 46 dogs with persistent bordetellosis that compared two different protocols for administration of nebulized gentamicin, administration of undiluted 5% gentamicin for 10 minutes q12h for several weeks (median, 4 weeks) appeared to be most efficacious.[56] A pediatric nebulizer was used to deliver the medication either via a face mask (dogs > 10 kg) or use of a cat carrier (dogs < 10 kg) covered with a blanket. The dogs in this study had disease that was refractory to oral antimicrobials, with a median duration of cough before aminoglycoside treatment of 2 months (range, 4 days to 2 years). For 36 dogs in the study, cough had been present since adoption from shelters, pet stores, or kennels. Limitations to this study were the use of historical controls and treatments with a variety of other medications based on clinician preference; because no saline control population was studied, it is possible that some dogs in the study recovered independent of the use of aminoglycosides. No adverse effects of nebulization were noted. However, because nebulization of aminoglycosides has the potential to cause airway irritation and select for resistant bacterial populations, its use should probably be restricted for dogs with refractory bronchopneumonia, or severe and persistent tracheobronchitis (e.g., >4 weeks in duration).

Supportive Care and Prognosis

The prognosis for dogs with uncomplicated bordetellosis is excellent. Cats and dogs with bronchopneumonia usually require other supportive treatments, such as IV fluid therapy, appropriate nutritional support, supplemental oxygen, and nebulization. In one study, bronchopneumonia associated with *B. bronchiseptica* infection was more severe than that associated with other bacterial agents, and affected dogs also had higher $PvCO_2$ values, were more likely to require supplemental oxygen, and had longer mean hospitalization times (7.2 days compared with 4.9 days).[26] In the study of dogs treated with nebulized gentamicin, dogs with a total cell count of less than 1000 cells/μL in BALF were more likely to be cured in 3–4 weeks than dogs with more than 1000 cells/μL.[56] The presence of other co-morbidities may also influence outcome.

IMMUNITY AND VACCINATION

Antibodies to outer surface molecules of *B. bronchiseptica,* especially IgA in mucosal secretions, are important for bacterial clearance. Several avirulent live, mucosal (intranasal or oral) *B. bronchiseptica* vaccines are available for dogs, some of which also contain CPIV with or without CAdV-2. These vaccines are designed to stimulate mucosal immunity and provide protection within 3 days after a single dose of vaccine.[57] Protection with intranasal vaccines also occurs in the face of maternal antibody and can last at least 1 year.[58,59] Inactivated parenteral *B. bronchiseptica* vaccines are also available for dogs, but two doses administered 3 to 4 weeks apart are required to optimize immunity, which occurs 1 week after the second dose. The rapid onset of protection that follows the use of intranasal vaccines makes them the vaccine type of choice for puppies and animals introduced into heavily contaminated environments, such as shelters, when immunization in advance of entry is usually not possible. Mucosal vaccines should not be given to animals treated with antimicrobial drugs (because they inactivate bacteria in the vaccine), and administration of intranasal vaccines to aggressive animals without sedation may not be feasible. Transient signs of mild to moderate respiratory disease occur in a small percentage of vaccinated dogs and cats several days after mucosal vaccination. In shelters, it may not be possible to differentiate between postvaccinal disease and infectious respiratory disease due to field pathogens, which complicates decisions that relate to isolation practices.

Administration of both intranasal and parenteral *B. bronchiseptica* vaccines is followed by the development of both serum IgG and nasal IgA responses, whereas serum IgA responses appear to be higher after intranasal vaccination.[60] Parenteral whole-cell vaccines, and more recently acellular vaccines that include virulence factors such as pertactin, FIM, FHA, and pertussis toxin, are widely used to prevent pertussis in humans.[26] Few scientific data are available on the efficacy of parenteral *B. bronchiseptica* vaccines in dogs when compared with intranasal vaccines. A 2007 study showed that an intranasal vaccine was more effective than a parenteral antigen extract vaccine.[61] In that study, cough scores of subcutaneously vaccinated dogs were not significantly different from placebo-vaccinated dogs. However, parenteral administration of a novel bacterial ghost vaccine, which is composed of the empty cell envelope of gram-negative bacteria, was shown to provide equivalent protection to a commercial parenteral antigen extract *B. bronchiseptica* vaccine (Bronchicine CAe, Zoetis). Use of both vaccines led to significant reduction in cough duration and score when compared with placebo-vaccinated control dogs ($P = .0001$).[62] Two doses of vaccine were given 3 weeks apart, and dogs were challenged 3 weeks later.

In addition, a limited number of studies have been performed that compare protection with oral versus intranasal vaccines. In a 2016 study, it was shown that research dogs vaccinated with an intranasal vaccine showed fewer clinical signs than those vaccinated with an oral vaccine,[63] whereas a more recent study that compared protection following challenge at 7 days after vaccination with an oral and an intranasal vaccine showed that both groups of dogs were equally protected from cough.[64]

Inadvertent parenteral administration of intranasal vaccines has the potential to lead to injection site reactions, hepatic necrosis, and even death in some dogs.[65] Subcutaneous fluids should be administered at the site of vaccination, and immediate treatment with antimicrobial drugs is indicated. It has been suggested that gentamicin sulfate solution be instilled into the affected area (2 to 4 mg/kg gentamicin sulfate in 10 to 30 mL of saline), and dogs should then be treated with oral doxycycline for 5 to 7 days.[66] Special packaging has been developed by some vaccine manufacturers in an attempt to prevent inadvertent parenteral administration of the intranasal vaccine.

Concerns have been raised that intranasal *B. bronchiseptica* vaccines may cause respiratory disease in immunosuppressed humans who inhale the vaccine during administration or who contact vaccine organisms shed by recently immunized dogs or cats.[67–69] However, as yet, there has been no molecular proof that the *B. bronchiseptica* strains isolated from affected human patients match vaccine strains. In fact, in one report of *B. bronchiseptica* pneumonia in an infant that was temporally related to intranasal vaccination of a pet dog, genetic analysis (ribotyping) showed that the vaccine was not the source of the infant's exposure.[70] The organism matched to another *B. bronchiseptica* strain that had previously been isolated from a human patient.

In some countries, intranasal *B. bronchiseptica* vaccines are available for cats, which can reduce signs of disease after challenge as long as 1 year after vaccination.[71] Because disease is rarely severe in cats more than 6 weeks of age, vaccination of cats has not been recommended on a routine basis,[71] but could be considered as an adjunct to management strategies such as reduction of overcrowding and proper disinfection if outbreaks of bordetellosis are a problem in group-housed cats. There is some evidence that vaccination of a FHV and FCV intranasal vaccine can convey some protection against a *B. bronchiseptica* infection.[72] Vaccination of immunocompromised cats is not recommended.[73]

PREVENTION

In the absence of management strategies to reduce stress, overcrowding, and comorbidities, vaccination is unlikely to completely prevent bordetellosis. The reader is referred to the sections on prevention in Chapters 16 (cats) and 17 (dogs) for additional information on prevention and management of outbreaks of respiratory infections in group-housed animals.

PUBLIC HEALTH ASPECTS

Bordetella bronchiseptica is an uncommon cause of respiratory disease in humans, but has been isolated from humans without clinical signs and humans with mild to severe respiratory disease, including pneumonia.[74–76] Most, but not all, affected humans have underlying immunosuppressive conditions that predispose them to infection. *Bordetella bronchiseptica* peritonitis has been reported in human patients receiving continuous peritoneal dialysis.[77,78] Bacteremia and meningitis have also been reported.[79,80] Bacteremia was described in an apparently immunocompetent patient from Greece with COVID-19.[81] Recent exposure to cats and to dogs with signs of "kennel cough" has been noted in most but not all human cases,[75,82] and airborne transmission between humans can occur in hospital settings.[83] At least in mouse models, human acellular pertussis vaccines appear to cross-protect against *B. bronchiseptica*.[84] Infections with *B. bronchiseptica* may be under recognized in people, because the direct fluorescent antibody test used for diagnosis of pertussis may not distinguish between *B. pertussis* and *B. bronchiseptica*. Clinically, recognition of *B. bronchiseptica* infections in humans is important, because *B. bronchiseptica* is resistant to macrolides, which are first-line agents for pertussis.[70] Until more is understood about the risks of canine mucosal *B. bronchiseptica* vaccines for immunocompromised humans, parenteral vaccination of at-risk dogs owned by seriously immunocompromised humans is probably warranted, and the owners of these dogs should be instructed to avoid or minimize situations in which their dogs could come into contact with large numbers of other dogs.

CASE EXAMPLE

Signalment

A 7-week-old intact female Persian kitten from California.

History

A research colony kitten was examined for a 3-day history of respiratory signs. Three days previously, sneezing was observed in this kitten and one of its littermates. A day later, the kitten developed lethargy, inappetence, and respiratory distress, and the littermate was found dead. The kitten had been treated with lactated Ringer's solution (LRS; 6 mL, SC, q24h) and azithromycin suspension (0.7 mg/kg, PO, q24h) since it became unwell. Two other kittens in the litter remained unaffected, and one had mild nasal discharge. All of the cats had tested negative for FeLV antigen and FIV antibody using a commercially available in-house ELISA kit.

Physical Examination

Body weight: 0.37 kg.

General: Alert, open-mouth breathing. T = 97.5°F (36.4°C), HR = 220 beats/minute, RR = 40 breaths/minute, mucous membranes pale pink.

Eyes, ears, nose, and throat: No abnormalities were noted.

Musculoskeletal: BCS 4/9.

Respiratory: Markedly increased inspiratory and expiratory effort, tachypnea, and open-mouth breathing were noted. Increased lung sounds were detected on auscultation.

Cardiovascular, GI, and genitourinary systems, and lymph nodes: No clinically significant abnormalities were detected.

Imaging Findings

Thoracic radiographs: There was collapse of the left cranial lung lobe and partial volume loss in the left caudal lung lobe with evidence of mediastinal shift to the left, possibly secondary to a bronchial mucus plug. A focal increase in opacity was noted in the area of the right middle lung lobe with hyperinflation of the right cranial and caudal lung lobes. There were regions of gas trapping, and the bronchi were enlarged. Emphysema was suspected, possibly congenital. Consolidation in the area of the right middle lung lobe was compatible with pneumonia.

Outcome

The kitten was treated with oxygen supplementation, terbutaline (0.01 mg/kg, SC, q6h), ticarcillin-clavulanate (50 mg/kg, IV, q8h), LRS with 5% dextrose (1 mL/hour

Continued

CASE EXAMPLE—cont'd

IV), a single dose of dexamethasone (1 mg/kg IV), and a single dose of furosemide (2 mg/kg IV). Euthanasia was performed 24 hours later due to lack of improvement and the poor prognosis.

Necropsy Findings

An endotracheal wash was performed immediately after euthanasia. This revealed marked, septic, suppurative inflammation and mild to moderate epithelial hyperplasia. Bacteria were present in large numbers extracellularly, within degenerate neutrophils, and in large mats.

Gross necropsy findings consisted of diffuse lung lobe collapse with multiple firm dark red areas throughout the parenchyma. On histopathology, there was severe, multifocal to coalescing, acute necrosuppurative bronchopneumonia with abundant clusters of gram-negative bacteria. Examination of the upper respiratory tract showed mild, multifocal neutrophilic rhinitis and mild, multifocal, lymphocytic tracheitis. The other kitten was also necropsied, with similar findings.

Microbiologic Testing (Endotracheal Wash Specimen)

Culture for aerobic bacteria, *Mycoplasma* spp., and virus isolation revealed only moderate numbers of *B. bronchiseptica.*

Diagnosis

Bordetella bronchiseptica bronchopneumonia.

Comments

This outbreak of severe bordetellosis in a research cat colony resulted in the death of several kittens, which deteriorated rapidly even in the face of supportive care. Co-infections were not detected, although PCR testing was not performed and the negative *Mycoplasma* culture and virus isolation results did not rule out the possibility of co-infection. Although susceptibility testing was not performed, resistance to the antimicrobials that were used can occur in *B. bronchiseptica.* Furthermore, the dose of azithromycin used as reported in the medical record was subtherapeutic.

LRS: Lactated Ringer's Solution

L-Form Infections

Victoria J. Chalker

KEY POINTS

- First Described: In 1935, London (Klieneberger).[1]
- Causes: Cell wall-deficient variants of a variety of gram-positive and gram-negative bacteria.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Chronic draining or ulcerated soft tissue and skin lesions, polyarthritis, possibly other chronic pyogenic and pyogranulomatous lesions.
- Differential Diagnoses: Infections due to other fastidious bacteria such as *Mycoplasma*, *Nocardia*, *Mycobacterium*, *Bartonella*, and *Brucella* spp., nutritionally variant streptococci such as *Granulicatella*, *Borrelia burgdorferi* (in the case of polyarthritis); fungal infections (e.g., due to *Sporothrix* or *Coccidioides* spp.); persistence of a foreign body; neoplasia; congenital immunodeficiency; primary immune-mediated disease.
- Human Health Significance: Likely similar to that for the corresponding walled (or "normal") variant of the bacterial species involved.

ETIOLOGY AND EPIDEMIOLOGY

L-forms of bacteria, also known as cell wall-deficient bacteria, are morphologically similar to mycoplasmas. They are distinguishable from the latter by the variable size (1 to 4 μm diameter), their greater pleomorphism, and their penicillin-binding affinities. In addition, *Mycoplasma* spp. do not originate from bacteria that normally possess a cell wall. The term L-form was given to these bacteria because they were first discovered at the Lister Institute in London. Cell wall deficiencies can be induced *in vitro* or *in vivo* in many bacterial species (Box 56.1) through a variety of stressors, including exposure to chemicals that damage the cell wall, antimicrobials (e.g. beta-lactam drugs, and more rapidly with fosfomycin and D-cycloserine) or host immune responses.[2,3] The molecular events in the host that result in conversion to and from the L-form state are yet to be accurately defined. Proliferation of L-form bacteria occurs via an increased rate of membrane synthesis.[4] Lysozyme is found throughout the animal kingdom, produced by macrophages and can drive L-form formation, contributing to antibacterial intolerance (Fig. 56.1).[3] Once inside the host, L-forms can persist and remain viable, proliferating in the presence of antimicrobial drugs. On cessation of antimicrobial drug treatment they can revert to the walled state that can presumably cause further infection.[5–7]

CLINICAL FEATURES

In human patients, L-form bacteria have been implicated as causes of a variety of clinical syndromes that include culture-negative endocarditis, bacteremia, uveitis, pneumonia, osteomyelitis and arthritis, recurrent UTIs, soft tissue infections, and meningitis.[8–10] There are few reports of L-form infection in the literature in dogs and cats, and this area is understudied. The role of L-forms in chronic or recurrent infections is controversial. Demonstration of internalization, persistence, and potential for contribution to chronic infections has been demonstrated in infected rats.[11]

Cell wall-deficient bacteria have been isolated from cats with fever and persistently draining, spreading cellulitis and synovitis that often involve the extremities.[12,13] The usual source of infection has been contamination of penetrating bite wounds or surgical incisions. Infection begins at the point of inoculation and lesions spread, drain, dehisce, and do not heal. Bacteremia can occur and polyarthritis or distant abscess formation may develop as a sequela. Progressive polyarthritis that was unresponsive to antibacterials and glucocorticoids occurred in a dog infected with an L-form of *Nocardia*.[14] A *Pseudomonas aeruginosa* L-form was isolated from the blood of a dog after antibiotic treatment for *P. aeruginosa* endocarditis.[15]

DIAGNOSIS

Infection with L-forms should be considered a possibility in cats and dogs with culture-negative pyogranulomatous or suppurative inflammatory lesions, or when a bacterial etiology is suspected on the basis of clinical

Streptococcus spp.

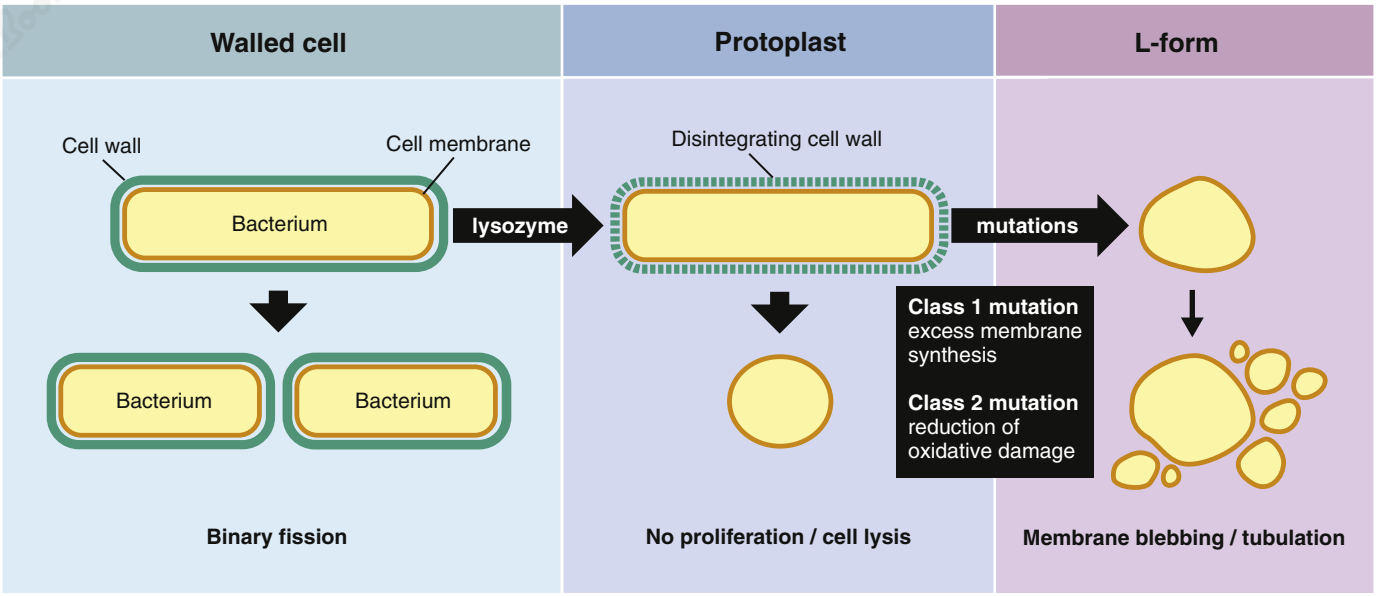

Fig. 56.1 Formation of L-form bacteria from walled bacterial cells. Walled cells of rod-shaped bacteria typically grow by elongation. Lysozyme removes the cell wall, with formation of protoplasts, but these are unable to grow due to oxidative damage. Subsequent mutations can allow the cell to grow as an L-form. (Adapted from Errington J, Mickiewicz K, Kawai Y, Wu LJ. L-form bacteria, chronic diseases and the origins of life. *Philos Trans R Soc B Biol Sci.* 2016;371:20150494.)

TABLE 56.1 Assays Available for Diagnosis of L-Form Bacterial Infections in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Biopsies, body fluids, wash specimens	L-form bacteria	Requires special L-form bacterial (hyperosmolar) media
Cytology or histopathology	Biopsies, smears of affected tissues	L-form bacteria	Organisms usually not visible owing to the lack of a cell wall, but may be Gram-variable. Low sensitivity and cannot be used to identify absence of a cell wall (although the presence of organisms that stain strongly with Gram stain indicates the presence of walled bacteria).
Electron microscopy	Biopsies	L-form bacteria	Confirms the presence of cell wall-deficient organisms in lesions. May not be possible to distinguish L-form bacteria from *Mycoplasma* spp. Often expensive and not readily available for routine diagnostic purposes.
Broad-range bacterial PCR and sequencing	Biopsies, body fluids, wash specimens	16S ribosomal subunit DNA of L-form bacteria	Confirms presence of bacteria in lesions when culture is negative. False positives may occur if contaminating bacteria are present. Does not distinguish between L-form bacteria and their walled counterparts. Sensitivity and specificity may vary between assays.

signs but routine cultures are negative. Physical examination and laboratory findings in cats and dogs infected with L-form bacteria may be similar to those in cats and dogs with other chronic, persistent bacterial infections.

Clinical laboratory abnormalities in cats with polyarthritis may include leukocytosis (over 25,000 cells/μL) with a mature neutrophilia and monocytosis, lymphocytosis, and eosinophilia.[12] Hyperfibrinogenemia and hyperglobulinemia may be found. Exudates contain predominantly macrophages and neutrophils with a few lymphocytes. Erythrophagia may be present; organisms cannot be detected by numerous cytologic stains. Radiographic abnormalities include periarticular soft tissue swelling and periosteal perforation.[12] In severe cases, damage occurs to the articular cartilage and subchondral bone.

Definitive diagnosis of L-form infection is difficult because the organisms are not visible using light microscopy and passage through special hypertonic laboratory media is required for growth of the organisms in culture. Traditional culture techniques may be negative. Infection has been transmitted experimentally by subcutaneous inoculation with cell-free material from tissues or exudates of infected cats. Other diagnostic tests are summarized in Table 56.1. Electron microscopic evaluation of tissues may show the characteristically pleomorphic, cell wall-deficient organisms in phagocytes (Fig. 56.2). The use of broad-range bacterial PCR assays that detect bacterial 16S ribosomal subunit DNA or metagenomics in tissues may be useful to detect L-form bacteria in tissues in the future when routine culture methods are negative, although this method does not distinguish between L-form bacteria and their walled counterparts. Infection with L-forms may also be suspected when lesions resolve in association with tetracycline antimicrobial drug treatment.

TREATMENT AND PROGNOSIS

Cell wall-deficient organisms found in cats have historically been most responsive to tetracyclines such as doxycycline; however, additional choices include macrolides, lincosamides, azalides, chloramphenicol, and fluoroquinolones. They are characteristically resistant to cell wall synthesis inhibitors such as the beta-lactam antibacterials or many other

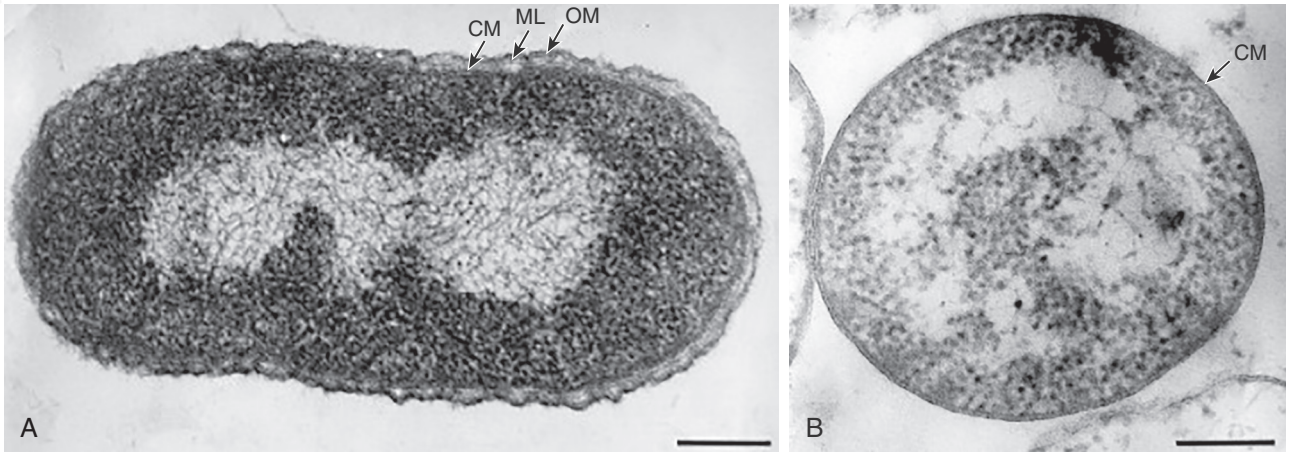

Fig. 56.2 Ultrathin sections of a cell of the N–form *Proteus mirabilis* VI (A) and its derived protoplast–type L–form *P. mirabilis* LVI (B). *CM*, cytoplasmic membrane; *ML*, peptidoglycan layer; *OM*, outer membrane. Bar: 0.2 μm. (From Allan, EJ, Hoischen, C, Gumpert, J. Bacterial L–Forms. *Advances in Applied Microbiology*. Volume 68, 2009; pp. 1–39. Copyright © 2009 Elsevier Inc. All rights reserved.)

broad-spectrum antimicrobials often chosen for persistent multifocal infections. Response to therapy should occur within 2 days, and therapy should continue for at least 1 week after discharges have stopped.[12,13]

PUBLIC HEALTH ASPECTS

The public health risk of L-form infections in dogs and cats is uncertain, because not all of the cell wall-deficient organisms have been adequately characterized. Instances of L-form infections in people are rare. A single report described isolation of an L-form of *Streptococcus sanguinis* from a vascular graft of a hemodialysis patient.[16] The L-form isolate was characterized as *S. sanguinis* of animal origin. The affected person's pet dog was reported to often lick the graft site, and *S. sanguinis* was also isolated from the dog's oral cavity. Although this was suggestive of zoonotic transmission, the identity of the isolates was not confirmed with molecular methods. L-form infections are not often considered or reported and the true extent of infections attributed to L-forms in humans and animals is not known.

Mycoplasma Infections

Victoria J. Chalker, Jane E. Sykes

KEY POINTS

- First Described: Dogs, 1934 (Shoetensack, 1934).[1] Reports of human *Mycoplasma* infections also occurred around this time.[2]
- Causes: *Mycoplasma cynos* and *Mycoplasma felis* have been most commonly associated with disease, but many other mycoplasma species infect dogs and cats.
- Geographic Distribution: Worldwide.
- Mode of Transmission: Direct contact (respiratory/sexual), fomite transmission in overcrowded environments. Opportunistic invasion of commensal mycoplasmas also occurs.
- Major Clinical Signs: Conjunctivitis, sneezing, and nasal discharge (cats); cough, tachypnea, fever, weight loss (lower respiratory disease); swollen, painful joints (polyarthritis); subcutaneous abscesses; neurologic signs (meningoencephalitis); prostatitis, epididymitis-orchitis, or lower urinary tract signs (dogs).
- Differential diagnoses: Other gram-positive and gram-negative bacterial infections. Differential diagnoses for mycoplasma respiratory disease include viral infections, fungal and parasitic causes of pneumonia, aspiration pneumonia, and neoplasia.
- Human health significance: Canine and feline mycoplasma species have rarely been detected in immunocompromised humans with mycoplasmosis who have had contact with pet cats and dogs.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Mycoplasmas are fastidious bacteria that lack a cell wall. They belong to the class Mollicutes (which translates to "soft skin") and are the smallest known free-living organisms. Many require sterols for growth, and *Ureaplasma* species require urea for fermentation. They measure only 0.3 to 0.8 μm in size. More than 120 different species of *Mycoplasma* and 7 species of *Ureaplasma* have been identified. The range of mycoplasma species that infect dogs and cats is incompletely understood because precise species identification has been difficult (Box 57.1).[3–8] Additional mycoplasma species are likely to be discovered with the application of molecular methods in the future. Some *Mycoplasma* spp. infect multiple host species. Mycoplasmas are often difficult to grow on cell-free media, and some, such as the hemotropic mycoplasmas, have never been successfully cultured in the laboratory (see Chapter 58). The remainder of this chapter will refer only to the non-hemotropic mycoplasma species.

Mycoplasmas are commensal bacteria that are found widely in association with mucous membranes of all mammalian species. Simultaneous colonization with more than one *Mycoplasma* species is common. Mycoplasmas have also been associated with keratoconjunctivitis and/or URTD in cats; reproductive disease and UTIs in dogs; and lower respiratory tract disease, skin and soft tissue infections, meningoencephalitis, and arthritis in both cats and dogs (Box 57.2).[9–20] Because mycoplasmas are commonly isolated from the upper respiratory and genital tracts of healthy dogs and cats, their role in ocular, URTD, and urogenital tract disease has been difficult to determine. Several studies have now found an increased prevalence of mycoplasmas in cats with conjunctivitis or URTD when compared with healthy cats.[15,21,22] Mycoplasmas may act as secondary invaders when other pathogenic viruses and bacteria are present, or normal host defenses are impaired by other factors, such as underlying neoplasia or immunosuppressive drug therapy. When mycoplasmas are associated with systemic disease or pneumonia, young animals (less than 1 year of age) are often involved. Some mycoplasma species appear to be more pathogenic than others. For example, evidence has accumulated that *Mycoplasma cynos* is associated with lower respiratory tract disease in dogs, whereas *Mycoplasma canis* and *Mycoplasma edwardii* are not.[9,23,24] In one study, *M. cynos* infection was associated with increased severity of canine infectious respiratory disease (CIRD), younger age, and longer time spent in a kennel.[24] Experimental infection with *M. cynos* leads to respiratory disease in dogs, but infection with *Mycoplasma gateae, M. canis,* and *Mycoplasma spumans* does not.[25] CIRD clinical score with *M. canis* infection is significantly lower in dogs than that for *M. cynos* infection.[26] Cases with co-infection are more likely to develop severe clinical signs, and *M. cynos*, canine parainfluenza virus (CPIV), *M. canis*, and *Bordetella bronchiseptica* are the most common pathogens seen, with *M. cynos* and CPIV being the most frequent pathogen combination, with stronger association than with *B. bronchiseptica*.[26] The same authors found young age to be the most significant predictor of severity.[26] The role of mycoplasmas in feline lower urinary tract disease and lymphoplasmacytic pododermatitis has also been investigated using molecular techniques, but no association was found.[27,28]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In order to colonize mammalian hosts, mycoplasmas must adhere to host cells. *M. cynos* possesses an adhesin, HapA, that confers cytadherance.[29] Neuraminidases are present in dog and cat mycoplasmas, which may play a role in pathogenesis.[30] A number of pathogenic mycoplasma species of humans can invade cells, which may contribute to organism persistence and difficulties associated with isolation in the laboratory. Transmission of pathogenic mycoplasmas such as *M. cynos* may occur in overcrowded environments as a result of close contact or fomite spread. The finding of identical strains in multiple dogs from a kennel environment (by use of molecular typing methods) supports the concept of transmission between dogs in this environment.[31] The extent to which mycoplasmas can survive in the environment varies between mycoplasma species and has not been determined for mycoplasmas that infect dogs and cats.

BOX 57.2 Diseases Associated with Mycoplasma Infections in Dogs and Cats

Disease	Species affected
Conjunctivitis	Cats
Upper respiratory tract disease	Cats
Pyothorax	Cats
Bronchopneumonia	Dogs, cats
Skin and soft tissue infections (abscesses)	Dogs, cats
Meningoencephalitis	Dogs, cats
Polyarthritis	Dogs, cats
Urinary tract infections	Dogs
Prostatitis	Dogs
Epididymitis and orchitis	Dogs

Conjunctivitis and Upper Respiratory Tract Disease

Mycoplasma spp. are commonly detected in cats in association with conjunctivitis and URTD. Concurrent infections with other upper respiratory pathogens (such as *B. bronchiseptica, Chlamydia felis*, and feline respiratory viruses) may contribute to clinical signs. Stressors such as overcrowding and unhygienic conditions may also promote proliferation of mycoplasmas and their transmission among cats. Ulcerative keratitis has been reported in association with mycoplasma infection, although the presence of corneal involvement may reflect the concurrent presence of FHV-1 or other factors that predispose to secondary invasion by *Mycoplasma* spp. (Fig. 57.1).

Pneumonia and Pyothorax

Virtually all dogs and cats can harbor mycoplasmas in their upper respiratory tract. Fewer than 25% of healthy dogs harbor mycoplasmas in their trachea or lungs. In one study, mycoplasmas were detected in tracheobronchial lavage specimens from 21% of 28 cats with pulmonary disease, but not from 18 healthy cats.[32,33] Mycoplasmas may be isolated from the lower airways and lungs of dogs and cats with pneumonia, sometimes in pure culture.[34] Factors that predispose to the development of pneumonia are not always apparent.[35] Clinical signs of pneumonia are not specific for mycoplasma infection and include variable fever, cough, tachypnea, lethargy, and decreased appetite. Concurrent signs of URTD have been reported in some affected cats.[35] Rarely, mycoplasmas have been cultured from the pleural fluid of cats and dogs with pyothorax, both in pure culture as well as in mixed infections with other organisms.[36–38]

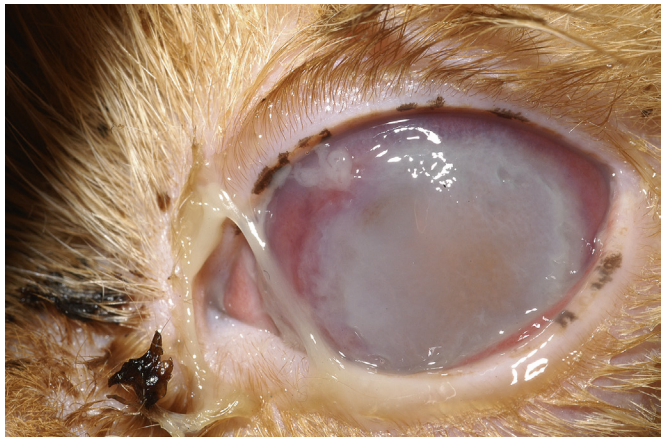

Fig. 57.1 Ulcerative keratitis in a 4-year-old female spayed Persian. Involvement of feline herpesvirus-1 was suspected, and *Mycoplasma* spp. was isolated from a corneal swab. The significance of the mycoplasma infection was unclear, but the ulcer healed after topical treatment with topical ofloxacin and azithromycin drops. (Image courtesy of the University of California, Davis Veterinary Ophthalmology service.)

Urogenital Tract

Mycoplasma and *Ureaplasma* spp. have been found in the semen and urine of dogs with infertility and purulent epididymitis.[39] The role of mycoplasmas in reproductive tract disease in dogs and cats is unclear because of their frequent isolation from the urogenital tract of healthy dogs and cats. Large numbers of mycoplasmas ($>10^5$ CFU/mL) can occasionally be isolated in pure culture from urine collected by cystocentesis from dogs with prostatitis and LUTS.[16,39] Dogs with mycoplasma UTIs often have other comorbidities that impair normal urinary defenses, such as urinary tract neoplasia, calculi, or neurologic disease.[16]

Arthritis and Bacteremia

Isolated case reports of polyarthritis exist as a result of *M. spumans* and *M. edwardii* infections in dogs, and *M. gateae* and *Mycoplasma felis* infections in cats. Synovial fluid analysis usually reveals the presence of large numbers of neutrophils. This may lead to diagnostic confusion with primary immune-mediated polyarthritis. Systemic signs such as lethargy, fever, and inappetence usually accompany lameness. Evidence of immune compromise, such as underlying neoplasia or surgery, young age, or a history of glucocorticoid treatment, has generally been present in dogs and cats with mycoplasma polyarthritis. *Mycoplasma felis* has also been isolated from cats with monoarthritis, possibly secondary to bite wound infections.[19]

Meningoencephalitis

Mycoplasmas may gain access to the CNS as a result of penetrating wounds, ascending infection from the middle ear, or hematogenous

spread. Meningoencephalitis associated with *M. felis* infection was described in a 10-month-old cat that showed signs of lethargy, fever, a head tilt, nystagmus, and tetraparesis.[14] *Mycoplasma felis* was isolated in pure culture from the CSF. The cat also had evidence of otitis media-interna at necropsy, but the role this played in development of the mycoplasma infection was unclear. *Mycoplasma edwardii* was isolated from the brain of a 6-week-old dog with a sudden onset of seizures.[10] Suppurative and histiocytic meningitis was detected at necropsy in conjunction with evidence of a possible penetrating wound to the skull. Infection with *M. canis* has been associated with some cases of granulomatous meningoencephalomyelitis and necrotizing meningoencephalitis in dogs, which requires further study.[40]

Physical Examination Findings

Physical examination findings in dogs and cats with mycoplasma infections depend on the organ affected, as well as underlying disease processes that facilitate opportunistic invasion by mycoplasmas. Ocular infections in cats are characterized by serous to mucopurulent ocular discharge, conjunctival hyperemia, and possibly keratitis. Upper respiratory tract infections may result in nasal discharge and sneezing, with or without conjunctivitis. Fever, tachypnea, and increased lung sounds may be present with pneumonia. Urinary tract infections may lead to clinical signs of lower urinary tract disease, such as hematuria or stranguria. *Mycoplasma* arthritis may be manifested by fever, joint pain and swelling, and sometimes local lymphadenopathy.[11–13]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Findings on the CBC, serum biochemistry panel, and urinalysis in dogs or cats with mycoplasma infections are nonspecific and influenced by underlying disease processes. Dogs and cats with pneumonia, mycoplasma bacteremia, and polyarthritis may have a neutrophilia with a left shift and neutrophil toxicity, a degenerative left shift, mild nonregenerative anemia, hypoalbuminemia, and evidence of organ dysfunction such as increased serum liver enzyme activities and azotemia.[11,12,17]

Diagnostic Imaging

Plain Radiography

Mycoplasma pneumonia may be characterized by interstitial to alveolar patterns or lung lobe consolidation (Fig. 57.2); sometimes, mild pleural effusion is present. Radiographs of the joints of dogs and cats with mycoplasma polyarthritis may reveal periarticular soft tissue swelling. Erosive changes to the subchondral bone have also been described.[11]

Microbiologic Tests

Assays available for diagnosis of mycoplasma infections in dogs and cats are shown in Table 57.1.

Cytologic Examination

Mycoplasma spp. are often not visible with light microscopy because of their small size. They do not stain with Gram stain as a result of

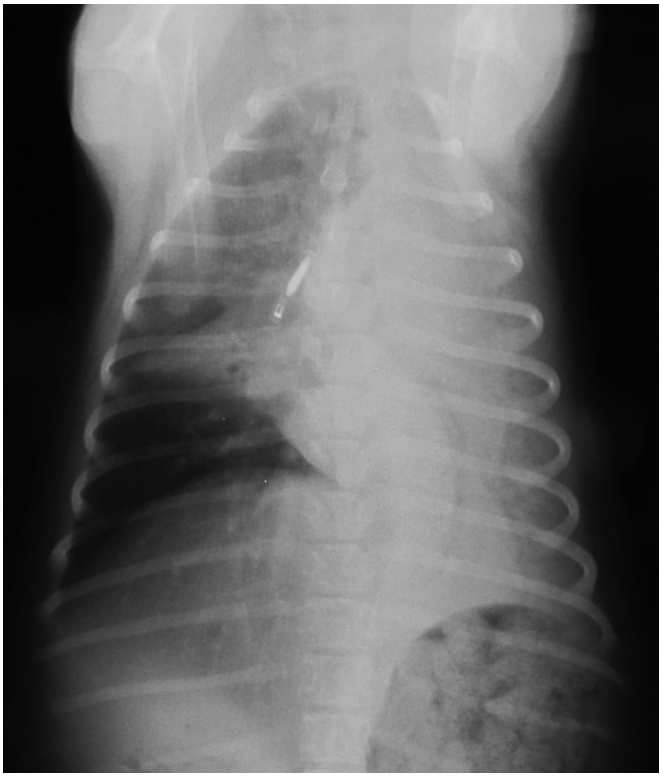

Fig. 57.2 Right lateral and ventrodorsal thoracic radiographs from a 3-month-old intact female pug with *Mycoplasma cynos* pneumonia. There is consolidation of the lung lobes associated with the left hemithorax and the right middle lung lobe. A diffuse interstitial pattern is present in the remainder of the right lung fields.

TABLE 57.1 Assays Available for Diagnosis of Mycoplasma Infections

Assay	Specimen Type	Target	Performance
Culture	Swabs, body fluids, wash specimens, tissue obtained at necropsy	Cultivable mycoplasma species	Some organisms grow on blood agar, but others require special mycoplasma media. Uncultivable mycoplasmas may also be present, which leads to false-negative results. Turnaround time may be slow (several days to weeks), species differentiation and antimicrobial drug susceptibility testing is often not performed. The significance of positive results from the upper respiratory and genital tract may be unclear.
PCR	Swabs, body fluids, wash specimens, tissue obtained at necropsy	*Mycoplasma* DNA	Allows rapid detection of the presence of mycoplasmas. More sensitive than culture for detection of fastidious or uncultivable mycoplasmas, although sensitivity and specificity may vary between assays. Some assays are designed to only detect certain pathogenic *Mycoplasma* species, such as *Mycoplasma cynos*. Sequencing of the PCR product may permit species identification. The significance of positive results may be unclear.

PCR, polymerase chain reaction.

the absence of a cell wall. Cytology of affected body fluids (such as bronchoalveolar lavage fluid, synovial fluid, and CSF) usually reveals a predominance of neutrophils with lesser numbers of histiocytes and lymphocytes.[11,12,14,34,35]

Isolation and Identification

Specimens suitable for culture of mycoplasmas include synovial fluid, blood, CSF, urine collected by cystocentesis, pleural fluid, semen, and tracheobronchial or bronchoalveolar lavage specimens. Swabs of the nasal cavity, conjunctiva, cornea, urethra, vagina, or cervix can also be submitted, but interpretation of results from these sites is difficult. If swabs are used, the swab should be rubbed vigorously on the mucosa because mycoplasmas are cell-associated. Rapid transport to the laboratory is important, because mycoplasmas are susceptible to deterioration with exposure to the environment. The use of special transport media (e.g., Stuart's medium or Amies medium without charcoal) for swab or tissue specimens may increase the yield of fastidious mycoplasma species if a delay of several hours is anticipated between collection of specimens and transport to the laboratory. Specimens should be refrigerated if delayed transport is unavoidable. If the delay is likely to be longer than 24 hours, specimens in transport media should ideally be frozen at –80°C.

Some mycoplasmas grow on blood agar under routine aerobic or anaerobic conditions. Others require special mycoplasma media, and some fail to grow under any laboratory conditions. The rate of growth in culture varies from one *Mycoplasma* species to another; for some mycoplasmas, colonies are visible in 2 or 3 days, whereas others require several weeks of incubation before colonies appear. Examination of plates under the light microscope may be required for detection of *Mycoplasma* colonies, because colonies range in size from 15 to 300 µm in diameter. The colonies of many mycoplasma species have a characteristic "fried egg" appearance (Fig. 57.3). Biochemical properties can be used to subgroup mycoplasmas, but species identification has traditionally required the use of species-specific antisera. Because cross-reactions can occur between species even when antisera are used, molecular typing methods (such as 16S rRNA gene or 16S/23S rRNA intergenic spacer region PCR and sequence analysis of the respective PCR products) or MALDI-TOF MS are now the method of choice for species identification.[7] Most veterinary diagnostic laboratories currently report only growth of a *Mycoplasma* spp., and do not identify organisms to the species level unless specifically requested. It is difficult to interpret the significance of a positive mycoplasma culture from mucosal sites that are not normally sterile, including the lower respiratory tracts of dogs, so results must be interpreted in light of the clinical findings and the results of other diagnostic tests.

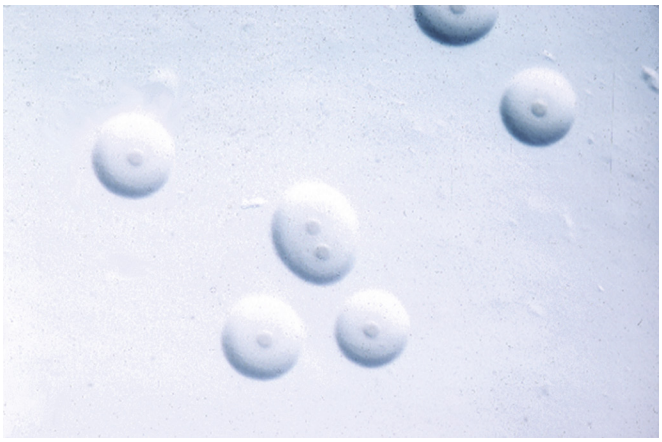

Fig. 57.3 Colonies of *Mycoplasma bovirhinis* showing the "fried egg" appearance that is typical of the growth of some *Mycoplasma* spp. in culture. (From The genera *Mycoplasma* and *Ureaplasma*. In: Songer JG Post KW, eds. *Veterinary Microbiology: Bacterial and Fungal Agents of Animal Disease*. 2nd ed. St. Louis, MO: Saunders; 2005.)

Antimicrobial susceptibility testing for mycoplasmas is labor intensive and not routinely performed, and established breakpoints are not available. The most widely used method is microbroth dilution (see Chapter 3).[41]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Some veterinary diagnostic laboratories offer PCR assays that rapidly directly detect mycoplasma DNA in clinical specimens, without the need for culture. Several conventional and real-time PCR assays have been used to detect mycoplasmas of dogs and cats.[42–45] These assays may be specific for certain mycoplasma species (such as *M. cynos* or *M. felis*), or they may be genus-specific assays that detect a variety of mycoplasma species. PCR assays may be more sensitive than culture for detection of fastidious mycoplasma species. Sequencing of the PCR product generated from genus-specific PCR assays may be used to identify the infecting species present, provided the product is sufficiently long. As with culture, the significance of a positive PCR test result for *Mycoplasma* spp. may be unclear given the frequent colonization of healthy animals with mycoplasmas, so results must be interpreted with the underlying disease process and the results of other diagnostic tests.

Pathologic Findings

Gross pathology in dogs and cats with mycoplasmal diseases usually reveals the presence of purulent material in affected tissues. Histopathology shows predominantly neutrophilic inflammation within affected tissues, although histiocytes may also be present. Reactive lymphadenopathy may also be evident as a result of immune stimulation (Fig. 57.4).

TREATMENT AND PROGNOSIS

Treatment of mycoplasma infections involves specific antimicrobial therapy (Table 57.2) as well as management of other underlying disorders that may have predisposed to invasion by mycoplasmas. Tetracyclines or fluoroquinolones are active against most mycoplasma isolates. The optimal duration is unknown, but treatment for at least 2 weeks is reasonable. In a prospective study of shelter cats with URTD and *M. felis* infection, a 14-day course of doxycycline was more effective in causing reduction in *M. felis* load as determined with real-time PCR than a 7-day course, but there was no overall significant difference in the reduction in clinical signs between the two groups.[46] Nevertheless, 25% of the cats treated for 14 days were still infected after that time. In another study of cats with conjunctivitis, 3 weeks of treatment with pradofloxacin or doxycycline was required to eliminate infection as indicated by the detection of *Mycoplasma* DNA.[45] β-lactam drugs are not active against mycoplasmas because they lack peptidoglycan. Mycoplasmas are also intrinsically resistant to trimethoprim-sulfonamide combinations and rifampin. Some species are resistant to macrolides.

IMMUNITY AND VACCINATION

Mycoplasma spp. persist in tissues and epithelial cells despite the immune response. Mechanisms to evade the host immune response such as intracellular localization and antigenic variation of outer surface proteins have been identified in several mycoplasma species. Innate, humoral (especially IgA), and cell-mediated immune

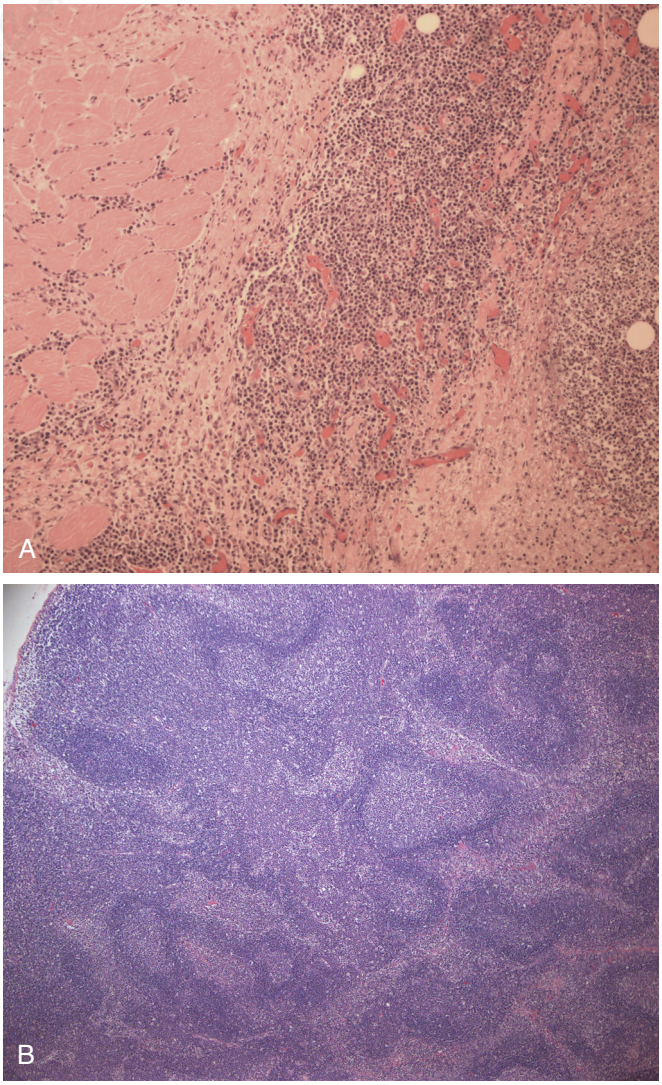

Fig. 57.4 Histopathology of the inguinal subcutaneous tissues (A) and sublumbar lymph node (B) from a 6 month-old, FIV-/FeLV-negative, male neutered domestic shorthair with severe suppurative cellulitis, steatitis, dermatitis, and myositis of the scrotal skin and subcutaneous tissue due to a *Mycoplasma* spp. infection. The cat had been neutered 13 days previously and was evaluated for a 2-day history of lethargy and reluctance to move. Physical examination revealed fever (104.6°F), severe conjunctivitis, generalized peripheral lymphadenomegaly, and firm mass lesions in the inguinal area. In addition to suppurative cellulitis and myositis, marked systemic lymph node hyperplasia was present. Hyperplasia was most profound in the sublumbar lymph nodes, which measured 4 cm in diameter.

responses may be required to clear mycoplasma infections, with humoral mechanisms of critical importance. Vaccines to limit disease caused by pathogenic mycoplasma species such as *M. cynos* are currently not available, although they have been used with success in food production animal species.

TABLE 57.2 Suggested Antimicrobial Drug Treatment for Mycoplasma Infections

Drug	Dose (mg/kg)	Route	Interval (Hours)
Doxycycline	5 to 10	PO or IV	12 to 24
Enrofloxacin[a]	5	PO or IV	24
Marbofloxacin	2 to 5.5	PO	24
Pradofloxacin[b]	5 to 10 (cats); 3 (dogs)	PO	24

[a]Use enrofloxacin only in cats when other alternatives are not possible due to risk for irreversible blindness.
[b]Use of pradofloxacin is extra-label in dogs in the United States (see Chapter 10). The dose for cats is for the oral suspension. The dose for the tablet formulation is 3 mg/kg.
IV, intravenous; *PO,* oral.

PREVENTION

Prevention of mycoplasma infections involves management or reversal of disorders that predispose to opportunistic invasion by mycoplasmas. Reduction of overcrowding and concurrent infections in shelter environments may also reduce the incidence and severity of mycoplasma infections (see Chapters 16 and 17). Routine disinfectants are sufficient to inactivate mycoplasmas that persist in the environment.

PUBLIC HEALTH ASPECTS

The vast majority of mycoplasma species associated with disease in humans are different to those found in dogs and cats. However, pharyngeal colonization with *M. canis* was also reported in a family and their pet dog.[47] *Mycoplasma felis* was isolated from multiple joints of a woman with common variable immunodeficiency who developed septic arthritis.[48] The woman had worked in an animal shelter, lived with a cat, and had been bitten on the hand by a healthy cat 6 months before she was evaluated. A mycoplasma was isolated from a cat scratch wound to the hand of a veterinarian.[49] Although *Staphylococcus aureus* was initially isolated from the wound, it failed to resolve completely after treatment with erythromycin. Subsequently the tenosynovitis developed, and a mycoplasma was isolated. The identity of the mycoplasma could not be determined using biochemical and serologic methods, and whether a cat was truly the source of this infection was not proven. Isolation of antibiotic-resistant *Mycoplasma maculosum* from immunocompromised patients[50] and *M. edwardii* from the peritoneal fluid of a 10-year-old child with polymicrobial peritonitis following a puncture of dialysis tubing by a pet dog have been documented.[51] *Mycoplasma canis*, identified using MALDI-TOF MS and 16S rDNA sequencing, was isolated from a dog bite wound in a 62-year-old woman.[52]

VetBooks.ir

CASE EXAMPLE

Signalment

"Delilah," a 3-month-old intact female pug dog from Reno, NV.

History

Delilah was brought to the University of California, Davis VMTH, for evaluation of pneumonia. She had been purchased from a pet store 3 weeks before the date of evaluation. The owner noticed nasal and ocular discharge when the dog was brought home from the store, as well as a dry, nonproductive cough. Delilah was taken to a local veterinary clinic where she was diagnosed with "kennel cough" and treated with clavulanic acid-amoxicillin (15 mg/kg, PO, q12h) for 2 weeks. However, the cough persisted and Delilah's respiratory effort increased. She was then hospitalized at the local veterinary clinic and treated with ticarcillin-clavulanate (50 mg/kg, IV, q8h), supplemental oxygen, nebulization, and coupage. Radiographs showed infiltrates in the left lung lobes and right middle lung lobe that worsened over the course of hospitalization, so she was referred for further evaluation and treatment. There had been no decrease in appetite, vomiting, or diarrhea. She was fed a commercial puppy food and had no history of ticks, travel, trauma, or toxin exposure. The owner was not aware of previous vaccinations.

Physical Examination

Body weight: 2.2 kg.

General: Quiet, alert, hydrated. T = 101.0°F, pulse rate = 220 beats/min, respiratory rate = 60 breaths/min, slightly tacky mucous membranes with a normal capillary refill time.

Eyes, ears, nose, and throat: Mild serous ocular and nasal discharge bilaterally. Conjunctival hyperemia and chemosis was present, as well as scleral injection. No other clinically significant findings were present.

Musculoskeletal: BCS 4/9. Fully ambulatory with no evidence of muscle atrophy. Poor body conformation was present, characterized by medial deviation of the tarsi and hyperextension of the carpi.

Cardiovascular: No murmurs or arrhythmias were ausculted. Femoral pulses were strong and synchronous.

Respiratory: Tachypnea was present with marked abdominal effort. Lung sounds were markedly increased, especially on the left side. There were no crackles or wheezes. Coughing occurred several times during the examination.

GI: No abnormalities were detected on abdominal palpation, but abdominal palpation was difficult and brief because of the dog's compromised respiratory status.

Lymph nodes: All within normal limits of size.

Neurologic examination: No obvious neurologic deficits were present. A full neurologic examination was not performed.

Laboratory Findings

Venous blood gas: pH = 7.348, pCO_2 44 mmHg, pO_2 44.7 mmHg, HCO_3^- 23.2 mmol/L, base excess –1.4 mmol/L, ionized calcium 1.43 mmol/L, lactate 3.3 mmol/L.

CBC: HCT 35.4% (40%–55%), MCV 68.6 fL (65–75 fL), MCHC 31.1 g/dL (33–36 g/dL), WBC 31,580 cells/μL (6,000–13,000 cells/μL), neutrophils 6,948 cells/μL (3,000–10,500 cells/μL), band neutrophils 9,790 cells/μL, lymphocytes 9,158 cells/μL (1,000–4,000 cells/μL), monocytes 4,737 cells/μL (150–1,200 cells/μL), eosinophils 947 cells/μL (150–1,100 cells/μL), platelets 307,000 platelets/μL (150,000–400,000 platelets/μL). Band neutrophils and mature neutrophils had evidence of toxic changes.

Serum chemistry profile: anion gap 24 mmol/L (12–25 mmol/L), sodium 147 mmol/L (145–154 mmol/L), potassium 4.9 mmol/L (3.6–5.3 mmol/L), chloride 104 mmol/L (108–118 mmol/L), bicarbonate 24 mmol/L (16–26 mmol/L), phosphorus 8.0 mg/dL (3.0–6.2 mg/dL), calcium 10.5 mg/dL (9.7–11.5 mg/dl), BUN 10 mg/dL (5–21 mg/dL), creatinine 0.5 mg/dL (0.3–1.2 mg/dL), glucose 110 mg/dL (64–123 mg/dL), total protein 5.9 g/dL (5.4–7.6 g/dL), albumin 2.5 g/dL (3.0–4.4 g/dL), globulin 3.4 g/dL (1.8–3.9 g/dL), ALT 12 U/L (19–67 U/L), AST 38 U/L (19–42 U/L), ALP 144 U/L (21–170 U/L), GGT 0 U/L (0–6 U/L), cholesterol 188 mg/dL (135–361 mg/dL), total bilirubin concentration 0.0 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.045; pH 7.0, no protein, glucose, ketones, bilirubin, 0 WBC/HPF, rare RBC/HPF, rare triple phosphate and a few sodium urate crystals, rare lipid droplets.

Imaging Findings

Thoracic radiographs: There was complete consolidation of the lung lobes associated with the left hemithorax (see Fig. 57.2). Prominent air bronchogram formation was noted in these lung lobes and in the right middle lung lobe, which also appeared consolidated. Diffuse interstitial markings were present in the remainder of the right lung fields.

Thoracic ultrasound: Complete consolidation of the left lung was appreciated. Pleural effusion was not present. There was no evidence of lung lobe torsion.

Cytologic Findings

Transtracheal wash: One direct smear was evaluated that was highly cellular and contained a minimal amount of mucus. Cells were essentially all neutrophils, which were primarily nondegenerate but occasionally mildly to moderately degenerate. A single extracellular rod, and 2 neutrophils with intracellular structures that resemble bacteria were found.

Interpretation: Marked suppurative inflammation, suspicious for sepsis.

Microbiologic Testing

Gram-stained direct smear of transtracheal wash fluid: Large numbers of neutrophils. No organisms seen.

Aerobic and anaerobic bacterial culture and *Mycoplasma* culture (transtracheal wash fluid): Large numbers of *Mycoplasma* spp.; DNA sequence analysis revealed 100% identity to *M. cynos*. No other aerobic or anaerobic organisms isolated.

Direct FA for distemper virus antigen (conjunctival smear): Negative.

Centrifugal zinc sulfate fecal flotation: Negative.

Diagnosis

Mycoplasma cynos bronchopneumonia.

Treatment

Delilah was treated with supplemental oxygen, nebulization, coupage, and IV fluids. Treatment with ticarcillin-clavulanate was continued for 3 days, then changed to enrofloxacin (5 mg/kg PO q24h) and amoxicillin-clavulanate (19 mg/kg PO q12h), and nebulization with gentamicin was performed once daily, because there had been no improvement and persistent bordetellosis was considered a possibility. The following morning, lung sounds were improved and Delilah was very playful. Her nasal discharge resolved and the frequency of cough reduced. The CBC showed a regenerative anemia (HCT 33.2%, with 95,300 reticulocytes); 14,112 slightly toxic neutrophils/μL; 1,008 slightly toxic band neutrophils/μL; 5,796 lymphocytes/μL; and 3,780 monocytes/μL. Growth of *Mycoplasma* spp. was reported 5 days after specimens were submitted for culture. Oxygen supplementation was gradually reduced, and Delilah was discharged on day 8 of hospitalization, although significant radiographic improvement was not evident at that time and an occasional productive cough was still present. Treatment with enrofloxacin, amoxicillin-clavulanate, coupage, and exercise restriction was continued at home. At a recheck 3 weeks later, Delilah had gained weight (3.45 kg). An intermittent, moist but nonproductive cough was present only in the morning. Her appetite remained excellent, and there was no evidence of lethargy or exercise intolerance, and no evidence of ocular or nasal discharge. A physical examination was unremarkable, and Delilah's respiratory rate was 30 breaths/min. A CBC showed persistent mild regenerative anemia, with 7,260 neutrophils/μL and 330 band neutrophils/μL. Thoracic radiographs showed significantly improved aeration of the left cranial and caudal lung lobes, and near-complete resolution of the right-sided infiltrates. Treatment with amoxicillin-clavulanate was

Continued

CASE EXAMPLE—cont'd

then discontinued. Further improvement in the cough and pulmonary infiltrates were observed at a recheck 3.5 weeks later. After an additional 7 weeks of treatment, the cough had completely resolved, although partial atelectasis of the cranial portion of the left lung lobe persisted.

Comments

The isolation of a pure culture of *M. cynos* from this dog's transtracheal wash, together with the lack of response to β-lactam antimicrobial drugs and a prompt response once treatment with enrofloxacin was initiated, supported a diagnosis of mycoplasma pneumonia (and possibly also conjunctivitis) in this dog. The concurrent presence of respiratory viruses remains a possibility because other than direct FA testing for CDV, diagnostic tests for respiratory viruses were not performed, and co-infections with multiple respiratory pathogens in dogs from pet stores and shelter environments are common. Resolution of the cough and radiographic changes occurred over several months. There was concern expressed over the possibility of abnormal cartilage development in such a young dog due to prolonged treatment with enrofloxacin, but no adverse effects were reported. The optimum duration of treatment of mycoplasma pneumonia in dogs requires further study. The development of a regenerative anemia was interesting and may have reflected pulmonary hemorrhage or immune-mediated hemolysis. Reticulocytosis has been reported in human patients with community-acquired pneumonia due to *Mycoplasma pneumoniae.*

Hemotropic Mycoplasma Infections

Emi N. Barker, Séverine Tasker

KEY POINTS

- Cause: *Mycoplasma haemocanis* and "*Candidatus* Mycoplasma haematoparvum" in dogs, and *Mycoplasma haemofelis*, "*Candidatus* Mycoplasma haemominutum," and "*Candidatus* Mycoplasma turicensis" in cats. All are gram-negative, obligate epierythrocytic bacteria that belong to the family Mycoplasmataceae.
- First Described: *M. haemocanis* (basonym *Haemobartonella canis* [Benjamin and Lumb 1959][1] nom. rev. *Bartonella canis*, Germany [*ex.* Kikuth 1928])[2]; *M. haemofelis* (basonym *Haemobartonella felis* [Flint and Moss 1953][3] nom. rev. *Eperythrozoon felis*, South Africa [*ex.* Clark 1942]).[4]
- Affected Hosts: Domesticated dogs and cats, wild canidae, and wild felidae. Other hemoplasma species cause disease in a variety of other animal species.
- Intermediate Hosts: Unknown.
- Geographic Distribution: Worldwide; prevalence varies geographically.
- Primary Mode of Transmission: The mode of transmission in the field is uncertain. Ticks (*Rhipicephalus sanguineus* in particular) are suspected to transmit *M. haemocanis*. Other unidentified arthropod vectors may also be involved. Biting or aggressive interactions are a suspected mode, and possibly vertical transmission. Experimentally, transmission can occur through ingestion or injection of infected blood.
- Major Clinical Signs: Fever, lethargy, inappetence, weakness, pallor, and dehydration.
- Differential Diagnoses: Primary IMHA, other infectious diseases (e.g., cytauxzoonosis, FIV infection, FeLV infection, FIP), Heinz body anemia, and inherited erythrocyte disorders (e.g., pyruvate kinase deficiency, red cell fragility disorders).
- Human Health Significance: Infections have also been described in humans with novel hemoplasma species, as well as species that have possibly originated in animals such as the cat or dog, pigs, and sheep, raising the possibility of zoonotic infections.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Hemotropic mycoplasmas (hemoplasmas) are small (0.3–1.0 μm), wall-less bacteria that infect erythrocytes living on the surface of the erythrocyte membrane (Fig. 58.1). They infect a wide variety of mammalian species, including humans, as well as beetles. Infection can result in hemolytic anemia of variable severity, dependent on host and hemoplasma factors. Hemoplasma infections have been reported throughout the world.

Previously classified as rickettsial organisms within the *Haemobartonella* and *Eperythrozoon* genera, sequence analysis of the 16S rRNA genes resulted in their reclassification within the genus *Mycoplasma*, alongside species more commonly found on the mucosal surfaces of the respiratory and urogenital tracts (e.g., *Mycoplasma pneumoniae* and *Mycoplasma genitalium*).[5–7] Gene sequence analysis also revealed the existence of different species of hemoplasmas within individual host species. Hemoplasmas cannot be cultured in the laboratory, which limits full phenotypic characterization, so the "*Candidatus*" prefix is applied to newly described hemoplasmas until more information becomes available to support their classification. Because bacterial species cannot be demoted, those species previously defined and named cannot be assigned the *Candidatus* status. Similarities between the hemoplasmas and mucosal mycoplasmas are recognized, such as the absence of a cell wall, their small (physical and genomic) sizes, and fastidious growth requirements. However, the hemoplasmas' niche environment of the blood is not one that is commonly recognized for mucosal mycoplasmas. Non-16S rRNA gene-based phylogeny suggests that, although the hemoplasmas belong to the family Mycoplasmataceae, they should reside in a genus separate to that of the mucosal mycoplasmas.[8,9]

Three major hemoplasma species infect domestic cats as well as wild felids, *Mycoplasma haemofelis*, "*Candidatus* Mycoplasma haemominutum", and "*Candidatus* Mycoplasma turicensis." The whole genome sequences of two strains of *M. haemofelis* have been determined, as has the near-whole genome sequence of one strain of "*Ca.* M. haemominutum."[10–12] Prevalence studies for feline hemoplasma species have been performed worldwide with diverse results (Table 58.1); however, variation in population characteristics (from healthy to anemic, suspected of having hemoplasmosis or retrovirus-infected; and from client-owned to feral) and PCR methodology (with likely differing sensitivities and specificities) limits comparison between studies. Geographic variation in prevalence also appears to exist, with cats in warmer countries having a higher prevalence of infection. Mixed infections with one or both of the other feline hemoplasma species occur, with one study of Brazilian cats reporting that over 80% of hemoplasma-infected cats harbored more than one hemoplasma species.[13]

Mycoplasma haemofelis (previously the Ohio strain, or large form of *Haemobartonella felis*) is the most pathogenic feline hemoplasma and can cause moderate to severe hemolytic anemia in immunocompetent cats. Using cytologic evaluation of blood smears, *M. haemofelis* organisms are cocci that are usually found individually on RBCs, but sometimes they form short chains of three to six organisms (see Fig. 58.1). *Mycoplasma haemofelis* has been found using PCR in 0.4% to 14.0% of sick cats presented for veterinary care, although occasionally a higher prevalence is reported (see Table 58.1).

"*Ca.* M. haemominutum" (previously the California strain or small form of *H. felis*) is generally smaller than *M. haemofelis* and has not

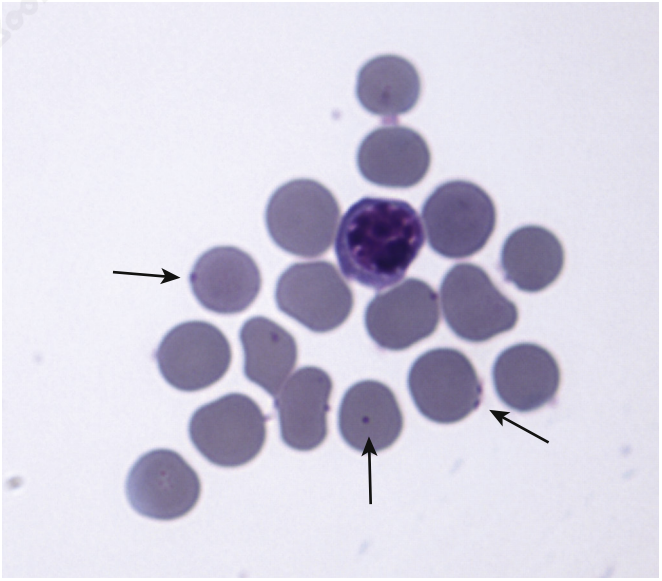

Fig. 58.1 Romanowsky-stained blood smear from an 8-year-old male neutered domestic shorthair cat showing epierythrocytic bacteria typical of *Mycoplasma haemofelis (arrows)*.

clearly been associated with clinically significant disease in immunocompetent cats. Using cytologic evaluation of blood smears, "*Ca.* M. haemominutum" are small cocci, 0.3 to 0.6 µm in diameter, although *M. haemofelis* and "*Ca.* M. haemominutum" cannot be reliably distinguished by size alone. "*Ca.* M. haemominutum" is usually the most common species found in prevalence studies in the cat population worldwide, infecting typically 10% to 25%, although a higher prevalence is occasionally reported (see Table 58.1).

"*Ca.* M. turicensis" was first described in a cat from Switzerland that had severe intravascular hemolysis.[14] Infections with "*Ca.* M. turicensis" have since been detected worldwide (see Table 58.1). "*Ca.* M. turicensis" has not been identified using light microscopic examination of blood smears, and organism loads in infected cats are typically low. Infection with "*Ca.* M. turicensis" is usually slightly more prevalent in the cat population than infection with *M. haemofelis*. Most studies show a prevalence of 0% to 10% (see Table 58.1).

Infection of cats by hemoplasmas is strongly associated with male sex, nonpedigree status, and outdoor access.[13,15–28] Infection with "*Ca.* M. haemominutum" is more prevalent in older cats, presumably because of the cumulative risk of acquiring persistent subclinical infection over time. Young cats may be more likely to develop severe clinical disease due to *M. haemofelis* compared with older cats.[29,30] Epidemiologic studies have, however, only variably demonstrated

associations between anemia and *M. haemofelis* infection.[15,30] This may be because these studies usually include chronically and subclinically *M. haemofelis*–infected cats. Some studies, but not others, have shown an association between retrovirus and infection with any hemoplasma species. Studies that have examined the relationship between individual hemoplasma species infections and retroviral status have shown variable results (see Table 58.1).

Long-term carrier status can occur with feline hemoplasma infections, with infected cats often being subclinical.[26,31] This is particularly common with "*Ca.* M. haemominutum" infection, although suspected clearance of infection with this species has been reported by others with and without antibiotic treatment.[27] Some *M. haemofelis*–infected cats spontaneously clear infection from peripheral blood a few months following acute infection; this also has been reported with "*Ca.* M. turicensis" infection. However, generalized statements regarding long-term carrier status cannot be made since great variation exists, likely because of differences in the host-organism interaction and hemoplasma isolates. Carrier cats often have subclinical infections, but reactivation of infection can occur and may result in clinical disease[32,33]; however, this is uncommon in our experience.

Two major hemoplasma species infect dogs: *Mycoplasma haemocanis* and "*Candidatus* Mycoplasma haematoparvum." The whole genome sequence of one strain of *M. haemocanis* has been determined.[34] The reported prevalence for canine hemoplasma infection also varies widely in different studies (Table 58.2), with *M. haemocanis* generally being more prevalent. Geographic variation is marked, possibly due to the presence of the proposed canine hemoplasma tick vector *Rhipicephalus sanguineus*.[35,36] Kenneled dogs, young dogs, crossbreeds, and dogs with mange were more likely to be infected in one study,[35] whereas other studies found no association with age.[16,36,37] A high prevalence of hemoplasma infection has also been reported in fighting dogs,[38,39] which supports the possibility of ingestion of blood as a transmission route.

Infection with *M. haemocanis* has been associated with hemolytic anemia in splenectomized dogs, and rarely in dogs with other immunosuppressive disease or concurrent infections. The 16S rRNA gene sequence of *M. haemocanis* cannot be distinguished from that of *M. haemofelis*, but phylogenetic analyses of other genes, as well as whole genome sequence comparison, distinguishes them as separate species.[9,34,40] *Mycoplasma haemocanis* is a coccoid organism that often forms chains of organisms (Fig. 58.2). "*Ca.* M. haematoparvum" is a small (0.3 μm) coccoid organism that resembles "*Ca.* M. haemominutum" morphologically (Fig. 58.3). The 16S rRNA gene sequence of "*Ca.* M. haematoparvum" is most closely related to that of "*Ca.* M.

haemominutum"; however, phylogenetic analysis of the *rnpB* gene has been used to distinguish them as separate species.[41]

Little work has been done regarding the time course of carrier status with canine hemoplasmas, but subclinical carrier dogs that are infected with *M. haemocanis* and "*Ca.* M. haematoparvum" exist.[36]

A "*Ca.* M. haematoparvum"–like organism has also been reported in a small number of cats in two studies.[24,42] In addition, "*Ca.* M. haemominutum" has been detected in several dogs using PCR assays. Organisms that resemble "*Ca.* M. haematoparvum" and "*Ca.* M. haemominutum" have been detected in European wolves and bush dogs from Brazil.[43] The ovine hemoplasma *Mycoplasma ovis* has been detected in a small number of dogs from the southeastern United States,[44] and the bovine hemoplasma "*Candidatus* Mycoplasma haemobos" was detected in a dog from northern Australia.[45] The clinical importance of these hemoplasma species in cats and dogs remains unclear.

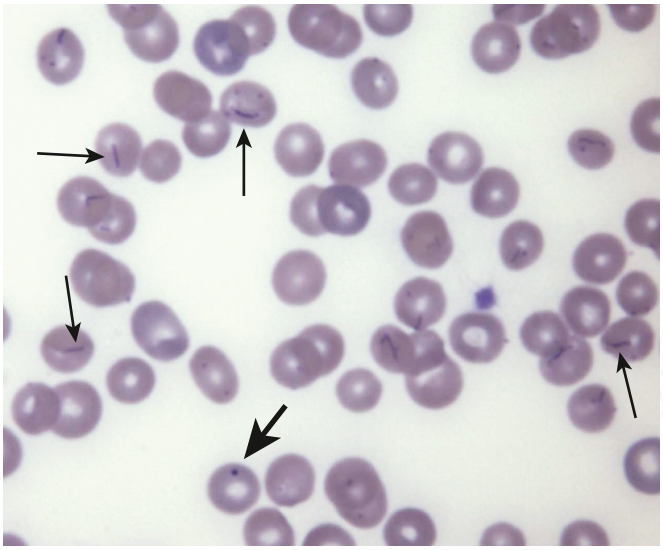

Fig. 58.2 Romanowsky-stained blood smear showing chains of epierythrocytic bacteria typical of *Mycoplasma haemocanis (thin arrows).* A Howell-Jolly body is also present *(large bolded arrow).*

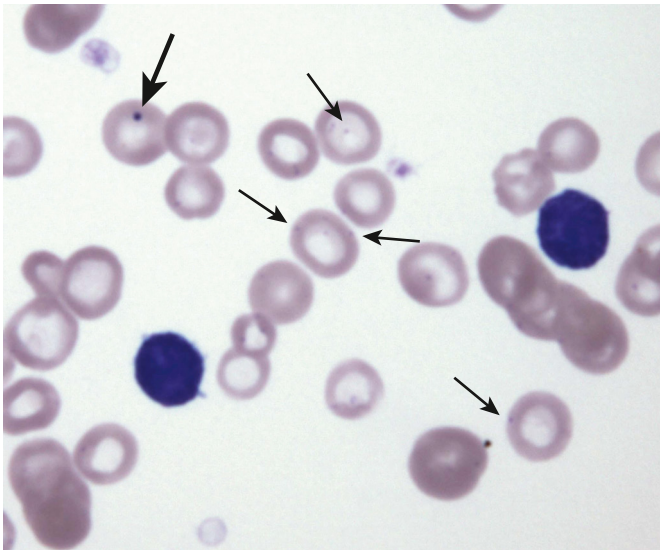

Fig. 58.3 Blood smear from a dog showing "*Candidatus* Mycoplasma haematoparvum" *(thin arrows)* and a Howell-Jolly body *(large bolded arrow).*

Pathogenesis

Mycoplasma haemofelis is the most pathogenic of the feline hemoplasma species. Cats do not need to be immunocompromised or splenectomized to succumb to clinical disease with *M. haemofelis* (however, even splenectomized cats infected with "*Ca.* M. haemominutum" do not seem to develop disease).[46]

Acute infection often results in severe hemolytic anemia (primarily extravascular, but occasionally intravascular hemolysis is reported) although in some cases only mild anemia occurs. In experimental studies, clinical signs occur around 2 to 34 days after infection, and anemia lasts from 18 to 30 days. The onset of anemia is usually followed by a significant regenerative response with reticulocytosis. Chronic infection is not usually associated with significant anemia.[27] Experimental infections have shown that *M. haemofelis* blood organism numbers can fluctuate greatly over short periods of time, especially in the first few weeks of infection (Fig. 58.4). Antigenic variation, to evade the host immune system, may mediate these *M. haemofelis* organism number fluctuations,[47] as a very large portion (62%) of the genome encodes a set of uncharacterized hypothetical proteins arranged in series of paralogous repeats which could facilitate differing expression of hemoplasma surface proteins over time.

Persistent autoagglutination or a positive Coombs' test, indicating the presence of erythrocyte-bound antibodies, have been demonstrated in anemic cats with acute *M. haemofelis* infection.[48–50] One study[50] showed that erythrocyte-bound antibodies reactive at 4°C (cold reactive antibodies; both IgM and IgG) appeared a few days earlier than those reactive at 37°C (warm reactive antibodies; primarily IgG). However, in most cats, these antibodies appeared only after the development of anemia had started, and disappeared with antibiotic and supportive treatment alone, without the need for specific glucocorticoid treatment. The absence of erythrocyte-bound antibodies at the onset of development of anemia could reflect lack of sensitivity in their detection or that erythrocyte-bound antibodies appear as a result of hemoplasma-induced hemolysis rather than initiating it. Osmotic fragility[14,49] and reduced erythrocyte lifespan[51] have also been reported with *M. haemofelis* infection.

Although acute "*Ca.* M. haemominutum" infection is associated with a fall in RBC parameters,[50] anemia is not usually induced except in cats with concurrent diseases or infections (e.g., lymphoma or FeLV infection).[52,53] For example, cats that are co-infected with FeLV and "*Ca.* M. haemominutum" develop more significant anemia than cats infected with "*Ca.* M. haemominutum" alone, and progression to FeLV-induced myeloproliferative disease occurred more rapidly in one study of experimentally infected cats.[53] Although concurrent problems are usually present in "*Ca.* M. haemominutum"–infected cats that develop anemia, cases of so-called primary "*Ca.* M. haemominutum" anemia (i.e., without any apparent concurrent disease or infection present) have also been reported,[54] so infection with this species cannot be ruled out as a cause of anemia in an individual case. However, conflicting data exist as one US study documented that "*Ca.* M. haemominutum"–infected cats were less likely to be anemic than cats not infected with "*Ca.* M. haemominutum."[24]

The pathogenic potential of "*Ca.* M. turicensis" is not fully understood. Experimental infection has resulted in anemia[14] or a small decline in RBC parameters in some studies,[50] but generally anemia is uncommon following infection. Concurrent disease and immunosuppression are both thought to be involved in the pathogenesis of "*Ca.* M. turicensis" disease,[28] in a similar way to the pathogenesis described for "*Ca.* M. haemominutum." Inoculation of an immunosuppressed cat with "*Ca.* M. turicensis" resulted in severe anemia,[14] but little or no anemia occurred in immunocompetent cats after inoculation with "*Ca.* M. turicensis." Determination of the pathogenicity of "*Ca.* M. turicensis" in naturally infected cats has been difficult in epidemiologic studies as cats are often co-infected with other hemoplasma species, which confounds disease associations.

It is possible that different strains of each of the feline hemoplasma species reported exist, and that these also vary in pathogenicity. This might explain some of the conflicting data reported in different studies. However, other factors such as the underlying health status of the cat, and possibly even the transmission route of infection, may play a role in the outcome of hemoplasma infection. One isolate of the porcine hemoplasma *Mycoplasma suis* was able to penetrate porcine erythrocytes; its subsequent intracellular location was associated with marked pathogenicity and resistance to antimicrobial therapy.[55] It is possible that this could occur for hemoplasmas in other species.

Studies of the pathogenicity of canine hemoplasmas are sparse. Hemoplasma infection in dogs usually results in hemolytic anemia only in splenectomized or immunocompromised dogs,[56–59] and subclinical latent *M. haemocanis* infections can be reactivated following splenectomy. However, recognition of the possibility of hemoplasma infection is important to differentiate such cases from cases of primary IMHA as some infected dogs have a positive Coombs' test.[60,61]

The natural route of transmission of hemoplasma infection among cats and dogs in the field has not yet been determined, and it may be that different routes predominate for different hemoplasma species. Canine and feline hemoplasma DNA have been found in fleas, ticks, and mosquitoes.[30,62–69] However, this does not imply that these vectors mediate transmission, as the hemoplasma DNA could reflect their hematophagous activity on infected hosts. The clustered geographic distribution of infection in some studies supports the role of an arthropod vector in hemoplasma transmission.[24] Although *Ctenocephalides felis* has been implicated in hemoplasma transmission in cats, only very transient *M. haemofelis* infection has been reported in cats experimentally infected via the hematophagous activity of fleas, and clinical and hematologic signs of *M. haemofelis* infection were not induced in the recipient cat.[70] Additionally, there was no evidence of hemoplasma transmission when fleas were introduced into groups of cats housed together.[71] Transmission of *M. haemocanis* by the brown dog tick, *Rh. sanguineus*, in experimental infections has been reported, although this study was performed before the advent of molecular diagnostic methods to confirm infection.[64]

The association between hemoplasma infection and male sex and/or retrovirus (particularly FIV) infection status seen in some studies could suggest that cat fights could be involved in transmission of infection. Studies in Switzerland have found that subcutaneous inoculation of "*Ca.* M. turicensis"–containing blood resulted in infection transmission, whereas the same inoculation method using "*Ca.* M. turicensis"–containing saliva did not. This suggests that hemoplasma transmission by social contact (saliva via mutual grooming etc.) is less likely than transmission by aggressive interaction (blood transmission during a cat bite incident).[72] However, one study[71] found evidence of horizontal transmission of "*Ca.* M. haemominutum", but not *M. haemofelis*, by direct contact between cats in the absence of aggressive interaction and vectors. Vertical transmission for canine or feline hemoplasma infections has not been definitively proven using molecular methods, but has been strongly suggested for *M. haemocanis*[73] and hemoplasmas that infect other host species.[74] Blood transfusion is another route of transmission, and blood donors should be screened for hemoplasma infection.[75]

CLINICAL FEATURES

The clinical disease that follows hemoplasma infection is influenced by the stage of infection, the host response to the organism, the health status of the host, and the species of hemoplasma involved.

Common clinical signs associated with hemoplasmosis are lethargy, pallor, and weakness. Inappetence, dehydration, weight loss, and intermittent fever are also reported. Splenomegaly may also be evident. In contrast, dogs with hemoplasmosis typically have a history of splenectomy (a predisposing factor in the development of clinical disease).

Affected animals with severe anemia may have tachycardia, tachypnea, and weak or bounding femoral pulses with hemic cardiac murmurs. Icterus is uncommon despite the severe nature of the anemia involved. Moribund cats may be hypothermic.

DIAGNOSIS

Hemoplasmosis should be considered as a differential diagnosis in cats or dogs presenting with regenerative (although occasionally nonregenerative) anemia and possibly associated fever. Other diagnoses to consider are primary IMHA (less common in cats when compared with dogs),

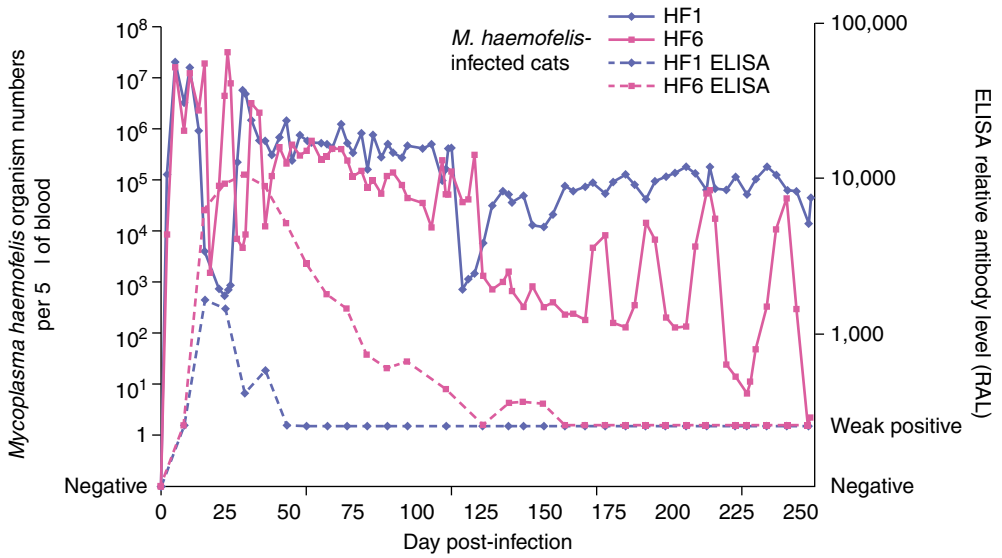

Fig. 58.4 *Mycoplasma haemofelis* copy number and *M. haemofelis* anti-DnaK ELISA following acute infection in two cats. HF1 = cat number 1 infected wtih *M. haemofelis;* HF6 = cat number 6 infected wtih *M. haemofelis. ELISA,* enzyme-linked immunosorbent assay. (From Barker EN, Helps CR, Heesom KJ, et al. Detection of humoral response using a recombinant heat shock protein 70, DnaK, of *Mycoplasma haemofelis* in experimentally and naturally hemoplasma-infected cats. *Clin Vaccine Immunol.* 2010;17:1926–32.)

secondary IMHA (e.g., secondary to drugs, neoplasia, or other infections), cytauxzoonosis (cats), retroviral infection (cats), babesiosis, Heinz body-associated hemolysis (cats), hypophosphatemia, and inherited RBC disorders (e.g., pyruvate kinase deficiency, and red cell fragility disorders).

Laboratory Abnormalities

Pathogenic hemoplasma infections typically cause a regenerative anemia that is macrocytic and hypochromic, although pronounced reticulocytosis is not always evident.[76] Normoblasts may be present. Manual reticulocyte counts should be interpreted with caution in *M. haemofelis*–infected cats, because hemoplasma-infected erythrocytes may have the same appearance as reticulocytes in blood smears stained with methylene blue. Occasionally, nonregenerative anemia can be present when insufficient time for a regenerative response has elapsed, or as a result of bone marrow suppression due to medication or concurrent disease such as FeLV infection. Neutrophil counts may be normal, elevated, or low, and lymphopenia may be present. Thrombocytopenia can also occur in affected dogs and cats, but the platelet count can also be within the reference range. Positive Coombs' test results, particularly with cold agglutinins, and persistent autoagglutination have been reported in acute hemoplasmosis. Hyperbilirubinemia is seen occasionally due to hemolysis. Hypoxic damage to the liver may result in increased activities of ALT and AST. Metabolic acidosis and prerenal azotemia may be noted. Hyperproteinemia, due to a polyclonal gammopathy, is sometimes seen in cats.[77] Urinalysis is usually unremarkable. Bilirubinuria may be present where hyperbilirubinemia is present. Soma cats may test positive for FIV or FeLV, which have been associated with infection (see Table 58.1).

Diagnostic Imaging

The most common radiographic or ultrasonographic finding in cats with hemoplasmosis is splenomegaly, due to a combination of increased splenic macrophage activity, splenic sequestration of erythrocytes, and extramedullary hematopoiesis (Fig. 58.5). The spleen may be absent in affected dogs because of splenectomy.

Microbiologic Tests

Assays available for diagnosis of hemoplasmosis in dogs and cats are listed in Table 58.3.

Cytologic Examination

Cytologic examination of blood smears may show hemoplasmas on the surface of erythrocytes (see Fig. 58.1) but this is very insensitive (0% to 37.5%)[21,26,29,78]; massive numbers of organisms must be present in blood before they can be visualized. Cytologic examination cannot easily differentiate between *M. haemofelis* and "*Ca.* M. haemominutum"[79]; "*Ca.* M. turicensis" has never been visualized by light microscopy. Specificity can also be an issue for cytologic diagnosis, as organisms need to be differentiated from stain precipitate, Howell-Jolly bodies, and basophilic stippling. As *M. haemocanis* organisms tend to form chains (see Fig. 58.2) and are visible in many clinically affected dogs, it is more readily differentiated from stain precipitate and erythrocyte morphologic changes. Hemoplasmas are not usually visible in chronically infected dogs or in dogs infected with "*Ca.* M. haematoparvum."

Culture

Attempts to isolate and grow feline hemotropic mycoplasmas in the laboratory have been unsuccessful.

Molecular Diagnosis Using Nucleic Acid–based Testing

PCR is now the diagnostic method of choice for hemoplasma infection. Numerous assays have been described to date, both conventional

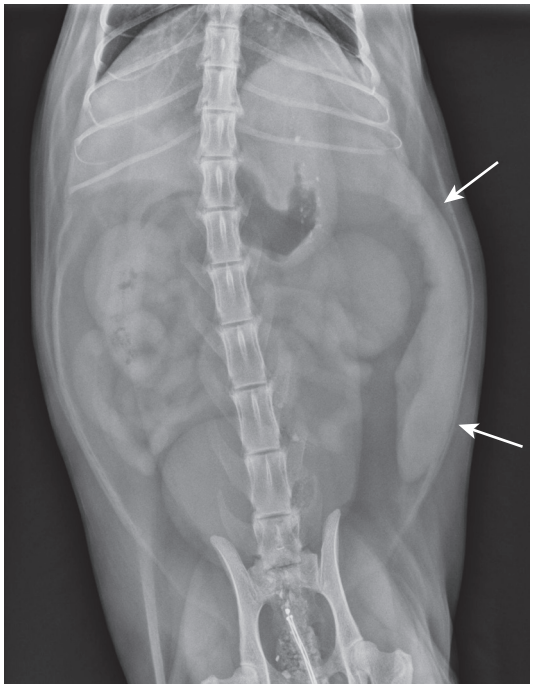

Fig. 58.5 Ventrodorsal abdominal radiograph from an 8-year-old male neutered domestic shorthair cat with hemolytic anemia secondary to *Mycoplasma haemofelis* infection. There is marked splenomegaly *(arrows)*.

TABLE 58.3 Assays Available for the Diagnosis of Hemoplasma Infection

Test	Specimen Required	Advantages	Disadvantages
Cytology	Thin blood smear of diagnostic quality stained with Diff-Quik, Wright stains, etc.	Results obtained very quickly Can be done at POC	Very limited sensitivity and specificity Requires PCR to confirm infecting species
PCR	EDTA-whole blood	High sensitivity and specificity Can identify infecting species If quantitative, may be used to monitor response to treatment	Expensive Not currently available as POC test with lag phase for results depending on turnaround time of PCR laboratory. (A POC test that uses isothermal non-quantitative amplification of DNA has been recently described to diagnose *Mycoplasma haemofelis* infection, but its sensitivity is variable)
Serology	Serum or plasma	May identify potential "carrier" cats May be more sensitive than PCR	Seropositive cats may not be actively infected with hemoplasmas Cross-reactivity between species Not currently available commercially

EDTA, ethylenediaminetetraacetic acid; *PCR,* polymerase chain reaction; *POC,* point of care.

and real-time quantitative PCR (qPCR), which are generally based on detection of segments of the 16S rRNA gene. When properly designed and executed, PCR is far more sensitive than cytology, although PCR may not detect organisms in some subclinical carrier cats that have very low numbers of organisms in the blood, below the detection limit of the PCR assay. Some hemoplasma PCR assays have been duplexed with a host housekeeping gene PCR, targeting the 28S rRNA gene[80] or glyceraldehyde-3-phosphate dehydrogenase gene[37]; the inclusion of such an internal control is important in order to identify false-negative results for hemoplasma infection due to the failure of DNA extraction, presence of PCR inhibitors, or setup errors. qPCR assays can enable the course of hemoplasma infection to be monitored, and permit evaluation of response to antimicrobial treatment. The fluctuations in blood organism numbers that can occur during acute *M. haemofelis* infection (see Fig. 58.4) should be considered when interpreting qPCR results, as decreases in organism number cannot always be deemed a consequence of effective antimicrobial treatment or host immune response. Because of the subclinical carrier state, a positive PCR result should be interpreted in light of clinical signs, clinicopathologic results, and any concurrent disease or immunosuppression present. The pathogenicity of the infecting hemoplasma detected should also be considered when deciding whether the positive PCR result represents the cause of the animal's signs.

A POC machine using isothermal nonquantitative amplification of DNA to diagnose *M. haemofelis* infection has been evaluated in a small study.[81] However, the technique requires in-house extraction of DNA from blood. The type of extraction kit used affects the sensitivity of the assay, which will need to be taken into account during interpretation.

TABLE 58.4 Suggested Antimicrobial Drug Dosages for Treatment of Hemoplasmosis in Cats[a]

Drug	Dose (mg/kg)	Route	Frequency	Notes/Comments
Doxycycline	5 10	PO PO	q12h q24h	First-line agent. Can be associated with gastrointestinal adverse effects, and esophagitis if incompletely swallowed
Marbofloxacin	2–5.5	PO	q24h	First-line agent. May be used in combination (sequentially) with doxycycline to clear *Mycoplasma haemofelis* infection[126]
Pradofloxacin	3–5	PO	q24h	Second-line agent. May be more efficacious at clearing *M. haemofelis* infection than doxycycline
Enrofloxacin	5	PO	q24h	Second-line agent. However, potential for irreversible retinal toxicity in cat as idiosyncratic reaction

[a]Drug availability and licensed dose rate may vary by country.

Serology

ELISAs that detect antibodies to an immunodominant protein of *M. haemofelis*, DnaK, have been developed (see Fig. 58.4).[82,83] Serologic cross-reactivity occurs to this antigen for all three feline hemoplasma species,[82] so the assay does not discriminate between infection with *M. haemofelis* and other hemoplasmas. Determination of acute and convalescent titers may be helpful to distinguish acute from chronic infection. Another study found that a similar serologic assay was more sensitive than PCR in detecting exposure to "*Ca.* M. turicensis."[83] Further work is required to determine the specificity of these assays before they can be made available commercially. Currently serologic assays are available only on a research basis.

Pathologic Findings

Generalized pallor, splenomegaly, and, in some cats, icterus are the main gross necropsy finding in cats that die or are euthanized as a result of hemoplasmosis. Histopathologic findings include extramedullary hematopoiesis, follicular hyperplasia, and splenic erythrophagocytosis.

TREATMENT

Both supportive and specific treatment is indicated for cats and dogs with clinical signs and clinicopathologic abnormalities consistent with hemoplasmosis. Clinical improvement usually occurs within 2–3 days of starting appropriate treatment. However, no antimicrobial treatment regimen exists that is known to predictably eliminate hemoplasma infection with any species.

Specific Therapy

The response of different hemoplasma species, and indeed different strains of the same species, to antimicrobials during infection varies. A number of antimicrobials (Table 58.4), notably tetracyclines[59,84] and fluoroquinolones,[84–88] can reduce hemoplasma organism numbers in cats and dogs, although the vast majority of studies published only examine *M. haemofelis* infection. Doxycycline is often used to treat hemoplasmosis as a first-line agent (see Chapter 10 for information on doxycycline). Because of the possibility of esophagitis in cats, administration of the hyclate preparation of doxycycline should always be followed by food or water. Fluoroquinolones are an alternative; marbofloxacin and pradofloxacin,[88] when available, are both efficacious. Enrofloxacin is also usually effective,[89] but caution must be exercised with its use in cats as it has been, rarely, associated with diffuse retinal degeneration and acute-onset irreversible blindness as an idiosyncratic reaction. Antimicrobials are typically given for 2–4 weeks, with longer treatment courses (e.g., 6–8 weeks) recommended by some to increase the likelihood of elimination of infection, although longer treatment courses still do not guarantee elimination. Azithromycin was not effective in one study of cats infected with *M. haemofelis* and/or "*Ca.* M. haemominutum."[78] Some cases appear to be refractory to standard antimicrobial treatments, and in one *M. haemocanis* case report[58] oxytetracycline, and subsequent enrofloxacin, treatment did not markedly reduce organism numbers, although clinical signs did improve.

A treatment protocol for clearance of chronic *M. haemofelis* infection has been described, with recrudescence of infection not induced following attempts at immunosuppression with methylprednisolone. The protocol comprised a course of doxycycline (5 mg/kg, PO, q12h for 4 weeks), followed by a course of marbofloxacin (2 mg/kg, PO, q24h for 2 weeks) for cats that remained positive by qPCR (as determined by repeated testing on multiple occasions). Treatment breaks of up to 4 weeks between the courses of antimicrobials did not influence the outcome.

Ideally, response to antimicrobials should be monitored by qPCR to ensure organism numbers are decreasing with therapy, or if clearance

of infection is being attempted as described above, as response to treatment is not predictable. However, repeat qPCR may not be necessary if the patient shows a rapid and favorable clinical response to treatment. Repeat hematology profiles should also be performed.

Supportive Care

Affected dogs and cats may also require supportive treatment with IV fluid therapy to correct dehydration, or blood products to provide oxygen-carrying capacity. Anemic dogs and cats with signs consistent with decompensated anemia (tachycardia, weakness, tachypnea, metabolic acidemia) are best treated with a packed RBC, or whole blood, transfusion. Oxygen therapy can be provided pending stabilization of the patient's oxygen-carrying capacity.

Administration of glucocorticoids to cats and dogs with suspected hemoplasmosis is controversial. Their efficacy is unproven, they are not required for a clinical response, and immunosuppressive doses of glucocorticoids have been used experimentally to enhance bacteremia and induce reactivation of latent infection. However, they may be necessary in cats that fail to respond to antimicrobial therapy alone, or when the diagnosis is uncertain, and if erythrocyte-bound antibodies are identified.

PROGNOSIS

The prognosis for hemoplasmosis in cats and dogs is generally good if effective treatment is instigated promptly. Some cases are refractory to initial antimicrobial therapy, necessitating alternative antimicrobial treatments. Additionally, some animals remain hemoplasma carriers following recovery, and recrudescence of disease is possible months or years later.

IMMUNITY AND VACCINATION

Limited information is available in regard to the immune response to hemoplasma infection, and no vaccines are available. Studies of serum cytokine levels during acute infection have resulted in conflicting results regarding Th1 versus Th2 responses.[77,90,91] *M. haemofelis*– and "*Ca.* M. turicensis"–recovered cats are protected against rechallenge, but this protection is independent of an anti-DnaK humoral immune response.[90,91] "*Ca.* M. turicensis"–recovered cats are not protected against *M. haemofelis* challenge, and become PCR positive significantly earlier than the naïve cats, suggesting possible antibody-dependent enhancement.[77] The lack of cross-protection is supported by the frequent identification of co-infections with multiple hemoplasma species during prevalence studies. Furthermore, passive immunization via transfusion of a small volume of pooled plasma from *M. haemofelis*–recovered cats failed to provide immunity to infection with *M. haemofelis* and may exacerbate clinical disease.[92]

PREVENTION

Blood donors should be screened for hemoplasma infection by PCR to help prevent inadvertent transmission by blood transfusion from carrier cats or dogs. As the carrier status cannot be definitively eliminated, infected individuals should not be considered as potential future donors.

Avoidance of potential risk factors are also likely to prevent infection. This includes restriction of outdoor access; prevention of aggressive interactions among cats; and, in view of the potential for vector transmission, preventative flea and tick treatment.

PUBLIC HEALTH ASPECTS

Infections have been described in humans with novel hemoplasma species,[93,94] as well as species that have possibly originated in animals such as the cat,[95] pigs,[96–98] sheep,[93,99] or dogs,[100] raising the possibility of zoonotic infections. However, identification of the DNA of animal hemoplasmas in humans should be viewed cautiously in some of these studies because only a small portion or portions of the hemoplasma genome was detected. Furthermore, application of molecular diagnostic methods to archived human blood smears believed to contain hemoplasmas based on cytologic evaluation yielded negative results, suggesting the possibility of historical misdiagnosis.[101] Limited PCR-based human epidemiologic studies have failed to detect significant infections; although human hemoplasma infection has been reported in China, these studies have not described clinical disease.

Available case reports suggest that hemoplasma-associated disease is more likely in immunocompromised individuals. Until further information is available, veterinarians should handle blood from animals with caution, particularly those with impaired immune systems.

CASE EXAMPLE

Signalment

"Shadow," an 8-year-old male neutered domestic shorthair cat from Fairfield, CA.

History

Shadow was an indoor-outdoor cat that was acquired as a stray kitten from the owner's backyard. There had been no previous history of illness.

Shadow was brought to the University of California, Davis, Veterinary Medical Teaching Hospital emergency service for treatment of severe anemia. The owners reported that he had disappeared 5 days previously. He was found splayed across a fence and was unwilling to move, and vocalizing and salivating profusely. He was immediately taken to a local emergency clinic where he was found to be obtunded, pale, and severely dehydrated. His pulse was 180 beats/minute, respiratory rate was 60 breaths/minute, and temperature was 94.0°F (34.4°C). His systolic blood pressure was 80 mmHg. PCV was 12%. Shadow's condition was stabilized after treatment with supplemental oxygen, active warming, and IV crystalloid fluids (Normosol-R, 50 mL over 30 minutes, then 25 mL/hour). He tested negative for FIV antibody and FeLV antigen with an in-practice ELISA assay.

Physical Examination

Body weight/condition: 6 kg; BCS 7/9.

General: Obtunded, laterally recumbent. T = 97.8°F (36.6°C), HR = 150 beats/minute, RR = 60 breaths/minute, purring, pale and tacky mucous membranes with no detectable capillary refill, weak pulses.

Integument: No ectoparasites were noted. The pinnae and ventral abdominal skin were icteric.

Eyes, ears, nose, and throat: Moderate dental calculus was present. Pallor and mild icterus of the mucous membranes, nictitans, and sclera were noted (Fig. 58.6).

Cardiovascular: Weak pulses. No other clinically significant abnormalities were detected. No murmurs were detected, but the heart sounds were difficult to auscultate because of persistent purring.

Respiratory: Tachypneic; auscultation was limited because of purring.

GI and genitourinary: Nonpainful abdomen. Moderate cranial organomegaly. Urinary bladder not palpable.

Neurologic: A full neurologic examination was not performed, but no abnormalities were detected on examination of cranial nerve functions.

Lymph nodes: No clinically significant abnormalities detected.

Continued

CASE EXAMPLE—cont'd

Laboratory Findings

PCV/TPP: 14%/7.3 g/dL; icteric plasma.

Saline slide agglutination test: Negative.

Blood smear examination: Marked polychromasia, normoblastosis, and mild anisocytosis were present. Coccoid bodies that resembled hemoplasmas were present in association with erythrocytes (see Fig. 58.1).

Electrolyte/acid-base panel (venous blood): HCO_3 = 14 mmol/L, pH = 7.365, pCO_2 = 21.9 mmHg, pO_2 = 35.4 mmHg, Hb = 2.8 g/dL, O_2 = 59.5%, potassium = 4.0 mmol/L, sodium = 144 mmol/L, ionized calcium = 1.2 mmol/L, glucose = 157 mg/dL, lactate = 8.4 mmol/L, base excess = –12.2 mmol/L.

Imaging Findings

Thoracic radiographs: No clinically significant abnormalities were detected.

Abdominal radiographs: The spleen was markedly enlarged (see Fig. 58.5). The liver was mildly enlarged. Small mineral densities were present within ingesta and feces in the stomach and colon, respectively.

Treatment

The cat was placed on a heating pad and transfused with 1 unit of packed RBC, and supplemental oxygen was administered, after which HR increased to 200 beats/minute and RR decreased to 40 breaths/minute. Rectal temperature increased to 103.7°F (39.8°C) during the transfusion, and so dexamethasone was administered because of the concern for a transfusion reaction (0.2 mg/kg, IV, once). The cat was also treated with enrofloxacin (5 mg/kg, IV, q24h) (see Comments below) for suspected hemoplasmosis. The results of laboratory testing after transfer to the internal medicine service the day after admission are shown here.

CBC post-transfusion and antimicrobial treatment (reference interval): HCT 12.7% (30%–50%), MCV 76.5 fL (42–53 fL), MCHC 26.8 g/dL (30–33.5 g/dL), reticulocytes 155,600 cells/μL (7,000–60,000 cells/μL), nucleated RBC 39/100 WBC (0/100 WBC), corrected WBC 9,800 cells/μL (4,500–14,000 cells/μL), neutrophils 8,134 cells/μL (2,000–9,000 cells/μL), band neutrophils 98 cells/μL, lymphocytes 784 cells/μL (1,000–7,000 cells/μL), monocytes 784 cells/μL (50–600 cells/μL), eosinophils 0 cells/μL (150–1100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 142,000/μL (180,000–500,000 platelets/μL).

Cytologic examination: Marked anisocytosis, marked polychromasia, few Howell-Jolly bodies, and many macrocytes and microcytes. No epierythrocytic organisms were identified.

Serum chemistry profile (reference interval): Sodium 143 mmol/L (151–158 mmol/L), potassium 5.2 mmol/L (3.6–4.9 mmol/L), chloride 107 mmol/L (117–126 mmol/L), bicarbonate 11 mmol/L (15–21 mmol/L), phosphorus 6.6 mg/dL (3.2–6.3 mg/dL), calcium 9.6 mg/dL (9.0–10.9 mg/dL), BUN 47 mg/dL (18–33 mg/dL), creatinine 1.2 mg/dL (1.1–2.2 mg/dL), glucose 98 mg/dL (63–118 mg/dL), total protein 7.2 g/dL (6.6–8.4 g/dL), albumin 3.0 g/dL (2.2–4.6 g/dL), globulin 4.2 g/dL (2.8–5.4 g/dL), ALT 166 U/L (27–101 U/L), AST 201 U/L (17–58 U/L), ALP 24 U/L (14–71 U/L), GGT 0 U/L (0–4 U/L), cholesterol 75 mg/dL (89–258 mg/dL), total bilirubin 6.1 mg/dL (0–0.2 mg/dL), magnesium 3.4 mg/dL (1.5–2.5 mg/dL), creatine kinase 446 U/L (73–260 U/L).

Urinalysis: SpG 1.040, pH 6, 75 mg/dL protein, no glucose, 5 mg/dL ketones, 6 mg/dL bilirubin, 250 erythrocytes/μL hemoprotein, 0-1 RBC/HPF, 0 WBC/HPF, rare transitional epithelial cells.

Fig. 58.6 Mild icterus of the nictating membrane in an 8-year-old male neutered domestic shorthair cat with hemolytic anemia secondary to *Mycoplasma haemofelis* infection.

Microbiologic testing: Real-time PCR (using blood smears on admission, pretreatment) for *M. haemofelis*, "*Ca.* M. haemominutum", and "*Ca.* M. turicensis": positive for *M. haemofelis* DNA.

Diagnosis

Anemia due to *M. haemofelis* infection.

Additional Treatment and Outcome

Treatment was changed to doxycycline (10 mg/kg, PO, q24h, followed by 5 mL of water for 3 weeks). Treatment with IV crystalloid fluids was continued and oxygen supplementation was discontinued. Two days after admission, the PCV was 16% and the cat became fear aggressive and began eating. The cat was discharged the following day with a PCV of 18%, and a recheck at the local veterinary clinic that included a CBC was recommended 1 week later. The owner subsequently elected to house Shadow indoors.

Comments

This represents a typical case of hemoplasmosis in a male, neutered cat with access to the outdoors. Specific testing for hemoplasmas with PCR was performed on blood smears because treatment with packed RBC and antimicrobials had been initiated immediately on admission and whole blood was not saved before treatment was instituted. Although PCR on blood smears has lower sensitivity than when whole liquid blood is used, in this case sufficient organisms were present to generate a positive result, which confirmed the diagnosis of hemoplasmosis. Because the cat was hypovolemic on admission, parenteral antimicrobial treatment was chosen. Subsequently, treatment with oral doxycycline was initiated. Although continued treatment with oral enrofloxacin may have been a suitable alternative to doxycycline, retinal degeneration was a possible adverse effect of continued treatment with enrofloxacin, as well as enrofloxacin ideally being reserved as a second-line antimicrobial agent. Retesting for retroviruses was indicated 2 months after the first test was performed at the local veterinary clinic, as the cat may have been exposed to retroviruses but not yet have developed positive test results (see Chapters 32 and 33).

TPP, total plasma protein

Actinomycosis

Jane E. Sykes

KEY POINTS

- First Described: Actinomycosis was first described in cattle in 1877 (Otto Bollinger, Germany).[1]
- Causes: *Actinomyces* spp. (and to a lesser extent, other related species such as *Trueperella* spp. and *Arcanobacterium* spp.).
- Geographic Distribution: Worldwide, but especially from regions where grass awns are prevalent.
- Mode of Transmission: Opportunistic invasion of commensal bacteria following disruption of cutaneous or mucosal barriers.
- Major Clinical Signs: Subcutaneous masses and draining skin lesions (cervicofacial and cutaneous-subcutaneous disease); pulmonary nodules, masses and/or effusion with cough and tachypnea (thoracic disease); abdominal effusion or masses (abdominal disease); thoracolumbar pain or pelvic limb paresis/paralysis (retroperitoneal disease); rarely neurologic signs due to meningitis or brain abscesses (CNS disease).
- Differential Diagnoses: Infections caused by *Mycobacterium*, *Nocardia*, *Bartonella*, and fungal pathogens; chronic bacterial osteomyelitis caused by typical bacterial species; neoplasia.
- Human Health Significance: Direct transmission of disease from animals to humans does not occur, but humans have developed disease after bites from healthy dogs or cats.

ETIOLOGIC AGENTS AND EPIDEMIOLOGY

Actinomycosis is typically a slowly progressive infection caused by anaerobic or microaerophilic, filamentous, gram-positive bacteria that belong to the genus *Actinomyces,* and to a lesser extent, species that now have been recently assigned to genera such as *Arcanobacterium* and *Trueperella* (additional species that cause disease in humans belong to the genera *Actinobaculum* and *Cellulomonas*). *Actinomyces* spp. are normal inhabitants of mucous membranes, especially of the oropharynx, but also the genital and GI tracts, and cause opportunistic infections. Together with other oral commensal bacteria, actinomycetes colonize the periodontal mucosal surfaces and adhere to the tooth surface to form plaque. Numerous *Actinomyces* species have been cultured from the mucous membranes (e.g., gingiva, vaginal vault), dental plaque, and saliva of healthy dogs and cats. It is important to recognize that *Actinomyces* spp. have never been cultured from the environment, and disease is not transmitted from one animal to another.

Usually, actinomycosis develops when *Actinomyces* spp. that reside in association with mucous membranes are inoculated into tissues along with other bacteria, often as a result of a deeply penetrating wound or foreign body migration. Organisms isolated from lesions of dogs and cats with actinomycosis are shown in Table 59.1. Young adult to middle-aged large-breed dogs that have access to the outdoors are often affected, especially retriever and hunting breeds.[2,3] There is no clear sex predisposition, and the median age of dogs with actinomycosis is approximately 5 years.[4] Actinomycosis in outdoor dogs is often related to exposure to penetrating plant foreign bodies such as grass awns. In cats, actinomycosis usually follows bite wounds, and so is more commonly diagnosed in male cats.[4,5] In the author's hospital, 11 of 17 cats with actinomycosis were male. However, underlying retroviral infection is uncommonly present and does not appear to predispose to disease.

Because *Actinomyces* species are difficult to culture and are susceptible to antimicrobial drugs that are often used empirically, the prevalence of actinomycosis in dogs and cats has probably been underestimated.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Actinomycosis occurs following disruption of mucosal barriers. After ingestion or inhalation, plant awns may become contaminated with *Actinomyces* spp. and other bacteria from the oropharynx, after which the awns migrate to various sites and act as a nidus of infection. Alternatively, organisms may be introduced into tissues at the time of a bite wound injury. The latter is the most common route of infection in cats, and can manifest as pyothorax, peritonitis, or cellulitis.[4,5] The presence of associated aerobic and anaerobic bacteria from the oral cavity or intestinal tract ("companion microbes") undermines normal host defenses and reduces oxygen tension, which allows *Actinomyces* spp. to persist. *Actinomyces* spp. that possess fimbriae can bind to specific cell surface receptors on other bacteria, especially streptococci.

TABLE 59.1 *Actinomyces* and *Arcanobacterium* Species Isolated from Dogs and Cats with Actinomycosis

Dogs	Cats
Actinomyces viscosus[12,16,31]	*Actinomyces viscosus*[24,56]
Actinomyces bowdenii[46]	*Actinomyces bowdenii*[46]

Trueperella pyogenes[a,27]	

[a]Previously *Arcanobacterium pyogenes.*

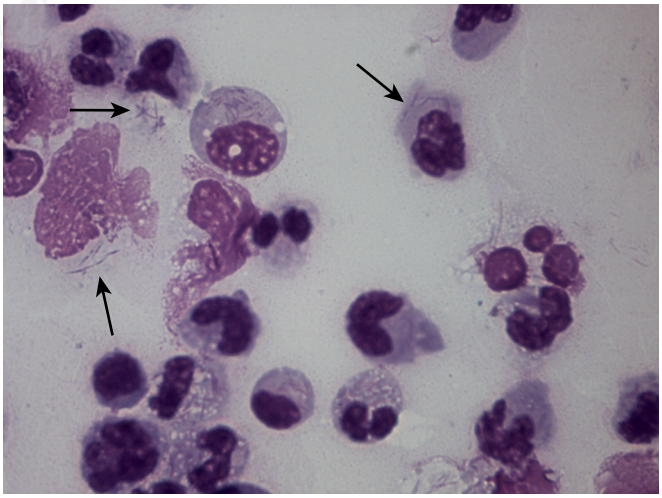

Fig. 59.1 Abdominal fluid cytology from a 3-year old male neutered domestic longhair cat with a 1-week history of progressive lethargy and anorexia, ascites, hyperbilirubinemia, and hypoproteinemia. Total protein was 2.2 g/dL and there were 75,500 nucleated cells/μL, with 92% neutrophils and 8% large mononuclear cells. High numbers of moderately degenerative neutrophils are present with low numbers of macrophages. Moderate numbers of filamentous beaded bacteria are present both in the background and within phagocytes *(arrows)*. *Actinomyces* spp. and *Fusobacterium nucleatum* were isolated from the peritoneal fluid. Necropsy revealed severe, chronic peritonitis with intralesional filamentous bacteria.

This bacterial co-aggregation inhibits the ability of neutrophils to phagocytize the organisms.[6] Dense colonies of *Actinomyces* spp. form, and these, together with other associated bacteria, are surrounded by neutrophils, macrophages, and plasma cells, with slowly progressive pyogranulomatous inflammation (Fig. 59.1). Large aggregations of organisms can lead to formation of "sulfur granules," tan to yellow colonies of actinomycetes, which may be microscopic or visible grossly. Proteolytic enzymes from the associated bacteria, macrophages, and degranulated neutrophils destroy connective tissue, which facilitates extension of the disease through normal tissue planes. Less often, organisms spread hematogenously to distant sites. In some cases, the inflammatory reaction is accompanied by mass formation and extensive fibrosis. The center of the lesions may eventually suppurate and soften, or draining tracts may develop. The tracts can close and reappear over weeks to months as infection gradually spreads through tissues.

The most common clinical forms of actinomycosis in cats and dogs involve the cervicofacial region, thorax, abdomen, and subcutaneous tissue, but CNS (meningitis and meningoencephalitis) and ocular infections (keratitis and endophthalmitis) can also occur.[7–9] *Cervicofacial actinomycosis* can follow bite wounds, perforation of the oropharynx by a foreign body, or chronic periodontal disease. The mandibular, submandibular, and ventral or lateral cervical areas are most frequently affected, but infections that involve the face, retrobulbar space, and temporal area can occur (Fig. 59.2A and B). *Cutaneous-subcutaneous actinomycosis* typically involves the lateral thoracic wall, flank region, and occasionally the limbs. Cutaneous lesions involving the thoracic or abdominal walls may represent extensions of thoracic, abdominal, or retroperitoneal actinomycosis.

Thoracic actinomycosis may be limited to the lung parenchyma but can involve other structures within the thorax, such as the mediastinum, pleura, pericardium, and chest wall. It follows aspiration of oropharyngeal material, often together with a contaminated grass awn. Alternative routes of thoracic infection include involvement of the mediastinum from esophageal perforation or direct extension of subcutaneous or abdominal disease. Clinical signs include cough and less commonly hemoptysis, tachypnea, dyspnea, decreased lung sounds (as a result of pyothorax or mass lesions), and subcutaneous soft tissue masses or draining skin lesions on the lateral thoracic wall. Sometimes there is a history of neck pain, gagging, or hypersalivation prior to the onset of tachypnea, possibly as a result of passage of a penetrating foreign body.

Abdominal actinomycosis develops when foreign bodies penetrate the GI mucosa, which leads to the formation of intraabdominal mass lesions and ascites.[2,10–12] Abdominal involvement may also follow direct extension from subcutaneous tissues or hematogenous spread of the organism to abdominal organs such as the liver. Although dogs are more often affected than cats, intraabdominal actinomycotic masses can occur in cats.[13–15] *Retroperitoneal actinomycosis* in dogs often follows the migration of plant awns through the lung and up the crus of the diaphragm to its dorsal attachment. Initially, fever of unknown origin may be the only clinical signs. Ultimately, progression can lead to osteomyelitis and compression fractures of the vertebral bodies, with spinal pain and paresis or paralysis of the pelvic limbs (Fig. 59.3).[16–18]

Actinomycosis of the brain and meninges in dogs can also occur (Fig. 59.4).[19–22] Brain abscesses may follow hematogenous dissemination from a distant site, or meningitis may result from extension of infection from an adjacent focus, such as the middle ear or skull.[21,23] In humans, risk factors for CNS actinomycosis include dental disease or tooth extraction, head trauma, GI tract surgery, and chronic otitis, mastoiditis, or sinusitis. CNS actinomycosis has been reported in dogs in association with concurrent otitis media/interna,[22] head trauma,[20] and in cats in association with retrobulbar abscesses[23] and cutaneous abscesses of the tail base.[24,25]

Rarely, infections of the urinary bladder,[26,27] gall bladder,[28,29] gastric wall,[15] and heart valve[30–33] have been recognized in dogs, cats, and human patients. One cat with actinomycotic rhinitis and optic neuritis was reported.[34]

Physical Examination Findings

Lesions in dogs and cats with cervicofacial or cutaneous-subcutaneous actinomycosis may be fluctuant or firm, indurated, have draining sinuses, and/or rarely be ulcerated. Pain and fever are variable. Thoracic or abdominal actinomycosis is often accompanied by a thin body condition and fever. Dogs and cats with thoracic actinomycosis may show tachypnea or dyspnea, and thoracic auscultation may reveal decreased lung sounds if pyothorax or severe pleuritis is present. Abdominal masses and/or ascites may be detected on abdominal palpation of dogs with abdominal actinomycosis. Dogs with retroperitoneal actinomycosis may show pain on palpation of the abdomen or lumbar spine, and when severe, signs of pelvic limb paralysis or paresis may be present, such as pelvic limb ataxia, deficits of conscious proprioception, increased segmental reflexes, and loss of pain sensation. Neurologic signs associated with *Actinomyces* meningitis or encephalitis include altered behavior, decreased consciousness, cervical pain, vision loss, ataxia, tetraparesis, and seizures.

DIAGNOSIS

It has been recommended that actinomycosis be considered as a diagnosis when one or more of three clinical features are present: (1) a combination of chronicity, progression across tissue boundaries, and mass-like features that resemble neoplasia; (2) the presence of a sinus tract, which may spontaneously resolve and reappear; (3) a refractory or relapsing infection after a short course of antimicrobial therapy, because cure requires prolonged treatment.[35] Historically, in the

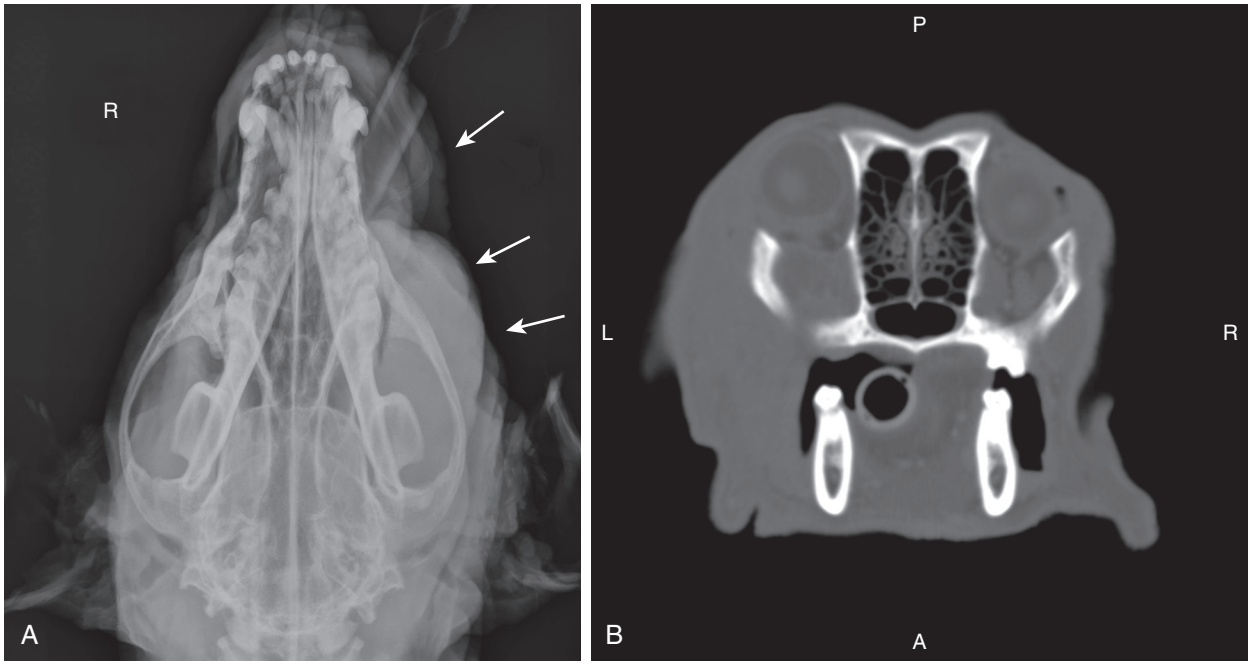

Fig. 59.2 Cervicofacial actinomycosis. (A) Skull radiograph and (B) computed tomography scan from an 8-year old female spayed Labrador retriever with slowly progressive, left-sided facial swelling. There is severe, regional soft tissue swelling over the left side of the face, which involved the left masseter muscle and zygomatic salivary glands, and extended into the retrobulbar space, with secondary exophthalmos *(arrows)*. Multiple premolars and molars of the left maxillary arcade were missing. Biopsy of the lesion revealed severe, diffuse, pyogranulomatous cellulitis with intralesional gram-positive, acid-fast negative bacilli. Culture yielded *Actinomyces hordeovulneris* (based on 16S rRNA gene sequencing), *Pasturella multocida* subsp. *multocida, Neisseria canis* (based on 16S rRNA gene sequencing), and an *Eikenella*-like organism.

Fig. 59.3 Left lateral spinal radiograph from a 3-year-old female Border collie with retroperitoneal actinomycosis. The dog was seen for a 3-day history of lethargy, fever, apparent abdominal pain, and progressive pelvic limb paresis. Severe, smoothly marginated ventral spondylosis bridges the L1-L4 space. There is also marked irregular osteolysis of the 2nd, 3rd, and 4th lumbar vertebrae. There is destruction of the floor of the ventral canal. There is loss of visualization, narrowing, and irregularity of the intervertebral disc spaces at L2-3 and L3-4. There is marked loss of detail within the retroperitoneal space and the colon appears displaced slightly ventrally. Small irregular mineral foreign bodies are present within the stomach and colon.

human literature, actinomycosis has been referred to as the "most misdiagnosed disease."[36] Fibrous masses are frequently mistaken for neoplastic lesions, although reports of *Actinomyces* spp. infections that complicate neoplasia exist in human medicine.[37,38] Aspiration of firm lesions is often unrewarding, organisms are often difficult to isolate from lesions, and short periods of antimicrobial drug treatment are ineffective, which all serve to further mislead the clinician to a diagnosis of neoplasia. Actinomycosis should be considered on the list of differential diagnosis in any animal with a history of penetrating plant awn foreign bodies, draining skin lesions, chronic fibrous masses, persistent bite wounds, pyothorax, retroperitoneal abscesses, and focal neurologic signs, especially when young adult to middle-aged dogs are affected. Ultimately, diagnosis is based on clinical signs, identification of organisms with typical morphology with cytology or histopathology, and culture.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Animals with extensive, chronic disease may have mild to moderate nonregenerative anemia, leukocytosis with a mild to moderate left shift and monocytosis, hypoalbuminemia, and hyperglobulinemia, which may be marked. Dogs with body cavity effusions may be hypoglycemic. There are usually no specific urinalysis findings.

Cytologic Examination of Body Fluids

Cytologic examination of aspirates of abscesses, effusions, or CSF typically reveals a suppurative to pyogranulomatous inflammatory response (>75% neutrophils). Total protein in pleural fluid is generally > 3.0 g/dL, with erythrocyte and nucleated cell counts often > 70,000 cells/μL. CSF from dogs and cats with cerebral actinomycosis may resemble pus grossly. Aspirates of firm masses may yield only blood. Sulfur granules may be visible in effusion fluid or draining purulent material from cutaneous lesions macroscopically, as white to tan to gray granules, or microscopically as dense clusters of organisms. When bacteria are visualized, they may be filamentous rods suggestive of *Actinomyces* spp., or "companion" microorganisms. The actinomycetes are gram-positive, non-acid-fast filamentous organisms that are

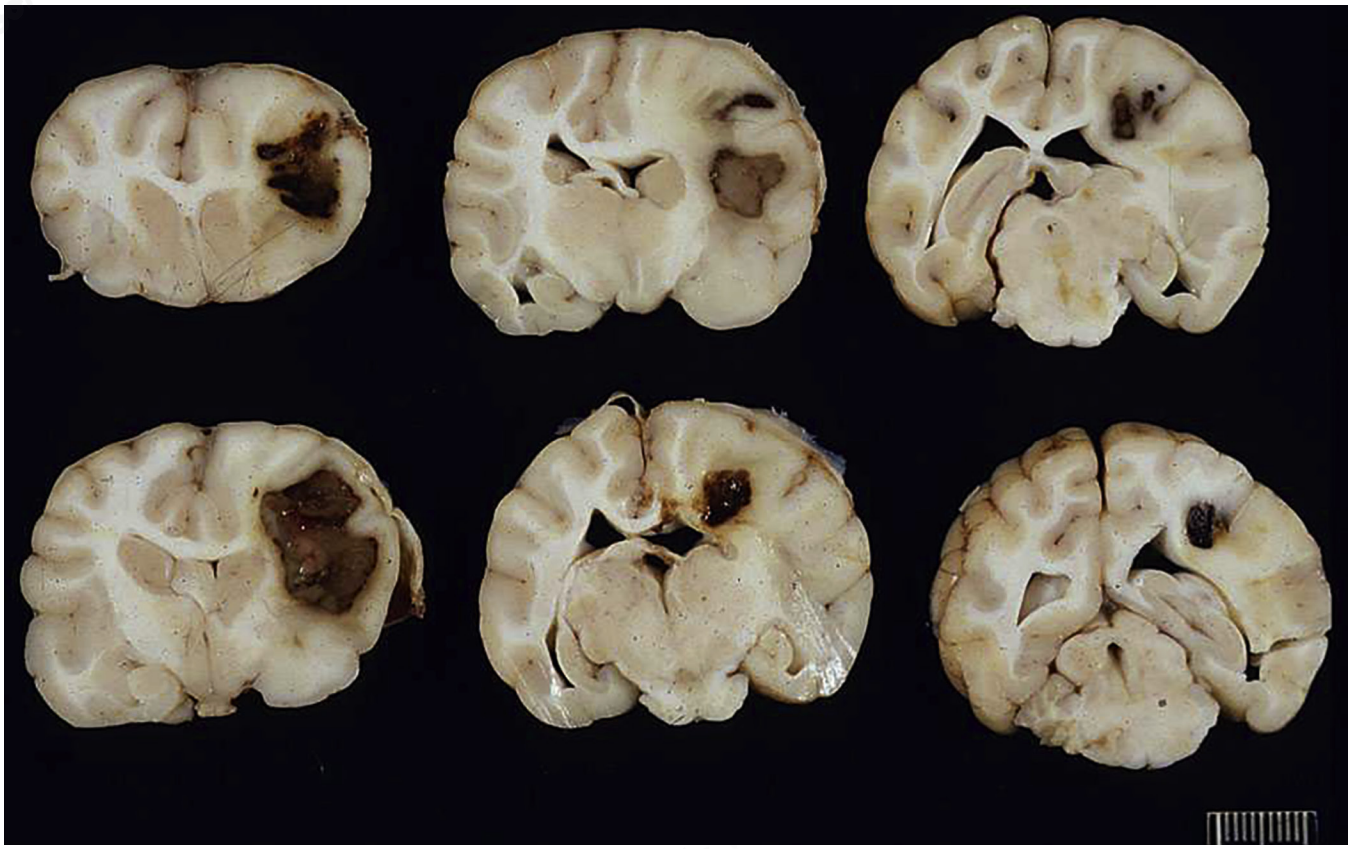

Fig. 59.4 Necropsy findings in a 1-year-old male neutered Yorkshire terrier with suspected CNS actinomycosis. Three weeks previously, surgery to correct an extrahepatic portosystemic shunt and remove a urate cystolith had been performed. The dog's appetite and activity level did not improve after the surgery, and for the week before the dog was reexamined, disorientation and weakness was noted. The dog deteriorated rapidly after it was hospitalized and euthanasia was performed. Osteogenesis imperfecta of the occipital bones was present and three separate abscesses were found in the left cerebral cortex. Histopathology revealed neutrophilic inflammation, hemorrhage, and granular mats of material that contained gram-positive, acid-fast negative branching bacteria (consistent with *Actinomyces* spp.), as well as a dense population of gram-negative, Giemsa-positive cocci. (Image courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

occasionally branched. The filaments are less than 1 μm wide, vary in length, and can stain irregularly, producing a beaded appearance (see Fig. 59.1). *Nocardia*, *Corynebacterium*, and *Mycobacterium* spp. can be confused with *Actinomyces* spp.

Diagnostic Imaging

Plain Radiography

Radiographs of cervicofacial or cutaneous-subcutaneous lesions may show lesions in adjacent bone, such as evidence of osteomyelitis and/or periosteal new bone formation. Pulmonary involvement may manifest as interstitial or alveolar infiltrates, sometimes with consolidation (Fig. 59.5A). Air bronchograms may be seen within mass lesions, suggesting the presence of a non-neoplastic process. Other variable findings include pleural thickening, pleural effusion, widening of the mediastinum, mass lesions, enlargement of the cardiac silhouette (with pericardial involvement), and periosteal new bone formation or osteomyelitis involving adjacent ribs, vertebral bodies, or sternebrae. Dogs with retroperitoneal actinomycosis may have evidence of periosteal new bone formation on the ventral aspects of two or three adjacent vertebral bodies (usually T13 through L4) on abdominal radiography; involvement of disc spaces is uncommon (see Fig. 59.3). Abdominal actinomycosis may be characterized by loss of abdominal detail due to peritoneal effusion and intraabdominal mass lesions.

Sonographic Findings

Ultrasonography can be useful to identify linear grass awn foreign bodies (see Fig. 59.5C).[39,40] Sonographic abnormalities in dogs with abdominal disease include variable amounts of flocculent ascites fluid, abdominal lymphadenopathy, and nodular or mass lesions that incorporate or displace adjacent structures. New bone formation may be detected on interrogation of the ventral aspects of the vertebral bodies during abdominal ultrasound in dogs with retroperitoneal disease.

Advanced Imaging

For animals with CNS involvement, MRI may reveal meningeal thickening, contrast enhancement, and/or intraparenchymal contrast-enhancing mass lesions.[4] MRI may also be useful for detection of grass awn foreign bodies. Advanced imaging allows assessment of the extent of actinomycosis (see Fig. 59.2) which may assist with surgical planning. In human cases, PET-CT with ^{18}F-fluorodeoxyglucose has been useful for diagnosis of actinomycosis and monitoring of response to treatment; evidence of intense hypermetabolism that resembles neoplasia has been associated with lesions.[41,42]

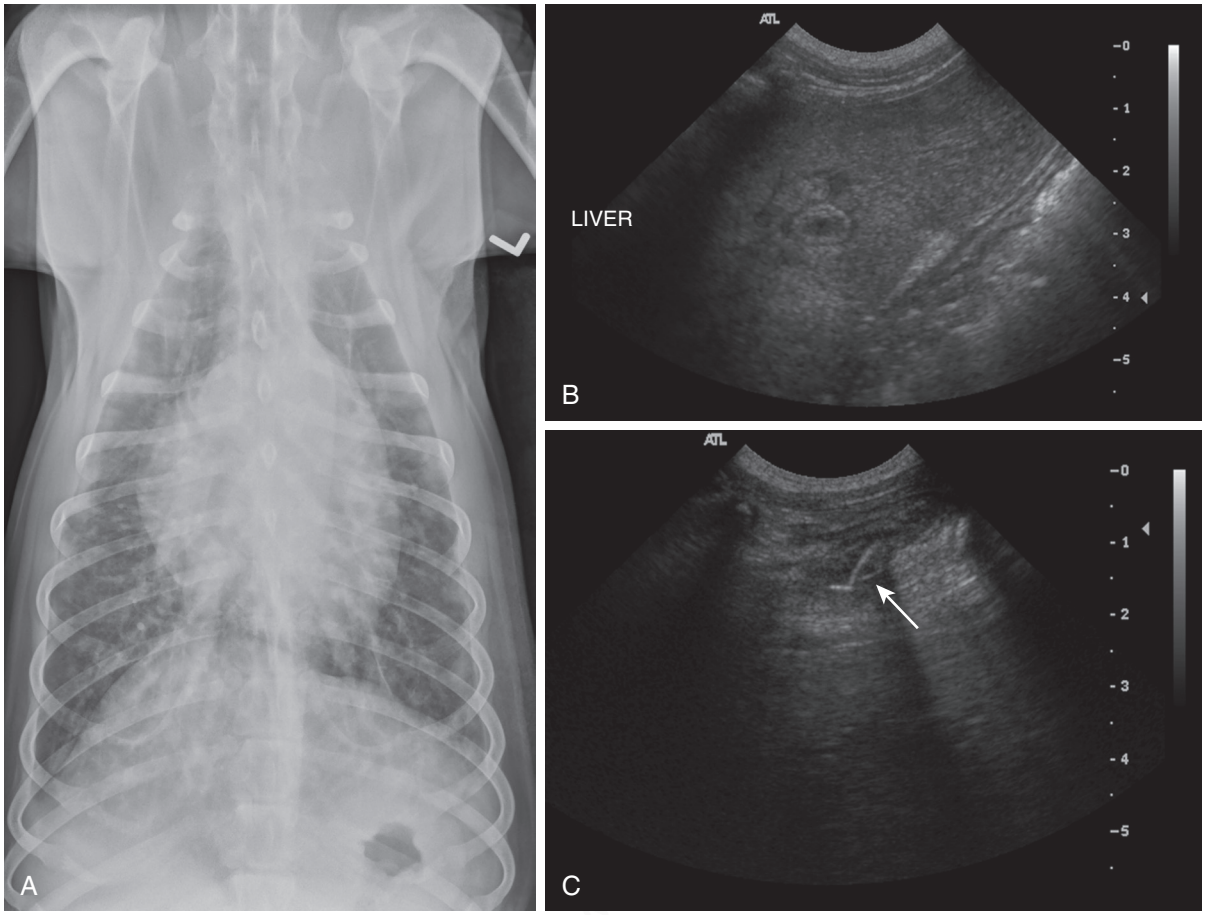

Fig. 59.5 Imaging findings in a 1-year-old female spayed Labrador retriever with systemic actinomycosis secondary to grass awn migration, which manifested as fever and lethargy. (A) Dorsoventral thoracic radiograph. Patchy diffuse interstitial opacities were present in all lung fields. (B) Ultrasound image of the liver. Within the left liver, there were focal, ill-defined heteroechoic or hypoechoic nodules. One of these areas (shown) had a well-demarcated, hyperechoic rim with irregular echogenic luminal contents. The nodules were consistent with multifocal hepatic abscesses. (C) Ultrasound image of the thoracic wall. A linear plant awn foreign body was identified *(arrow)*.

Microbiological Tests (Table 59.2)

Isolation and Identification

Because *Actinomyces* is a commensal of the oral cavity, it is commonly swallowed, inhaled, and transferred by licking; therefore, culture of the organism from the airways, GI tract, or skin does not necessarily constitute infection. Consistent cytologic or histopathologic findings (pyogranulomatous inflammation with or without the presence of filamentous bacteria) and the presence of companion microorganisms supports the diagnosis of actinomycosis.

Specimens for culture can be collected through fine-needle aspiration or, if possible, biopsy. Because *Actinomyces* spp. are exquisitely sensitive to many antimicrobial drugs, treatment of animals before obtaining specimens for culture can also prevent recovery of the organisms. Even a single dose of an antimicrobial can prevent successful isolation. Culture may be negative or yield only companion microorganisms, which may obscure the presence of *Actinomyces* spp.. As a result, diagnosis is often based on cytologic or histologic identification of the organism in specimens from animals with appropriate clinical signs.

Most *Actinomyces* spp. known to cause disease in dogs and cats are facultative anaerobes, but a few *Actinomyces* species are obligate anaerobes (*Actinomyces bovis, Actinomyces israelii, Actinomyces meyeri*).[43–46] Species that are facultatively anaerobic can grow aerobically, and some, such as *Actinomyces viscosus*, grow best in aerobic conditions. In addition, companion microorganisms are often obligate anaerobes or other aerobes, so both aerobic and anaerobic cultures should be requested when *Actinomyces* spp. infections may be present and the laboratory should be notified that *Actinomyces* spp. may be present. Tissue, aspirates of pus, or sulfur granules represent ideal specimens for anaerobic culture; swabs should be avoided.

Visible growth of *Actinomyces* spp. can occur within 48 hours but usually requires 5 to 7 days. It may be necessary to hold plates for 2 to 4 weeks. Species identification using traditional biochemical tests is difficult. PCR and sequence analysis of the 16S rRNA gene may be necessary for precise species identification. In the future, mass spectrometry (MALDI-TOF MS) may prove most useful for identification of *Actinomyces* species (see Chapter 3).[47]

In addition to actinomycetes, one to five other associated bacteria are often recovered from properly handled specimens. The most commonly isolated organisms are resident flora of the oral cavity or intestinal tract and include the anaerobes *Fusobacterium*, *Peptostreptococcus*, *Prevotella*, and *Bacteroides* spp.; and *Pasteurella multocida, Escherichia coli,* and *Streptococcus* spp.. Occasionally, pure cultures of *Actinomyces* spp. are isolated, but this does not exclude the concurrent presence of other organisms, especially strict anaerobes.

TABLE 59.2 Diagnostic Assays Available for *Actinomyces* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Aspirates of purulent material (e.g., abscesses, pleural effusion); whole blood; CSF; tissue specimens obtained by biopsy or at necropsy (e.g., subcutaneous tissue, heart valve, lung tissue); sulfur granules	*Actinomyces* spp.	Some organisms require anaerobic conditions. Requires several weeks' incubation and overgrowth by companion bacteria may occur. Because *Actinomyces* spp. are mucosal commensal bacteria, isolation from contaminated sites does not imply disease causation. PCR and sequencing may be required to identify the species present.
Cytology or histopathology with organism detection using special stains	Aspirates or tissue specimens	*Actinomyces* spp. organisms	Organisms are gram positive, do not take up acid-fast stain, and are often accompanied by other bacteria and sulfur granules. Definitive diagnosis requires culture because *Nocardia* can resemble *Actinomyces* spp.

CSF, cerebrospinal fluid; *PCR,* polymerase chain reaction.

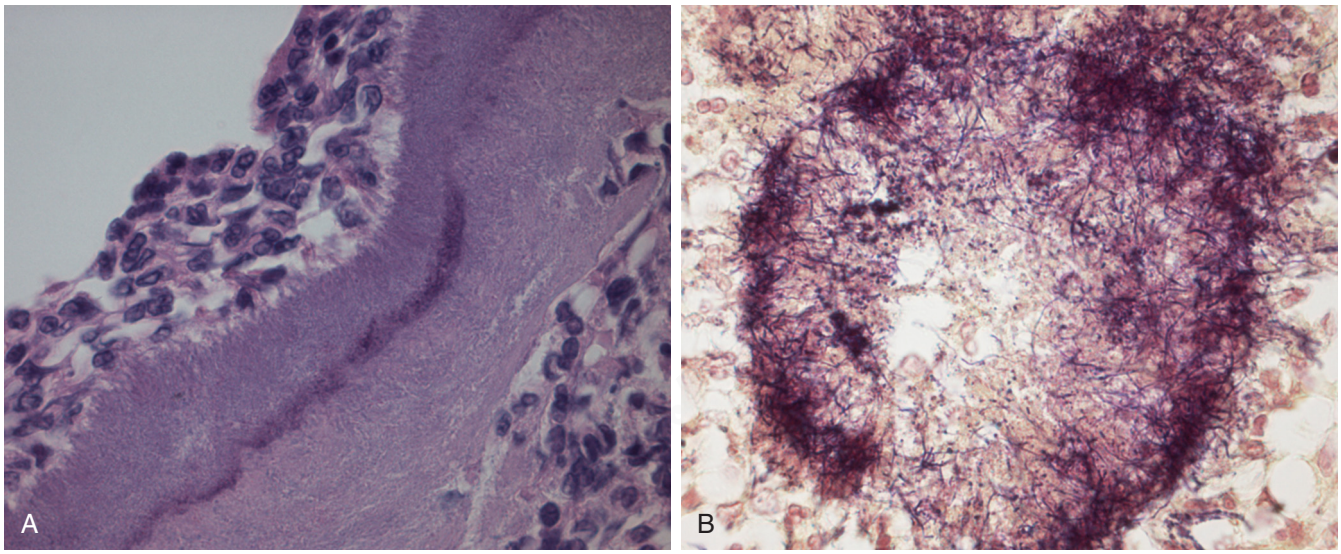

Fig. 59.6 Histopathology of a biopsy specimen from the xiphoid of a 10-year-old intact male English pointer dog with actinomycosis due to a migrating plant awn foreign body. The dog had 1-month history of a ventral thoracic wall mass. (A) Dense, granular mats of branching bacteria were present in a background of extensive granulation tissue and embedded plant material (not shown). H&E stain. (B) Brown and Benn (Gram) stain revealed colonies of gram-positive, filamentous, branching bacteria. *Actinomyces bowdenii* (based on 16S rRNA gene sequencing), *Pasteurella canis*, *Porphyromonas canoris*, *Cutibacterium acnes*, a *Bacteroides gingivalis*-like organism and a *Bacteroides ureolyticus*-like organism were isolated from the lesion.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Specific assays for *Actinomyces* spp. have been developed and used for diagnosis of human actinomycosis[48] but are not commercially available for veterinary diagnosis.

Pathologic Findings

Gross lesions in animals with actinomycosis often consist of one or more poorly defined, indurated masses of the subcutaneous tissues, thoracic cavity, lungs, abdominal cavity, or retroperitoneal space, which incorporate adjacent structures. Masses may contain one or more pockets of a reddish-brown exudate. Fistulas, plant material, and sulfur granules may be found. Abdominal or thoracic effusions are often reddish-brown and may contain sulfur granules. Animals with thoracic and abdominal infections may also have a diffuse, red, velvety to granular thickening of the pleura or peritoneum and omentum. Rarely, abscesses may be present in the brain or there may be evidence of purulent meningitis.

Histopathology of affected tissues reveals abscesses with a core of neutrophils encapsulated by granulation tissue that contains macrophages, plasma cells, and lymphocytes in a dense, fibrous tissue matrix. Suppuration is always present in association with active disease, but some parts of lesions may lack neutrophil presence. When present, sulfur granules are generally in the center of microabscesses, but multiple tissue sections may be needed to find them. In tissue sections stained with H&E, the granules are round, oval, or scalloped amphophilic solid masses (Fig. 59.6A). The granules vary in size (from 30 to 3,000 μm in diameter) and often are rimmed by partially confluent radiating eosinophilic club-shaped structures collectively known as the *Splendore-Hoeppli phenomenon*. This phenomenon can also occur with zygomycosis, sporotrichosis, parasitic infections, foreign body reactions, and hypereosinophilic syndrome.[49,50] Antigen-antibody complexes, complement, and major basic protein of eosinophils have been detected within the Splendore-Hoeppli phenomenon. Special stains (Gram, Giemsa, and silver) are required to stain *Actinomyces* spp., and reveal clumps of tangled, intermittently branched, thin (<1 μm) filaments (Fig. 59.6B). Other nonfilamentous bacteria and/or plant material may also be present. *Actinomyces* are not acid fast. With the rare exception of some *Nocardia* spp. that

TABLE 59.3 Medications That Could Be Used to Treat *Actinomyces* spp. Infections in Dogs and Cats with Actinomycosis

Drug	Dose	Route	Interval (Hours)
Penicillin G	100,000 U/kg	IV, IM	6–8
Ampicillin sodium	20 mg/kg	IV, IM, SC	6–8
Amoxicillin	20 mg/kg	PO	8
Clindamycin[a]	11 mg/kg	PO	12 (dogs), 24 (cats)
Doxycycline[b]	5–10 mg/kg	PO	12–24

[a]For IV administration of clindamycin phosphate, see Chapter 10.
[b]10 mg/kg q12h preferred if tolerated without gastrointestinal adverse effects. Doxycycline or clindamycin should always be administered with a bolus of water to avoid esophagitis.
IM, intramuscular; *IV,* intravenous; *PO,* per os; *SC,* subcutaneous.

Fig. 59.7 A 1-year-old female spayed Labrador retriever with systemic actinomycosis secondary to a plant awn foreign body, after surgical removal of the plant awn and placement of a grenade drain.

are not acid fast, other fungi and bacteria that produce tissue granules can be distinguished from *Actinomyces* based on their staining and morphologic properties.

TREATMENT AND PROGNOSIS

Treatment of actinomycosis usually requires prolonged administration of antimicrobial drugs. Penicillin is the antimicrobial drug of choice because isolates are uniformly susceptible to penicillins (Table 59.3). High-dose therapy for prolonged periods (weeks to months) is generally required for animals with chronic infections and extensive fibrosis. In human patients with actinomycosis, high doses of penicillin are given parenterally for 2 to 6 weeks, followed by oral therapy with amoxicillin for 6 to 12 months.[35] If the animal is stable clinically, oral therapy can be tried from the outset,[11,51] but it should be recognized that weeks of parenteral treatment is strongly recommended for human infections.[35] Treatment must be extended significantly (weeks to months) beyond resolution of measurable disease to prevent relapse; in some cases, treatment for longer than a year may be required.[2,11] However, when actinomycosis is associated with foreign body migration, shorter durations of treatment may be possible if the foreign body is removed, drainage is established, and extensive scar tissue is not present. Alternative antimicrobial drug choices include clindamycin, doxycycline, chloramphenicol, imipenem-cilastatin, and ceftriaxone.[35] It has been recommended that cephalexin, metronidazole, and aminoglycosides be avoided for treatment of human actinomycosis.[35] Infections associated with companion microbes also usually resolve with penicillin, but on occasion they require broader-spectrum antibiotics during the initial treatment period followed by long-term administration of penicillin.

With the exception of foreign body material (Fig. 59.7), surgery has a controversial role in the treatment of actinomycosis, but may be required if there is extensive fibrous tissue formation or large accumulations of purulent material to facilitate drug penetration (see Chapter 124 for information on management of pyothorax). In human medicine, an initial attempt to control disease with aggressive medical therapy alone has been suggested, with surgical therapy if there is an inadequate response to therapy.[35] In animals with pulmonary abscesses, removal of affected lung lobes may be required. Fibrotic lesions are often extensively vascularized and may obliterate tissue planes, which complicates dissection. In dogs with solitary masses that involve the thoracic and abdominal walls, radical surgical excision is often curative, although repeat surgeries may be needed. An initial period of antibiotic therapy may reduce the size of lesions and improve lesion definition, which facilitates surgery followed by continued antimicrobial drug treatment at a later date. Surgery is also required if a nidus such as a grass awn is present.

Appropriate treatment of actinomycosis results in a cure rate of greater than 90%.[2,11,52] Cure rates with meningitis/meningoencephalitis and advanced thoracic or peritoneal disease with extensive mass lesions may be lower.

PREVENTION

Prevention of actinomycosis involves restriction of access to areas with extensive grass awn formation, and avoidance of fighting and biting activity between animals. When wounds occur, they should be carefully examined for foreign material and cleaned promptly. Plant awns found on animals' coats should also be removed and discarded as soon as possible.

PUBLIC HEALTH ASPECTS

No reports exist of actinomycosis being transmitted from clinically infected animals to humans or other animals; however, humans bitten by dogs, cats, or other humans can develop actinomycosis (see Chapter 75).[35,53] The most common species that infects humans is *A. israelii*.[35] This species is a commensal of the canine oral cavity but has not been isolated from dogs or cats with actinomycosis. Nevertheless, *A. viscosus*, *Actinomyces odontolyticus*, and *A. meyeri* are organisms that have been isolated from canine and feline as well as human actinomycosis cases.

VetBooks.ir

CASE EXAMPLE

Signalment

"Penny," a 1-year old, female spayed Labrador retriever from Herald, CA.

History

Penny was evaluated by the UC Davis VMTH emergency service for a 1-week history of progressive inappetence, weight loss, lethargy, and fever. The inappetence was present for 7 days. Two days ago, Penny vomited up a small amount of kibble, and she had not eaten anything since. The owner reported that her feces had been formed and there were no changes in thirst or urination. Earlier in the day, Penny was evaluated at another veterinary clinic where a grade IV/VI left-sided cardiac murmur was auscultated and thoracic radiographs showed a bronchoalveolar and interstitial lung pattern. She was treated with cefazolin (27 mg/kg, IV) and furosemide (1 mg/kg, SC) and referred. Penny had been fully vaccinated for CDV, CPV, CAdV, and rabies. She missed some doses of heartworm prophylaxis medication recently, and otherwise receives no other medications. She lived with three other Labrador retrievers that were all well. She roamed on 8 acres of land and there was a pond on the property where she swam and had been known to eat small crayfish and frogs. Before she became inappetent, she was fed a commercial dry puppy food. Seven months ago she was evaluated at another veterinary clinic for vomiting and inappetence. At that time, she was moderately azotemic; an exploratory laparotomy was performed for a suspected foreign body, but no foreign body was found.

Physical Examination

Body weight: 22.5 kg.

General: Quiet, alert, responsive and wagging tail. Approximately 5% dehydrated. T = 105.2°F (40.7°C), HR 160 beats/minute, RR = 42 breaths/minute. Pink, slightly tacky mucous membranes, CRT < 2 seconds.

Integument: Full clean haircoat, no evidence of ectoparasites.

Eyes, ears, nose, and throat: No clinically significant abnormalities.

Musculoskeletal: BCS 3/9. Generalized mild muscle atrophy was present.

Cardiovascular: A grade II/VI left systolic murmur was auscultated. Femoral pulses were strong, regular, and synchronous.

Respiratory: Increased breath sounds were present bilaterally and diffusely. There was a mild increase in respiratory effort.

GI/genitourinary: No clinically significant abnormalities. Rectal palpation was unremarkable.

Lymph nodes: All within normal limits (approximately 1 cm).

Laboratory Findings

CBC: HCT 24.0% (40%–55%), MCV 65.6 fL (65–75 fL), MCHC 35.0 g/dL (33–36 g/dL), WBC 29,850 cells/μL (6,000–13,000 cells/μL), neutrophils 16,119 cells/μL (3,000–10,500 cells/μL), lymphocytes 2,985 cells/μL (1,000–4,000 cells/μL), monocytes 7,761 cells/μL (150–1,200 cells/μL), eosinophils 0 cells/μL (0–1,500 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 98,000 platelets/μL (150,000–400,000 platelets/μL), MPV 20.1 fL (7–13 fL). A few slightly toxic band neutrophils and moderate numbers of macroplatelets were present.

Serum chemistry profile: Sodium 144 mmol/L (145–154 mmol/L), potassium 4.3 mmol/L (3.6–5.3 mmol/L), chloride 114 mmol/L (108–118 mmol/L), bicarbonate 15 mmol/L (16–26 mmol/L), phosphorus 5.3 mg/dL (3.0–6.2 mg/dL), calcium 9.6 mg/dL (9.7–11.5 mg/dL), BUN 22 mg/dL (5–21 mg/dL), creatinine 0.8 mg/dL (0.3–1.2 mg/dL), glucose 44 mg/dL (64–123 mg/dL), total protein 7.8 g/dL (5.4–7.6 g/dL), albumin 2.5 g/dL (3.0–4.4 g/dL), globulin 5.3 g/dL (1.8–3.9 g/dL), ALT 31 U/L (19–67 U/L), AST 76 U/L (19–42 U/L), ALP 612 U/L (21–170 U/L), GGT 5 U/L (0–6 U/L), cholesterol 292 mg/dL (135–361 mg/dL), total bilirubin 0.8 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.016; pH 5.0, 1+ protein (SSA), 1+ bilirubin, 2+ hemoprotein, 1+ glucose, 0–1 WBC/HPF, 0–3 RBC/HPF, rare granular casts, many amorphous crystals, rare bilirubin crystals, many lipid droplets.

Coagulation panel: PT 7.7 seconds (7.5–10.5 seconds), APTT 15.2 seconds (9–12 seconds), fibrinogen 232 mg/dL (90–255 mg/dL), D-dimer 1.0–2.0 μg/mL (0–0.25 μg/mL).

Imaging Findings

Thoracic radiographs (three views): There were patchy diffuse unstructured interstitial opacities in all lung lobes (see Fig. 59.5A). The cardiovascular structures appeared within normal limits. The liver appeared markedly enlarged.

Echocardiography: The left ventricle was eccentrically hypertrophied. The papillary muscles had normal shape and echogenicity. There was no enlargement of the left atrium. There was no evidence of endocarditis. Decreased fractional shortening (26%; reference range, approximately 34%–46%) and increased end systolic diameter (3.9 cm; reference range, approximately 1.8–3.5 cm) and E-point septal separation (6.8 mm) were indicative of systolic dysfunction, which could also be appreciated subjectively. There was mild tricuspid regurgitation and trivial pulmonic insufficiency. Conclusions: moderate systolic dysfunction. It was recommended that the dog's diet and taurine blood/plasma levels be evaluated. It was also considered possible that the dog's febrile state was responsible for some of abnormalities observed on the echocardiogram.

Abdominal ultrasound: The liver appeared diffusely mottled, particularly in the left caudal region (see Fig. 59.5B). Within the left caudal liver, there was a focal, ill-defined heteroechoic area approximately 1 cm in diameter. Other smaller, ill-defined hypoechoic nodules were also present within the left liver. One of these areas in particular contained a well-demarcated, hyperechoic rim with irregular echogenic luminal contents and measured approximately 0.5 cm in diameter. Multiple large mesenteric lymph nodes were noted just caudal to the liver with the largest measuring approximately 1.3 cm by 4.5 cm. There was a mild amount of anechoic free abdominal fluid. The spleen was moderately enlarged, but the echotexture and echogenicity appeared within normal limits. There was mild renal pyelectasia bilaterally, but the associated renal papillae appeared within normal limits.

Microbiologic Testing

Aerobic and anaerobic blood cultures (five specimens): Negative.

IFA serology for serum antibody to *Ehrlichia canis*, *Anaplasma phagocytophilum, Rickettsia* , and *Babesia canis*: Negative.

IFA serology for serum antibody to *Bartonella vinsonii* subsp. *berkhoffii*, *Bartonella clarridgeiae*, and *Bartonella henselae*: Negative.

Bartonella culture (whole blood): Negative.

Serology for *Coccidioides* serum antibodies: Negative.

Cytologic Findings

Splenic aspirate (ultrasound-guided): Two smears were examined that contained a large amount of blood in the background and were highly cellular. Several small clumps of splenic stromal cells were noted. A large heterogeneous population of lymphocytes was found, with a moderate increase in plasma cells. A moderate number of hematopoietic cells also was observed, including megakaryocytes, myeloid, and erythroid precursors.

Interpretation: Moderate reactive lymphoid hyperplasia and extramedullary hematopoiesis.

Liver aspirate (ultrasound-guided): Two smears were examined that contained a diffusely stippled background containing abundant nuclear debris and were highly cellular. A large population of mildly to markedly degenerate neutrophils was observed. Degenerate cells ranged from highly pyknotic to severely karyolytic. A few neutrophils contained small intracellular bacterial rods.

Interpretation: Marked suppurative inflammation with bacterial sepsis.

CASE EXAMPLE—cont'd

Further Microbiologic Testing

Aerobic and anaerobic culture (ultrasound-guided liver aspirate): Small numbers of suspect *Actinomyces* spp. No anaerobes cultured. Partial 16S rRNA gene PCR and sequence analysis revealed 99% identity to *A. bowdenii*.

Diagnosis

Systemic *A. bowdenii* infection with hepatic involvement.

Treatment

Immediately upon admission, Penny was treated with IV lactated Ringer's solution with 20 mEq/L KCl and 5% dextrose at 75 mL/hour. After the specimens for blood culture were collected, treatment with enrofloxacin (10 mg/kg, IV, q24h) and ampicillin (22 mg/kg, IV, q8h) was initiated. Within 24 hours, the dog's rectal temperature had decreased to 101.3°F (38.5°C), the blood glucose had increased from 41 mg/dL to 107 mg/dL, and the dog began eating. A liver aspirate was submitted for culture on day 2 of hospitalization. A recheck abdominal ultrasound examination on day 3 showed progressive abscessation of the left liver and further enlargement of the gastrohepatic lymph nodes; the mesentery that surrounded the liver was mildly hyperechoic but less so than on the previous examination. By day 4 of hospitalization, growth of an *Actinomyces*-like organism was reported. On day 5, antimicrobial drug treatment was changed to clavulanic acid-amoxicillin (17 mg/kg, q8h). However, later in the day, Penny's temperature increased to 103.6°F (39.8°C), and so the initial antimicrobial drug prescription was reinstated. The dog's hematocrit had also dropped to 19%. Thoracic radiographs were repeated and showed almost complete resolution of the patchy pulmonary infiltrates. A follow-up echocardiogram was unchanged. An abdominal ultrasound examination was again repeated and showed persistent hypoechogenicity of the left liver lobe, but during the procedure a hyperechoic lesion that was consistent with a plant awn foreign body was discovered in the subcutaneous tissue in a caudoventral intercostal space. On day 6, surgery was performed to remove the plant awn. Packed red cells were administered during the procedure and a 16F chest tube was placed because the thoracic cavity was entered during the search for the foxtail, which, with the assistance of intraoperative ultrasound examination, was eventually located under the 13th rib just outside the pleural space. Sulfur granules were found embedded in the tissue during surgery. A closed suction grenade drain was also placed (see Fig. 59.7). The chest tube was removed later in the day. Treatment with enrofloxacin and ampicillin was continued, as well as with oxymorphone (0.04 mg/kg, SC, q6h) to control pain. On day 7, Penny's temperature was 100.7°F (38.2°C) and the drain was removed. Aerobic and anaerobic culture of the foxtail revealed small numbers of penicillin-susceptible *Enterococcus faecalis* and a *Streptomyces*-like organism. No anaerobes were cultured. Penny was discharged on day 8 with instructions to continue treatment with clavulanic-acid amoxicillin for an additional month. The dog subsequently did not return for a recheck examination but had no further clinical signs of illness.

Comments

This is an unusual case of disseminated *A. bowdenii* infection that led to hematogenous pneumonia and hepatic abscessation. Although there was an initial defervescence with antimicrobial drug treatment, anemia and pyrexia persisted, which led to a search for an abscess that might require drainage or a plant awn. Fortunately, a plant awn was ultimately identified with ultrasound, after which the dog's illness resolved completely. *E. faecalis* was isolated from the plant awn and represented a "companion microbe," but whether dissemination of this organism occurred was unclear. The *Streptomyces* spp. may have been a contaminant or the *Actinomyces* spp. may have been misidentified. Continuation of treatment with enrofloxacin and clavulanic acid after the culture results became available was probably unnecessary in this dog; amoxicillin would likely have been sufficient. The owner was warned that additional plant awns may still be present. The cause of the cardiomyopathy was not determined; plasma and whole blood taurine concentrations were within normal limits and follow-up examination was not performed.

Nocardiosis

Jane E. Sykes

KEY POINTS

- First Described: In 1888, Alfort, France (Edmond Nocard).[1]
- Causes: *Nocardia* spp..
- Geographic Distribution: Worldwide, although infections in dogs and cats are most commonly reported from Brazil, the western United States, and Australia.
- Mode of Transmission: Inhalation or cutaneous inoculation of organisms in the environment, with opportunistic proliferation in the face of impaired host immune defenses.
- Major Clinical Signs: Lethargy, weight loss, inappetence; subcutaneous masses and nonhealing, crusted or draining skin lesions; pulmonary nodules, masses and/or effusion with cough and tachypnea; signs of dissemination (neurologic signs, chorioretinitis, abdominal effusion or masses, lameness).
- Differential Diagnoses: Actinomycosis, streptomycosis, mycobacteriosis, bartonellosis, fungal infections, neoplasia.
- Human Health Significance: Direct transmission of disease from animals to humans does not generally occur, but humans have developed disease after bites or scratches from healthy dogs or cats.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Nocardia are filamentous, branching, gram-positive bacteria that belong to the family Nocardiaceae (Fig. 60.1). Approximately 100 different *Nocardia* species have been recognized since the advent of molecular identification methods, half of which are human and animal pathogens.[2,3] The advent of molecular methods led to extensive revision of the taxonomy of *Nocardia* spp.[2] Species that belonged to the former *Nocardia asteroides* complex are now distinct species, and include *Nocardia cyriacigeorgica* (formerly *N. asteroides* sensu stricto), *Nocardia abscessus*, *Nocardia nova*, *Nocardia farcinica*, and *Nocardia otitidiscaviarum*.[2,4] Knowledge of the species involved is important because different *Nocardia* species differ in their antimicrobial susceptibility patterns, epidemiology, and pathogenicity. They also differ in the amount of mycolic acid in their cell wall, which affects their ability to stain with acid-fast stains.

Like actinomycosis, nocardiosis is a suppurative to granulomatous, localized or disseminated opportunistic infection caused by filamentous bacteria. However, unlike *Actinomyces* spp. (which are commensals of mucous membranes), *Nocardia* spp. are ubiquitous soil saprophytes that degrade organic matter. They are also found in fresh and salt water, dust, and on decaying plants and fecal matter.[4] They may be carried mechanically on the claws or skin. Infections are acquired via inhalation of organisms or inoculation via puncture wounds. Transfer of infection between animals does not occur.

Nocardiosis is much less frequently reported in dogs and cats than actinomycosis (which can have a similar clinical appearance), although nocardiosis is increasingly recognized in both human medicine and companion animals in association with a higher prevalence of immunocompromised hosts, such as those treated with potent immunosuppressive drugs (especially cyclosporine).[5–9] Where vaccination for CDV is inadequate or not widely instituted, nocardiosis in dogs has been associated with CDV-induced immunosuppression.[10–12]

The prevalence of nocardiosis and the prevailing *Nocardia* species that cause disease vary geographically. For example, within the United States, human nocardiosis has been most commonly reported from the southwestern states. Dry, dusty, and windy conditions in these areas may facilitate aerosolization and dispersal of nocardiae.[13] Dogs and cats from Australia and the western United States are most commonly infected with *N. nova*.[14–16] Other species isolated from dogs and cats are listed in Table 60.1. In humans, *Nocardia brasiliensis* is the most common species isolated from patients residing in tropical locations such as the southwestern United States, Central and South America, and Australia.

More than 60% of people with nocardiosis have underlying immunosuppressive disorders such as AIDS, COPD, autoimmune diseases that require immunosuppressive drug therapy, solid organ transplantation, diabetes mellitus, and hemic neoplasia.[17] Underlying immunosuppressive disease or drug treatment also seems to predispose dogs to nocardiosis. Nocardiosis has been documented in several dogs treated with cyclosporine and a dog with lymphoma.[5,7–9,15] Most affected cats have cutaneous infections that are associated with scratches or bite wounds.[14,18] Accordingly, > 75%–80% of affected cats are male; in the author's hospital, 9 of 10 affected cats were male.[14,15,18] Cats of any age can be affected and no breed predilection has been identified.[14] Some cats have underlying disorders that predispose them to nocardiosis, such as a history of renal transplantation, underlying retroviral infection, or glucocorticoid administration. Others have no obvious underlying immunosuppressive disease.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The pathogenicity of *Nocardia* spp. is influenced by the strain and growth phase of the organism, together with host susceptibility. Virulent strains of *Nocardia* are facultative intracellular pathogens that

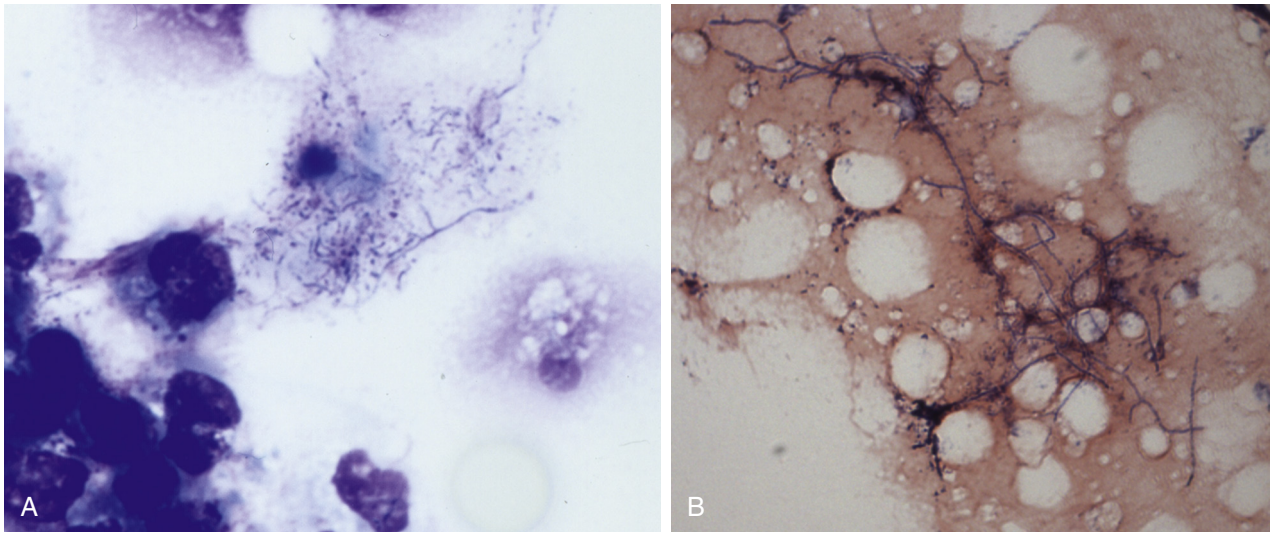

Fig. 60.1 (A) and (B) Gram-stained specimens showing *Nocardia* spp. The organisms are gram positive, filamentous, branching and slightly beaded. (A, Courtesy David F. Edwards, University of Tennessee, Knoxville, TN.)

TABLE 60.1 *Nocardia* Species Isolated from Dogs and Cats with Nocardiosis

Host Species	Dogs	Country
Dogs	*N. nova*	USA, Australia[14,15]
	N. paucivorans	USA[15]
	N. asiatica	USA, Brazil[10,15]
	N. abscessus	USA[9]
	N. otitidiscaviarum	Brazil[12]
	N. farcinica	Australia[14]
	N. brasiliensis	USA, Australia[5,42]
	N. niigatensis	USA[6]
	N. veterana	USA, Germany[11,34]
	N. cyriacigeorgica	Turkey[43]
	N. pseudobrasiliensis	USA[44]
Cats	*N. nova*	USA, Australia[15]
	N. cyriacigeorgica	Australia, West Indies (St Kitts)[14,30]
	N. africana	Japan, Brazil[29,45]
	N. elegans	Japan[46]
	N. brasiliensis	USA[42]
	N. otitidiscaviarum	Spain[47]
	N. jiangxiensis	West Indies (Nevis)[48]
	N. flavorosea/N. carnea	Japan[49]

inhibit phagosome-lysosome fusion, neutralize phagosomal acidification, resist oxidative burst, secrete superoxide dismutase, and alter lysosomal enzymes within neutrophils and macrophages.[17] These effects are partly related to the content and structure of mycolic acids within the bacterial cell wall, which vary among strains and throughout the growth phase. Filamentous log phase cells in the environment can be highly resistant to phagocytosis. Some strains have a greater propensity to invade the CNS.[19,20]

The normal host response to infection is characterized by an initial pyogenic inflammatory response, but a cell-mediated immune response is necessary to destroy the organisms. Diminished host resistance, especially in the form of impaired CMI, is a primary factor in susceptibility to nocardiosis and the extent to which dissemination occurs.

Cutaneous-subcutaneous nocardiosis, the most common form seen in cats (>75% of affected cats), is characterized by slow and progressive circumferential spread of a nonhealing, draining wound (Fig. 60.2). Lesions are typically subacute to chronic. Infections of feeding tube sites may also occur.[21] Mycetoma-like lesions in the inguinal area resemble those described for rapidly growing mycobacterial infections (see Chapter 61), with multiple draining sinuses. These may result from contamination of "raking" injuries inflicted by the hindlimbs during fighting behavior.[14] Alternatively, they might represent contamination of traumatic wounds from penetrating plant material. Cutaneous-subcutaneous nocardiosis was documented in eight of nine dogs from Brazil,[12] but represents the minority of nocardiosis cases in dogs from California, USA and Australia.[14,15] Dogs with cutaneous involvement typically develop draining wounds and masses, often on the head and limbs. Osteomyelitis can occur in association with cutaneous lesions.

The pathogenesis of *pulmonary or disseminated nocardiosis* is similar to that of the deep mycoses. Branching nocardial filaments fragment, which results in the formation of small, unicellular particles that are aerosolized and inhaled, possibly in dust. Once within the lung, *Nocardia* spp. proliferate in the face of immune suppression, which leads to formation of intrapulmonary masses or pneumonia, hilar lymphadenomegaly, and/or extrapulmonary masses and pleural effusion (pyothorax) (Figs. 60.3A and 60.4). Pulmonary nocardiosis is the most common form reported in humans, and also occurs in dogs and less commonly in cats. In dogs, it can have a peracute onset characterized by tachypnea, hemoptysis, hypothermia, collapse, and death; however, subacute to chronic clinical signs are more characteristic.[22–25] Co-infection with CDV is occasionally reported.[10–12,26,27] Disseminated nocardiosis occurs when organisms in the lung erode into blood vessels and spread systemically, with abscess formation in a variety of organs. This leads to signs of lethargy, fever, decreased appetite, and signs that relate to the location of the infectious process. Disseminated disease can occur in cats as well as in dogs. The most frequently involved extrathoracic organs are skin and subcutaneous tissue, kidney, liver, spleen, lymph nodes, CNS, eye, bone, and joints (see Fig. 60.3B). In dogs and cats, CNS lesions may cause seizures or a variety of other neurologic signs that relate to the local effects of abscesses or granulomas in the brain, meninges, or spinal cord. CNS

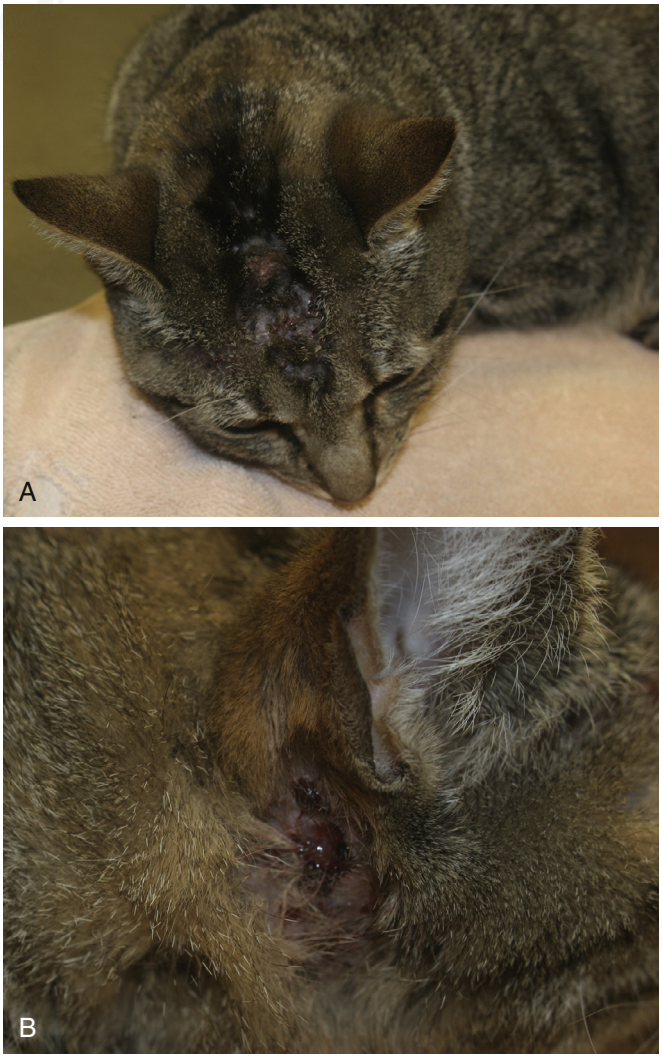

Fig. 60.2 A 6-year-old male neutered domestic shorthair cat with cutaneous-subcutaneous nocardiosis. The lesions progressed over at least a year after a cat bite abscess that was initially treated with clavulanic acid-amoxicillin, and consisted of nodular and crusted lesions on the head (A) and cervical region (B) that drained fluid and extended down the cervical region to the cranioventral thorax. The cat tested negative for feline immunodeficiency virus and feline leukemia virus. (Image courtesy University of California-Davis, Veterinary Dermatology Service.)

involvement is common in human nocardiosis. Peritoneal nocardiosis has also been rarely reported in cats, possibly as a result of penetrating wounds to the abdomen.[14,28]

Physical Examination Findings

Physical examination findings in animals with cutaneous-subcutaneous disease are similar to those in actinomycosis, with chronic, sometimes crusted, ulcerated, nonhealing draining wounds, and in cats may involve the extremities, inguinal area, flank, bridge of the nose, and neck (see Fig. 60.2). Animals with pulmonary or systemic involvement may have a thin body condition, lethargy, and fever. Tachypnea and cough may be present, and lung sounds may be increased (from bronchopneumonia) or decreased (from a mass lesion or pyothorax). Involvement of the liver, spleen, and lymph nodes may be associated with development of hepatomegaly, splenomegaly, and/or peripheral or abdominal lymphadenopathy. Subcutaneous mass lesions that sometimes drain purulent fluid may be present as a result of dissemination to the skin.[9] Ocular involvement may be associated with development of chorioretinitis. Bone or joint infection results in focal limb swelling and lameness. Mandibular involvement ("lumpy jaw") has been reported in some cats.[29,30] Animals with CNS involvement have had mental obtundation, anisocoria, decreased menace and pupillary light responses, head tilt, nystagmus, decreased gag reflexes, and/or deficits of conscious proprioception. Spinal pain, lower motor neuron signs that involved the pelvic limbs, and opisthotonus were described in one dog with suspected nocardiosis with pyogranulomas that involved the subdural and extradural space at multiple locations along the spinal cord.[7]

DIAGNOSIS

A diagnosis of nocardiosis is usually suspected based on the presence of persistent pyogenic to pyogranulomatous inflammatory lesions, the presence of filamentous bacteria, together with a history of immunosuppression, although the latter is not always present. Confirmation of the diagnosis generally requires culture.

Laboratory Abnormalities

Complete Blood Count and Serum Biochemical Tests

Laboratory abnormalities are similar to those with actinomycosis (nonregenerative anemia, neutrophilic leukocytosis with a left shift, monocytosis, and sometimes marked hyperglobulinemia). However, in immunosuppressed animals, lymphopenia, monocytopenia, and eosinopenia may be present. Hypercalcemia associated with granulomatous disease has been reported in a cat.[31]

Cytologic Examination of Body Fluids

Examination of pleural effusion, bronchial lavages, and aspirates of abscesses from animals with nocardiosis typically reveals suppurative to pyogranulomatous inflammation, with large numbers of degenerate neutrophils. Gram-positive, often partially or weakly acid-fast, beaded, filamentous organisms that branch at right angles may be observed individually or in loose aggregates (see Fig. 60.1). The filaments may also fragment to form rods and coccoid forms. *Actinomyces* spp. is not acid fast and *Mycobacterium* spp. do not branch. When the infecting *Nocardia* spp. is not acid fast, it may not be possible to distinguish it from an *Actinomyces* spp. organism. With Romanowsky-type stains, organisms may be eosinophilic or basophilic and have a beaded appearance. Organisms are usually around 0.5 μm in diameter and up to 30 μm long, but thicker organisms were described in one dog infected with *N. abscessus* (2 μm).[9] Macroaggregates (i.e., sulfur granules) have been noted infrequently in effusions. In contrast to actinomycosis, mixed bacterial populations in deep tissue sites are rarely present.

Diagnostic Imaging

Plain Radiography

Radiography of cutaneous-subcutaneous lesions may reveal soft tissue swelling with or without associated bone lysis and periosteal proliferation. The radiographic appearance of pulmonary lesions varies and includes multiple, diffuse pulmonary nodules, intrapulmonary or extrapulmonary solitary masses, focal or diffuse bronchointerstitial to alveolar infiltrates, lobar consolidations, pleural effusions, and often, dramatic hilar lymphadenopathy (Fig. 60.5).

Sonographic Findings

Abdominal ultrasound findings in dogs and cats with disseminated nocardiosis have not been described in detail because disseminated disease with abdominal organ involvement is rare. However, intraparenchymal mass lesions and flocculent ascites fluid may be noted.

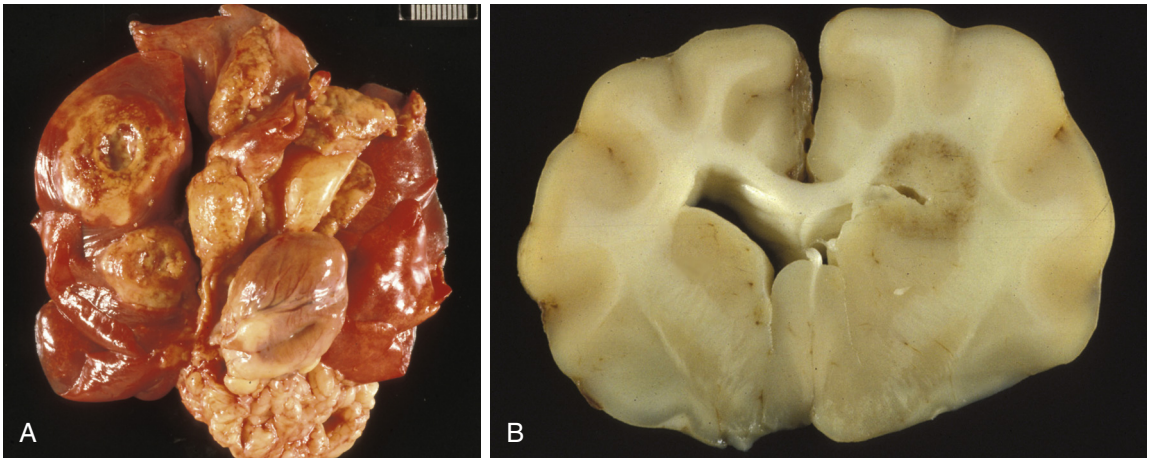

Fig. 60.3 Gross necropsy findings in a 4-year old male neutered domestic shorthair cat with disseminated nocardiosis caused by *Nocardia nova*. The cat was a renal transplant recipient. (A) Multifocal to coalescing large, white to grey, caseous pulmonary masses are present within the lungs. (B) The brain contained multifocal, white to grey foci that histologically consisted of large numbers of neutrophils and filamentous bacteria.

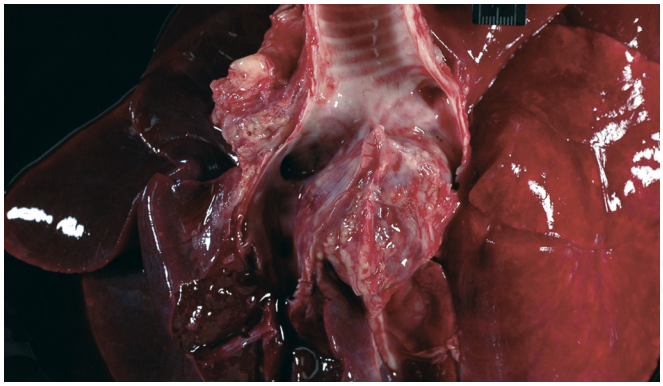

Fig. 60.4 Chronic abscess of the hilar lymph nodes and hilar soft tissue of a 5-year-old female spayed golden retriever. The lesion caused complete compressive occlusion of the left mainstem bronchus, with atelectasis of the left lung lobes. Histopathologic examination revealed pyogranulomatous and necrotizing cellulitis with intralesional filamentous bacteria. *Nocardia* spp. were isolated from the lesion. (Courtesy Chuck Mohr, University of California-Davis, CA)

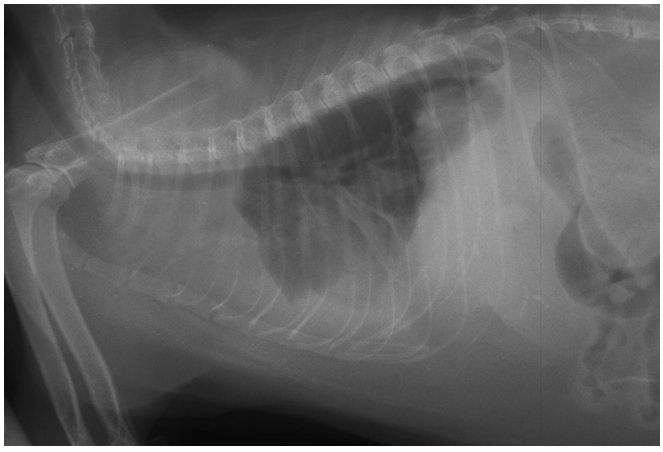

Fig. 60.5 Lateral thoracic radiograph of a 4-year-old male neutered domestic shorthair cat with disseminated nocardiosis. Pleural effusion is present and obscures the cardiac silhouette. A mass is associated with the caudal aspect of the left caudal lung lobe.

Advanced Imaging

Nodular lung lesions similar to those described in humans were identified with CT in one dog with disseminated nocardiosis.[9] CT and MRI abnormalities in dogs and cats with confirmed CNS nocardiosis have not been reported. One dog suspected to have nocardiosis had a large, T2-hyperintense circumscribed lesion in the occipital cortex that was consistent with a brain abscess, together with widespread cerebral edema and herniation of the cerebellum through the foramen magnum.[8]

Microbiologic Tests (Table 60.2)

Isolation and Identification

Nocardia spp. grow aerobically at a wide temperature range on simple media (e.g., Sabouraud's glucose agar, blood agar). Organisms are usually recovered in pure cultures, and colonies are often visible after 2 days. However, in some cases, 2 to 4 weeks of incubation may be necessary, and the organism may be overgrown by contaminating bacteria. Thus, the laboratory should be alerted if nocardiosis is suspected so that selective media and long incubation times are used. Colonies are smooth and moist, or rugose with a powdery surface due to aerial filamentation, and may be pigmented. Organisms may then be identified based on their microscopic appearance and their ability to take up acid-fast stains. However, not all pathogenic strains of *Nocardia* species are acid fast.[19,20,32] L-form *Nocardia* spp., cell wall-deficient variants, have been associated with clinical disease in humans and a dog.[33] These bacteria require special media for isolation and culture, similar to mycoplasmas (see Chapter 57).

Traditionally, *Nocardia* species have been distinguished based on growth characteristics and antibiotic susceptibility patterns; however, molecular methods provide a more reliable and rapid means of speciation. Biochemical methods of identification of *Nocardia* species are now considered inadequate. Sequence analysis of PCR products from the 16S rRNA gene identifies most pathogenic *Nocardia* spp., but differentiation of closely related species may require analysis of other genes or DNA-DNA hybridization.[4,17] The latter is considered the gold standard for *Nocardia* species determination.[4] MALDI-TOF MS permits rapid and reliable identification of *Nocardia* species in clinical microbiology laboratories.[34,35] PCR assays have also been used for direct detection of *Nocardia* spp. in clinical specimens, without prior isolation.[4]

TABLE 60.2 Diagnostic Assays Available for *Nocardia* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Aspirates of purulent material (e.g., abscesses, pleural effusion); whole blood; tissue specimens obtained by biopsy or at necropsy (e.g., subcutaneous tissue, lung tissue)	*Nocardia* spp.	Grows on most simple media. May require several weeks' incubation. Because *Nocardia* spp. are soil saprophytes, isolation from skin lesions does not imply disease causation. PCR and sequencing may be required to identify the species present.
Cytology or histopathology with organism detection using special stains	Aspirates or tissue specimens	*Nocardia* spp. organisms	Organisms are gram positive, variably acid fast, and not usually accompanied by sulfur granules or the Splendore-Hoeppli phenomenon. Definitive diagnosis requires culture because non-acid-fast *Nocardia* can resemble *Actinomyces* spp.

PCR, polymerase chain reaction.

Because *Nocardia* organisms are ubiquitous in soil and may be inhaled by healthy animals, the isolation of small numbers of organisms from ulcerated skin lesions or the respiratory tract must be interpreted in conjunction with clinical signs and history of immune compromise. Repeated positive cultures or isolation of pure or large quantities of the organism are also suggestive of nocardiosis, and the isolation of a single colony from a normally sterile site is significant. Visualization of gram-positive filamentous bacteria in cytology specimens in association with acute inflammatory cells also assists in determination of clinical significance.

The susceptibility of *Nocardia* spp. to antimicrobial drugs varies considerably between different *Nocardia* species, and so species identification can guide appropriate antimicrobial drug selection (see Treatment, below, and Table 60.3). Susceptibility testing for *Nocardia* spp. is difficult and should be done by laboratories with special expertise. Susceptibility testing may be helpful when there is a failure to respond to initial therapy or relapse occurs from drug resistance. It may also be useful if there are concerns that relate to adverse drug reactions to sulfonamides, which are the initial treatment of choice (e.g., in dogs with immune-mediated disease that is complicated by cyclosporine-associated nocardiosis). Testing is also indicated when *N. farcinica* is present, which tends to be highly resistant to antimicrobial drugs, or when a *Nocardia* species with unpredictable susceptibility is isolated.

Pathologic Findings

Nocardiosis is characterized by suppurative necrosis and abscess formation and infrequently produces granulomas (see Figs. 60.3 and 60.5). Gross lesions in organs such as the spleen, lung, liver, and brain typically consist of numerous small (1 mm) to large (several centimeters), discrete or coalescing, intraparenchymal white or gray-white nodules. On cut section, nodules appear caseous to purulent. Lymph nodes are enlarged, often massively, and are firm to fluctuant with a caseous to purulent core. A reddish-brown exudate may be present in the pleural or peritoneal space or within abscesses. Although formation of sulfur granules by *Nocardia* spp. is uncommon compared with *Actinomyces* spp., small granules have occasionally been noted in skin lesions and pleural and peritoneal fluid.[16,22,28,36]

Histopathology usually reveals a central region of necrosis and suppuration, which, depending on the host immune response, may be surrounded by macrophages, lymphocytes, and plasma cells (Figs. 60.6A and 60.7A). In chronic cutaneous-subcutaneous infections, pyogranulomatous foci may be interspersed within dense fibrous tissue. Plant material may be observed if plants were involved in inoculation of *Nocardia* spp. into tissues, but the presence of plant material is more common with actinomycosis.

Nocardia are usually present in abundance within regions of necrosis and suppuration. *Nocardia* filaments are poorly visible in tissue sections stained with H&E or with Gridley's fungal or PAS. Organisms can be stained with Gram stain (Fig. 60.6B) or methenamine silver preparations,[9] especially with prolonged silver nitrate exposure. They are usually partially acid fast (Fig. 60.7B) and have the same appearance described in the Cytology section, earlier. In chronic skin infections, tissue granules characterized by colonies arranged in large, rosette-like arrays have been reported. In contrast to actinomycosis, other bacteria and the Splendore-Hoeppli phenomenon are not generally present.

TREATMENT AND PROGNOSIS

Treatment

Successful treatment of nocardiosis relies upon the combination of appropriate antimicrobial therapy combined with the use of surgical drainage or debridement. Chronic, extensive lesions may require surgical debridement or resection. Appropriate antimicrobial therapy that includes surgical drainage is not always effective, possibly because of an inadequate host immune response.[14] Existing immunosuppressive drug treatment should be discontinued or reduced, provided it does not cause relapse of a life-threatening underlying disease process.

The initial selection of an antimicrobial drug or drug combination should take into account the site of the infection, the host immune status, the infecting species of *Nocardia* (Table 60.3), and if available, susceptibility test results.[17] However, *in vitro* susceptibilities do not always translate into a clinical response *in vivo*. Sulfonamides, including trimethoprim-sulfonamide combinations (TMS), are the primary antimicrobial drugs for treating nocardiosis (Table 60.4). Treatment durations from 1 to 3 months are recommended in humans with cutaneous infections, up to 6 months for uncomplicated pulmonary infections, and 12 months or longer for systemic infections or infections in those who are immunocompromised.[17] Clinical improvement is generally observed within 7 to 10 days of starting treatment. High doses of TMS given for long periods to dogs (and to a lesser extent, cats) can produce a variety of adverse effects such as keratoconjunctivitis sicca and myelosuppression (see Chapter 10). If adverse drug reactions occur, selection of drugs other than TMS should ideally be based on susceptibility test results. If these are not available, choices should be made based on *in vitro* data (see Table 60.3). *Nocardia nova* is susceptible to amoxicillin but resistant to clavulanic acid-amoxicillin because of induction of chromosomal β-lactamase by clavulanic acid.[14,16] Substitution of antimicrobial drugs within a drug class may not provide effective treatment; for example, although sensitive to amikacin, *N. farcinica* isolates are resistant to gentamicin, and although sensitive to minocycline, *N. brasiliensis* isolates are mostly resistant to doxycycline.[37]

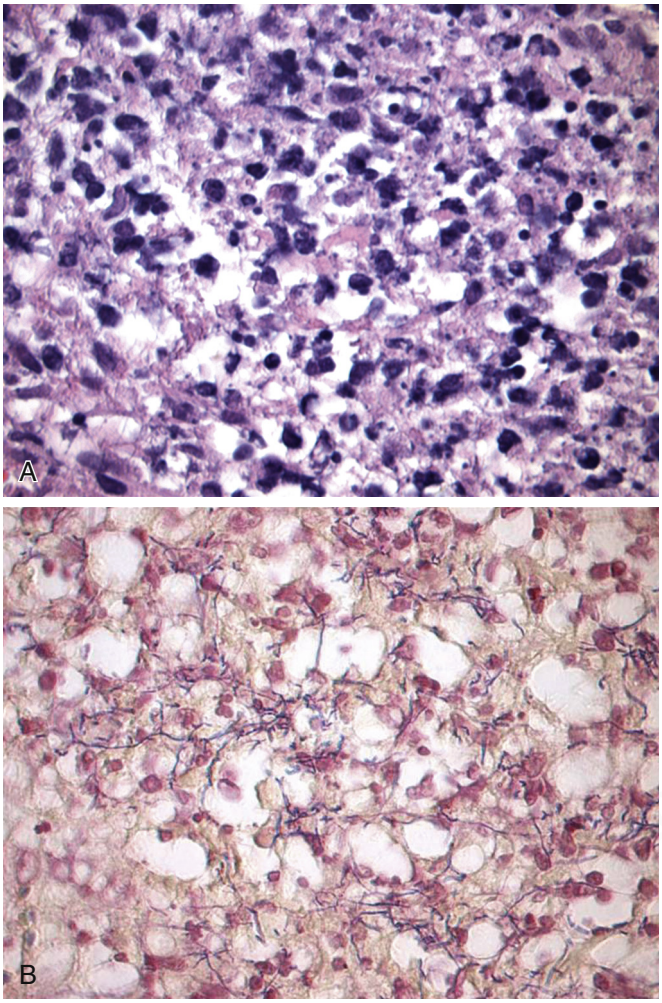

Fig. 60.6 Histopathologic findings in the cat described in Figs. 60.3 and 60.5. (A) Severe, necrotizing pyogranulomatous inflammation is present with intralesional bacteria, which are barely visible. H&E stain. (B) Gram staining revealed tangles of filamentous, branching gram-positive bacteria. Brown and Benn stain.

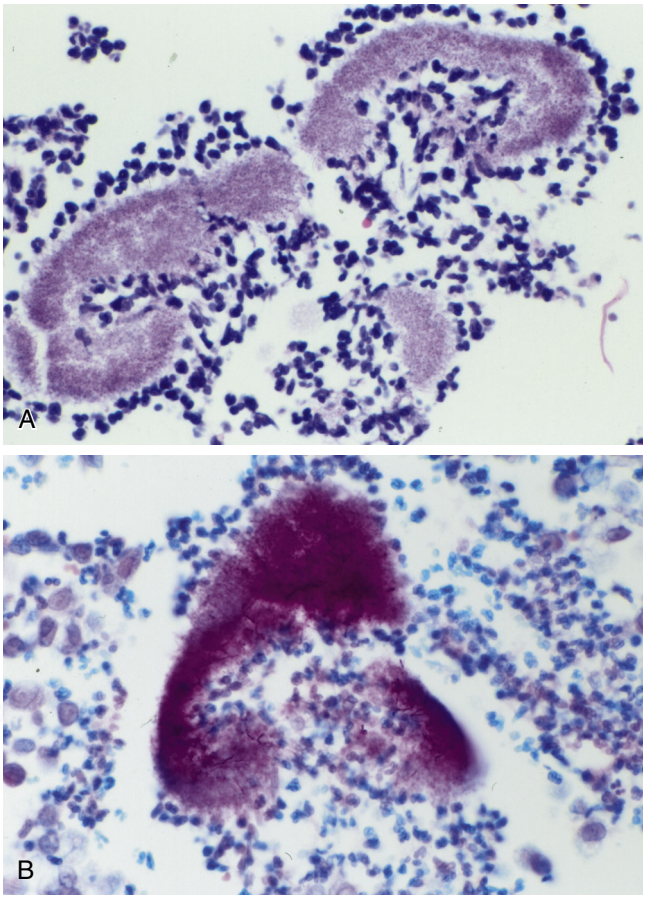

Fig. 60.7 (A) H&E-stained section of chronic, ulcerated cutaneous lesion on flank of 3-year-old male domestic longhaired cat. *Nocardia* tissue granules are surrounded by pyogranulomatous inflammatory reaction. (Long dimension of largest granule is 110 μm; ×66.). (B) Acid-fast stain (Fite-Faraco modification of Ziehl-Neelsen technique) of same tissue section (×132). (Courtesy David F. Edwards, University of Tennessee, Knoxville, TN.)

TABLE 60.3 Suggested Antimicrobial Drug Selection for Treatment of Pathogenic *Nocardia* spp. Based on Minimum Inhibitory Concentration Data[4]

Nocardia Species	Appropriate Antimicrobial Drug Choices	Antimicrobial Drugs To Avoid
N. abscessus	Ampicillin, amoxicillin-clavulanic acid, ceftriaxone, linezolid, amikacin and gentamicin, sulfamethoxazole	Imipenem, ciprofloxacin, clarithromycin
N. brevicatena/paucivorans complex	Ampicillin, amoxicillin-clavulanic acid, ceftriaxone, amikacin, sulfamethoxazole, ciprofloxacin	Gentamicin, clarithromycin
N. nova complex (includes *N. nova*, *N. africana*)	Ampicillin, sulfamethoxazole, erythromycin, clarithromycin, ceftriaxone, imipenem, amikacin	Amoxicillin-clavulanic acid
N. farcinica	Amikacin, sulfamethoxazole, ciprofloxacin (most isolates), imipenem (most isolates)	Ampicillin, broad-spectrum cephalosporins, clarithromycin, aminoglycosides other than amikacin
N. cyriacigeorgica	Ceftriaxone, amikacin, imipenem	Ampicillin, amoxicillin-clavulanic acid, clarithromycin, ciprofloxacin
N. brasiliensis	Minocycline, amoxicillin-clavulanic acid, sulfamethoxazole	Ampicillin, ciprofloxacin, clarithromycin
N. otitidiscaviarum	Gentamicin, amikacin, sulfamethoxazole, ciprofloxacin	All β-lactam antibiotics

TABLE 60.4 Medications that Could Be Used To Treat Dogs and Cats with Nocardiosis Pending Species Identification With or Without Susceptibility Testing

Drug	Dose (mg/kg)	Route	Interval (Hours)
Trimethoprim-sulfamethoxazole	30	PO, IV	12
Amikacin[a]	10–15	IV, IM, SC	24
Imipenem-cilastatin[a]	2–5	IV	8

[a]Amikacin and imipenem-cilastatin are generally used in combination with each other or with trimethoprim-sulfamethoxazole
IV, intravenous; *IM,* intramuscular; *PO,* oral or by mouth; *SC,* subcutaneous.

If CNS disease is present, either high doses of TMS given parenterally, or drugs with excellent CNS penetration, which include third-generation cephalosporins, imipenem, or meropenem, should be considered. Two- or three-drug combinations including TMS, amikacin, and either ceftriaxone or imipenem have been used pending the susceptibility test results to treat severe nocardiosis in human patients.[4] A combination of amikacin and imipenem should be effective against all isolates. Combination treatment with amikacin and TMS was suggested for cats with *N. farcinica* infections, which generally require aggressive, combination drug treatment.[14]

Prognosis

In a review of 53 dogs with nocardiosis, 50% of the dogs died and 39% were euthanized.[27] Of 36 cats with nocardiosis, 16 were either euthanized or died.[14] The high mortality rate may relate to underlying immunosuppressive disease and drug treatment, delayed diagnosis, and inappropriate treatment. With earlier diagnosis and more aggressive, multidrug therapy, mortality of nocardiosis in animals may decrease to the rate reported in humans. Only 20% of humans with primary infections died, whereas 42% of patients with predisposing conditions and more than 50% of patients with either systemic or CNS nocardiosis died.[19]

IMMUNITY AND VACCINATION

Immunity to nocardiosis is dependent on intact CMI, which is why infections often occur in animals and humans with conditions or drug treatment that compromise CMI. There are no vaccines for nocardiosis.

PREVENTION

Nocardiosis in cats may be prevented by housing cats indoors and limitation of fighting or biting activity. When wounds occur, they should be carefully examined for foreign material and cleaned promptly. Disease in both dogs and cats may be prevented by avoidance of excessive immunosuppression with potent drugs such as cyclosporine.

PUBLIC HEALTH ASPECTS

No cases of human nocardiosis acquired from direct contact with an animal have been reported; however, several cases of cutaneous nocardiosis transmitted to humans by cat scratches have been documented.[38–41] Humans with impaired CMI (such as those receiving immunosuppressive drug therapy or those with HIV infection) should wear gloves and practice hand washing after handling pets known to have nocardiosis, or another individual in the household should treat these animals.

CASE EXAMPLE

Signalment

"Bob," a 4-year-old male neutered domestic shorthair cat from San Francisco, CA.

History

Bob, a renal transplant recipient, was evaluated for a 2-week history of decreased activity and lethargy. Five days ago, the lethargy became more severe. Bob also stopped eating and urinated on himself several times. He was taken to a local emergency clinic where they noted mild hyponatremia (130 mmol/L) and a WBC count of 19,000 cells/μL, but there was no evidence of azotemia or elevated liver enzyme activities. No abnormalities were detected on abdominal ultrasound examination. Bob was treated overnight with IV fluids and sent home with instructions to administer clavulanic acid-amoxicillin (12.5 mg/kg, PO, q12h). However, the cat's condition failed to improve and so he was taken to a local veterinary clinic 3 days later. Further laboratory testing showed persistent hyponatremia, hypoalbuminemia, and mild hyperbilirubinemia. Urinalysis showed a specific gravity of 1.054, 3+ bilirubin, 1+hemoprotein, 0–2 WBC/HPF, 6–10 RBC/HPF, and no bacteria or casts. Aerobic bacterial urine culture was negative. The following day he became tachypneic and pleural effusion developed. In-house examination of the effusion fluid revealed cloudy fluid that contained large numbers of erythrocytes, degenerate neutrophils, and macrophages. No bacteria were seen with Gram stain. Bob was then referred to the University of California, Davis, VMTH, for further evaluation.

Bob received a renal transplant 2.5 years ago and had been treated with prednisone (0.5 mg/kg, PO, q12h) and cyclosporine (4 mg/kg, PO, q12h) since that time. A recent whole blood trough cyclosporine concentration was 1,100 ng/mL.

Physical and Neurologic Examinations

Body weight: 5.1 kg.

General: Severely obtunded, T = 100.8°F (38.2°C), HR = 240 beats/minute, RR = 55 breaths/minute, mild generalized icterus, mucous membranes pink to icteric, CRT = 1 second.

Integument: Clean coat, no evidence of ectoparasites.

Eyes, ears, nose, and throat: Anisocoria with the left pupil larger than the right, direct and consensual pupillary light reflexes were present, clear cornea and anterior chamber, no ocular discharge. Fundoscopic examination showed focal areas of tapetal hyperreflectivity and focal dark and dull lesions with peripheral hyperreflectivity.

Musculoskeletal: BCS 7/9, generalized weakness, recumbent, and unwilling to walk.

Cardiovascular: No murmurs or arrhythmias ausculted, pulses moderate and synchronous.

Respiratory: Tachypnea with a shallow respiratory pattern. Decreased lung sounds were present ventrally.

GI/genitourinary: No clinically significant abnormalities. The transplanted kidney could be palpated in the right abdomen. The bladder was small.

Lymph nodes: No clinically significant abnormalities.

Neurologic Examination

Mentation: Obtunded.

Gait/Posture: The cat had a tendency to lean to the right, but could not or would not walk more than a few steps.

CASE EXAMPLE—cont'd

Cranial nerves: Menace responses were absent bilaterally.
Postural reactions: Decreased conscious proprioception was present in all four limbs.
Spinal reflexes and panniculus reflex: Normal.
Neuroanatomic location: Cerebrothalamic, possibly right sided.

Laboratory Findings

CBC: HCT 30.4% (30%–50%), MCV 46.5 fL (42–53 fL), MCHC 32.6 g/dL (30–33.5 g/dL), reticulocytes 18,000 cells/μL (7,000–60,000 cells/μL), WBC 22,860 cells/μL (4,500–14,000 cells/μL), neutrophils 19,660 cells/μL (2,000–9,000 cells/μL), band neutrophils 2,286 cells/μL, lymphocytes 457 cells/μL (1,000–7,000 cells/μL), monocytes 229 cells/μL (50–600 cells/μL), eosinophils 229 cells/μL (150–1,100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets clumped but adequate. Neutrophils had slight toxic change and band neutrophils had marked toxic change.

Serum chemistry profile: Anion gap 24 mmol/L (15–28 mmol/L), sodium 136 mmol/L (151–158 mmol/L), potassium 3.5 mmol/L (3.6–4.9 mmol/L), chloride 98 mmol/L (113–121 mmol/L), bicarbonate 18 mmol/L (15–21 mmol/L), phosphorus 4.3 mg/dL (3.2–6.3 mg/dL), calcium 8.3 mg/dL (9.4–11.4 mg/dL), BUN 48 mg/dL (18–33 mg/dL), creatinine 0.8 mg/dL (1.1–2.2 mg/dL), glucose 140 mg/dL (73–134 mg/dL), total protein 4.8 g/dL (6.6–8.4 g/dL), albumin 1.4 g/dL (1.9–3.9 g/dL), globulin 3.4 g/dL (2.9–5.3 g/dL), ALT 19 U/L (28–106 U/L), AST 27 U/L (12–46 U/L), ALP 5 U/L (14–71 U/L), GGT 0 U/L (0–4 U/L), cholesterol 141 mg/dL (89–258 mg/dL), total bilirubin 1.5 mg/dL (0–0.2 mg/dL).

Imaging Findings

Thoracic radiographs (see Fig. 60.5): There was a moderate amount of pleural effusion present. There was a mass associated with the caudal aspect of the left caudal lung lobe. The cardiac silhouette was completely obscured on the lateral projection. On the VD projection, there appeared to be a mass effect superimposed over the caudal border of the cardiac silhouette that deformed the left and right caudal lung lobes.

Abdominal ultrasound: The native kidneys were markedly diminished in size, irregular in contour, and had a markedly irregular parenchyma with a lack of corticomedullary distinction. The transplanted kidney appeared within normal limits. The muscularis layer of the small intestine was mildly thickened diffusely. A Y-shaped region of mineralization is identified within the right liver lobes, which is likely associated with the biliary system.

Treatment and Outcome

Thoracocentesis was performed and 35 mL of turbid red fluid was removed. Preliminary examination of the fluid confirmed the referring veterinarian's findings. Unfortunately, the cat became progressively more agitated and tachypneic, thoracocentesis was aborted, and Bob was placed in a cage with oxygen supplementation. Treatment with IV crystalloid fluids (0.9% NaCl with 20 mEq/L KCl at 12 mL/hour), enrofloxacin (2.5 mg/kg, IV, q12h) and ampicillin (22 mg/kg, IV, q8h) was initiated and pleural fluid was submitted to the laboratory for cytologic examination and aerobic and anaerobic bacterial culture. The plan was to stabilize Bob with this treatment until additional thoracocentesis and chest tube placement could be performed, and specimens could be collected for additional diagnostic tests, if necessary. Differential diagnoses that were considered were cryptococcosis, toxoplasmosis, FIP, a systemic bacterial infection, and neoplasia. However, 10 hours after admission, at 2:00 AM, Bob developed respiratory and cardiac arrest. The owner elected euthanasia.

Necropsy Findings

Gross necropsy findings consisted of 120 mL of flocculent, serosanguinous fluid within the thoracic cavity and multifocal to coalescing, variably sized, white to grey, firm to caseous nodules that largely effaced the caudal lung lobes and extended through the pleural surface, with adhesions to the thoracic diaphragm and pleura (see Fig. 60.3A). A 2.5-mm nodule was also present in the wall of the left ventricle. The peritoneal cavity contained multiple adhesions from the small intestines to the omentum and the stomach to the left abdominal wall. The right medial liver lobe contained a focal, white to grey mass that was 10 cm in diameter and oozed purulent material when cut. The spleen contained multiple, white, raised, pinpoint foci. The native kidneys were shrunken, pale, irregular, and had loss of corticomedullary definition. The right transplanted kidney contained three to four, tan, firm, homogenous cortical nodules that ranged 2 to 4 mm in diameter. On cut section, the brain contained multifocal, randomly distributed, soft, white to grey, homogenous foci that measured 1 to 4 mm in diameter (see Fig. 60.3B). Histopathology of the lung, pleura, myocardium, thoracic diaphragm, spleen, liver, transplanted kidney, adrenal medulla, stomach, salivary gland, brain, and meninges revealed chronic, severe, necrotizing pyogranulomatous inflammation with intralesional branching filamentous bacteria. There was also chronic, moderate, multifocal, and necrotizing pyogranulomatous choroiditis and cyclitis in both eyes. The bacteria were gram positive but were not acid fast (see Fig. 60.6).

Microbiologic Testing

Aerobic and anaerobic bacterial culture (liver, lung specimens collected at necropsy): Small numbers of *N. nova*. No other bacteria were cultured.

Diagnosis

Disseminated *N. nova* infection.

Comments

In this case, disease followed a rapid clinical course, as can occur in human patients with severe immunodeficiency. The trough whole blood cyclosporine concentration was high; the goal of treatment is to obtain blood concentrations of approximately 300 to 500 ng/mL, although the optimum concentration that achieves adequate but not excessive immunosuppression in cats is not known.[21] Treatment with antimicrobial drugs was not effective given the advanced nature and severity of the disease in this cat.

Mycobacterial Infections

Carolyn R. O'Brien, Conor O'Halloran, Danièlle A. Gunn-Moore, Jane E. Sykes

KEY POINTS

- First Described: Evidence of tuberculosis in humans dates back to between 2400 and 3400 B.C., but the causative agent was not demonstrated until 1882 (Robert Koch).[1]
- Cause: Companion animals can become infected by a number of different mycobacteria, including members of the *Mycobacterium tuberculosis* complex (MTBC) and non-tuberculous mycobacteria (NTM; family *Mycobacteriaceae,* order *Actinomycetales*). Mycobacteria belonging to the MTBC that have been detected in cats and dogs include *Mycobacterium bovis* and *Mycobacterium microti*; *M. tuberculosis* has also been detected in dogs. Many NTM are opportunistic pathogens of cats (and occasionally dogs); definitively identified species have been characterized as belonging to the *Mycobacterium leprae*-complex, *Mycobacterium avium*-complex, the rapid-growing mycobacteria (RGM), the slow-growing mycobacteria, and fastidious species with an enigmatic epidemiology.
- Affected Hosts: Mycobacteria can cause disease in almost all mammals. Each species within the MTBC is host adapted, and host species include humans, cattle, voles, goats, meerkats, mongoose, and deer. However, spillover from these hosts into other mammals is frequent, and infections have been identified in mammals as diverse as cats and dogs to lions and elephants. NTM have a host range that is even broader than the tuberculous mycobacteria, as they are also pathogens of fish and amphibians.
- Geographic Distribution: Mycobacterial infections are globally ubiquitous, but the relative frequency of infections with each species differs by location.
- Primary Mode of Transmission: The most frequent route of transmission to companion animals is thought to be inoculation of mycobacteria into the skin; less-frequent routes of transmission include the inhalation of aerosolized mycobacteria, ingestion of contaminated foodstuffs (e.g., raw milk, contaminated meat, or infected prey), direct contact of open wounds with contaminated environments, and, possibly, direct contact with an infected wildlife host, companion animal, or humans.
- Major Clinical Signs: Cutaneous nodular, ulcerated, or draining skin lesions; peripheral or internal lymphadenopathy; pneumonia with tachypnea and/or cough; osteomyelitis; granulomatous or pyogranulomatous infiltrates in a variety of abdominal organs; and, rarely, the CNS and/or eyes.
- Differential Diagnoses: Neoplasia (especially lymphoma and carcinoma), feline infectious peritonitis (cats), toxoplasmosis, tularemia, nocardiosis, actinomycosis, rhodococcosis, bartonellosis, leishmaniosis, and fungal infections.
- Human Health Significance: A third of the global human population is infected with an organism that belongs to the MTBC, while NTM are an emerging health risk for humans with comorbidities. The major zoonotic risk is associated with MTBC organisms, but there are only a small number of cases that have confirmed companion animals as the source of human infection, so the risk appears very low.

INTRODUCTION

Mycobacteria (genus *Mycobacterium,* family *Mycobacteriaceae,* order *Actinomycetales*) are aerobic (or in some cases, microaerophilic), non–spore-forming, non-motile, pleomorphic bacterial rods. They are more resistant to extremes of temperature and pH, and routine disinfection than most other bacteria, properties conferred by their notably thick, hydrophobic cell wall, which contains high concentrations of mycolic acids and lipids. This cell wall also confers resistance to decolorization with acid-alcohol. This acid-fast staining property, combined with their morphology, makes species of the genus recognizable microscopically, including in histopathologic and cytologic specimens.

The genus contains an increasing number of species that cause widely divergent clinical syndromes. At one extreme, these species have among them some of the most ancient, notorious, and arguably successful obligate pathogens of both people and animals. The most widely known and best characterized diseases of people are tuberculosis (most commonly caused by *Mycobacterium tuberculosis*) and leprosy (*Mycobacterium leprae*). Nine thousand-year-old human remains in the eastern Mediterranean contain evidence of the DNA of mycobacteria belonging to the *M. tuberculosis* complex (MTBC),[2] and MTBC DNA has been recovered from the diseased bones of a bison trapped in permafrost *circa* 17,000 years ago.[3] Nevertheless, strict criteria to exclude environmental contamination have only been validated in specimens that date from up to *circa* 5000 years ago.[4] The MTBC are of significant global concern; a third of the current global human population is estimated to be infected with an MTBC organism, of which 5% to 10% will eventually develop active clinical disease. It is estimated that up to 85% of all African bovids reside in areas with a high prevalence of poorly controlled bovine tuberculosis.[5]

At the other end of the spectrum are numerous potentially pathogenic environmental non-tuberculous mycobacteria (NTM). These opportunistic pathogens are also now recognized as a major global public health problem. Members of the *M. avium*-complex (MAC), in particular, are an emerging threat to human health. There is a growing body of evidence that hospital admissions due to associated pulmonary disease are increasing, particularly in countries with a low incidence of tuberculosis. This is ascribed to increased numbers of

immunocompromised patients, the use of advanced diagnostic tools, and a larger awareness of the role of NTM in disease.[6]

The taxonomy of the genus is complex. Two primary systems exist for the taxonomic division of the genus. The Runyon scheme was developed in the latter half of the 20th century.[7] It is based on an isolate's laboratory growth characteristics, including substrate usage, growth time until colonies are visible, and colony phenotype. However, as it is not possible to grow all species under artificial conditions, with the advent of molecular techniques (such as whole-genome sequencing), there has been a departure from the Runyon system in favor of molecular phylogeny.

Mycobacteria can be divided into two main groups (Table 61.1):

1. The *Mycobacterium tuberculosis* complex (MTBC). The MTBC consists of 10 phylogenetically related species of mycobacteria associated with tuberculosis in man and/or other animals (*M. tuberculosis, Mycobacterium bovis, Mycobacterium africanum, Mycobacterium pinnipedii, Mycobacterium caprae, Mycobacterium canettii, Mycobacterium microti, Mycobacterium orygis, Mycobacterium suricattae*, and *Mycobacterium mungi*). These are obligate intracellular pathogens.
2. The NTM. These are opportunistic saprophytes, variably distributed in the environment, especially in soil and water systems (both natural and man-made). Of over 170 characterized NTM species, approximately 25 may be pathogenic in people and animals.[8] This group can be further subdivided into: (i) "slow-growing" (e.g., MAC), (ii) "rapid-growing", and (iii) "fastidious" mycobacteria. Slow-growing mycobacteria typically take longer than 7 days to culture in laboratory conditions.[9] RGM usually grow in the laboratory within 7 days at 24° to 45°C. Fastidious mycobacteria cannot be cultured by routine laboratory methods and have an enigmatic ecological niche.

MYCOBACTERIUM TUBERCULOSIS COMPLEX INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Of the MTBC, only *M. tuberculosis*, *M. bovis*, and *M. microti* have been shown to infect dogs and cats (Table 61.2). *Mycobacterium africanum* and *M. canetti* are rare causes of human tuberculosis in Africa, *M. pinnipedii* infects seals, and *M. caprae* is primarily a ruminant pathogen. MTBC organisms share > 95% of DNA-DNA

TABLE 61.1 Mycobacterial Pathogens of Clinical Significance for Cats and Dogs

Group	Mycobacterial Species	Description
M. tuberculosis complex	*M. tuberculosis, M. bovis, M. microti*	Host-associated, slow-growing species. Cause cutaneous and disseminated granulomatous disease in dogs (all three species) and cats (*M. bovis* and *M. microti*)
Slow-growing non-tuberculous mycobacteria	*M. avium* subsp. *avium, M. avium* subsp. *hominissuis, M. avium* subsp. *paratuberculosis, M. kansasii, M. ulcerans, M. genavense, M. malmoense, M. celatum, M. terrae, M. simiae, M. nebraskense, "M. visibile"**	Opportunistic, environmental, slow-growing species. Cause pyogranulomatous cutaneous or disseminated disease in dogs or cats. Some may cause leprosy syndromes in cats
Rapidly growing non-tuberculous mycobacteria	*M. fortuitum, M. smegmatis, M. abscessus, M. chelonae, M. thermoresistibile, M. goodii, M. flavescens, M. alvei*	Opportunistic, environmental, rapidly growing species. Cause pyogranulomatous panniculitis, pneumonia, or disseminated infections in cats or dogs
Lepromatous mycobacteria	*M. lepraemurium*, the CLG organism, and other unnamed species, some with genetic resemblance to known non-tuberculous mycobacteria	Highly fastidious or unculturable mycobacteria. Cause nodular granulomatous to pyogranulomatous cutaneous disease in cats (all species) or dogs (CLG organism)

*The exact position of "*M. visibile*" is not clear; it has also been grouped within the lepromatous mycobacteria.
CLG, canine leproid granuloma.

TABLE 61.2 Organisms of the *Mycobacterium tuberculosis* Complex of Clinical Significance for Dogs and Cats

Species	Host(s)	Major Reservoir Hosts	Geographic Distribution of Reported Cases in Companion Animals	Clinical Signs	Human Health Significance
M. tuberculosis	Dogs	Humans	USA, Africa, southern Europe	Pneumonia and tracheobronchial lymphadenopathy; rarely dissemination to the CNS, liver, kidney	Primary cause of tuberculosis in humans. Reverse zoonosis. Transmission back to humans not reported but may be possible
M. bovis	Cats, dogs	Cattle, Eurasian badgers, other wildlife species	Southwestern England and Wales, New Zealand, Argentina, rarely USA	Cutaneous lesions, peripheral lymphadenopathy, occasionally dissemination to abdominal lymph nodes and other organs, osteomyelitis	Rare cause of tuberculosis in humans but transmission from animals to humans possible
M. microti	Cats, very rarely dogs	Voles, wood mice, shrews, camelids	Southwestern Scotland, northern and southern England, western Europe	Cutaneous lesions, peripheral lymphadenopathy, less often pneumonia, arthritis, osteomyelitis, ocular lesions	Very rare cause of tuberculosis in humans

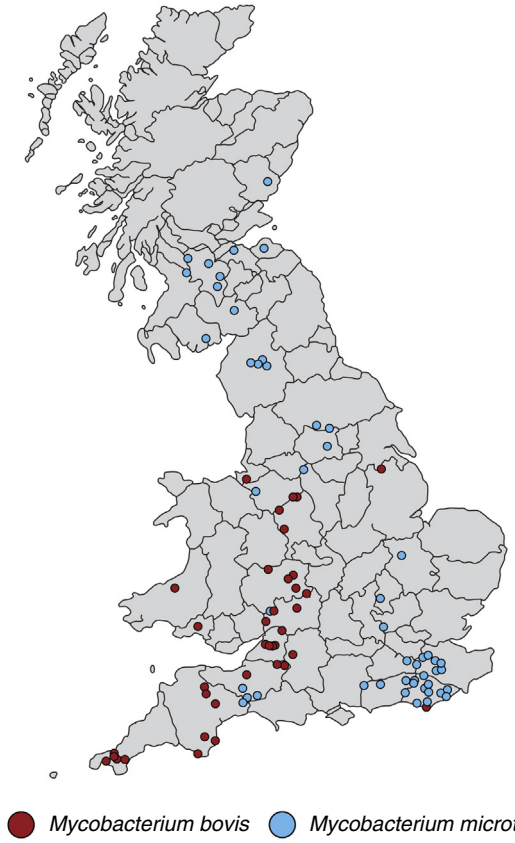

Fig. 61.1 Geographic distribution of *M. microti, M. bovis* and *M. avium* isolates from cats in the United Kingdom. (Redrawn from Gunn-Moore DA, McFarland SE, Brewer JI, et al. Mycobacterial disease in cats in Great Britain: I. Culture results, geographical distribution and clinical presentation of 339 cases. *J Feline Med Surg.* 2011;13:934-944.)

homology hence it is challenging to differentiate them from each other. Compared with other mycobacterial species, MTBC bacteria do not survive well in the environment, although *M. bovis* can survive months in feces, carcasses, or soil. Humans are the only reservoir host for *M. tuberculosis*, and *M. tuberculosis* is responsible for > 90% of tuberculosis in humans.

Cats

Only *M. bovis* and *M. microti* have frequently been detected in cats.[10-12] Rodents (especially voles and shrews) are reservoir hosts for *M. microti*, and cattle and a variety of wildlife species are reservoir hosts for *M. bovis*. The overwhelming majority of feline infections with *M. microti* and *M. bovis* have been reported from the United Kingdom (Fig. 61.1), where *M. microti* infection is endemic in voles, wood mice, and shrews, and *M. bovis* infection is endemic in Eurasian badgers and cattle. In one United Kingdom study, 19% of feline mycobacterial infections were caused by *M. microti* and 15% by *M. bovis* (Table 61.3).[13] Therefore any given cat with a mycobacterial infection in the United Kingdom has a greater than 1/3 probability of having tuberculosis. Similar data do not exist for other tuberculosis-endemic locations. Infection by *M. tuberculosis* is extremely rare in the cat; and it appears that cats have a natural resistance to this pathogen. Only very occasional infections are documented, generally through anthropozoonotic spread.[14]

In the United Kingdom, *M. bovis* infections occur where there are high levels of endemic infection in local bovine and wildlife populations such as the southwest of England.[13,15] In comparison, *M. microti* infections are much more common in areas with high prevalence of this infection in the wild rodent population, typically southeast of London, the north of England, and throughout Scotland.[13]

TABLE 61.3 Mycobacterial Culture Results from United Kingdom Cats

Species	Number of Isolates	Percentage of Total Submissions	Percentage of Culture Positive
M. microti	63	19	40
M. bovis	52	15	33
M. avium	24	7	15
M. malmoense	4	1	3
M. fortuitum	4	1	3
M. celatum	1	<1	<1
M. intracellulare	1	<1	<1
Unclassified	10	2	6
No growth	180	53	-
Culture-positive total	159	47	-
Total	339	100	-

Specimens were from cats with histologic findings indicative of mycobacteriosis. Specimens were submitted to the Animal Health and Veterinary Laboratories Agency (now Animal and Plant Health Agency [APHA]) for mycobacterial culture between January 2005 and December 2008.[13,15]

Tuberculosis is most frequently diagnosed in adult male cats with a history of hunting.[13] The median age at diagnosis is 3 years for *M. bovis* and 8 years for *M. microti*. There is no link between MTBC infections and retrovirus infection in cats.

The distribution of lesions together with the facts that: (1) the highest incidence of infections occurs in young, male, active hunting cats (particularly those that prey on small rodents); (2) mice and voles are permissive hosts for *M. microti*[16]; and (3) mice, rats, stoats, mink, and ferrets (as well as a wide range of larger mammals) can harbor *M. bovis*,[17] suggests that cats are infected through injuries sustained while hunting. The geographic distribution of spoligotypes of *M. microti* and *M. bovis* aligns almost perfectly for feline, bovine, and wildlife mycobacterial strains. In the case of *M. bovis*, prey species likely act as intermediate hosts, and infection may also be acquired when wounds become contaminated by environmental sources, such as the areas around infected badger setts where *M. bovis* can persist for extended periods.[18]

Recently, the United Kingdom experienced an outbreak of *M. bovis* tuberculosis in cats that appeared to be associated with consumption of a commercial raw venison-based diet. Initially, six sick cats and seven cohabiting cats were identified with evidence of *M. bovis* infection. Five were either too sick to treat or deteriorated despite therapy. The cats were exclusively housed indoors and were fed the same commercially available raw food produced by a single manufacturer. Other possible sources of exposure to *M. bovis* were excluded. Infection with *M. bovis* genotype 10:a was confirmed by culture and DNA typing of isolates in five cats. Ultimately, infection was either confirmed or strongly suspected in more than 120 cats based on a positive immunological response in an IFN gamma-release assay (IGRA, see Diagnosis, below) with or without PCR-based confirmation of infection, 84 of which were subclinical contact cats. This outbreak demonstrated the critical nature of meat inspection procedures in the safe production of raw food diets for companion animals and also highlights the microbiologic risks that these diets can present.

The incidence of feline tuberculosis outside the United Kingdom appears to be lower. This may reflect differences in the epidemiology of these organisms—for example, *M. bovis* has been eliminated from much of central Europe, Australia, and some states in the United States. However, feline *M. bovis* infections have been reported from New Zealand, where brushtail possums act as reservoir hosts[19]; Argentina, where stray cats are often fed raw cattle lung[20]; and rarely the United States.[21] Major wildlife reservoirs in North America, which include the white-tailed deer, bison, and elk, are less likely to interact with cats compared with small mammals, which may explain why fewer *M. bovis* infections are reported in cats from the USA when compared with the United Kingdom. It is not known if *M. bovis* spreads from large herbivores to small rodents in the United States as it does in the United Kingdom, but that route of transmission remains possible. *Mycobacterium microti* infections occur in companion animals as well as species such as the wild boar in countries including France and Germany, where *M. bovis* is no longer a concern.

Tuberculosis has occurred where cats within the same household or in close geographical proximity develop signs within a short time of each other.[22,23] The epidemiological significance of such situations is unclear, as these cats may share a source of infected prey (e.g., local woodland); it is therefore possible that such infections are independently acquired rather than being representative of cat-to-cat transmission. However, multiple within-household cases have occurred where at least one cat has had no history of outdoor access (authors' unpublished observations). In these cases, cat-to-cat transmission is likely, probably as a result of close contact such as grooming. Cat-to-cat transmission was documented in an outbreak of *M. bovis* infection in a group of research cats in Australia,[24] after importing an infected kitten from the Ukraine into a cattery in Italy,[25] and was suspected in a household in Ireland.[26] It should be noted that the number of these cases remains small and the risk to healthy, immunocompetent cats in contact with an infected cat is low.

Nosocomial transmission of *M. bovis* has been reported.[26,27] In one outbreak, the index case, with a purulent ulcerated submandibular lesion, was euthanized and two cats that underwent elective surgery in the same practice developed tuberculosis. The subsequent cases developed severe systemic disease in a much shorter timescale than is typical of disease acquired through sylvatic infection.[21,26]

Although not definitively demonstrated, there is strong circumstantial evidence for transmission of tuberculosis from humans to pet cats.[28,29] This is unsurprising given the small infectious dose of *M. bovis* required to cause disease in mammals, including cats.[30,31]

Dogs

Most of the information about tuberculosis in dogs comes from sporadic case reports, mostly of *M. tuberculosis*[32-37] and *M. bovis* infections.[30,38-44] Dogs with tuberculous mycobacterial infections typically have either significant GI disease (weight loss, vomiting, and diarrhea; usually in association with *M. bovis* infection) or pulmonary pathology (Fig. 61.2). There are extremely rare reports of *M. microti* infection in dogs, to date exclusively reported in Europe.[45]

Dogs are uncommonly infected with *M. bovis*.[46-48] Wounds inflicted by badgers or a squirrel have preceded disease in affected dogs.[46] In the United Kingdom, disease in dogs has been restricted to southwestern England or Ireland. However, in 2016 and 2017 an outbreak of *M. bovis* tuberculosis affected a working pack of foxhounds in the United Kingdom.[49] The pack initially housed nearly 200 hounds and was located in the medium-risk area of the United Kingdom for endemic *M. bovis* infection (the "Edge area"). The pack were fed animal (beef or horse) by-products from local farms. Affected hounds showed signs of acute lethargy, hyporexia, marked polyuria and polydipsia, and then collapse and death or euthanasia within 48 hours of the onset of signs. Overall 164 clinically well hounds were tested for *M. bovis* infection with a combination of IGRA and antibody tests (DPP VetTB, Chembio); 59% responded positively to at least one of the tests. Infection was confirmed in three dogs at necropsy. Moderate to severe necrotizing granulomatous glomerulonephritis was identified in all affected animals, with rare intralesional acid-fast bacteria (AFB). Some dogs also had enlarged abdominal lymph nodes. This outbreak suggested that dog-to-dog transmission may be possible within certain epidemiological contexts and also that diagnostic tests used to identify infected individuals of other species can be useful in dogs.

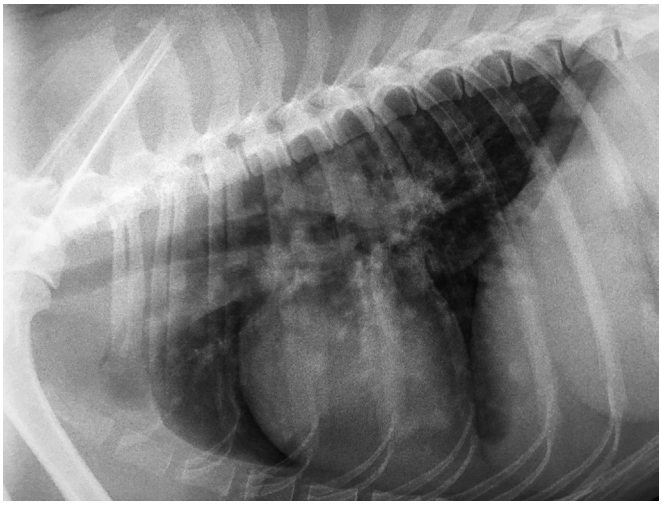

Fig. 61.2 Lateral thoracic radiograph from a 6-year-old, male, neutered, Jack Russell terrier dog infected with *M. bovis*. There are multifocal to coalescing areas of soft-tissue opacity (granulomas) distributed throughout the lung fields.

Disease due to *M. tuberculosis* has been reported in dogs worldwide.[32-34,40,44,50-53] Dogs are usually infected after prolonged aerosol exposure to contaminated human respiratory secretions, so the disease is a "reverse zoonosis" (*anthropozoonosis*). Thus, disease occurs in dogs in regions where tuberculosis occurs in humans. In the US, *M. tuberculosis* infection is most prevalent in humans from the northeast/mid-Atlantic states, southern states, Alaska, California, and Nevada (Fig. 61.3). Dogs have not been reported to spread *M. tuberculosis* infection to humans despite prolonged close contact in some situations,[34] possibly because the cavitary lesions that are required for transmission do not develop to the same extent in dogs as they do in humans. However, organisms have been detected in dogs' sputum, so transmission remains possible.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

MTBC organisms are inhaled (*M. tuberculosis* and possibly *M. bovis*), ingested (*M. bovis* or *M. microti*), or inoculated into the skin (*M. bovis* or *M. microti*) and replicate locally. Organisms are then phagocytosed by macrophages but they survive and replicate within these cells, and macrophage destruction leads to recruitment of lymphocytes and additional monocytes, which initiates tubercle formation. Infected macrophages also travel to local lymph nodes, with development of a *primary complex* lesion. When CMI is either defective or actively subverted by mycobacteria, dissemination to distant sites occurs. Development of delayed-type hypersensitivity responses acts to control the initial infection, or

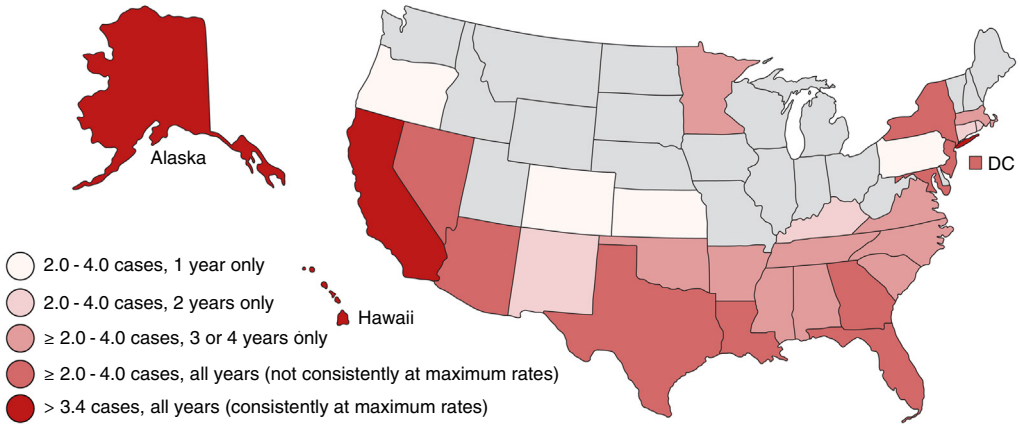

Fig. 61.3 Geographic distribution of human cases of *Mycobacterium tuberculosis* infection in the USA, 2005–2011. (Compiled from Morbidity and Mortality Weekly reports data on trends in human tuberculosis, years 2005, 2007, 2008, 2010, and 2011.)

Fig. 61.4 Typical alopecic cutaneous nodule (granuloma) above the right eye of a 4-year-old, male, neutered, retrovirus-negative, domestic shorthair cat with *M. bovis* infection.

Fig. 61.5 A facial granuloma (a "fight and bite site") over the rostrolateral aspect of the temporomandibular joint of a 4-year-old, female, neutered, retrovirus-negative, domestic shorthair cat with *M. microti* infection.

may lead to central necrosis and calcification of the primary complex lesions, with persistence of organisms in the center of the lesions.

Most cats with tuberculosis have localized nodular cutaneous disease (Fig. 61.4), frequently with ulceration, and occasionally a draining sinus tract.[10,11,13] The lesions are typically distributed around the face, extremities, and tail base—the so-called "fight and bite sites" (Fig. 61.5). Skin lesions may be accompanied by a localized or even generalized lymphadenopathy. Lymphadenopathy, usually of the submandibular or popliteal nodes, may be the only sign (termed an *incomplete primary complex*). A predominately GI form of the disease exists, where granulomas form in the intestines.[30] Intestinal thickening, accompanied by multicentric abdominal lymph node involvement, almost always includes the mesenteric nodes. Subsequent intestinal malabsorption is associated with weight loss, diarrhea, vomiting, and anemia.[13] This form of the disease typically historically occurred in cats that drank tuberculous cows' milk. Since the introduction of pasteurization, this is less prevalent. More recently it occurred as a result of the ingestion of contaminated raw meat by cats in the United Kingdom.[49] Pulmonary lesions occur when bacteria are inhaled, with classic tubercle formation in lungs and hilar lymph nodes. Much more common, however, is pulmonary disease secondary to putative hematogenous spread of bacteria from the site of inoculation in the skin. This generates a diffuse interstitial pattern of disease (Fig. 61.6),[54] which eventually becomes bronchial and is clinically observable as progressive dyspnea followed by the development of a soft productive cough. Disseminated disease is associated with a range of clinical signs, including hepatosplenomegaly, pleural and pericardial effusions, generalized lymphadenopathy, weight loss, and pyrexia.[30] Ocular involvement (chorioretinitis,[55] conjunctivitis[47]) and tuberculous arthritis/osteomyelitis have been occasionally reported.[11,56]

Clinical signs in dogs with pulmonary tuberculosis due to *M. tuberculosis* are slowly progressive and consist of chronic, productive or non-productive cough, inappetence, weight loss, and lethargy.[34,51] Dissemination to non-pulmonary sites such as the CNS, liver, or kidney can result in neurologic signs,[50] weight loss, vomiting, or diarrhea.[44,52] Involvement of the lungs, liver, kidneys, and/or lymph nodes can occur in dogs infected with *M. bovis*.[46,48,57] Isolated lung and tracheobronchial node involvement similar to that often

Fig. 61.6 Lateral thoracic radiograph from a 5-year-old, male, entire, retrovirus-negative, Egyptian Mau cat infected with *M. microti*. There is diffuse interstitial pathology with soft-tissue opacity and sternal lymphadenopathy; these are typical findings associated with secondary pulmonary dissemination of tuberculosis in the cat.

reported for *M. tuberculosis* was described in one dog.[48] Foxhounds with *M. bovis* infection had signs of lethargy, anorexia, polyuria/polydipsia, collapse, and death or euthanasia secondary to renal infection and necrosis.[49]

Physical Examination Findings

The most common physical examination findings in cats (and to a lesser extent in dogs) that are infected with *M. bovis* or *M. microti* include single or multiple firm cutaneous nodules, and enlargement of one or more peripheral lymph nodes. Cutaneous nodules may be mobile or fixed to underlying tissues (muscle and bone), and can ulcerate or drain purulent fluid. Skin lesions are most prevalent on the head, but can also occur on the limbs and the trunk.[10,11] Enlarged mesenteric lymph nodes, spleen, and/or liver may be detected on abdominal palpation. Involvement of internal lymph nodes is more common with *M. bovis* infections (21% of cats) than with *M. microti* infections (9% of cats).[13] Lameness may be present in cats with bone involvement.

Dogs with pulmonary involvement caused by *M. tuberculosis* may show fever, increased lung sounds, and cough. Other physical examination findings that relate to dissemination of infection may be present, such as thin body condition, neurologic signs, or hepatomegaly. Abnormal findings on examination of the respiratory tract and/or abdominal organs may also be detected in dogs with disseminated *M. bovis* or *M. microti* infection.

DIAGNOSIS

Diagnosis of MTBC infection usually relies on suggestive history, clinical signs, and radiographic abnormalities, combined with histopathology, molecular tests, and culture. When mycobacterial infection is suspected, specimens collected for analysis should be divided into two portions—one for histopathology (in formalin), one for mycobacterial culture, and/or mycobacterial PCR (fresh or frozen). The receiving laboratory should be informed that mycobacterial infection is a possibility.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Laboratory abnormalities in dogs and cats infected with MTBC organisms are nonspecific. Mild anemia of inflammatory disease and neutrophilic leukocytosis, sometimes with a left shift, and monocytosis are occasionally present. The serum chemistry profile may show hypoalbuminemia and hyperglobulinemia. Increased serum liver enzyme activities have been reported in dogs with hepatic involvement.[44]

Hypercalcemia secondary to granulomatous disease can also occur in dogs or cats.[13,47] If total serum calcium concentration is elevated, then evaluation of serum ionized calcium concentration is recommended. Rates of hypercalcemia in *M. tuberculosis*-infected (human) adults vary from 6% to 48%.[58] Symptomatic hypercalcemia in human tuberculosis cases is uncommon, with rates of ~3% in adults.[59] Vitamin D concentrations are associated with mycobacterial immunity, and calcitriol has anti-mycobacterial activity *in vitro*. Macrophages produce calcitriol when they phagocytose mycobacteria following TLR2 stimulation. The serum concentration of 25(OH)D decreases, and ionized calcium concentration increases. These effects may manifest as hypovitaminosis D and hypercalcemia. This phenomenon has been long established in human medicine and more recently in cats with tuberculosis.[60,61] In both species, the presence of either factor at diagnosis is a poor prognostic indicator. It is unclear whether these findings are a marker of disseminated disease (and so will be harder to treat), or whether they inherently influence disease outcome. Clinical trials in humans have attempted to establish the benefit, if any, of treating with supplemental vitamin D to reduce subclinical hypercalcemia, but the results to date have been discordant, and its use is not currently included in any treatment guidelines.

Diagnostic Imaging

Plain Radiography

Findings on plain thoracic radiography in dogs infected with *M. tuberculosis* or *M. bovis* include tracheobronchial or mediastinal lymphadenopathy,[34,44,51] interstitial to alveolar infiltrates,[57] pleural effusion,[44] and lobar consolidation (Figs. 61.2 and 61.7).[34,57] Similar abnormalities may occur in cats infected with *M. microti* and *M. bovis* (see Fig. 61.6). Bronchial, alveolar, nodular interstitial, and unstructured interstitial patterns predominate in cats, and perihilar lymphadenopathy can be present.[10,12] Calcification of pulmonary lesions or lymph nodes may be evident in dogs or cats. Hepatomegaly, splenomegaly, or lymphadenopathy, with or without ascites, may be present on abdominal radiography, or abdominal radiographs may be unremarkable.[12] Radiographic evidence of osteomyelitis (especially osteolytic lesions) may occur in cats infected with *M. microti* or *M. bovis*, often in association with overlying cutaneous lesions.[12]

Computed Tomography

Thoracic CT findings have been reported for a dog infected with *M. tuberculosis*.[34] Lung lobe consolidation, multifocal stellate opacities, bronchial stenosis, bronchiectasis, tracheobronchial wall thickening, and partially mineralized masses consistent with enlarged mediastinal and tracheobronchial lymph nodes were present (see Fig. 61.7). In this dog, mineralization was not visible on plain thoracic radiographs. CT in human patients with tuberculosis is considered more sensitive than plain radiography for detection of pulmonary lesions and enlarged lymph nodes, and provides better visualization of calcifications.

In 20 cats from the United Kingdom with tuberculosis, CT abnormalities were most commonly seen in the thorax, and consisted of bronchial (n = 9), alveolar (n = 8), ground glass (n = 6), or structured interstitial (n = 15) lung patterns, which were often mixed. Tracheobronchial,

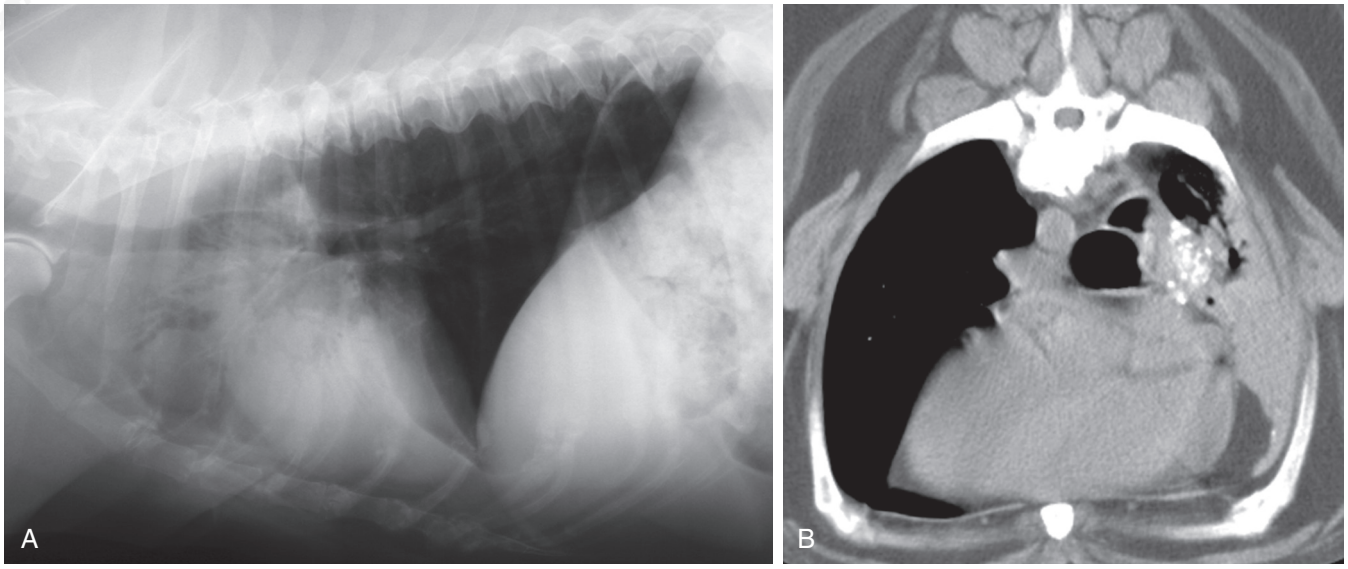

Fig. 61.7 Lateral thoracic radiograph (A) and 7-mm collimated CT image immediately cranial to the carina (B) from a 9-year-old female spayed golden retriever with pulmonary tuberculosis. (A) Consolidation of the right cranial lung lobe is present together with interstitial to alveolar infiltrates in the right middle lung lobe. (B) On the CT scan, the right cranial lung lobe is consolidated and markedly volume reduced. Air bronchograms are present centrally that extend dorsally toward a focal region of aerated lung. The granular mineral opacity adjacent to the right margin of the trachea represents mineralized lymphadenopathy of the right tracheobronchial lymph nodes. (From Sykes JE, Cannon AB, Norris AJ, et al. *Mycobacterium tuberculosis* complex infection in a dog. *J Vet Intern Med*. 2007;21:1108-1112.)

sternal, and cranial mediastinal lymphadenomegaly were common (n = 16). Other abnormalities included abdominal (n = 8) or peripheral (n = 18) lymphadenomegaly, hepatosplenomegaly (n = 7), mixed osteolytic/osteoproliferative skeletal lesions (n = 7), and cutaneous or subcutaneous soft-tissue masses/nodules (n = 4)[62] (Fig. 61.8).

Sonographic Findings

Abdominal sonography may be unremarkable or reveal hepatomegaly, splenomegaly, abdominal lymphadenopathy, and/or ascites. A dog with disseminated *M. tuberculosis* infection had multifocal hypoechoic masses within the kidneys and liver, and mineralization of the hepatic and renal parenchyma.[51]

Microbiologic Tests (Table 61.4)

Cytologic Diagnosis

Cytologic examination of bronchoalveolar lavage fluid is frequently unrewarding in cats with tuberculosis, whereas examination of aspirates from skin nodules can be very informative. Large numbers of activated macrophages as well as neutrophils are typically present.

Cytologic examination of aspirates, effusion, or lavage specimens from the respiratory tract of dogs with pulmonary tuberculosis typically reveals a mixed population of often heavily vacuolated histiocytes, and smaller numbers of degenerate or non-degenerate neutrophils and small lymphocytes.[34,44,57] Intracytoplasmic, nonstaining bacilli may be seen in macrophages (Fig. 61.9).[57] Moderate anisocytosis or anisokaryosis of exfoliated respiratory epithelial cells may be present, which might lead the clinician to suspect pulmonary neoplasia.[34] The presence of cholesterol crystals, caseous debris, and concentrically laminated crystalline structures known as calcospherite bodies can be a clue for the presence of MTBC infection.[34,57]

Acid-fast stains. Acid-fast stains can be applied to smears or tissue sections for detection of tuberculous mycobacteria (Fig. 61.10). Organisms are faintly beaded bacilli, and are often found within macrophages. The presence of AFB suggests mycobacterial infection, but is not specific for infection with MTBC organisms. Acid-fast staining of smear or cytospin preparations may be insensitive for detection of MTBC organisms and negative results do not rule out infection.

Fig. 61.8 A transverse CT-scanned section through the caudal thorax of a 3-year-old, male, neutered, retrovirus-negative, Oriental cat with *M. microti* infection. The scan reveals a diffuse-structured interstitial pattern comprising mixed nodular and linear structures, characteristic of a reticulonodular pattern which is typical of feline tuberculous pulmonary pathology.

TABLE 61.4 Assays Available for Diagnosis of Mycobacterial Infections in Dogs and Cats

Assay	Specimen Type	Target	Performance
Acid-fast staining	Tissue aspirates, buffy coat smears, body fluids, airway lavage specimens, tissues obtained at biopsy or necropsy	Acid-fast bacteria	Insensitive, especially for some mycobacterial species like MTBC bacteria. Other bacteria, such as *Rhodococcus* and *Nocardia* may also be acid-fast, so positive results are not specific for *Mycobacterium* spp.
Interferon gamma-release assay	Whole blood (peripheral blood mononuclear cells)	Cell-mediated immune response to mycobacterial antigens	Assists in discrimination between *M. bovis*, *M. microti*, and NTM infections, available in the United Kingdom
Mycobacterial culture	See acid-fast staining; avoid use of aspirates or swabs if possible	Culturable *Mycobacterium* spp.	Some mycobacterial species are unculturable. Growth of MTBC organisms and slowly growing NTM may take weeks to months and identification requires special expertise. Allows molecular typing and susceptibility testing
PCR	See acid-fast staining	Mycobacterial DNA	Permits rapid identification of mycobacterial infection and differentiates MTBC from other mycobacteria, so appropriate precautions can be instituted. False-negative results can occur with insufficient specimen size, if there are very few bacteria present, or if degradation of DNA occurs. False-positive results are possible as a result of laboratory contamination

MTBC, *Mycobacterium tuberculosis* complex; NTM, non-tuberculous mycobacteria.

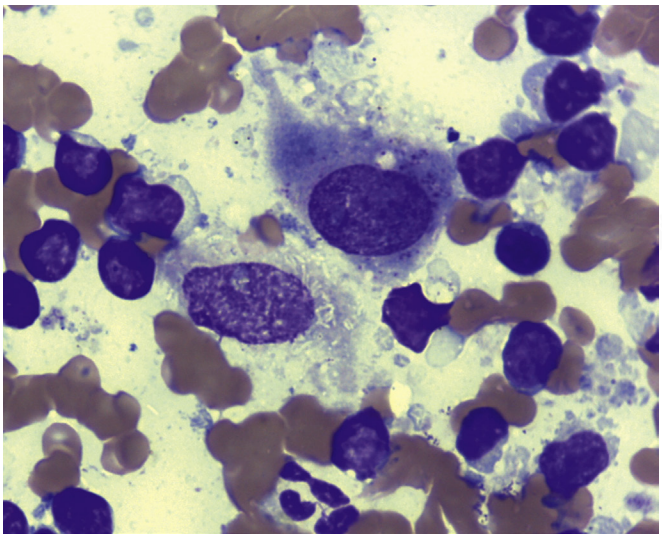

Fig. 61.9 Cytologic appearance of a fine-needle aspirate of a dermal granuloma in the skin of a 3-year-old domestic shorthair cat with *M. bovis* infection (Diff-Quik stain). Some reactive epithelioid macrophages contain intracytoplasmic negative-staining ("ghost") bacilli. Contributing to a pyogranulomatous inflammatory response were several mature and toxic neutrophils.

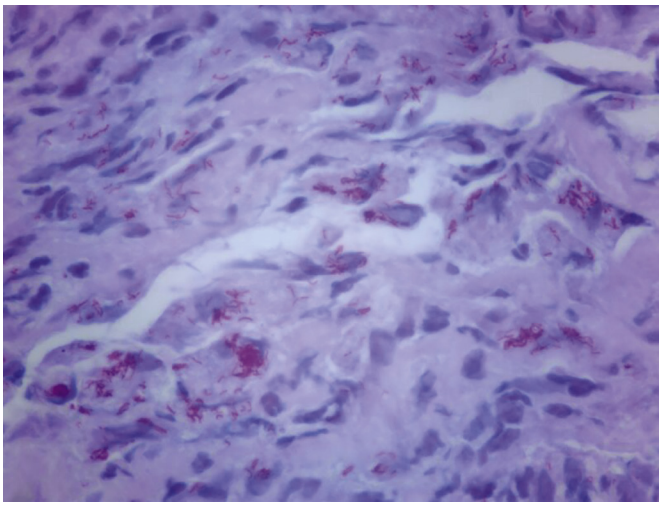

Fig. 61.10 A Ziehl-Neelsen-stained section of a granulomatous lesion biopsied from the nose of a 1-year-old, male, neutered, retrovirus-negative, domestic shorthair cat associated with *M. microti* infection. Staining reveals numerous positively stained (pink), slender, curved bacilli both intracellularly and in the extracellular space.

Immunologic Assays

Intradermal inoculation of tuberculin (a purified protein derivative from *M. tuberculosis*) is well validated and widely used for diagnosis of, and screening for, infection with MTBC organisms in humans. It is also known as the *Mantoux test*. Infected individuals develop a cutaneous delayed-type hypersensitivity reaction at the site of inoculation 48 to 72 hours later. False-negative test results can occur as a result of underlying immunosuppression. False-positive results occur as a result of non-tuberculous mycobacterial infection. Cats do not respond reliably to tuberculin skin testing. Tuberculin skin testing has been performed on the medial surface of the pinna of dogs, but false-positive results occur with a variety of other bacterial infections. Tests for anti-mycobacterial antibodies also appear to be nonspecific.[63]

IGRAs were developed on the principle of quantitatively evaluating IFN-γ production by peripherally circulating antigen-specific effector T-memory cells upon *in vitro* stimulation with mycobacterial antigens, to aid the diagnosis of both active and latent tuberculosis in cattle and, subsequently, human patients.[64] These assays have been widely adopted in the form of the QuantiFERON-TB Gold Test[65] and the T-SPOT.TB[66] as, in people, they have both greater sensitivity and specificity than the Mantoux test. Peripherally circulating blood mononuclear cells (PBMCs) are incubated *in vitro* in the presence of antigens that are present only on specific subsets of mycobacterial species, either in whole blood or as purified cell suspensions (depending on the assay used). Following a prescribed incubation period, either the number of

IFN-γ producing cells (T-SPOT.TB) or the amount of IFN-γ produced (QuantiFERON-TB Gold Test) is then quantified by ELISA.[64] This value is then interpreted to support a diagnosis, in the context of clinical signs and other diagnostic investigations. For example, in human diagnostics whole blood is incubated with the *M. tuberculosis*-specific antigen TB7.7, and two virulence-associated proteins— the 6-kDa early secretory antigenic target (ESAT-6) and the 10-kDa culture filtrate protein-10 (CFP-10). After 16 hours of incubation, the amount of IFN-γ is measured.[67]

IGRAs have several advantages over other diagnostic techniques; they generate results more rapidly than culture and even PCR methods, they are relatively noninvasive (requiring only a single peripheral blood sample), and they can be repeated if necessary as conducting the assay does not alter the systemic immune response (unlike the Mantoux test).

Since 2008, an adapted IGRA has been validated for use in cats, and since 2018 it has been used reliably in dogs.[49] For these assays, PMBCs are isolated from heparinized peripheral blood samples obtained from animals with clinical signs and/or histologic findings that strongly suggest mycobacterial disease. These cells are then incubated for 4 days *in vitro* under several conditions:

a) normal cell culture media (negative control),
b) a mitogen that stimulates IFN-γ production by αβT-cells (positive control),
c) purified protein derived from *M. avium*-complex (PPDA),
d) purified protein derived from *M. bovis* (PPDB), and
e) a combination of the peptides ESAT-6 and CFP-10.

After 4 days, the amount of IFN-γ in the cell culture supernatant is measured by ELISA. A response to the PPDB antigen that exceeds a response to PPDA is indicative of MTBC infection with a sensitivity of 100% in cats.[50,68] The response to ESAT-6 and CFP-10 can discriminate among MTBC as *M. microti* does not produce these molecules but all other members of the MTBC do.[69] Therefore in dogs the pattern "PPDB > PPDA, and ESAT-6/CFP-10 positive" would be generated in response to either *M. tuberculosis* or *M. bovis* infection. However, in cats this pattern suggests *M. bovis* infection, as cats are so rarely infected with *M. tuberculosis*. Unfortunately, some cats infected with *M. bovis* do not respond to the ESAT-6 and CFP-10 peptides; a small study showed that this occurred in 20% of infected cats, so this test does not always discriminate between *M. bovis* and *M. microti* infection.[68,70,71] Refinement of the cut-off values for cats increased test sensitivity for MTBC infections from 83.1% to 90.2%, and *M. bovis* infection from 43% to 68% while maintaining specificity at 100% for both pathogens.[72]

A response to PPDA peptide that exceeds that to PPDB supports a diagnosis of MAC infection. A lack of response to diagnostic peptides when mycobacteria have been identified through other methods (cytology, histopathology) suggests infection with another NTM organism.

IGRA tests can be used to test in-contact animals that have no clinical signs. However, the test must be interpreted with caution. The proportion of subclinical but IGRA-positive patients that go on to develop active clinical disease is unknown.

Bacterial Isolation and Identification

Mycobacterial culture is the "gold standard" for diagnosis of infection by MTBC. The use of laboratories with expertise in isolation of MTBC is recommended. Respiratory specimens such as respiratory washes are usually treated with the mucolytic N-acetylcysteine (NAC) and a sodium hydroxide solution to destroy contaminating bacteria. Specimens from normally sterile sites, such as pleural fluid, are not decontaminated in order to preserve viable mycobacteria as much as possible. Specimens are then inoculated onto special liquid or solid media for isolation of mycobacteria, such as 7H11 agar or Lowenstein-Jensen media (an egg-based medium). Modifications to the media composition may be required on the basis of the mycobacterial species suspected, so good communication between the clinician and the microbiology laboratory can optimize the chance of successful culture. Growth is occasionally evident only several weeks after inoculation of liquid media, and potentially months after inoculation of solid media. However, inoculation of solid media is required because some strains only grow on solid media and growth on solid media allows assessment of colony morphology. Once growth is evident, nucleic acid–based assays, mycolic acid analysis with high-performance liquid chromatography, or mass spectrometry (MALDI-TOF)[73] can be used to determine whether the organism belongs to the MTBC. Molecular mycobacterial antimicrobial drug susceptibility testing can also be performed.

Currently, performance of a series of phenotypic (biochemical) assays on cultured isolates is the gold standard method for differentiation of mycobacterial species that belong to the MTBC. Molecular techniques such as PCR-restriction endonuclease analysis, DNA probing, and 16S rRNA gene sequencing do not always differentiate between MTBC species. Specialized techniques for further typing of MTBC isolates include mycobacterial interspersed repetitive unit-variable-number tandem repeat (MIRU-VNTR) typing, and spoligotyping. Spoligotyping is a PCR-hybridization typing method that targets the direct repeat region of MTBC strains. This region contains multiple sequence repeats interspersed with nonrepetitive spacer sequences. MTBC species vary in the numbers of repeats and the presence or absence of some spacers, and can be differentiated on the basis of their hybridization patterns. Spoligotyping also allows identification of prevalent *M. tuberculosis* genotypes, such as the Beijing genotype, an aggressive, highly transmissible strain that has been associated with multiple drug resistance.[74] MIRU-VNTR is often combined with spoligotyping for identification of MTBC organism genotypes. Spoligotyping has been performed on several MTBC isolates from dogs and cats.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR-based assays are available on a commercial basis for rapid detection of *Mycobacterium* spp. DNA in clinical specimens from dogs and cats in some countries. Genus-specific *Mycobacterium* spp. assays are available, as well as assays that detect mycobacteria other than tuberculosis (MOTT) organisms. These assays can be used in combination to determine whether an organism that belongs to the MTBC is present. A positive result with a genus-specific assay but a negative result with an assay for MOTT organisms implies the presence of an MTBC organism. The results of mycobacterial PCR assays should be interpreted in light of clinical findings, and PCR assays should ideally be used in conjunction with culture, which is the only way to confirm the mycobacterial species involved and allows antimicrobial drug susceptibility testing. The latter is important given the public health implications of MTBC infections.

Pathologic Findings

Gross Pathologic Findings

In addition to cutaneous lesions and peripheral lymphadenomegaly, cats with disseminated *M. bovis* or *M. microti* infections may have enlarged abdominal lymph nodes and multifocal tumor-like, greyish-white masses within parenchymal organs that may have hemorrhagic margins and/or a soft purulent or caseous center. Pulmonary lesions are often greyish-red and may be associated with serosanguineous pleural fluid.

The most frequent gross pathologic findings in dogs infected with *M. tuberculosis* include pulmonary congestion, lobar consolidation, or

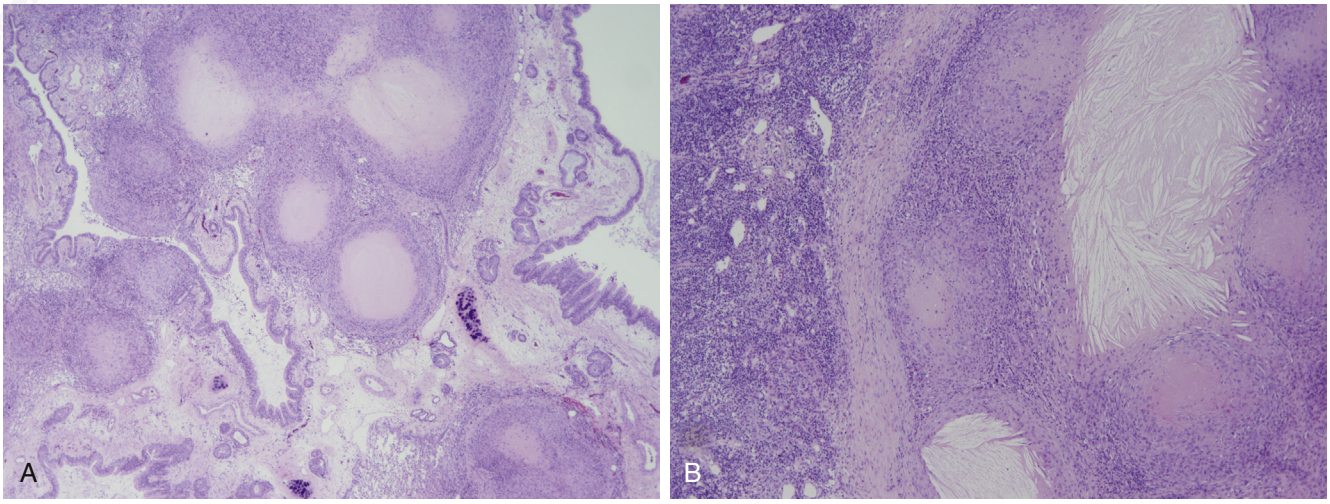

Fig. 61.11 Granulomatous inflammation associated *M. bovis* infection demonstrating a typical focal, subdermal organizing granuloma with a large area of central necrosis (hematoxylin and eosin stain, 10× magnification). Higher magnification revealed extensive effacement of the normal tissue architecture with numerous palisading macrophages with large nuclei and foamy cytoplasm infiltrating the tissue surrounding the necrotic area. Ziehl-Neelsen staining of the same biopsy (not shown) revealed moderate numbers of acid-fast bacteria within the area of necrosis.

granulomatous mass formation and sometimes massive enlargement of tracheobronchial and mediastinal nodes, which may contain multifocal gritty, yellow, caseous material.[34,51,57] Pleural effusion may also be present.[44] In dogs with dissemination, pale nodular lesions may be found in abdominal organs such the liver, peritoneal surfaces, and kidneys.[50,51,57] A dog from Africa that was infected with *M. tuberculosis* had nodular lesions that were confined to the liver and brain.[50] Dogs infected with *M. bovis* have abnormalities similar to those infected with *M. tuberculosis*.[46-48]

Histopathologic Findings

Histopathology may be performed on specimens obtained by excisional or incisional biopsy (e.g., nonhealing skin lesions, subcutaneous masses, or enlarged lymph nodes). In some cases, if there is only a single cutaneous lesion, excisional biopsy may be curative.[15] When specimens are submitted and mycobacteriosis is a differential diagnosis, this should be clearly stated on the submission form, along with a request for acid-fast staining of tissue sections; this will ensure that the samples are handled appropriately by the receiving laboratory. Direct communication with the laboratory about the suspicion for mycobacteriosis is also recommended, if possible.

Specimens collected for histopathology should be cut in half; one piece should be placed in formalin and the other frozen in a sterile container for subsequent culture or molecular testing should this be necessary. Histopathology alone cannot speciate mycobacteria, and is needed to establish the risk to owners and other animals in the household, potential treatment options, and prognosis.

Histopathologic findings are similar for all MTBC diseases. Characteristic tubercles or granulomas are present in tissues, which vary in size and may coalesce with one another (Fig. 61.11). Tubercles mostly consist of large numbers of epithelioid macrophages and a lesser numbers of neutrophils. Multinucleated giant cells are rarely identified in lesions from dogs or cats.[15,51] The inflammatory foci are surrounded by a layer of macrophages, neutrophils, lymphocytes and plasma cells, and an outer layer (or background) of granulation tissue. The center of the tubercle may be necrotic. Central mineralization and lipid accumulation have been described in some dogs infected with *M. tuberculosis*[34,57] but mineralization is rare in cats with *M. microti* or *M. bovis* infections. One study showed that in cats, *M. bovis* was associated with large multilayered granulomas that had central necrosis, whereas *M. microti* was more often found in small granulomas without central necrosis. For both pathogens, the presence of a fibrous capsule and the number of acid-fast bacilli were variable; some infections were associated with numerous acid-fast bacilli.[75] Acid-fast stains often reveal low numbers of centrally located AFB in most affected animals, but a careful search may be required, because organisms may be present in very low numbers.[34,51]

TREATMENT AND PROGNOSIS

Owners of animals with mycobacterial infections should be informed that a successful outcome requires a prolonged course of combination antibiotic therapy, and success is influenced both by owner and patient compliance. Drug toxicity, and the cost associated with treatment and monitoring can make optimal regimens difficult to maintain. For all mycobacterial infections, it is recommended that medical therapy be continued for at least 2 months past resolution of clinical signs or following resection of all visible lesions.

Drug-resistant tuberculosis with the detection of multidrug-, extensive drug-, or total drug-resistant isolates, as well as the human HIV pandemic, has dominated the focus of many of the recent changes to anti-mycobacterial drug therapies, and anti-tuberculosis therapy.[76–78] A fundamental goal of the management of mycobacterial infections is to avoid selection for drug-resistant isolates. This can only be achieved where clients understand the critical need to adhere to proper dosing protocols.

At the time of writing, treatment with rifampicin, isoniazid, pyrazinamide, and ethambutol (combined) for a minimum duration of 18 weeks is advocated for treatment of human tuberculosis by the CDC.[79] Unfortunately, isoniazid and ethambutol have been associated with severe nephrotoxicity, hepatotoxicity, and neurotoxicity in cats and dogs, and isoniazid has been associated with optic neuritis. Therefore these drugs should not be used as first-line therapies for companion animals.[80-85] Pyrazinamide is not active against *M. bovis*[86] and has also been associated with hepatotoxicity in cats, so is also not recommended.

TABLE 61.5 Anti-Tuberculosis Medications for Use in Cats and Dogs

Drug	Formulations	Dosing	Contraindications	Adverse Effects
Pradofloxacin	Suspension or tablets	5–7.5 mg/kg PO q24h	Not in dogs <12 months of age (18 months in giant breeds) or cats <6 weeks of age. Do not use in animals with epilepsy. See Chapter 10 for information on pradofloxacin in dogs	Neutropenia with high doses and/or long courses
Marbofloxacin	Tablets	2 mg/kg PO q24h	See pradofloxacin	Intermittent vomiting and transient diarrhea
Moxifloxacin	Tablets	10 mg/kg PO q24h	See pradofloxacin	Occasional vomiting. Potential for ocular toxicity unknown
Enrofloxacin (dogs only)	Tablets	5–20 mg/kg PO q24h	Not in dogs <12 months of age (18 months in giant breeds) due to potential adverse effects on cartilage. Avoid in animals with epilepsy	GI signs
Ciprofloxacin	Tablets	5–15 mg/kg PO q12h	See pradofloxacin	Occasional vomiting
Azithromycin	Capsule, suspension	5–15 mg/kg PO q24h	Pre-existing cardiomyopathy especially when arrhythmias are present. Pre-existing hepatopathy	Intermittent vomiting and diarrhea possible but uncommon
Clarithromycin	Tablets, suspension	7.5 mg/kg PO q12h	Concurrent use of NSAIDs or antacids. Pre-existing hepatopathy	Pinnal erythema. Generalized erythema. Hepatotoxicity
Rifampicin	Capsules, suspension	5–10 mg/kg PO q24h	Pre-existing hepatopathy. Pregnant queens	Hepatotoxicity; induction of liver enzymes, anorexia, generalized erythema, and pruritus. CNS signs. Discoloration of body fluids

A three-drug combination should be used (a fluoroquinolone, macrolide/azalide, and rifampicin).

Cats

Excisional biopsy can be curative for cats with single or small numbers of skin nodules caused by *M. bovis* or *M. microti*. Nevertheless, adjunctive medical therapy is recommended (Table 61.5). There is a significant risk of wound dehiscence following surgery. Currently, there is no evidence that surgery confers any additional benefit to rigorous medical management, so it is not widely advocated once a diagnosis has been obtained. The one possible exception is cats with intra-articular tuberculosis or significant osteomyelitis (Fig. 61.12).[86,87] For these cats, amputation of all or part (at least one joint above the lesion) of the limb with adjunctive medical therapy should be strongly considered.

A combination of a fluoroquinolone, a macrolide/azalide, and rifampicin is suggested for cats with tuberculosis. The fluoroquinolone of choice is pradofloxacin (where available) due to its excellent safety profile in the cat and its known activity against mycobacteria when compared to older fluoroquinolones.[88] Where this is not available, the use of moxifloxacin is advocated.[88] Less active alternatives are marbofloxacin or ciprofloxacin. The use of enrofloxacin in the cat is discouraged due to its association with acute irreversible retinopathy.[89] The macrolide/azalide of choice is azithromycin, because it requires only daily dosing and concentrates within pulmonary macrophages;[90,91] an alternative is clarithromycin.

Rifampicin has long been a cornerstone of anti-tuberculosis medical therapy, and anti-mycobacterial medical therapy in general. It should never be used as a monotherapy for mycobacterial disease as resistance develops rapidly.[92] Rifampicin has the potential to be significantly hepatotoxic when administered for long periods of time.[93,94] Liver function should, ideally, be monitored during treatment (days 0, 14, and then monthly or if clinical signs that might be due to liver disease develop). Treatment with rifampicin should be stopped if serum liver enzyme activities significantly exceed the upper reference interval, hyperbilirubinemia

Fig. 61.12 Lateral radiograph of the right distal thoracic limb of a 4-year-old, male, neutered, retrovirus-negative Maine Coon cat with an intra-articular *M. microti* infection. There is severe osteolysis of the carpal bones as well as the distal radius and ulna surrounded by extensive soft-tissue swelling.

develops, or the patient develops clinical signs attributable to hepatic dysfunction. Use of medications that support liver function should be considered (e.g., S-adenosyl-L-methionine or NAC). Once recovered from apparent hepatotoxicity, rifampicin may be reintroduced at half of the initial dose, with close monitoring to ensure hepatopathy does not recur. Owners should be informed that rifampicin may cause urine, tears, and saliva to discolor to red-orange in color.[95] Deposition of the drug within the skin can cause skin discoloration, irritation erythema, and, occasionally, hyperesthesia. Premedicating with chlorpheniramine can help to reduce these problems in some cats. Rifampicin is teratogenic and so owners should be instructed to wear gloves when they handle it, and it should not be administered to pregnant queens.

Three months of combination therapy should be considered a minimum duration of treatment in all cases. Treatment should be extended for 2 months beyond the resolution of all clinical signs which includes any evidence of pulmonary dissemination detectable on plain radiography. Because of the sensitivity of CT imaging, subtle changes such as minor scars remain detectable and may persist indefinitely beyond the need for treatment.[96] Monitoring of IGRA results in cats did not appear to yield useful information for making treatment decisions.[97]

Drug administration to cats can be facilitated by drawing all medications into a single syringe for administration. Mixing liquid medications with food is typically unrewarding as many of these drugs are unpalatable to cats, especially rifampicin. The contents of reconstituted capsules plus split tablets can also be combined into a single gelatin capsule for daily administration. If oral dosing is not possible then drugs can be administered through an esophagostomy tube, which can significantly facilitate medicating these cats for a long duration of their treatment.

Therapy of refractory cases is more difficult as it requires more frequent drug administration and has the potential for more adverse effects. Rifampicin therapy should be maintained whenever possible and can be combined with isoniazid and ethambutol (Table 61.6). With good compliance, prognosis is fair. One review noted that 40% of treated cats reached and maintained complete clinical remission.[15] The remaining 60% of cats had temporary or partial remission, or no response to treatment.[98] However, many of the cats in this retrospective study were treated with sub-optimal therapies, such as short courses of a fluoroquinolone as monotherapy. With triple therapy, the authors' clinical experience suggests a positive prognosis for 70% to 80% of feline tuberculosis cases, particularly those with cutaneous and/or pulmonary involvement (Fig. 61.13).

Dogs

Dogs with pulmonary MTBC infections should be placed in isolation and aerosol precautions are indicated. Antimicrobial drug treatment of dogs (and cats) with confirmed *M. tuberculosis* infection is controversial and generally not recommended because of zoonotic concerns. Treatment of *M. bovis* cases should only be performed after owners have been fully educated about the potential risks of disease transmission.

As for feline MTBC infections, dogs undergoing therapy should be treated with a combination of rifampicin, a macrolide/azalide and a fluoroquinolone (see Table 61.5). Clarithromycin is the macrolide of choice based on evidence of efficacy and the greater ease of multi-day dosing in dogs when compared with cats. Treatment of a dog with *M. tuberculosis* infection was attempted with rifampin, isoniazid, and clarithromycin but the dog was euthanized after seizures developed.[34] Seizures in this case were suspected to be an adverse effect of isoniazid administration (see Table 61.6).

The prognosis for dogs with tuberculosis is considered guarded to poor. This is likely a reflection of the advanced degree of systemic disease that is typically present at the time of diagnosis and the high likelihood of adverse effects with more active anti-tuberculosis drugs used in humans (such as isoniazid). Early recognition and treatment of *M. bovis* or *M. microti* infections may yield similar outcomes as those seen for feline tuberculosis.

TABLE 61.6 Second-Line Anti-tuberculosis Medications for Use in Cats and Dogs as Part of Triple Therapy (Isoniazid, Ethambutol, and Rifampicin)

Drug	Dosing	Contraindications	Adverse Effects
Isoniazid	5–10 mg/kg PO q24h. Start at a low dose; do not exceed 300 mg/day.	Poorly evaluated in cats. Hepatic dysfunction. History of seizures	Hepatotoxicity; monitor liver enzymes. Peripheral neuritis. Seizures, especially in dogs (avoid use in dogs if possible). Acute kidney injury
Ethambutol	10–25 mg/kg PO q24h	Poorly evaluated in cats	Optic neuritis

See Table 61.5 for rifampicin dosing.

IMMUNITY AND VACCINATION

There are no vaccines available for prevention of mycobacterial disease in animals.

PREVENTION

In cats, prevention of *M. bovis* and *M. microti* infections can be achieved when cats are housed indoors and rodent populations are controlled. The feeding of raw cattle or game (e.g., deer, elk) also has the potential to transmit *M. bovis* to dogs or cats and should be discouraged.[99]

Prevention of *M. tuberculosis* infections in dogs relies on appropriate control and treatment of *M. tuberculosis* infections in affected humans that are in close contact with dogs. The possibility of serious zoonotic diseases such as tuberculosis should also be considered before stray dogs are adopted from countries where such infections are endemic.

PUBLIC HEALTH ASPECTS

Of all mycobacterial species that infect dogs and cats, the greatest risk to human health is posed by members of the MTBC. Confirmed disease by MTBC bacteria is usually notifiable to public health authorities. Over 90% of human tuberculosis is caused by *M. tuberculosis*. Only 1% of cases result from *M. bovis* infection, and human infection with *M. microti* is very rare.[100] Factors such as HIV infection, homelessness, and intravenous drug use predispose humans to *M. tuberculosis* infection. Tuberculosis continues to be an important public health problem worldwide, and drug resistance is emerging globally. Over the last 2 decades, case numbers have decreased to the lowest levels in history in the United States.[101] However, the incidence rate is highest among non-Hispanic Asian, non-Hispanic black, and Hispanic groups in the United States, which is 25, 8, and 7 times greater, respectively, than the rate for non-Hispanic whites.[101] Disease in immigrants to the United States results from reactivation of disease acquired in other countries.

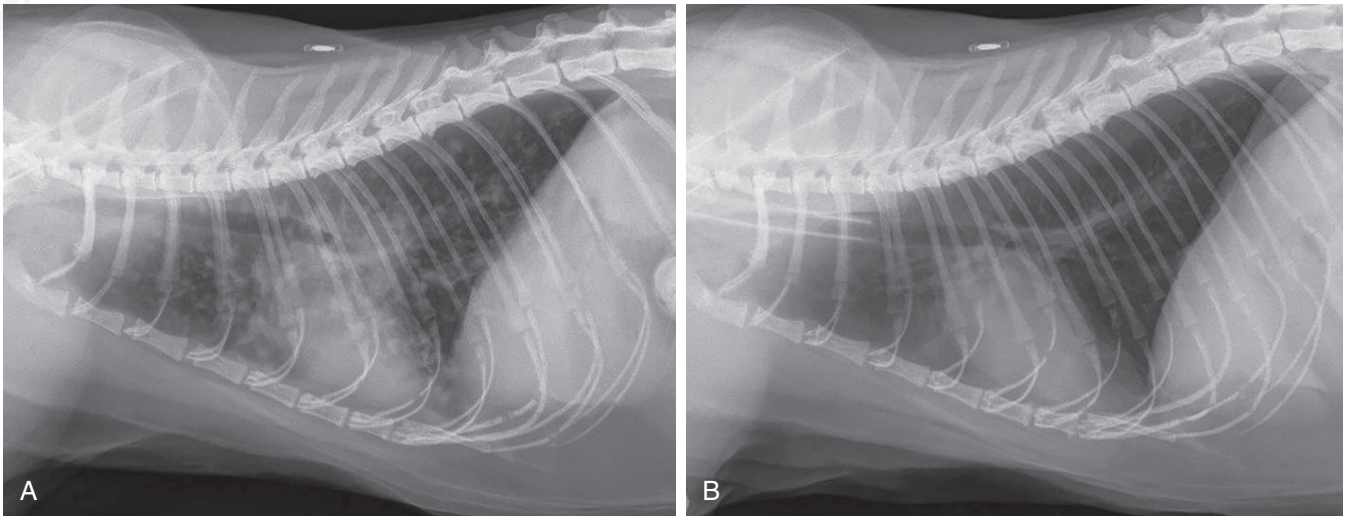

Fig. 61.13 (A) Lateral thoracic radiograph from a 3-year-old, female, intact, retrovirus-negative, domestic shorthair cat infected with *M. bovis*. The radiograph, taken at the time of diagnosis, shows multifocal to coalescing areas of soft-tissue opacity (granulomas) distributed throughout the lung fields. (B) Lateral thoracic radiograph taken from the same cat following 3 months of triple antibiosis consisting of rifampicin (10 mg/kg), azithromycin (10 mg/kg), and pradofloxacin (5 mg/kg) PO q24h.

Mycobacterium tuberculosis

If *M. tuberculosis* infection is suspected or confirmed in a dog, this should trigger a notification to the appropriate health care authorities for human testing. Euthanasia, rather than treatment, should always be undertaken for confirmed infected animals given the potential human health risk. However, it should be recognized that transmission of *M. tuberculosis* from dogs to humans has not been reported, and in one case report, no transmission to a diabetic child occurred despite extremely close and prolonged contact.[34] An investigation may be performed in order to identify the source of infection, and it may be necessary to perform one or more Mantoux tests on any individuals with significant contact with infected animals. Although transmission of *M. tuberculosis* from infected dogs to humans has not been reported as a result of direct contact, veterinary staff were infected when a necropsy of an infected dog was performed, possibly following aerosolization of infected brain tissue when the skull was sectioned with an electric saw.[50] High-density surgical masks (N95 masks) should be worn if surgery or necropsy is performed on a dog or cat suspected to have tuberculosis.

Mycobacterium bovis

Human disease resulting from exposure to companion animals infected with *M. bovis* is extremely rare. Globally, in the last 150 years, only six cases of human *M. bovis* tuberculosis have resulted from exposure to cats, and these cats had skin lesions that were draining pus that contained many Ziehl-Neelsen (ZN)-positive bacteria. As of September 2015, Public Health England, Public Health Wales, and Health Protection Scotland all consider the risks to humans to be "very low." That said, the risk should be considered seriously in the context of humans with specific risk factors for transmission (Box 61.1). Extensive and/or purulent lesions pose the greatest risk to human health and are generally less responsive to treatment. By comparison, single nonulcerated skin lesions and/or regional lymphadenopathy carry low zoonotic risk and may be very amenable to treatment.

Mycobacterium microti

The risk to humans for *M. microti* is significantly lower than that of *M. bovis*.[100] Fewer than 30 human cases of *M. microti* infection have been documented in published literature and 11 (~40%) of these had specific risk factors (see Box 61.1). None have resulted from exposure to an infected cat.

BOX 61.1 Risk Factors for Zoonotic Transmission of MTBC Infections

- Under 5 years old (some sources suggest 12 years)
- Pregnant
- HIV-positive
- Substance misuse
- Diabetes mellitus
- Severe kidney disease
- Solid organ transplant recipient
- Cancer patient receiving chemotherapy or radiation therapy
- Medical condition requiring treatment with systemic glucocorticoids
- Specialized treatment for rheumatoid arthritis or Crohn's disease
- On TNF-α inhibitors
- History of gastrectomy or jejunoileal bypass
- Silicosis

Compiled from advice published by United Kingdom public health organizations and WHO guidelines. Animal treatment should be discouraged when the above conditions are present in their owners, and at minimum, owners should be counseled on the potential for zoonotic transmission when the above conditions are present.

SLOW-GROWING NON-TUBERCULOUS MYCOBACTERIAL INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Slow-growing NTM include organisms that belong to the MAC and a number of other fastidious mycobacterial pathogens that grow slowly in culture. Unlike organisms that belong to the MTBC, they are environmental saprophytes with a worldwide distribution. MAC organisms, for example, can be found in soil, dust, and aquatic environments

that include showers, faucets, household drinking water, swimming pools, and hot tub spas.[102] The organisms also infect free-living amebae and form biofilms, which may promote environmental persistence. Subclinical infections with *M. avium* subsp. *avium* are common among birds, and *M. avium* subsp. *avium* is the main cause of avian tuberculosis.[103] Ingestion of infected birds or bird feces may be a route of transmission to dogs and cats.

The MAC consists of two closely related species, *M. avium* and *Mycobacterium intracellulare*. Four subspecies of *M. avium* have been described: subspecies *hominissuis*, *avium*, *paratuberculosis*, and *silvaticum*. It has been proposed that *M. avium* subsp. *hominissuis* and *M. avium* subsp. *silvaticum* be reclassified as variants of *M. avium* subsp. *avium*, and *M. lepraemurium* be reclassified as a new subspecies of *M. avium*, *M. avium* subsp. *lepraemurium* (see Fastidious NTM Infections, below),[104] leaving three subspecies of *M. avium*. However, this has not been universally adopted, and for the purpose of this chapter, the previous nomenclature will be used.

Mycobacterium avium subsp. *hominissuis* causes most infections in human patients, but the distribution of subspecies in affected dogs and cats is currently not fully understood, because molecular methods are required for identification at the subspecies level. *Mycobacterium avium* subsp. *hominissuis* infections have been identified in several dogs from continental Europe,[105,106] and *M. avium* subsp. *avium* was isolated from an affected cat.[107] The DNA of *M. avium* subsp. *paratuberculosis* was detected in intestinal biopsies from dogs with chronic GI signs, where it was of uncertain clinical significance.[108] More recently, it was cultured from enlarged mesenteric lymph nodes of a dachshund from South Africa that had evidence of disseminated infection with large numbers of intralesional AFB at necropsy.[109]

MAC organisms cause opportunistic infections in immunocompromised individuals. Most affected dogs and cats have been between 1 and 5 years of age. Infection is not directly transmissible from one infected individual to another, but disease may initially be indistinguishable from that caused by MTBC bacteria. In the US, although still rare, infection of cats and dogs with MAC organisms is more common than infection with MTBC organisms.

Cats

Slow-growing mycobacteria reported in association with disease in cats include organisms that belong to the MAC[110–129] (specifically, *M. avium* subsp. *avium*,[107–130] *M. avium* subsp. *hominissuis*,[131–133] and *M. intracellulare*[134,135]), *M. genavense*,[136] *M. malmoense*,[13,137] *Mycobacterium celatum*, *Mycobacterium terrae* complex,[138] *Mycobacterium simiae*,[139] *Mycobacterium xenopi*,[140–143] *Mycobacterium ulcerans*,[144] *Mycobacterium heckeshornense*,[145] *Mycobacterium nebraskense*,[146,147] and *Mycobacterium kansasii*.[147,148] Of all NTM, organisms that belong to the MAC were cultured most frequently from cats from the United Kingdom (see Table 61.3)[13]; however, in general, the culture data for NTM infections is inevitably skewed by the fact that fastidious organisms cannot be cultured. *Mycobacterium avium* accounted for 15% of 159 culturable mycobacterial infections in cats (73% were MTBC infections).[13] A spatial cluster of infection was identified in cats from eastern England.[13]

Advanced retrovirus infection or treatment with immunosuppressive drugs may predispose cats to MAC infection, although most affected cats have no identifiable immunodeficiency. A possible breed predisposition has been recognized in Siamese cats as well as Abyssinian and Somalis.[112,120] Diagnosis of *M. kansasii* infections in two indoor-only domestic shorthair cats from the same litter suggested a genetic predisposition to infection.[148] Other potential risk factors identified in cats with disease caused by slow-growing NTM include administration of exogenous glucocorticoids,[107] multidrug chemotherapy for lymphoma,[117] cyclosporine treatment in the context of renal transplantation,[114] retrovirus infection,[136,149] idiopathic αβ-T cell lymphopenia (particularly $CD4^+$ αβ-T-cells),[143] or concurrent comorbidities such as advanced chronic renal disease and cryptococcosis.[150]

Fig. 61.14 Localized dermal infections in a dog due to *M. ulcerans*, the causative agent of Buruli ulcer. This organism produces a cytotoxic toxin, mycolactone, which is responsible for the deep skin ulcerations that are a hallmark of the disease.

Dogs

MAC organisms that have been associated with disease in dogs include *M. avium* subspecies *avium*,[151] *M. avium* subspecies *paratuberculosis* (MAP),[109] and *M. avium* subspecies *hominissuis*.[105,106,152,153] Disease occurs sporadically in any breed, but basset hounds, miniature schnauzers, and possibly Yorkshire terriers may be predisposed, possibly because of an inherited deficiency of CMI (see Chapter 130). Other slow-growing NTM isolated from dogs with mycobacterial infections are *M. kansasii*, *M. genavense*, *M. nebraskense*, and *M. ulcerans*. *Mycobacterium ulcerans* causes localized dermal infections in dogs (Buruli ulcer) in endemic areas of Victoria, Australia.[154] This organism produces a cytotoxic toxin, mycolactone, that is responsible for the deep skin ulcerations that are a hallmark of the disease (Fig. 61.14). Although the exact ecology of *M. ulcerans* has not been determined, it has a worldwide but highly focal endemicity, with most human infections occurring in West Africa and coastal southeastern Australia. It is suspected that the organism gains entry via breaches in the epidermis, possibly in some cases involving mechanical insect vectors.[155] Animal cases have only been reported from Australia, and also include possums[156,157], koalas,[158] a long-footed potoroo,[159] alpacas,[160] horses,[161] and a cat.[144]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In cats, disease caused by MAC organisms resembles that caused by *M. bovis* or *M. microti*. Some cats have cutaneous lesions (especially

Fig. 61.15 An alopecic, erythematous granuloma on the medial aspect of the first digit of the right foot of a 6-year-old, male, neutered, retrovirus-negative, domestic shorthair cat caused by *M. avium* infection. The lesion is notable for its similarity in gross appearance to tuberculous lesions.

on the head and limbs) (Fig. 61.15). Other clinical abnormalities are osteomyelitis, pulmonary involvement with tachypnea or cough, peripheral and abdominal lymphadenomegaly, and GI, liver, splenic, renal, omental and uncommonly CNS or marrow involvement.[110,112–114,116,126,129,149,150] GI involvement may initially manifest as weight loss despite a good appetite.[112]

Canine MAC infection is typically associated with multisystemic disease, including any combination of generalized lymphadenopathy, anemia, weight loss, hepatopathy, and/or splenomegaly. Dogs with MAC infections often develop marked peripheral and abdominal lymphadenopathy, tonsillar enlargement, hepatosplenomegaly, and/or osteomyelitis. In some dogs, mandibular or cervical lymphadenopathy may be so severe that respiratory distress and dysphagia occur.[162] Less severe cases, with single cutaneous nodules have also been reported and should not be overlooked.[163] Secondary immune-mediated inflammatory disease, such as polyarthritis, has also been reported.[164] At necropsy, AFB and associated inflammatory lesions may also be found in the small and large intestines, liver, spleen, lung and pleura, bone marrow, and rarely the spinal cord.[105,165–169] Involvement of the GI tract may lead to chronic vomiting, diarrhea, hematochezia, melena, inappetence, and weight loss. Intestinal rupture in one dog led to bacterial peritonitis. Even though inflammatory lesions with intralesional AFB have been detected in the lung at necropsy, pulmonary involvement is not a prominent clinical feature of MAC infections in dogs, which may help distinguish the disease from *M. tuberculosis* infection.

Mycobacterium kansasii was isolated from a 3-year-old whippet with chronic pleural effusion[170] and also from a mammary mass of a 2-year-old Chihuahua.[171] The latter case also had chronic generalized demodicosis implying an underlying immune deficit was present, and it subsequently succumbed to the infection after prednisolone treatment for cutaneous lymphoma. Disseminated *M. genavense* infection was diagnosed in a 2-year-old pug with generalized lymphadenopathy, abdominal organomegaly, pyrexia, and limb pain.[172] *Mycobacterium ulcerans* is associated with localized ulcerative cutaneous disease (see Fig. 61.14). *Mycobacterium nebraskense* was isolated from a dog in Switzerland with multifocal cutaneous disease.[173]

Physical Examination Findings

Physical examination of cats with slow-growing NTM infections may reveal fever, a thin body condition, cutaneous lesions similar to those described for MTBC infection, peripheral or abdominal lymphadenopathy, renomegaly, hepatomegaly, tachypnea, and/or increased lung sounds. Rarely neurologic signs such as nystagmus occur.[112] Ocular involvement[174–176] as either a localized or systemic disease process has been reported.

In dogs, low-grade fever, a thin body condition, dehydration, mucosal pallor, tonsillar enlargement, lymphadenomegaly (especially of the mandibular or abdominal nodes), hepatosplenomegaly, and/or abdominal pain may be found. Melena or hematochezia may be detected on rectal examination. Osteomyelitis may be associated with lameness or mass lesions in association with underlying bone involvement. A dog with spinal cord involvement had pelvic limb paresis.[165] Other findings may be present depending on specific organ involvement.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Findings on routine laboratory tests for cats and dogs with slow-growing NTM infections are similar to those described for MTBC infection. Most affected dogs or cats have had mild to moderate nonregenerative anemia, neutrophilia with mild to moderate bandemia, lymphopenia, hypoalbuminemia, hyperglobulinemia or hypoglobulinemia, and sometimes, hypercalcemia, hyperbilirubinemia and increased liver enzyme activities.[113,166,177] An absence of hematological or biochemical abnormalities has also been described.

Diagnostic Imaging

Plain Radiography

When radiographic abnormalities are present in cats infected with MAC, they often consist of diffuse interstitial or bronchointerstitial patterns.[112,113] Diffuse interstitial patterns may be present in the absence of clinical signs of respiratory involvement. Thoracic lymphadenopathy, mediastinal masses, or pleural effusion may be present in dogs.[106,170] Abdominal radiographs may show abdominal masses or hepatosplenomegaly in dogs as well as in cats. Radiographs of affected bone may reveal soft-tissue swelling and bony lytic lesions or periosteal proliferation.

Sonographic Findings

Abdominal sonography may be unremarkable or reveal hepatomegaly, splenomegaly, hypoechoic nodular lesions within the liver or spleen, a thickened intestinal wall, hyperechoic mesentery, or enlarged, hypoechoic or heteroechoic abdominal lymph nodes.[178]

Microbiologic Tests (see Table 61.4)

Cytologic Examination

Cytologic examination of aspirates from enlarged lymph nodes, abdominal organs, or lavage specimens from the respiratory tract of cats and dogs with MAC infections reveals large numbers of histiocytes with nonstaining intracellular bacteria (Fig. 61.16), and lower numbers of neutrophils.

Acid-fast stains. In general, AFB are identified more readily in smears or biopsies in slow-growing NTM infections when compared

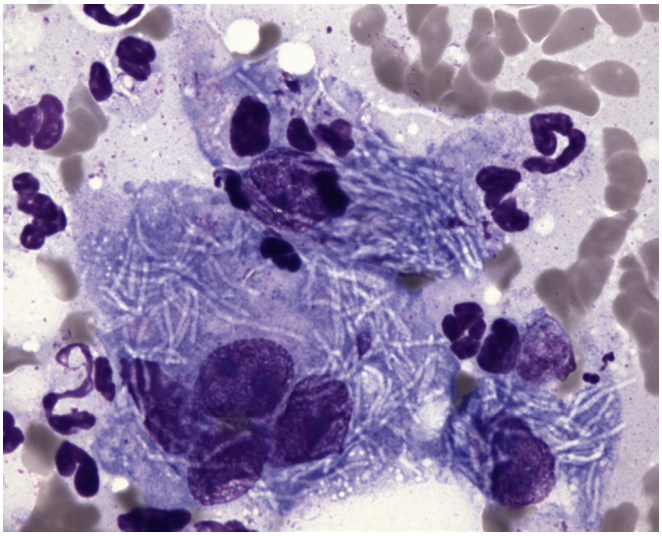

Fig. 61.16 Aspirate cytology from a cutaneous mass in a cat that developed after prolonged (> 1 year) treatment with cyclosporine. Large numbers of negatively stained mycobacterial organisms are present. (Image courtesy Dr. William Vernau, University of California-Davis Clinical Pathology Service.)

with MTBC infections and rapid-growing NTM infections, possibly because of the frequent presence of immunosuppression. Most reports of affected dogs and cats with either MAC or other slow-growing NTM show the detection of organisms in cytology specimens stained with acid-fast stains. One report described a dog with localized nasopharyngeal disease and absence of AFB, which was noted to be unusual.[163]

Bacterial Isolation and Identification

Up to 12 weeks of incubation may be required for visible growth of slow-growing NTM. Species can then be identified through the use of commercial DNA probe-based assays or PCR analysis. MAC subspecies determination requires specialized typing techniques such as IS*1245* restriction fragment length polymorphism typing, MIRU-VNTR, or the use of PCR assays that detect gene fragments present in some *M. avium* subspecies but not others.[105,107,178]

The CLSI criteria for the antimicrobial susceptibility testing of NTM recommends broth microdilution as the gold standard, preferably performed by a mycobacterial reference laboratory, or a similarly experienced facility.[180]

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR testing provides a rapid and typically accurate diagnosis and can be performed on fresh, frozen, or formalin-fixed paraffin-embedded tissue and Romanowsky-stained (but not ZN-stained) cytology slides.[181]

The most frequently utilized genes for mycobacterial identification are those which encode for 16S rRNA,[182] the 65-kDa heat shock protein (*hsp*65),[183] the β-subunit of bacterial RNA polymerase (*rpoB*),[184] 16-23S rRNA internal transcribed spacer ITS region,[185,186] and, less frequently, the DNA gyrases (*gyr*). Assays that target the IS*6110* element for MTBC,[187] IS*2404* for *M. ulcerans*,[188] and multiplex IS*901* and IS*1245* for differentiation of *M. avium* subsp. *avium* and M. *avium* subsp. *hominissuis*[189] have been utilized in the diagnosis of small animal infections.[131,144]

Although its popularity has reduced with the accessibility of genetic sequencing, PCR-restriction fragment analysis (PRA) (or restriction fragment length polymorphism [RFLP]) is a commonly used DNA profiling technique for identification of NTM. This technique involves amplification of a particular gene (e.g., ITS,[190] hsp65,[191,192] IS*1245* for *M. avium*[193]), and subsequent restriction enzyme digestion, followed by analysis via gel electrophoresis.

Pathologic Findings

In general, pathologic findings in cats or dogs with MAC infection consist of focal, multifocal, or generalized lymph node enlargement (up to 5 cm in diameter), and nodules in the spleen, liver, lungs, omentum, intestinal wall, and occasionally the kidneys. Nodules are white, grey, or yellow and may be caseous on cut section. Evidence of GI hemorrhage may be present in the intestine of affected dogs.[166]

Histopathology in slow-growing NTM infections typically reveals large numbers of histiocytes and lesser numbers of neutrophils, which in some cases may surround necrotic foci. Multinucleated giant cells are rarely seen, and mineralization has not been described. Moderate to large numbers of AFB are usually present within histiocytes (Fig. 61.17).

TREATMENT AND PROGNOSIS

Treatment of slow-growing NTM infections in dogs or cats is challenging. The majority of animals are euthanized as a result of their disease, but apparent cure has been reported in a few cats.[107,112,113,138] Successful treatment with a combination of enrofloxacin, clarithromycin, and rifampicin was reported in one dog with localized cutaneous lesions.[163] Another dog was successfully treated for disseminated *M. genavense* infection with clarithromycin, ethambutol, and enrofloxacin.[172] Treatment of *M. ulcerans* infection in dogs has typically involved 8 to 10 weeks of a third-generation fluoroquinolone (e.g., enrofloxacin) plus either clarithromycin or rifampicin.[194] Occasionally, surgical debridement has been helpful for recalcitrant lesions.

As for infection with MTBC organisms, the use of two or three drugs in combination is recommended to prevent emergence of resistance. The use of macrolides (especially clarithromycin) has greatly improved outcome for human patients with MAC infections, so inclusion of clarithromycin or azithromycin is recommended. The currently recommended treatment for humans with MAC infections consists of a rifamycin, ethambutol, and a macrolide such as clarithromycin. Combinations that include isoniazid have been used to treat other slow-growing NTM infections.[195]

Drug resistance patterns of slow-growing NTM vary widely, not just between species but also between isolates of the same species.[196] Furthermore, susceptibility test results do not always correlate with clinical outcome, as some of the genes that confer resistance (e.g., to macrolides) are inducible, especially for MAC.[197] Recommendations for susceptibility testing of uncommonly isolated species, which have been assessed to be clinically significant in people, may include testing against rifampicin, clarithromycin, amikacin, ciprofloxacin, ethambutol, linezolid, moxifloxacin, and trimethoprim-sulfamethoxazole.[179] MAC isolates are typically resistant to commonly used fluoroquinolones (e.g., enrofloxacin, marbofloxacin, orbifloxacin). The most successful protocols consist of triple therapy with a macrolide (clarithromycin or azithromycin), a fluoroquinolone (pradofloxacin, moxifloxacin, or possibly marbofloxacin [in the case of isolates other than *M. avium*]), rifampicin, or clofazimine. Some cats require extended (up to a year) or indefinite therapy. Relapses have been reported.[112] Various combinations of clarithromycin, clofazimine, doxycycline, rifamycins, and fluoroquinolones have been used to treat affected cats (Table 61.7). Clofazimine is an antimycobacterial drug with an

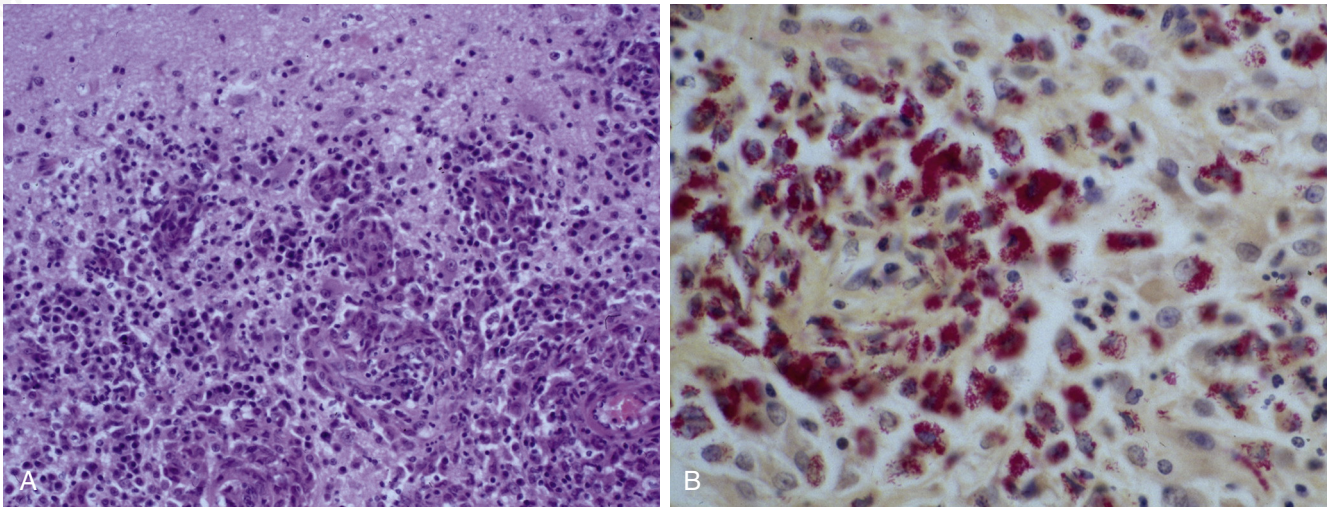

Fig. 61.17 (A) Granulomatous inflammation in the brain of a 10-year-old male neutered Siamese mix cat with disseminated *Mycobacterium avium* infection. Hematoxylin and eosin stain. (B) Section from the same cat stained with Ziehl-Neelsen (acid-fast) stain. There are large numbers of intracellular acid-fast bacteria.

unknown mechanism of action. In human patients, it has primarily been used to treat lepromatous or rapidly growing opportunistic mycobacteria, but may have some activity against MAC organisms.

PUBLIC HEALTH ASPECTS

As for dogs and cats, humans acquire slow-growing NTM infections from the environment; direct transmission from diseased animals to people has not been described. A *M. kansasii* infection in a person was associated with a dog bite to the hand,[197] although the infection occurred at the elbow 6 months later, so whether the dog was the source of infection remained unconfirmed. Ownership of caged birds by immunocompromised humans has been discouraged in the past because of the potential that these birds might shed MAC organisms. However, human disease is caused by *M. avium* subsp. *hominissuis* and not the avian organism (subsp. *avium*), so the feces of caged birds may not represent a significant source of infection. Three major clinical forms of MAC disease occur in people: localized pulmonary disease (which includes "hot tub lung disease", a hypersensitivity pneumonitis), cervicofacial lymphadenitis, and disseminated disease.[198] Rarely, cutaneous disease and disease in other locations occur. Disseminated disease occurs most often in humans with HIV infection, but children with congenital immunodeficiencies can also be affected. Prophylactic treatment with an antimycobacterial drug is recommended for HIV-infected humans with CD4+ T cell counts that are less than 50 cells/mm^3.[198] Cervicofacial lymphadenitis is an uncommon disease of children less than 3 years of age.

Although transmission of MAC organisms from diseased dogs and cats to humans should not, in theory, occur by direct contact, it may not be possible to distinguish MAC infection from infection with MTBC organisms (especially *M. bovis*) based on initial clinical findings. Veterinary staff should take care to avoid needle-stick injuries or cutaneous inoculation when collecting specimens (such as lymph node aspirates) from dogs and cats with NTM infections because of the possibility that disease might occur after cutaneous inoculation. Sedation is recommended whenever lymph node aspiration is indicated for an animal with an unknown cause of lymphadenopathy. Care should also be taken not to aerosolize tissues at necropsy when mycobacterial disease is suspected (such as that occurring with electric saws).

TABLE 61.7 Treatment of NTM Infections

Drug	Dosing	Contraindications	Adverse Effects
Clofazimine	4–10 mg/kg q24h PO *or* 25–50 mg/cat q24h PO	Poorly evaluated in cats	Hepatotoxicity GI signs Pitting corneal lesions Photosensitization (keep cats indoors during treatment)
Doxycycline monohydrate	10 mg/kg q12–24h PO	Concurrent barbiturate administration	GI signs; most frequently vomiting. Esophagitis with hyclate forms of the drug
Amikacin	10–15 mg/kg q24h IV, IM, or SC	Poorly evaluated in cats	Nephrotoxicity Ototoxicity

In addition to those in Table 61.5 *NTM,* non-tuberculous mycobacteria.

RAPID-GROWING NON-TUBERCULOUS MYCOBACTERIAL INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Rapid-growing NTM grow in culture within 7 days and are responsible for most cutaneous mycobacterial disease in cats in the USA and Australia. Infections have also been described in the United Kingdom, Canada, western Europe, New Zealand, and South America.

Cats

Rapid-growing NTM that are pathogens in cats include members of the *Mycobacterium fortuitum* group[13,199–206] (*M. fortuitum*,[133,207] *Mycobacterium porcinum*,[88] and *Mycobacterium alvei*[88]), *Mycobacterium smegmatis* group[135,200,208,209] (*M. smegmatis sensu stricto*,[88,133] *Mycobacterium goodii*,[88,133,201] *Mycobacterium wolinskyi*[133]),

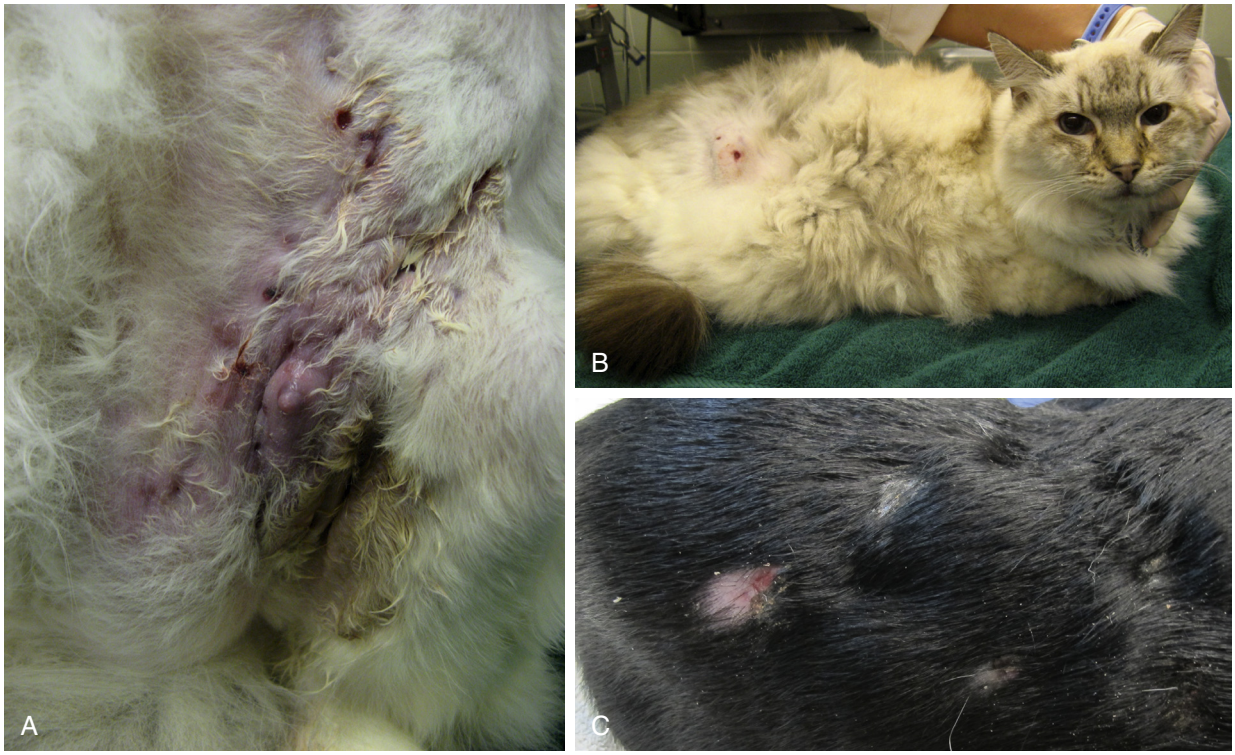

Fig. 61.18 Cutaneous-subcutaneous infections with rapidly-growing mycobacteria. A and B, Thirteen-year-old male neutered siamese cat with mycobacterial panniculitis. There are multiple nodular lesions in the inguinal region (A) and lateral flank and dorsal lumbar regions (B). In this cat, lesions progressed slowly over 8 years despite treatment with antimicrobial drugs. (C) Dorsum of an 8-year old dachshund mix with a multidrug resistant *Mycobacterium abscessus* infection. Multiple draining wounds and extensive scarring are present.

Mycobacterium chelonae/abscessus group[199,201,204,210] (*M. abscessus* subsp. *bolletti* [formerly *Mycobacterium massiliense*[211]]), *Mycobacterium mageritense* group,[88] *Mycobacterium mucogenicum* group,[135] *Mycobacterium falvenscens,*[199] *Mycobacterium phlei,*[212] and *Mycobacterium thermoresistibile.*[133,213–216] Cases have been reported from tropical (Brazil),[207] subtropical (southeastern and southwestern USA),[203,204,212] and temperate regions, including Australia,[88,209,214] New Zealand,[135] Canada,[135] Finland,[217] Germany,[215] United Kingdom,[13] and the Netherlands.[210,213] Geographical differences exist with respect to species distribution.

Dogs

Sporadic infections of dogs with rapid-growing NTM have been reported. *Mycobacterium goodii* was isolated from a dog with uncontrolled hyperadrenocorticism.[218] Systemic *M. smegmatis* infection was diagnosed in a young basset hound[219] (perhaps due to the same immunological defect that renders this breed susceptible to MAC infections). *Mycobacterium fortuitum* skin, bloodstream, and pulmonary infections have also been reported.[220–225]

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Rapid-growing NTM are thought to infect dogs and cats by cutaneous inoculation, which is reflected by the distribution of lesions. Inoculation of the organism directly into subcutaneous adipose tissue appears to increase the severity of disease in cats, to which overweight cats are predisposed.

Cats

Granulomatous panniculitis is the most common manifestation of disease caused by the rapid-growing NTM.[135,199,201–204,208–212,217,225–229] It is characterized by multiple punctate draining tracts and subcutaneous nodules which can coalesce to form large areas of typically non-painful, nonhealing ulcerated skin that overlies inflamed fat pads (Fig. 61.18). Initially, a circumscribed plaque or nodule of the skin and subcutis may be the only sign present. Later, subcutaneous tissue becomes thickened, and the overlying skin becomes adherent, alopecic, and punctuated with draining tracts. In cats, lesions often first appear in the inguinal region, although they can begin in the axillae, flanks, or dorsum. The disease may subsequently spread to contiguous areas of the lateral and ventral abdominal wall, perineum, and tail base. Severely affected cats may become pyrexic, anorexic, and reluctant to move, particularly if lesions are secondarily infected with skin commensals such as *Staphylococcus* and *Streptococcus* spp., but most cats are otherwise bright and appetent. Rarely, pneumonia caused by rapid-growing NTM has been described in cats. Lipoid mycobacterial pneumonia may arise in association with lactulose or paraffin treatment for furballs.[89] Pneumonia was also described in a cat infected with *M. thermoresistibile*; in one cat, infection followed a bath.[90] Clinical signs are typically cough, dyspnea, fever, malaise, and weight loss.

Dogs

In dogs, nodular lesions or nonhealing wounds with draining tracts often occur in the inguinal region, cervical region, and/or other proximal body locations.

Mycobacterium fortuitum also can cause pulmonary disease in dogs[85–89] as well as bacteremia.[81] Lipoid pneumonia was described in one young German shepherd from Louisiana.[230] Disseminated

RGM infections are very rare. Disseminated disease that resembled MAC infection was described in a basset hound infected with *M. smegmatis*.[91]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count and Serum Chemistry Profile

Findings on the CBC, serum chemistry profile, and urinalysis in rapid-growing NTM infections are nonspecific. Cats with mycobacterial panniculitis may have no abnormalities.

Microbiologic Tests

Cytologic Diagnosis

Cytologic examination of aspirates from cutaneous lesions may reveal granulomatous to pyogranulomatous inflammation. Slides also should be stained with acid-fast stains (e.g., ZN or Fite's) to assist in identification of mycobacteria. A modified ZN-staining procedure may be needed for rapid-growing NTM, as they are not as acid-fast as other species. Although less invasive than biopsy, an FNA is likely to have lower sensitivity; panniculitis lesions frequently have few (if any) visible mycobacteria.

Bacterial Isolation and Identification

Isolation of mycobacteria in culture is currently the gold standard diagnostic test for confirmation of rapid-growing NTM infection. However, in some laboratories, it has a low sensitivity and may fail. MALDI-TOF can be used to identify rapid-growing NTM following culture (see Chapter 3). It is now also being used directly on clinical specimens, and the available spectral database for mycobacteria is steadily improving. Mycobacteria require prior inactivation and disruption of the mycolic acid-rich cell wall, both for biosafety reasons (in the case of the MTBC) and to liberate proteins within the cells. Success rates vary between 55% and 98% for correct species-level identification.[231]

Drug susceptibility testing of rapid-growing NTM is not only useful for clinical purposes, but historically has also been used to provide phenotypic data for typing of isolates (for example, susceptibility to trimethoprim, polymyxin B, and tobramycin). The National Committee for Clinical Laboratory Standards Mycobacterial Subcommittee has nominated broth dilution as the gold standard,[6] although this can be technically demanding and is not offered by many diagnostic laboratories.

Molecular Diagnosis Using Nucleic Acid–Based Testing

See slow-growing NTM infections. Molecular methods are rarely needed for diagnosis of rapid-growing NTM infections because they are often isolated readily in culture. PCR-sequencing may be used to identify rapid-growing NTM to the species level.

Pathologic Findings

Typical histopathologic findings in most cats with mycobacteriosis include granulomatous inflammation with foamy, epithelioid, and/or palisading macrophages, with significant infiltration of lymphocytes and/or neutrophils (pyogranulomatous inflammation).[15] With ZN stain, rapid-growing NTM infections generally have fewer AFB compared to slow-growing and fastidious NTM infections, though this is not always the case, and is not diagnostic. The use of modified Fite's or fluorescent Auramine-O stain may increase the sensitivity for detection of mycobacteria.[232]

TREATMENT AND PROGNOSIS

Infections caused by rapid-growing NTM can be successfully treated with lipophilic antimicrobial agents as directed by susceptibility data, together with surgical resection and reconstructive techniques. Because of the common presence of drug resistance, infections caused by rapid-growing NTM should undergo culture and susceptibility testing; however, the following information can be used to guide initial therapy. Based on the use of human breakpoints, members of the *M. smegmatis* complex are usually susceptible to doxycycline and fluoroquinolones but are often resistant to clarithromycin.[233,234] MICs tend to be higher for *M. fortuitum* in general, although it tends to be susceptible to fluoroquinolones and clarithromycin.[235,236] *Mycobacterium chelonae* tends to be resistant to all commonly used drugs except clarithromycin, gatifloxacin, and linezolid.[89,235–237] MICs for ciprofloxacin, enrofloxacin, moxifloxacin, and pradofloxacin using the broth microdilution method have been reported for feline *M. fortuitum*, *M. goodii*, and *M. smegmatis sensu stricto* isolates.[88,238] In areas where *M. smegmatis* and *M. fortuitum* complex infections predominate, treatment should commence empirically with a newer-generation fluoroquinolone (pradofloxacin or moxifloxacin). Where *M. chelonae* infections are more commonly diagnosed, the best first-line choice is clarithromycin or azithromycin. Multidrug therapy is recommended to reduce selection for resistant strains. In refractory cases, clofazimine, cefoxitin, linezolid, or amikacin may be used if indicated by drug susceptibility data. Cats should be reassessed every few weeks to monitor response to treatment. Cure may be achieved with medical therapy alone; however, some cases eventually become refractory to treatment, requiring wide, sometimes radical, surgical resection of residual infection, and then continuation of appropriate antibiotics for months. Referral to a board-certified surgeon is strongly recommended. The use of advanced reconstructive techniques and vacuum-assisted drainage may facilitate cure in some cases.[216] The total duration of therapy for mycobacterial panniculitis is usually 3 to 12 months. As for cats, panniculitis caused by rapid-growing NTM in dogs has been successfully treated using combination therapy combined with surgical excision of lesions, although relapse can occur.[201,239]

Empiric treatment of pneumonia caused by RGM should consist of either pradofloxacin or clarithromycin with adjustment based on susceptibility data. Pulmonary lesions that are refractory to appropriate medical therapy may need surgical resection, and antibiotic therapy should then be continued postoperatively for several months.

IMMUNITY AND VACCINATION

There are no vaccines for rapid-growing NTM infections.

PREVENTION

Because infections are associated with cutaneous inoculation of environmental organisms, housing cats indoors may reduce the risk of infection.

PUBLIC HEALTH ASPECTS

Rapid-growing NTM are opportunistic, environmental mycobacteria that are not usually transmitted from animals to humans. Disease in humans resembles that in dogs and cats. Localized cutaneous and soft-tissue infections with rapid-growing NTM have occurred after traumatic wounds and lacerations, including after dog and cat bites.[240,241] Infections with RGM have also occurred after surgical procedures like liposuction, LASIK surgery, and acupuncture.[242]

FASTIDIOUS NON-TUBERCULOUS MYCOBACTERIAL INFECTIONS

ETIOLOGY AND EPIDEMIOLOGY

Fastidious mycobacteria cannot be cultured by routine laboratory methods and have an enigmatic ecological niche. They generally cause nodular cutaneous lesions in dogs or cats. Genetic studies of fastidious mycobacteria typically group some of them amongst the slow growers, while others form a separate group containing *Mycobacterium leprae* and related bacteria.

Cats

To date, *Mycobacterium lepraemurium* (closely related to *M. avium*), "*Candidatus* Mycobacterium tarwinense" (related to the *M. simiae* group), *M. visibile*, and "*Candidatus* M. lepraefelis" (both related to *M. leprae* and *M. lepromatosis*) have been associated with feline leprosy syndrome (FLS). Infections have been reported from New Zealand,[243,244] eastern Australia,[245,246] western Canada,[247,248] the United Kingdom,[249,250] south-western USA,[251] the Netherlands,[252] France,[253,254] New Caledonia, Italy,[255] the Greek island of Kythira,[256] and Japan.[257] Affected cats have ranged in age from 1 year to 14 years and are often from rural or semi-rural environments. Inoculation of organisms into the skin through rodent bites or cat fight wounds is the suspected mode of transmission.

Historically, feline leprosy was divided into a tuberculoid form of disease which classically affected young cats with few mycobacteria being seen within the lesions, and a separate, leproid form which affected older cats, with numerous mycobacteria.[258] The pathologic picture now appears to depend more on the infective species rather than patient demographics, with most infections caused by "*Candidatus* M. tarwinense" and "*Candidatus* M. lepraefelis" being leproid in nature (91–95%), whereas just over half (58%) of the *M. lepraemurium* cases were of this pathologic type in one study.[259–261]

Dogs

Disease in dogs is known as canine leproid granuloma syndrome (CLGS). CLGS is caused by an as-yet uncharacterized, fastidious mycobacterium related to "*Candidatus* M. tarwinense" and *M. simiae*. Most reports have been from Australia,[262] New Zealand,[263,264] Brazil,[265–267] and the USA.[268] Zimbabwe[269] and Colombia have also reported cases. In 2014, a case was reported from Europe (Italy) for the first time[270] and cases have continued to be confirmed since.[271] Cases have also been suspected in dogs with a history of travel into the United Kingdom (authors' unpublished data). The mode of transmission to dogs is unknown. Transmission by biting insects has been hypothesized because most lesions occur on the pinnae and head. Possibly over-represented breeds include boxer and boxer mixes, Staffordshire bull terriers, German shepherd dogs, foxhounds, and Doberman pinschers. Short-coated hunting dogs, especially spaniels, may also be predisposed; active hunting work is a risk factor for infection.[264,268]

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Cats

In cats, infections caused by fastidious NTM typically manifest as single or multiple cutaneous and/or subcutaneous nodules on the head, limbs, or trunk and regional lymph nodes.[258,272] As with slow-growing NTM infections, nodules are typically non-painful and not adherent to underlying tissues. Skin over the lesions may be intact, alopecic, or ulcerated. Lesions caused by *M. lepraemurium* and "*Candidatus* M. lepraefelis" tend to be found on the head, limbs, and trunk; or may be widespread, involving many cutaneous sites.[258] Lesions caused by "*Candidatus* M. tarwinense" are mostly found on the head (particularly the eyes, lips, or mouth and thoracic limbs, and are not typically widespread.[272] Cats with *M. visibile* infection,[273] and at least one cat infected with "*Candidatus* M. lepraefelis",[260] have systemic involvement at necropsy.

Dogs

In dogs, firm cutaneous nodules are primarily localized on the head, especially the dorsal fold of the pinnae (Fig. 61.19), but may also be located on the lateral trunk, caudal dorsal area, and/or limbs. Nodules range in diameter from millimeters to several centimeters. Lesions may be singular or coalesce to cover large areas. As lesions get larger, they may ulcerate and can become pruritic if secondarily infected.[181] Affected dogs are typically systemically well; there is no involvement of draining lymph nodes, contiguous structures, or internal organs.

DIAGNOSIS

Diagnosis of fastidious NTM infections is based on the presence of consistent skin lesions, absence of signs of dissemination or systemic illness, suggestive cytologic and histopathologic findings, negative mycobacterial culture results, and positive 16S rRNA gene PCR assay results where PCR assays are available. Cytologic examination of fine-needle aspirates usually reveals pyogranulomatous inflammation with intracellular, negatively stained bacteria, which subsequently stain with acid-fast stains. Sequence analysis of PCR products that are generated from biopsy specimens is required to determine the likely species present.

TREATMENT

There have been rare instances of spontaneous resolution of feline leprosy, especially when *M. lepraemurium* is involved,[274] although most cases require treatment for cure. Viability assays that use *M. lepraemurium* grown in cell culture suggest a high degree of susceptibility to rifampicin and clofazimine.[275] Although *M. lepraemurium* appears to be somewhat susceptible to dapsone,[276] adverse effects of hepato- and neurotoxicity and blood dyscrasias limit the use of this drug in cats. Wide surgical resection of nodular skin lesions, plus clarithromycin combined with rifampicin, pradofloxacin, or moxifloxacin (with or without clofazimine) appears to be efficacious.[181,258]

CLGS typically resolves spontaneously within 1 to 3 months of diagnosis.[265,268,275] The efficacy of reported treatments is difficult to establish; however, occasionally persistent infections of greater than 3 to 6 months are observed, and in these instances treatment with antimycobacterial agents is probably warranted. Where lesions are localized, minimal surgical resection and then adjunctive medical therapy is frequently curative. Combination antibiotics with activity against slow-growing mycobacteria are appropriate choices, for example, pradofloxacin/moxifloxacin, rifampicin, clofazimine, and/or clarithromycin. Some authors report successful use of topical clofazimine in silver sulfasalazine, with or without dimethyl sulfoxide.[2]

IMMUNITY, VACCINATION, AND PREVENTION

See rapid-growing NTM infections.

PUBLIC HEALTH ASPECTS

There are no reports of transmission of fastidious NTM from companion animals to humans.

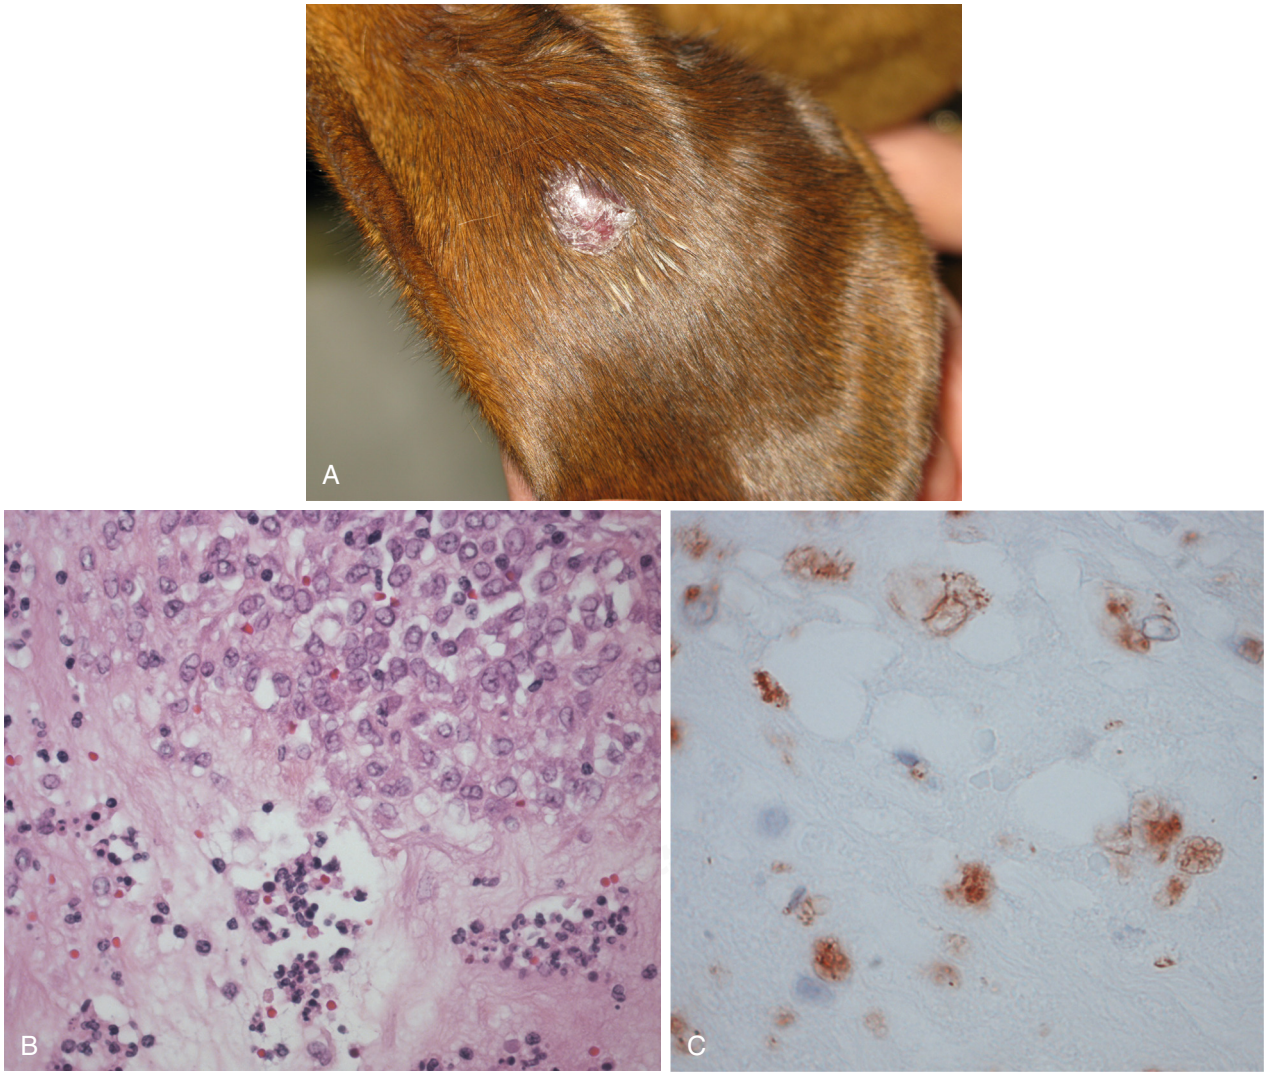

Fig. 61.19 Pinna of a 5-year-old male neutered boxer dog with canine leproid granuloma syndrome (CGLS). (A) A crusted lesion was present that measured 1 × 2 cm in diameter. (B) Histopathology of the CLGS lesions reveals pyogranulomatous inflammation. (C) A BCG immunostain (brown) identified the presence of intracellular *Mycobacterium* spp. organisms.

CASE EXAMPLE

Signalment

A 9-year-old, female neutered domestic shorthair cat that resided within the United Kingdom.

History

The cat was examined by a veterinarian for a mass on the left antebrachium. The owner reported the mass had been steadily increasing in size for 3 weeks. The cat was otherwise well. The cat had outdoor access and was a known avid hunter of local wildlife including birds and small rodents. There were no current medications or significant medical history.

Physical Examination

On physical examination, there was a raised, crusting, erythematous dermal nodular mass 2 cm in diameter over the cranial aspect of the left antebrachium, 3 cm proximal to the carpal joint. The left superficial cervical and left mandibular lymph nodes were mildly enlarged. Body weight was 4.4 kg with a body condition score of 5/9. No other abnormalities were present on the remainder of the clinical examination. The cat was prescribed a 7-day course of oral amoxicillin-clavulanate and meloxicam at standard doses.

On examination after the 7-day course of treatment, there was no change in the lesion or lymph nodes. The cat was anesthetized and incisional biopsies were taken from the lesion and both lymph nodes. The lesion biopsy was bisected and half was frozen in a sterile container while the remaining section and the sections of lymph node were fixed in formalin and submitted for histopathologic examination.

All specimens had multifocal, variably sized areas of necrosis with almost total effacement of the normal tissue. There was infiltration by large numbers of inflammatory cells comprising mostly of reactive (epithelioid) macrophages with enlarged nuclei and copious vacuolated cytoplasm. The macrophage infiltrate

Continued

CASE EXAMPLE—cont'd

was admixed with smaller numbers of mature and degenerate neutrophils and sparse numbers of lymphocytes, plasma cells, and reactive fibroblasts. Histologic diagnosis was chronic active necrotizing pyogranulomatous inflammation. ZN staining revealed rare, intracellular, slender, curved acid-fast bacilli that were consistent with mycobacteria.

Laboratory Findings

Hematology was unremarkable. On serum biochemistry, total serum calcium concentration was increased, but serum ionized calcium concentration was normal.

Imaging Findings

Thoracic radiographs were unremarkable.

Infectious Disease Testing

The cat was negative for both FeLV antigen and FIV antibody (SNAP, IDEXX Laboratories). IGRA revealed a significant response to all three test conditions (PPDA, PPDB, and ESAT-6/CFP-10) with a greater response to PPDB than PPDA; this suggested infection with a member of the MTBC other than *M. microti,* which in the United Kingdom was taken to be indicative of *M. bovis* infection.

To confirm the causative agent, the frozen section of the lesion biopsy was submitted to the Animal and Plant Health Agency for mycobacterial culture. After 8 weeks, *M. bovis* was isolated. Molecular typing resulted in identification of the isolate spoligotype, the same strain that had been isolated from infected cattle in the region.

Diagnosis

Mycobacterium bovis infection.

Treatment

Treatment with pradofloxacin (15 mg PO q24h), 50 mg azithromycin (50 mg PO q24h), and 50 mg rifampicin (50 mg PO q24h) was commenced.

After 1 month, repeat examination revealed resolution of all previously detectable gross abnormalities. Repeat hematology and serum biochemistry were unremarkable, showing only a mild increase in the activities of serum ALT and ALP. Treatment with all three medications was therefore continued for a further 2 months before cessation. The cat remained clinically normal one year after discontinuation of treatment.

62

Salmonellosis

Jane E. Sykes, Patrick L. McDonough

KEY POINTS

- First Described: Washington, DC, United States, 1885 (Theobald Smith and Daniel Salmon).[1]
- Cause: *Salmonella* spp. (gram-negative rods that belong to the order Enterobacterales).[2]
- Affected Hosts: A large variety of warm-blooded animals and humans; cold-blooded animals may be subclinically to clinically infected.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Fecal-oral.
- Major Clinical Signs: Fever, lethargy, anorexia, diarrhea, vomiting, and less commonly reproductive failure, neurologic and/or respiratory signs.
- Differential Diagnoses: Differential diagnoses for suspected *Salmonella* enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, other viral gastroenteritides, campylobacteriosis, clostridial diarrhea, salmon poisoning disease, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, leptospirosis, dietary indiscretion, gastrointestinal foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, hyperthyroidism, toxins (including drugs).
- Human Health Significance: Important zoonosis. Dogs and cats may be a source of human infection with some *Salmonella* serotypes, some of which may be resistant to multiple antimicrobial drugs.

ETIOLOGY AND EPIDEMIOLOGY

Salmonella are gram-negative, motile, non–spore-forming facultative anaerobic rods that belong to the order Enterobacterales. Most *Salmonella* exist in two antigenic phases, which differ in composition of their flagellar antigens.

Salmonella are ubiquitous organisms that can be isolated from the intestinal tracts of an enormous variety of animal species and are a major cause of enterocolitis and sometimes severe systemic illness in humans and animals. Infections can be transferred among animal species and are zoonotic (Fig. 62.1). Many infections in humans are food-borne, especially in association with unpasteurized milk, meat (especially ground poultry meat), and eggs. *Salmonella* spp. have a remarkable ability to survive long periods of time (weeks to years) in the environment, and so fomite transmission is important. *Salmonella* thrive in moist environments (a good example is egg layer flock housing). In addition, *Salmonella* can multiply rapidly in contaminated food left at room temperature and can survive freezing for several weeks.[3]

The genus *Salmonella* comprises two species, *Salmonella enterica* and *Salmonella bongori*, each of which contains multiple serotypes.[4,5] Serotypes of *S. bongori* are generally associated with cold-blooded animals and rarely have been isolated from warm-blooded animals, including a dog with diarrhea.[6] There are six subspecies of *S. enterica* (Table 62.1) and approximately 2600 different serotypes. Before the availability of multiplex PCR assays, serotypes were identified on the basis of agglutination reactions of their O (somatic) and H (flagellar) antigens (see Chapter 53); most reference laboratories today have switched to commercial kits to identify *Salmonella* serotypes by multiplex PCR.[7] Subspecies I serotypes, which are responsible for almost all diseases in humans and warm-blooded animals worldwide, are assigned names such as *S.* ser. Typhimurium. Unless named before 1966, serotypes that belong to other subspecies are designated using antigenic formulas. The formulas describe the subspecies, O antigens: H antigens (phase 1): and if present, H antigens (phase 2) (e.g., *S.* IV 45:g,z_{51}:—).[5]

Certain serotypes of *Salmonella* are host restricted (also called host adapted), whereas others infect a broad range of host species (or called non–host adapted). *Salmonella* serotype Typhi, for example, is adapted to humans, causing typhoid fever, and does not infect animals. Other serotypes are adapted to certain host species (e.g., *S.* Pullorum and poultry), with rare transmission to other hosts. *Salmonella* Typhimurium is the most commonly isolated non–host adapted serotype from diseased humans and animals.

Infection of dogs and cats with *Salmonella* has been associated with the feeding of raw meat diets,[8-16] although commercial dry and raw dog food and pig ear pet treats have also become contaminated with the organism.[10,17-21] One study used whole genome sequencing to show that *Salmonella* infections in pets were associated with contaminated raw pet food diets.[11] The organism has been shown to survive weeks to months on pig ear treats, although viability over time decreases more rapidly at room temperature than under refrigeration.[22] Occasionally, co-infections with multiple *Salmonella* serotypes occur.[23] Outbreaks of *S.* Typhimurium infection in cats have been associated with seasonal bird migrations ("songbird fever").[24,25] An outbreak of salmonellosis was described in a colony of blood donor cats that developed severe enterocolitis; the source of infection was not identified.[26]

Salmonella is generally isolated less than 1% of the time from the feces of dogs and cats that are fed processed commercial pet foods,[27-31] although one study of household pet dogs in Ontario, Canada revealed a shedding prevalence of 23%[32] and a study from Thailand revealed a prevalence of 12.9%.[33] The highest rates of infection have been found in group-housed dogs, especially those fed raw meat diets, such as racing sled dogs and greyhound breeding facilities, where prevalences have exceeded 75%.[14,34,35] In South Africa, based on culture, the prevalence of *Salmonella* shedding in 74 hospitalized puppies with CPV-2 infection

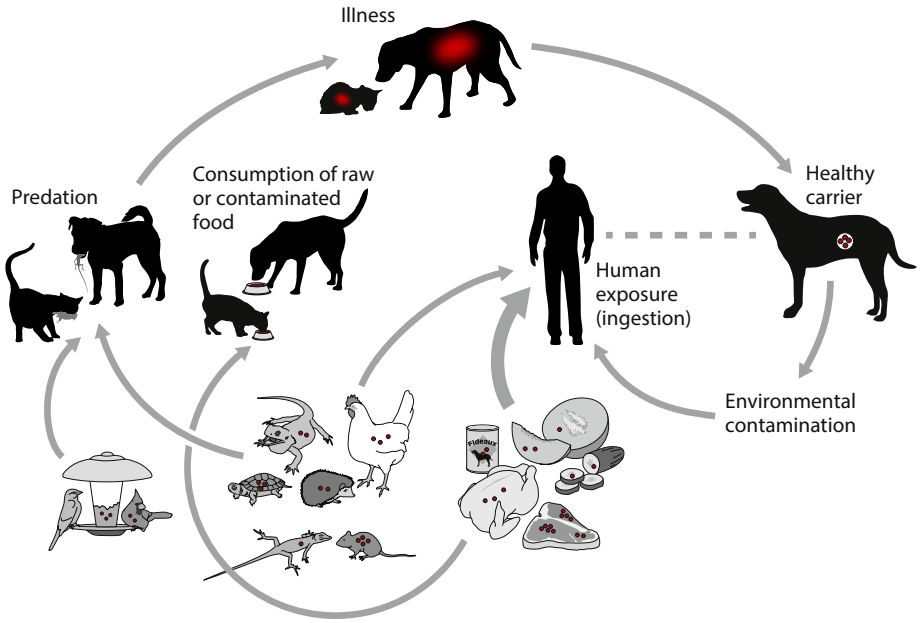

Fig. 62.1 Epidemiology of salmonellosis.

TABLE 62.1 Classification of Salmonellae

Species	Subspecies	Serotype Examples
Salmonella enterica	*enterica* (I)	*Salmonella* Typhimurium
		S. Typhi
		S. Choleraesuis
	salamae (II)	*S.* Greenside
	arizonae (IIIa)	*S.* IIIa 18:z_4,z_{23}:—
	diarizonae (IIIb)	*S.* IIIb 60:k:z
	houtenae (IV)	*S.* Marina
	indica (VI)	*S.* Srinagar
Salmonella bongori	V	*S.* Brookfield

was 22%, but this compared with a prevalence of 31% in a control group of 42 apparently healthy dogs.[36] *Salmonella* was isolated from the feces of 18 of 26 (69%) healthy pre-race Alaskan sled dogs, and 19 of 30 (63%) diarrheic racing Alaskan sled dogs, which underscored the lack of an association between the isolation of *Salmonella* and clinical diarrhea.[14] In one large study of dogs and cats visiting veterinary clinics from the United States between January 2012 and April 2014, *Salmonella* was isolated from 2.5% of 2,422 dogs and 0.06% of 542 cats.[37] Risk factors for infection based on univariate analysis were consumption of raw food, consumption of probiotics, administration of antimicrobial drugs, rural background (versus urban or suburban), and the presence of diarrhea; however, multivariate logistic regression analysis revealed that probiotic administration was associated with diarrhea, so it was no longer identified as a risk factor. The percentages of positive isolations were also highest in Georgia (8%) and Texas (10%). Coprophagic behavior may also contribute to salmonellosis in dogs. In cats, the feeding of raw poultry may increase risk for *Salmonella* infection,[38] and occasionally, high prevalences of infection have been detected in group-housed cats[31] and shelter cats. Ingestion of infected wild bird species by cats during seasonal bird migrations can also lead to salmonellosis.[24,25] In a study of diarrheic and nondiarrheic shelter cats in Florida, the prevalence of *Salmonella* shedding as determined by PCR assay was 6% and 4%, respectively.[39] In *Salmonella* isolates from dogs in Texas shelters, the most frequently identified serotypes were Newport and Javiana, for which there was evidence of within-shelter transmission in addition to introduction of new infections.[40] Susceptibility to shedding and disease is highest in immunosuppressed dogs and cats, including young animals, pregnant animals, those in overcrowded conditions, and those with underlying immunosuppressive illness (such as neoplasia, diabetes mellitus, retrovirus infection, and immune-mediated disease) or immunosuppressive drug therapy.[41-44]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After ingestion, salmonellae that survive the acidic environment of the stomach gain access to the intestine, where they disrupt tight junctions and, through a process known as bacteria-mediated endocytosis, they actively invade: (1) enterocytes; (2) M cells within the ileum (which sample luminal antigens); and (3) dendritic cells, which send protrusions into the gut lumen between intestinal epithelial cells (Fig. 62.2). As few as 200 organisms may be sufficient to produce nontyphoidal human disease, although the median dose required was 10^6 organisms.[45] A T3SS, together with other proteins encoded by *Salmonella* pathogenicity island 1 (SPI-1), is required for invasion of enterocytes, but invasion of dendritic cells is SPI-1-independent. Interaction of *Salmonella* with immune cells and epithelial cells within the gut leads to production of cytokines and chemokines, with massive influx of lymphocytes, macrophages, and neutrophils, sometimes with severe epithelial injury and mucosal sloughing.[46,47] This occurs in response to the presence of SPI-1 translocated proteins as well as activation of TLR4 by LPS and TLR5 by flagellin. Localization in the mesenteric lymph nodes, Peyer's patches, solitary intestinal lymphoid tissues, and intestinal epithelium, along with evasion of the host immune response, is followed by persistent shedding, often for several weeks, after which animals can become latently infected. Reactivation of shedding, with or without clinical illness, may occur, sometimes as a result of stress or immunosuppression.[48,49]

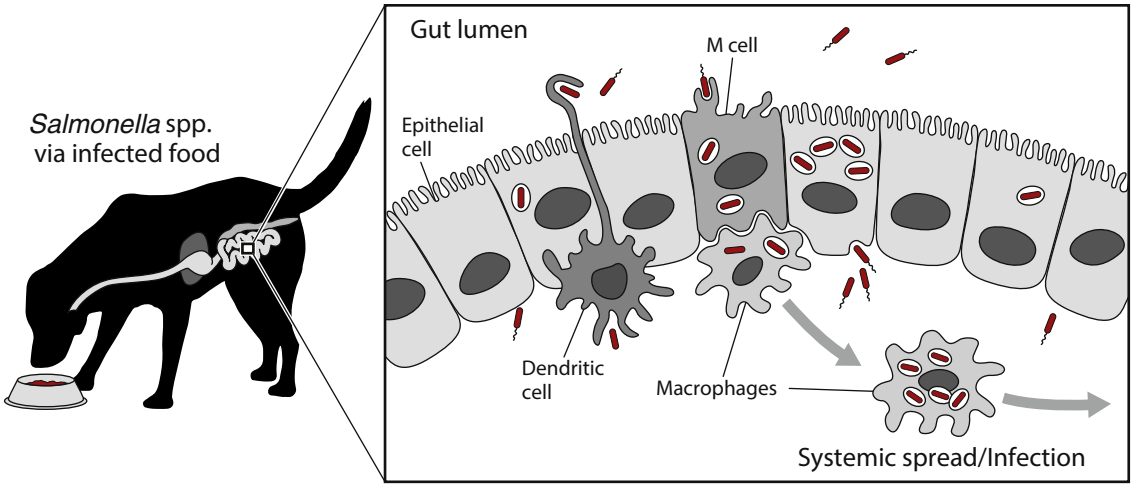

Fig. 62.2 The pathogenesis of *Salmonella* infection. (Modified from Hume PJ, Singh V, Davidson AC, et al. Swiss Army Pathogen: The *Salmonella* entry toolkit. *Front Cell Infect Microbiol*. 2017;7:348.)

If the organism has properties that allow it to spread systemically and host defenses are impaired, bacteremia and extraintestinal infection follow.[50] After crossing the intestinal barrier, *Salmonella* invade and replicate within macrophages using a second T3SS (present in SPI-2), which contributes to their dissemination and development of systemic infection. Virulent strains have a greater ability to multiply intracellularly in nonphagocytic cells.[46] Fever, hypoglycemia, and leukopenia occur. The *Salmonella* LPS can then induce endotoxic shock, with hypotension and activation of the complement and coagulation cascade. The coagulation cascade is also activated with exposure to *Salmonella* porins, which are hydrophobic outer membrane proteins. This is followed by DIC.

Dogs and cats infected with *Salmonella* spp. may show no signs or they may develop enterocolitis, focal suppurative infection, or severe systemic illness. The majority of dogs are chronically and subclinically infected. When disease occurs, signs often begin 3 to 5 days after infection or onset of immunosuppression. Fever (occasionally as high as 106°F [41°C]), lethargy, and anorexia may be followed by abdominal pain, vomiting, and watery to mucoid, often hemorrhagic, diarrhea and dehydration. Weight loss may be seen. Diarrhea may take several weeks to resolve. Rarely, chronic intermittent diarrhea that lasts up to 8 weeks develops.[51]

Severely affected animals develop signs of septic shock (see Chapter 123). Neurologic signs, and signs that relate to endocarditis, myocarditis, arthritis, pancreatitis, pneumonia, peritonitis, prostatitis, mesenteric lymphadenitis, and cholecystitis occur in some animals.[44,52-56] Infected cats may develop severe enterocolitis, with fever, pancytopenia, and hyperbilirubinemia. Some cats show persistent fever and anorexia with no diarrhea. Conjunctivitis has been described in cats in association with *Salmonella* infection.[57]

Occasionally salmonellae localize in a particular organ, such as the lungs, CNS, or urinary tract (Fig. 62.3). Signs of dysfunction of that organ system may follow, even when enteric signs or positive fecal culture results are absent.[58] Abortion and stillbirth can occur after transplacental infection, and the dam may also infect neonates, which leads to fading puppies.[59-61]

DIAGNOSIS

The traditional diagnosis of canine and feline salmonellosis is made based on culture of the organism in conjunction with clinical signs and assessment of potential risk factors, such as hospitalization, age, environmental exposure, and antibiotic administration. Diagnostic assays available for salmonellosis in dogs and cats are shown in Table 62.2.

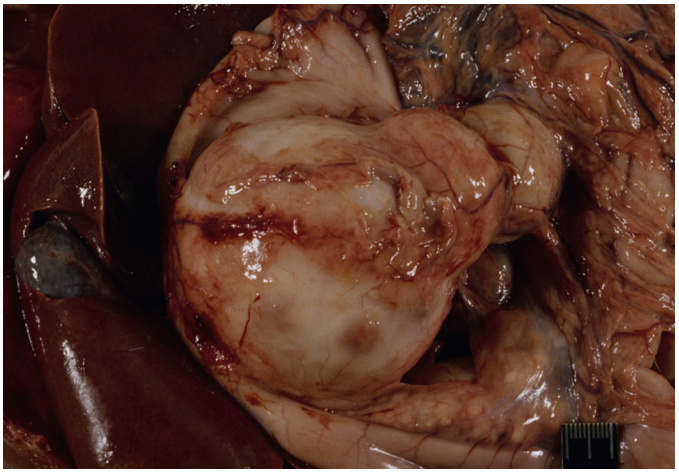

Fig. 62.3 Large, chronic pancreatic abscess due to *Salmonella* Typhimurium associated with a pancreatic adenocarcinoma in a 15-year-old castrated male domestic shorthair cat. The mass was multicystic and fluctuant, and when cut open was filled with cloudy fluid and lined by thick tan debris. (Courtesy University of California, Davis, Veterinary Anatomic Pathology Service.)

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs or cats with salmonellosis may be unremarkable or may show a neutrophilia with a left shift; in bacteremic animals, anemia, a degenerative left shift, toxic neutrophils, lymphopenia, and thrombocytopenia are usually present. Rarely, intracellular bacteria are seen within neutrophils.

Serum Chemistry Profile

In animals with severe salmonellosis, changes in the serum chemistry profile include elevated liver enzyme activities, hyperbilirubinemia, azotemia, hypoalbuminemia, hypocholesterolemia, hypoglycemia, and electrolyte abnormalities.

Urinalysis

Salmonella spp. occasionally localize in the kidneys, with associated isosthenuria, pyuria, proteinuria, casts, and bacteriuria.

TABLE 62.2 Diagnostic Assays Available for Salmonellosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Feces, blood, synovial fluid, tissue aspirates, bronchoalveolar lavage fluid, peritoneal or pleural effusions, urine, CSF, tissues obtained at necropsy	*Salmonella* species	Sensitive and specific. False negatives may occur, especially following antimicrobial therapy. Isolation from feces does not imply that *Salmonella* is the cause of disease. Allows subsequent antimicrobial susceptibility testing.
PCR	As for isolation	*Salmonella* DNA	Rapid (within hours); can be highly sensitive and specific. Positive results from feces do not imply that *Salmonella* is the cause of disease. Does not allow susceptibility testing or typing for epidemiologic purposes.

Clotting Function

Dogs and cats that develop DIC may have clotting function abnormalities that include prolonged coagulation times, increased fibrin degradation product concentrations, and decreased antithrombin concentrations.

Diagnostic Imaging

Plain Radiography

Thoracic radiographs may reveal bronchointerstitial to alveolar infiltrates in animals with pneumonia, or pleural effusion with pyothorax. Abdominal radiographs can reveal fluid-filled intestines, decreased serosal detail, and/or mild hepatomegaly.

Sonographic Findings

Depending on the severity of the infection, abdominal ultrasound may be unremarkable in dogs and cats with salmonellosis, or show changes that include abdominal lymphadenomegaly, intestinal wall thickening, fluid-filled bowel segments, hepatomegaly, splenomegaly, or ascites.

Microbiologic Testing

Bacterial Isolation

A diagnosis of salmonellosis can be made when *Salmonella* is isolated from a normally sterile site, such as the blood, bronchoalveolar lavage specimens, synovial fluid, or urine specimens collected by cystocentesis. Isolation of *Salmonella* from feces does not confirm that the organism is the cause of disease,[61] but it can raise suspicion that *Salmonella* may be playing a role in enterocolitis, and it has zoonotic significance (see Public Health Aspects, later). Isolation also allows antimicrobial susceptibility testing, which is important because many isolates of *Salmonella* are resistant to multiple antimicrobial drugs.

Salmonella grow readily at 37°C on routine bacteriologic media from specimens that have been collected from a normally sterile site. Selective broth enrichment followed by plating on selective media are required for specimens that are heavily contaminated with other bacteria such as feces. The best selective broth enrichment is Rappaport-Vassiliadis soya peptone broth (RVS) medium. After enrichment, subculturing is performed on media such as xylose lysine deoxycholate (XLD) and brilliant green (BG) agar media, which also favor growth of *Salmonella*. These methods have been used in veterinary microbiology laboratories to facilitate growth of more fastidious serotypes such as *S.* Dublin.[62] Many veterinary laboratories incorporate such protocols for isolation of *Salmonella* as part of a panel for detection of enteropathogenic bacteria. Once a *Salmonella* suspect colony appears, the organism can be identified to genus using MALDI-TOF MS. This allows identification of *Salmonella* at the species level within minutes.[63,64] It also can identify some important *S. enterica* subsp. *enterica* to the serovar level, and could reduce the need for laborious subtyping procedures.[63] Veterinary laboratories also retain the use of antisera to identify the major serogroups of *Salmonella* that may be of immediate veterinary and public health significance.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Some veterinary diagnostic laboratories offer PCR assays for *Salmonella*, some of which are highly sensitive and specific when compared with culture.[62,65,66] PCR is more rapid than culture but currently does not provide information on antimicrobial susceptibility. It has been recommended that PCR assay after overnight enrichment in a nonselective broth be adopted as the gold standard for diagnosis, and that all specimens that test positive by PCR assay be cultured using selective enrichment to isolate and identify the infecting organism.[62,67] As with culture, detection of the organism in feces using PCR assays does not prove that it is the cause of gastrointestinal illness.

Pathologic Findings

Gross Pathologic Findings

Gross necropsy findings in dogs and cats with severe salmonellosis include widespread petechial and ecchymotic hemorrhages, hemorrhagic enteritis, abscesses within parenchymal organs, enlarged mesenteric lymph nodes, and fibrinohemorrhagic ascites fluid. Pulmonary consolidation and edema may also be present.

Histopathologic Findings

Histopathologic lesions in dogs and cats with salmonellosis are highly variable. Changes in severely affected animals may include suppurative pneumonia, necrotizing hepatitis, and necrotizing and fibrinohemorrhagic enterocolitis, typhlitis, and cholecystitis. More chronic lesions such as chronic cholecystitis have also been described.[68,69] Sometimes, gram-negative bacilli are identified within lesions with tissue Gram stains (Fig. 62.4).

TREATMENT AND PROGNOSIS

The movement of dogs and cats that test positive for *Salmonella* should be limited, and if possible, hospitalized animals should be isolated. The detection of *Salmonella* in the feces of dogs and cats with uncomplicated diarrhea does not warrant antimicrobial administration, and supportive care only is recommended. Most of these animals have self-limiting disease and shedding, and injudicious antimicrobial administration has the potential to prolong the carrier

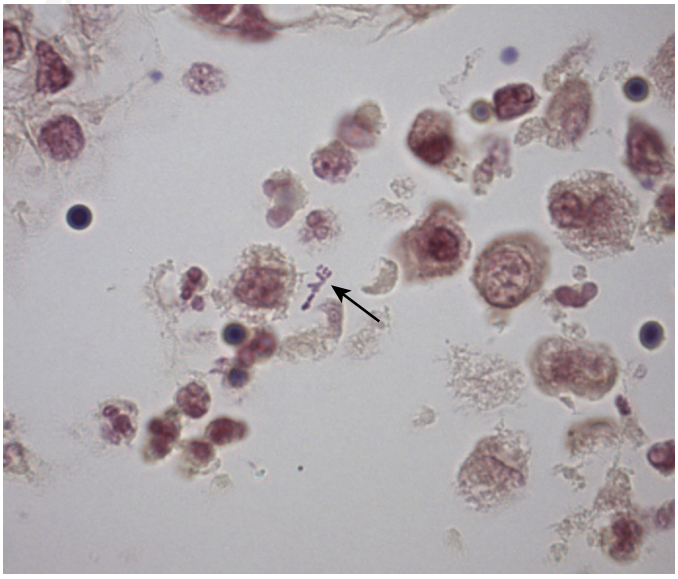

Fig. 62.4 Gram-negative bacilli (*arrow*) in the lungs of a cat with suppurative cholecystitis and pneumonia due to *Salmonella arizonae*. The cat had been treated with prednisone and cyclosporine for immune-mediated hemolytic anemia. Brown and Benn stain, 1000× magnification.

state and contribute to antimicrobial resistance. In humans, both short- and long-duration of antimicrobial treatment of uncomplicated non-typhoidal gastroenteritis did not reduce the duration of fever or diarrhea, and was associated with increased likelihood of positive fecal cultures 1 month after treatment as well as adverse drug reactions.[45] Treatment of an animal with uncomplicated diarrhea is also not advocated if the owner is immunocompromised, although appropriate husbandry recommendations and barrier control must be enforced.

Dogs and cats with systemic salmonellosis may require aggressive intravenous fluid therapy and colloidal support with hydroxyethyl starch or plasma, together with parenteral antimicrobial drugs. The choice of antimicrobial drugs should be based on the results of culture and susceptibility, because of the potential for resistance to multiple antimicrobial drugs through plasmid transfer. In the event of systemic disease, administration of a combination of ampicillin and a fluoroquinolone is advocated as empiric therapy while awaiting results of culture and susceptibility. Because of the importance of endotoxin in the pathogenesis of sepsis due to gram-negative bacteria such as *Salmonella*, considerable effort has been invested in development and application of drugs targeting endotoxin.[70] Clear benefit through reduction in mortality has not yet been demonstrated for these treatments, and to date they have not been widely used in dogs and cats. Several investigations have been focused on antagonists of TLR4, the LPS receptor.[71] Eritoran tetrasodium (E5564) and TAK-242 are examples of TLR4 antagonists that have been used in clinical trials involving septic humans, but no clear benefit has been shown.[71,72]

IMMUNITY AND VACCINATION

Salmonella spp. can persist in the host by interfering with dendritic cell function in the intestinal tract. The organism penetrates dendritic cells and avoids lysosomal degradation, which prevents subsequent antigen presentation by dendritic cells on molecules of the major histocompatibility complex.[73] Reduced intracellular proliferation of the organism within antigen-presenting cells may also limit antigen presentation and the development of an effective immune response.[74] Suppression and clearance of infection depends on the innate immune system, a Th1-type CD4 T-cell response, and production of antibodies by B cells. Although typhoid *Salmonella* vaccines have been developed for humans, none are available for dogs and cats.

PREVENTION OF ENTERIC BACTERIAL INFECTIONS

Prevention of enteric bacterial infections includes feeding dogs and cats properly cooked foods, hand washing before and after handling pets and pet food, and prevention of coprophagic behavior and predation. Proper handling and storage of pet foods can also limit the potential for food contamination during storage by rodents, insects, and human hands.

Within the hospital setting, fomites such as food dishes, endoscopes, proctoscopes, and rectal thermometers should be disinfected between uses, and single-use disposable thermometer covers should be used. Cages should be cleaned and properly disinfected (see Chapter 14) between animals. Blood donors should not be housed with the regular hospital population, as they may be a source of *Salmonella* infection.

Dogs and cats diagnosed with salmonellosis or *Salmonella* shedding should be isolated from other animals until shedding stops. Fecal cultures should be repeated every 2 weeks, and termination of shedding is identified when three successive negative cultures have been obtained.

PUBLIC HEALTH ASPECTS

All enteric bacterial infections of dogs and cats have the potential to infect and cause illness in humans. Nontyphoid salmonellosis (salmonellosis other than that caused by *S.* Typhi) can be transmitted from domestic animals to humans and cause serious enterocolitis, with fever, severe abdominal pain, diarrhea, nausea, inappetence, chills, and headache. Serious complications tend to occur in children, the elderly, or otherwise immunocompromised individuals such as those infected with HIV. The majority of cases result from ingestion of improperly cooked foods of animal origin, such as meat, milk, and eggs. Most, if not all, pet reptiles carry *Salmonella*, and there has been considerable effort to educate the public about the hazards of reptile-associated salmonellosis.[75] Dogs, and to a lesser extent cats, are less commonly incriminated as a source of *Salmonella*. Of particular concern, multidrug-resistant *Salmonella* strains, such as *S.* Typhimurium strain DT104, have been isolated from dogs, cats, and reptiles.[32,76] People exposed to dogs and cats that are fed raw meat diets are at increased risk of exposure. Nevertheless, there is a reasonable degree of mismatch between human and animal serotypes, which suggests that some serotypes are more likely to be transmitted to humans than others.

Proper hand washing after handling pets, pet food, and fomites such as bedding and food dishes can help prevent zoonotic transmission of *Salmonella*. Reptile ownership by families with children younger than 5 years of age or among the immunosuppressed is discouraged by public health authorities.[76] Proper food handling practices, including separating raw meat from vegetables and proper cooking of meat, can also reduce salmonellosis in humans.[19,77] Prevention of coprophagy and predation by dogs may also reduce the risk of human disease.

CASE EXAMPLE

Signalment

"Sampson," a 3-year-old male castrated shepherd mix from Fresno in southern California (Fig. 62.5).

History

Sampson was brought to a veterinarian for evaluation of a 3-month history of bilateral tarsal joint swelling. Some clinical improvement had been noted after treatment with oral tetracycline (28 mg/kg PO q8h) for 2 weeks. Subsequently, he was treated with oral prednisone (1.1 mg/kg PO q12h). Two weeks after the prednisone treatment was initiated, Sampson became nonambulatory in his pelvic limbs, and all of his peripheral joints became swollen and he was referred to the University of California, Davis, VMTH. A mass had been removed from his left dorsolateral thorax 3 weeks before referral that was assumed to be a foxtail abscess. Sampson had a good appetite. Increased thirst and urination had been noted after the prednisone treatment was initiated. There had been no coughing, sneezing, vomiting, or diarrhea. He was fed a duck- and potato-based diet for food allergy dermatitis and had been treated intermittently with prednisone, 4 mg PO q24h, for this condition since he was 6 months old. He had not traveled outside his local area, but he lived on a ranch and was known to consume horse feces and dead wild animals. There was no known tick exposure. He was up to date on vaccinations including canine distemper, adenovirus, parvovirus, and rabies vaccines.

Current medications: Prednisone 0.9 mg/kg PO q12h

Physical Examination

Body weight: 35.8 kg.

General: Quiet, alert, and responsive, 5% to 7% dehydrated. Recumbent. T = 102.9°F (39.4°C), HR = 140 beats/min, panting, mucous membranes pink and tacky, CRT = 1 s.

Integument: Multifocal epidermal collarettes were present and the haircoat was dry. A shaved area was present on the left lateral thoracic wall.

Fig. 62.5 "Sampson," a 3-year-old male castrated shepherd mix with salmonellosis.

Eyes, ears, nose, and throat: Moderate periodontal disease was present. A fundic examination was within normal limits.

Musculoskeletal: BCS was 5/9 with pelvic limb muscle atrophy. Pain and effusion of the carpi, tarsi, and stifles with decreased range of motion was noted. Spinal and pericervical pain was detected on palpation of these regions.

Cardiovascular: Weak but synchronous femoral pulses were noted. No murmurs or arrhythmias were auscultated.

Respiratory: There were moderately increased breath sounds in all lung fields.

GI/genitourinary: The abdomen was tense on palpation and moderate hepatomegaly was detected. The dog urinated a large amount of odiferous urine during the examination. No abnormalities were detected on rectal examination.

Lymph nodes: Moderate peripheral lymphadenopathy was present. Mandibular, superficial cervical, and popliteal lymph nodes were all 1.5 to 2.5 cm in diameter.

Laboratory findings

CBC: HCT 35.4% (40%–55%), MCV 67 fL (65–75 fL), MCHC 35.6 g/dL (33–36 g/dL), reticulocytes 101,200 cells/μL (7000–65,000 cells/μL), WBC 7870 cells/μL (6000–13,000 cells/μL), neutrophils 6139 cells/μL (3000–10,500 cells/μL), band neutrophils 1495 cells/μL, metamyelocytes 79 cells/μL, lymphocytes 0 cells/μL (1000–4000 cells/μL), monocytes 79 cells/μL (150–1200 cells/μL), platelets 419,000 platelets/μL (150,000–400,000 platelets/μL), neutrophils, band neutrophils, and metamyelocytes all showed moderate toxic changes.

Serum chemistry profile: Sodium 148 mmol/L (145–154 mmol/L), potassium 4.4 mmol/L (3.6–5.3 mmol/L), chloride 105 mmol/L (108–118 mmol/L), bicarbonate 14 mmol/L (16–26 mmol/L), phosphorus 5.8 mg/dL (3.0–6.2 mg/dL), calcium 10.3 mg/dL (9.7–11.5 mg/dl), BUN 10 mg/dL (5–21 mg/dL), creatinine 0.4 mg/dL (0.3–1.2 mg/dL), glucose 111 mg/dL (64–123 mg/dL), total protein 6.1 g/dL (5.4–7.6 g/dL), albumin 2.3 g/dL (3.0–4.4 g/dL), globulin 3.8 g/dL (1.8–3.9 g/dL), ALT 560 U/L (19–67 U/L), AST 72 U/L (19–42 U/L), ALP 3318 U/L (21–170 U/L), creatine kinase 197 U/L (51–399 U/L), GGT 59 U/L (0–6 U/L), cholesterol 212 mg/dL (135–361 mg/dL), total bilirubin 0.3 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.010; pH 8.0, 1+ protein (SSA), 3+ hemoprotein, no bilirubin or glucose, 25–35 WBC/HPF, 10–15 RBC/HPF, many rods.

Imaging Findings

Thoracic radiographs: The cardiovascular and pulmonary structures appeared within normal limits.

Right and left carpal, stifle, and tarsal radiographs: Intracapsular soft tissue swelling was associated with all joints.

Spinal radiographs: No abnormalities were detected.

Abdominal ultrasound: The liver was enlarged and hyperechoic. There was echogenic sediment in the urinary bladder.

Echocardiogram: Thickening and hyperechogenicity of the posterior leaflet of the tricuspid valve was noted which raised suspicion for endocarditis (Fig. 62.6).

Cytology Findings

Arthrocentesis of right and left carpi, right tarsus, and right stifle: Purulent inflammation was noted in the right tarsus, right stifle, and left carpus, with approximately 85% neutrophils and the remaining cells were a mixture of small and large mononuclear cells. In the right stifle, degenerate neutrophils are visualized, and some contained intracellular rod-shaped bacteria.

Microbiologic Testing

Serologic testing: An in-clinic ELISA for antibodies to *Borrelia burgdorferi*, *Anaplasma phagocytophilum*, and *Ehrlichia canis* was negative. Serum IFA for antibodies to *Bartonella vinsonii* subsp. *berkhoffii* was negative. Serology for *Coccidioides* spp. antibodies was also negative.

Continued

CASE EXAMPLE—cont'd

Aerobic bacterial culture of blood, joint fluid, and urine collected by cystocentesis: *Salmonella arizonae*, susceptible to all antimicrobials tested.

Diagnosis

Salmonella arizonae septic polyarthritis, bacteremia, and possible tricuspid valve endocarditis.

Treatment

Before obtaining susceptibility results, Sampson was treated with intravenous crystalloids, opioids for pain control, enrofloxacin (5 mg/kg IV q24h), and ampicillin (30 mg/kg IV q8h). The ampicillin was discontinued when the susceptibility results became available. The prednisone was tapered over a 3-day period and discontinued. The dog was moved to an isolation ward on diagnosis of salmonellosis. During hospitalization, Sampson's appetite declined initially, and he remained very painful for 6 days. After that time, he was able to sit up, began eating, and was discharged 8 days after admission.

Comments

Salmonella arizonae infections in humans have been associated with direct or indirect contact with reptiles. Reptile-associated salmonellosis is an increasing problem in humans in the United States and is especially a problem in infants and immunocompromised adults in contact with snakes and iguanas, or those who eat sun-dried rattlesnake meat for medicinal purposes. Horse feces from the farm were cultured for *Salmonella* and were negative. It is possible that the infection in this dog occurred as a result of ingestion of wild reptiles. The long history of glucocorticoid therapy for atopic dermatitis in this dog may have contributed to immunosuppression and predisposition to systemic salmonellosis.

Fig. 62.6 Thickening and hyperechogenicity of the posterior tricuspid valve leaflet (*arrowhead*) in a dog with *Salmonella arizonae* bacteremia.

63

Enteric *Escherichia coli* Infections

Jane E. Sykes

KEY POINTS

- First Described: Germany, 1885 (Theodor Escherich).[1]
- Cause: *Escherichia coli* (gram-negative rods that belong to the Enterobacterales).
- Affected Hosts: Humans and a large variety of animals.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Fecal-oral.
- Major Clinical Signs: Fever, lethargy, inappetence, diarrhea, vomiting.
- Differential Diagnoses: Differential diagnoses for suspected *E. coli* enterocolitis include canine and feline parvovirus infection, canine distemper virus infection, salmon poisoning disease, campylobacteriosis, clostridial diarrhea, salmonellosis, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, pythiosis, histoplasmosis, leptospirosis, dietary indiscretion, GI foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, hyperthyroidism (cats), toxins (including drugs).
- Human Health Significance: Based on strain typing, dogs and cats have the potential to be a source of human infection by pathogenic *E. coli* strains capable of causing diarrhea. However, the vast majority of infections in humans occur in developing countries, in travelers, and are foodborne.

ETIOLOGY AND EPIDEMIOLOGY

Escherichia coli are pleomorphic gram-negative, non–spore-forming rods that belong to the family Enterobacterales. Like *Salmonella, E. coli* can survive long periods of time in feces, dust, and water. They are part of the normal flora of the GI tract but can be associated with enterocolitis in the presence of bacterial virulence factors and impaired local or systemic immunity. *Escherichia coli* infections can be transferred between animal species and some may be zoonotic; many infections are food borne.

There are more than 170 serogroups of *E. coli* based on the identity of the bacterial O (somatic) antigen, the sugar that is on the most external portion of the bacterial LPS (see Chapter 53). Organisms are also identified on the basis of their H (flagellar) antigens—for example, O157:H7 *E. coli.* Over 50 H antigens have been identified, but only a limited number of O and H combinations are associated with disease. Both the bacterial LPS (endotoxin) and the flagellar antigens are bacterial virulence factors. Other virulence factors in *E. coli* include adhesins, bacterial exotoxins such as cytotoxic necrotizing factor (CNF), hemolysins, heat-labile (LT) and heat-stable (ST) enterotoxins, and the capsular polysaccharide (K).

Escherichia coli strains that cause GI disease have been divided into distinct pathogenic categories (pathovars). Each pathovar is defined by a characteristic set of virulence factors that act in concert to determine the clinical, pathologic, and epidemiologic features of the disease they cause. However, it should also be noted that hybrid strains exist that possess features of multiple pathovars. The pathovars include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), adherent-invasive *E. coli* (AIEC), and possibly an additional group, diffusely adherent *E. coli* (DAEC) (Table 63.1 and Fig. 63.1). Currently, the epidemiology of many of these strains and their role in disease causation is not well defined in small animals, with most work having been done in humans and farm animal species. Many strains have been isolated from both nondiarrheic and diarrheic dogs and cats. An association between EPEC and EHEC (including H7:O157) infection and diarrhea in dogs has been detected.[2,3] In addition, AIEC strains have been well associated with granulomatous colitis in boxer dogs.[4,5]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

EPEC strains carry the *eae*A gene on their chromosome (*E. coli* attaching effacing), which is located in a "pathogenicity island" referred to as LEE (locus of enterocyte effacement). The *eae*A gene encodes a 94-kDa protein, intimin, which allows the organism to adhere intimately to intestinal epithelial cells. This leads to local effacement of the microvilli and formation of numerous, actin-rich pedestals on which the bacteria reside (Fig. 63.2).[6] The bacteria secrete their own receptor using a T3SS, the Tir receptor, and Tir-intimin interactions are involved in pedestal formation. The pedestals may help the bacteria to remain extracellular and thus escape immune recognition by the host. The resulting characteristic histopathologic lesions on enterocytes have been referred to as "attaching and effacing lesions." Although the exact mechanism by which EPEC produce diarrhea is not known, several factors may be involved including loss of microvillous surface area, loss of tight junction integrity, and altered electrolyte transport, with associated secretory watery diarrhea.[7] Other effector proteins inoculated by the T3SS interrupt the NK-κB pathway to inhibit the host immune response. By definition, the EPEC pathovar does not produce Shiga toxin, Shiga-like toxin, or verotoxins. EPEC serotypes that have been associated with diarrhea in humans have been identified in dogs and cats.[2,8-12] EPEC strains have been divided into "typical" EPEC strains (tEPEC) and "atypical" EPEC strains (aEPEC); typical strains possess a plasmid known as the *E. coli* adherence factor (EAF) plasmid, which encodes the bundle-forming pilus (bfp) operon.[13] Typical EPEC strains are well recognized as a cause of diarrhea in humans, and aEPEC are emerging as a cause of diarrhea in children in developed countries.[14] In one study of kittens from shelters, aEPEC were isolated from both diarrheic and non-diarrheic kittens.[11] However, kittens with diarrhea harbored a greater load of aEPEC than those without, and kittens infected with

TABLE 63.1 Pathogenic Strains of *Escherichia coli* That Cause Enterocolitis

Strain	Lesion	Signs	Virulence Characteristic
Enteropathogenic *E. coli* (EPEC)	Attaching and effacing lesions (effacement of microvilli and pedestal formation)	Watery diarrhea	*eaeA* gene (encodes intimin). Typical EPEC (tEPEC) produce type IV bundle-forming pili
Enterotoxigenic *E. coli* (ETEC)	Adhere using fimbria (colonization factors) and produce heat-labile (LT) and/or heat-stable (ST) toxins	Diarrhea	LT and ST production
Shiga-toxin–producing *E. coli* (STEC); includes enterohemorrhagic *E. coli* (EHEC)	Produce Shiga-like toxins (verotoxins) that cause vascular endothelial damage, also produce attaching and effacing lesions	Diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome	Shiga-like toxin production, EHEC also produce attaching and effacing lesions
Enteroinvasive *E. coli* (EIEC)	Actively invade colonic epithelial cells	Large bowel diarrhea	Plasmid-encoded invasion genes such as *ipaH*
Diffusely adherent *E. coli* (DAEC)	Uniform coverage of surface of epithelial cells rather than bricklike effect	Diarrhea in humans (children)	AIDA-1 (adhesin involved in diffuse adherence), *daaC* (fimbrial adhesin gene)
Adherent-invasive *E. coli* (AIEC)	Invade colonic epithelial cells using unknown virulence mechanisms	Granulomatous/histiocytic ulcerative colitis in dogs (especially boxers)	None known
Enteroaggregative *E. coli* (EAEC)	Adhere to intestinal epithelium via fimbriae and aggregate in bricklike fashion	Persistent watery diarrhea in humans	*aggR* gene; also produce toxins such as EAST-1

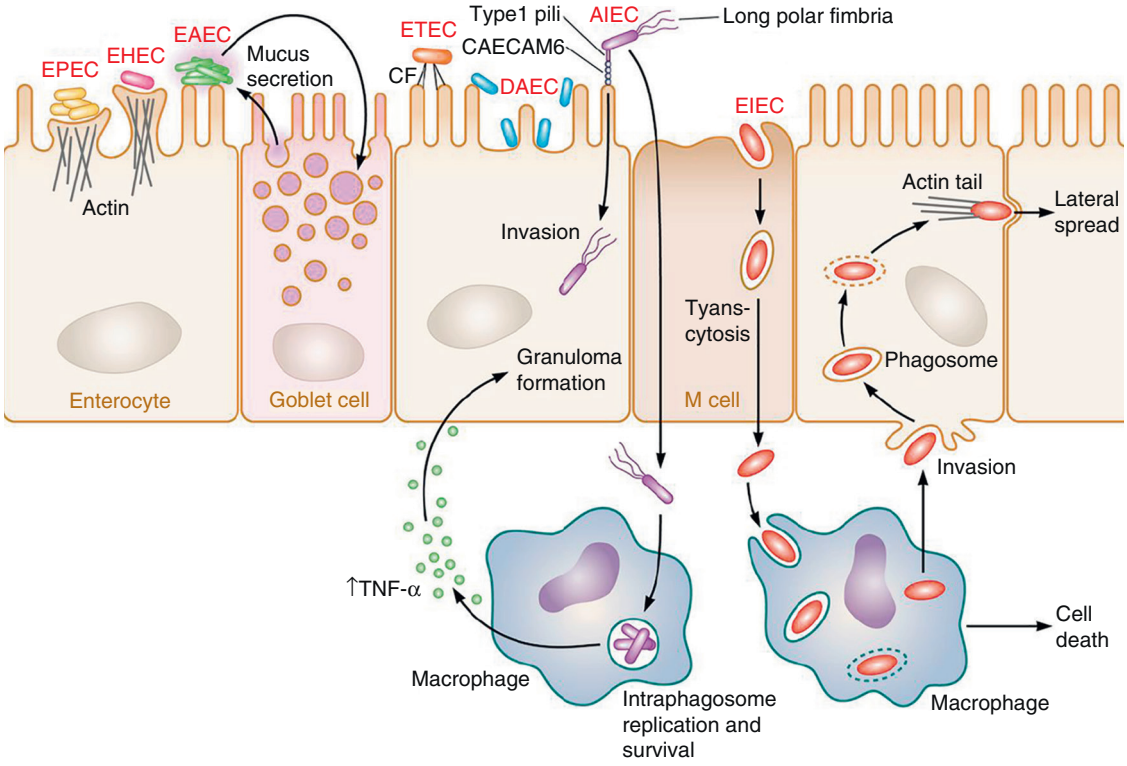

Fig. 63.1 Adherence patterns of enteric *Escherichia coli*. Pathogenic *E. coli* requires adherence to the host epithelium. Enteropathogenic *E. coli (EPEC) (yellow)* and enterohemorrhagic *E. coli (EHEC) (pink)* are extracellular pathogens that attach to the intestinal epithelium and efface microvilli, forming characteristic attaching and effacing lesions. Due to the presence of bundle-forming pili, EPEC is capable of forming microcolonies, resulting in a localized adherence (LA) pattern. Enterotoxigenic *E. coli (ETEC) (orange)* uses colonization factors *(CFs)* for attachment to host intestinal cells. Enteroaggregative *E. coli (EAEC) (green)* forms biofilms on the intestinal mucosa, and bacteria adhere to each other as well as to the cell surface to form an aggregative adherence pattern (AA) known as "stacked brick." Diffusely adherent *E. coli (DAEC) (blue)* is dispersed over the surfaces of intestinal cells, resulting in a diffuse adherence (DA) pattern. Adherent invasive *E. coli (AIEC) (purple)* colonizes the intestinal mucosa and is capable of invading epithelial cells as well as replicating within macrophages. AIEC uses type I pili to adhere to intestinal cells and long polar fimbriae that contribute to invasion. Enteroinvasive *E. coli (EIEC) (red)* are intracellular pathogens that penetrate the intestinal epithelium through M cells to gain access to the submucosa. EIEC escape submucosal macrophages by induction of macrophage cell death followed by basolateral invasion of colonocytes and lateral spread. (Modified from Croxen MA, Law RJ, Scholz R, et al. Recent advances in understanding enteric pathogenic *Escherichia coli*. *Clin Microbiol Rev*. 2013;26:822-880.)

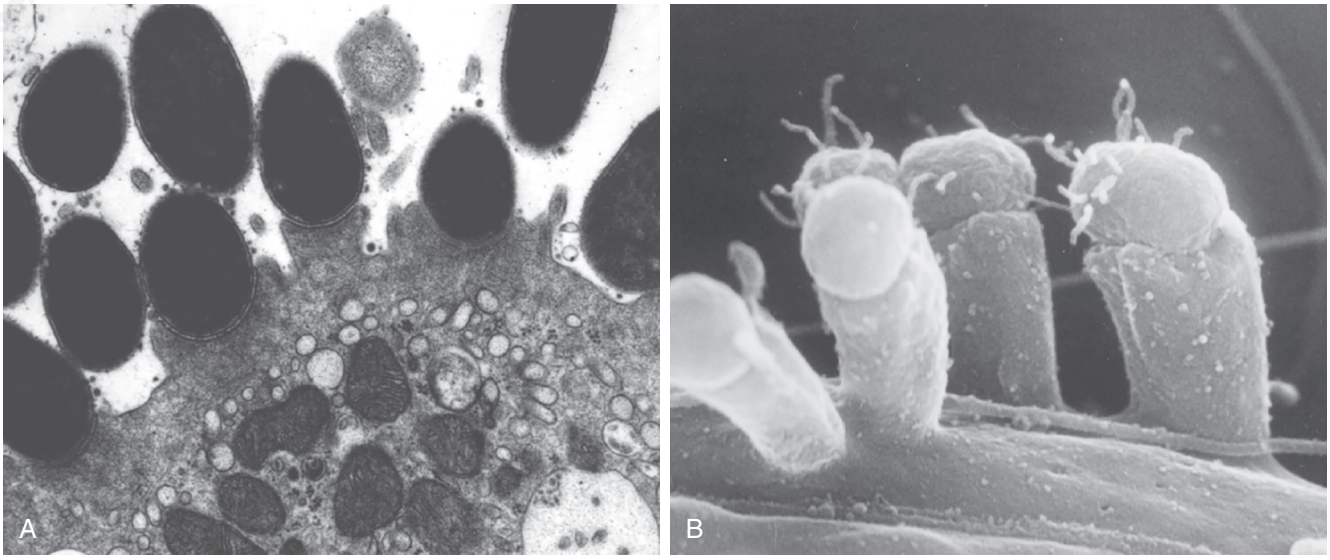

Fig. 63.2 Scanning and transmission electron micrographs showing actin pedestals induced by enteropathogenic and enterohemorrhagic *Escherichia coli* (EPEC and EHEC). (A) EPEC generates attaching and effacing (AE) lesions on the intestinal epithelium after infection of gnotobiotic piglets. Note the pedestal-like structures on host cells beneath attached bacteria. (From Campellone KG, Leong JM. Tails of two Tirs: actin pedestal formation by enteropathogenic *E. coli* and enterohemorrhagic *E. coli. Curr Opin Microbiol.* 2003;6(1):82-90.) (B) Actin pedestals that resemble AE lesions formed *in vivo* are also generated on cultured epithelial (HeLa) cells. (Courtesy of Knutton S. In: Knutton S, Rosenshine L, Pallen, MJ, et al. A novel EspA-associated surface organelle of enteropathogenic *Escherichia coli* involved in protein translocation into epithelial cells. *EMBO J.* 1998;17:2166-2176.)

aEPEC had more severe small intestinal and colonic lesions and were more likely to require subcutaneous fluid administration.[13]

ETEC are a major cause of diarrhea in human infants in developing countries and are the agents most frequently responsive for traveler's diarrhea. They are known for their ability to produce two broad types of virulence factors: adhesins (primarily fimbrial adhesins, also known as colonization factors) and enterotoxins. There are more than 20 different types of adhesins recognized. The enterotoxins are divided into high-molecular-weight labile toxins (LT), which are inactivated by heating at 60°C for 15 minutes; and low-molecular-weight stable toxins (ST), which are stable when exposed to a temperature of 100°C for 15 minutes.[15]

ETEC pathovars have been associated with up to 31% of cases of canine diarrhea, particularly in young dogs.[16-18] Most of the canine ETEC strains express ST enterotoxin, whereas ETEC strains that produce LT enterotoxin are rarely found. The bacteria adhere to the proximal small intestinal mucosa and produce plasmid-encoded LT and ST enterotoxins. LT is related to cholera toxin and is taken up by enterocytes. Once within intestinal epithelial cells, it activates adenylate cyclase, which leads to increased concentrations of intracellular cyclic AMP. This in turn activates protein kinase A, which activates the cystic fibrosis transmembrane conductance receptor (CFTR) with active secretion of chloride ions. Sodium and water follow, leading to diarrhea, hypovolemia, and metabolic acidosis. LT may also loosen intestinal epithelial cell tight junctions, further contributing to fluid loss.[19] It has been suggested that ST binds to the extracellular domain of guanylyl cyclase C, which leads to accumulation of intracellular cyclic guanosine monophosphate (GMP), activation of protein kinase C then the CFTR, and ultimately secretion of chloride, with resultant osmotic diarrhea. However, other mechanisms of action also likely operate, including inhibition of sodium uptake and increased intracellular calcium concentration, which opens a calcium-gated chloride channel and stimulates the arachidonic acid cascade.[20] Two different ST enterotoxins have been identified, STa and STb. STs also appear to be able to reduce the integrity of intestinal epithelial cell tight junctions.[19] ST-producing ETEC have been detected in young dogs with diarrhea.[16-18]

In addition to producing attaching and effacing lesions similar to those created by EPEC, STEC (Shiga-toxin–producing *E. coli*, which include EHEC) produce Shiga-like toxins (also known as verotoxins). They cause diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS) (e.g., *E. coli* strain O157:H7). The primary reservoir for these strains of *E. coli* are large herbivorous mammals, especially cattle, but the organisms can also persist for long periods of time in the environment. Shiga-like toxins are absorbed from the intestinal lumen and cause vascular endothelial damage, which may lead to a multiorgan thrombotic process in the absence of bacteremia. STEC can also produce other toxins that contribute to the pathogenesis of the disease. HUS in humans is characterized by renal failure, widespread microthrombotic damage to a variety of organs, hemolytic anemia, and sometimes diarrhea. Similar syndromes have been described in dogs, but an associated *E. coli* infection was not demonstrated.[21,22] In Argentina, STEC were detected in dogs that were contacts of humans with HUS.[23] HUS has been reproduced experimentally in dogs with a non-O157:H7 *E. coli* serotype.[24] Based on the similarity of renal lesions to those described in HUS, and the practice of feeding predominantly raw meat diets to greyhounds, it has been hypothesized that cutaneous and renal glomerular vasculopathy of greyhounds (also known as "Alabama rot" or "Greenetrack disease") may result from infection with STEC strains such as O157:H7.[25] A similar condition was described in a great Dane from Germany[26] and pet dogs in the United Kingdom.[27] Some dogs develop cutaneous lesions in the absence of renal failure; other dogs develop renal failure before the onset of cutaneous lesions.

EIEC actively invade colonic epithelial cells by way of a T3SS that allows them to escape macrophage phagocytosis and use the host

actin-filament machinery to spread from cell to cell.[14] This, together with the associated inflammatory response, leads to hemorrhagic, large bowel diarrhea. In human patients, the EIEC pathovar is uncommonly detected compared with EPEC and ETEC. AIEC, which lack the virulence genes that identify EIEC, have been associated with granulomatous colitis in boxer dogs and infrequently in French bulldogs, Border collies, and breeds in the mastiff cluster.[28] This infection typically affects young adult boxer dogs that show signs of severe colitis, with colonic thickening and ulceration, and weight loss that is often marked.[5,29] Genetic susceptibility in boxer dogs and French bulldogs is associated with mutations in a region that encodes the CD48/SLAM family of genes on chromosome 48; mutations in this region have also been associated with inflammatory bowel disease in humans.[28,30]

The EAEC pathovar is considered an emerging pathogen in human patients. It adheres to epithelial cells of the terminal ileum and colon using fimbriae in a characteristic "stacked brick" pattern. Expression of these fimbriae is encoded by a plasmid gene known as *aggR*. Bacterial aggregation results in deposition of a thick biofilm on the gut mucosa, and this is followed by malabsorpsion and a subsequent inflammatory response, which leads to development of persistent watery diarrhea. Occasionally, EAEC strains also produce toxins, such as enteroaggregative heat-stable toxin-1 (EAST-1), which somewhat resembles the stable toxin of ETEC and can increase intracellular cyclic GMP.[31] There is also a diffusely adherent pathotype (DAEC) that uses a variety of adhesins to bind in a diffuse manner to enterocytes, interfering with microvillus function and stimulating an inflammatory response through activation of TLR5.[14] The role of EAEC and DAEC in dogs and cats requires further investigation.

Physical Examination Findings

Physical examination may reveal dehydration and abdominal pain in puppies or kittens with *E. coli* diarrhea. Dogs with HUS have had cutaneous erythema and well-demarcated, multifocal cutaneous ulcers of the limbs. Fever and peripheral edema have also been described. Dogs with granulomatous colitis may have poor body condition. A thickened and irregular rectal wall may be detected on rectal palpation, and the feces may contain fresh blood and mucus.

DIAGNOSIS

Diagnosis of intestinal *E. coli* infections, with the exception of granulomatous colitis of boxer dogs, is difficult or impossible with currently available diagnostic assays, because of the fact that healthy dogs and cats shed *E. coli*, and it is a combination of bacterial virulence factors and host immune competence that contributes to the development of clinical signs. This section therefore focuses primarily on the more specific clinical syndromes caused by EHEC and AIEC.

Laboratory Abnormalities

Complete Blood Count

CBC changes in dogs with *E. coli* diarrhea are generally mild and nonspecific. Leukocytosis may be present. Dogs infected with EHEC may be thrombocytopenic and have evidence of microangiopathic hemolysis. Microcytic anemia may be present in dogs with granulomatous colitis.

Serum Chemistry Panel and Urinalysis

Laboratory abnormalities in dogs with *E. coli* diarrhea could include electrolyte abnormalities and prerenal azotemia in dogs with severe diarrhea. Dogs infected with EHEC have had variable evidence of hypoalbuminemia, prerenal azotemia, increased activities of ALT and creatine kinase, hematuria, proteinuria, and isosthenuria. Boxer dogs with granulomatous colitis are commonly hypoalbuminemic.

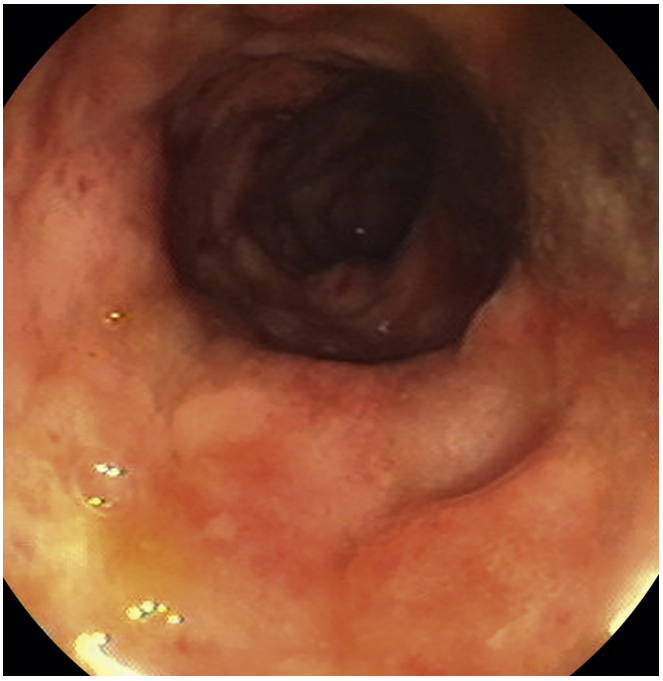

Fig. 63.3 Ulcerated and erythematous colon of a 2-year-old intact male boxer dog with granulomatous colitis as viewed during colonoscopy. The dog had a 7-month history of marked weight loss and severe diarrhea, with increased frequency of defecation and hematochezia.

Diagnostic Imaging

Findings on abdominal radiography and abdominal ultrasound are typically unremarkable or show fluid-filled intestinal loops. Abdominal ultrasound examination in dogs with granulomatous colitis often reveals mild or moderate mesenteric or sublumbar lymphadenomegaly, and the colonic wall can appear thickened.

Endoscopic Findings

Proctoscopy or colonoscopy is usually performed in order to obtain colonic biopsies from boxer dogs suspected to have granulomatous colitis. Proctoscopy requires less fastidious colonic preparation compared to colonoscopy, can be performed under heavy sedation, and is more cost-effective compared to colonoscopy. Most dogs with granulomatous colitis have involvement of the descending colon, underscoring the diagnostic utility of proctoscopy. Common changes in appearance to the colonic wall include erythema, irregularity, and ulceration of the rectal wall (Fig. 63.3).

Microbiologic Testing

Bacterial Isolation and Typing

Escherichia coli is commonly isolated on routine bacteriologic media from feces of both healthy and diarrheic dogs. A differential medium such as MacConkey agar is often used. Apart from dogs with granulomatous colitis, attempts to specifically identify *E. coli* as a cause of diarrhea are generally performed only by reference or public health laboratories when an outbreak has occurred, or for research purposes. *Escherichia coli* can be isolated from colonic biopsies of dogs with granulomatous colitis, which permits subsequent antimicrobial susceptibility testing.[32] Serologic identification, which is performed using specific O and H antisera, can be costly and is generally performed by large public health laboratories in epidemiologic investigations.

Virulence Assays

Immunoassays are available for detection of Shiga toxin, ST, and LT. A Vero cell cytotoxicity assay has been used to detect verocytotoxin. Identification of EPEC and AIEC often relies on assays that assess adherence in tissue culture. In research settings, molecular diagnostic techniques using DNA probes or PCR assays (including MLST) have revolutionized the ability to detect and differentiate between pathogenic and nonpathogenic strains of *E. coli*. EPEC characteristically possess the *eaeA* gene. Detection of genes that encode LT, ST, and Shiga-like toxin allows identification of ETEC and STEC. EIEC are identified based on the presence of invasion-associated genes such as *ipaH*.[31]

Pathologic Findings

The most significant pathologic findings in intestinal *E. coli* infections occur with EHEC and AIEC infections.

EHEC Infections

Cutaneous ulcerative lesions in dogs with suspected HUS are characterized histopathologically by fibrinoid vascular necrosis, with dermal thrombosis and leukocytoclastic vasculitis. Grossly, the kidneys may be swollen and have cortical petechiae. Histopathology reveals hyaline fibrinous thrombi in glomerular capillaries and afferent arterioles, glomerular and multifocal tubular necrosis, and leukocytoclastic vasculitis with fibrinoid necrosis.

AIEC Infections

Histopathologic lesions in dogs with granulomatous colitis are pathognomonic and include neutrophilic inflammation, epithelial ulceration, crypt hyperplasia and distortion, decreased goblet cell numbers, and abundant macrophages that stain positive with PAS stain (Fig. 63.4). The presence of *E. coli* within macrophages can be confirmed using fluorescence in situ hybridization, which has been recommended as part of the diagnostic workup of dogs suspected to have histiocytic ulcerative colitis.[6,30]

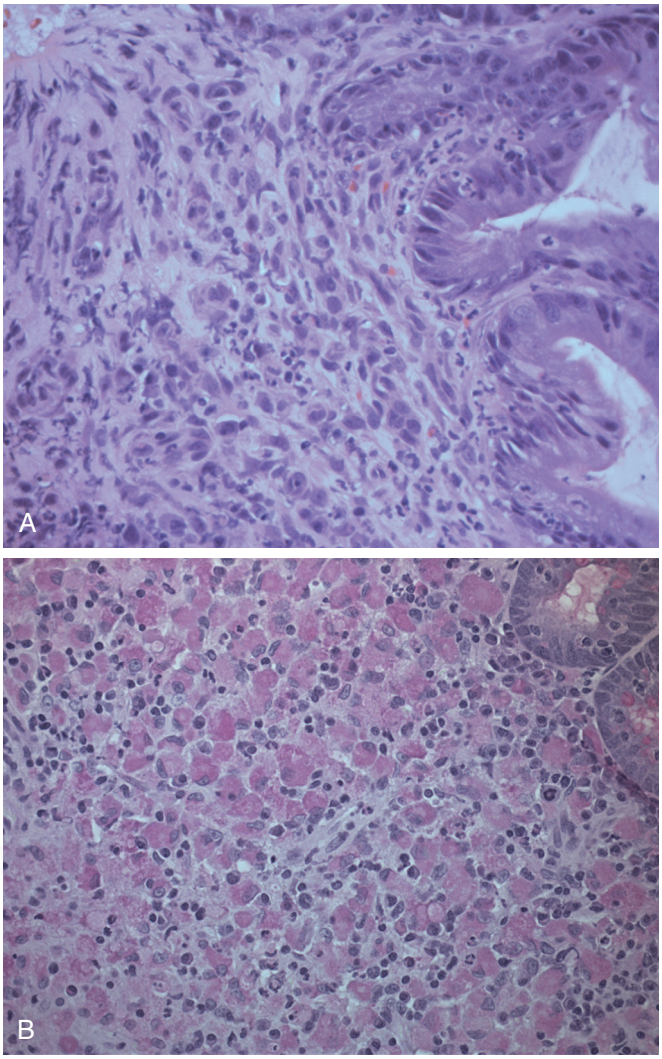

Fig. 63.4 (A) Histopathology showing severe, chronic, histiocytic colitis in a 2-year-old male boxer dog. The inflammatory infiltrate is comprised of large, epithelioid macrophages and lesser numbers of neutrophils, plasma cells, and lymphocytes. (B) Histiocytes in the lamina propria contain PAS-positive material.

TREATMENT AND PROGNOSIS

Dogs and cats with severe diarrhea due to pathogenic *E. coli* may require intravenous fluid therapy. With the exception of granulomatous colitis, antimicrobial therapy is generally not indicated unless there is fever and evidence of sepsis (see Chapter 125). Dogs with granulomatous colitis can show dramatic responses to treatment with enrofloxacin (10 mg/kg PO q24h), and a minimum treatment duration of 8 weeks is recommended.[30] Administration of fluoroquinolones is usually associated with rapid resolution of clinical signs and resolves cellular infiltration characteristic of this disorder on colonic biopsy. Because multidrug resistance has been documented in some isolates from dogs with granulomatous colitis, attempts to isolate *E. coli* from colonic biopsies before treatment are recommended so that antimicrobial susceptibility testing can be performed.[28,32] Antimicrobials that penetrate intracellularly, such as fluoroquinolones, chloramphenicol, rifampin, or trimethoprim-sulfonamides, should be chosen for treatment based on the results of susceptibility testing. For some isolates, carbapenems were the only drugs that penetrate intracellularly for which susceptibility was identified.[28]

IMMUNITY AND VACCINATION

Currently, no vaccines for *E. coli* infections are available for dogs and cats. Vaccines for EPEC, ETEC, and EHEC have been investigated for animals and humans on a research basis,[33-35] including a transdermal LT vaccine for prevention of travelers' diarrhea, although this was not shown to be effective in Phase III clinical trials.[36]

PUBLIC HEALTH ASPECTS

Pathogenic *E. coli* that cause diarrhea have been particularly prevalent in children in developing countries and in travelers to developing countries. STEC can be acquired following ingestion of undercooked ground hamburger meat, vegetables, and nonchlorinated drinking and swimming water that have been contaminated with fecal material, and as few as 100 organisms are required for infection. Infection has also been reported following contact with animals housed in petting zoos.[37] In a 2021 study from Switzerland, STEC were identified in 41% of commercially available raw meat-based diets for pets; of 28 strains identified, 29% carried genes linked to STEC of high pathogenic potential.[38] HUS is reported as the most common cause of acute renal failure in children. Clinical signs in humans consist of GI signs, often with profuse, bloody diarrhea, abdominal cramps, pallor, weakness, and oliguria or anuria.[39] Dogs have been suggested as a source of human infection with EPEC and EHEC.[8,10,11,40,41]

The possibility of zoonotic transmission of multidrug-resistant *E. coli* that are shed by dogs and cats is an emerging concern. A variety

of resistance mechanisms have been identified in *E. coli* isolates from dogs and cats, which include production of efflux pumps and extended-spectrum and AmpC β-lactamase enzymes. There is some evidence that *E. coli* strains shed by healthy companion animals can be shared with humans that reside in the same household,[9,42-44] but more studies are required to determine the extent to which this occurs and its zoonotic significance. Transfer of plasmids that carry resistance genes from canine or feline *E. coli* isolates and those of humans also has the potential to occur.

For hospitalized animals, staff should use contact precautions for any dog or cat suspected to have enteropathogenic illness, including the use of warning signs, gloves and gowns, hand washing, and cleaning with bleach-based or accelerated hydrogen peroxide–based disinfectants. Endoscopes should be disinfected thoroughly between uses. Veterinarians should discuss the zoonotic implications of enteropathogenic bacterial infection with pet owners, especially in relation to the presence of young children or otherwise immunocompromised individuals in the household.

CASE EXAMPLE

Signalment

"Caesar," a 2-year-old male boxer dog from Tulare, CA (Fig. 63.5).

History

Caesar was evaluated for chronic diarrhea, which had been present since he was 6 months of age. His feces were loose and contained a small amount of frank blood. He strained to defecate many times a day, and the owner sometimes noticed mucus in the diarrhea. Every few months, Caesar's appetite and energy level declined and the diarrhea became more severe. His signs transiently improved after treatment with subcutaneous fluids and metronidazole. The owners had tried a variety of different diets such as fiber-supplemented diets and elimination diets that contain novel, single protein sources, but these strategies did not help. His current diet was a digestible commercial diet, and his appetite was good. He was up to date on vaccinations, including those for rabies, canine distemper, canine parvovirus, canine adenovirus, and *Bordetella bronchiseptica*. He was primarily an indoor dog with access to a suburban backyard.

Fig. 63.5 "Caesar," a 2-year-old male boxer dog from Tulare, CA, that was diagnosed with granulomatous colitis following colonoscopy and biopsy.

Physical Examination

Body weight: 23.4 kg

General: Bright, alert, and responsive. Ambulatory on all four limbs. T = 102.5°F (39.2°C), HR = 102 beats/min, panting, mucous membranes pink, CRT = 1 s.

Integument, eyes, ears, nose, and throat: No significant abnormalities were noted. A moderate amount of dental calculus was present.

Musculoskeletal: Body condition score was 3/9 with symmetrical muscling.

All other systems: On rectal examination, the walls of the rectum were smooth. There was fresh blood on the glove following palpation. No other clinically significant abnormalities were noted.

Laboratory Findings

CBC: HCT 54.4% (40%–55%), MCV 76.8 fL (65–75 fL), MCHC 32.9 g/dL (33–36 g/dL), WBC 12,590 cells/μL (6000-13,000 cells/μL), neutrophils 9631 cells/μL (3000–10,500 cells/μL), lymphocytes 1674 cells/μL (1000–4000 cells/μL), monocytes 781 cells/μL (150–1200 cells/μL). Platelets were clumped but appeared adequate in number.

Serum chemistry profile: Sodium 155 mmol/L (145–154 mmol/L), potassium 4.2 mmol/L (3.6–5.3 mmol/L), chloride 116 mmol/L (108–118 mmol/L), bicarbonate 23 mmol/L (16–26 mmol/L), phosphorus 4.4 mg/dL (3.0–6.2 mg/dL), calcium 10.4 mg/dL (9.7–11.5 mg/dL), BUN 18 mg/dL (5–21 mg/dL), creatinine 1.1 mg/dL (0.3–1.2 mg/dL), glucose 105 mg/dL (64–123 mg/dL), total protein 6.5 g/dL (5.4–7.6 g/dL), albumin 2.9 g/dL (3.0–4.4 g/dL), globulin 3.6 g/dL (1.8–3.9 g/dL), ALT 68 U/L (19–67 U/L), AST 46 U/L (19–42 U/L), ALP 86 U/L (21–170 U/L), GGT 5 U/L (0–6 U/L), cholesterol 200 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Fecal Examination

Centrifugal fecal flotation: Negative for parasites.

Colonoscopy: The entire mucosal surface of the colon was erythematous and irregular, with multifocal areas of mucosal ulceration (see Fig. 63.3).

Histopathology of colonic biopsies: Severe, chronic, histiocytic, and ulcerative colitis. Histiocytes in the lamina propria contained PAS-positive material (see Fig. 63.4).

Diagnosis

Granulomatous colitis of boxer dogs.

Treatment

Enrofloxacin, 6 mg/kg PO q24h for 8 weeks and a commercial low-residue dry and canned dog food. This was associated with clinical improvement within a week after starting the medication. At a recheck 4 weeks later, the owner reported that Caesar's feces were completely normal in consistency and frequency.

Comments

In this dog, the diagnosis of granulomatous colitis was made solely based on histopathologic findings. Culture of a biopsy specimen could also have been performed and is now recommended given the emergence of fluoroquinolone-resistant AIEC strains of *E. coli*.

Enteric Clostridial Infections

Jane E. Sykes, Stanley L. Marks

KEY POINTS

- First Described: 1978 (causative role of *Clostridioides difficile* in pseudomembranous colitis) (George et al., 1978);[1] 1892 (*Clostridium perfringens*, by Nuttall and Welch);[2] evidence for a role of *C. perfringens* in foodborne illness was gathered over 50 years later.[3]
- Cause: *Clostridioides difficile* (previously *Clostridium difficile*) and *Clostridium perfringens.*
- Affected Hosts: Humans and a variety of other animals.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Fecal-oral; disease may result from toxin production by bacteria resident in the GI tract.
- Major Clinical Signs: Lethargy, anorexia, diarrhea, occasionally fever.
- Differential Diagnoses: Differential diagnoses for hemorrhagic gastroenteritis include salmon poisoning disease, CDV infection, canine and feline parvovirus infection, campylobacteriosis, salmonellosis, giardiasis, tritrichomoniasis (cats), cryptosporidiosis, whipworms, leptospirosis, dietary indiscretion, GI foreign body, pancreatitis, inflammatory bowel disease, lymphoma, hypoadrenocorticism, toxins (including drugs).
- Human Health Significance: Dogs and cats have the potential to be a source of human infection with *C. perfringens* and *C. difficile*, some of which may be resistant to antimicrobial drugs. Transmission of *C. difficile* from animals to humans has not been documented. The vast majority of human infections are acquired through other routes.

ETIOLOGY AND EPIDEMIOLOGY

Clostridioides difficile (formerly *Clostridium difficile*) and *Clostridium perfringens* are gram-positive, spore-forming, obligately anaerobic rods that are capable of toxin production. Clostridial spores are spherical to oval and distend the bacterial cells when they form within them (Fig. 64.1). They are very resistant to disinfection and can persist in the environment, including that within hospitals, for years. Clostridial species are found in soil and the intestinal tracts of a variety of different animal species. Despite these similarities, many differences exist between *C. difficile* and *C. perfringens* that relate to epidemiology, interpretation of diagnostic test results and treatment.

Clostridioides difficile is the most common cause of hospital and antimicrobial-associated diarrhea in hospitalized humans and can cause nosocomial diarrhea in dogs and cats in veterinary hospitals.[4,5] In one study, living with an immunocompromised human was a risk factor for *C. difficile* infection in dogs, but strains present in dogs were different to those found in the household environment.[6] Dogs visiting human health care facilities have also been shown to be at risk of acquiring *C. difficile* infections.[7] The recent emergence of "hypervirulent" *C. difficile* strains in people has resulted in the increased incidence of disease, increased mortality rates, increased relapse rates and recognition of community-associated diseases.[8,9] A similar change has not been observed in animals; however, a hypervirulent strain (North American pulsotype 1 or NAP1) was identified in a dog.[10] Strains with ribotypes that match those found in humans were identified in the feces of dogs visiting dog parks in Denmark,[11] fecal specimens from dogs in Germany,[12,13] Spain,[14,15] Italy,[16] Texas, USA,[17] and in dogs and cats from Brazil[18,19] and China.[20] Multiple studies have identified antimicrobial-resistant strains of *C. difficile* in the feces of dogs and cats, including strains resistant to clindamycin or metronidazole .[14-16,18,20,21] While pets have been implicated as a reservoir for human infection with toxigenic strains,[22-24] the extent to which dogs and cats play a role in human infection remains unclear.

Clostridium perfringens is especially widespread in soil and dust, and is now classified into 7 toxinotypes, A to G, based on the possession of major toxin genes that permit production of the toxins CPA (alpha), CPB (beta), ETX (epsilon), ITX (iota), CPE (enterotoxin), and NetB (necrotizing enteritis B-like toxin) (Table 64.1).[25] All *C. perfringens* strains produce CPA, which is encoded by a gene located in a stable region on the chromosome.[26] The other toxin genes are located on plasmids. The majority of clostridial foodborne illness in humans is caused by Type F strains, which produce CPE but not CPB, ETX or ITX. Strains that produce CPB, ETX, ITX, and NetB have been associated with diarrhea in food-producing animals.[27]

In dogs, *C. perfringens* infection has been associated with nosocomial diarrhea,[28] hemorrhagic enteritis,[29,30] and acute and chronic large bowel diarrhea. *Clostridium perfringens*–associated diarrhea can manifest with small intestinal, large intestinal, or diffuse clinical signs.[29-31] However, the importance of *C. perfringens* and *C. difficile* as causes of diarrhea in dogs and cats has been controversial, because these organisms have been isolated from both diarrheic and healthy animals. For example, *C. perfringens* can be isolated using culture in up to 100% of both diarrheic and non-diarrheic dogs.[31-33] The prevalence of *C. perfringens* colonization in healthy cats appears lower than that in the dog, ranging from 20% to 63%. Toxigenic strains can be found in both healthy and diarrheic dogs, although most studies have shown a correlation between detection of certain clostridial toxins (CPE, *C. difficile* toxin A, NetF) and diarrhea.[32,34]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Both *C. difficile* and *C. perfringens* cause diarrhea as a result of toxin production. The diarrhea can be mild and self-limiting or severe, acute, and hemorrhagic, with life-threatening consequences relating to dehydration and hypovolemic shock. Decreased appetite, vomiting, fever, and abdominal pain have also been reported in cats in association with clostridial

infection, although the prevalence of infection is far lower in cats when compared to dogs.[35] Vomiting may also occur in dogs. Although clostridial diarrhea is often described as a large bowel-type diarrhea, clinical manifestations of both small and large bowel diarrhea have been described.

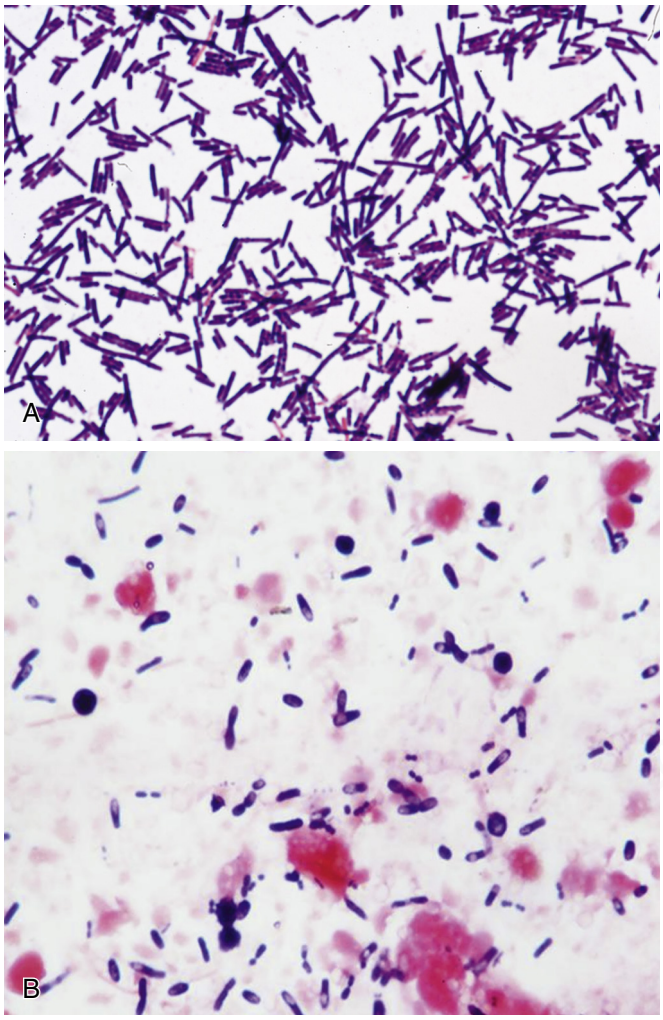

Fig. 64.1 (A) Gram stain of a pure culture of *Clostridium perfringens*. (From Onderdonk AB, Garrett WS. Diseases caused by *Clostridium*. In: Bennett JE, Dolin R, Blaser MJ (eds). *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 9th ed. Philadelphia, PA: Elsevier; 2020:2960-2968. (B) Fecal smear from a dog with diarrhea showing spore-distended clostridial rods, leading to a characteristic "safety pin" and "tennis racquet" appearance.

Mechanism of Toxin Action

Clostridioides difficile *Toxins.* *Clostridioides difficile* can produce up to five toxins. The best studied are toxin A (TcdA), toxin B (TcdB), and *C. difficile* binary toxin (CDT, an ADP-ribosyltransferase which is made up of two components, hence the name binary). Studies suggest that strains that produce CDT in addition to TcdA and TcdB are more likely to be associated with severe disease in humans.[36] In contrast to humans, a history of antibiotic use does not always seem to be necessary for disease in dogs and cats. However, in one study, administration of antimicrobials prior to admission and the use of immunosuppressive drugs during hospitalization were risk factors for nosocomial colonization in both dogs and cats.[4] In another study of 136 fecal specimens from dogs in Texas, rates of colonization with toxigenic *C. difficile* increased significantly during antimicrobial therapy (to 33%) then declined to baseline (11%) when treatment was stopped.[17] Toxins A and B are large toxins that bind to small GTP-binding proteins (Rho, Rac, and Cdc42), which normally regulate intracellular actin dynamics. The result is a disruption of the cell cytoskeleton, with subsequent rounding and death of intestinal epithelial cells, and impairment of tight junctions, with resulting fluid accumulation and extensive damage, primarily to the large intestine. The two toxins also cause release of inflammatory cytokines from mast cells, macrophages, and epithelial cells.[37] The binary toxin CDT is composed of CDTb, which binds to a receptor on intestinal epithelial cells, and CDTa, which is then internalized and catalyzes the ADP-ribosylation of actin, resulting in its depolymerization and destruction of the cell cytoskeleton.[38]

Clostridium perfringens *toxins.* In addition to the toxins used for classification of toxinotypes, *C. perfringens* is capable of producing more than 20 other toxins or enzymes that can contribute to disease severity, such as perfringolysin O (PFO) and the pore-forming toxin NetF. CPE is a key toxin because it has been clearly associated with foodborne disease in humans.[27] It also has consistently been found in significantly more dogs with diarrhea than healthy dogs.[31-33] The gene for CPE (*cpe*) can be found on the chromosome or on plasmids, and expression occurs during sporulation. CPE causes pore formation and disrupts epithelial tight junctions by binding primarily to claudin, with increased paracellular permeability; large quantities of toxin can cause cell death.[27,39] CPE was detected with ELISA in 19.6% of 46 diarrheic dogs versus 2.1% of 48 healthy dogs, and in 8.3% of 48 diarrheic cats versus 0% of 39 healthy cats.[31,32,40] In another study, CPE was detected at a similar rate in 219 diarrheic and 54 non-diarrheic cats (4.1 versus 1.6%).[41] Strains of *C. perfringens* that possessed the *cpe* gene were identified in 32 (34%) of 95 healthy dogs and 50 (48%) of 104 dogs with GI disease.[33] In contrast, CPE was detected using ELISA in 1 (1%) of the healthy dogs and 17 (16%) of the diseased

TABLE 64.1 *Clostridium perfringens* Toxinotypes

Toxinotype	Alpha (CPA) (*cpa*)	Beta (CPB) (*cpb*)	Epsilon (ETX) (*etx*)	IOTA (ITX) (*iap* and *ibp*)[b]	Enterotoxin (*cpe*)	NetB (*netB*)

F[a]	+	–	–	–	+	–
G[a]	+	–	–	–	–	+

[a]Type F and G strains were classified as Type A before reclassification in 2018.[25]
[b]Binary toxin encoded by two genes, similar to that of *Clostridium botulinum*.

dogs. It should be emphasized that the commercially available ELISA test for detection of fecal CPE is a human-based immunoassay that has not yet been validated for use in the dog or cat. In addition, the mere detection of CPE using ELISA does not infer that the amount of toxin is sufficient to cause clinical signs. It is plausible that clinical signs only occur when a certain quantity of CPE is present, or only when it is produced in association with other virulence factors. CPE-associated *C. perfringens* diarrhea in dogs and cats is thought to occur subsequent to proliferation and sporulation of resident clostridial organisms in the intestinal lumen following an alteration in local intestinal conditions, with production of CPE. Decreased peristalsis, the effects of antimicrobial drugs on the resident intestinal microbiota, diet changes, or coinfections with other intestinal pathogens are factors that have the potential to lead to sporulation.

More recently, the *C. perfringens* toxin NetF has been recognized in association with disease in dogs and horses, specifically acute hemorrhagic diarrhea syndrome (AHDS) in dogs and foal necrotizing enterocolitis (see Chapter 125).[42-44] NetF can be found on a large plasmid together with NetE, another pore-forming toxin gene. NetF has sequence homology to the leukocidin/hemolysin family of pore-forming toxins which are able to permeabilize cell membranes through the formation of barrel-shaped pores.[45]

Canine AHDS, previously known as hemorrhagic gastroenteritis (HGE), is an acute syndrome of hemorrhagic diarrhea with dehydration and hemoconcentration that occurs worldwide.[46,47] The name was changed to AHDS because lesions are typically limited to the small and large intestines. However, vomiting precedes diarrhea in many dogs, and may contain blood.[46] Although any breed can be affected, in one large study, dogs with AHDS were smaller (median body weight 9.8 kg) and younger (median age 5 years) than dogs in the background hospital population, and Yorkshire terriers, miniature schnauzers, Maltese terriers and miniature pinschers were predisposed.[46] *Clostridium perfringens* can be detected in large numbers in association with necrotic small and large intestinal mucosal lesions of dogs with AHDS using immunohistochemistry.[47,48] Quantitative PCR also showed a significant increase in *C. perfringens* DNA copy number in dogs with AHDS when compared with healthy dogs and dogs with inflammatory bowel disease (IBD).[49] CPE was detected in 8/12 dogs (67%) with AHDS in one study.[16] A study from Germany evaluated the prevalence of clostridial toxin genes (using PCR) and toxin (using ELISA) in stool specimens from 54 dogs with idiopathic AHDS and 23 healthy control dogs. The toxin genes *tcdB* (*C. difficile*) and *cpe* were detected in 10/54 and 35/54 fecal specimens from dogs with AHDS and 3/23 and 9/23 healthy dogs, respectively. CDT A/B and CPE were detected in 2/54 and 13/54 fecal specimens from dogs with AHDS and none of the healthy dogs.[50] NetF appears to play a more important role than CPE in AHDS based on studies to date, but it is possible that other toxins may also be involved. In one study of dogs with AHDS associated with intralesional *C. perfringens* organisms on histopathology, the *netF* gene was detected in five of five *C. perfringens* isolates from duodenal biopsies of 10 dogs with AHDS, whereas *C. perfringens* was not detected in any duodenal biopsies from nine healthy control dogs.[48] In another study, *netF* was detected in 26 (48%) of 54 dogs with AHDS, 0 of 54 dogs with canine parvoviral enteritis, and 8 (12%) of 66 healthy dogs.[34] Studies based on detection of NetF itself (or NetF expression) are required, which has the potential to correlate to a greater extent with disease, as is the case with CPE. Pathogens other than *C. perfringens* may also play a role in some AHDS cases. For example, microbiome analysis of dogs with AHDS revealed not only a high proportion of *C. perfringens*, but also *Sutterella* spp.[49] *Sutterella* spp. play an uncertain role in GI disorders in humans, but have been implicated in IBD and treatment-resistant ulcerative colitis; some strains have the ability to degrade IgA.[51] However, their role as human commensals with potentially beneficial immunoregulatory properties has also been demonstrated.[52]

Physical Examination Findings

Physical examination findings in dogs and cats with severe clostridial diarrhea may include dehydration, fever, and abdominal pain, with or without signs of hypovolemic shock. Rectal examination in dogs may reveal loose or watery stools, sometimes containing fresh blood and mucus.

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count and Chemistry Panel

Basic laboratory testing in dogs and cats with clostridial diarrhea usually reveals mild and nonspecific changes. A neutrophilic leukocytosis with a left shift and toxic changes may be present in dogs and cats with acute clostridial gastroenteritis or AHDS. Dogs with AHDS may also have evidence of polycythemia despite a normal or decreased plasma protein concentration. The increase in hematocrit can be seen secondary to splenic contraction or dehydration, but plasma protein concentration decreases secondary to hypovolemic or hemorrhagic shock, with rapid leakage of albumin into the interstitial space. Electrolyte changes such as hypochloremia, hypokalemia, and metabolic acidosis may also be present.[46]

Diagnostic Imaging

Findings on plain abdominal radiography and abdominal ultrasound are typically unremarkable or show fluid-filled intestinal loops. Mild thickening and corrugation of the wall of the small intestine or colon may be detected using abdominal ultrasound (Fig. 64.2). Endoscopic findings in dogs with AHDS include mucosal erythema, friability, erosions, and hemorrhage in the colon and especially the duodenum.[47] However, endoscopy is rarely required because of the acute nature of the disease.

Microbiologic Tests (Table 64.2)

Cytologic Diagnosis

Spore-forming rods may be identified on microscopic examination of fecal smears that have been stained with Wright stains (see Fig. 64.1). These have been described as having the appearance of tennis racquets or safety pins. However, there is no association between fecal endospore counts and the presence of diarrhea, or between spore counts and the detection of CPE in fecal specimens. Detection of fecal endospores is thus an unreliable test for diagnosis of *C. perfringens* or *C. difficile* diarrhea in dogs and cats, and should not be used as a stand-alone test to make clinical inferences in diarrheic dogs and cats.[32,53]

Bacterial Isolation and Identification

Both *C. difficile* and *C. perfringens* can be isolated from the feces of both normal and diarrheic dogs and cats using strict anaerobic conditions for incubation. *Clostridium perfringens* is more tolerant of oxygen than *C. difficile*, and therefore may be easier to isolate (hence the name *difficile*, because of its difficulty to isolate in the laboratory).

Clostridioides difficile can be isolated from 0% to 58% of diarrheic and healthy dogs.[54] When fecal culture for *C. difficile* is performed on a viable fecal specimen by a reputable laboratory, a negative result strongly suggests that *C. difficile* is not present. In contrast, a positive culture does not differentiate between toxigenic and non-toxigenic strains, and further testing for the presence of toxin is warranted (see below).

Because of the high carriage rate of *C. perfringens* in both healthy and diarrheic dogs (> 70% in both groups), routine isolation of *C. perfringens* is not recommended for diagnosis, unless genetic typing of isolates is being performed, or epidemiologic studies are undertaken in outbreak situations. Use of culture to quantify organism burdens is recommended

in conjunction with toxin gene detection to aid diagnosis of *C. perfringens* diarrhea in humans, with organism counts of >10^6 CFU per gram of feces together with toxin gene detection supportive of the diagnosis.[55,56] Spore counts involve treating stool with heat or alcohol before culturing it in an anaerobic environment and counting colonies. Such counts alone can still be detected in humans that have no signs of illness, and the method, when used without assessment of toxin production, has not proven useful for diagnosis of *C. perfringens* diarrhea in dogs.[31]

ELISA for *C. difficile* Antigen

Clostridioides difficile antigen ELISA can be useful as a screening test because it is easy to perform, rapid (< 1 hour to perform), and highly sensitive. The antigen test detects "common antigen" (glutamate dehydrogenase; GDH) that is predominantly present in toxigenic and non-toxigenic *C. difficile* strains and a few uncommon clostridial species. Although this test has the same limitations as culture in terms of detection of non-toxigenic strains and colonization, it is significantly more rapid and more practical to perform than culture, and given its sensitivity, a negative test allows the clinician to rapidly rule out *C. difficile* as a potential cause of diarrhea.

Assays for Toxin Production

Several commercial ELISAs are available for detection of *C. difficile* toxin A and toxin B in feces; however, none of these ELISAs have been validated for use in dogs and cats. Fecal swabs generally do not contain a sufficient quantity of stool for these assays. Even when performed on larger volumes of stool, the sensitivities and specificities of these assays may vary considerably. Importantly, a positive result does not prove that a clostridial infection is the cause of a dog or cat's diarrhea. Panels should include assays for both *C. difficile* toxin A and toxin B, because TcdA-negative, TcdB-positive strains have been documented in dogs, and production of both toxins is not needed for disease causation.[57] In humans, diagnosis is now accomplished by screening for the common antigen, and if positive, testing for toxin A and toxin B antigens. If those tests are negative, PCR assays can be done to detect toxin genes *tcdA* and *tcdB*. If the PCR assays are positive, a presumptive diagnosis of *C. difficile* infection is made. However, concerns have been raised that diagnosis on the basis of a positive PCR result does not imply toxin is being produced, and so other approaches that require toxin detection in conjunction with PCR have been recommended.[56]

Immunodetection for *C. perfringens* fecal enterotoxin is the most widely used diagnostic tool for *C. perfringens* in both humans and animals. Two commercially available immunoassays are currently used in veterinary diagnostic laboratories: a reverse passive latex agglutination assay (RPLA) and an ELISA. The assays have not been validated in animals to date. The RPLA has had poorer specificity when compared to several different ELISA methods, so ELISA assays are preferred.

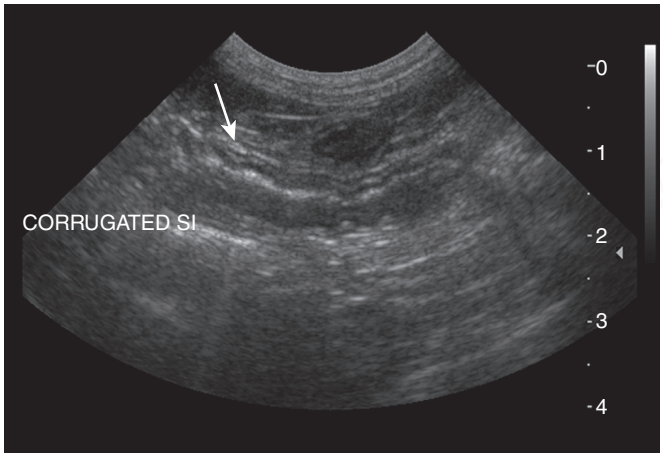

Fig. 64.2 Abdominal ultrasound image showing thickening and corrugation of the small intestinal wall (*arrow*) of a 2-year-old intact male Chihuahua with *Clostridium perfringens*–associated vomiting, hematemesis, diarrhea, and hematochezia. Large numbers of spore-forming gram-positive rods were seen on a fecal smear and *C. perfringens* enterotoxin (CPE) was detected in the feces using an ELISA assay.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays are commercially available for detection of *C. perfringens* and *C. difficile* toxin genes in the feces of dogs and cats. It is important to recognize that the presence of clostridial toxin genes within fecal specimens does not prove that clostridia are the cause of an animal's diarrhea, because they do not prove that the organism can produce toxin within the intestinal tract of a patient. Conversely, negative PCR results for clostridial toxin genes do not rule out clostridial diarrhea, as clostridia lacking specific toxin genes may be present that possess other virulence factors, and inhibitors of PCR are common in fecal specimens. As mentioned earlier, real-time PCR assays for *C. difficile* toxin genes are used in conjunction with toxin antigen assays for diagnosis of *C. difficile* diarrhea in humans.[56] Similarly, detection of the *cpe* gene has been used to diagnose *C. perfringens* diarrhea in humans.[58] Fecal specimens from non-diarrheic dogs were less likely to be positive for CPE as detected using ELISA and PCR for the *cpe* gene (4%) when compared with diarrheic dogs (28%), and a combination of testing for the toxin (CPE) via ELISA and the enterotoxin gene (*cpe*) via PCR is likely superior to either test alone.[31] Some laboratories now offer PCR assays for detection of *netF* in fecal specimens from dogs.[34] Again, because the *netF* gene has been found in healthy dogs,[34] a positive result must be interpreted in light of clinical signs and other findings.

TABLE 64.2 Diagnostic Assays Available for Clostridial Enterocolitis in Dogs and Cats

Assay	Specimen Type	Target	Peformance
Bacterial isolation	Feces	*C. perfringens* and *C. difficile*	Isolation from feces does not imply that *Clostridium* is the cause of disease. Allows genotyping and subsequent antimicrobial susceptibility testing. False negatives may occur, especially for *C. difficile*, which requires strict anaerobic conditions
Common antigen test	Feces	*C. difficile*	Excellent negative predictive value for *C. difficile*
Toxin immunoassays	Feces	*C. perfringens* enterotoxin (CPE); *C. difficile* toxin A and toxin B	Positive test results may occur in dogs and cats that do not have diarrhea; negative results do not rule out clostridial diarrhea as other toxins may be involved and CPE is relatively labile
Polymerase chain reaction	Feces	*Clostridium perfringens* toxin genes (e.g., *cpe*, *netF*)	Rapid. Positive results from feces do not imply that *Clostridium* is the cause of disease. Toxin gene PCR may be useful in conjunction with positive ELISA results for toxin production. Negative results may occur if other toxin genes are important or if inhibitors of PCR are present

Pathologic Findings

Histopathologic findings in dogs with AHDS have been described and include acute necrosis of the mucosa with neutrophil infiltration.[47,48] A dense layer of bacteria on the surface of necrotic lesions can be identified, which stain gram positive using Brown and Benn stain.

TREATMENT AND PROGNOSIS

The mainstay of treatment is supportive care with aggressive crystalloid fluid therapy, antiemetics such as maropitant, and a diet formulated for GI disease that is fat-restricted. Although famotidine or omeprazole are often used for acid suppression, in humans their use has been associated with increased risk of *C. difficile* infection[59] and given the lack of gastric lesions in AHDS, their routine use is not warranted. Acid suppressant therapy should be considered in dogs and cats with intractable vomiting to reduce the likelihood of esophagitis. Only animals that are systemically ill merit appropriate antimicrobial therapy (Table 64.3). There is no documented evidence for the benefits of antimicrobial therapy in dogs with uncomplicated diarrhea associated with *C. perfringens* or *C. difficile* infection, even when hemorrhagic, and most of these animals can be managed supportively to ensure adequate hydration status without antimicrobial therapy. A prospective, blinded study that randomized dogs with *C. perfringens*–associated hemorrhagic gastroenteritis that showed no signs of sepsis to two groups, one treated with clavulanic acid-amoxicillin for 7 days and one treated with placebo, showed no difference in mortality rate, dropout rate, duration of hospitalization, or severity of clinical signs, either on any individual day or over the course of disease.[60] Importantly, the results of this study should be cautiously interpreted because dogs with other causes of hemorrhagic diarrhea (e.g., other infections, metabolic, drug-associated, neoplastic) were excluded. In addition, the prevalence of bacteremia in 87 dogs with idiopathic AHDS (11%) was not significantly different from the prevalence of bacteremia in healthy dogs (14%), and no difference in the severity of clinical signs, laboratory parameters, duration of hospitalization, or mortality between bacteremic and non-bacteremic dogs with AHDS was observed.[61]

Metronidazole (10–15 mg/kg PO q12h for 5 to 7 days) is the drug of choice for treatment of complicated *C. difficile* infections should they be suspected in dogs or cats. The vast majority of *C. perfringens* isolates from dogs have been susceptible to metronidazole, ampicillin, amoxicillin, tylosin, and macrolides such as erythromycin.[62] Because of the infrequency of resistance to these drugs, the lack of known breakpoints for veterinary anaerobes, and the lack of relationship between positive stool cultures and disease, antimicrobial susceptibilities are not performed on a routine basis for these organisms when isolated from dogs and cats. Most animals can be successfully treated with antimicrobials for 5 to 7 days, and appropriate treatment is generally associated with clinical improvement within 24 to 36 hours.

IMMUNITY AND VACCINATION

No vaccines are available to prevent clostridial diarrhea in dogs and cats.

PUBLIC HEALTH ASPECTS

Clostridioides difficile is an emerging pathogen and is increasingly recognized as an important cause of nosocomial diarrhea and pseudomembranous colitis in humans, especially the elderly, which is induced by antimicrobial treatment (especially ampicillin, amoxicillin, clindamycin, cephalosporins, and fluoroquinolones) or disruption of the normal GI flora. Humans with *C. difficile* infection develop bloating, and often foul-smelling diarrhea with abdominal pain, usually 5 to 10 days after starting antibiotics. Other signs include fever, nausea, anorexia, and malaise. Rare and life-threatening complications of pseudomembranous colitis include acute toxic megacolon, an acute dilatation of the colon with signs of obstruction, and colonic perforation. Hypervirulent strains (ribotypes O27 and O78) producing CDT, TcdA, and TcdB have been increasingly identified recently which cause a more severe disease, higher relapse rates, and increased mortality. Hypervirulent strains also have a deletion in the toxin C gene (*tcdC*), which normally downregulates toxin production.[56] Because of a high prevalence of metronidazole resistance in *C. difficile* isolates from humans, drugs such as vancomycin, the macrolide fidamoxacin, and fecal microbiota transplantation have been used for treatment.[63] It is theoretically possible that dogs may acquire *C. difficile* strains from humans; however, there has not been a documented case of zoonotic transmission from dogs to humans to date. Human colonization and disease usually occurs in hospital situations. However, in recent years, the importance of community-acquired infections has increased, comprising over 40% of cases reported, with concern about the role of companion animals as reservoirs.[24]

Clostridium perfringens infections are associated with sporadic and antimicrobial-associated diarrhea in humans and CPE is one of the most commonly identified causes of food poisoning in the industrialized world.[56,64] In Canada, it was identified as the second most common cause of foodborne illness (177,000 cases/year) after norovirus (1 million cases/year), with *Campylobacter* spp. (145,000 cases/year) and nontyphoidal *Salmonella* spp. (88,000 cases) accounting for the remaining cases that account for 90% of 1.6 million illnesses caused by known pathogens.[64] Clinical signs of infection include foul-smelling, frothy diarrhea, cramping and abdominal pain, and occasionally nausea and vomiting, usually 7 to 15 hours after eating suspected food, especially meat products that have been cooked with improper cooling and reheating. Vegetative cells are then ingested, and this can be followed by massive sporulation with toxin production in the intestinal tract. The zoonotic potential of *C. perfringens* isolates from dogs and cats requires further investigation.

TABLE 64.3 Antimicrobials That Can Be Used to Treat Complicated Clostridial Diarrhea* in Dogs and Cats

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)
Metronidazole	10	PO	12	5–7
Ampicillin	22	PO	8–12	5–7
Amoxicillin	22	PO	12	5–7
Tylosin	5–10	PO	24	5–7
Erythromycin	15	PO	8	5–7

*Accompanied by signs of sepsis.

CASE EXAMPLE

Signalment

"Bradley," 2-year-old male Chihuahua from Grass Valley, California.

History

Bradley was brought to an emergency clinic for a 12-hour history of hematemesis and diarrhea. He initially vomited up dog food, after which he continued to vomit hourly, the vomiting progressing to hematemesis. He also developed hemorrhagic diarrhea. He had been inappetent and not drinking, and the owner felt he was much quieter than usual. He primarily resided indoors and in the owner's backyard, and there was no travel history or history of access to toxins. There were two other dogs in the household that were apparently healthy. He was up to date on vaccinations for canine parvovirus, distemper virus, canine adenovirus, and rabies. His diet consisted of commercial dry dog food and table scraps.

Physical Examination

Body weight: 3.4 kg

General: Quiet, alert, and responsive, 5% to 7% dehydrated. Recumbent. Temperature = 100.0°F (37.8°C), heart rate = 100 beats/min, respiratory rate = 30 breaths/min, mucous membranes pink and tacky, CRT = 2 s.

Integument: Full coat with a small amount of flea excrement present. Diarrhea that contained fresh blood contaminated the hair in the perianal region.

Eyes, ears, nose, and throat: No abnormalities noted.

Musculoskeletal: Body condition score 4/9. Ambulatory.

Cardiovascular: Fair, synchronous femoral pulses. No murmurs or arrhythmias auscultated.

Respiratory: Normal breath sounds in all lung fields.

GI: Nonpainful on abdominal palpation, but defecated red, jelly-like material several times in the room following the examination.

Genitourinary: Urinated a large amount of odiferous urine during the examination.

Rectal examination: No abnormalities detected.

Lymph nodes: All within normal limits.

Laboratory Findings

CBC: HCT 46% (40%–55%), MCV 68 fL (65–75 fL), MCHC 36.3 g/dL (33–36 g/dL), WBC 11,030 cells/μL (6000–13,000 cells/μL), neutrophils 7280 cells/μL (3000–10,500 cells/μL), band neutrophils 1324 cells/μL, lymphocytes 1655 cells/μL (1000–4000 cells/μL), monocytes 772 cells/μL (150–1200 cells/μL), eosinophils 0 cells/μL (0–1500 cells/μL), platelets 273,000/μL (150,000–400,000 platelets/μL), TPP 5.5 g/dL (6.0–8.0 g/dL). Neutrophils and band neutrophils showed mild to moderate toxic changes.

Serum chemistry profile: Sodium 147 mmol/L (145–154 mmol/L), potassium 4.5 mmol/L (3.6–5.3 mmol/L), chloride 111 mmol/L (108–118 mmol/L), bicarbonate 29 mmol/L (16–26 mmol/L), phosphorus 3.9 mg/dL (3.0–6.2 mg/dL), calcium 9.6 mg/dL (9.7–11.5 mg/dl), BUN 15 mg/dL (5–21 mg/dL), creatinine 0.4 mg/dL (0.3–1.2 mg/dL), glucose 123 mg/dL (64–123 mg/dL), total protein 5.1 g/dL (5.4–7.6 g/dL), albumin 3.1 g/dL (3.0–4.4 g/dL), globulin 2.0 g/dL (1.8–3.9 g/dL), ALT 68 U/L (19–67 U/L), AST 31 U/L (19–42 U/L), ALP 30 U/L (21–170 U/L), GGT < 3 U/L (0–6 U/L), cholesterol 168 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.042, pH 6.0, 1+ protein (SSA), 1+ bilirubin, no hemoprotein, no glucose, 1-2 WBC/HPF, 0 RBC/HPF, rare granular casts.

Coagulation panel: Prothrombin time 8.9 s (7.5–10.5 s), partial thromboplastin time 18.1 s (9–12 s); fibrinogen 349 mg/dL (90–255 mg/dL).

Imaging Findings

Abdominal ultrasound: Mild mesenteric and sublumbar lymphadenopathy was identified. Echogenicity of all lymph nodes was within normal limits. The small intestines had mild wall thickening and a corrugated appearance (see Fig. 64.2). The colon was fluid-filled.

Fecal Examination

Fecal centrifugation flotation: Negative for parasites.

Fecal sedimentation: Negative for parasites.

Microbiologic Testing

Parvovirus fecal antigen ELISA: Negative.

Fecal enteric panel: *Clostridioides difficile* TcdA and TcdB common antigen ELISA negative. ELISA positive for *Clostridium perfringens* enterotoxin A (CPE). No *Salmonella* spp. cultured. No *Clostridioides difficile* cultured. No *Campylobacter* spp. cultured.

Diagnosis

Suspected *C. perfringens*–associated acute hemorrhagic diarrhea syndrome.

Treatment

Bradley was initially hospitalized and treated with intravenous fluids, nil per os, and metronidazole, 7.5 mg/kg IV q12h. Vomiting did not continue, but red gelatinous diarrhea continued every hour for the next 12 hours. Within 24 hours, he had become bright and alert and was offered a fat-restricted bland diet, which he ate well. He was discharged and treated with metronidazole for an additional 5 days, with gradual reintroduction of his regular food.

Comments

Infection by *C. perfringens* was strongly suspected in this case based on the combination of consistent clinical signs, negative assay results for other pathogens, a positive toxin ELISA assay, and response to treatment. However, because the feces of healthy dogs can contain *C. perfringens* enterotoxin, a definitive diagnosis of *C. perfringens* enterocolitis could not be made. The use of antibiotics in this case was controversial; the dog was systemically unwell, but one could also argue that most dogs with AHDS have evidence of systemic illness, and use of antimicrobials to treat these dogs may represent suboptimal antimicrobial stewardship.

Campylobacteriosis

Els Acke

KEY POINTS

- First Described: In Germany, 1886, by Theodor Escherich, noted in stool specimens and intestinal mucus from human neonates with diarrhea.[1]
- Cause: *Campylobacter* spp. (*Campylo* meaning curved, *bacter* meaning rod), microaerophilic gram-negative bacteria belonging to the family Campylobacteraceae.
- Affected Hosts: A large variety of animal species, humans.
- Geographic Distribution: Worldwide.
- Route of Transmission: Fecal-oral.
- Major Clinical Signs: Lethargy, anorexia, small and large bowel diarrhea, vomiting, fever.
- Differential Diagnoses: Differential diagnoses for suspected *Campylobacter* enteritis include GI causes of diarrhea (other infections like salmonellosis, giardiasis, tritrichomoniasis (cats), or other disorders like intestinal lymphoma, inflammatory bowel disease, foreign body ingestion), dietary indiscretion, toxin/drug ingestion, but also extra-GI causes of diarrhea such as endocrine, hepatic disease, pancreatitis.
- Human Health Significance: Important zoonosis. Dogs and cats are a potential source of infection for human campylobacteriosis, and resistance to antimicrobials has been reported.

ETIOLOGY AND EPIDEMIOLOGY

Campylobacter organisms are gram-negative rods (0.2–0.8 μm wide by 0.5–5 μm long) with a polar flagellum giving them the characteristic "cork-screw" motility. Some species are nonmotile or have multiple flagella. They can occur singularly, in pairs (resulting in the typical "gull-winged" appearance), or in chains as long spirals (Fig. 65.1).[2,3] Degenerative coccoid forms can exist in adverse conditions, described as "viable but nonculturable" forms.[4] The first successful isolation of *Campylobacter* was in 1906, when the organism became established as a pathogen of veterinary importance in farm animals, causing infertility, abortion, and dysentery.[5] In 1963, Sebald and Véron proposed the formation of the genus *Campylobacter* and subsequently, different species were named.[3,6] Following the development of a selective culture medium,[7] *Campylobacter* became recognized as a common cause of acute diarrhea in humans.[6,8] Dogs[7] and cats[9] were confirmed to carry *Campylobacter* organisms in their feces, which implicated companion animals in the epidemiology of campylobacteriosis, and *Campylobacter* spp. as possible pathogens for dogs and cats. The organisms are considered commensals in many host animals, but especially in avian species, and campylobacteriosis is the leading cause of bacterial foodborne enteritis in humans worldwide with the major source of infection being the consumption of contaminated poultry meat.[10] The genus *Campylobacter* currently accounts over 30 different species and subspecies isolated from humans and animals; many of these are considered nonpathogenic (http://www.bacterio.net/campylobacter.html). A closely related and clinically important genus previously belonging to the family Campylobacteraceae is the genus *Helicobacter*.[11,12]

Campylobacter organisms are spread by the fecal-oral route with the main sources of infection for pet animals being undercooked/raw food and unpasteurized milk, water, and direct (fresh feces from infected animals) or indirect (fomites, vectors, and environment) contact with other animals including other cats and dogs, farm animals, poultry, ferrets, and hamsters.[13] Commercially available raw meat-based diets for cats and dogs were recently identified as a potential source of *Campylobacter* spp. infection with 28% (14/50) of collected meat samples testing positive, the majority in this study for *Campylobacter jejuni*.[14] The main *Campylobacter* species isolated in companion animals to date include *C. jejuni, Campylobacter upsaliensis,* and *Campylobacter helveticus*, with *C. upsaliensis* more frequently isolated from dogs and *C. helveticus* from cats.[14–23] Detection methods in the laboratory diagnosis of *Campylobacter* spp. infection are biased towards confirmation of *C. jejuni* and *Campylobacter coli* as these are considered the main species causing clinical *Campylobacter* infections in humans. However, the importance of "emerging" (or previously unidentified) *Campylobacter* species has become a major research field in human and veterinary medicine since the development of improved culture-based and molecular detection methods.[24–26] *Campylobacter upsaliensis*, *Campylobacter lari*, *Campylobacter concisus*, *Campylobacter ureolyticus,* and several other species are considered "emerging" species and have been implicated in human cases of campylobacteriosis with a range of clinical presentations (Table 65.1).[25,27,28] *Campylobacter ureolyticus* was recently identified in 10/31 and 4/44 fecal specimens collected from cats and dogs, respectively, in a study in Ireland where *C. ureolyticus* was confirmed to be an important cause of human campylobacteriosis,[29] and several potentially zoonotic "emerging" *Campylobacter* spp. were confirmed in fecal specimens from dogs with diarrhea by quantitative PCR.[26] An overview of *Campylobacter* species reported in dogs and cats is given in Table 65.1.

The detection rates of *Campylobacter* spp. from rectal swabs or fecal specimens obtained from dogs and cats vary depending on the age of the animals, animal species tested, housing, concomitant infection with other enteropathogenic organisms, the presence of enteric or other disease, the sampling season, the geographic region where the study was performed, and the study design.[14,18,30–37] Numerous prevalence studies have been published since the first isolation of *Campylobacter* spp. from domestic dogs and cats, with overall prevalences of *Campylobacter* spp. ranging 0%–87% for dogs and 0%–75% for cats.[9,14–17,19–22,31–57] Accurate speciation with use of molecular methods has been performed since the 21st century,[58] and study results

are method dependent, which complicates comparison among studies. Higher prevalences were obtained when a combination of culture methods was used to optimize the recovery of a range of species.[36,59] A direct fecal quantitative PCR technique applied to specimens from healthy and diarrheic pet dogs showed an unprecedented number of positive detections with a significantly higher number of detectable species (up to 12) in diarrheic dogs when compared with healthy dogs (up to 7), demonstrating increased *Campylobacter* spp. richness in the diarrheic dog population.[26] Application of real-time PCR assays to feces from healthy and diarrheic cats also revealed a significantly higher prevalence of infection and a wider range of species when compared with a single culture method.[23]

A review and meta-analysis of 34 *Campylobacter* spp. prevalence studies reported a mean prevalence of 24.7% in household pets. Because of the lack of standardization of methods and reporting, several knowledge gaps still exist on the significance of *Campylobacter* spp. infections in companion animals and their risk to human health.[60] However, several factors have been significantly associated with *Campylobacter* spp. detection in dogs and cats. The prevalence in dogs and cats living as single household pets is lower than for in animals living in groups (e.g., in pounds and kennels), and intensive housing of dogs and cats is a risk factor for infection.[18,30,32,33,36,42,45,61–63] The higher isolation rate in intensively housed animals can be explained by increased likelihood of exposure due to horizontal spread arising from the living conditions with close contact between animals, stress, dietary changes, and increased incidence of GI disease from other pathogens. In the majority of studies, immature dogs and cats have higher prevalences than adult animals,[9,16,20,22,31,32,35–37,46,48,50,55,64–67] suggesting an age-related immunity.[13] This acquired gut immunity may also explain the lower incidence of campylobacteriosis observed in older animals and adult humans. The link between the presence of intestinal signs in pets and different *Campylobacter* species has been investigated, but adequate pathogenicity studies are needed. Several studies suggested an association between *C. jejuni* detection and signs of diarrhea in dogs and cats.[9,19,31,39,44,46,48,55,64,67,68] In addition, a wider range of *Campylobacter* species was detected in dogs with diarrhea than in those without diarrhea.[26] However, a significant association between clinical signs and detection of *Campylobacter* spp. in dogs or cats was not shown in other studies.[9,22,23,33,34,36,41–43,45,46,49,50,69–74] Co-infecting pathogens, and other pre-existing or concurrent disease may also predispose to *Campylobacter* spp. infection and the development of clinical signs.[49,75,76]

The prevalence of *Campylobacter* spp. infection is higher in dogs than in cats in the majority of studies,[14,22,33–35,42,44,58,64,77] suggesting that cats may be less susceptible to infection. However, similar prevalences have also been found in dogs and cats,[37] and higher prevalences were identified in shelter cats.[36] Compared with dogs, fewer studies have been performed in cats.

TABLE 65.1 *Campylobacter* Species Reported in Dogs and/or Cats and Humans, and Possible Clinical Manifestations Reported.[a]

	POSSIBLE CLINICAL MANIFESTIONS REPORTED[b]	
***Campylobacter* spp.**	**Dogs and/or Cats**	**Humans**
C. coli	None, enteritis, IBD	Enteritis, bacteremia, meningitis, cholecystitis
C. concisus	Enteritis, oral disease	Enteritis, IBD, Barrett's esophagitis, bacteremia, periodontal disease, abscesses
C. curvus	None, enteritis	Enteritis, ulcerative colitis, Barrett's esophagitis, bacteremia, abscesses
C. fetus	None, enteritis	Enteritis, bacteremia, abscesses, cellulitis, endocarditis, mycotic aneurysm, peritonitis
C. gracilis	Enteritis	Periodontal disease, IBD, head and neck infections, abscesses
C. helveticus	None, enteritis	Enteritis
C. hyointestinalis	None, enteritis	Enteritis and bacteremia
C. jejuni	None, enteritis, bacteremia and cholangiohepatitis/cholecystitis, abortion, acute polyradiculoneuritis	Enteritis, bacteremia, myocarditis, meningitis, cholecystitis, UTI, IBD, Guillain-Barré syndrome, etc.
C. lari	None, enteritis, oral disease	Enteritis, bacteremia
C. mucosalis	Enteritis	Enteritis
C. rectus	None, enteritis, oral disease	Periodontal disease, enteritis, IBD, abscesses, bacteremia, tissue infections
C. showae	None, enteritis, oral disease	IBD, abscesses, bacteremia, periodontal disease
C. sputorum	None, enteritis	Enteritis, abscesses, bacteremia
C. upsaliensis	None, enteritis, acute polyradiculoneuritis	Enteritis, bacteremia, abscesses, placentitis
C. ureolyticus	None	Enteritis, IBD, abscesses, tissue or bone infections
C. volucris	None	Bacteremia

[a]See references 14, 28, 29, 37, 56, 81, 84, 87, 98, 101, 104, 105, 156, 157. The most commonly detected species are in bold.
[b]"Clinical manifestations" imply confirmed presence of *Campylobacter* spp. and not confirmed causation of clinical signs in dogs and cats.
IBD, Inflammatory bowel disease; *UTI,* urinary tract infection.

Campylobacter spp. were isolated more frequently from dogs sampled in the spring,[19,56] autumn,[32] or summer[34] and in cats in the summer[50] and autumn.[34,50] This may relate to the increased population of young susceptible puppies and kittens in the warmer months, or other season-related changes.

Raw meat-based diets (RMBD) are popular but are commonly contaminated with enteropathogens, which could pose a risk to animals consuming the diets, humans handling the diets, and to the environment.[78,79] A recent study confirmed 12/25 dogs fed RMBD and only 4/25 dogs fed dry kibble excreted *Campylobacter* spp.[80] However, two other studies have failed to confirm a significant association between raw meat feeding and fecal shedding of *Campylobacter* spp. in dogs.[79,81] Raw chicken consumption was a risk factor in the development of acute polyradiculoneuritis (APN) in a case-control study of Australian dogs, with a significantly higher number of APN cases testing positive for *C. upsaliensis* or *C. jejuni* on fecal culture and PCR within 7 days after developing lower motor neuron signs compared with healthy control dogs.[82] Further work is needed to evaluate the risk of feeding these diets to dogs and cats, and their association with shedding of zoonotic enteropathogens.

Multiple *Campylobacter* species can be simultaneously present in feces[14,21,23,26,37,83,84] and genetic heterogeneity has been detected in several *Campylobacter* species isolated from dogs and cats via molecular subtyping.[14,52,85–87] Also, the presence of co-infections with other organisms such as *Helicobacter* spp.,[73,88,89] endoparasites, and CPV-2[22,47,49,90] suggests that *Campylobacter* spp. may be a secondary or synergistic pathogen. In dogs that frequented dog parks in northern California, co-infections of *Campylobacter* spp. with *Clostridium* spp., coronavirus, circovirus, and *Cryptosporidium* spp. were identified.[57] In this study, enteropathogens were detected in 114 of 300 dogs using a large commercial fecal PCR panel. Co-infections with other organisms were confirmed in four of eight dogs that tested positive for *C. jejuni* and/or *C. coli*.[57] PCR assays that detected other *Campylobacter* spp. were not used in this study, which may have resulted in the low prevalence of *Campylobacter* spp. detection. Many animals excrete *Campylobacter* spp. intermittently or transiently, and a single animal will shed one or several different *Campylobacter* spp. and strains at some stage or stages in its life. Collection of multiple specimens increases the recovery rate of *Campylobacter* spp.[30,83,91] All healthy domestic dogs monitored by monthly fecal swab culture until 2 years of age excreted *Campylobacter* spp. at some stage in one longitudinal study, with 67% of the dogs testing positive at conclusion. The highest prevalence of shedding was in dogs under 1 year of age.[83] *Campylobacter upsaliensis* was shed more continuously and for longer duration than *C. jejuni*, which suggested that dogs may be a reservoir for *C. upsaliensis* or that the organism is a commensal in dogs.[62,83] In cats, the median duration of *Campylobacter* carriage in feces was 44 days and a small number of cats shed *Campylobacter* spp. over 5 months.[50]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The complete mechanisms by which *Campylobacter* spp. induce illness still remain unclear even after many years of human campylobacteriosis research. *Campylobacter jejuni* colonizes the jejunum, ileum, and colon, and the severity of infection and development of clinical signs are dependent on factors such as age, previous exposure, immune status, number and virulence of ingested organisms, environmental and physiological stressors, and the presence of other enteric pathogens or disease.[4,13] The virulence and survival of campylobacters involves motility, adhesion, invasion, and toxin production. Motility of the organisms relies on the presence of one or two polar flagella and chemotaxis. The *FlaA* and *FlaB* genes, which encode the major flagellin proteins, are highly conserved among campylobacters and have been used in molecular typing schemes.[92] The most important chemo-attractants are mucins and glycoproteins in the intestinal tract mucus.[93] *Campylobacter* organisms have several surface adhesins, which are necessary to establish colonization. CadF, an outer membrane adhesin, and CapA (*Campylobacter* adhesion protein A) are the most studied adhesins. Several invasion virulence factors have also been identified. Campylobacters produce several toxins, of which the cytolethal distending toxin (CDT) is the best characterized. In addition, several multidrug resistance and stress response genes have been identified.[4] *Campylobacter* multidrug efflux pumps are also important in the pathogenesis of clinical campylobacteriosis, and antimicrobial resistance rates for *Campylobacter* are rising.[4]

Pathogenicity and experimental studies in companion animals are scarce and have only involved a limited number of animals, challenge strains, and challenge dosages. In one third of *C. jejuni*–infected dogs, clinical signs of diarrhea were present after experimental infection, and soft feces developed in one of three *C. upsaliensis*–infected dogs.[49] Mild signs of enteric disease occurred after oral inoculation of puppies with *C. jejuni*.[94] Enteritis with histopathologic evidence of typhlitis and colitis was reported after oral infection of gnotobiotically raised beagle puppies with *C. jejuni*.[95] In a small number of young kittens and puppies experimentally infected with a *C. jejuni* strain associated with gastroenteritis in children, shedding without clinical signs occurred.[96]

In both dogs and cats, *Campylobacter* infections are usually subclinical and many animals carry *Campylobacter* spp. in their intestinal tract. Clinical signs typically occur in immature animals and where predisposing factors are present.[18] The incubation period is short; in experimental infection, signs of enteritis appeared within 3 days of oral challenge with *C. jejuni*.[95]

Mild to watery diarrhea (occasionally bloody or mucoid with tenesmus), lethargy, anorexia, and, less commonly, vomiting and fever have been reported in dogs and cats with natural infections.[13,18,97] Infection is self-limiting in most cases and affected animals recover within 2 weeks.[13,97] Extra-intestinal infections with *C. jejuni* bacteremia and cholangiohepatitis/cholecystitis have been described.[97,98] Campylobacteriosis may be associated with reproductive disorders[99]; *C. jejuni* was isolated from vaginal discharge in three bitches after they aborted,[100] was implicated in fetal bacteremia following *C. jejuni* infection and diarrhea in a bitch,[101] and perinatal death with infection of fetoplacental organs.[99] Chronic and intermittent diarrhea has been reported in dogs[46,76,102] and cats.[46,103] In a retrospective study where FISH was applied to intestinal histopathology samples of cats with inflammatory bowel disease (IBD), significantly higher numbers of *C. coli* were identified in cats with neutrophilic compared with lymphoplasmacytic IBD.[104] Some "emerging" *Campylobacter* spp. have been identified in saliva samples from pets with oral disease (see Table 65.1) but no definitive association with oral disease has been made, and the zoonotic risk from exposure to *Campylobacter* spp. in oral secretions is unknown.[105,106] Table 65.1 provides an overview of *Campylobacter* spp. detected in dogs and cats and possible clinical manifestations of infection.

Physical Examination Findings

Findings on physical examination of dogs and cats with campylobacteriosis are nonspecific and depend on severity and extent of infection. In animals with severe enteritis, signs of dehydration, lethargy, abdominal pain, and fever can be present, with evidence of melena and hematochezia in some patients.[18,97] Hepatic involvement may be associated with icterus and other signs of liver disease.[97]

DIAGNOSIS

Detection of *Campylobacter* spp. in dogs and cats does not necessarily confirm a diagnosis of campylobacteriosis. Possible underlying or concurrent diseases should always be considered taking signalment, history, clinical signs, and other differential diagnoses into consideration. Further diagnostic work-up should include testing for other infectious causes of enteritis and a broader evaluation for causes of GI disease. These tests might include a CBC and serum biochemistry panel and imaging studies. Complicated cases may require collection of other body fluid specimens for cytologic examination and culture (e.g., blood, bile).[18,97]

Laboratory Abnormalities

Findings on analysis of blood samples for CBC and serum chemistry, if present, are nonspecific. The CBC may reveal a leukocytosis. Regenerative anemia would be uncommon but may be present in animals with blood loss. Animals with bacteremia may have a left shift neutrophilia and thrombocytopenia. Serum chemistry may demonstrate the effects of dehydration associated with diarrhea and associated electrolyte abnormalities. When extra-intestinal infection is present, other changes can be detected such as elevated liver parameters.[97,98]

Diagnostic Imaging

Abdominal radiography and ultrasound in animals with enteritis often reveals only nonspecific changes. Animals with enteritis may have thickened intestinal mucosa, abnormal motility, reduced wall layering, and abdominal lymphadenopathy detected on abdominal ultrasonography.[107] Depending on the presence of extra-intestinal infection, involvement of other organs can be present (e.g., evidence of cholecystitis such as a thickened gall bladder wall) (Fig. 65.2).[97,98]

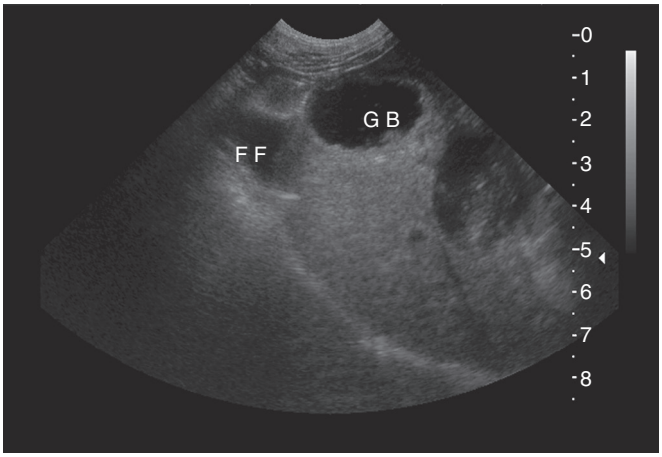

Fig. 65.2 Abdominal ultrasound image from a 10-year-old intact male Brittany spaniel with *Campylobacter* bacteremia, gastroenteritis, and probable cholecystitis, showing thickening of the gall bladder *(GB)* wall and free abdominal fluid *(FF)*.

Microbiologic Tests

Microscopic Examination

Based on microscopic morphology alone, a diagnosis of campylobacteriosis cannot be confirmed. On fecal Gram stains, large numbers of faintly staining gram-negative, slender, gull-wing-shaped rods may be present in animals with *C. jejuni* enteritis (Fig. 65.3).[18] Using dark field or phase contrast microscopy on fresh feces mixed with saline, curved bacteria that are highly motile and show the characteristic darting motion of *C. jejuni* may be detected. However, this technique is not routinely available in veterinary diagnostic laboratories and also lacks specificity.[13,108] Detection by microscopy only suggests the presence of *Campylobacter*-like organisms and should *not* be used to diagnose campylobacteriosis because of the inability to differentiate between similar-appearing organisms such as *Arcobacter* or nonpathogenic campylobacters (Table 65.2).

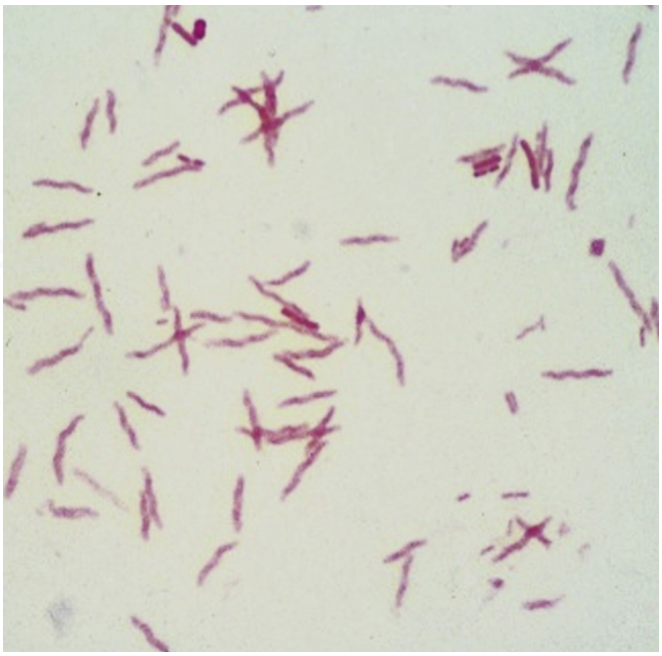

Fig. 65.3 Cytology showing *Campylobacter* organisms. Gram stain, 1000× magnification.

Isolation and Identification

For animals with enteritis, submission of 2–3 g of fresh feces in a sealed sterile container to a laboratory as soon as possible is advised for bacterial culture. If rectal swabs are collected, sterile swabs with Amies or Cary-Blair transport medium are recommended.[18] Certain *Campylobacter* spp. have a reduced viability when stored. For example, *C. concisus* should be cultured within 1 day of specimen collection. *Campylobacter jejuni* and *C. coli* are more resistant and can survive in refrigerated fecal samples up to 2 weeks.[109] Isolation rates of specific *Campylobacter* spp. strongly depend on the isolation techniques used. *Campylobacter* spp. culture is complicated due to the slow growth of some species; the requirement of a microaerophilic environment with an atmosphere of 5% to 10% oxygen and 1% to 10% carbon dioxide at 37°C to allow recovery of a range of thermotolerant *Campylobacter* species; and of selective culture media as antimicrobials present in conventional selective media inhibit growth.[10,28,110] The modified charcoal cefoperazone deoxycholate agar (mCCDA) medium was developed specifically and is still most widely used for the recovery of *Campylobacter* spp. in diagnostic laboratories.[111,112] Subsequently, a basal agar that contains cefoperazone, amphotericin, and teicoplanin (CAT) selective agents was developed for improved detection of *C. upsaliensis*.[113] For the isolation of a range of *Campylobacter* spp. from rectal swabs collected from cats and dogs, a combination of culture methods significantly improved the recovery rate and more accurately reflected the prevalence of *Campylobacter* spp. As a single method in the culture for *C. jejuni, C. upsaliensis, C. helveticus, C. lari* and *C. coli* from rectal swabs, CAT agar was most suitable.[14,59] Membrane filtration, a passive filtration culture method (the motile campylobacters pass through the filter to blood agar), with incubation

TABLE 65.2 Diagnostic Assays Available for Campylobacteriosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Feces, blood, bile, intestinal tissues	*Campylobacter* organism	False negatives may occur, especially following antimicrobial therapy, and some species may not grow under routine conditions used to isolate *Campylobacter*. Isolation from feces does not imply that *Campylobacter* is the cause of disease. Allows subsequent antimicrobial susceptibility testing if available.
Polymerase chain reaction	As for isolation	*Campylobacter* DNA	Rapid, can be highly sensitive and specific. Positive results from feces do not imply that *Campylobacter* is the cause of disease.

in hydrogen-enriched microaerophilic atmosphere, also known as the "Cape Town protocol," proved successful in the isolation of several of the "emerging" species such as *C. concisus*, *Campylobacter sputorum*, *Campylobacter rectus*, and *Campylobacter curvus*, the prevalence of which is underestimated where traditional methods are used.[28,114,115] Incubation for 6 days for these species is recommended while examining the plates every 2 days with subculturing of morphologically different colonies. *Campylobacter jejuni* and *C. coli* grow relatively rapidly and if plates are not re-incubated, slower-growing and "emerging" campylobacters may not be recovered.[109] Phenotypic methods were traditionally used to identify cultured *Campylobacter* species; however, with discovery of more and more species and the close phylogenetic relationship with *Arcobacter* and *Helicobacter* spp., these tests have limited discriminatory potential and are not deemed suitable for accurate identification.[116] MALDI-TOF MS is a superior, rapid, and relatively inexpensive technique for the identification of *Campylobacter* spp. (see Chapter 3).[117,118] Antimicrobial resistance testing can be performed following culture, but unfortunately this is not routinely done for *Campylobacter* spp. by veterinary laboratories due to practical considerations and the lack of internationally accepted criteria for susceptibility testing.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Nonculture-based molecular techniques for detection of *Campylobacter* spp. have become commercially available, allow rapid diagnosis, and overcome problems with culture media and growth conditions, and with reduced viability of organisms and bacterial overgrowth. Molecular techniques are considered the gold standard for genus and species identification also in the routine laboratory setting and are invaluable in epidemiologic studies.[28,116,119] Several PCR-based techniques for genus confirmation and speciation of campylobacters including multiplex PCR have been described.[116,120–122] Direct fecal real-time PCR techniques have been developed to detect a wide range of species.[26,123] Significantly improved diagnostic accuracy was reported using a real-time fecal PCR for four *Campylobacter* spp. versus bacterial isolation using one single culture method in cats with and without signs of diarrhea.[23] Other work reported improved sensitivity when a direct fecal PCR was used compared with culture; however, some isolates had negative PCR results which could be explained by degradation of bacterial DNA and presence of inhibitory substances in feces.[16] A PCR-denaturing gradient gel electrophoresis (PCR-DGGE) method for the detection and identification of *Campylobacter*, *Helicobacter*, and *Arcobacter* species has been applied to saliva specimens from humans and pets.[105]

Investigation of the significance of *Campylobacter* spp. as a cause of zoonotic disease, assessment of the importance of different sources of *Campylobacter* infection (e.g., animal, food, or environmental reservoirs), and development of measures to prevent transmission from animals to humans requires reliable and highly discriminatory subtyping methods.[119] Initial subtyping techniques were based on detection of variation in the flagellin (*fla*A) gene, but the need for more discriminatory techniques led to application of pulsed field gel electrophoresis (PFGE) in epidemiologic investigations (see Chapter 7).[124] Because PFGE is time-consuming, cumbersome, and costly, multilocus sequence typing (MLST) has become the subtyping gold standard due to its excellent discriminatory potential, portability, and reproducibility. MLST was initially developed for *C. jejuni* subtyping and then also described for several other species including *C. coli*, *C. upsaliensis*, and *C. helveticus*.[119,124,125] Whole genome sequencing has become widely available and allows not only superior strain differentiation but also identification of virulence and antimicrobial resistance determinants in *C. jejuni* and *C. coli*,[126,127] and further research applications are rapidly evolving.

Serology

Serologic assays are used in human medicine in epidemiologic investigations to confirm exposure and to investigate some of the long-term sequelae associated with *Campylobacter* spp. infections such as Guillain-Barré syndrome and reactive arthritis.[128] The use of antibody testing in clinical *Campylobacter* infections of dogs and cats has not been investigated extensively and serologic testing is not commercially available. Enzyme immunoassays have been developed for human fecal specimens. These are rapid, simple, and low-cost fecal antigen tests developed specifically to detect *C. jejuni* and *C. coli* with performance reported to be comparable with culture.[129] One study revealed significant cross reactivity with *C. upsaliensis*, *C. helveticus*, and *Campylobacter hyointestinalis* isolates from dogs, cats, and deer for one of the commercial fecal antigen tests, questioning the accuracy of results in the diagnosis of *C. jejuni* and *C. coli* enteritis in humans.[24] With refinement, these tests may be useful for future investigations of a wide range of *Campylobacter* spp. infections in humans and animals.

Pathologic Findings

Changes described on necropsy of dogs with campylobacteriosis include grossly abnormal small and large intestines[76] with thickening of mucosa of the ileum[130] and enlargement of mesenteric lymph nodes.[94,130] On histopathology, laboratory dogs with *Campylobacter* spp. enterocolitis had changes especially in the distal jejunum and ileum with fusion or blunting of the villi, rare crypt epithelial cell degeneration, and lymphoplasmacytic infiltration into the lamina propria. In the colon, superficial erosions were described, lymphoplasmacytic infiltration of the lamina propria, crypt epithelial hyperplasia, and *Campylobacter* spp. were confirmed by IHC.[76] One report described proliferative enteritis associated with *Campylobacter* spp. infection in two pups with marked hyperplasia of the ileal mucosa, elongated glandular crypts, inflammatory infiltrate in the lamina propria, and hyperplastic regions in the colonic mucosa.[130] Silver staining has shown filamentous bacteria in crypts (Fig. 65.4) and IHC can be used to confirm *Campylobacter* spp. infiltration.[76] Application of FISH to identify *Campylobacter* spp. on biopsy specimens from animals with neutrophilic IBD has suggested an association with *C. coli* infection in cats.[104]

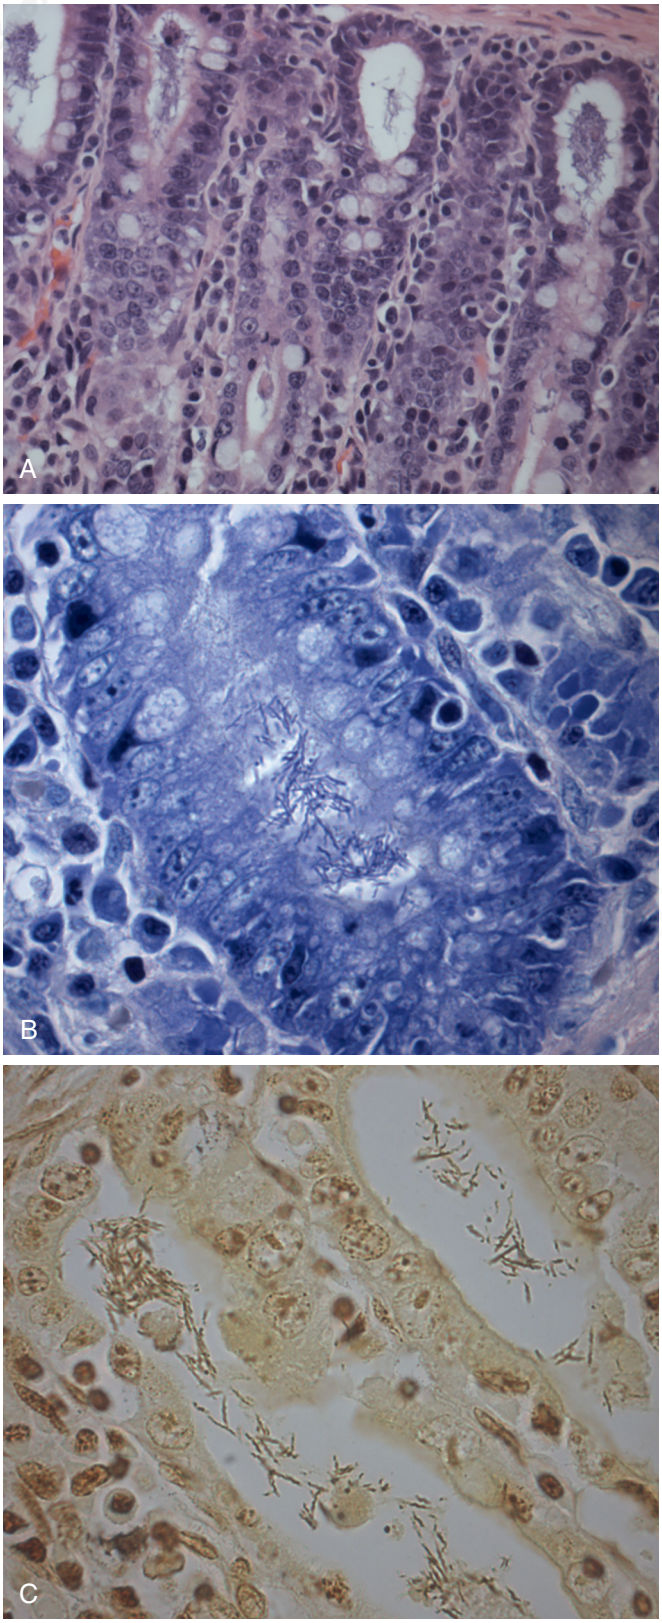

Fig. 65.4 Histopathology of an intestinal section from a 3-month-old Chihuahua puppy with *Campylobacter jejuni*–associated diarrhea. Abundant filamentous, spiral bacteria pack the crypts and there is an associated lymphoplasmacytic enterocolitis. (A) Hematoxylin and eosin stain. (B) Giemsa stain. (C) Warthin-Starry silver stain.

TREATMENT AND PROGNOSIS

As in humans, the majority of *Campylobacter* spp. infections in dogs and cats with signs of enteritis are self-limiting and only require supportive treatment. Antimicrobial therapy should be reserved for patients that are immunocompromised, febrile, or who have severe clinical signs, with or without extra-intestinal signs.[18] Also in clinical cases where shedding is confirmed and there is possible increased infectious risk (e.g., young children or immunocompromised people in the household, other animals), antimicrobial therapy should be considered if isolation of the animals is not possible. Few data are available on the efficacy of antimicrobial therapy of *Campylobacter* spp. enteritis in cats and dogs. There is increasing evidence that *Campylobacter* spp. isolated from dogs and cats show significant antimicrobial resistance to commonly used antimicrobial drugs, thus the judicious use of antibiotics is advised.[131–134] The macrolide and fluoroquinolone groups of antimicrobials have been traditionally recommended, but with the increasing resistance to enrofloxacin and ciprofloxacin, fluoroquinolones should not be considered first choice where results of susceptibility testing are unavailable.[18,135] In addition, this group of antimicrobials is not recommended for prolonged use in young animals due to possible adverse effects on cartilage development.[18,136] An overview of antimicrobial therapy options for enteric *Campylobacter* infections in dogs and cats is given in Table 65.3. Duration of therapy should be based on clinical response. Reported cases of C. *jejuni*–associated bacteremia and cholangiohepatitis or cholecystitis in dogs have been successfully treated with cefoxitin, erythromycin, or enrofloxacin.[97,98] Reinfection, intermittent excretion, specific *Campylobacter* species and strain variation, and the development of antimicrobial resistance have to be taken into account when evaluating therapeutic success. Incorrect diagnosis with subclinical *Campylobacter* spp. infection or carrier state should also be considered in cases with a poor response to therapy. The prognosis for campylobacteriosis in dogs and cats with self-limiting disease, and in those treated with appropriate antimicrobials if indicated, is excellent in the absence of systemic complications.

IMMUNITY AND VACCINATION

Clearance of *Campylobacter* infection depends on adequate innate, humoral, and cell-mediated immune responses. Short-term immunity develops after infection, but reinfection, colonization and development of long-term sequelae are possible.[137] Work in human campylobacteriosis has focused on intestinal microbiota shifts and how *C. jejuni* organisms could overcome intestinal colonization resistance following ingestion.[138] Vaccination of humans and especially poultry, as birds are the main reservoir for human *C. jejuni* infections, has been researched for many years but none of the vaccines developed have succeeded in induction of prolonged immunity, or in complete prevention of intestinal colonization in chickens.[137,139]

PREVENTION

Isolation of animals with confirmed clinical campylobacteriosis and fecal shedding is advised to minimize the risk of environmental contamination and of infection of other animals and humans predisposed to developing clinical signs. *Campylobacter* spp. are susceptible to routinely used disinfectants, and adequate hygiene measures should be communicated and implemented especially where animals are from intensive housing backgrounds,[140,141] and when raw meat-based diets are fed.[78,81]

TABLE 65.3 Drug Therapy for *Campylobacter* spp. Infections in Dogs and Cats[a,b]

Drug	Species	Dose[c] (mg/kg)	Route	Interval (Hours)
Erythromycin	B	10–15	PO	8
Azithromycin	B	5–10	PO	24
Enrofloxacin[d]	B	5	PO, SC, IV	24
Chloramphenicol	D	25–50	PO, SC, IM, IV	8
	C	10–25	PO	12
Tetracycline	B	10–20	PO	8
Tylosin	B	10	PO	12
Cefoxitin	B	15–20	SC, IM, IV	8

[a]See references 13, 18, 158.
[b]Duration of treatment should be based on clinical response.
[c]Dose per administration at specified interval.
[d]Other quinolones such as ciprofloxacin, difloxacin, or marbofloxacin are alternatives, although dosages vary.
B, both dog and cat; *C,* cat; *D,* dog; *IM,* intramuscular; *IV,* intravascular; *PO,* by mouth; *SC,* subcutaneous.

PUBLIC HEALTH ASPECTS

Campylobacter spp. remain the most significant cause of bacterial gastroenteritis in humans, and campylobacteriosis is a notifiable disease in many countries.[28,142] The main *Campylobacter* spp. isolated in enteritis patients worldwide remains *C. jejuni* followed by other species including *C. coli*, *C. concisus*, and *C. ureolyticus*.[28] Asymptomatic *C. jejuni* infections are rare in humans in developed countries. Children under the age of 5 years, young adults, and immunosuppressed or elderly people are most commonly affected. The handling or consumption of contaminated or undercooked meat and, less commonly, contaminated water or unpasteurized milk and dairy products, other foods, international travel, and contact with animals have been confirmed risk factors for human campylobacteriosis.[28,143] The mean incubation period is 3.2 days, with a range from 18 hours to 8 days. Clinical signs range from mild self-limiting enterocolitis to severe watery or bloody diarrhea with abdominal cramping, nausea, vomiting, and headache and fever. Patients usually improve after a few days of illness, although abdominal pain can persist for longer. Weight loss is common and some patients will relapse. Excretion of *Campylobacter* spp. can occur for weeks after clinical recovery, unless the infection has been treated with antimicrobials.[28,144] Bacteremia, extra-intestinal, and complicated or chronic disease may develop, and *Campylobacter* spp. have been associated with abscess formation, hepatic disease, meningitis and abortion, IBD, esophageal and periodontal diseases, the polyneuropathy Guillain-Barré syndrome, reactive arthritis, and many other disorders (see Table 65.1).[28] Contact with dogs and cats (especially immature and diarrheic animals) is a significant risk factor for *C. jejuni* and *C. coli* infection in humans, especially infants and children.[145–151] Clinical cases with confirmed identical subtypes of *Campylobacter* spp. in pets and humans from the same household have been reported,[152,153] and several studies applying MLST or whole genome sequencing to *C. jejuni* isolates from pets have identified identical sequence types in pets compared with those commonly found in human campylobacteriosis, suggesting common sources of infection and zoonotic risk from contact with dogs and cats.[14,52,79,87,154] As *C. upsaliensis* and *C. helveticus* isolates have mostly been confirmed in dogs and cats, respectively, and no other possible animal reservoir has been identified to date, cats and dogs may play an important role in the epidemiology of these species.[16,24,62,79,155] People living or working in close contact with cats and dogs should be aware of the potentially zoonotic organisms these animals may carry. Families with young children and immunocompromised people should be informed about the risks and recommended hygiene measures when handling puppies or kittens, animals with signs of gastroenteritis, and particularly when an animal is newly obtained from a shelter environment.[140,141]

CASE EXAMPLE

Signalment

"Maurice," a 4-month-old male entire Keeshond puppy from Flanders, Belgium.

History

Maurice was evaluated on an emergency basis with a 3-day history of inappetence, lethargy, vomiting, and hemorrhagic diarrhea. He had been purchased 5 weeks before from a local breeder, and routine vaccination and anthelmintic treatments were current. He was fed a dry puppy diet and had not traveled out of his local area. Other puppies from the litter were healthy, except for one that had signs of diarrhea which had responded to antimicrobial therapy prescribed by a veterinarian. There were no other animals in the household and none of the family members were ill. Maurice had free access to a large garden and went on walks.

Physical Examination

Body weight: 2.3 kg (BCS 3/9).

Abnormalities detected: Severely lethargic, 7% dehydrated, HR = 200 beats/minute with weak femoral pulses, RR = 36 breaths/minute, mucous membranes slightly pale, CRT > 2 seconds. Rectal temperature = 102.9°F (39.4°C). Maurice was uncomfortable on abdominal palpation.

Laboratory Findings

CBC: HCT 37.5% (37.3%–61.7%), Hgb 12.6 g/dL (13.1–20.5 g/dL), MCV 63.1 fL (61.6–73.5 fL), MCHC 33.6 g/dL (32–37.9 g/dL), reticulocytes 38,000/μL (10,000–110,000/μL), red cell distribution width 16.7% (13.6%–21.7%), WBC 4.24×10^9 cells/L (5.05–16.76 cells/L), neutrophils 1.13×10^9 cells/L (2.95–11.64 cells/L), lymphocytes 2.90×10^9 cells/L (1.05–5.10 cells/L), monocytes 0.18×10^9 cells/L (0.16–1.12 cells/L), eosinophils 0.03×10^9 cells/L (0.06–1.23 cells/L), platelets 169,000/μL (148,000–484,000/μL). Blood smear examination revealed thrombocyte aggregates and neutropenia.

Serum chemistry profile: Sodium 147 mmol/L (145–154 mmol/L), potassium 3.2 mmol/L (3.6–5.3 mmol/L), chloride 109 mmol/L (108–118 mmol/L), bicarbonate 13 mmol/L (16–26 mmol/L), phosphorus 3.0 mg/dL (3.0–6.2 mg/dL), calcium 9.9 mg/dL (9.7–11.5 mg/dL), BUN 12 mg/dL (5–21 mg/dL), creatinine 1.2 mg/dL (0.3–1.2 mg/dL), glucose 86 mg/dL (64–123 mg/dL), total protein 4.0 g/dL (4.8–7.2 g/dL),

CASE EXAMPLE—cont'd

albumin 1.9 g/dL (2.1–3.6 g/dL), globulin 2.1 g/dL (2.3–3.8 g/dL), ALT 102 U/L (19–67 U/L), AST 36 U/L (19–42 U/L), ALP 189 U/L (21–170 U/L), creatine kinase 280 U/L (51–399 U/L), GGT 2 U/L (0–6 U/L), cholesterol 292 mg/dL (135–361 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL), magnesium 1.4 mg/dL (1.5–2.6 mg/dL).

Imaging Findings

Abdominal ultrasound: The stomach was moderately distended with anechoic fluid, the duodenum and jejunum were diffusely and moderately distended with fluid and the mucosa was hyperechoic. There was decreased peristalsis. The colon was distended and fluid filled with a thickened hyperechoic wall. The jejunal lymph nodes were prominent with irregular shape but normal echogenicity and length/width ratio. Conclusion: signs of severe gastroenteritis with ileus and mucosal edema. Reactive lymphadenopathy.

Fecal Examination

Fecal real-time PCR panel was positive for CPV-2 (confirmed as CPV-2a), but negative for CCoV, CDV, and *Clostridium perfringens* toxin genes.

Screening for bacterial enteropathogens, parasites, giardiasis, and cryptosporidiosis revealed only positive *Campylobacter* spp. culture. Susceptible to ampicillin, amoxicillin clavulanate, erythromycin, tetracycline, and ciprofloxacin. PCR confirmed the presence of *C. jejuni*.

Diagnosis

Parvovirus enteritis combined with *C. jejuni* infection.

Treatment and Follow-Up

Maurice was kenneled in isolation and treated with crystalloid and colloid IV fluid therapy supplemented with potassium. Serum total protein, electrolytes, glucose, and CBC were monitored. Initial treatments consisted of amoxicillin clavulanate (20 mg/kg, IV, q8h for 3 days then switch to oral), enrofloxacin (5 mg/kg, IV, q24h for 5 days), maropitant (1 mg/kg, SC, q24h), metoclopramide CRI (1 mg/kg, IV, per 24h), and pantoprazole (1 mg/kg, IV, q24h). Fever resolved and there was clinical improvement, but nasoesophageal tube feeding was initiated on day 2 due to persistent anorexia. Within 1 week of hospitalization, he improved dramatically; vomiting, hemorrhagic diarrhea, and neutropenia resolved, and he started eating spontaneously. Maurice was discharged with treatment with oral amoxicillin clavulanate (20 mg/kg, PO, for 1 week), omeprazole (1 mg/kg, PO) and ranitidine (2 mg/kg, PO, q12h for 5 days). Fenbendazole was administered at 50 mg/kg, PO, q24h for 3 days. Repeat *Campylobacter* culture 1 week after discontinuing antibiotic treatment was negative.

Comments

This is a typical case of concomitant parvovirus and *Campylobacter* spp. infection. Broad-spectrum antimicrobial therapy was indicated with the presence of parvovirus-induced neutropenia, fever, hemorrhagic diarrhea, and suspected sepsis in this case. Choice was based on the clinical status of the patient, and antibiogram results were available 3 days after sample collection. Almost 50% of dogs with parvovirus enteritis had co-infection with *Campylobacter* spp. in one report,[90] and appropriate antimicrobial therapy is indicated in severely affected cases to reduce the risk of systemic complications and improve outcome.

Helicobacter Infections

Jane E. Sykes

KEY POINTS

- First Described: 1881 by Rappin (France),[1] who observed spiral bacteria in a dog's stomach; the association between *Helicobacter pylori* infection and disease in humans was made in 1983.[2]
- Cause: Various species of non-*H. pylori* helicobacters, rarely *H. pylori*.
- Primary Mode of Transmission: Fecal-oral and oral-oral transmission proposed, possibly water-borne. Transmission through contact with vomitus may also occur.
- Affected Hosts: Humans and a variety of other animals.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Possibly associated with chronic vomiting (gastric helicobacters) or diarrhea (intestinal helicobacters), although evidence for a causative role in disease is weak.
- Differential Diagnoses: Dietary indiscretion, gastrointestinal foreign body, chronic pancreatitis, inflammatory bowel disease, food-responsive enteropathy, eosinophilic fibrosing gastritis (cats), bilious vomiting syndrome, gastrointestinal neoplasia (lymphoma, mast cell neoplasia, gastric adenocarcinoma), chronic infiltrative infectious diseases of the gastrointestinal tract (including FIP, mycobacteriosis, canine cryptococcosis, pythiosis), hypoadrenocorticism, hyperthyroidism (cats), toxins (including drugs), gastric helminthiasis (e.g., *Physaloptera* and *Ollulanus* spp.).
- Human Health Significance: Dogs and cats may be a source of human infection with non-*H. pylori* helicobacters that have been associated with gastritis, gastroduodenal ulceration, and low-grade MALT lymphoma in humans.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Helicobacter spp. are flagellate, gram-negative, microaerophilic, curved to spiral-shaped motile bacteria (Figs. 66.1 and 66.2). They are grouped into oral, gastric, hepatic, and intestinal *Helicobacter* species, with intestinal species residing primarily in the large intestine.[3-5] In humans, gastric *Helicobacter* spp. are an important cause of gastritis and gastroduodenal ulceration, and increase the risk for development of gastric adenocarcinoma and lymphoma. However, they have also been associated with positive health effects, such as decreased gastroesophageal reflux and protection from some gastrointestinal neoplasms. In contrast, the extent to which *Helicobacter* spp. are capable of causing disease in dogs and cats is not fully understood, and newly discovered organisms in dogs and cats have drawn most attention with regard to their zoonotic potential.[6]

Helicobacter pylori is the type organism, and the most important organism infecting humans. *Helicobacter pylori* infection is rare in cats and dogs, and has been identified in one colony of cats and rarely in domestic pet and stray cats, usually in mixed infections with other *Helicobacter* species.[7-10] In 2021, infection with *H. pylori* was reported in two dogs and their owner in Japan.[11] Dogs and cats are generally infected with gastric non-*H. pylori* helicobacters[6] (also referred to as gastric *Helicobacter*-like organisms, or GHLOs). These are much larger than *H. pylori* (5 to 10 μm long versus 1.5 to 3 μm long for *H. pylori*) and species cannot be differentiated from one another based on their light or electron microscopic appearance alone. The nomenclature of non-*H. pylori* helicobacters is complicated, and species that have been identified in dogs and cats are listed in Table 66.1. Before they were characterized genetically, non-*H. pylori* helicobacters were originally referred to as "*Gastrospirillum hominis*" and later "*Helicobacter heilmannii*." Subsequent analysis of multiple gene sequences from a variety of "*H. heilmannii*" from dogs and cats has revealed that "*H. heilmannii*"

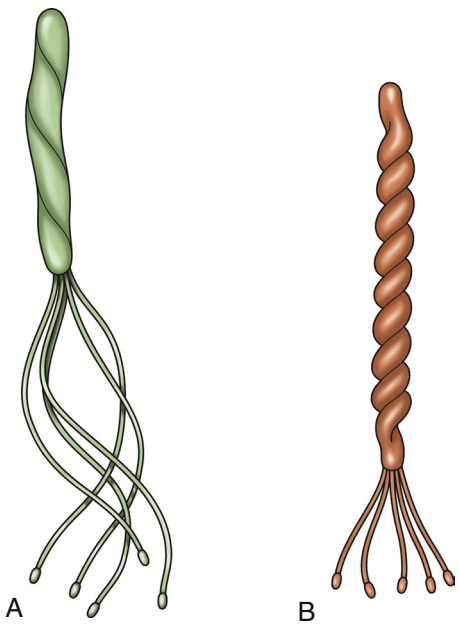

Fig. 66.1 Structure of gastric *Helicobacter* species. Note the terminal bunches of flagellar filaments. (A) *Helicobacter pylori*. (B) Gastric helicobacter-like organism.

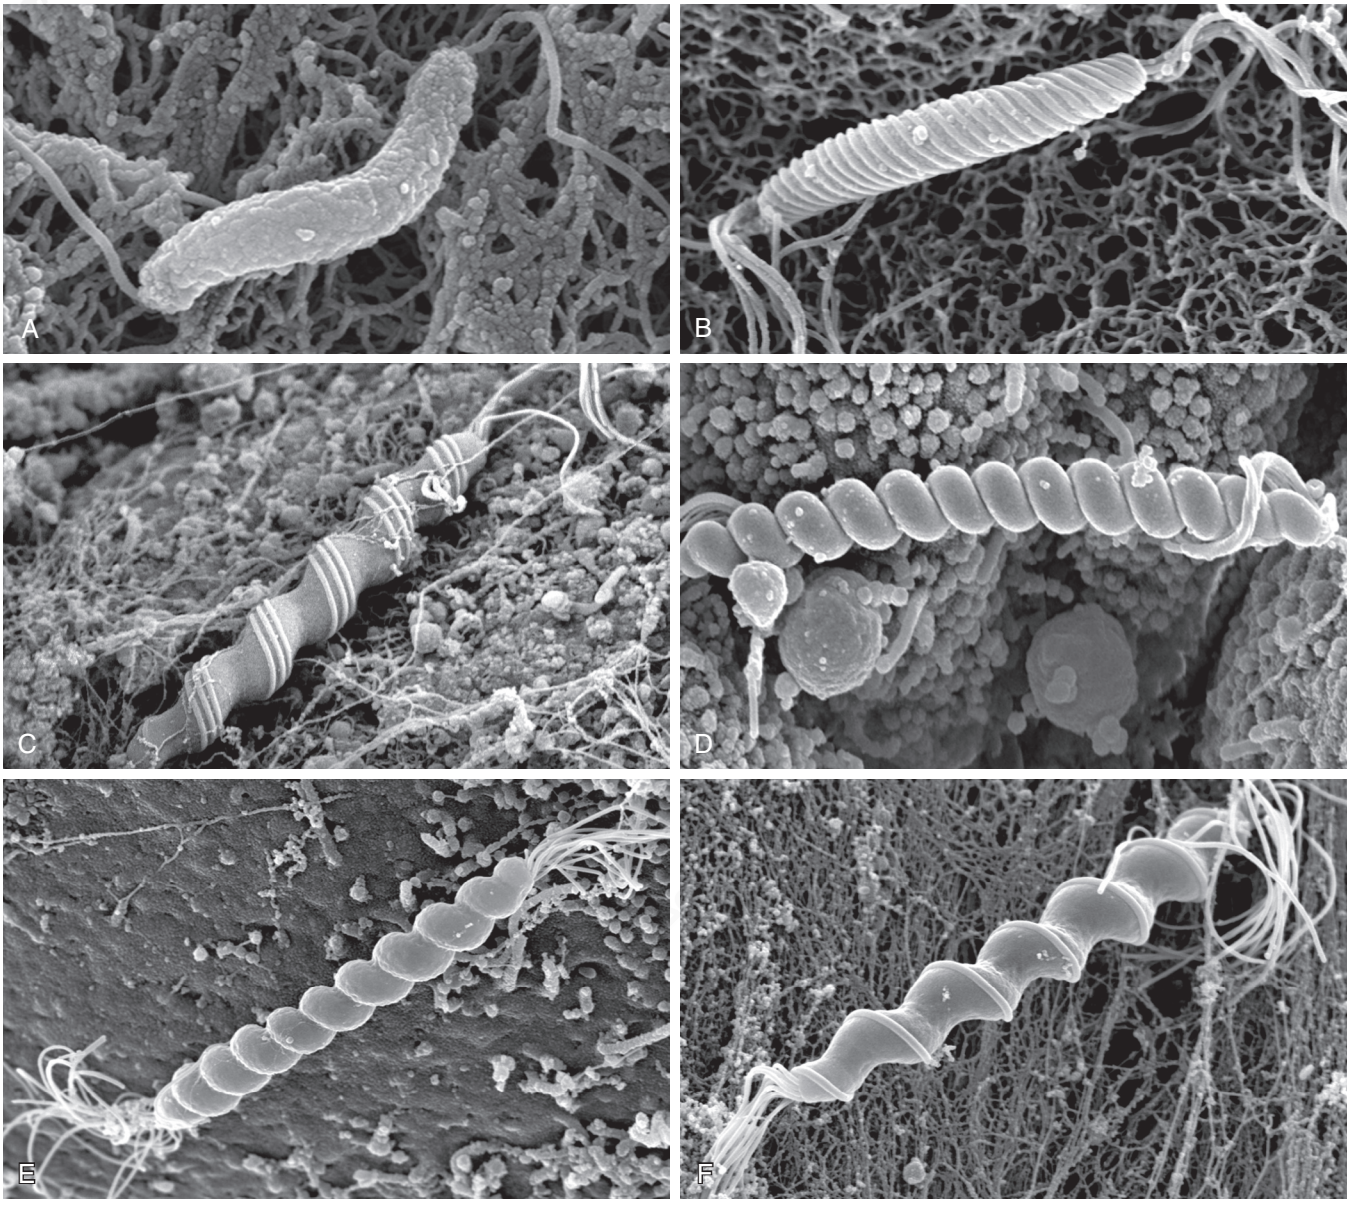

Fig. 66.2 Scanning electron micrographs of (A) *Helicobacter pylori*; (B) *Helicobacter rappini*; (C) *Helicobacter felis*; (D) *Helicobacter heilmannii*; (E) *Helicobacter bizzozeronii*; and (F) *Helicobacter salomonis*. (Courtesy M. H. Stoffel, University of Bern, Bern, Switzerland.)

is not one but a group of organisms that includes *Helicobacter felis*, *Helicobacter bizzozeronii*, *Helicobacter salomonis*, and an unculturable organism that has been confusingly named "*Candidatus* Helicobacter heilmannii." These organisms have also been implicated in human disease, albeit less commonly than *H. pylori*.[6]

Depending on the study, between 35% and 100% of dogs and cats have been found to be infected with non-*H. pylori* helicobacters, and gastric *Helicobacter* spp. can be found in apparently healthy animals and dogs and cats without signs of vomiting.[6,12-19] *Helicobacter* spp. infection has shown an association with gastric pathology in dogs and cats in some studies[13,20] but not in others.[12,21]

Dogs and cats are probably infected shortly after birth, as a result of fecal-oral and oral-oral transmission.[22] Transmission through contact with vomitus may also occur. Water-borne transmission has been hypothesized to play a role in spread of *H. pylori* to humans.[23] Shelter and colony dogs and cats appear to have a higher prevalence of infection, most likely due to the close proximity of animals to one another. One *Helicobacter* species may be able to suppress the presence of another, so that dogs and cats are primarily colonized with a single species, although in some animals the simultaneous presence of multiple species has been found.[8,24] The organisms have a remarkable ability to survive the low pH of the stomach, which they resist by living deep in the mucus glands of the stomach and through production of the enzyme *urease* (Fig. 66.3). The urease catalyzes the hydrolysis of urea to carbon dioxide and ammonia, thus raising the pH of the organism's milieu. In dogs and cats, the organisms can also be found inside parietal cells.[22,25]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The majority of dogs and cats infected with gastric helicobacters show no clinical signs. *Helicobacter* infection of some dogs and cats has been hypothesized to cause chronic intermittent vomiting, inappetence, pica, belching, weight loss, fever, and polyphagia.[25,26] Unfortunately, strong evidence supporting an association with such disease in dogs and cats is lacking. Some animals with biopsy-confirmed infection develop resolution of clinical signs following specific therapy for gastric helicobacter infection,[27-29] although the results of one study were difficult to interpret because of the concurrent administration of an elimination diet.[28] Experimental and natural infections of dogs and cats with non-*H. pylori* helicobacters have been associated with chronic lymphoplasmacytic gastritis and lymphoid follicular hyperplasia. Gastroduodenal ulceration and marked alterations in the gastric acid secretory axis have not been observed.[21,29,30] However, not all animals infected with non-*H. pylori* helicobacters have histopathologic evidence of gastritis, and there has been no correlation observed between the severity of gastric pathology and the degree of colonization by helicobacters.[31] More severe gastritis with marked lymphoid follicular hyperplasia and neutrophilic inflammatory infiltrates has been reported in cats and acutely in puppies experimentally infected with *H. pylori*.[32,33] The puppies developed gastrointestinal signs, including vomiting and loose stool shortly after inoculation. One cat was described with severe atrophic gastritis and linear gastric tears in association with a possible *H. pylori* infection.[27] It is conceivable that the degree of gastritis in dogs and cats may vary with the *Helicobacter* species or even strain, but this requires further study. In humans, gastric pathology has been associated with possession of a number of pathogenicity genes by *H. pylori*, including *cag*A (cytotoxin-associated gene A), *vac*A (vacuolating cytotoxin), and *ice*A (induced by contact with epithelium) (see Fig. 66.3).[34] The degree of vacuolating cytotoxin production can also vary between strains.[35]

In human patients, *H. pylori* infection has been well associated with gastric low-grade, B cell, MALT lymphoma. Clinical studies have documented that *H. pylori* eradication can achieve complete remission in some patients with *H. pylori*–positive early-stage gastric MALT lymphoma.[36] One study suggested a possible association between *Helicobacter* spp. infection and gastric lymphoma in cats.[37] In another report of 55 cats with nonhematopoietic intestinal carcinomas, helicobacters were detected using FISH in 56% of cases; furthermore, there was an association with large intestinal location (68% of tumors) and mucinous adenocarcinomas (92% of tumors).[38] More studies are required to confirm whether an association exists between intestinal neoplasia in cats and *Helicobacter* spp. infection.

Some evidence exists that colonization of the gall bladder by *H. pylori* in humans is associated with an increased risk of chronic cholecystitis and cholelithiasis.[39] Non-*H. pylori* helicobacters were reported in the hepatobiliary system of 2 of 32 cats with cholangiohepatitis.[9] *Helicobacter* spp. were also detected in the liver of 21% of 33 dogs with hepatic disease and none of 17 dogs that had normal liver pathology.[40] *Helicobacter canis* was detected in the liver of a 2-month-old puppy with multifocal necrotizing hepatitis that had acute weakness, vomiting, and death within hours.[41] *Helicobacter canis* was also detected in a colony of Bengal cats with diarrhea, but its role as a causative agent was uncertain.[42] Abundant organisms that genetically resembled *H. canis* were detected microscopically throughout the large intestine of a 2-month-old kitten with severe diarrhea, vomiting, dehydration, weight loss, and inappetence.[3]

DIAGNOSIS

Microbiologic Tests (Table 66.2)

Clinical diagnosis of *Helicobacter* infection in dogs and cats has most commonly been based on histopathology, cytology, rapid urease testing, and, to a lesser extent, PCR on gastric biopsies. Other tests such as the urea breath and blood tests, fecal PCR, and serological tests are primarily used in human patients and in the research arena.

Diagnosis Using Cytology and Histopathology

Spiral organisms can be readily detected using touch impressions of gastric tissue obtained following biopsy or necropsy, after staining with Gram or Diff-Quik stains, even when low numbers of organisms are present (Fig. 66.4). A cytology brush can also be used to obtain a specimen during endoscopy. Several biopsies or brush specimens may need to be evaluated from different regions of the stomach (fundus, cardia, antrum/pylorus) when the distribution of organisms is patchy. When organism burdens are high, the organisms can be detected using histopathology, which allows assessment of concurrent gastric pathology (Figs. 66.5 and 66.6). The use of silver stains (such as Warthin-Starry stain or Steiner stain), Giemsa, or toluidine blue stain, as well as immunostaining can dramatically increase sensitivity for organism detection, especially when low numbers of organisms are present (Figs. 66.5C and 66.6C).[43]

Bacterial Isolation

Isolation of gastric helicobacters can be difficult and as a result can have low sensitivity. Growth typically requires incubation on selective media in microaerobic conditions for 5 to 10 days. Isolation may be advantageous in research settings because it allows subsequent identification of the organism using conventional biochemical testing, whole-cell protein profiling, and DNA analysis.[18,44] It also allows antimicrobial susceptibility testing, which has recently been recommended before treating humans for *H. pylori* infection because of the increasing prevalence of antimicrobial resistance.[45] Resistance to antimicrobials has also been documented in non-*H. pylori* helicobacters isolated from dogs and cats.[46]

TABLE 66.1 *Helicobacter* Species That Have Been Identified in Dogs, Cats, and Humans[a]

Helicobacter Species	Location	Host Species
H. bizzozeronii	Stomach	Dog, humans
H. salomonis	Stomach	Dog
H. cynogastricus	Stomach	Dog
"Candidatus H. heilmannii"	Stomach	Dog, cat, humans
H. felis	Stomach	Dog, cat, humans
H. pametensis	Stomach	Cat
H. baculiformis	Stomach	Cat
H. pylori	Stomach	Cat
"Flexispira rappini"	Stomach, intestine	Dog, cat
H. bilis	Stomach, intestine	Dog, cat
H. canicola (H. cinaedi)	Intestine	Dog, cat
H. finneliae	Intestine	Dog, cat
"H. colifelis"	Intestine	Cat
H. marmotae	Intestine	Cat
H. canis	Intestine, liver	Dog, cat, human

[a]See references 4, 66, 74–83.

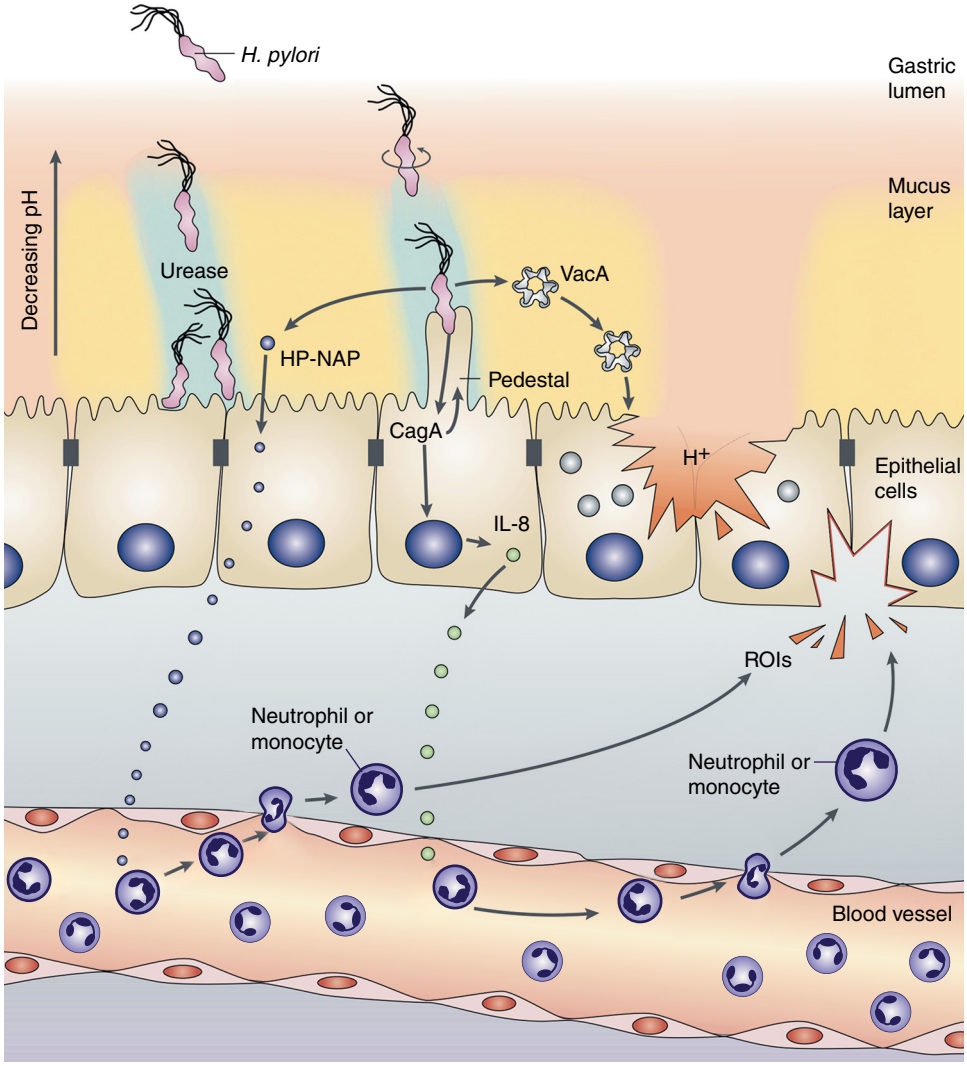

Fig. 66.3 Pathogenesis of *Helicobacter pylori* infection. During infection, *H. pylori* enters the gastric lumen where urease allows survival in the acidic environment (pink indicates a strongly acidic environment, yellow a mildly acidic one) by producing ammonia that buffers cytosolic and periplasmic pH as well as the surface layer around the bacterium (light blue). The flagella propel the organism into the mucus layer and allow it to reach the apical domain of gastric epithelial cells, to which it adheres using adhesins. The organism then injects the cagA protein into host cells with a type IV secretion system and releases other toxic factors such as VacA and a neutrophil activating protein (*HP-NAP*). VacA induces tight junction alterations, and HP-NAP crosses the epithelial lining and recruits neutrophils and monocytes. CagA causes alteration of the cytoskeleton, pedestal formation, and stimulates release of proinflammatory lymphokines, with release of reactive oxygen intermediates (*ROIs*). The combined toxic activity of VacA and ROIs leads to tissue damage that is enhanced by loosening of the protective mucus layer and acid permeation. (From Montecucco C, Rappuoli R. Living dangerously: how *Helicobacter pylori* survives in the human stomach. *Nature Rev Mol Cell Biol.* 2001;2:457-465. Figure 1)

Rapid Urease Testing

The rapid urease test involves incubating a gastric biopsy in a urea broth that contains the pH indicator phenol red. If gastric helicobacters are present in the biopsy, helicobacter urease breaks down the urea in the broth, with the release of ammonia, a rise in pH, and a color change occurs. The change in color can occur within 1 to 3 hours, although the broth is generally incubated at room temperature for 24 hours. The test is very sensitive, although false-negative results can occur if the distribution within the stomach is patchy or if organism loads are low. False-positive results have rarely been reported when other urease-producing bacteria are present in the stomach, such as *Proteus* spp.

Molecular Diagnosis Using Nucleic Acid-Based Testing

PCR assays have been used extensively to detect *Helicobacter* species in tissues, including those from dogs and cats. Sequence analysis of the PCR products can allow identification of the species present, which has been important in epidemiologic studies. FISH has also been used to detect, localize, and identify *Helicobacter* species infection in tissues from dogs and cats.[4,5,28,37,47]

Serologic Diagnosis

A variety of serum ELISA and immunoblotting assays have been used extensively in humans for screening for *H. pylori* infection, and some can be used to some extent to monitor the success of

TABLE 66.2 Diagnostic Assays Available for Gastric *Helicobacter* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Bacterial isolation	Gastric biopsies	*Helicobacter* organisms	Can take up to 10 days. Low sensitivity for non-*H. pylori* helicobacters, which can be difficult to culture. Patchy distribution may also lead to false negatives. Allows typing and antimicrobial susceptibility testing
Cytology	Impression smears of gastric biopsies or cytology brush specimens	*Helicobacter* organisms	Rapid and sensitive, but false negatives can occur rarely. Patchy distribution may also lead to false negatives. No information on inflammatory or architectural changes in underlying tissue
Histopathology	Gastric biopsies	*Helicobacter* organisms	Less sensitive than cytology. Patchy distribution may also lead to false negatives. Use of silver stains increases sensitivity when organism numbers are low. Allows determination of associated gastric histopathology
Rapid urease testing	Gastric biopsies	*Helicobacter* urease	Rapid and very sensitive. Patchy distribution and low organism loads may lead to false negatives. Very rare false positives with other urease-producing organisms
Fluorescence in situ hybridization	Gastric or intestinal biopsies	*Helicobacter* DNA	Allows visualization of organisms within lesions
Polymerase chain reaction	Gastric or intestinal biopsies	*Helicobacter* DNA	Rapid (within hours), can be highly sensitive and specific. Sequence analysis can determine the species involved
Serology	Serum	Antibodies to *Helicobacter* spp.	Moderate sensitivity in dogs and cats. Results do not correlate well with gastric histopathology. Does not always correlate with active infection. Has been primarily used in research settings to date
Urea breath and blood testing	Breath, blood	Radiolabelled carbon dioxide derived from the activity of *Helicobacter* urease	Requires specialized detection equipment. Although sensitive, false negatives may occur, such as following acid suppression. In dogs and cats, has been primarily used in research settings to date.

For all tests, positive results do not imply that *Helicobacter* is the cause of disease.

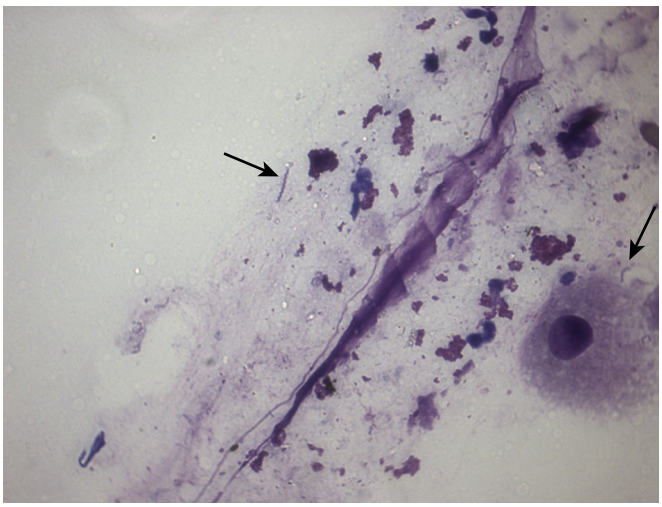

Fig. 66.4 Spiral-shaped gastric *Helicobacter*-like organisms visible in a Diff-Quik–stained smear *(arrows)* of a gastric biopsy from a 2-year-old male neutered Cavalier King Charles spaniel with chronic vomiting and regurgitation for which no other cause was apparent (1000× magnification).

therapy.[48,49] Serologic assays have been used on a research basis to noninvasively detect non-*H. pylori* helicobacter infection in dogs and cats, in some studies demonstrating moderate sensitivity and good specificity.[50-52]

Urea Breath and Blood Testing

Diagnosis and monitoring of the extent of *H. pylori* infection in human patients can also be accomplished noninvasively using urea breath and blood testing, which involves oral administration of urea that contains ^{14}C or the stable isotope ^{13}C. After ingestion, the labeled urea is converted to ammonia by *Helicobacter* urease, and the released carbon is absorbed systemically, where it can be measured in the blood. Subsequently, the labeled carbon dioxide is exhaled, and can be measured in the breath. Acid suppression may interfere with test results by decreasing *Helicobacter* urease activity, and so testing is generally performed several days after discontinuing treatment. False positives can also occur with the test.[53] Urea breath and blood testing has been used with success in dogs,[54] and breath testing has been used in cats[17,55] both before and following specific treatment for *Helicobacter* infection.

Fecal Antigen Assays

Assays detecting *H. pylori* infection in feces have been used for diagnosis in human patients[53] but their use in dogs and cats has not been described.

Pathologic Findings

Infection with non-*H. pylori* helicobacters in dogs and cats has been primarily associated with chronic lymphocytic or lymphoplasmacytic gastritis, with lymphoid follicular hyperplasia (Figs. 66.5A and 66.6A), although the extent of inflammation can vary dramatically from absent to severe.[16,56,57] Some extent of eosinophil infiltration has been described in some cats.[56] Neutrophil and eosinophil infiltrates may

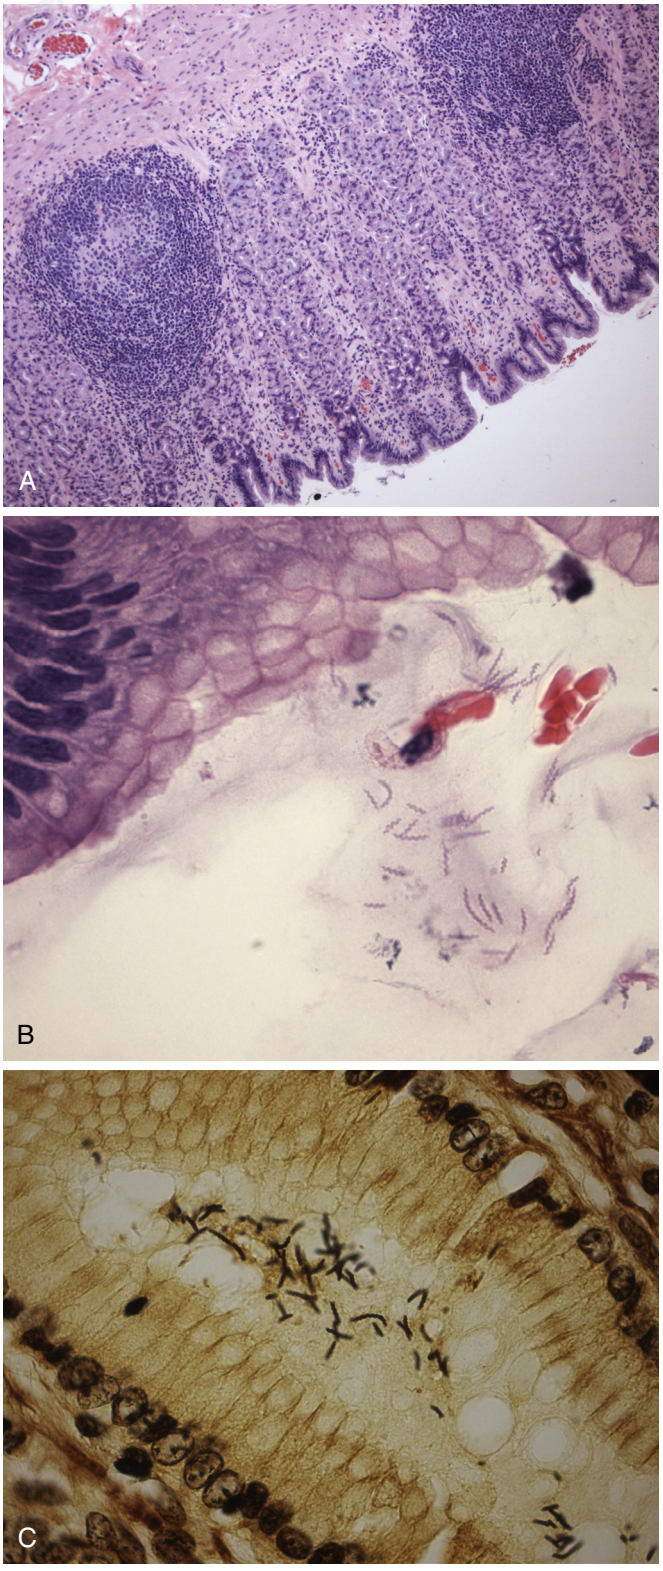

Fig. 66.5 Histopathology of the stomach of a 2-year old female spayed Maltese terrier with chronic vomiting and regurgitation. (A) Lymphoid follicular nodules. The remaining lamina propria was infiltrated by small numbers of eosinophils, neutrophils, lymphocytes, and plasma cells. H&E stain, 40× magnification. (B) Large numbers of spiral-shaped bacteria were visible in the superficial mucus and gastric glands. H&E stain, 1000× magnification. (C) Warthin-Starry stain showing agyrophilic intralesional spiral-shaped bacteria within the gastric glands (1000× magnification).

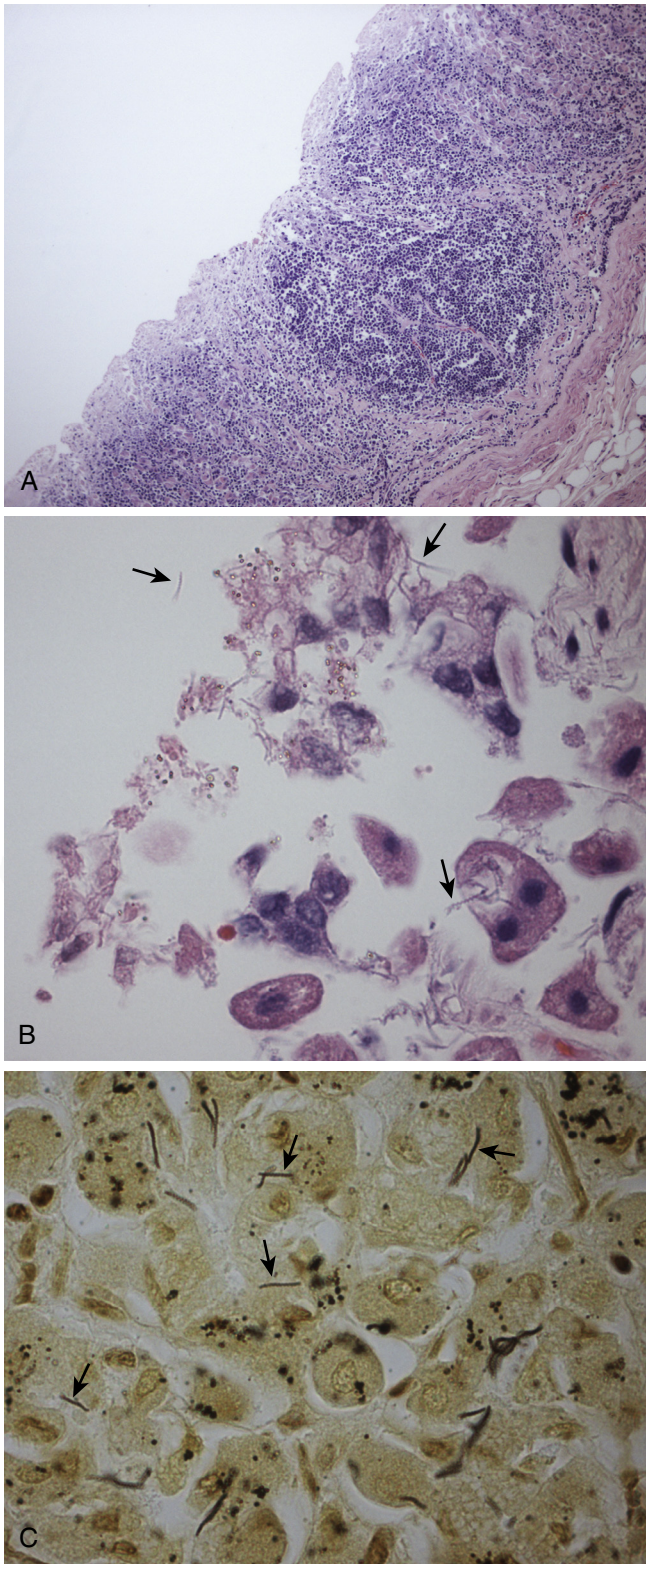

Fig. 66.6 Histopathology of the stomach of a 14-year-old male neutered domestic shorthair that was infected with feline immunodeficiency virus and was euthanized because of squamous cell carcinoma. Gastrointestinal signs were not reported. H&E stain. (A) Severe, chronic, lymphofollicular gastritis. H&E stain, 40× magnification. (B) Abundant fine, spiral-shaped bacteria were visualized in the superficial mucus and within parietal cells *(arrows)*. H&E stain. (C) Warthin-Starry stain showing intracellular agyrophilic spiral-shaped bacteria *(arrows)*; 1000× magnification.

accompany mononuclear inflammation in some cats infected with *H. pylori*.[56,58] Organisms may be found in the superficial mucus and crypts, and sometimes within parietal cells (Fig. 66.6).

Histopathologic findings in a cat infected with an intestinal helicobacter included large numbers of densely packed spiral bacteria covering the intestinal mucosa and present within the crypts, and minimal inflammatory changes. Hepatic changes in a dog with *H. canis* infection consisted of randomly distributed and coalescing hepatocellular necrosis with associated neutrophilic and mononuclear infiltrates.[41]

TREATMENT AND PROGNOSIS

Whether antimicrobial treatment should be used for gastric *Helicobacter* infections in dogs and cats is unknown. Humans with *H. pylori* infections are typically treated with a combination of a proton pump inhibitor, amoxicillin, and clarithromycin, with or without bismuth salicylate. An alternative treatment option is triple therapy with a proton pump inhibitor, fluoroquinolone (typically levofloxacin), and amoxicillin for 14 days, which is recommended when treatment failure occurs. Treatment of humans is reserved for symptomatic individuals, and the development of antimicrobial resistance by *H. pylori* is increasingly of concern.[59]

If instituted, treatment should be reserved for dogs and cats with gastrointestinal signs that have no other identifiable cause of illness, after a diagnosis of gastritis and *Helicobacter* infection has been confirmed using biopsy. A 2-week course of combination therapy with antimicrobials and a proton pump inhibitor or an H2 antagonist has not reliably eliminated gastric helicobacters in dogs and cats, although clinical signs often resolve.[29,54,60,61] It is possible that reinfection may occur in some animals after treatment. This theory is underscored by a study of 20 dogs that were naturally infected with *Helicobacter* spp. and treated with triple therapy (clarithromycin, amoxicillin, and lansoprazole) for 7 days. The dogs were then randomized into a control group, which was kept in isolation, and an experimental group, which was placed in contact with *Helicobacter*-positive dogs for 60 days. Triple therapy was effective in 100% of the dogs; however, recurrence of infection occurred in 80% of dogs in the experimental group, and in none of the dogs in the control group after 60 days.[62] A 3-week course of amoxicillin, metronidazole, and bismuth salicylate (Table 66.3) was efficacious in clearing gastric helicobacters in dogs and cats as determined using FISH, with resolution of associated vomiting, although histopathologic evidence of gastritis did not resolve.[28] Clarithromycin could be substituted for metronidazole.[18] One study showed that concurrent use of an H2 antagonist in dogs did not change outcome.[29] This is consistent with the observation that abnormalities in the gastric acid secretory axis, which occur in humans infected with *H. pylori*, do not appear to occur in dogs infected with non-*H. pylori* helicobacters.[21,30]

TABLE 66.3 Antimicrobials Used with Success to Treat *Helicobacter* spp. Infection in Dogs and Cats

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Days)
Metronidazole	11–15	PO	12	14–21
Amoxicillin	22	PO	12	14–21
Clarithromycin	5–10	PO	12	14–21
Bismuth salicylate	0.22 mL/kg	PO	6–8	14–21
Omeprazole	0.7–1.0	PO	24	14–21
Famotidine	0.5–1.0	PO	12	14–21

The first three drugs are administered as a combination. Alternatively, clarithromycin can be combined with amoxicillin and administered with either omeprazole or famotidine.

IMMUNITY AND VACCINATION

Gastric helicobacters are able to persist in the stomach despite a vigorous humoral immune response to the organism. Research has been underway to develop an effective vaccine for *H. pylori* infection in humans, and a variety of *H. pylori* antigens have been shown to induce protection in healthy human volunteers or mouse models.[63] No vaccine is available for *Helicobacter* infection in dogs and cats, and a greater understanding of the role of gastric helicobacters in canine and feline disease will be required in order to assess the need for effective vaccines against these organisms.

PUBLIC HEALTH ASPECTS

At least 50% of the world's human population is infected with *H. pylori*, although the prevalence of infection has been decreasing in developed countries.[64] In the Western world, 1 to 10% of people develop gastroduodenal ulceration as a result of chronic *H. pylori* infection. A smaller percentage of infected people (< 3%) develop gastric adenocarcinoma or MALT lymphoma in association with infection. Duodenal ulceration results from increased gastrin release in response to *H. pylori*-induced gastric antral inflammation. The factors influencing outcome are not well understood, but an individual's immune response to the organism, as well as the possession of virulence factors by *H. pylori* strains, appear to play an important role.[64] Eradication of infection using antimicrobial therapy can cure gastroduodenal ulceration and MALT lymphoma, but gastric adenocarcinoma generally persists despite treatment.[65] Although *H. pylori* has been documented to infect a colony of cats, infection of cats with this species is extremely rare and exposure to pets is not a risk factor for *H. pylori* infection in humans. However, in a 2021 study from Japan, *H. pylori* DNA was detected in two related dogs in a household as well as the owner of the dogs, and partial sequencing of the *ureAB* gene suggested the strains were identical.[11]

Non-*H. pylori* gastric helicobacter infection is uncommon in humans compared with *H. pylori* infection. Nevertheless, these helicobacters have also been associated with chronic active gastritis, gastroduodenal ulceration, and MALT lymphomas in people, although disease is generally less severe than that caused by *H. pylori*.[6] Clinical signs in humans may be absent or consist of nausea, epigastric pain, vomiting, hematemesis, heartburn, and decreased appetite. Treatment with triple antibiotic therapy and bismuth salicylate has led to resolution of infection and gastritis. Pets have been suggested as a source of these helicobacters for humans,[6,66-67] with close contact with dogs and cats being a risk factor for infection.[71] Licking has been suggested as a mode of transmission, based on the presence of non-*H. pylori* helicobacter DNA in the oral cavity of dogs.[22] Pigs are thought to play an even more important role in zoonotic transmission of non-*H. pylori* gastric helicobacters, with the swine *Helicobacter suis* being the most prevalent species identified in humans.[6]

Helicobacter cinaedi is an intestinal helicobacter associated with enteric disease and bacteremia in immunocompromised humans.[72] Although this organism has been described in dogs and cats, and nosocomial spread of *H. cinaedi* was suggested in one report,[73] further analysis of strains isolated from dogs suggested that they belonged to a distinct species, with the proposed name *Helicobacter canicola* sp. nov.[74]

CASE EXAMPLE 1

Signalment
"Mocha," 2-year-old female spayed Maltese terrier from Dixon, California.

History
Mocha had been vomiting and regurgitating intermittently since she was 1 year of age. As a puppy, the owner (a veterinary student) reported intermittent episodes of "burping." Mocha had a history of vomiting anywhere from 2 to 5 times a day. The vomiting was not associated with eating, drinking, or exercise, and occurred at random times throughout the day. The vomitus usually consisted of brown fluid and there were generally no recognizable food particles. Treatment with dietary changes that included a digestible elimination diet containing a novel, single protein source followed by a fat-restricted prescription diet had not resulted in improvement in her clinical signs. In addition, therapy with cisapride (3 mg PO q8h) and famotidine (2.5 mg PO q24h) or omeprazole (3.5 mg PO q24h) resulted in only slight improvement in the frequency of vomiting. Her appetite was appropriate and there had been no weight loss or diarrhea. She primarily lived indoors and there was a cat in the household. The dog was up to date on vaccinations, which included those for rabies, distemper, parvovirus, and canine adenovirus.

Physical Examination
Body weight: 3 kg.

General: Bright, alert and responsive, hydrated, nervous. Ambulatory on all four limbs. Temperature = 100.4°F (38.0°C), heart rate = 120 beats/min, respiratory rate 28 breaths/min, mucous membranes pink and moist, CRT = 1 s.

Integument: Full, clean hair coat.

Eyes, ears, nose, and throat: The only abnormality noticed was a left maxillary persistent deciduous canine tooth with calculus between the deciduous and adult teeth only.

Musculoskeletal: Body condition score 4/9 with symmetrical muscling.

Cardiovascular: Strong and synchronous femoral pulses. No murmurs or arrhythmias were detected.

Respiratory: Eupneic with normal breath sounds.

Gastrointestinal and genitourinary: Unremarkable abdominal palpation. "Burping" behavior was observed in the room, which occurred without any prodromal signs or abdominal effort. Lip-smacking behavior was noticed immediately afterwards.

Rectal examination: No abnormalities detected.

Lymph nodes: All within normal limits.

Laboratory Findings
CBC: HCT 46.5% (40–55%), MCV 64.4 fL (65–75 fL), MCHC 35.9 g/dL (33–36 g/dL), WBC 5,700 cells/μL (6,000–13,000 cells/μL), neutrophils 3,112 cells/μL (3,000–10,500 cells/μL), lymphocytes 1,830 cells/μL (1,000–4,000 cells/μL), monocytes 257 cells/μL (150–1,200 cells/μL), eosinophils 479 cells/μL (0–1,500 cells/μL), platelets 277,000/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: sodium 147 mmol/L (145–154 mmol/L), potassium 4.4 mmol/L (3.6–5.3 mmol/L), chloride 111 mmol/L (108–118 mmol/L), bicarbonate 23 mmol/L (16–26 mmol/L), phosphorus 5.3 mg/dL (3.0–6.2 mg/dL), calcium 10.6 mg/dL (9.7–11.5 mg/dL), BUN 22 mg/dL (5–21 mg/dL), creatinine 1.1 mg/dL (0.3–1.2 mg/dL), glucose 95 mg/dL (64–123 mg/dL), total protein 5.7 g/dL (5.4–7.6 g/dL), albumin 4.0 g/dL (3.0–4.4 g/dL), globulin 1.7 g/dL (1.8–3.9 g/dL), ALT 42 U/L (19–67 U/L), AST 45 U/L (19–42 U/L), ALP 52 U/L (21–170 U/L), GGT < 3 U/L (0–6 U/L), cholesterol 241 mg/dL (135–361 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.040, pH 7.0, no protein, glucose, or ketones, trace hemoprotein, 0–1 WBC/HPF, 0–1 RBC/HPF, moderate lipid droplets.

Serum pancreatic lipase immunoreactivity: < 30 μg/L (reference range 0–200 μg/L).

Imaging Findings
Abdominal radiographs: A moderate amount of gas was identified within multiple small intestinal loops, but an obstructive pattern was not identified. There was mildly decreased serosal detail, consistent with patient age and body condition score. A moderate amount of feces was present within the descending colon.

Thoracic radiographs: The cardiopulmonary structures were within normal limits. A small amount of gas was visualized within the esophagus on the left lateral projections.

Esophagram: Unremarkable study.

Abdominal ultrasound: No abnormalities identified.

Gastroduodenoscopy: Gross findings were suggestive of diffuse lymphoid follicular hyperplasia, with a mild "goose pimple" appearance to the gastric mucosa (Fig. 66.7). Multiple biopsies of all regions of the stomach, as well as multiple duodenal biopsies were obtained.

Stomach: Moderate, lymphofollicular, eosinophilic, and lymphoplasmacytic gastritis with intralesional spiral bacteria (see Fig. 66.5). Duodenum: mild, chronic, lymphofollicular, eosinophilic, and lymphoplasmacytic duodenitis and ileitis. Jejunum: diffuse, mild, eosinophilic, and lymphoplasmacytic enteritis.

Diagnosis
Eosinophilic and lymphoplasmacytic enteritis; chronic gastritis associated with *Helicobacter* spp. infection.

Treatment
Treatment for the *Helicobacter* infection was initiated with metronidazole (30 mg PO q12h), amoxicillin (60 mg PO q12h), and bismuth salicylate for 2 weeks. The owner reported almost complete resolution of the vomiting following treatment, but signs returned after they were discontinued and an additional course of treatment was instituted. Treatment with a fat-restricted prescription diet was continued. The frequency of vomiting has decreased to once a week.

Comments
Whether the *Helicobacter* spp. infection in this dog contributed to clinical signs or was an incidental finding in a dog with underlying eosinophilic and lymphoplasmacytic enteritis was not clear. The failure to respond to multiple diet changes, including an elimination diet, and the dramatic response to triple therapy supported a possible role for *Helicobacter* spp. infection, or a diagnosis of antibiotic-responsive gastroenteropathy unrelated to *Helicobacter* spp.

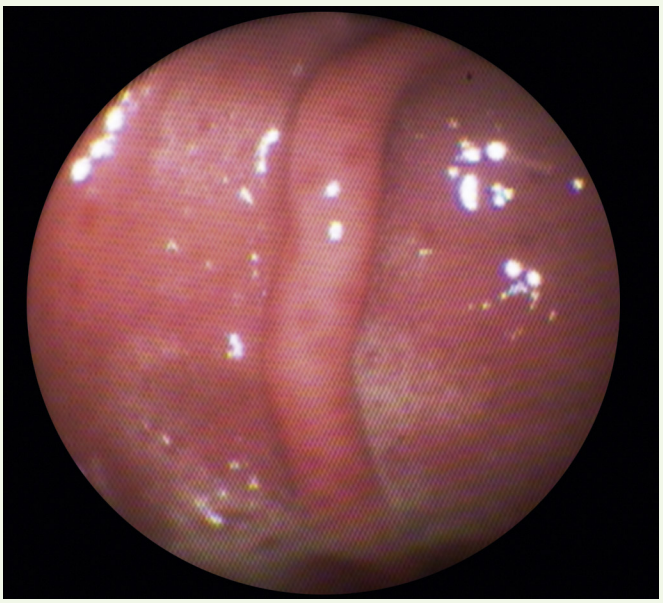

Fig. 66.7 Endoscopic image of lymphoid follicular gastritis in a 2-year-old Maltese terrier with chronic vomiting and regurgitation that was associated with the presence of large numbers of gastric *Helicobacter*-like organisms.

CASE EXAMPLE 2

Signalment

"Poppy," a 2-year-old female spayed Australian shepherd mix from northern California.

History

Poppy was evaluated at the University of California-Davis Small Animal Internal Medicine Service for a history of chronic intermittent large bowel diarrhea for the last 18 months. The diarrhea was watery to soft, and contained mucus and frank blood. Frequent straining had been noted when Poppy was attempting to defecate and only small quantities of feces were passed. Treatment with fenbendazole, metronidazole, or tylosin had resulted in temporary cessation of diarrhea, but the diarrhea returned after the medications were discontinued; during this period, tylosin treatment had been administered for 2 months. The owners noted that the diarrhea also resolved when Poppy was treated for a dog bite wound 2 months previously with cephalexin and carprofen, but returned when the drugs were discontinued 10 days later. A potato and whitefish prescription diet was fed exclusively for several months but the diarrhea persisted.

Current medications

Prescription low-fat, digestible diet; metronidazole 15 mg/kg PO q12h.

Other medical history

Poppy had been adopted as a puppy and was up to date on vaccinations.

Physical Examination

Body weight: 16 kg.

General: Bright, alert and responsive, hydrated. Ambulatory on all four limbs. Temperature = 102.1°F (38.9°C), heart rate = 96 beats/min, panting, mucous membranes pink and moist, CRT = 1–2 s.

Integument: Full, clean hair coat, no ectoparasites noted.

Eyes, ears, nose, and throat: No clinically significant abnormalities.

Musculoskeletal: Body condition score 4/9 with symmetrical muscling.

Cardiovascular: Strong and synchronous femoral pulses. No murmurs or arrhythmias were detected.

Respiratory: Eupneic with normal breath sounds.

Gastrointestinal and genitourinary: Mildly tense abdomen on abdominal palpation.

Rectal examination: No abnormalities detected.

Lymph nodes: All within normal limits.

Laboratory Findings

PCV 57%, TP 7.2 g/dL, SpG 1.042.

Serum chemistry profile: All values within reference ranges.

Vitamin B12: 764 ng/L (RR, 271–875 ng/L).

Fecal flotation: Negative for parasites.

Giardia and *Cryptosporidium* direct FA: Negative.

Imaging Findings

Abdominal ultrasound: The mesenteric lymph nodes were prominent measuring up to 8 mm in thickness. The stomach, small intestine, and colon were ultrasonographically normal with normal wall layering and thickness. The remainder of the complete abdominal ultrasound examination was within normal limits.

Gastroduodenoscopy and ileocolonoscopy: Mild hyperemia of the duodenal and colonic mucosa (Fig. 66.8A) was identified. Biopsy specimens from the stomach (9), duodenum (9), ileum (3), and colon (12) were collected for histopathology.

Histopathology Findings

Stomach: mild, chronic, lymphofollicular gastritis with luminal spiral bacteria (consistent with *Helicobacter* spp.)

Duodenum and ileum: Moderate, acute neutrophilic, and eosinophilic enteritis with mild central lacteal dilation.

Colon: Severe, acute neutrophilic, and eosinophilic colitis with epithelial necrosis, crypt hyperplasia, and abundant beaded bacteria (Fig. 66.8B). The luminal surface and mucosal crypts contained large numbers of thin beaded bacterial rods that did not stain with Brown and Brenn stain. Silver staining highlighted the bacteria and identified small numbers of bacteria within mucosal epithelial cells (Fig. 66.8C). These bacteria were frequently curved, and occasionally a spiral structure was discernable. Based on the number of bacteria and the associated damage and inflammation within the mucosa, these bacteria are likely to be the cause of pathology.

Fecal enteric panel: Direct smear: rare, wavy, gram-negative rods. Negative for *Clostridioides difficile* toxins type A and B by enzyme immunoassay, *Clostridium perfringens* enterotoxin type A by immunoassay, no *Salmonella* spp. cultured. No *Campylobacter* spp. cultured. Anaerobic culture: moderate numbers of *Clostridium sordellii*, small numbers of *Fusobacterium* spp.

FISH (Simpson Laboratory, CVM, Cornell University) (colonic biopsy specimen): With a eubacterial probe, in multiple regions there were adherent and

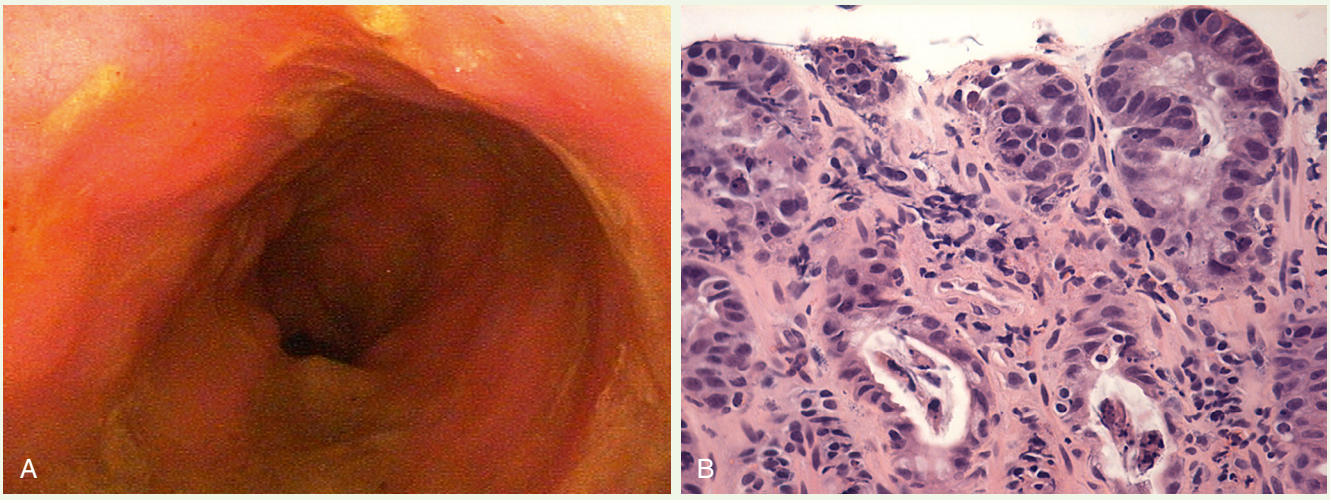

Fig. 66.8 (A) Endoscopic image of colitis in a 2-year-old Australian cattle dog with chronic intermittent large bowel diarrhea that was associated with neutrophilic and eosinophilic colitis with large numbers of intralesional spiral-shaped bacteria. (B) Histopathology image of a colonic biopsy showing neutrophilic and eosinophilic colitis (hematoxylin & eosin stain, 40× magnification). (A, Courtesy University of California-Davis Small Animal Internal Medicine Service; B, courtesy University of California-Davis Veterinary Anatomic Pathology Service.)

Continued

CASE EXAMPLE 2—cont'd

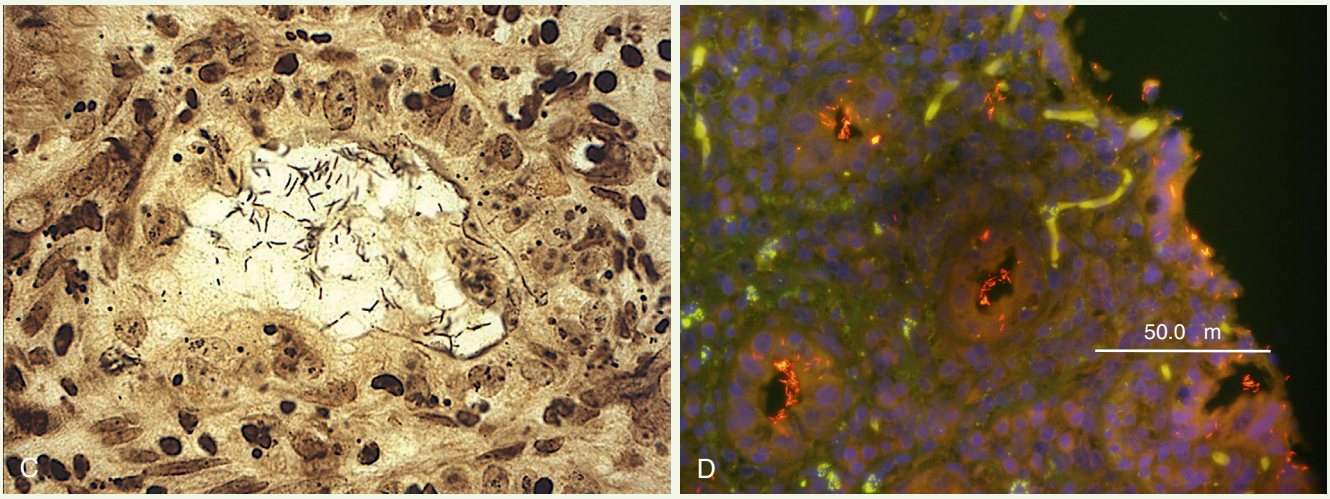

Fig. 66.8, cont'd (C) Warthin-Starry stain. There are numerous spiral-shaped bacteria within crypts (100× magnification). (D) FISH using a *Helicobacter* spp.-specific probe. The bacteria stain red with the probes and can be seen within crypts and the crypt epithelium, and adherent to colonic mucosa. (C, Courtesy University of California-Davis Veterinary Anatomic Pathology Service; D courtesy the Simpson Laboratory, Cornell University College of Veterinary Medicine.)

invasive bacteria that ranged from fat rods to long and slender to variegated/beaded rods within crypts that were invading the crypt epithelium. When a *Helicobacter* spp. probe was applied, fluorescence was associated with masses of bacteria within the crypts that were also invading the crypt epithelium and areas adjacent to the crypts (Fig. 66.8D).

Helicobacter spp. PCR-Sequencing (University of California-Davis molecular core facility) (colonic biopsy specimen): A 400-base pair amplicon was amplified with a *Helicobacter*-specific 16S rRNA gene PCR assay. When sequenced, the amplicon had 100% sequence identity to the 16S rRNA gene of *Helicobacter bilis* and 99% sequence identity (two base pair mismatches) to that of *H. canis*.

Diagnosis

Neutrophilic and eosinophilic colitis, likely secondary to infection by a *H. bilis*–like organism.

Treatment

Amoxicillin (19 mg/kg PO q12h) and enrofloxacin (8.5 mg/kg PO q24h) for 30 days. Treatment was associated with resolution of the diarrhea for 3 years. However, 3 years later Poppy was seen for acute onset of large bowel diarrhea, vomiting, and decreased appetite, and was found to have panhypoproteinemia (albumin 2.8 g/dL, globulin 1.4 g/dL). A serum cobalamin concentration and adrenocorticotropic hormone stimulation test were normal. The owner declined additional endoscopic biopsies and she was treated with another course of amoxicillin and enrofloxacin for 30 days, as well as a hydrolyzed protein diet. Her clinical signs resolved and at recheck appointments over the following 3 months, her hypoproteinemia resolved. A diagnosis of food-responsive enteropathy was made.

Comments

This was an unusual case of *Helicobacter*-associated colitis where disease association was implied by large numbers of curved to spiral-shaped organisms invading the mucosa together with inflammation, and a long-lasting response to antimicrobial therapy as the sole therapy. In addition to *Helicobacter* spp., differential diagnoses for the curved to spiral bacteria were *Campylobacter* spp., *Arcobacter* spp., *Anaerobiospirillum* spp., and *Brachyspira* spp. (see Chapter 67). Use of the FISH assay allowed specific identification of *Helicobacter* spp. within lesions. An alternative treatment would have been to use clarithromycin or azithromycin together with amoxicillin.

Interestingly, there was evidence of a similar inflammatory response (eosinophils and neutrophils) in the ileum in the absence of large numbers of bacteria. Because this dog developed clinical signs of a protein-losing enteropathy 3 years later, it is possible that the dog had a slowly progressive preexisting inflammatory bowel disease that predisposed it to *Helicobacter* spp. infection. However, at the time of diagnosis of helicobacteriosis, there was no evidence of hypoproteinemia, so the clinical expression of disease at each time point differed.

Miscellaneous Enteric Bacterial Infections

Jane E. Sykes

KEY POINTS

- Several bacterial species have been implicated in gastrointestinal disease with or without extraintestinal disease in dogs and cats, but have uncertain clinical significance or are uncommon to rare.
- *Anaerobiospirillum* spp., *Brachyspira* spp., and *Arcobacter* spp. are fastidious spiral bacteria that can be found in the intestinal tracts of healthy dogs and cats. They resemble *Campylobacter* spp. and *Helicobacter* spp. and some species have been reported to cause diarrhea and extraintestinal disease in humans. Their association with diarrhea in dogs and cats is unclear. There are rare reports of disease associated with *Anaerobiospirillum succiniciproducens* in dogs and cats.
- *Shigella* spp. is a nonmotile gram-negative bacteria that is one of the leading causes of bacterial diarrhea in humans worldwide. It can uncommonly cause subclinical infection in dogs and has not been reported to infect cats.
- *Pleisiomonas shigelloides* is a motile gram-negative bacterial pathogen that can cause gastrointestinal illness in humans (large-bowel diarrhea and vomiting). Risk factors for infection are consumption of raw or undercooked shellfish, traveling to tropical destinations, or exposure to reptiles and tropical fish. *Lawsonia intracellularis* is a gram-negative obligately intracellular bacteria that causes proliferative enteropathy in pigs and occasionally other species. These organisms have rarely been isolated from the feces of healthy and diarrheic dogs and cats; whether they cause diarrhea in dogs and cats is uncertain.
- *Clostridium piliforme* is a filamentous, spore-forming, motile, gram-negative rod that causes Tyzzer's disease in a variety of animal species, most commonly rodents and rabbits. Tyzzer's disease is an acute necrotizing enterocolitis that may also be associated with hepatitis and myocarditis. Rare cases in dogs and cats typically occur in puppies and kittens with concurrent viral diseases or animals that are immunosuppressed for other reasons.

This chapter covers miscellaneous enteric bacterial species that have been associated with disease in dogs and cats, or that have been isolated from the gastrointestinal tract of healthy dogs and cats but are associated with disease in humans. Pathogens covered are *Anaerobiospirillum* spp., *Arcobacter* spp., *Brachyspira* spp., *Shigella* spp., *Pleisomonas shigelloides*, *Lawsonia intracellularis*, and *Clostridium piliforme*. *Anaerobiospirillum succiniciproducens*, *Arcobacter* spp., and *Brachyspira pilosicoli* should be considered along with *Campylobacter* spp. and *Helicobacter* spp. in animals with disease caused by spiral or curved bacteria.

Anaerobiospirillum spp.

Anaerobiospirillum spp. are motile, gram-negative spiral-shaped anaerobic bacteria that are considered to be normal fecal flora of dogs and cats, but not humans. They have been reported to cause diarrhea, bacteremia, or prosthetic joint infections in humans, especially *A. succiniciproducens*[1-4] and to a lesser extent, *Anaerobiospirillum thomasii*.[5,6] Some affected humans have reported no history of animal contact.[7]

No significant statistical correlation has been found between the presence or absence of diarrhea in dogs or cats and infection with *Anaerobiospirillum*.[8] However, organisms closely related to *A. succiniciproducens* were identified in intestinal lesions of six cats with ileocolitis.[9] *Anaerobiospirillum succiniciproducens* was identified in peritoneal fluid of a dog with septic peritonitis,[10] and the sternal lymph node of a cat with ileocolic B-cell lymphoma.[11] In the latter case, the sternal node was markedly enlarged, and organisms were visible together with pyogranulomatous inflammation on cytological examination of a fine-needle aspirate. *Anaerobiospirillum* spp. resemble *Campylobacter* spp. and *Helicobacter* spp. using light microscopy and Gram staining, but do not grow on media for *Campylobacter* spp. and have a corkscrew-like motility as a result of a unique tuft of multiple flagella at one pole (lophotrichous morphology).[12] The organism can be identified using 16S rRNA gene broad-spectrum PCR and sequencing[11] or MALDI-TOF mass spectrometry.[4] It is generally resistant to metronidazole and clindamycin, variably susceptible to penicillin, but susceptible to beta lactam-beta lactamase inhibitors (e.g., clavulanic acid-amoxicillin), fluoroquinolones, carbapenems, and third-generation cephalosporins.[7]

Arcobacter spp.

Arcobacter spp. are gram-negative, motile, aerotolerant, spiral-shaped bacteria that are thought to be a cause of diarrhea, endocarditis, bacteremia, and peritonitis in humans. They can be found in feces of humans and other animals, as well as food products (especially poultry, pork, and beef), and other environmental sources.[5,13] *Arcobacter* spp. have been identified in the feces and saliva of dogs[14,15] and the oral cavity of cats,[16] but have not been reported in association with disease in dogs or cats.

Brachyspira spp.

Brachyspira spp. are flagellated, slow-growing, gram-negative spirochetes found in the large intestinal tract and feces of a variety of animal species, including humans, nonhuman primates, dogs, pigs, and avian species. The genus includes 16 species, some previously known as *Serpulina* spp. or *Treponema* spp.[17] *Brachyspira pilosicoli* and *Brachyspira hyodysenteriae* are established pathogens of pigs, causing porcine colonic spirochetosis and swine dysentery, respectively.

Brachyspira pilosicoli also causes disease in poultry (avian intestinal spirochetosis). *Brachyspira pilosicoli* and *Brachyspira aalborgi* have been reported as a cause of human intestinal spirochetosis (HIS), especially in immunocompromised individuals, although the association of *B. aalborgi* with disease is more tenuous.[18-21] In severe cases, large numbers of spirochetes can be seen using light microscopy attached to the luminal aspect of the colonic epithelium, creating a "false brush border."[18] The organisms can be visualized more readily using Warthin-Starry stains. Because of the slow growth of *B. pilosicoli* in culture, specialized selective media are generally required for isolation.[21]

Several *Brachyspira* species have been detected in healthy and diarrheic dogs, including *B. pilosicoli*, *Brachyspira canis*, *Brachyspira intermedia*, and *Brachyspira alvinipulli*.[22-24] In one study of dogs from Spain, *Brachyspira* spp. were detected using PCR in the feces of 41 (13%) of 311 dogs, including *B. pilosicoli* (5%), *B. canis* (8%), and one *B. intermedia*-like organism. Infection with *B. pilosicoli* was significantly associated with diarrhea, and dogs were more likely to be infected with *B. pilosicoli* if they were under one year of age.[24] However, because of intestinal adherence, spirochetes are not shed in formed feces of dogs and cats, and during large-bowel diarrheal episodes, especially in puppies, they dislodge from the epithelia and appear in large numbers in feces. Therefore a higher prevalence of detection of spirochetes in diarrheic stool does not necessarily imply disease causation. However, diarrheic dogs have been described where large numbers of organisms have been found in association with colonic mucosal lesions.[25,26] An SPF beagle pup with a history of chronic diarrhea and concurrent giardiasis had suspected colonic spirochetosis.[25] The treatment of choice in human patients with HIS is metronidazole for 10 to 14 days.[18,21] Routine disinfectants are sufficient to inactivate *Brachyspira* spp. in the environment.[27]

Shigella spp.

Shigella is a genus of nonmotile gram-negative bacteria that are morphologically indistinguishable from other enterobacteria and cause bacillary dysentery in apes and humans. On the basis of biochemical and serologic properties, *Shigella* are divided into four species: *Shigella dysenteriae, Shigella flexneri, Shigella boydii*, and *Shigella sonnei*. Each group is further divided into numerous subserotypes that vary in pathogenicity. Shigellae are not as environmentally resistant as salmonellae; they survive best in dried fecal matter on cloth that is kept in a dark, moist place. Because of their short survival time, the carrier host is most important in maintaining these organisms in nature. Dogs may become infected after contamination of their food or water supplies with infected human feces. Because of their coprophagous habits, some pets may become exposed in areas with improper sewage disposal. Dogs only transiently excrete the organisms. Cats have not been reported to be naturally infected.

Shigella spp. produce diarrhea by intestinal epithelial cell invasion and production of Shiga toxin (see also Shiga toxin–producing *Escherichia coli*, Chapter 63). Systemic manifestations of the toxin in infected humans include DIC with renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. In primates the organism causes severe hemorrhagic, mucoid, large-bowel diarrhea. Lesions are usually ulcerative, and they spread from the distal to the proximal colon with time. In children and (although rarely) in adults, bacteremia may develop with or without diarrhea. Organisms have been isolated from a small number of clinically normal dogs, but they have not been directly implicated as a cause of diarrhea in this species.

Plesiomonas shigelloides

Plesiomonas shigelloides is a motile, gram-negative, rod-shaped facultatively anaerobic bacteria in the family Vibrionaceae. In humans, infection can result in diarrhea that can vary from mildly self-limiting to diarrhea that is severe and has a bloody mucoid consistency. Bacteremia, which can result in embolic spread to many organs, generally occurs in immunocompromised humans. Human infection usually follows consumption of poorly cooked or uncooked shellfish, but can also occur in individuals traveling to tropical regions and following exposure to reptiles and tropical fish. Feeding of fish, shellfish, or aquatic foodstuffs to dogs or cats may be a source for infection.[28]

Diarrheic illness has sometimes been attributed to *P. shigelloides* in dogs and cats.[29,30] However, the organism has rarely been reported in the feces of healthy dogs and cats.[31-33] Given this and the lack of evidence for an association with diarrhea, should the organisms be found in the feces of a diarrheic dog or cat, other diagnoses should be considered.

Lawsonia intracellularis

Lawsonia intracellularis is a gram-negative, anaerobic, obligate intracellular bacterium that occupies the distal portion of the small intestine of a variety of animal species. *Lawsonia intracellularis* infection has been associated with acute and chronic proliferative enteropathies in pigs[34] and other species.[35,36] There are rare reports of its detection using molecular methods in dogs with and without enteropathies.[37-41] As with *P. shigelloides*, its clinical significance in dogs remains unclear.

Clostridium piliforme

Clostridium piliforme causes *Tyzzer's disease*, a bacterial disease that occurs in a variety of mammalian and avian species including dogs and cats. Rodents and rabbits are most often affected. It is a long (0.5 μm × 10 to 40 μm), filamentous, spore-forming, gram-negative obligate intracellular bacterial species that moves by means of peritrichous flagella. Clinical disease in rodents appears to be precipitated by stress, such as crowding, unsanitary conditions, weaning, or transportation and irradiation, concurrent infections, glucocorticoid therapy, or other forms of immunosuppression.

The organism is ingested and replicates in the ileocecocolic region; with host immunocompromise, systemic dissemination can occur, with necrotizing enterocolitis, hepatitis, and myocarditis. Reports of spontaneous disease in dogs and cats have been described, usually in puppies and kittens and often in association with co-infections such as canine distemper virus infection or feline panleukopenia virus infection.[42-46] One group of affected kittens had familial lipoprotein lipase deficiency and were persistently lipidemic.[47]

Affected dogs and cats typically have rapid onset of lethargy, depression, anorexia, and abdominal discomfort. Hepatomegaly and abdominal distention are followed by hypothermia, with the animal becoming moribund very rapidly, with death within 24 to 48 hours. Diarrhea may not be evident. Icterus has been apparent in some animals, especially cats.

Because of the rapidly fatal course of Tyzzer's disease, diagnosis is usually made at necropsy. Laboratory abnormalities that may be apparent before death include bandemia with neutrophil toxicity, lymphopenia, hypoalbuminemia, and moderate to severe increases in the activity of serum liver enzymes. Characteristic findings at necropsy are multiple whitish-gray to hemorrhagic foci, 1 to 2 mm in diameter, on the capsule and cut surface of the liver. Similar lesions may be apparent on other viscera. The intestinal mucosa may be thickened and congested in the region of the terminal ileum and proximal colon.

Histologic findings usually include multifocal periportal hepatic necrosis with or without necrotic enterocolitis; other tissues, such as the myocardium, may be affected in some animals. Infiltrates of neutrophils and mononuclear cells are usually present at the margins of necrotic lesions. Numerous intracellular filamentous organisms are only faintly visible by

H&E stain in the hepatocytes at the margins of necrotic lesions and in the intestinal epithelial cells. Special stains such as Giemsa stain or Warthin-Starry or Gomori silver stain must be used to confirm the morphology of the organisms, which have a characteristic beaded appearance in a "pick-up sticks" arrangement (Fig. 67.1). Immunochemical stains can also be used to detect specific antigens of *C. piliforme*.[43] Nucleic acid hybridization or PCR can be used to demonstrate organism-specific nucleic acid in tissues.[48] *Clostridium piliforme* cannot be isolated on cell-free medium and so far has been cultured only in eggs or cell cultures.[49] Because *C. piliforme* can be found in the feces of clinically healthy animals, care should be taken not to make a diagnosis of Tyzzer's disease based on a positive result from feces or intestinal specimens alone.

Treatment of Tyzzer's disease has not been reported in dogs or cats, because diagnosis has always been made at necropsy, and infection tends to be overwhelming and associated with rapid mortality. Antibacterial efficacy is undetermined. In naturally infected foals, successful antibacterial treatment has been reported using ampicillin, aminoglycosides (amikacin or gentamicin), or penicillin.[48] Aggressive parenteral fluid therapy was also used. Prevention in puppies and kittens involves reducing factors such as overcrowding, unsanitary conditions, and poor nutrition.

Infection with *C. piliforme* has only been reported once in a person in 1996, and manifested as chronic verrucous cutaneous lesions in association with HIV–acquired immunodeficiency syndrome.[50] The source of infection of this person was not determined. Because transmission of the disease between hosts appears uncommon and the disease is so rare, cats and dogs would be expected to be an unlikely source of infection for humans.

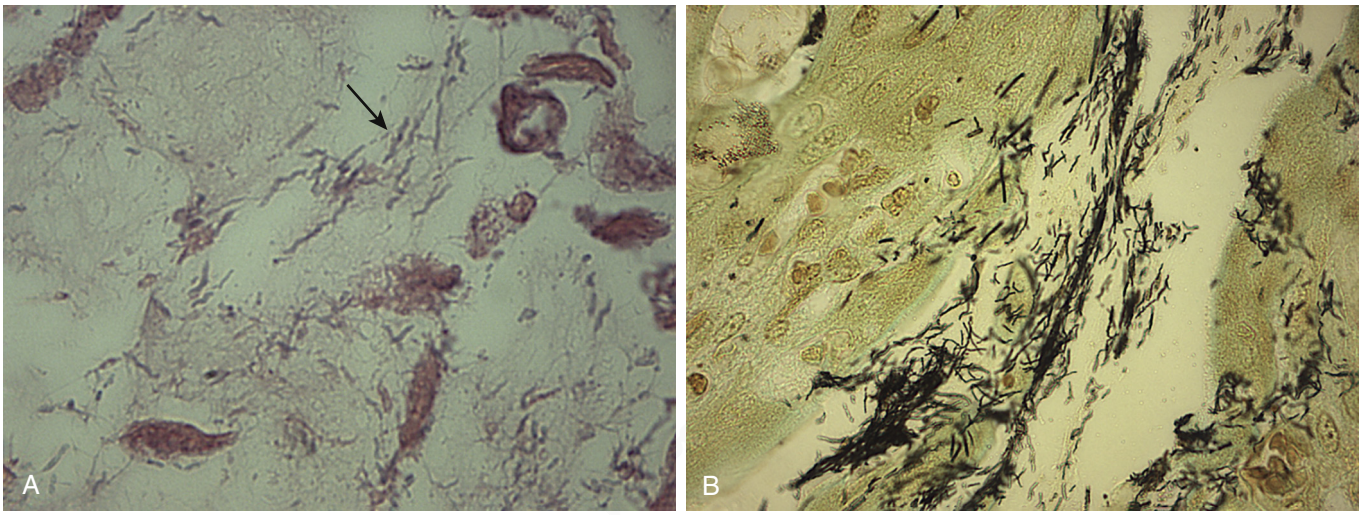

Fig. 67.1 Histopathology images of *Clostridium piliforme* enterocolitis (Tyzzer's disease) in a 5-week-old intact male domestic shorthair kitten that had a 3-day history of mucoid hemorrhagic diarrhea, inappetence, lethargy, and weight loss. A parvovirus fecal antigen test was negative. (A) Large numbers of pale basophilic filamentous rods *(arrow)* can be seen in the lumen of the colon. Hematoxylin and eosin stain, 1000× magnification. (B) The bacteria stain black with Warthin-Starry stain, demonstrating the characteristic "pick-up sticks" appearance that occurs with Tyzzer's disease. CASE EXAMPLE

Signalment:
"Callie," a 10-year-old female spayed Brittany spaniel from northern California.

History:
Callie was seen by the University of California-Davis Small Animal Emergency and Critical Care Service for a 10-day history of progressive lethargy, intermittent vomiting, and bleeding from the mouth. The oral bleeding began the day before the examination and was thought to be precipitated by a vomiting episode when Callie bit her cheek and had continued since then. Callie had shown no interest in food for the last 24 hours and had some intermittent yellow diarrhea. Two months previously, Callie had been diagnosed with IMHA/ITP which was initially detected as an incidental finding on routine bloodwork. At that time, her platelet count was < 5,000 platelets/μL, she had a hematocrit of 34% with 638,900 reticulocytes/μL, and neutrophilia (16,640 cells/μL), bandemia (208 cells/μL) and hypoalbuminemia were present (2.6 g/dL; RR, 2.8–4.2 g/dL). Thoracic radiographs were unremarkable, and the only finding on abdominal ultrasound examination was a slightly small liver. No spherocytes were seen, Coombs' test was negative, an antinuclear antibody test was negative, and an antimegakaryocyte antibody test on a bone marrow aspirate was negative. Cytologic examination of bone marrow showed mild myeloid hyperplasia and moderate megakaryocyte and erythroid hyperplasia. She was treated with prednisone, 1.25 mg/kg PO q12h as well as famotidine and sucralfate. Two weeks later, because the platelet count had not increased and she was experiencing significant adverse effects of prednisone administration, she was also treated with azathioprine for 2 weeks (2.5 mg/kg PO q48h), then cyclophosphamide (200 mg/m^2 PO, once), then cyclosporine for 2 weeks, and her prednisone dose was reduced.

Current medications:
Prednisone 0.6 mg/kg PO q12h; cyclosporine (5 mg/kg PO q12h), famotidine (0.5 mg/kg PO q24h), sucralfate (1 g PO q8h), levothyroxine (0.01 mg/kg PO q24h), monthly heartworm prophylaxis.

Other medical history:
Callie had been diagnosed with hypothyroidism several years previously and was well managed with levothyroxine.

Continued

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 19.8 kg.

General: Severely obtunded, 5% dehydrated, nonambulatory. Mucous membranes pink and tacky, CRT 4 s, T = 104.5°F (40.3°C), P = 160 beats/min, R = 60 breaths/min, BCS 4/9.

Integument: Full clean haircoat. Fresh blood was identified around the mouth as a result of buccal bleeding, and there were multiple ecchymoses on the ventral abdomen and around the eyes.

Eyes, ears, nose, and throat: Bilateral epistaxis was identified with normal nasal airflow. Multiple ulcers were identified in the oral cavity, and there was evidence of mild periodontal disease.

Musculoskeletal: Moderate peripheral muscle atrophy, especially in the pelvic limbs.

Cardiovascular: Grade III/VI left systolic heart murmur, sinus tachycardia.

Respiratory: Mildly increased lung sounds.

Gastrointestinal and genitourinary: No clinically significant abnormalities. Rectal examination revealed melena.

Lymph nodes: All < 1 cm in diameter.

Laboratory Findings

CBC: HCT 29.7% (40–55%), MCV 74 fL (65–75 fL), MCHC 31.6 g/dL (33–36 g/dL), WBC 9310 cells/μL (6000–13,000 cells/μL), neutrophils 6587 cells/μL (3000–10,500 cells/μL), bands 1405 cells/μL (slight toxicity), lymphocytes 351 cells/μL (1000–4000 cells/μL), monocytes 176 cells/μL (150–1200 cells/μL), eosinophils 263 cells/μL (0–1500 cells/μL), platelets 8,000 platelets/μL (150,000–400,000 platelets/μL), mean platelet volume 7.5 fL (7–13 fL), reticulocytes 90,000/μL, nucleated RBC 6 cells/μL.

Serum chemistry profile: Sodium 142 mmol/L (145–154 mmol/L), potassium 4.9 mmol/L (3.6–5.3 mmol/L), chloride 103 mmol/L (108–118 mmol/L), bicarbonate 14 mmol/L (16–26 mmol/L), phosphorus 5.8 mg/dL (3.0–6.2 mg/dL), calcium 8.7 mg/dL (9.7–11.5 mg/dL), BUN 20 mg/dL (5–21 mg/dL), creatinine 1.1 mg/dL (0.3–1.2 mg/dL), glucose 97 mg/dL (64–123 mg/dL), total protein 3.7 g/dL (5.4–7.6 g/dL), albumin 1.7 g/dL (3.0–4.4 g/dL), globulin 2.0 g/dL (1.8–3.9 g/dL), ALT 1902 U/L (19–67 U/L), AST 489 U/L (19–42 U/L), ALP 1548 U/L (21–170 U/L), GGT 229 U/L (0–6 U/L), cholesterol 163 mg/dL (135–361 mg/dL), total bilirubin 2.0 mg/dL (0–0.2 mg/dL).

Urinalysis (postfluid bolus): SpG 1.024; pH 7.5, 2+ protein (SSA), 1+ bilirubin, 1+ hemoprotein, no glucose, 15–25 WBC/HPF, 2–5 RBC/HPF, 0–3 granular cases/HPF, many bacterial rods.

Aerobic bacterial urine culture: *Escherichia coli*, susceptible to amoxicillin-clavulanic acid, cephalexin, and enrofloxacin but resistant to amoxicillin and trimethoprim-sulfamethoxazole.

Treatment

Callie was treated for shock with aggressive fluid therapy, supplemental oxygen, and intravenous broad-spectrum antimicrobial drugs. However, she became progressively more obtunded and vomited multiple times. Epistaxis and additional cutaneous ecchymoses were noted. An activated clotting time was 163 s (normal < 75 s) and blood lactate was 9.0 mmol/L (normal < 2.5 mmol/L). The owner elected euthanasia.

Necropsy Findings:

A cosmetic necropsy was performed. Grossly, the main findings were multifocally extensive areas of ecchymoses and petechiation over the distal pelvic limbs extending into the inguinal region and caudal abdomen. The perineal region was stained with tarry fecal material. The liver was markedly enlarged and pale tan with a prominent reticular pattern and numerous pinpoint red foci. There was extensive serosal and mucosal petechial hemorrhage throughout the entire length of the intestinal tract. Histopathology revealed a severe, multifocal, acute, necrotizing hepatitis with numerous intrahepatocellular filamentous rod-shaped bacteria consistent with infection by *Clostridium piliforme*. No enterocolitis was identified, the melena likely being associated with microvascular hemorrhage.

Diagnosis

Tyzzer's disease.

Comments

Reported cases of Tyzzer's disease in dogs and cats in the literature have been puppies or kittens, often with co-infections (distemper, panleukopenia virus). This case was unusual in that it was an adult dog treated with immunosuppressive drugs for suspected primary immune-mediated thrombocytopenia and anemia. A whole blood cyclosporine concentration was obtained before euthanasia and was 280 ng/mL, in the range recommended for initial immunosuppression. The use of multiple different immunosuppressive drugs in sequence may have been a factor that predisposed to Tyzzer's disease. The *E. coli* lower urinary tract infection may also have occurred secondary to treatment with prednisone.

Leptospirosis

Simone Schuller, George E. Moore, Jane E. Sykes

KEY POINTS

- First Described: Heidelberg, Germany, 1886 (Adolf Weil).[1]
- Cause: *Leptospira* spp. (a spirochete bacterial pathogen, phylum Spirochaetes).
- Affected Hosts: Dogs, rarely cats, more than 150 other mammalian species.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Fever, lethargy, reluctance to move, anorexia, polyuria and polydipsia, vomiting, diarrhea, icterus, abnormal respiratory function.
- Major Differential Diagnoses: Nephrotoxicoses (e.g., NSAIDs, grapes and raisins, ethylene glycol), Lyme nephritis, acute glomerulonephritides, bacterial pyelonephritis, cholangiohepatitis, acute pancreatitis, canine monocytic ehrlichiosis, Rocky Mountain spotted fever, bacterial sepsis, leishmaniosis.
- Human Health Significance: Zoonosis. Human infection results from direct or indirect contact with contaminated urine. Mild influenza-like illness to severe illness with multiorgan failure (Weil's disease) have the potential to occur.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Leptospirosis is a zoonotic disease of worldwide significance affecting most mammalian species. It is caused by infection with spirochetes of the genus *Leptospira*. *Leptospira* spp. are thin, flexible, motile, spiral-shaped bacteria with hook-shaped ends, measuring 0.1 µm in width and 6 to 12 µm in length (Fig. 68.1). The organism owes its name to this specific morphology (*leptos* = "thin," *spira* = "coil"; *interrogans* = "question mark shape"). Leptospires are gram negative and have a double membrane structure consisting of cytoplasmic and outer membranes enclosing the periplasmic space. *Leptospira* are motile due to two periplasmic endoflagellae, which are inserted subterminally and wrapped around an internal protoplasmic cylinder. The leptospiral outer membrane contains LPS, multiple antigenic lipoproteins (e.g. LipL21, LipL32, LipL36, LipL41) and integral transmembrane proteins (e.g., porin OmpL1), and secretins (e.g., GspD).[2] Despite intensive research, the function of the majority of these proteins is incompletely understood. For example, much research has been conducted to show a relationship of LipL32, a major outer membrane protein present only in pathogenic *Leptospira* species, with clinical illness. However, pathogenic lesions with LipL32 mutants were indistinguishable from those produced with wild-type infections.[3]

Leptospira species have been grouped into pathogenic (group I, of which there are nine), intermediately pathogenic (group II, of which there are five), and six saprophytic species based on their 16S rRNA gene sequences. Saprophytic leptospires, such as *Leptospira biflexa*, grow at lower temperatures (11°C to 13°C) and in the presence of 8-azaguanine. These cultural criteria can be used to differentiate them from pathogenic leptospires, which have their growth optimized at 28°C to 30°C. More extensive phenotypic criteria commonly used for further subclassification of bacteria such as chemical properties and activities are largely unsuitable for *Leptospira*. Before the development of molecular typing methods, further subclassification was therefore almost exclusively based on serologic techniques.[2] Serovars are distinct by differences in their LPS antigens, which can be detected by specific monoclonal antisera. More than 250 serovars of *Leptospira interrogans* have been described and further classified into antigenically related serogroups. The term "serogroup" refers to serovars that share common antigens that often lead to serologic cross-reactions. Although serogroups currently have no taxonomic basis, they have been historically useful for epidemiologic tracking and understanding of the disease.[4] Each serovar is adapted to one or more wild or domestic animal reservoir host species (e.g., Icterohaemorrhagiae and rats, Ballum and mice), although molecular typing methods have revealed that there may be tighter associations between different sequence types (STs) and specific reservoir host species. The arrival of molecular typing methods has introduced further complexity, as serovars within the same serogroup can belong to multiple different *Leptospira* species (different species but similar LPS antigens). For example, serovars within the serogroup Grippotyphosa can be found in both *L. interrogans* and *Leptospira kirschneri*[5] (Table 68.1).

Leptospira spp. have a complex life cycle inside and outside of the host. Host-adapted serovars colonize the kidneys of infected wild and domestic mammalian *reservoir hosts* which shed leptospires in their urine. *Incidental hosts* become infected either by direct contact with infected urine, ingestion of reservoir hosts, or indirectly through exposure to contaminated water or soil. Lacking co-evolutionary adaptation, infected incidental hosts develop more severe clinical illness and shed organisms for shorter periods than reservoir hosts.

Pathogenic *Leptospira* spp. are readily inactivated in the environment when exposed to excessive heat, ultraviolet radiation, desiccation, a variety of disinfectants, and freezing conditions. Their association with stagnant water may relate to inactivation by mechanical damage, although cases have occurred after exposure to rapidly moving water sources such as waterfalls and following white-water rafting. However, in moist, warm, and neutral or slightly alkaline pH conditions, pathogenic leptospires can survive for weeks to months and successfully infect new hosts.[6] Current evidence suggests that leptospires do not multiply in the environment. They can be detected using molecular methods in water sources, but a number of studies have found them more prevalent in soil from the same geographic region. When conditions are optimal, it appears they can survive weeks

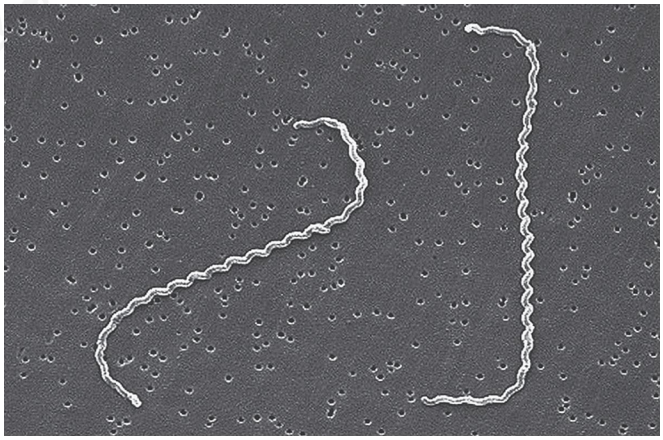

Fig. 68.1 Scanning electron micrograph of *Leptospira* spp. spirochetes showing helical structure and curved (hooked) ends (original magnification ×60,000). (Courtesy of Rob Weyant, Centers for Disease Control and Prevention.)

TABLE 68.1 Selected Serovars of *Leptospira interrogans* and *Leptospira kirschneri* that Infect Dogs*

Species	Serogroup	Serovar
Leptospira interrogans	Icterohaemorrhagiae	Icterohaemorrhagiae
	Canicola	Canicola
	Pomona	Pomona
	Australis	Bratislava
	Sejroe	ND
	Ballum	Ballum
Leptospira kirschneri	Grippotyphosa	Grippotyphosa

*Isolated from dogs with naturally occurring leptospirosis, or that induce disease in dogs after experimental inoculation.
ND, not determined.

to months in water-saturated soil.[7] The ability of leptospires to survive in the environment under different conditions appears to be somewhat strain dependent. One study showed that *L. kirschneri* serovar Grippotyphosa could survive 1 hour to 3 days (although generally up to 4 hours) in dog or cattle urine that had been diluted with distilled water or phosphate-buffered saline, but was unable to survive even for periods as short as 1 minute in undiluted dog urine (pH 5.8) and undiluted cow urine (pH 8.4) (across a range of temperatures from 15°C to 37°C); another study showed survival of *L. interrogans* serovar Hardjo in undiluted cow urine for 0 to 6 hours; survival was again promoted by dilution of the urine.[8]

Reservoir Hosts

Worldwide, small rodents are considered the most important reservoir hosts of pathogenic *Leptospira* spp. However, it is likely that every known mammalian species, including humans, and even reptiles can act as reservoir hosts for pathogenic *Leptospira* strains.[9] Multiple wildlife species were documented to show seroreactivity (up to 60% seropositive) to *Leptospira* serovars in a large multiyear national review in the United States.[10] Raccoons have been implicated as a source of serogroup Icterohaemorrhagiae in the northeastern United States[11] and Grippotyphosa infections in the midwest and northeastern regions of the United States and eastern Canada.[12-15] Raccoons might also be involved in serogroup Autumnalis, Bratislava, or Pomona infections in Washington state.[16] In the past, most of our knowledge about serovars in reservoir hosts has been based on serologic studies, which do not accurately reflect the epidemiology of infecting serovars.[17] Isolation of *Leptospira* spp. is generally necessary for accurate serovar identification or molecular typing. Isolation of *Leptospira* spp., however, is not straightforward. As molecular methods are being refined, limited typing of leptospires without prior culture is becoming feasible.[18] The use of PCR on kidney tissue and urine specimens collected from a variety of wildlife species worldwide is shedding light on the diversity of potential reservoir hosts of *Leptospira* spp. Several studies have shown a high prevalence of positive test results in small rodents,[19-24] supporting their role as a major reservoir. Other investigators have identified a high prevalence of urinary colonization in unexpected animal populations, such as wild hedgehogs in Europe,[25,26] Blanding's turtles in Illinois, USA,[27] and mountain lions in northern California.[28] Striped skunks, raccoons, and gray squirrels were also found to be reservoirs in northern California.[29]

California sea lions are infected with a specific molecular type of serovar Pomona, which is adapted to sea lions and causes episodic outbreaks of disease in juvenile sea lions.[30] The identification of a high prevalence of urinary colonization in feral cats in Western Australia has led to interest in the role of feral cats as reservoir hosts for leptospirosis.[31] In limited studies from Réunion Island[32] and east-central Illinois,[33] there was no evidence that feral cats played a role as reservoirs.

The simple detection of pathogenic leptospires in domestic and wildlife reservoir hosts in a geographic region does not necessarily imply that those *Leptospira* strains infect and cause disease in humans and domestic dogs in that region. Using molecular typing methods, it has been possible to show that strains of *Leptospira* identified in reservoir hosts do not always correlate with strains found in humans with leptospirosis.[34] In a study from French Polynesia, *Leptospira* strains detected using molecular methods in 244 human patients were compared with those found in several potential reservoir hosts.[35] The main source of infection for *Leptospira borgpetersenii* serovar Ballum and *L. interrogans* serovar Icterohaemorrhagiae was rats, for *L. interrogans* serovar Australis was dogs, and for *L. interrogans* serovar Pomona or Canicola was farmed pigs. *Leptospira interrogans* was associated with the most severe infections in humans, with 10 and 5 fatal cases being associated with serovars Icterohaemorrhagiae and Australis, respectively. More studies like this will be required to gain a better understanding of the link between animal reservoirs and human infections.

Factors that might influence transmission include strain virulence, the number of organisms shed/mL of urine by a reservoir host, the density and distribution of the reservoir host population (including their proximity to water sources that might be contaminated and their proximity to incidental hosts), and the volume of urine to which an incidental host is exposed. One study showed that of cows, deer, dogs, humans, mice, and rats, rats excreted the highest quantity of spirochetes/mL (median, 5.7×10^6 cells), but large mammals excrete a larger volume of urine and shed more organisms/day (5.1×10^8 to 1.3×10^9 cells).[36]

Dogs and Cats as Incidental Hosts

Both dogs and cats can contract leptospirosis and can shed leptospires in their urine, but cats appear to be relatively resistant to development of clinical illness. As a result, leptospirosis is uncommonly described in cats.[37–48] Cats may be infected after ingestion of infected prey, so outdoor exposure and hunting behavior may be risk factors for cats.[37] In experimentally and naturally infected cats, interstitial nephritis is the most consistent histopathological finding.[37,39,42,47]

Disease in dogs is primarily caused by the pathogenic (group I) species *L. interrogans* and *L. kirschneri.* Within these two species,

more than 10 different serovars have been associated with disease in dogs worldwide, although the exact serovars causing disease in dogs in different geographic locations remains poorly understood, in part because of the difficulties associated with culture of leptospires. The most common serovars thought to infect dogs before the introduction of canine *Leptospira* vaccines several decades ago belonged to the serogroups Icterohaemorrhagiae and Canicola. Since that time, widespread seroconversion to other serogroups, especially Grippotyphosa and Pomona in North America, and Grippotyphosa and Australis in Europe has been noted in sick dogs. This apparent serovar shift could be due to the inclusion of additional serovars into the serologic testing panels (based on the microscopic agglutination test [MAT]), as well as increased contact between dogs, wildlife, and farm animal reservoir hosts for these serovars. Most of our knowledge regarding the *Leptospira* serogroups that infect dogs is derived from MAT results, but these do not accurately indicate the infecting serovar. However, with the advent of molecular methods such as multilocus sequence typing (MLST) and variable-number tandem repeat (VNTR) analysis, we are beginning to understand the true identity of serovars and strains of *Leptospira* spp. that cause disease in domestic dogs from different geographic locations, and typing may be possible in some circumstances following amplification of DNA directly from clinical specimens, without previous culture.[49] At the time of writing, only a small number of studies have been published that report serovars and strains infecting dogs. In Japan, the predominant serovars associated with diseased dogs in one study were Australis, Autumnalis, and Hebdomadis.[50] Furthermore, strains from humans clustered with those detected in dogs but not mice, and the profile of one human isolate was identical to that from a dog.[51] In northeast Italy, six STs were detected in 193 dogs with leptospirosis that belonged to *L. interrogans* (3 STs), *L. kirschneri* (2 STs), and *L. borgpetersenii* (1 ST), and the organisms detected belonged to serogroups Icterohaemorrhagiae, Australis, Sejroe, and Pomona.[25] Sequence types detected in the dogs were compared with STs in an Italian database and matched STs identified in rats, mice, cats, hedgehogs, horses, and one each of a goat, cow, pig, wild boar, and a wolf. Because vaccine-derived immunity to leptospirosis is considered serogroup specific, improved understanding of serogroups infecting dogs has the potential to lead to more protective vaccines.

Leptospirosis is considered a seasonal disease, with human and animal outbreaks often linked to heavy rainfall or flooding.[2,52] The peak seasonal distribution in parts of North America where freezing winters occur is late fall,[53-55] but in more temperate regions, peak seasonal distribution occurs after months of high rainfall (such as in late winter in northern California).[55,56] In parts of the United States where rainfall occurs throughout the year, there may be no seasonality to infections. Similarly, the number of acute leptospirosis cases per month was strongly correlated with the average monthly temperature and moderately correlated with the average rainfall in a cohort of 256 dogs from Switzerland presented to a referral hospital.[57] However, despite its seasonality, leptospirosis can be diagnosed at any time during the year. Outbreaks of leptospirosis in dogs can also occur in relatively arid regions, possibly because of predation of infected wildlife by dogs, or factors such as irrigation. An outbreak of leptospirosis in dogs in Arizona, for example, was reported and investigated by the CDC.[58,59] In late 2021, an outbreak in dogs occurred in Los Angeles, and was monitored by the Los Angeles county Department of Public Health.

Consistent with the transmission cycle of leptospires, dogs with leptospirosis in the United States were more likely to be living in the proximity of outdoor water, swimming or drinking from outdoor water sources, and having indirect exposure to wildlife.[60] Risk factors identified for age, sex, and breed of dogs with acute leptospirosis have yielded conflicting results and might be subject to temporal changes.[61] Males, herding dogs, hounds, working dogs, and mixed breeds have previously been reported to be at increased risk in the United States.[62] In a cohort of dogs from Switzerland, puppies (<1 year) and male dogs were significantly overrepresented compared to the general dog population.[57] However, in other studies, neither sex, age, nor breed predispositions were confirmed.[61,63] In a study in the United States using the Veterinary Medical DataBase (VMDB), dogs weighing less than 6.8 kg (15 lbs), and in particular, Yorkshire terriers, had the highest hospital prevalence for leptospirosis between 2000 and 2009.[61] This may be because small breeds are less likely to be vaccinated because of the perception that they are at increased risk for adverse effects following vaccination.[64] Over the past decade, residence in urban areas has emerged as a risk factor for *Leptospira* infection in dogs in some parts of North America, possibly due to exposure to urban wildlife species.[65,66]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Infection with pathogenic leptospires can lead to a wide range of clinical manifestations from subclinical to severe, and potentially lethal disease. The outcome of acute infection depends on the age and immune response of the host, the virulence and inoculum size of the pathogen, and the degree of co-adaptation of host and infecting serovar.[1] Further genetic analysis of isolates from natural disease outbreaks will be needed to determine if clinical signs can be linked to genetic features of specific strains. Pathogenic leptospires possess several virulence factors that help them to invade and establish infection in the mammalian host. These include leptospiral immunoglobulin-like proteins, adhesins, hemolysins, LPS, and a variety of other outer membrane proteins that may contribute to tissue injury and promote the inflammatory response.[67]

Hosts become infected when mucous membranes or abraded, scratched, or macerated skin come into contact with infected urine, tissues (such as following predation), or contaminated water or soil. After entering the warmer mammalian body environment, transcriptional changes occur that enhance the spirochete's pathogenicity.[68–70] Leptospires quickly establish a systemic infection via hematogenous spread. Unlike bloodstream infections with other gram-negative bacteria, leptospires do not cause fulminant disease shortly after the onset of infection. This has been attributed to the low endotoxic potential of leptospiral LPS.[71] The leptospires then spread and further replicate in many tissues, including the kidney, liver, spleen, CNS, pancreas, GI tract, eyes, and genital tract. Through numerous mechanisms, pathogenic leptospires are able to evade destruction by complement, as well as killing by neutrophils through inhibition of myeloperoxidase activity.[67] Leptospiral PAMPs stimulate the innate immune system by interacting with a number of pattern recognition receptors (PRRs), such as TLRs and nucleotide oligomerization domain (NOD)-like receptors (NLRs), which can then trigger a proinflammatory "cytokine storm" that contributes to tissue damage and organ dysfunction.[72] In particular, animals with severe leptospirosis have significant increases in TNF-α and IL-10, considered hallmarks of a cytokine storm. Interestingly, IL-10 may contribute either to inflammatory or anti-inflammatory responses to infection, depending on the stage and severity of disease.[72] It has been suggested that TGF-β1 may contribute to renal injury and fibrosis in incidental hosts. Virulence factors such as hemolytic toxins also may contribute to tissue damage, and surface lipoproteins such as LipL32 appear to be important in the pathogenesis of renal injury.[73]

Leptospiremia continues until the host mounts an effective acquired immune response, which clears the organism from bloodstream and most tissues. Thereafter, leptospires can persist in immune-privileged sites, such as the renal tubules and the eye.[1]

Differential expression of surface antigens of the spirochete may be responsible for its ability to evade host immune responses during the chronic shedding period.[74] Downregulation of TGF-β1 may lead to persistence of the organism in the absence of renal injury.[72]

The incubation period for acute leptospirosis is approximately 7 days, but may be shorter or longer depending on the dose and strain virulence, and the host immune response.[75]

Leptospirosis should be suspected in dogs that develop signs of acute febrile illness, kidney and/or hepatic injury, uveitis, pancreatitis in conjunction with kidney injury, or pulmonary hemorrhage; it should also be suspected in breeding dogs with abortion, stillbirths, or neonatal deaths.[76] In a study from Switzerland assessing the main organ manifestations (renal, hepatic, pulmonary, hemorrhagic) in 298 dogs with acute leptospirosis, 99.7% showed renal involvement, 35.4% showed hepatic involvement (as indicated by hepatic hyperbilirubinemia), 68.8% showed pulmonary involvement, and 18.4% signs were consistent with DIC. While most dogs (43.6%) demonstrated involvement of two different systems, 24.5% had involvement of only one organ, 23.2% of three, and 8.7% of all four systems.[57]

Fever, if present, occurs only at the onset of illness and is often accompanied by shivering, reluctance to move, and generalized muscle tenderness that may result from myositis. This may be followed by signs of lethargy, polyuria and polydipsia, inappetence, vomiting, and diarrhea.[77–87] GI signs in some dogs may result from pancreatitis and enteritis, in addition to acute renal and liver damage. Intestinal intussusception as a complication of acute leptospirosis, presumably associated with GI inflammation and motility disorders (paralytic ileus), has been described in several case reports.[88,89]

Polyuria and polydipsia may be the only initial sign and results from tubular dysfunction or a decreased responsiveness of the inner medullary connecting ducts to antidiuretic hormone (acquired nephrogenic diabetes insipidus). Oliguric/anuric renal failure was reported in 30% of dogs with acute leptospirosis from Switzerland.[57] During the acute phase, the predominant renal lesions are those of an acute interstitial nephritis, with tubular cell necrosis, apoptosis, and regeneration.[90,91] However, glomerular abnormalities have been described in both naturally infected dogs and experimentally infected animals with leptospirosis and indicate structural and functional glomerular involvement.[84,92] Tubular lesions are assumed to be due to direct effects of the organisms because renal lesions are generally associated with the presence of *Leptospira,*[90] and *Leptospira* outer membrane components can induce cell damage and inflammation in tubular epithelial cells *in vitro*[93] and *in vivo* using a zebrafish model.[94] During this phase of infection, a clinically significant reduction in renal function is present in most, but not all, patients with leptospirosis.[57,85]

Hepatic involvement can vary from mild liver enzyme elevations with or without hyperbilirubinemia to severe liver failure with signs of hepatic encephalopathy (Fig. 68.2). In human patients, both icteric and non-icteric forms of leptospirosis have been described, the icteric form being considered more severe and rapidly progressive.[1] This may also be true in dogs. In a cohort of 254 dogs with acute leptospirosis, a serum bilirubin of ≥10 μmol/L (reference range 0.5–4.0 μmol/L) was strongly associated (odds ratio 16.3; $P < 0.001$) with a negative outcome (death or euthanasia).[55] Hyperbilirubinemia coincided with the invasion of hepatic intercellular junction by migrating leptospires and disruption of bile canaliculi in experimentally infected hamsters.[95] In infected human and guinea pig livers, reduced staining for the cell-cell adhesion molecule E-cadherin was associated with liver plate disarray.[90] Hyperbilirubinemia and a cholestatic pattern of liver injury may be exacerbated by the presence of pancreatitis in some dogs.

Respiratory signs such as tachypnea and mild to severe dyspnea can occur in dogs with leptospirosis for many reasons, such as pulmonary edema due to overhydration, aspiration pneumonia, pain, or acidosis; however, clinicians should also consider leptospiral pulmonary hemorrhage (LPHS) as a cause of respiratory dysfunction. LPHS has been increasingly commonly reported in humans and animals with severe leptospirosis and has become a major cause of mortality.[56,57,96] Patients with LPHS can develop rapidly progressive intraalveolar pulmonary hemorrhage with cough, dyspnea, hemoptysis, and respiratory failure.

Fig. 68.2 Uveitis in an Australian shepherd with leptospirosis with leakage of serum bilirubin into the aqueous humor. (From Sykes JE. *Canine and Feline Infectious Diseases.* Elsevier; 2014.)

The pathogenic mechanisms of LPHS are poorly understood. Several hypotheses, including systemic inflammatory,[97,98] immune-mediated,[91,99,100] and direct leptospiral effects,[92,101] are under investigation. It is likely that the pathogenic mechanisms of LPHS are multifactorial, with both host- and pathogen-related factors playing a role.[102] The prevalence of LPHS in dogs appears to be particularly high in parts of continental Europe, with pulmonary complications reported in approximately two-thirds of dogs with leptospirosis in Berlin and a cohort from Switzerland.[57,87,96] It has therefore been hypothesized that LPHS may be linked to infection with specific regionally prevalent serovars or strains. However, the prevalence of LPHS may also be underrecognized in other parts of the world.

Bleeding tendencies in dogs with leptospirosis may be manifested as petechial hemorrhages, hematuria, hematemesis, epistaxis, hematochezia, punctate retinal hemorrhages, or melena.[79,84,103] Most dogs with leptospirosis in the United States show no evidence of bleeding diatheses. Although the precise mechanisms are unknown, bleeding tendencies may reflect endothelial damage and/or disordered coagulation.[104] Importantly, animals with LPHS can show severe intraalveolar hemorrhage in the absence of a systemic hemostatic disorder.[91]

Vasculitis can also contribute to the development of peripheral edema and mild pleural and peritoneal effusions. Electrocardiographic abnormalities, such as ventricular tachyarrhythmias, and elevations of serum troponin concentrations in some dogs suggest myocardial damage.[84,105] In human patients, aseptic meningitis is a common complication of leptospirosis and results in severe headache, delirium, and less commonly seizures or altered sensory perception.[1] Whether meningitis occurs in infected dogs is unknown, but mental dullness is often described in affected dogs, the severity of which may not be reflected by laboratory abnormalities.

Abortion is associated with leptospirosis in mares, cows, and sows; however, there are few reports in dogs. *Leptospira* serovar Buenos Aires (serogroup Djasiman) was isolated from an aborted fetus of a

seropositive bitch.[106] Abortion and infertility was associated with a serogroup Batavia infection in a dog.[107]

Clinical signs in affected cats resemble those in dogs, although some cats have lacked evidence of hepatic injury and may show effusive disease.[37,38,45]

The role of persistent *Leptospira* infection as a cause of chronic kidney disease (CKD) in both cats and dogs requires more study. Progression of tubulointerstitial nephritis to tubular atrophy and renal fibrosis has been described in dogs infected with serovar Canicola[108] and rats infected with serovar Icterohaemorrhagiae.[109] A study from an endemic region in Brazil detected subclinical shedding of leptospires using PCR in 75% of 16 dogs with CKD and 21% of 48 healthy dogs.[110] In one study, cats with kidney disease (acute and chronic) were more likely to have antibodies against *Leptospira* spp. and to shed pathogenic leptospires in their urine than cats without kidney disease.[44] However, the prevalence of *Leptospira* antibodies in domestic cats is low and the vast majority of cats with kidney disease are seronegative.

The extent to which leptospires cause chronic hepatic injury in dogs is also unknown. In one report from France, leptospires were detected in bile canaliculi of young dogs with chronic hepatitis using immunohistochemistry and electron microscopy. These dogs showed signs of poor growth, weight loss, and ascites.[111] Chronic active hepatitis was associated with rising titers to serogroup Grippotyphosa in four of five American foxhounds living in a kennel.[112] Although noted as a cause of chronic hepatitis in dogs, attempts to detect *Leptospira* DNA in liver tissue from dogs with chronic hepatitis have generally been unrewarding.[112]

Physical Examination Findings

Findings on physical examination of dogs with leptospirosis vary with disease severity, chronicity, and possibly the infecting *Leptospira* strain. Severely affected dogs may show fever, dull mentation, dehydration, mild generalized peripheral lymphadenopathy, diffuse muscle pain, and pain on palpation of the abdomen or kidneys. Fever is typically only present early in the course of infection. In oliguric or anuric dogs that have been treated aggressively with intravenous fluids, evidence of overhydration may be present. Rarely, arrhythmias are detected on cardiac auscultation. Careful ophthalmologic examination may reveal conjunctivitis, scleral injection, and occasionally uveitis. Mild pallor, petechial or ecchymotic hemorrhages, and, less commonly, epistaxis may be present, although these findings appear to be rare in dogs from the United States and more commonly described in dogs from Europe. Respiratory difficulty, tachypnea, and harsh lung sounds may be evident in dogs that develop pulmonary complications. Dogs with liver involvement may be icteric. Rectal examination occasionally reveals melena or hematochezia. Young dogs with leptospirosis have been reported to develop severe systemic or skin calcifications in isolated case reports.[113,114]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

The hemogram in dogs with leptospirosis may reveal neutrophilia, sometimes with a left shift; nonregenerative anemia; lymphopenia; and/or thrombocytopenia (Table 68.2). Approximately half of dogs with leptospirosis have anemia, which is mostly mild to moderate. Causes of anemia can be blood loss via the respiratory or GI tract, vasculitis, and anemia of inflammatory disease. Hemolysis due to the effect of *Leptospira* toxins on erythrocytic membranes appears to be rare in dogs when compared to cattle or sheep, but rare cases of hemolytic anemia have been described in dogs.[115,116]

During the course of disease, leukemoid reactions with WBC counts > 80×10^9/L have been rarely reported.[96] Thrombocytopenia occurs in up to 63% of dogs and can raise the level of suspicion for leptospirosis in dogs with acute kidney injury (AKI) with or without hepatic injury.[77,78,84,87,96] The mechanism is unclear. Consumption due to activation, adhesion, and aggregation to a stimulated vascular endothelium,[117] Kupffer cell phagocytosis,[118] immune-mediated platelet destruction,[119] or splenic sequestration could play variable roles.

Serum Biochemical Tests

Findings on the serum chemistry panel are shown in Tables 68.3 and 68.4. Azotemia is present in more than 80% to 90% of dogs,[57,77-79] although in two European studies, increased serum creatinine concentration was present in only 55% and 57% of affected dogs.[83,85] Hepatic injury, as evidenced by increases in the activities of serum ALT, AST, ALP, and hyperbilirubinemia, almost exclusively occur in conjunction with azotemia,[82,85] although isolated hepatic injury can occur. Typically a cholestatic pattern is present where there are mild to moderate increases in serum activity of ALP and total bilirubin, and mild increases in serum ALT activity. Dogs with very high serum liver enzyme activities (e.g., ALT in the thousands) and evidence of hepatic failure (i.e., hypocholesterolemia, hypoglycemia) are unlikely to have leptospirosis. Severe increases in serum total bilirubin concentration may reflect concurrent presence of *Leptospira*-induced pancreatitis.

Other findings on the serum chemistry panel include hypoalbuminemia and a variety of electrolyte abnormalities. Hyponatremia, hypochloremia, or hyperphosphatemia occur in most dogs. Decreased expression of sodium transporters by proximal convoluted tubule cells contributes to impaired sodium resorption, increased distal sodium delivery, and potassium wasting.[120] As a result, dogs with acute oliguric renal failure may have paradoxical hypokalemia or normokalemia rather than hyperkalemia.

Moderately and occasionally markedly increased serum CK activity is present in some dogs due to myositis. Increased serum troponin concentrations have been found in some dogs with leptospirosis, which suggests myocardial damage.[84,105] Increased serum pancreatic lipase immunoreactivity may occur, probably as a result of pancreatitis, or decreased renal excretion.[77,84]

Coagulation Function

In experimentally and naturally occurring leptospirosis in dogs, varying degrees of thrombocytopenia, reduced fibrinogen concentration, prolonged activated partial thromboplastin and prothrombin time values, reduced antithrombin activity, increased D-dimer concentration, and increased fibrinogen degradation products have been found, presumably as a result of excessive intravascular coagulation.[84,96,104,121] In many dogs, clotting parameters are within reference limits, or variable thrombocytopenia may be the only abnormality, suggesting compensated hemostatic mechanisms. The degree of thrombocytopenia in dogs with leptospirosis has been correlated with the severity of pulmonary manifestations and higher mortality.[96]

Urinalysis

Findings on urinalysis in dogs with leptospirosis include isosthenuria, occasionally hyposthenuria, and variable glucosuria, proteinuria, pyuria, cylindruria, and bilirubinuria.[82,84] UPCRs may be increased, although typically not as high as that occurring in dogs with Lyme nephritis (which is primarily a glomerulonephritis rather than an interstitial nephritis). Urine protein electrophoresis revealed that both high-molecular-weight proteins consistent with glomerular damage and/or low-molecular-weight proteins consistent with a tubular origin can be present.[84,122]

Leptospires are not visible in routine urine sediment examination because the width of the organism is below the resolution of light microscopy.

Diagnostic Imaging

Plain thoracic radiography in dogs with leptospirosis may show no abnormalities, or mild to severe, diffuse interstitial pulmonary patterns may be present. Thoracic radiographs from dogs with LPHS can show severe focal to diffuse interstitial and alveolar patterns (Fig. 68.3). Initially, radiographic pulmonary changes typically appear in the caudodorsal parts of the lung fields.[96] Uncommonly, mild pleural effusion is present. Thoracic radiography might underestimate the lesion type and the severity in dogs with leptospirosis as compared with thoracic CT.[123]

Findings on abdominal sonography in dogs with leptospirosis include mild renomegaly, increased renal cortical echogenicity, cortical thickening, mild pyelectasia, perirenal fluid accumulation or mild ascites, a medullary band of increased echogenicity within the kidneys, and reduced corticomedullary definition (Fig. 68.4A).[124,125] None of these signs are specific for leptospirosis. Ultrasonographic changes suggestive of pancreatitis are occasionally present, such as enlargement and hypoechogenicity of the pancreas (Fig. 68.4B). Thickening of the gastric and, less commonly, small intestinal wall may also be present. Mild to moderate hepatomegaly, hypoechoic hepatic echotexture, and splenomegaly with mottling of the splenic echotexture may be detected, with or without evidence of mild abdominal lymphadenomegaly.

Microbiologic Tests

Diagnostic assays available for leptospirosis in dogs are summarized in Table 68.5.

Darkfield Microscopy

Examination of voided urine using darkfield microscopy is insensitive for diagnosis of leptospirosis. Considerable experience is required to accurately identify the spirochetes, so false positives also have the potential to occur.

Culture

Culture of leptospires is not routinely performed, because it is often slow, insensitive, and not widely available. Special *Leptospira* growth medium, such as Ellinghausen-McCullough-Johnson-Harris (EMJH) or Hornsby-Alt-Nally (HAN) medium, is required.[126] Cultures may require incubation for weeks, and overgrowth with other bacteria can occur if cultures become contaminated. Venous blood and/or urine should be collected using aseptic technique before initiating antimicrobial drug treatment. Ideally, a few drops of blood or urine are inoculated directly into culture medium alongside the patient. In humans, blood is optimally collected during the initial febrile period; urine can be collected after the first week of illness. Because the exact time of infection may be unknown, submission of both blood and urine can increase the chance of a positive test result.

Only certain reference laboratories have expertise in culture of leptospires and the ability to identify leptospires to the serovar level, which is performed using a cross agglutinin absorption test. Molecular typing methods can also be performed. Despite the difficulties associated with culture and identification of leptospires, a proper understanding of the epidemiology of leptospirosis depends on the use of these methods.

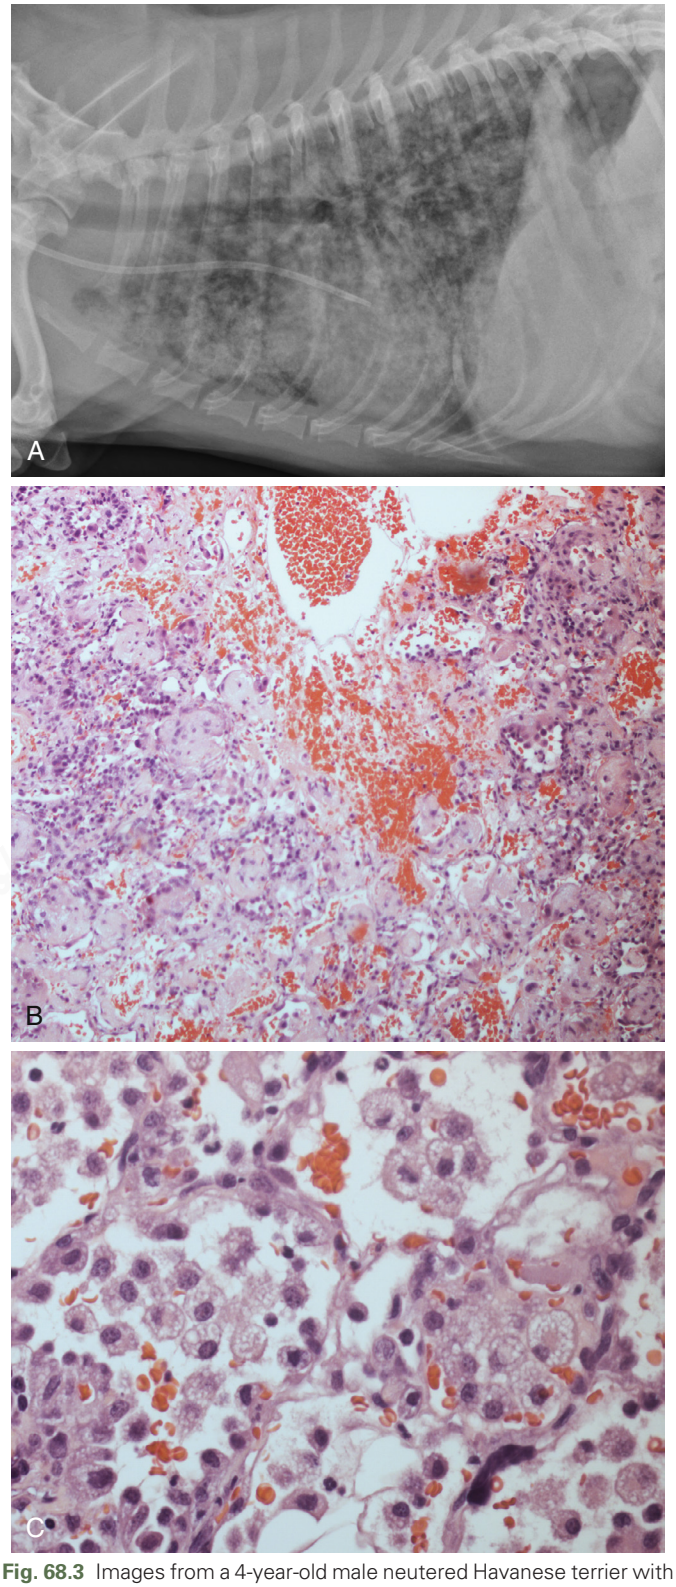

Fig. 68.3 Images from a 4-year-old male neutered Havanese terrier with severe leptospiral pulmonary hemorrhage syndrome and anuric renal failure. (A) Right lateral thoracic radiograph. A severe, diffuse alveolar pattern is present. Mechanical ventilation was needed and ultimately euthanasia was performed because of respiratory failure. Histopathology of a lung biopsy showed severe pulmonary hemorrhage (B) and marked alveolar histiocytosis (C). (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Serologic Diagnosis

When performed properly, serologic diagnosis of leptospirosis is retrospective, and so dogs that are suspected to have leptospirosis should be treated as such until the results of serologic testing are available. Currently the test of choice for diagnosis of leptospirosis is serology using the MAT.[76,127] In this assay, serial dilutions of patient sera are incubated with a panel of live *Leptospira* serovars. This serovar panel should be defined based on the antibody prevalence data for the host species in the relevant geographic location, as failure to include the infecting serogroup can lead to false-negative results. Agglutination of leptospires by serum anti-*Leptospira* IgM and IgG is then assessed using darkfield microscopy (Fig. 68.5). The highest dilution of serum that causes ≥50% of the organisms of each serovar to agglutinate is reported either as titer (i.e., 100) or as reciprocal titer (i.e., 1:100).

The MAT has marked limitations with regard to sensitivity, specificity, and repeatability, especially if only single titers are interpreted.[128,129] Infected dogs are often antibody negative or have low titers early on in the course of illness, because of the relatively short incubation period and the normal delay in appearance of serum antibodies. On the other hand, noninfected dogs vaccinated with whole-cell *Leptospira* vaccines can have post-vaccinal titers of 1:6400 or higher to both vaccinal and nonvaccinal serovars.[130–132] While the majority of vaccinated dogs become antibody negative by week 15 post vaccination, vaccinal titers can persist for 12 months in a small percentage of dogs.[131] In addition, dogs evaluated for illness other than leptospirosis may possess antibodies from previous subclinical infection. A moderate to high titer very early in the course of illness (when most dogs are negative or have low titers) may actually be a clue to these confounders. Reactivity of anti-*Leptospira* antibodies with multiple serogroups and inclusion of only a limited number of serovars in the panel typically prevents determination of the infecting serogroup. Moreover, the serogroup with the highest MAT titer can vary over time ("paradoxical seroreactivity"), and the MAT does not reliably predict the infecting serogroup in acutely infected animals.[129]

Because a positive MAT can result from recent subclinical exposure or vaccination, the most reliable means to confirm a recent infection by MAT is to test paired samples, collected 10 to 14 days apart.[128,129] Waiting much longer than 2 weeks to collect the convalescent specimen is not recommended as the titer may begin to decline, so any change in

TABLE 68.5 Diagnostic Assays Available for Leptospirosis in Dogs

Assay	Specimen Type	Target	Performance
Darkfield microscopy	Urine	Leptospires	Low sensitivity and specificity. Requires technical expertise to interpret correctly.
Culture	Whole blood, urine	Leptospires	Low sensitivity. Special media and prolonged incubation times required. Difficult and not widely available. Antimicrobial therapy may lead to false-negative results.
Microscopic agglutination test	Serum	Antibodies against various *Leptospira* serovars	False negatives can occur early in the course of illness or with immunosuppression. False positives can occur with a history of vaccination or with previous exposure. Paired titers performed at the same laboratory generally required for diagnosis. Inter-laboratory variation in results may occur.
Rapid diagnostic chromatographic or ELISA-based tests	Serum or plasma	IgM or IgG against *Leptospira*	False negatives can occur early in the course of illness or with immunosuppression. False positives can occur with a history of vaccination or with previous exposure.
Histopathology	Kidney tissue collected via biopsy or necropsy	Leptospires	Organisms may be visualized with silver stains, immunohistochemistry, or FISH. Antimicrobial therapy may lead to false-negative results.
PCR	Blood, urine, tissue specimens	*Leptospira* DNA	Sensitivity and specificity unclear and may vary between assays offered by different laboratories. Antimicrobial therapy may lead to negative PCR results.

titer could be missed. The rise in titer may also be somewhat blunted by early antimicrobial treatment, and delayed responses have also been documented in humans (Fig. 68.6). Obtaining a serum sample for a follow-up titer at the time of discharge from the hospital (or at the first recheck appointment after discharge) could be a practical approach. A fourfold or greater rise in MAT is highly suggestive of leptospirosis (e.g., a titer of 1:200 rises to 1:800, corresponding to the fact that the serum is positive for two more consecutive dilutions—this represents a significant change in titer) or when an initially antibody-negative dog exhibits a convalescent titer ≥ 800 to one or multiple serovars.

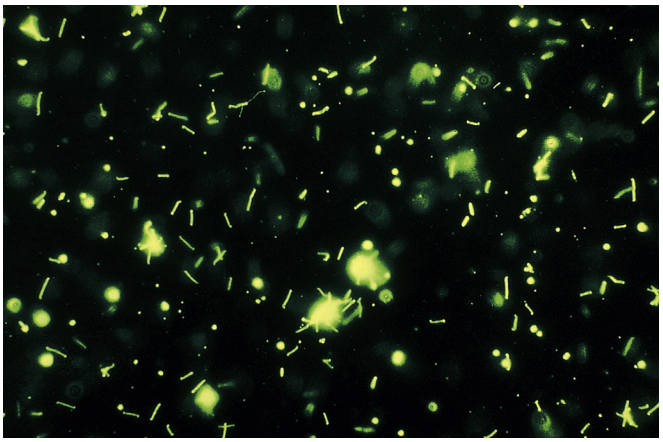

Fig. 68.5 Leptospires viewed using darkfield microscopy (original magnification ×100). (Courtesy of Mildred Galton, Public Health Image Library, Centers for Disease Control and Prevention. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:2898–2905.)

The MAT is widely available and relatively inexpensive in the United States, but is complex to perform and interpret. Performance of the test is hazardous to laboratory workers because live serovars are used, and the test is difficult to standardize. The identity of serovars used in the assay must be verified periodically to ensure that cross-contamination or culture deterioration has not occurred. A leptospirosis proficiency testing scheme is offered by the International Leptospirosis Society (ILS) to assist laboratories in the maintenance of quality assurance for the MAT.[133] Veterinarians should strive to use laboratories that participate in this quality assurance scheme, and should use the same laboratory on a regular basis.

Other serologic assays available for diagnosis of leptospirosis include ELISAs and chromatographic assays for IgG and IgM antibodies that are directed against *Leptospira* surface antigens. The performance of such assays have the potential to vary geographically based on the serogroups that are prevalent in the region. In Europe and in the United States, lateral-flow chromatographic assays detecting canine anti-*Leptospira* antibodies are commercially available (e.g., Test-it *Leptospira* Canine IgM Lateral Flow Assay, Life Assay; WITNESS Lepto Rapid Test, Zoetis; SNAP Lepto, IDEXX Laboratories; Immunocomb Canine *Leptospira* Antibody Test Kit, Biogal Galed Laboratories). At the time of writing, only the SNAP Lepto and WITNESS assays are available in the United States. The Test-it and WITNESS assays are IgM-based assays based on antigen from *L. interrogans* serovar Copenhageni strain Wijnberg or filtered whole-cell extracts of serovars Grippotyphosa and Bratislava,

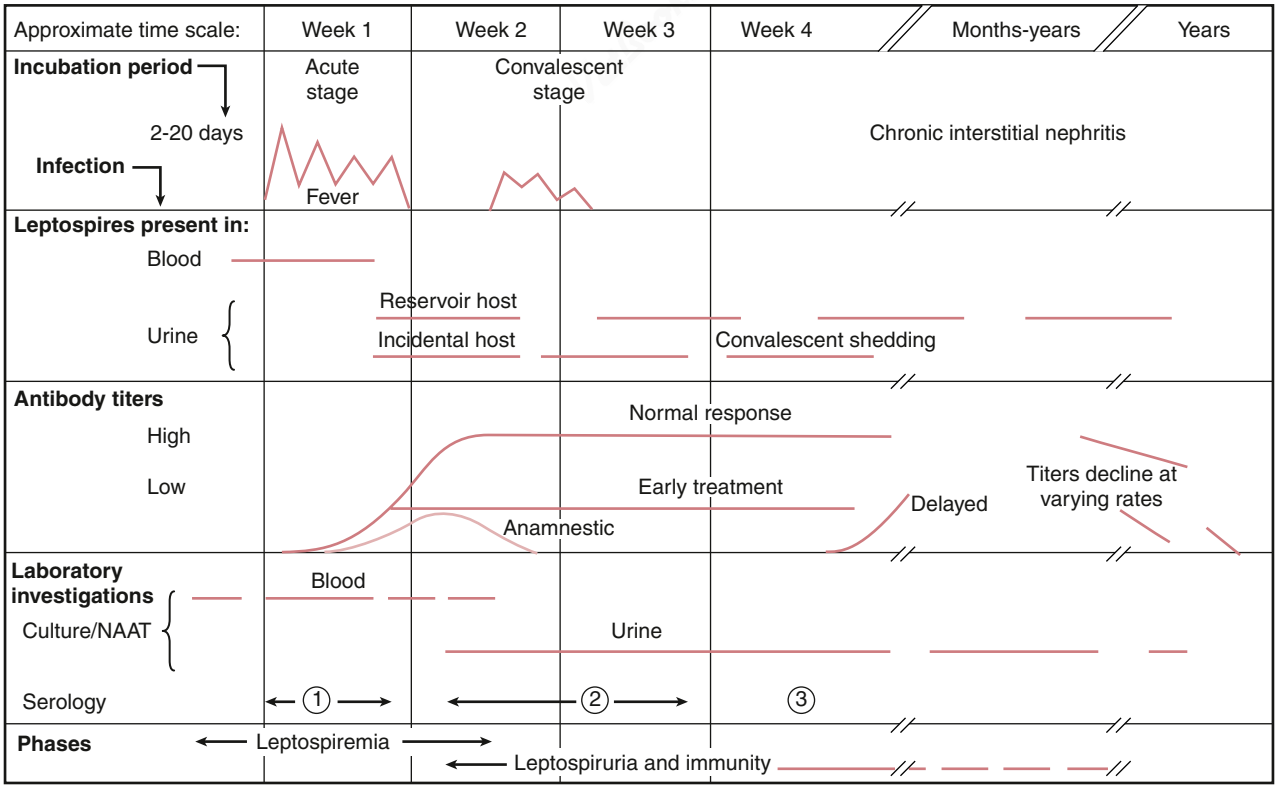

Fig. 68.6 Biphasic nature of leptospirosis and relevant investigations at different stages of disease. Specimens 1 and 2 for serology are acute and early convalescent phase specimens; 3 is a late convalescent phase specimen. (Modified from Turner LH. Leptospirosis. *Br Med J.* 1969;1:231-235; Levett PN. Leptospirosis. *Clin Microbiol Rev*. 2001;14:296-326; and Haake DA, Levett PN. *Leptospira* species (Leptospirosis). In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:2898-2905.)

respectively, which are proteolytically digested and heat treated to make them broadly reactive with antibodies raised in response to infection with a wide range of serogroups. The SNAP Lepto assay uses a recombinant LipL32 antigen, found only in pathogenic leptospires, as the basis for detection of IgG and IgM antibodies to *Leptospira*, and is available as a diagnostic laboratory-based ELISA assay as well as a POC lateral-flow assay. The Immunocomb kit is a POC-modified ELISA assay designed to detect IgM and IgG antibodies to *L. interrogans* serovars Icterohaemorrhagiae, Canicola, Pomona, and Grippotyphosa. The performance of these assays when compared to acute and convalescent MAT serology requires further validation using a large number of dogs from a broad range of geographic locations. Because these are antibody assays, dogs may test negative early in the course of illness. In one study of experimentally infected beagle dogs, positive test results were more prevalent at day 10 after challenge with the WITNESS assay (100% of 32 dogs) and MAT (80–100% of dogs) when compared with the SNAP Lepto (10%).[134] These rapid POC assays may be useful to rapidly screen for an *absence* of antibodies as an alternative to relying on MAT, which is more expensive and has a slower turnaround time.[135] A negative test result could be followed with a second POC test 1 to 2 weeks later (to show a change from negative to positive should seroconversion have occurred). Positive results may reflect the presence of antibodies due to previous vaccination or exposure, so in this situation a titer should be immediately determined using MAT, with a convalescent titer performed 1 to 2 weeks later to demonstrate a fourfold rise in titer. Because the WITNESS and Test-it assays are IgM-based assays, they are less likely to be influenced by previous exposure and vaccination. However, one study showed that 12 weeks after vaccination of 25 healthy beagle dogs with a 4-serovar *Leptospira* vaccine, 6 dogs still tested positive with the WITNESS assay.[136] Therefore, even 3 months after vaccination or previous exposure, IgM-detection assays have the potential to remain positive, further underscoring the importance of obtaining quantitative acute and convalescent phase titers to confirm recent exposure.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Several veterinary diagnostic laboratories in the United States and Europe offer real-time PCR assays for the detection of the DNA of pathogenic leptospires in blood and/or urine, or tissue specimens collected at necropsy such as liver and kidneys. The assays are commonly based on the amplification of segments of the 16S or 23S ribosomal RNA gene sequences[137] or the LipL32 gene, which is specific for pathogenic *Leptospira* spp.[138-140] The sensitivity and specificity of these assays in dogs with leptospirosis have not been thoroughly assessed. However, positive results were documented in 13% of free catch canine urine specimens in one study due to amplification of contamination of random bacterial DNA by a 16S rDNA PCR method.[141] Thus, assay performance likely varies from one laboratory to another. In-clinic PCR assays have also been developed to detect pathogenic leptospires in dogs (e.g., PCRun, Biogal Galed Laboratories, Israel),[142] although the clinical sensitivity and specificity of these assays require further study.

PCR assays have the potential to be advantageous for rapid diagnosis early in the course of illness, when serologic tests are negative and organism numbers in the blood are high. In a study in dogs experimentally infected with *L. interrogans* serovar Canicola, both culture and *lipL32* PCR in blood were positive on day 4 and negative thereafter, whereas urine culture and *lipL32* PCR were negative on day 4 and positive on day 8, 19, and 26.[139] Findings in this untreated cohort reflect the classic concept of an initial leptospiremic phase followed by urinary shedding. However, in naturally infected dogs, the exact time of infection is typically unknown, therefore testing of both blood and urine collected before initiation of antimicrobial drug treatment should be submitted in order to optimize sensitivity. The use of stabilizers to neutralize the urine pH and to inactivate DNases in order to preserve *Leptospira* DNA might be advantageous.[143] Even with sensitive PCR assays, negative results do not rule out a diagnosis of leptospirosis because dogs may shed very low numbers of organisms or shedding may be intermittent. Because subclinically infected dogs can shed leptospires, a positive PCR test result on urine may not necessarily correlate with illness. The prevalence of urinary shedding as detected using PCR was 0% of 100 dogs seen at the University of California-Davis VMTH with problems other than leptospirosis[144]; 13% of 198 shelter dogs from Tennessee, Virginia, and Kentucky[145]; 7.1% of 525 dogs from shelters and a veterinary teaching hospital in Ireland[138]; 1.5% of 200 healthy pet dogs in Germany[146]; 4.4% of dogs from New Caledonia[147]; 4.4% of 273 dogs from Thailand[148]; and 10.6% of 123 stray and shelter dogs in Brazil.[149] Vaccination of healthy dogs with inactivated *Leptospira* vaccines should not lead to positive PCR assay results,[132] so a history of *Leptospira* vaccination should not interfere with PCR diagnosis. Available PCR assays do not provide information on the infecting serovar or serogroup. However, techniques such as MLST and VNTR can be applied to PCR products for typing of the infecting strain, and in some cases this can be correlated to a serotype identity.[18] Correlation to the serovar level is not straightforward, and can require isolation and accurate serotyping and molecular typing of leptospires infecting dogs in the region, which can then be used as a reference for comparison.

Ultimately, application of a combination of serologic assays and PCR may optimize diagnosis of leptospirosis in dogs.[150] Figure 68.7 illustrates a possible approach to diagnosis through the use of a combination of MAT, POC assays, and PCR.

Machine Learning

Because of the characteristic patterns of laboratory abnormalities in leptospirosis, the disease lends itself well to diagnosis using machine learning. An algorithm for early diagnosis of leptospirosis that took into account CBC, serum biochemistry, and urinalysis findings had a sensitivity of 94% and a specificity of 98% when applied to the hospital population at the University of California-Davis. An algorithm that also included the results of an acute MAT had a sensitivity of 92% and specificity of 90%.[151]

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs with leptospirosis include jaundice, petechial and ecchymotic hemorrhages, and sometimes fibrin thrombi throughout the body. The lungs of dogs with LPHS may be wet, mottled, heavy, and dark-pink to red in color.[152] Ascites and/or pleural or pericardial effusion may be present, and the intestinal lumen may be filled with blood or contain melena. The kidneys of dogs with acute disease may be mildly enlarged, pale, and sometimes mottled or petechiated; they may also contain infarcts. Dogs with chronic renal injury secondary to leptospirosis can have kidneys that are shrunken and irregular (Fig. 68.8).

Histopathologic Findings

Infection of the kidneys by leptospires leads to an interstitial nephritis, with mixed inflammatory infiltrates. Acute tubular necrosis can also occur as a result of vasculitis and renal ischemia (Fig. 68.9A).[36]

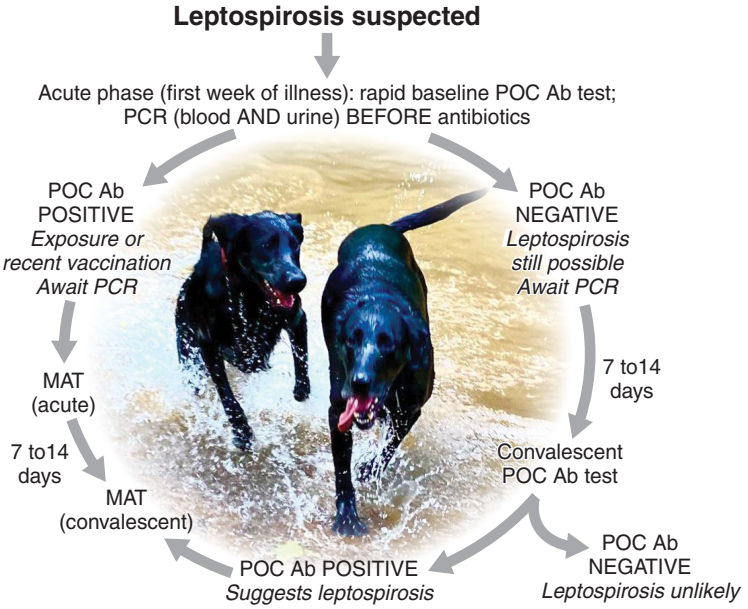

Fig. 68.7 Diagnostic algorithm that could be used to optimize diagnosis of leptospirosis using a combination of POC lateral-flow assays, PCR, and MAT.

Histopathologic changes in the liver are often mild and include mild random hepatic necrosis, mild neutrophilic periportal hepatitis, cholestasis, or liver plate disarray (Fig. 68.10). Multifocal, random, neutrophilic, and necrotizing myocarditis can also occur; myonecrosis is occasionally described in skeletal muscle. Histopathologic lesions of LPHS are similar across species and are characterized by various degrees of intraalveolar hemorrhage in the absence of a marked inflammatory cell infiltrate or vasculitis. Intraalveolar edema, fibrin, and hyaline membranes which are characteristic of disorders with diffuse alveolar damage can be present, but are not a predominant feature.[91,152,153] In contrast to liver and kidney, few organisms are present in lung tissue of immunocompetent hosts and do not co-localize with the pulmonary lesions.[91,100]

Silver stains such as Warthin-Starry stain and immunohistochemistry can be used to visualize bacteria within tissue specimens (see Fig. 68.9B). Direct fluorescent antibody staining and FISH (see Fig. 6.1B) have also been used to identify and localize leptospires within the kidneys. However, the number of organisms in incidental hosts is typically low and if antimicrobials were administered, spirochetes may be absent.

TREATMENT

Effective treatment of acute leptospirosis involves appropriate antimicrobial therapy and supportive therapy for involved organ systems.

Antimicrobial Drugs

Leptospires are susceptible to a wide range of antibiotics. Treatment should be initiated as early as possible, before the results of diagnostic assays become available. In hamster models, doxycycline clears spirochetes from all tissues, including the kidney, within 3 days of infection; ampicillin is less effective at clearing organisms from the kidney.[154] Based on current evidence, current consensus statements on leptospirosis in dogs recommend that all dogs with leptospirosis should be treated with doxycycline, 5 mg/kg q12h or 10 mg/kg q24h for 2 weeks.[76,127] If vomiting or other adverse reactions preclude the

Fig. 68.8 Shrunken, irregular kidneys from a 16-year-old male neutered Jack Russell terrier. The dog was treated for severe acute leptospirosis at 12 years of age. At that time, after six dialysis treatments, the dog was discharged from the hospital with a creatinine of 4.2 mg/dL. Four years later, the dog died for reasons unrelated to renal injury but had evidence of chronic renal injury at necropsy. (Courtesy of UC Davis Veterinary Anatomic Pathology Service.)

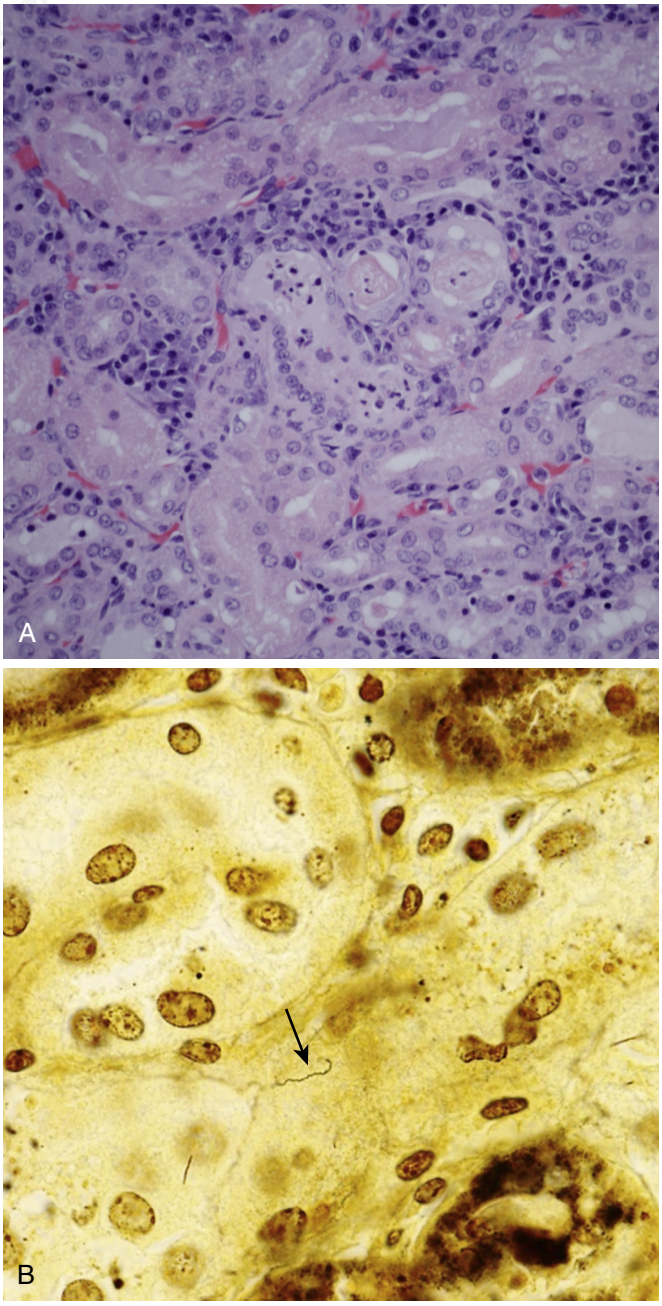

Fig. 68.9 (A) Histopathology of the kidney of a dog that died of leptospirosis. Acute tubular necrosis and interstitial nephritis is present. Hematoxylin and eosin stain. (B, Courtesy of John Cullen, North Carolina State University and Jean-Jacques Fontaine, École Nationale Vétérinaire d'Alfort.)

use of doxycycline, parenteral ampicillin or penicillin G can be used (Table 68.6). The dosage should be adapted in dogs with decreased renal function. A safe and practical approach would be to double the administration interval in dogs with AKI Grade 4 and higher (creatinine > 440 µmol/L). Dogs initially treated with a penicillin derivative should be treated with doxycycline for 2 weeks after GI signs resolve. Fluoroquinolones are not highly efficacious for clearance of leptospires from tissues.[155] Other antimicrobials that have been efficacious in clinical trials involving human patients with leptospirosis include

TABLE 68.6 Antimicrobials Recommended for Treatment of Leptospirosis in Dogs

Drug	Dose	Route	Interval (Hours)	Duration (Days)
Doxycycline	5 mg/kg	PO, IV	12	14
Ampicillin	20 mg/kg*	IV	6	Variable
Penicillin	25,000–40,000 U/kg	IV	12	Variable

*Reduce dose in renal failure.

ceftriaxone, cefotaxime, and azithromycin,[156,157] but clinical trials of these drugs in canine leptospirosis are lacking.

Supportive Care

Treatment of dogs with AKI from leptospirosis generally follows the therapeutic recommendations for AKI from other etiologies. Correction of fluid, electrolyte, and acid-base disorders with appropriate fluid therapy remains the mainstay of the treatment, together with treatment of systemic hypertension and GI complications, pain management, and active nutritional support. Referral to a 24-hour care facility, ideally with access to dialysis, should be considered for severely ill dogs because of the need for intensive monitoring and close observation. Electrolyte and acid-base status may require frequent monitoring.

Fluid therapy is critical and should be calculated based on measurement of "outs and ins," together with careful attention to body weight, respiratory rate, lung sounds, blood pressure, and if possible, central venous pressure. For dogs with oliguric or anuric renal failure, high fluid rates can lead to overhydration. The occurrence of LPHS or vasculitis further limits the tolerance of patients to iatrogenic fluid excess. Diuretics such as furosemide or mannitol may be indicated. Failure of urine production after adequate hydration is achieved is an indication for hemodialysis. Dogs with polyuric renal failure may require extremely high fluid rates. Once recovery of kidney function has occurred, fluids should be tapered slowly before they are discontinued to ensure that proper hydration status is maintained. Treatment of dogs with GI signs includes a combination of antiemetics and gastroprotectants. Intussusceptions should be considered in dogs with persistent vomiting before antiemetics are contemplated.[88,89] In some dogs, possibly because of enteritis or pancreatitis, inappetence persists for several days after kidney and liver values normalize. The use of enteral feeding tubes is strongly advocated in dogs with anorexia as they allow efficient and early nutritional support with minimal risk of complications. Parenteral nutrition can be necessary in dogs with persistent vomiting. Pain management is particularly important in the early phases of the disease when painful swelling of the kidney, added to muscle, joint, pancreatitis, and GI pain can contribute markedly to the disease manifestations. Opioids, including buprenorphine or fentanyl, are usually recommended.

The treatment of LPHS is mainly supportive because the pathogenesis of this disease manifestation is poorly understood. Systematic radiographic screening even in the absence of respiratory signs allows early precautionary measures to be adopted. These include minimization of manipulations and stress and avoidance of systemic hypertension, overhydration, or hypervolemia. Dogs with LPHS may require oxygen therapy and, in severe cases, mechanical ventilation. Humans with LPHS have poor lung compliance, and ventilator treatment for ARDS is recommended, with low tidal volumes to prevent alveolar damage secondary to high ventilation pressures.[73] Treatment of active hemorrhage with desmopressin has yielded controversial results in humans[158,159] and did not appear to improve outcome in dogs, at least when administered as ocular drops.[160] Plasma or whole blood transfusions are only indicated in dogs with associated systemic disorders of hemostasis. Based on the hypothesis of an immune-mediated mechanism, immunomodulation has been investigated in humans with LPHS with promising preliminary results. Combination of cyclophosphamide, pulse glucocorticoid therapy, and therapeutic plasma exchanges to remove potentially autoreactive antibodies improved survival.[161–164] However, considering their complexity and the risk for complications, these therapies still need to be further investigated before they can be recommended for clinical practice.

Hemostatic disorders in dogs with leptospirosis vary widely in severity and they are multifactorial in origin. Both hyper- and hypocoagulable states have been shown to occur. DIC was described in 23% of dogs in one study, but was not associated with a negative outcome.[104] In dogs with DIC, plasma transfusions are indicated. Thrombocytopenia is common in dogs with leptospirosis, but rarely necessitates specific therapy.

Renal Replacement Therapy

Early hemodialysis results in improved survival and shorter hospital stays in human patients with leptospirosis.[165] Renal replacement therapy is indicated for dogs with inadequate urine output that develop volume overload, hyperkalemia, or uremia that do not respond to medical management. Approximately 50% of 89 dogs with leptospirosis at the University of California, Davis, VMTH over a 10-year period received hemodialysis; the median number of hemodialysis treatments required was 3 (range, 1–14). Recovery of adequate renal function usually occurs within 2 to 4 weeks of starting dialysis.

PROGNOSIS

When treatment is initiated early and aggressively, the prognosis for recovery from acute leptospirosis is excellent. Survival rates are in excess of 50%, and in centers where hemodialysis is available, survival rates can exceed 80%. Successful treatment is associated with normalization of the platelet count, serum BUN and creatinine concentrations, and serum liver enzyme activities within 10 to 14 days. Icterus may be slow to resolve, and urine-concentrating ability may not return for at least 4 weeks. A follow-up study of dogs with leptospirosis indicated that approximately 50% of the dogs surviving the acute phase of the disease displayed impairment of their renal function more than 1 year after hospital discharge,[166] thus chronic renal failure can be a sequela of acute infection/injury. Long-term monitoring of renal function is therefore strongly recommended in these dogs.

IMMUNITY AND VACCINATION

Recurrence of leptospirosis in dogs after recovery from natural infection appears to be rare, but the duration of immunity after natural infection is unknown. Immunity after vaccination with inactivated vaccines is serogroup specific and possibly serovar specific, with only partial immunity to heterologous serogroups.[167]

Current vaccines for dogs are inactivated bacterins that have been purified to optimize safety. Bivalent vaccines that contained only serovars Icterohaemorrhagiae and Canicola were first introduced for prevention of leptospirosis in dogs. Canine leptospirosis has been reported widely in dogs after vaccination with bivalent Icterohaemorrhagiae and Canicola vaccines,[96] thus bivalent vaccines do not sufficiently cross-protect against serovars responsible for the majority of current infections in dogs. Quadrivalent vaccines that contain Canicola, Icterohaemorrhagiae, Grippotyphosa, and Pomona have been available in the United States since 2001. Trivalent and quadrivalent vaccines are also available in Europe (Icterohaemorrhagiae, Canicola, and Grippotyphosa; Icterohaemorrhagiae, Canicola, Grippotyphosa, and Bratislava; and Icterohaemorrhagiae, Canicola, Grippotyphosa, and Australis) and increasingly in other parts of the world. One study showed that the trivalent vaccine was able to provide protection against challenge with serovar Copenhageni (serogroup Icterohaemorrhagiae) 2 weeks after vaccination.[168] Anecdotally, in the United States and Europe, quadrivalent vaccines appear to protect dogs from leptospirosis because the disease is now

almost exclusively diagnosed in unvaccinated dogs.[13] In a retrospective case-control study in a Swiss cohort of 469 dogs with AKI, vaccination with a quadrivalent *Leptospira* vaccine including serogroups Icterohemorrhagiae, Canicola, Grippotyphosa, and Australis was associated with significantly lower odds to be diagnosed with leptospirosis.[169] However, one study from Italy reported instances of vaccine failure.[25] The duration of immunity following vaccination with bacterins is at least 12 months, with some studies showing protection from challenge 15 months after vaccination.[170–173]

Leptospira vaccines effectively prevent disease and reduce shedding after challenge with the serovar included in the vaccine. In preapproval vaccine trials, in order to produce a high incidence of clinical disease, dogs are challenged with conjunctival and intraperitoneal injection of $>10^6$, often $>10^9$, live leptospires.[170,171,174] As the quantity and nature of this experimental challenge does not truly mimic natural exposure, interpretation should be made cautiously of experimentally induced post-challenge urine shedding of leptospires in vaccinated dogs. Documentation of urine shedding in vaccinated dogs following natural exposure is very limited.

In the past, vaccination with *Leptospira* vaccines has been associated with type I hypersensitivity reactions such as anaphylaxis, especially in small-breed dogs. Anecdotal evidence from industry and veterinary practitioners in North America suggests that the prevalence of these reactions has considerably reduced in recent years (to <1%, with the majority of reactions being local reactions at the site of vaccination, rather than anaphylaxis) following efforts from industry to remove residual cell culture constituents, for example, excipient bovine proteins that have been associated with vaccine reactivity.[76,175]

Immunization is recommended for all dogs at risk of exposure. In some regions, this may be dogs that contact wildlife or farm animals, or dogs that swim, wade, or drink from environmental water sources. However, dogs in urban or suburban backyards may be at risk if there is exposure to wildlife or rodents in the immediate home environment; in other words all dogs may be at risk. A study of vaccination compliance in dogs from Germany revealed that only 50.1% of 3874 dogs had been vaccinated for leptospirosis, and the primary risk factor for lack of vaccination was recommendation from a veterinarian not to vaccinate for leptospirosis.[176] Evidence to show the protective effect of currently available leptospirosis vaccines beyond 12 or 15 months is lacking. Until more data become available, it has been recommended to restart a basic vaccination schedule with two doses administered 3 or 4 weeks apart in dogs that have not been revaccinated against leptospirosis for more than 18 months.[127] However, it is possible that a single booster at this time would restore immunity, as is generally recommended for even delays of many years in vaccination with bacterins for humans. Because positive titers do not indicate protection, antibody testing cannot be used to make decisions about need for vaccination.

For dogs that experience natural infection, immunization could commence after recovery, assuming that natural immunity is also serogroup specific and the possibility of exposure to other serovars exists. However, the duration of immunity after natural infection and the degree and duration of cross-protection to heterologous serovars that follows natural infection requires further investigation.

PREVENTION

Leptospirosis can be prevented by restricting dogs' access to potential reservoir host species or environmental water sources. Access to wildlife and farm animals can be reduced through fencing and rodent control. These measures, however, do not replace vaccination.

PUBLIC HEALTH ASPECTS

Leptospirosis is one of the most common zoonotic diseases worldwide. In humans, leptospirosis occurs after an incubation period of 2 to 20 days (mean, 10 days). In 90% of infections, it is a mild, influenza-like illness. Less commonly, it is manifested by severe multiorgan failure, with renal failure, hepatic failure, or LPHS. Abortion can occur during pregnancy. Weil's disease, which is characterized by impaired renal and hepatic function, usually occurs a week after an initial illness characterized by fever, myalgia, headache, chills, and conjunctivitis.[1]

In developed countries, most human leptospirosis cases follow recreational activities that involve water, such as houseboating or participation in triathlons, canoeing, kayaking, caving, adventure racing, or white-water rafting.[177] Individuals who contact or work with farm animals, for example, veterinarians, or wildlife can also develop leptospirosis. Contact with wild rodents adopted as pets has also led to human disease.[68] In developing countries, stray dogs may be a source of human infection, although rodents are likely also important.[69] The extent to which domestic cats might serve as reservoir hosts is not understood.

Reports of transmission from clinically affected incidental hosts (as opposed to subclinically infected reservoir hosts) to other animals are rare, and there are no reports that document transmission of leptospires from pet dogs to humans with the support of molecular typing methods. Humans are more likely to acquire leptospirosis from contact with subclinically infected reservoir hosts than from incidental hosts. Appropriate antimicrobial therapy may also reduce the possibility of transmission to humans. In an outbreak of leptospirosis in dogs in Arizona, no evidence of transmission to caregivers or owners was identified in an investigation by the CDC, despite significant contact with infected dogs with insufficient infection control protocols.[59] Nevertheless, precautions should be taken in the hospital environment to minimize zoonotic transmission (see Chapter 15). All dogs with AKI should be handled as leptospirosis suspects until an alternative diagnosis is established. Suggested precautions are shown in Box 68.1. Urine from dogs with leptospirosis can be inactivated with a variety of disinfectant solutions, including iodine-based disinfectants, quaternary ammonium solutions, and accelerated hydrogen peroxide. Large

BOX 68.1 Suggested In-Hospital Precautions for Dogs with Known or Suspected Leptospirosis*

- Warning signage on the cage or run
- Minimize movement around the hospital, avoiding transport along common hallways
- Wear gloves and disposable gowns
- Protective eyewear and face shields if aerosolization of urine likely
- Handwashing before and after handling
- No pregnant or immunocompromised staff to work with the patient
- Prompt disinfection of urine and urine spills
- Treatment with appropriate antimicrobial drugs
- Indwelling rather than intermittent urinary catheterization for monitoring urine output
- Dogs walked or gurneyed outside to urinate frequently if urinary catheter not in place
- Urination outside in a designated area that can be easily disinfected
- Warnings to others who handle the dog or specimens from the dog

*Precautions can be removed following 48–72 hours of ampicillin or doxycycline treatment.

volumes of urine can be inactivated by a 1:1 dilution with a 10% solution of household bleach. In dogs with indwelling urinary catheters, 10% bleach should be injected directly into the collection bag before disposal. All blood, urine, and tissues from dogs should be treated as medical waste. If a dog dies or is euthanized, individuals who are to handle the remains should be alerted of the possibility of leptospirosis.

Owners of affected dogs should be educated with regard to the zoonotic nature of the disease. The risk of infection to owners is probably low, because urinary shedding generally does not occur until 7 to 10 days after the onset of illness, and doxycycline treatment likely results in clearance of bacteria from the kidneys and urine within 2 to 3 days. Nevertheless, until antimicrobial therapy is completed, owners should avoid contact with their dog's urine. Thus, owners or family members may have unknowingly been exposed during pre-treatment at-home-care of their sick dog. Routine household disinfectants and gloved hands should be used to clean up urinary accidents that occur indoors. Dogs should be taken to urinate in a place that is away from water and away from other pets and people, especially children. Owners should wash their hands after they handle their pets. Veterinarians should recommend that owners seek medical attention if illness occurs around the time their dog is diagnosed with leptospirosis, or if they have any questions about the disease in humans. Immunocompromised humans should be referred to their medical practitioners for advice. Owners should also be informed that environmental sources of infection may represent an ongoing risk, not only to other dogs in the household but also to humans. If other dogs in the household had the same exposure history as a dog diagnosed with leptospirosis (e.g., they all went on a hike or swam in a lake), treatment of those dogs with 2 weeks of doxycycline should be considered, because subclinical infection and shedding may have occurred.[76,127]

Veterinarians should contact their local or state health department or the CDC if additional questions arise regarding the public health risks and zoonotic transmission of leptospirosis.

CASE EXAMPLE

Signalment

"Makalu," a 1.5-year-old male neutered kelpie dog from Dixon, California (Fig. 68.11).

History

Makalu had a 1-day history of lethargy and inappetence. The owner, a veterinarian, took his temperature at home and it was > 104°F (40°C). There had been no evidence of vomiting, diarrhea, coughing, sneezing, or increased thirst and urination. He lived on a property with another dog, three cats, sheep, goats, and a pot-bellied pig. He normally ate a commercial dry dog food, and was observed to eat a rawhide the day before he became ill. There was no history of previous travel, toxins, trauma, or tick exposure. He was 3 months overdue for vaccination, but was vaccinated as a puppy for distemper, hepatitis, parvovirus, rabies, and leptospirosis. The owner did not recall which *Leptospira* vaccines he received.

Current Medications

None.

Fig. 68.11 "Makalu," a 1.5-year-old male neutered kelpie dog that developed leptospirosis. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Physical Examination

Body weight: 22.4 kg.

General: Quiet, alert, and responsive. Ambulatory on all four limbs, temperature = 103.7°F, heart rate = 80 beats/min, respiratory rate = 20 breaths/min, mucous membranes pink, CRT = 1 sec. Estimated to be 7 to 8% dehydrated based on skin turgor.

Integument: Full, shiny hair coat. No evidence of ectoparasites.

Eyes, ears, nose, and throat: Mild scleral injection and chemosis bilaterally. No other abnormalities noted.

Musculoskeletal: Appeared stiff, but no evidence of synovial effusion. Vocalized upon flexion of the right thoracic limb.

Cardiovascular: Strong femoral pulses. No murmurs or arrhythmias ausculted. Systolic blood pressure 145 mmHg.

Respiratory: Quiet bronchovesicular sounds in all fields.

GI: Tense abdomen, with abdominal splinting noted on palpation.

Rectal examination: No abnormalities detected. Prostate palpable and symmetrical.

Lymph nodes: No abnormalities detected.

Laboratory Findings

CBC: HCT 41.4% (40–55%), MCV 70.2 fL (65–75 fL), MCHC 36.0 g/dL (33–36 g/dL), WBC 8820 cells/μL (6000–13,000 cells/μL), neutrophils 7673 cells/μL (3000–10,500 cells/μL), lymphocytes 353 cells/μL (1000–4000 cells/μL), monocytes 441 cells/μL (150–1200 cells/μL), platelets 74,000 platelets/μL (150,000–400,000 platelets/μL).

Serum chemistry profile: Sodium 143 mmol/L (145–154 mmol/L), potassium 3.7 mmol/L (4.1–5.3 mmol/L), chloride 104 mmol/L (105–116 mmol/L), bicarbonate 17 mmol/L (16–26 mmol/L), phosphorus 5.1 mg/dL (3.0–6.2 mg/dL), calcium 9.6 mg/dL (9.9–11.4 mg/dL), BUN 90 mg/dL (8–31 mg/dL), creatinine 4.6 mg/dL (0.5–1.6 mg/dL), glucose 110 mg/dL (70–118 mg/dL), total protein 5.1 g/dL (5.4–7.4 g/dL), albumin 2.4 g/dL (2.9–4.2 g/dL), globulin 2.7 g/dL (2.3–4.4 g/dL), ALT 42 U/L (19–67 U/L), AST 146 U/L (21–54 U/L), ALP 73 U/L (15–127 U/L), creatine kinase 1387 U/L (46–320 U/L), GGT 2 U/L (0–6 U/L), cholesterol 189 mg/dL (135–345 mg/dL), total bilirubin 0.4 mg/dL (0–0.4 mg/dL).

Urinalysis: SpG 1.013; pH 7.5, 2+ protein (SSA), 1+ bilirubin, 3+ hemoprotein, 2+ glucose, 0 WBC/HPF, 20–30 RBC/HPF, rare transitional epithelial cells.

Coagulation profile: PT 8.8 (7.5–10.5), PTT 16.8 (9–12), fibrinogen 280 (90–255).

Serum ethylene glycol assay: Negative.

Imaging Findings

Thoracic radiographs: The cardiovascular and pulmonary structures were within normal limits.

CASE EXAMPLE—cont'd

Abdominal ultrasound: The liver and spleen were both enlarged. The tail of the spleen had a mildly mottled echotexture. Both kidneys were mildly enlarged, and approximately 8 cm in length. The renal cortices were mildly echogenic. Both kidneys were associated with a small amount of subcapsular and retroperitoneal fluid. The mesenteric lymph nodes were prominent.

Microbiologic Testing

Aerobic bacterial culture of blood and urine: No growth.

Serologic testing (MAT): Day 2 after the onset of illness, negative for antibodies to *Leptospira* serovars Canicola, Grippotyphosa, Hardjo, Icterohaemorrhagiae, and Pomona @ 1:100. Positive for antibodies to serovar Bratislava @ 1:100. Day 10 after the onset of illness, negative for antibodies to serovar Canicola. Positive for antibodies to serovars Grippotyphosa (1:400), Hardjo (1:100), Icterohaemorrhagiae (1:800), Pomona (1:12800), and Bratislava (1:3200).

Diagnosis

Leptospirosis.

Treatment

Makalu was treated aggressively with intravenous fluids, mannitol, famotidine, antiemetics, and ampicillin (20 mg/kg IV q6h). Despite treatment with fluids, mannitol, and furosemide, urine output remained at < 0.8 mL/kg per hour. After 18 hours of hospitalization, dialysis was initiated. A second dialysis treatment was given 2 days later, after which polyuria ensued (Table 68.7). On day 3, evidence of DIC developed, which included further prolongation of the PT (14.3 s) and PTT (21.1 s), hypofibrinogenemia (< 90 mg/dL), and a positive D-dimer assay, and he was treated with multiple units of fresh frozen plasma. Treatment with ondansetron was also initiated on day 3 because of persistent vomiting, and central parenteral nutrition was instituted on day 4. Makalu's mentation improved on day 5 and he began eating on day 8.

Comments

Liver enzyme activities were not increased in this dog on admission, but increased subsequently.

TABLE 68.7 Changes in Clinicopathologic Variables Over Time in a Dog Hospitalized with Leptospirosis that Was Treated with Hemodialysis

Variable	Day 1	Day 3	Day 4	Day 5	Day 8	Day 10
ALT	62	ND	105	110	82	71
ALP	83	ND	97	97	79	75
Bilirubin	0.4	ND	0.5	0.8	0.3	0.3
BUN	105 (27)*	144 (30)	54	47	35	27
Creatinine	5.6 (2.2)	12.9 (3.1)	4.8	3.3	2.1	1.6
Albumin	2.2	2.4	2.5	2.9	3.0	3.1
Platelets	74	ND	26	91	92	Clumped
Urine output	< 0.8	0.25	10	10	7	ND

*Values in parentheses are post-dialysis values.

Borreliosis

Meryl P. Littman, Reinhard K. Straubinger, Jane E. Sykes

KEY POINTS

- First Described: Lyme disease (LD) – Connecticut, United States, 1982 (Burgdorfer)[1]; tick-borne relapsing fever (TBRF) – Colorado, United States, 1915.[2]
- Cause: Spirochetal bacteria of the genus *Borrelia* (and *Borreliella*); LD – *Borrelia burgdorferi* sensu lato,[3] *Borrelia mayonii*.[4] TBRF – *Borrelia hermsii*,[5–7] *Borrelia turicatae*,[7–9] *Borrelia persica*,[10–12] *Borrelia parkeri*,[7] *Borrelia miyamotoi*,[13,14] and others. At the time of writing, the taxonomy of *Borrelia* is in flux; the genus name *Borreliella* has been proposed for organisms other than relapsing fever borreliae.
- Primary Mode of Transmission: LD – *Ixodes* spp. ticks; TBRF – *Ornithodoros* spp. ticks for most, except *Ixodes* spp. for *B. miyamotoi*.
- Affected Hosts: LD – Humans and a large variety of animals; disease occurs in dogs, cats, humans, horses; TBRF – humans, dogs, cats, many reservoir and end hosts.
- Geographic Distribution: LD – North America, Europe, Asia; TBRF – North America, Europe, Middle East, Asia, Africa.
- Major Clinical Signs: LD – Fever, lethargy, inappetence, lameness due to oligoarthritis or polyarthritis; Lyme nephritis – vomiting, weight loss, signs of protein-losing nephropathy (PLN; thromboembolic events, effusions/edema, hypertension, eventual renal failure); TBRF – fever, lethargy, anorexia, neurologic signs, thrombocytopenia; anemia in cats.
- Differential Diagnoses: Lyme arthritis – lameness due to cruciate ligament rupture, primary immune-mediated polyarthritis, septic polyarthritis, and polyarthritis secondary to infection with other pathogens such as *Anaplasma* spp., *Ehrlichia* spp., *Bartonella* spp., *Rickettsia rickettsii*, and fungal organisms. Lyme nephritis – leptospirosis, bacterial pyelonephritis, primary immune-complex glomerulonephritis, familial nephropathies, amyloidosis, and glomerulonephritis secondary to other chronic infections such as dirofilariasis, babesiosis, ehrlichiosis, hepatozoonosis, leishmaniosis, and endocarditis. TBRF – fever of unknown origin, ITP, neurologic diseases.
- Human Health Significance: Dogs and cats are not a direct source of human infection but may bring unfed infected ticks into the house. Evidence of canine exposure to borreliosis is a sentinel for human exposure.

INTRODUCTION

The borrelioses are vector-borne infections that affect mammalian and avian hosts. Members of the genus *Borrelia*, which contains a large variety of species,[15] are usually categorized into one of two groups: the Lyme borreliosis organisms or the relapsing fever borreliae (Table 69.1). Both groups contain pathogenic species in addition to other borreliae that have been isolated only from ticks or non-clinical animals.

Lyme borreliosis is the most commonly diagnosed vector-borne disease of humans. It has been reported from North America, Europe, and Asia. Spontaneous and experimentally induced Lyme borreliosis has been described in dogs, cats, and other animals. Because of the difficulty in confirming a diagnosis and the diversity of borrelial species being isolated from ticks, controversy still exists regarding the exact prevalence and geographic distribution of infection. The relapsing fever borreliae affect humans and domestic animals. There are a few confirmed cases in which these organisms were isolated from sick dogs.

LYME BORRELIOSIS

ETIOLOGY AND EPIDEMIOLOGY

Like most spirochetes, borreliae are thin and elongated spiral-shaped bacteria (0.2 μm × 30 μm), consisting of a protoplasmic cylinder wound around an axial filament composed of multiple periplasmic endoflagella (Fig. 69.1). Dark-field, phase microscopy, or special staining techniques are needed for proper visualization of organisms. *Borrelia burgdorferi* sensu lato (s.l.; "in the broad sense") is a group of more than 20 accepted and proposed species.[15,16] Disease-relevant genospecies are listed in Table 69.1.[15,17] At the time of writing, the taxonomy of *Borrelia* is in flux and the name *Borreliella* has been proposed for non-relapsing fever borreliae; the relapsing fever borreliae would retain the genus name *Borrelia*. Because this has not been widely accepted, the name *Borrelia* will be used for both relapsing and non-relapsing fever organisms in this chapter. *Borrelia burgdorferi* sensu stricto (s.s.; "in the narrow sense") is the primary species responsible for Lyme disease in the United States. In humans, it is associated with annular skin lesions, oligo- or polyarthritis, meningitis, and carditis. In the United States, *Borrelia mayonii* in the upper midwest[4] and other borrelial species have been isolated from humans and *Ixodes* ticks on rabbits, rodents, and birds; their pathogenic significance for companion animals is uncertain.

In Eurasia, there are four main *Borrelia* genospecies: *Borrelia afzelii*, *Borrelia bavariensis*, *Borrelia garinii*, and *B. burgdorferi* s.s. Other species in Eurasia include *Borrelia lusitaniae*, *Borrelia valaisiana*, and *Borrelia japonica*. These appear to have common rodent and avian hosts, and many hosts harbor multiple infectious agents.[18–20] The greater diversity among species in Eurasia suggests that this complex of organisms originated in this region.[16,21] In Eurasia, meningopolyneuritis (Bannwarth syndrome) is the primary clinical sign in humans infected with *B. garinii* and *B. bavariensis*, whereas seropositivity due to infection with *B. afzelii* has been associated with chronic arthritis and acute and chronic dermatitis (erythema migrans and acrodermatitis chronica atrophicans, respectively).[22] *Borrelia lusitaniae* was isolated from a person in Portugal with an erythema migrans and produced experimental infection in mice.[23,24] *Borrelia valaisiana* has been isolated from *Ixodes ricinus* ticks on vegetation and birds; its DNA was also found in a human with meningoencephalitis.[25] *Borrelia afzelii* has been isolated from a naturally infected dog,[26] and mixed infections

TABLE 69.1 *Borrelia* Species of Medical and Veterinary Importance[a,b]

Species	Disease	Geographic Location	Vector	Wild Animal Reservoir	Domestic Hosts
***Borrelia burgdorferi* sensu lato**					
Borrelia burgdorferi sensu stricto	Lyme borreliosis. Humans: erythema migrans (annular skin lesions), polyarthritis, meningitis, carditis. Dogs: Lyme arthritis, Lyme nephritis	North America	*Ixodes scapularis*, *Ixodes pacificus*, and *Ixodes neotomae*	Larvae and nymphs: rodents, small mammals, birds Adults: deer, larger mammals, birds	Human, dog, cat, horse
	Lyme borreliosis	Europe	*Ixodes ricinus*	Same as above, except birds more prevalent for all stages	Human, dog, horse
Borrelia bavariensis *Borrelia garinii*	Erythema migrans, meningopolyneuritis, arthritis	Europe, Asia	*I. ricinus*, *Ixodes persulcatus*	Birds, small mammals	Human, dog?, cat?
Borrelia mayonii	Fever, headache, rash, neck pain, vomiting, spirochetemia	Upper Midwestern United States	*I. scapularis*	Small mammals	Human, other?
Borrelia afzelii	Erythema migrans, meningopolyneuritis, arthritis, ACA	Europe, Asia	*I. ricinus*, *I. persulcatus*	Small mammals	Human, dog?, cat?
Borrelia japonica	Unknown	Japan	*Ixodes ovatus*, *I. persulcatus*	Rodents, birds	Unknown
Borrelia bissettii[c]	Erythema migrans, lymphocytoma	Slovenia	*I. ricinus*	Rodents, birds	Human
	Unknown	North America	*I. neotomae*, *I. scapularis*	Rodents, birds?	Rodent[d]
Borrelia valaisiana	Meningoencephalitis	Europe, Asia	*I. ricinus*	Birds	Human
Borrelia spielmanii	Meningoencephalitis	Germany, Slovenia	*I. ricinus*	Birds?	Human
Borrelia lusitaniae	Erythema migrans	Europe, North Africa	*I. ricinus*	Rodents, lizards	Human, rodent[e]
Relapsing Fever Borreliae					
Borrelia turicatae	Spirochetemia, lymphadenomegaly, lameness, anterior uveitis, fever	Florida, Texas	*Ornithodoros turicata*	Unknown	Dog
Borrelia lonestari	STARI	Southeastern and south central United States	*Amblyomma americanum*	Deer	Human
Borrelia miyamotoi sensu lato	Fever, chills, headache, joint pain, fatigue, spirochetemia, possible neurologic signs	North America, Japan, Europe	*Ixodes* spp.	Rodents?	Human, other?
Borrelia recurrentis	Epidemic louse-borne relapsing fever	Central and East Africa, South America, Europe, Asia	*Pediculus humanus* (body louse)	None	Human
Borrelia anserine	Avian spirochetosis	Worldwide	*Argas persicus*	Birds	Poultry
Borrelia hermsii, *Borrelia parkeri*	Endemic tick-borne relapsing fevers, visible spirochetemia	North America (northwest, west)	*Ornithodoros* spp.	Rodents, small mammals	Human, dog
Borrelia persica	As above	Asia, Middle East	As above	As above	Human, dog, cat
Borrelia hispanica	As above	Spain	As above	As above	As above
Borrelia duttonii	As above	East Africa	As above	As above	As above
Borrelia coriaceae	Enzootic abortion	Western United States	*Ornithodoros coriaceus*	Deer	Cow

[a]Other species isolated from ticks or their reservoir hosts, but not established to infect domestic hosts include: *Borrelia andersonii* in *Ixodes dentatis*, United States; *Borrelia californiensis.*, western United States; *B. carolinensis.* southeastern United States; *Borrelia americana.*, southeastern and western United States; *Borrelia tanukii* in *I. tanuki*, Japan; *Borrelia turdi* in *I. turdis*, Japan; *Borrelia sinica* in *Ixodes ovatus* and *Niviventer confucianus*, China.
[b]At the time of writing, the taxonomy of borreliae is in flux; the genus name *Borreliella* has been proposed for species belonging to *Borrelia burgdorferi* sensu lato; relapsing fever borreliae would retain the genus name *Borrelia*.
[c]Isolated reports exist for infection of humans with these *Borrelia* species.
[d]Experimental infection.
[e]Experimental infection.
ACA, acrodermatitis chronica atrophicans; *STARI*, southern tick-associated rash illness; *?*, uncertain involvement.

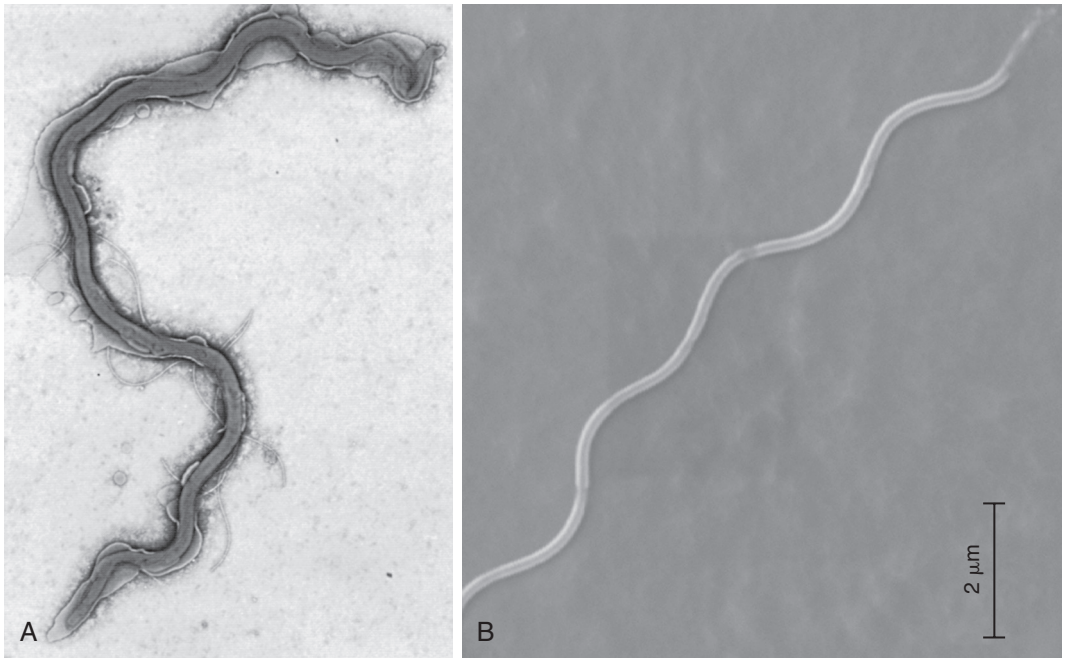

Fig. 69.1 (A) Transmission electron micrograph of *Borrelia burgdorferi* showing periplasmic flagella that have been released from the confines of the outer membrane secondary to specimen preparation (phosphotungstic acid, ×7100). (B) Scanning microscopic view of *B. burgdorferi* (×15,000). (Courtesy of R. Straubinger, LMU Munich, Germany.)

with this and other European species have been described. *Borrelia japonica* has been isolated from ticks found on dogs and humans in Japan.[27] In the same region, additional borrelial species have been isolated from ticks from small mammals; however, their pathogenic significance is uncertain.

Borreliae cannot survive as free-living organisms in the environment. They are host-associated, being transmitted between vertebrate reservoir hosts (mammals, birds, and lizards) and hematophagous arthropod vectors. *Borrelia burgdorferi* s.l. infections are geographically dispersed (see Table 69.1). In general, Lyme borreliosis occurs in the northern hemisphere in temperate latitudes with cooler climatic conditions. In North America, the majority of canine and human cases occur in the mid-Atlantic to New England coastal states, northeastern states into southern Canada, and upper midwestern states. Ecology supporting Lyme disease exists in adjacent states and also on the west coast down into northeastern Mexico (and especially just north of San Francisco),[28–30] and the areas affected are expanding as tick populations, reservoir hosts, and white-tailed deer populations expand (Fig. 69.2). In North America, evidence of exposure in dogs is often detected earlier and to a greater extent than in humans in areas of Lyme emergence. In a serosurvey of dogs in the United States, overall positive prevalence rates were highest in the northeast (11.6%), followed by the midwest (4.0%), west (1.4%), and southeast (1%) in decreasing order.[31,32] These data mirror the human prevalence data for disease prevalence.[33] Analysis of over 20 million antibody test results in dogs from 2010 to 2017 in 25 states from the eastern United States showed a trend for declining seroprevalence in 8 states along the mid-Atlantic coast from Virginia to New Hampshire, and Wisconsin; an increasing seroprevalence in 5 northeastern states and midwestern states where Lyme is endemic or emerging; and an increasing seroprevalence in 3 southern states that are not considered endemic regions.[34] In Canada, Lyme borreliosis in humans is endemic in southeastern Ontario. In a study that included 753,468 C_6 antibody test results from 2008 to 2015, there was a significant increase in seroprevalence (144%) over the course of the study, from 0.9% to 2.2%.[35] The risk of seropositivity

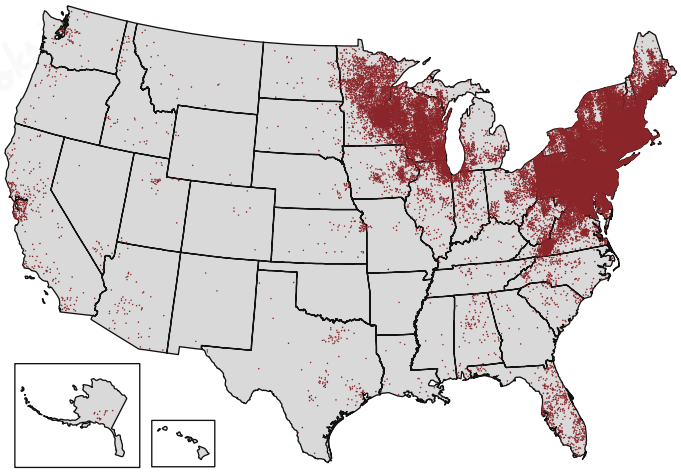

Fig. 69.2 Approximate geographic distribution of Lyme borreliosis in humans (and dogs) in the United States.

was greater in Manitoba (2.4%), Quebec (2.3%), Nova Scotia (9.5%), and New Brunswick (7.4%) than in the reference province of Ontario (1.8%), and lower in Alberta (0.8%) and British Columbia (0.5%). The seroprevalence in 199 dogs from Prince Edward Island was 3%, where 10% of *Ixodes scapularis* ticks were found to be infected.[36]

The principal vectors of *B. burgdorferi* s.l. are various species of slow-feeding hard ticks of the *Ixodes* spp. complex, the distribution of which reflects disease prevalence (Table 69.2). In the United States and Canada, closely related black-legged ticks, *I. scapularis* (in the northeastern, midwestern, and southeastern states to northeastern Mexico, and southern Canada) and *Ixodes pacificus* together with *Ixodes neotomae* (in the western states) appear to be involved.[37] Two major clades of *I. scapularis* have been identified in the United States, the American (northern) clade and the Southern clade.[38] *Ixodes scapularis* ticks found on dogs and cats in the northeast and midwest are almost exclusively of

TABLE 69.2 Selected Vectors of *Borrelia burgdorferi*[a]

Species	Geographic Location	FEEDING PREFERENCE		Infection Prevalence
		Larvae, Nymphs	Adults	
Ixodes scapularis American clade	United States (mid- and north-Atlantic coast, northern Midwest)	White-footed mouse (*Peromyscus leucopus*), small mammals, birds	Deer, larger mammals	<1% larvae 10%–25% nymphs 10%–80% adults
Ixodes scapularis Southern clade	United States (southeastern)	Lizards	Lizards (occasionally mammals)	<1% larvae <1% nymphs <1% adults
Ixodes pacificus, Ixodes neotomae	United States (western)	Lizards	Lizards (occasionally mammals)	1%–5%
Ixodes ricinus	Europe (western and central)	Small mammals, birds, mice (*Apodemus flavicollis, Apodemus sylvaticus, Clethrionomys glareolus*)	Deer, larger mammals	10%–25%
Ixodes persulcatus	Europe through central and northern Asia to China and Japan	Small mammals, birds	Deer, larger mammals	10%–25%

[a]*Borrelia burgdorferi* or related organisms have been recovered from numerous other ticks and arthropods in nature, but the significance is uncertain. Many sylvan cycles exist in nature in which tick vectors do not feed on large mammals. Only the established vectors for humans or domestic animals are listed here.

the American clade; two thirds of *I. scapularis* found on dogs and cats in the southeast were of the American clade and one third was of the Southern clade.[38] Ticks in the north central United States prefer deciduous, dry to mesic forests and sandy or loamy soils overlying sedimentary rock.[39] Ticks are not associated with grasslands, conifer forests, or acidic soils with low fertility or a claylike consistency. In the coastal states, tick infection and dog seroprevalence are greatest in the coastal counties,[40] presumably reflecting the tick's preference for moisture.[41]

These small (less than 3 mm) ixodid ticks generally feed on more than one host during their life cycle (Figs. 69.3 and 69.4). The number of hosts varies depending on the tick species. In North America, where approximately 50 to 80 vertebrate species serve as hosts, larvae and nymphs of *I. scapularis* in the north and parts of the south generally feed on small mammals and birds, whereas immature stages of *I. scapularis* in the south often feed on a variety of hosts including lizards.[42,43] Adults of these ticks feed on deer or larger mammals. Reptiles and other preferential hosts of *I. scapularis* in the southern and western regions are not competent reservoir hosts, and differences in the timing of feeding on these hosts do not allow for efficient transfer of infection for its overwintering in ticks. Therefore, the infection rate of southern *I. scapularis* ticks (less than 1%) is much lower than that of *I. scapularis* ticks in the northeastern United States (10% to 50%).[44] At least one lizard species possesses a borreliacidal substance in its blood similar to complement that reduces or prevents infection with *B. burgdorferi*.[45] Furthermore, because the southern *I. scapularis* ticks do not always feed on mammals, the prevalence of Lyme borreliosis in humans and domestic animals is low in the south.[46] Infected *Ixodes* ticks may be dispersed to new areas by feeding on migratory birds.[47–52]

In Europe, *B. afzelii, B. bavariensis, B. garinii*, and *B. burgdorferi* s.s. are responsible for the majority of infections. Most cases occur in the Scandinavian countries and in central Europe in areas with moderate temperature and moderate humidity (Austria, Belgium, Croatia, Czech Republic, parts of France, Germany, Hungary, Netherlands, Portugal, Slovenia, Switzerland etc.), with the prevalence tending to increase from west to east in association with *I. ricinus* activity (Fig. 69.5). *Ixodes ricinus* ticks, across the Mediterranean Sea in northern Africa, are also infected with *B. burgdorferi* s.l.[53] *Ixodes ricinus* ticks have also been infected with other *Borrelia* spp., including *Borrelia*

Fig. 69.3 *Ixodes scapularis* ticks. From largest to smallest, two adults (male, female), two nymphs, two larvae (bar = 1 mm). (Courtesy of Mike DeRosa, West Somerville, MA.)

bissettii, B. valaisiana, and *B. lusitaniae*.[54–56] In these cases, the infection is being maintained in nature; however, the clinical significance of such infections in humans or domestic animals is unknown. The distribution of infection stretches eastward across Eurasia, corresponding to the habitat of the tick *Ixodes persulcatus*, which transmits *B. bavariensis, B. garinii*, and *B. afzelii*.[57] Whereas *B. burgdorferi* s.s., *B. bavariensis*, and *B. afzelii* are associated with rodent reservoirs, *B. garinii* and *B. valaisiana* are associated with bird reservoirs.[58] *Ixodes ricinus* and *I. persulcatus* parasitize more than 200 vertebrate species. Several species of mice, voles, and rats are important reservoir hosts. Squirrels,

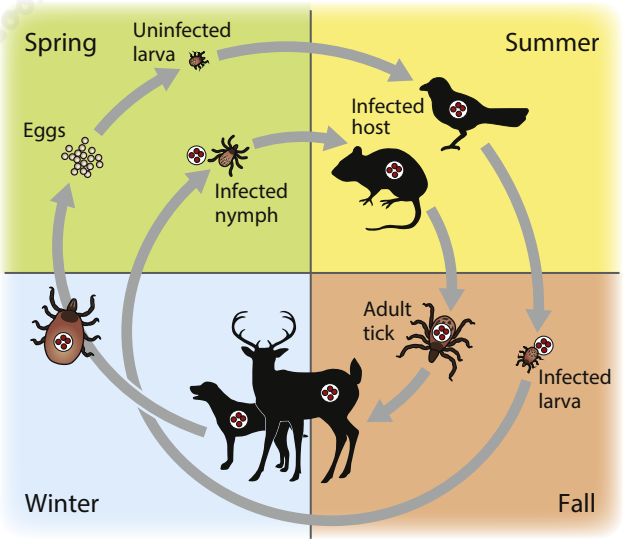

Fig. 69.4 Life cycle of *Ixodes scapularis*. The life cycle lasts a minimum of 2 years. Eggs are oviposited in the spring, and the larvae emerge approximately 1 month later. They feed once in the summer, usually on birds and small mammals, and then overwinter. The following spring, the larvae molt into nymphs, which then feed in late spring or early summer. The nymphs feed on mice or larger mammals such as dogs, deer, or humans and are considered the most likely source of *Borrelia burgdorferi* (and/or *Anaplasma phagocytophilum*) infection for dogs and people. Nymphs then molt into adults in the fall. The adults usually feed on larger mammals (often white-tailed deer), where they mate. The females die after laying their eggs, and the 2-year cycle is repeated. Circles that contain red dots represent infection with *B. burgdorferi* and/or *A. phagocytophilum*.

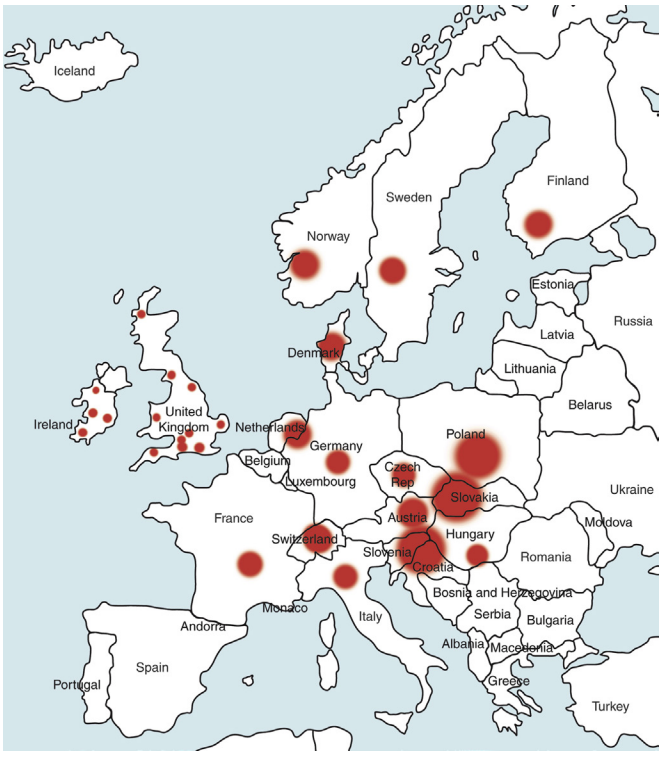

Fig. 69.5 Countries and regions where Lyme borreliosis occurs in Europe. The size of the red dot correlates with the relative prevalence of the infection in those areas.

hedgehogs, shrews, and birds are also involved in the maintenance of the infection cycle.

On the North American and Eurasian continents, larger ungulates such as deer and moose are important in the life cycle because adult *Ixodes* ticks feed on them and are carried for long distances. However, the level of infection in these large mammals is insufficient to transmit to feeding ticks, making them unsuitable reservoir hosts.[59–61] The *Ixodes* ticks that transmit Lyme borreliosis normally have a minimum 2-year life cycle and maintain infection in nature by harboring the organism over the winter period (see Fig. 69.4). In the northeastern and upper midwestern United States, *I. scapularis* primarily becomes infected when immature stages (especially larvae) feed on infected white-footed mice (*Peromyscus leucopus*) and birds.

Direct transmission of borreliae between reservoir hosts is unlikely, and transovarial transmission in ticks that carry Lyme borreliosis organisms is practically nonexistent, except for *Borrelia miyamotoi*.[62,63] Larvae, which have become infected by feeding in the summer and fall, harbor the organism over the winter and molt to infected nymphs.[64] When these nymphs feed in the spring, they transmit organisms to competent reservoir hosts. Nymphs, which feed on a wide variety of animals, are primarily responsible for the transmission of infection to domestic animals and humans, as well as infecting new rodent reservoir hosts.

Larvae and other tick stages can become infected from previously uninfected hosts by co-feeding with infected ticks that have attached in close temporal and spatial proximity.[65,66] However, co-feeding of infected and noninfected *I. ricinus* ticks was not as efficient in transmitting *B. afzelii* infection as was the transmission of the organism from previously infected mice to uninfected larvae.[19] Adult female ticks feed on larger mammals such as white-tailed deer, dogs, and livestock. Although feeding on deer is necessary to maintain the tick population, deer and cattle are not effective reservoir hosts for infection.[67] Nymphs are more likely to cause human infections because they remain undetected due to their small size (see Fig. 69.3). This allows them to remain attached for sufficient periods for successful transmission of spirochetes. Despite the zoonotic risk from nymphal ticks, adult ticks appear to have the highest rate of infectivity among stages, presumably because of repeated exposure to infected mammals and birds.

In the western United States, immature *I. pacificus* become infected by feeding primarily on western gray squirrels (*Sciurus griseus*), and the adult ticks transmit the infection to larger mammals during subsequent feedings. As occurs in Eurasia, birds may be more important in the sylvatic cycle of infection in the western United States.[68] *Ixodes trianguliceps* may also play an analogous but lesser role in Eurasia of maintaining infection in nature, similar to that of *I. spinipalpis* in the western United States, by feeding exclusively on rodent reservoirs.[69]

Ixodes ticks can be simultaneously infected with additional animal and human pathogens, including *Ehrlichia* spp. and *Rickettsia* spp. (e.g., *Ehrlichia muris* in the upper midwest),[70] *Anaplasma phagocytophilum* (see Chapter 45), *Babesia* spp. (*Babesia microti*, *Babesia odocoilei*, and *Babesia gibsoni*) (see Chapter 97), multiple *Borrelia* spp. (e.g., *B. miyamotoi* in the east, *B. mayonii* in the upper midwest), and tick-borne encephalitis viruses.[71–74] Diagnosis and interpretation of serologic tests, and correlating them with specific signs of clinical illness, are problematic when a co-infection exists (see Diagnosis).

Numerous hematophagous arthropods, including other tick species, fleas, flies, mites, and mosquitoes, carry *Borrelia* organisms in nature. These findings most likely indicate accidental contamination, and arthropods do not transmit infection. Contamination from feeding on infected vertebrates is suspected; accordingly, these other arthropods have not been documented to transfer infection to new hosts.[75] Only *I. scapularis*—and not *Amblyomma americanum* or *Dermacentor variabilis*—has effectively transmitted *B. burgdorferi* in North America.[75]

Although Lyme borreliosis is generally associated with mice and small mammals in forests, bordering shrubs of backyards, and gardens, it may be acquired in parks in major metropolitan centers where rats appear to be the effective reservoir host for feeding ticks.[76–78] In the northern midwestern United States, seropositivity among dogs was positively associated with numerous risk factors including increased tick exposure, time spent outdoors, and living in forested or urban wooded habitats and on sandy, fertile soils.[79]

In a natural infection model study with ticks, control dogs that were in direct contact with infected dogs for up to a year did not undergo seroconversion, and organisms could not be isolated from the urine or urinary bladder of infected dogs.[80] Canine urine is an unlikely source of infection. After natural infection, *in utero* spread to pups did not occur from seropositive dams. *Borrelia burgdorferi* can survive in blood processed for transfusion and stored under blood bank conditions,[81,82] but they do not induce infection after blood transfusion.[83] However, not a single case of *B. burgdorferi* infection caused by blood transfusion has been documented in humans[84,85] or animals, and no animal model exists in which Lyme borreliosis can be induced by artificial insemination or by IV injection of *B. burgdorferi* organisms.[83]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Borrelia burgdorferi carries up to 12 linear and 9 circular plasmids. The plasmid genome codes largely for outer surface proteins responsible for survival and persistence in vertebrate hosts and successful transmission by tick vectors.[86–88] Borreliae grown *in vitro* can lose plasmids and hence pathogenic potential.

The onset of spirochete transmission requires 12 to 24h (average 18h) of tick attachment, during which organisms multiply and cross the gut epithelium into the hemolymph, disseminate to the salivary glands, and infect the host through tick saliva.[89,90] Outer surface protein A (OspA), the predominant surface protein, is expressed on the outer surface of borreliae in the midgut of infected ticks and allows the spirochetes to adhere to the midgut by attaching to a receptor known as TROSPA.[91,92] In unfed ticks, virtually all spirochetes reside in the midgut. During feeding and because of the warmth of the new environment (skin surface temperature of the host), spirochetes begin to express OspC, which correlates with the migration of the spirochetes from the midgut into the hemolymph and finally to the salivary glands of the feeding tick.[86,87,89,93–98] Although originally thought that OspA is downregulated during feeding, more recent studies suggest that strong OspA expression is maintained throughout the tick feeding process; expression decreases only after infection of the mammalian host occurs.[92]

After dermal inoculation into the mammalian host, aided by tick salivary protein 15 (Salp15), OspC inhibits phagocytosis and promotes spirochete dissemination.[97–101] Salp15 binds to OspC and protects it from immune recognition; it also inhibits adaptive immune responses against Borrelia and tick antigens.[97] The expression of OspC allows the organism to become established in the host; however, it is not required for persistence beyond several weeks.[102] Levels of the immunodominant variable surface lipoprotein component (VlsE; variable major protein-like sequence, expressed) increase during the last 2 days of tick engorgement; the increase continues after OspC production ceases.[103] VlsE and other proteins are involved in chronic persistence of the spirochete and its avoidance of the host immune response. A genetically conserved, invariable region of VlsE protein is strongly immunodominant and important in serodiagnosis (see below, Serologic Testing).

Despite the numerous humans and animals that are bitten by infected ticks, only a few develop clinical disease. Host immune reactions are likely involved in preventing many of these infections. Studies show that the percentage of dogs that develop severe clinical signs of the disease is low when compared with the frequency of exposure based on seropositivity (3%–10% in central Europe; 70%–90% in highly endemic areas in the United States) and the rate of infection demonstrated in ticks.[104–109] Part of this seropositivity in dogs may indicate exposure to low numbers of *B. burgdorferi* organisms in a host with an efficient immune system or represent an exposure to infectious but nonpathogenic isolates of *Borrelia*.[110] Even among genetically similar *B. burgdorferi* s.s. strains, pathogenicity may vary based on plasmid content. Based on OspC genotyping, over 30 strains of *B. burgdorferi* s.s. have been identified. In the New England region of northeastern United States, OspC types A, B, I, K, and N were most common in humans, whereas infected dogs showed types A, B, F, I, and N; strains may differ in geological areas, hosts, pathogenicity, and tissue tropism.[111–115] Lack of cross-reactive immunity allows for multiple strain infections and reinfection.[116]

From the site of the tick bite, spirochetes replicate and migrate through the skin and connective tissues (Fig. 69.6). Later, they colonize many tissues, including the joints. Active migration in tissues is the likely route of dissemination as opposed to passive dissemination via the blood,[85] although spirochetemia occurs with *B. mayonii*.[4] This has implications for diagnosis. The spirochetes' requirement for N-acetyl-glucosamine, a component of collagen synthesis, may explain tissue tropism.[117]

Once in the body, *B. burgdorferi* acts as a persistent pathogen. The host immune response is capable of reducing spirochete numbers, and although the spirochete is not eliminated from the host after a few weeks of infection, *B. burgdorferi* is virtually undetectable in body fluids or internal organs, and exceedingly few spirochetes are found in other tissues.[80,118,119] The organism can evade host antibody and exist extracellularly by varying or masking its immunoreactive proteins,[86,87,99,120,121] and by changing its shape. Spiral, motile borreliae can convert into spherical life forms within minutes after they have encountered unfavorable environmental conditions (Fig. 69.7).[122,123] In this form, they survive for days without nutrition and without metabolic activity and revert into the well-known spiral form when conditions improve. These spherical forms are able to infect mice.[124,125] This may explain why *B. burgdorferi* can persist and be detected in tissue specimens by PCR or occasionally by culture even after months of antibacterial treatment.[125] Spirochete antigen has also been found in joints after treatment in mice.[126] Clinical illness results from the host's

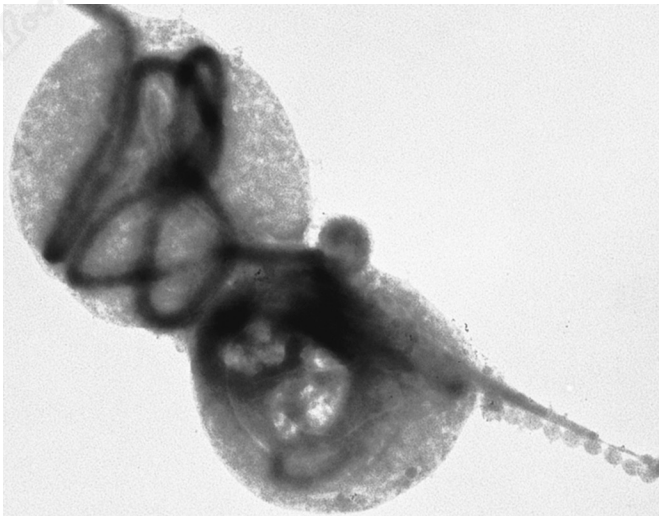

Fig. 69.7 Transmission electron microscopic (×12,000) appearance of the cystic form of *Borrelia burgdorferi,* a defense mechanism of the organism for survival under adverse conditions such as antimicrobial therapy or host immune defenses. (Courtesy of R. Straubinger, LMU Munich, Germany.)

own inflammatory response. Some of the immunopathologic events in joint, cardiac, or nervous tissue may be related to immune responses generated against specific borrelial antigens.[127] One of the most immunogenic proteins, flagellin, can elicit production of an antibody that binds to host neuroaxonal proteins. This sequence may in turn stimulate the inflammatory response in nervous tissue.[128] Clonal analysis indicates that the immune response in nervous tissue may be directed at the pathogen and neural self-antigens.[129]

Cytokine release results in damage to the surrounding tissue. In the joints, upregulation of IL-8, which recruits neutrophils to inflammatory sites, has been found in the synovial membranes of experimentally infected dogs.[130] This may contribute to the development of suppurative polyarthritis. In a few animals, the development of arthritis is probably related to pathologic perpetual host immune reactions. Humans with certain MHC haplotypes are prone to more severe, treatment-resistant clinical manifestations of the disease in which *B. burgdorferi* cannot be detected.[131]

The tissues of preferential localization may vary by *Borrelia* species and determine pathogenicity and, therefore, differences in clinical manifestations seen in various geographic regions. *Borrelia garinii* was found in the liver of dogs having elevated serum liver enzyme activities, a finding not associated with *B. burgdorferi* s.s. infection.[132] Despite the presence of glomerulonephritis in seropositive dogs, evidence of the presence of spirochetes has not been found in renal lesions.[133,134] The glomerular injury may relate to deposition of circulating immune complexes (CICs) secondary to infection rather than primary spirochetal localization. *Borrelia burgdorferi*–specific CICs have been found in the serum of infected dogs and elution studies of kidneys taken from suspect dogs after death showed *B. burgdorferi*–specific complexes in the glomerular deposits.[135,136]

Clinical Signs in Humans When Compared with Dogs

Clinical features of Lyme borreliosis in humans include an acute phase within a week of exposure with dermatitis (erythema migrans, an expanding bull's eye rash at the site of the tick bite) and influenza-like signs, followed weeks to months later by oligoarthritis in 60% of untreated cases (usually of the knee), or possibly (more common in Europe) neurologic manifestations (e.g., cranial nerve palsy, polyradiculitis, meningitis), myocarditis, or chronic dermatitis.[3,137] In contrast to humans in which asymptomatic seroconversion is uncommon in North America,[138] the vast majority of exposed dogs experience subclinical seroconversion.[104,106,107,139] Experimentally, no acute signs of illness occur in dogs, and signs of arthritis are not noted until at least 2 months post-exposure, well after seroconversion.[80,104,107,139] Erythema migrans is not reported in dogs, and neurologic,[140–144] cardiac,[145,146] or dermal signs are rare or poorly documented. However, perhaps 2% of naturally exposed dogs develop Lyme nephritis (immune-complex glomerulonephritis), which is rarely seen in humans.[147,148] Co-infections in both dogs and humans are common, especially with other tick-borne pathogens that are transmitted simultaneously and may precipitate or exacerbate clinical signs.[149]

Lyme Borreliosis in Dogs

Experimental infections. Initial attempts to recreate experimental Lyme borreliosis in dogs using laboratory-derived strains were unsuccessful, as they were in cats.[150,151] However, fever and lameness due to oligo- or polyarthritis have been experimentally produced after dermal inoculation or natural exposure to tick-derived *B. burgdorferi.*[80,130,152–155] Inoculation of spirochetes using field-collected ticks has been most successful; however, co-infections are common, especially with *A. phagocytophilum* (see Chapter 45). Clinical illness in experimentally infected young puppies occurred 2 to 9 months after tick exposure, well after seroconversion, and the severity and propensity to develop signs of illness seem to vary inversely with the animal's age and immune status. Exposed 6- to 12-week-old puppies had a self-limiting 4-day illness starting 2 to 5 months after exposure, consisting of fever and lameness due to acute arthritis in the limb closest to where ticks fed, sometimes with several similar relapses at 2-week intervals in the same or different limb. Exposed 13- to 26-week-old puppies had milder signs, and adult dogs seroconverted but showed no signs of illness.[80,155] Interestingly, about half of the experimental dogs were inadvertently co-infected with *A. phagocytophilum* and some were weakly positive for antibodies to *Babesia microti*. Signs of experimental disease appear milder than those in the field, possibly due to multiple tick exposures in the field (times and sites).

Systemic signs. Acute signs of fever (103.1°F to 104.9°F [39.5°C to 40.5°C]), shifting leg lameness, articular swelling, lymphadenomegaly, anorexia, and general malaise, all of which are responsive to antimicrobials, may be seen in experimentally[80,130,155] and in naturally exposed dogs.[102,104,105,139,156–158] The accuracy of diagnosis in natural infection is difficult to determine because limb and joint signs (swelling, lameness, and pain) with fever and inappetence have been observed with equal frequency in dogs with and without *B. burgdorferi*–specific antibodies.[159–161] One study found that 40% of dogs initially diagnosed with Lyme borreliosis were eventually found to have other causes for their clinical signs.[162]

Arthritis. Oligo- or polyarthritis is the most overt syndrome caused by acute *B. burgdorferi* infection in dogs. The first limb affected is usually closest to the site of tick attachment.[80] The onset of lameness can correspond to an increased body temperature. Lameness often lasts for a few days and then may shift to another limb or disappear. Despite the transient nature of the arthritis, inflammatory changes may persist in the joint.[152] Microscopic lesions have been most consistently found in the skin, lymphatic tissues, and joints, even though the organism can be isolated from other tissues.[163] Dogs with naturally occurring cranial cruciate ligament arthropathy in a Lyme borreliosis endemic area had a higher prevalence of *B. burgdorferi* and other bacterial gene sequences within synovial biopsy tissue than dogs with clinically healthy stifle joints and those with experimental cranial cruciate ligament rupture.[164,165] These bacteria may be important in the causation and pathogenesis of the inflammatory arthritis.

Glomerulonephritis (Lyme nephritis). Although an experimental model is lacking, protein-losing glomerulonephritis has been described in naturally infected dogs, mostly in Labrador and golden retrievers.[134,166–169] Even among retrievers, Lyme nephritis

is uncommon and seropositivity is neither predictive nor associated with proteinuria.[170] Lyme nephritis is characterized by protein-losing nephropathy (PLN) in a seropositive dog, e.g., as a progressive or acute renal failure associated with proteinuria, azotemia/uremia, hypertension, thromboembolic events, peripheral edema, body cavity effusions, and occasionally neurologic signs.[104,107,167,171] The duration of clinical illness before evaluation has varied from 24 hours to 8 weeks, with a sudden onset of anorexia, vomiting, and lethargy. Dogs with more chronic progression show weight loss. About a third of dogs exhibit recent or concurrent lameness. Many dogs with advanced disease when first evaluated die or are euthanized as a result of renal failure. Since *B. burgdorferi* seropositivity is a marker for tick and wildlife exposure, it is important that other causes of renal proteinuria are ruled out (e.g., dirofilariasis, other tick-borne diseases, leptospirosis).[172,173] Renal biopsies of dogs with suspected Lyme nephritis do not show spirochetal invasion but rather immune-complex glomerulonephritis, tubular necrosis/regeneration, and interstitial nephritis.[134,166,167] Bernese mountain dogs in Europe have an increased prevalence of antibodies against *B. burgdorferi* s.l. compared with other breeds; however, seropositivity was not associated with proteinuria or lameness over a 2.5- to 3-year observation period.[174–179] Another case-control study also found no association between proteinuric kidney disease and *Borrelia* spp. seropositivity in Bernese mountain dogs.[180] Therefore, glomerular disease in this breed may be due to genetic and other causes. A genetic predisposition for resistance to *B. burgdorferi* infection was noted in purpose-bred beagles.[181]

Meningitis. Neurologic signs are later manifestations of Lyme borreliosis in humans, especially in *B. garinii* infections, which was reproducible in primate models.[182,183] Experimentally, young infected dogs developed mild focal meningitis, encephalitis, and perineuritis; however, neurologic signs were not observed.[155] Neurologic signs were not associated with seropositivity to *B. burgdorferi* in naturally infected dogs.[142–144] Nucleic acids of *B. burgdorferi* were not found in the CNS of dogs with a variety of natural CNS diseases.[141]

Other manifestations. A small, erythematous skin lesion (not the dramatic erythema migrans seen in humans) may develop at the site of tick attachment in dogs but disappears within the first week (Fig. 69.8). Spirochetes can be isolated from the skin for extended periods. Other syndromes rarely or poorly documented, and possibly circumstantial in seropositive dogs, include carditis,[145,146,184] rheumatoid arthritis,[185] or myositis.[186] In one dog with myocarditis from Poland, intralesional *Borrelia* DNA was detected at necropsy.[184]

Lyme Borreliosis in Cats

Despite the evidence of seropositivity for *B. burgdorferi* in cats, evidence of natural disease is relatively lacking when compared with dogs. Cats in endemic areas of the northeastern United States can become infested with *Ixodes* ticks. Reported prevalence rates of exposure to *B. burgdorferi* have ranged from 13% to 47% based on seropositive results by IFA, ELISA, immunoblotting, or C_6 peptide[187] antibody testing. In some studies, no difference in seroreactivity was found between cats with or without lameness, even if infected twice.[188–190] Cats in these studies were seroreactive to *A. phagocytophilum*, suggesting co-infection exposure.[189] Because anaplasmosis in cats may mimic signs of Lyme borreliosis, it is difficult to ascribe signs to Lyme borreliosis in co-infected cats.[190–192] However, in a study of 117 apparently healthy cats and 42 with clinical signs consistent with anaplasmosis or borreliosis from a single clinic in Maine, cats with signs of disease were fourfold more likely to be seropositive to *Anaplasma* spp. (9.5%), *Borrelia* C_6 antigen (23.8%), or both agents (7.1%) than healthy cats.[193] Based on serologic testing, clinical information, and response to treatment, *B. burgdorferi* was thought to be the most likely cause of illness. Lameness, lethargy, anorexia, and/or fever were the main signs described in cats seropositive for *B. burgdorferi* but seronegative for *A. phagocytophilum*. Sick cats in the United Kingdom had a low rate (4.2%) of *B. burgdorferi* seroreactivity, and clinical signs in the seropositive cats in that study did not include lameness.[194] *Borrelia burgdorferi* was suspected as a cause of bradyarrhythmia in two cats from the United Kingdom (in one cat, the spirochete was detected in blood using PCR),[195] and two cats with recurrent fever.[196] In Germany and European endemic areas, 2.2% (6/271) cats had C_6 peptide antibodies (5 with clinical signs); it was suggested that cats with shifting leg lameness or neurologic signs of unknown cause be tested.[197] Cats may be more resistant than dogs to the development of Lyme borreliosis. When cats were inoculated with organisms directly from arthropods, they developed multiple-limb lameness and had joint, pulmonary, lymphoid, and CNS inflammation at necropsy.[198,199] Arthritis or meningitis seems to be the predominant manifestation that would warrant investigation of Lyme borreliosis in cats, but it should also be considered as a cause of bradyarrhythmias/carditis in cats from endemic areas when other causes have been excluded.

DIAGNOSIS

There is no test that definitively confirms Lyme borreliosis; however, dogs with compatible clinical signs in endemic areas that have been exposed to ticks bear the highest consideration. Overestimation of case numbers may result from cross-reactivity to other infectious agents in older tests with low specificity (e.g., IFA), serologic test inaccuracies, and the fact that dogs with seropositive test results can have other illnesses that cause signs similar to Lyme borreliosis.[162,200,201] Furthermore, the interpretation of serologic results may be hampered by the existence of co-infections with other vector-borne pathogens.[74] In a survey from Baxter, MN, where *I. scapularis* is endemic, sick dogs were more likely to have positive antibody and PCR test results for both *A. phagocytophilum* and *B. burgdorferi* (than to either alone), compared to clinically healthy

dogs in the same clinic population.[149] Therefore, co-infections may be important in determining whether infected animals develop clinical illness. Diagnosis of Lyme borreliosis should be based on known tick exposure in the endemic region, compatible clinical signs, and laboratory findings with exclusion of other diseases and favorable response to selective antimicrobial administration (although Lyme nephritis may not respond as readily). Major differential diagnoses for Lyme arthritis include trauma, other tick-borne diseases, immune-mediated arthritis, and degenerative joint disease; major differentials for Lyme nephritis are other causes of renal proteinuria such as leptospirosis, other tick-borne diseases, dirofilariasis, leishmaniosis, chronic infections, immune-complex glomerulonephritis, glomerulosclerosis, amyloidosis, and genetic glomerular diseases. Treatment response could be due to treatment of other unidentified causative pathogens or spontaneous resolution of signs; therefore, the diagnosis of Lyme borreliosis can be difficult.

Serologic screening of clinically healthy dogs for infection with *B. burgdorferi* is controversial.[104,107,202] From a positive standpoint, infection or exposure might be found at a preclinical stage of illness before immunopathologic consequences such as renal dysfunction occur; screening for occult proteinuria has been recommended for all seropositive dogs.[104,107,202] Conversely, should proteinuria be detected first, a diagnostic workup should include testing for antibodies to *B. burgdorferi* in dogs from endemic areas.[203,204] Detection of seropositive dogs is an opportunity to improve tick prevention strategies (see below) and alerts owners of their own potential exposure to ticks. On the negative side, routine testing can lead to overdiagnosis, overtreatment, or unnecessary owner concerns. Four of six panelists in the updated ACVIM consensus statement did not routinely recommend antimicrobial treatment for nonclinical nonproteinuric *B. burgdorferi* seropositive dogs.[104]

Laboratory Abnormalities

Complete Blood Count, Serum Biochemistry Profile, and Urinalysis

No specific hematologic or biochemical changes are pathognomonic for borreliosis. The presence of leukopenia or thrombocytopenia in tick endemic areas may be more likely to be caused by infection or co-infection with other vector-borne pathogens (especially *A. phagocytophilum*). Laboratory blood abnormalities in dogs with Lyme nephritis include hypoalbuminemia, azotemia, and hypercholesterolemia, and may include nonregenerative anemia, stress leukogram, mild/moderate thrombocytopenia, hyperphosphatemia, and variable hyperkalemia.[166] Urinalysis abnormalities in dogs with Lyme nephritis include proteinuria, with variable loss of concentrating ability, and possible hemoglobinuria, hematuria, glucosuria, and pyuria. However, other causes of renal disease such as leptospirosis and babesiosis were not always ruled out in studies that reported these findings in dogs suspected to have Lyme nephritis.[167] UPCRs are often greater than 5 and may be above 15 in some dogs. In one study from northern California, 40 dogs with positive C_6 serology and PLN were more likely to have thrombocytopenia, anemia, neutrophilia, azotemia, hyperphosphatemia, hematuria, glucosuria, and pyuria than 78 C_6-seronegative dogs with PLN. The prevalence of polyarthritis was not significantly different between groups. Of interest, pyuria was detected in 12/39 seropositive dogs but none of the seronegative dogs.[166]

Cytology of Synovial and Cerebrospinal Fluid

Synovial fluid changes in dogs with Lyme borreliosis consist of increased cell counts (5,000 to 100,000 cells/μL) with neutrophils predominating (up to 95%). Because not all joints may be affected, synovial fluid should be collected from at least three and preferably four peripheral joints. Protein concentration and turbidity are increased. CSF from humans with neuroborreliosis demonstrates lymphocytic pleocytosis and a mild protein increase. Consistent CSF values have not been found in dogs with suspected neurologic dysfunction.

Diagnostic Imaging

Plain Radiography

Radiographs of involved joints may show increased periarticular soft tissue opacity. Erosive arthritis has not been described.

Sonographic Findings

Abdominal sonographic findings in dogs with Lyme arthritis are unremarkable. In dogs with nephritis, the kidneys may look normal, or there may be thickening and increased echogenicity of the renal cortices, decreased renal corticomedullary distinction, and peritoneal effusion.

Microbiologic Tests

Serologic Testing

The presence of antibodies to *B. burgdorferi* signifies exposure but does not prove that clinical signs are caused by the organism. In endemic areas, apparently healthy dogs are often seropositive, possibly as a result of adequate host immune responses or, with less specific assays, from exposure to nonpathogenic forms of *B. burgdorferi* or other closely related spirochetes.[205] The diagnosis of Lyme borreliosis involves serologic testing because it is difficult to detect the organism in specimens of tissue samples or body fluids. However, seropositivity should be viewed as determining "seroreactivity to *B. burgdorferi*" and not evidence of causation. Paired sera (acute and convalescent) are not needed for Lyme disease since dogs typically seroconvert before clinical signs develop (in contrast to humans when seen for acute Lyme borreliosis). Paired serologic testing, however, may be needed to rule out other acute vector-borne diseases that cause signs similar to Lyme borreliosis (e.g., anaplasmosis, ehrlichiosis, RMSF, leptospirosis). Serial quantitative serologic testing may be helpful to determine a new baseline after antimicrobial therapy, which is associated with a reduction in C_6 antibody levels (clearance or decreased antigenic load). Subsequent rises in quantitative levels from the post-treatment baseline may signal relapse or reinfection, which may warrant further treatment and monitoring for proteinuria.

Antibody detection (whole cell). The first available immunodiagnostic tests for Lyme borreliosis used antigens from whole spirochete preparations. These methods were not standardized and had a high level of cross-reactivity with other bacteria such as *Leptospira* and *Borrelia turicatae*, the cause of TBRF in dogs from Florida and Texas.[9,158,201,206–213] With these assays, experimentally infected dogs developed positive IgG-ELISA-titers by 4 to 6 weeks after exposure.[80,152] Titers peaked 3 months after exposure and lasted for at least 2 years.[214] ELISA assays that detect only IgM are not useful in dogs since they only show signs once an IgG response has occurred. Antibody titers do not decline rapidly after treatment and IgG titers can remain positive for many years. An increase in titer that occurs 6 months or later after termination of antimicrobial therapy has been interpreted as proliferation of surviving spirochetes,[130,215] but may also result from reinfection. Dogs vaccinated with *Borrelia* vaccines may remain seroreactive for months to years after vaccination, making a diagnosis of *B. burgdorferi* infection based only on ELISA with whole cell preparations difficult.[216] Because of the shortcomings of antibody measurements with whole cell antigens, serologic tests of this type have been largely discontinued.

Immunoblotting, line immunoassay (LIA). Rarely used for initial screening, immunoblotting or LIA may be employed as a second-tier test to help confirm positive results, to differentiate infected from vaccinated animals, and to detect reactivity to other *Borrelia* spp. that

may be missed by recombinant protein-based ELISA methods. The pattern of antibody reactivity after natural infection differs from that following vaccination. The size of bands on immunoblots varies in different investigations depending on techniques and strain differences and so the following information should only be used as a guideline. After natural exposure to *B. burgdorferi*, antibodies develop to proteins in the range of 100/83, 75, 66, 60, 58, 43, 41 (flagellin), 39, 30, 23 (OspC), and 21 kDa[139,217]; a diversity of antibody responses were found in experimentally exposed beagles.[218] Strong reactivity to OspA (31 kDa) occurs in vaccinated dogs[80,219–222] Reactivity to OspC (23 kDa) was generally useful as a marker for recent exposure; however, Lyme bacterins and the chimeric recombinant vaccine stimulate production of OspC-specific antibodies. Depending on the vaccine used, the interpretation of band patterns can be difficult.[139,221,223] Assays that incorporate recombinant VlsE antigen (see below) are useful because antibodies to this antigen only result from natural exposure (Fig. 69.9).

VlsE and C6-based assays. During the course of infection, *B. burgdorferi* evades the host immune response by varying the genes that encode for the immunodominant VlsE surface lipoprotein. One immunodominant region of VlsE, IR_6, is genetically, structurally, and antigenically highly conserved among many *B. burgdorferi* strains and genospecies. The genes that encode IR_6 are expressed only during infection of and replication in the mammalian host and not in culture (which is required for vaccine production) or in the arthropod vector. Therefore, antibodies to these genes signify natural exposure. The synthetically produced peptide C_6 is encoded by the IR_6 gene sequence. The C_6 peptide has been used for serodiagnostic testing of humans and animals as a marker for host invasion and infection. C_6-based assays have been substituted for conventional whole cell ELISA and immunoblotting in clinical diagnosis of human borreliosis.[224–228]

A commercially available POC test, SNAP 4Dx Plus (IDEXX Laboratories, Westbrook, ME), and the diagnostic laboratory-based Accuplex 4 assay (Antech Laboratories) detect serum antibody to the C_6 peptide (as well as heartworm antigen and antibodies to common *Anaplasma* spp. and *Ehrlichia* spp.). The C_6 assay can be used to more accurately differentiate between vaccinated and infected dogs compared with whole spirochete and immunoblot test methods (Table 69.3). C_6-based ELISA has been used to evaluate serologic responses in experimentally[229,230] and naturally[231,232] infected dogs. The C_6 antibody response increased 3 to 5 weeks after experimental infection, before antibody increases with conventional assays and before onset of lameness. C_6 antibody titers decreased more quickly after treatment than the antibody response measured by whole cell ELISA.[230] C_6 antibody levels were not increased in sera from healthy, uninfected dogs, those with other infections (e.g., dirofilariasis, babesiosis, ehrlichiosis, RMSF, leptospirosis), or those vaccinated with OspA, whole spirochete vaccines, or commonly used vaccines for other diseases.[229,233] When compared with immunoblotting, the sensitivity and specificity of the C_6 POC test in dogs were 98.8% and 100%, respectively.[234] Because not all dogs infected with spirochetes become ill, and because species and strains within *B. burgdorferi* s.l. complex vary in pathogenicity, the C_6 antibody response does not always correlate with clinical illness in dogs in North America or Eur ope.[104,107,235] Caution in overinterpreting the significance of a positive test result in a clinically healthy dog has been addressed by the initial and updated ACVIM consensus statement on Lyme borreliosis in dogs and cats.[104,107] Positive results may be observed in young pups as a result of *in utero* or colostral antibody transfer.[236] These results will become negative on subsequent evaluation through the postnatal period.

A quantitative C_6 antibody test (Quant C6, IDEXX Laboratories, Westbrook, ME) is available for monitoring the level and changes in antibody response after treatment. C_6 antibody concentrations remained high for 69 weeks in untreated, experimentally infected dogs.[230] If treated at week 31 with doxycycline for 28 days, C_6 antibody concentrations declined 12 weeks after beginning treatment from 63% to 92% (mean 81%) relative to pre-treatment values.[234] In treated, naturally infected, clinically healthy dogs with moderate-to-high C_6 antibody levels, titers declined over a period of 12 months.[232] This decline was more dramatic than that of clinically healthy untreated control dogs (also originally with moderate-to-high C_6 titers) at 6- and 12-month intervals. Generally, at least a 50% decline was noted after treatment, although there was minimal change in C_6 antibody levels in dogs with low initial values. Therefore, determination of baseline and follow-up titers at 3- to 6-month intervals may be beneficial in monitoring treatment efficacy.[237] Others argue that if clinical

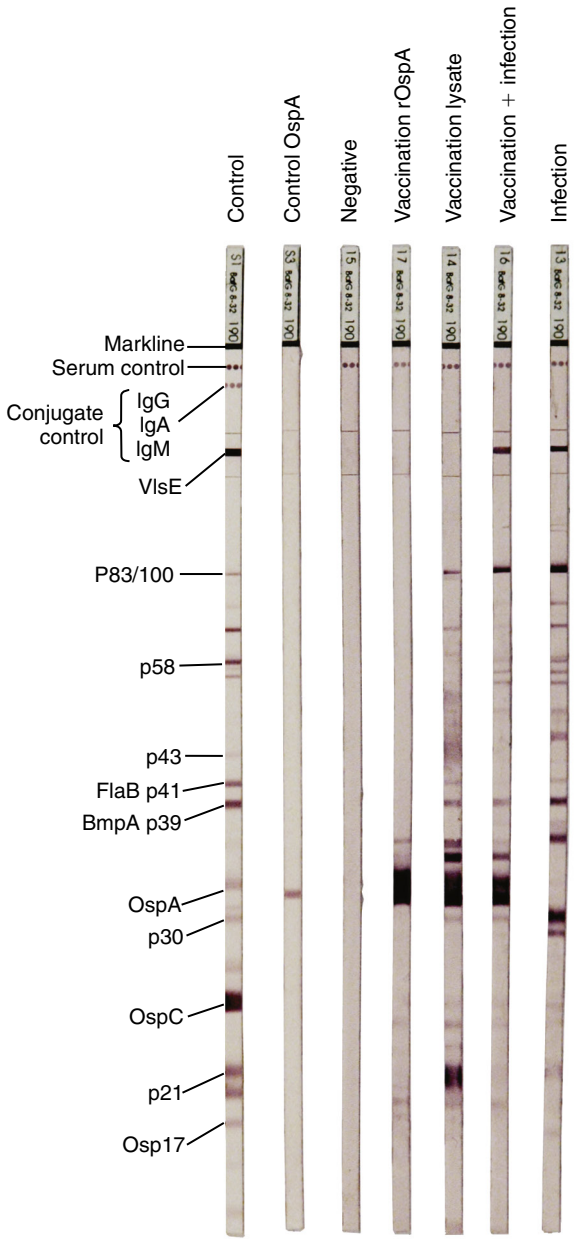

Fig. 69.9 Immunoblots of sera from dogs not infected with *Borrelia burgdorferi* (negative); immunized with recombinant OspA (vaccination rOspA); immunized with a lysate vaccine (vaccination lysate); immunized and infected with *B. burgdorferi* (vaccination + infection); and infected with *B. burgdorferi* (infection); the left strip shows all major signals available on the blot (control); the second strip from the left is stained with a monoclonal antibody against OspA (control OspA). TABLE 69.3 Comparative Serologic Test Results for Lyme Borreliosis in Dogs

Serologic Test	Naturally Infected Via Tick Exposure	Vaccinated with Whole Cell Bacterins	Vaccinated with rOspA Subunit	Vaccinated with crLyme (OspA and 7 Types of OspC)
IgM whole cell ELISA or IFA[a]	Positive within first 60–90 days for a transient duration	Positive within 2–4 weeks, can last for months to years	Positive within 2–4 weeks, can last for months to years	As for other vaccines
IgG whole cell ELISA or IFA[b]	After 60–90 days, positive for months or years	Detectable antibody levels starting at 4–6 weeks, will last for months to years	Detectable antibody levels starting at 4–6 weeks, will last for months to years	As for other vaccines
Immunoblot/LIA[c]	Numerous bands but generally *not* OspA or OspB; positive VlsE if that line is included	Predominant OspA; some also produce OspC bands; numerous other bands	OspA and few bands in the lower molecular range	OspA and OspC bands
C_6 ELISA assay[d]	Positive, even after treatment; months to years	Negative	Negative	Negative
VETSCAN Canine Lyme Rapid (Zoetis)	Positive	Possibly positive (OspC and flagellin)	Negative	Possibly positive (OspC)
Multiplex antibody testing	Positive OspC (>2–3 weeks, wanes in 3–5 months) Positive OspF (>6–8 weeks); possible positive OspA	Positive OspA; possibly positive OspC	Positive (OspA)	Positive OspA; possibly positive OspC

[a]IgM whole cell assays are the most nonspecific.
[b]IgG whole cell false-positive results can be caused by previous infections in recovered animals, vaccine, and reactions to many other closely related spirochetes. IFA is more specific in this regard but not as specific as specific protein-based assays.
[c]Immunoblot false-positive results include reactions with pathogenic and nonpathogenic isolates. Positive results can persist even after infection has been eliminated.
[d]Subclinical infection occurs with *Borrelia burgdorferi* strains when host immunity is adequately controlling infection. Qualitative C_6 assay is very sensitive and may be positive for months to years, even after treatment, so quantitative testing after treatment is preferred.
ELISA, enzyme-linked immunosorbent assay; *IFA*, indirect fluorescent antibody; *LIA*, line immunoassay; *Osp*, outer surface protein.

signs resolve, there is no value in monitoring C_6 antibody levels as there is no evidence that continuing treatment beyond resolution of clinical signs improves outcomes, and may contribute to antimicrobial resistance. In addition, increases in antibody titers may reflect continued exposure rather than treatment failure. The updated ACVIM consensus statement provides panelist perspectives on this issue.[104] Antimicrobial treatment for reasons other than Lyme borreliosis, or before its confirmation by serologic means, may reduce spirochetal burden and blunt the C_6 antibody response to *Borrelia*. This situation would limit the use of C_6 ELISA as a tool for monitoring. There have not been similar studies with ill dogs to allow association of serologic findings with clinical disease parameters.

The C_6 ELISA has also been evaluated in cats on a limited basis since the technology does not use species-specific reagents.[187,190] In experimentally tick-exposed cats, 8 of 13 seroconverted, but duration of positive results varied, as short as 1 week in one cat.[187,190] Of 24 cats tested in an endemic area, 17 had positive C_6 antibody test results that matched those obtained by a whole spirochete IFA assay.[187] Five cats had negative antibody test results on both assays, and two C_6-negative test results were positive at low serum dilutions with IFA; one of these was also positive using immunoblotting. No correlation was made with clinical illness. As with dogs, if a cat is evaluated with clinical signs such as fever and joint swelling, the C_6 assay may be helpful as an adjunctive test for diagnosis of Lyme borreliosis; however, co-infections with *A. phagocytophilum* or other diseases must also be considered. Caution is advised when interpreting the results of the C_6 assay in cats as further optimization experiments may be needed.[104]

Antibodies to other outer surface proteins—OspA, OspC, and OspF. During tick feeding, OspC begins to be expressed as the spirochetes lose their attachment to the midgut. Thus, OspC is presented early to the host's immune system; antibodies rise in 2–3 weeks, and are a marker for recent natural exposure in unvaccinated dogs. Without continued exposure, OspC antibodies wane in 3–5 months. Eventually OspF is expressed, with antibodies detected later at 6–8 weeks which remain elevated in untreated dogs. The Multiplex test (Cornell University Animal Health Diagnostic Center) offers quantitative testing of OspA, OspC, and OspF antibodies via the use of a fluorescent bead assay.[222,238,239] The interpretation of the OspA and OspC antibody test results may be difficult since 17% of nonvaccinated dogs were reactive to OspA.[221] There may be transient reactivity against OspA early after infection.[222] Humans with chronic Lyme disease (in North America but not Europe)[240] have high levels of anti-OspA antibodies (possibly due to expression of OspA during chronic infection as the organism goes through its antigenic repertoire),[131] and OspC-specific antibodies may be produced after vaccination with the newer bacterins and recombinant chimeric vaccines that contain OspC. The VETSCAN Lyme Rapid Test (Zoetis, Parsippany, NJ)[201,241] is a POC assay that tests for antibodies against proprietary synthetic chimeric recombinant peptides (VlsE, OspC, flagellin) as markers for natural exposure. As above, OspC antibodies may be induced by the newer bacterins and the recombinant chimeric vaccine. Canine OspC antibodies differ in intensity, frequency, and antigenicities when compared with those of humans.[242]

Measurement of CSF antibody. In humans, CSF antibody titers have been compared with those of serum in an attempt to diagnose neuroborreliosis.[243,244] Intrathecal production of specific antibodies to *B. burgdorferi* can be demonstrated if the ratio of CSF to serum *B. burgdorferi* antibody is greater than the CSF to serum albumin, total IgG, or specific IgG to another infectious agent. When the same assay method is used to measure specific IgG, the specific method has the most reliability.[245,246] In humans with neuroborreliosis, antibodies to both OspA and OspC have been found at higher titers in CSF than in serum.[247]

An increased intrathecal antibody concentration was demonstrated in dogs with neurologic dysfunction.[248,249] These results are difficult to

assess because the dogs were from endemic areas and no supporting histopathologic or culture findings were supplied. The older (nonspecific) antibody tests were used, with possible cross-reactions from TBRF *Borrelia* spp. infections, which can cause neurologic signs in dogs. Lyme neuroborreliosis has not been well documented in dogs.[141–143]

Microscopic Detection of Spirochetes

Borrelia species that cause Lyme disease are rarely, if ever, visualized in body fluids such as synovial fluid using phase or dark-field microscopy or in tissues after nonspecific silver or specific immunologic staining methods. The spirochete density in clinical specimens is low, as is the specificity and sensitivity of microscopy.[250,251] Microscopy is best used to detect organisms in tick preparations (ticks squashed between microscope slides).

Culture

Culture of spirochetes from specimens collected from dogs with signs consistent with Lyme borreliosis is the most definitive means of documentation but is often difficult because of the low numbers of organisms present. The probability of isolating Lyme disease borreliae from blood is extremely low because these spirochetes (in contrast to the relapsing fever borreliae, see below) migrate through connective tissues and only incidentally enter the circulatory system, with the exception of *B. mayonii*.[4,252] A special medium, Barbour-Stoenner-Kelly (BSK) medium, is required for isolation. Skin and collagen-rich connective tissues (fascia, pericardium, peritoneum, meninges, synovium) are the most reliable tissues for culture from dogs when specimens are taken at or near the site of tick attachment.[252,253] Biopsy is performed using a 6-mm punch, and the specimens are placed in sterile tubes after removing the haired skin using a sterile technique. Specimens are processed with sterile pestles in medium, sequentially transferred to larger volumes of media, cultured at 33°C, and microscopically examined at 2-week intervals for 6 weeks. Culture may be more sensitive than PCR before antimicrobial therapy[215]; however, the turnaround time for culture results is longer than for PCR.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR primers that target conserved DNA sequences can be used to detect various genospecies and strains of *Borrelia* spp. Primers that target plasmid (*OspA*) DNA are thought to be much more sensitive than chromosomal DNA because multiple copies of plasmids can be present in a single bacterium; however, the detection of plasmid DNA does not translate to the presence of viable spirochetes.[139,217,254] PCR should be performed on skin or synovial tissue (or affected tissue) biopsy rather than on body or synovial fluids because they are more likely to contain the organism in chronically infected, treated, or untreated dogs.[215] With respect to these concerns, PCR results of CSF and blood from dogs with neurologic disease have been negative.[143] PCR-positive results on blood have been found in dogs with suspected clinical borreliosis[255,256]; however, corresponding studies of control dogs were not reported to confirm a correlation with disease. Because of extremely low organism numbers, even with sensitive PCR assays, *B. burgdorferi* DNA is rarely found in tissues of naturally infected dogs.[139] Real-time quantitative PCR assays have been developed to detect spirochetal DNA in human clinical specimens.[257] By itself, detection of *B. burgdorferi* by PCR may be misleading, and its presence should always be correlated with clinical illness and serologic findings.[196]

Detection of Borreliae by Other Techniques

Tissue specimens can be examined microscopically for pathogenic spirochetes using direct FA, FISH, IHC, or gold particles that are visible on transmission electron microscopy. Xenodiagnosis, in which naïve ticks become infected after feeding on suspect infected hosts, has proved very reliable in the research laboratory setting but is expensive and time consuming.

Pathologic Findings

Gross Pathologic Findings

On gross necropsy, severely affected animals have swollen joints with synovial effusion. The synovial fluid may be yellow-tinged and cloudy, with decreased viscosity. Peripheral lymphadenomegaly may be present, especially in nodes draining the affected limbs. In dogs with nephritis, the kidneys are diffusely light tan and may have pinpoint red foci over cortical surfaces.[167] In addition, evidence of systemic edema, thrombosis and infarction, and uremia (parathyroid hyperplasia, ulcerative stomatitis, and gastritis) may be present.

Histopathologic Findings

In experimentally infected dogs (puppies more than adults), inflammation within the synovial membrane and the effusion consists of fibrin and neutrophils in acute cases. In more chronic infections, dogs develop nonsuppurative, predominantly lymphoplasmacytic, inflammation within the synovial membrane and joint capsule.[163,258] Some dogs that never develop lameness still have histologic evidence of arthritis. Histologic lesions may be present in the lymph nodes, joints, pericardium, and skin.[80] In addition, vasculitis, arteritis, perineuritis, and meningitis may be evident (Fig. 69.10).[259] Follicular enlargement and increased size of parafollicular areas in lymph nodes has been documented. Skin biopsy specimens have superficial perivascular lymphoplasmacytic infiltrates with mast cell accumulations.

Renal lesions have not been found in experimentally infected dogs but were evident in naturally diseased dogs (especially retrievers) with suspected Lyme nephritis.[167] Silver staining and PCR testing of the kidneys of dogs with suspected Lyme nephritis revealed rare spirochetes unrelated to lesion development,[133,134,167] but histologically immune-complex (membranoproliferative) glomerulonephritis, dilation of cortical renal tubules, diffuse tubular necrosis with regeneration, and interstitial lymphoplasmacytic inflammation have been found (Fig. 69.11). Elution studies on necropsy samples showed a variety of *B. burgdorferi*–specific antigen-antibody complexes.[135] Renal core biopsies are recommended as part of the diagnostic work-up for PLN to document immune-complex disease using electron microscopy and immunofluorescence studies[203,204,260]; however, there are no validated stains to use on antemortem specimens to prove that complexes are directed to *Borrelia* spp. antigens.

In experimentally infected cats, hepatic degeneration, splenic hyperplasia, regional lymph node plasmacytosis, nonsuppurative meningoencephalitis, pneumonitis, and renal lesions were noted.[198,199]

TREATMENT AND PROGNOSIS

Lyme Arthritis

Because of the difficulty in obtaining an accurate diagnosis, antibacterials are often given empirically in an attempt to make a therapeutic diagnosis. Many reports exist of successful recovery after administration of antimicrobial drugs in dogs with suspected Lyme arthritis. Improvement often occurs within 24 to 48 hours after antimicrobial therapy is initiated. The greatest success is achieved with treatment in the initial phases of clinical illness. Clinical improvement after any therapeutic intervention should be viewed with caution, because the acute limb and joint dysfunction is intermittent and often resolves after several days to weeks regardless of whether antimicrobials are given.[160] Treatment response may also reflect response to treatment of overlooked co-infections. In addition, doxycycline can cause

nonspecific anti-inflammatory changes in injured joints and may have chondroprotective activity in noninfectious arthritis in dogs.[261] The lipid-soluble tetracyclines may inhibit inflammation associated with *B. burgdorferi* infection.[262] Should a response to treatment not occur in a 3-day time period, antimicrobial treatment should be discontinued and other causes of the clinical signs should be considered.

Early treatment is associated with a reduction in antibody titers and organisms in tissues and prevention or cure of clinical lameness and joint lesions.[252,259] Most treatment schemes are instituted for a minimum of 30 days. Amoxicillin, azithromycin, cefovecin, ceftriaxone, doxycycline, and minocycline have all been used. A 30-day treatment duration has been recommended based on the spirochete's generation time and to mimic treatment protocols for people with chronic infection.[253] However, on the basis of research studies, clearance of the organism after 30 days of treatment in dogs and rodents is not guaranteed, and relapse and recrudescence of infection can occur after antimicrobial therapy is discontinued.[156,214,215,252,259,263–268] Similar treatment outcomes have sometimes been reported for human patients,[269] although most people with chronic disease clear infection.[3,137,270] Clinical relapse may reflect reinfection with another strain

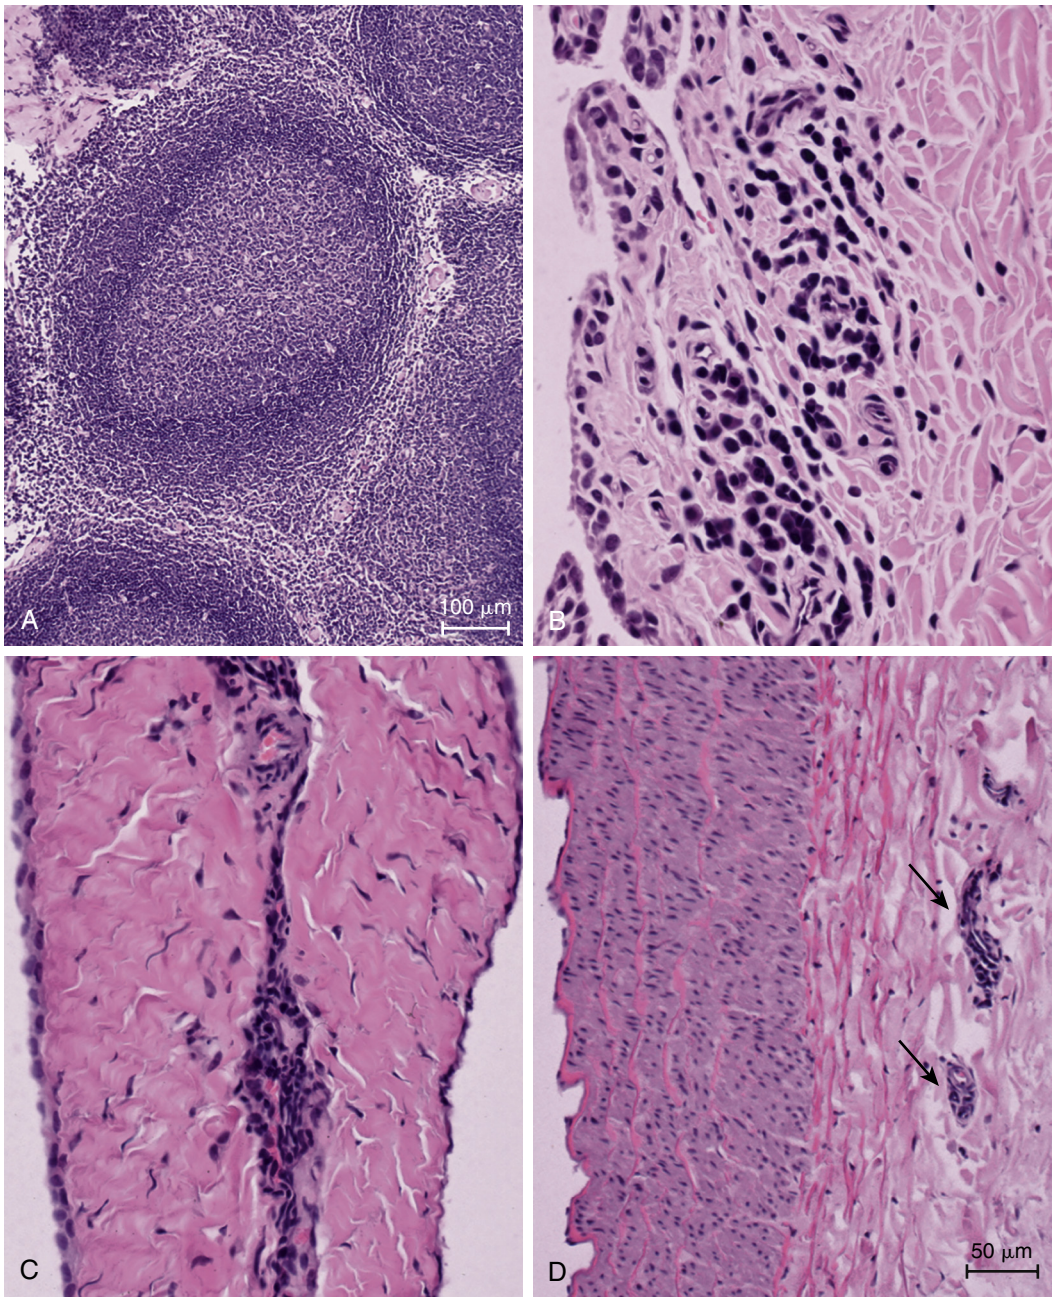

Fig. 69.10 Histopathologic lesions in a dog infected with *Borrelia burgdorferi*. Representative tissue sections of inflammatory lesions (hematoxylin and eosin stain). (A) Severe follicular hyperplasia of left axillary lymph node. (B) Synovial membrane of the left elbow with moderate nonsuppurative arthritis. Note accumulation of plasma cells in subsynovial tissue. (C) Mild nonsuppurative pericarditis with several cellular aggregates—mostly mononuclear cells in tissue. (D) Tunica media and tunica adventia of artery with small cuffs of mononuclear cells around the branch of vasa vasorum *(arrows)*. (Courtesy of R. Straubinger, LMU Munich, Germany.)

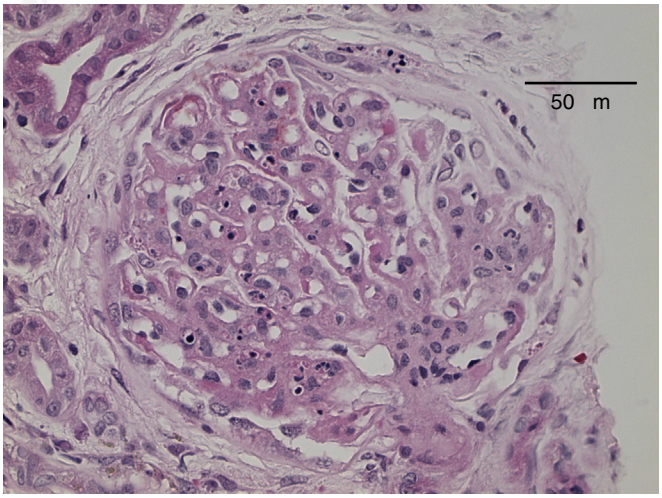

Fig. 69.11 Membranoproliferative glomerulonephritis in a 6-year-old, intact male golden retriever dog that was seropositive for *B. burgdorferi* C_6 protein antibodies and had clinical and biochemical evidence of protein-losing nephropathy. The morphologic diagnosis was moderate to severe, diffuse, global membranoproliferative glomerulonephritis with moderate chronic-active tubulointerstitial nephritis. The capillary walls are thickened and there is mesangial cell proliferation. There was also evidence of focal arteriolar mural disorganization, lamination, and sclerosis in this biopsy specimen. (Courtesy Dr. George Lees, Texas A&M University.)

of *B. burgdorferi*.[116,271] In addition to possible inability to clear all organisms or remnants, chronic inflammatory changes that occur in tissues such as the joints may become self-perpetuating. Intra-articular persistence of metabolically inactive spirochetes may occur even though the organisms cannot be cultured.[259,272] Persistence may stimulate chronic immune and inflammatory processes. Dogs with more chronic Lyme borreliosis are less likely to improve or more likely to have relapses, even if treatment continues for weeks or months.

Nevertheless, antimicrobial therapy is still the mainstay for treatment of borreliosis (Table 69.4). Antimicrobial susceptibility testing has shown ceftriaxone, erythromycin or its derivatives, amoxicillin, cefuroxime, doxycycline, tetracycline, and penicillin G to range from most to least effective.[81] Tetracyclines, ampicillin, and erythromycin have been used to treat human and animal patients. Cefovecin was shown to be efficacious in dogs, but may not have activity against other co-pathogens such as *Anaplasma*.[273] Newer erythromycin derivatives, such as azithromycin, or third-generation cephalosporins, such as ceftriaxone, have been administered for more refractory human cases.[274] High-dose IV penicillin G has been advocated in an attempt to treat unresponsive animals. Borreliae are not responsive to aminoglycosides and quinolones.[275]

Doxycycline is considered the drug of choice because it is a lipid-soluble tetracycline and is relatively inexpensive. The advantages of lipid solubility are that a lower dosage is needed, tissue distribution is greater, and intracellular penetration is better than that achieved with conventional tetracycline. Doxycycline is also active against common co-infecting organisms (*Rickettsia*, *Anaplasma*, *Ehrlichia*, *Leptospira*, or *Bartonella* spp.). For growing animals, amoxicillin is usually recommended because tetracyclines may stain dentition; however, doxycycline is less likely to cause this when compared with other tetracyclines.[276,277] Ceftriaxone is reserved as parenteral therapy for parenchymal CNS inflammation (encephalitis) in humans.[278,279] Oral doxycycline (3 weeks to 2 months), however, is effective and still recommended in treating peripheral CNS inflammation (meningitis and neuritis).[278,280–282]

In experimentally infected dogs, doxycycline, amoxicillin, azithromycin, or ceftriaxone have been administered for 1 month with resolution of clinical signs. There is inconsistent evidence for persistence of viable spirochetes after treatment in dogs.[139] In one study, positive tissue cultures, PCR, and rising ELISA titers were found months after treatment.[259] Later studies showed negative skin cultures, persistent *Borrelia* DNA, but lowered ELISA and C_6 peptide antibody titers, which did not rise at least 35 weeks after treatment.[214,215,230,252]

Treatment of clinically healthy seropositive dogs with antimicrobial therapy is controversial.[104,107,202,283] The existence or magnitude of a positive antibody titer does not predict illness.[104,107,235] Those opposing empiric antimicrobial therapy argue that, even though seroconversion occurs, many infected hosts have a natural immunity that prevents the organism from causing clinical disease. Furthermore, treatment of dogs in endemic areas that might have antibody titers could lead to the development of resistant strains of spirochetes and other resident bacterial microflora. Adverse reactions might also result from antimicrobial therapy. Finally, the carrier status may be somewhat protective. Arguments for treatment of apparently healthy seropositive dogs are that the incubation period can be prolonged and immunopathologic consequences of infection develop; treatment may help to prevent progression of these events during a subclinical period. Furthermore, even though dogs appear healthy, they can still have subclinical manifestations, such as proteinuria from immune-complex disease and associated renal inflammation. The level of quantitative C_6 antibody titer seems to correlate with levels of CICs. Quantitative C_6 and possibly OspF antibody titers and corresponding CICs seem to decrease after therapy.[136,222,284] At a minimum, preventive measures (tick control and possibly vaccination) should be recommended for seropositive dogs to prevent reinfection. The effect of vaccination in proteinuric dogs is unknown and some have recommended that it be avoided.[284]

In addition to antimicrobials, dogs with signs of arthritis may be treated with NSAIDs or analgesics. NSAIDs are not preferred should steroids become necessary (to avoid a wash-out period or potential GI irritation). Glucocorticoids are not recommended for Lyme arthritis, but seropositive dogs that are nonresponsive to antimicrobial therapy may have immune-mediated polyarthritis which is responsive to immunosuppressive therapy. Experimentally, dogs treated with high doses of antibiotics for 1 month and then high-dose prednisone (2 mg/kg, q12h, 2 weeks) showed no clinical signs of lameness while being treated, but after therapy was discontinued, signs of arthritis or reactivation of disease developed within 1 week.[214] This finding has not been reported in field cases. Immunosuppressive doses of glucocorticoids should be avoided in chronically infected dogs because of possible infection exacerbation, or they should be given in combination with antibacterials.

Lyme Nephritis

Treatment and prognosis of renal dysfunction associated with Lyme borreliosis varies according to the stage and severity of the illness at the time diagnosis is made. Without an experimental model, it is unknown whether prompt treatment with antibiotics can be curative, and the correct duration of antimicrobial treatment is unknown (some clinicians choose to treat 3–6 months, until the C_6 antibody level has waned). With progression, glomerular proteinuria can be associated with complications such as hypertension, thromboembolic events, nephrotic syndrome, and/or renal failure. In the early stages, standard treatments for PLN are recommended: angiotensin-converting enzyme inhibitors and/or angiotensin II receptor blockers, antithrombotics, omega-3 fatty acid supplement, renal diet (restricted in protein, phosphorus, and salt), and as indicated, antihypertensives, IV colloids/crystalloids, spironolactone, phosphate binders, antacids, and other

TABLE 69.4 Suggested Antibacterial Regimens for Lyme Borreliosis in Dogs

Drug[a]	Dose[b]	Route[b]	Interval (Hours)[b]	Duration (Days)[b]	Preferred Uses in Humans
Doxycycline or minocycline[d]	10 mg/kg	PO, IV	12–24	30–42[c]	Early disease, arthritis or neurologic manifestations, children ≥ 8 years old
Amoxicillin	20 mg/kg	PO	8	30	Early, arthritis or neurologic manifestations, children < 8 years old
Azithromycin	25 mg/kg	PO	24	10–20	Early disease
Clarithromycin	7.5–12.5 mg/kg	PO	12	30	
Cefovecin	8 mg/kg	SC	2 doses, 14 days apart	28	
Penicillin G	22,000 U/kg	IV	8	(14–)30	Persistent arthritis, neurologic manifestations, or carditis
Ceftriaxone	25 mg/kg	IV, SC	24	(14–)30	Late neurologic or cardiac manifestations, persistent arthritis
Cefotaxime	50 mg/kg or 20 mg/kg	IV	12 8	(14–)30	Neurologic manifestations

[a]See Chapter 10. Information on many drugs is based on extrapolation from literature on humans. Use of some drugs may be restricted depending on geographic location.
[b]Dose per administration at specified interval and duration are given for dogs.
[c]Proteinuric dogs may need longer treatment duration (see text) as well as appropriate medication and diet for protein-losing nephropathy.
[d]Doxycycline (or minocycline) is the preferred treatment for dogs with suspected Lyme disease (see text). Doxycycline may cause gastric or esophageal irritation, leading to vomiting or inappetence, and should be given with food.
IM, intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

renal failure support.[104,148,171,285] Immunosuppressive drug therapy is recommended if renal biopsy confirms immune-complex disease[286] or in cases that are deteriorating even without confirmation, since about half of all dogs with renal proteinuria have immune-complex glomerulonephritis.[204,287,288] Although the best protocol is unknown, current recommendations include mycophenolate or cyclophosphamide, sometimes with glucocorticoid treatment. The IRIS Study Group recommends mycophenolate as the first-choice immunosuppressive drug, perhaps with a tapering dose of prednisolone for dogs with acute rapidly progressive glomerular disease.[286] However, it should be kept in mind that glucocorticoids also may exacerbate hypertension, thromboembolic events, GI ulceration, and proteinuria. For dogs with stable disease, a combination of mycophenolate or chlorambucil alone or in combination with azathioprine on alternating days may be used. As the disease progresses, dogs may develop severe hypoproteinemia and decreased renal perfusion, which necessitates volume expanders, vasoactive agents, and osmotic diuresis. Plasmapheresis to remove CICs may be tried. Unfortunately, chronic renal manifestations are usually progressive despite therapy.

IMMUNITY AND VACCINATION

Controversy exists about the need for vaccination even in Lyme endemic areas (Table 69.5). The efficacy and safety profiles of the first available vaccines were disappointing.[104,107] While the results of field studies appear promising, they do not control for the use of tick prevention products, and experimental models use small numbers of dogs with tick challenges at less than 1 month to 1 year.[289–296]

A number of vaccines are commercially available in North America to prevent borreliosis in dogs.[118,289,294,297–303] In Europe, whole cell bacterins are available. The multiplicity of infecting species of *Borrelia* in Europe complicates vaccine-induced protection. In dogs, heterologous vaccines produce weak antibody cross-reactivity,[281] suggesting that *Borrelia* species–specific vaccines are necessary for adequate protection.[304] At the time of writing, a recombinant chimeric OspA Lyme vaccine for humans (Valnerva/Pfizer) that exhibits cross-species protection has advanced to Phase 3 clinical studies.

Vaccines for Lyme borreliosis are available for use beginning at 6 to 12 weeks of age, depending on the product. Primary vaccination schedules consist of two inoculations 3 weeks apart. Vaccination is not a replacement for adequate tick control measures. Dogs should be selected for vaccination based on the geographic location where they reside or travel and by the geographic location of their activities and habits. Outdoor, hunting, or field-trial dogs that frequent known tick-infested areas should be prioritized for vaccination. Dogs vaccinated with adjuvanted whole cell vaccines or recombinant OspA (rOspA) vaccines before infection develop enhanced resistance to infection.[289,290,294,301–303] This type of protection does not appear to develop in naturally infected animals. Reinfection by other strains is possible in animals that are treated or recover from natural infections.[116,305]

Lyme vaccines have a unique mechanism of action. Vaccination induces production of antibodies by the host, which are ingested by the tick and immobilize spirochetes in the tick gut during tick feeding. Because the vaccine-induced antibodies to OspA (and for some vaccines, to OspC variants) act within the tick, natural boostering can be limited and so frequent boostering with vaccines may be needed to maintain effective titers.[306] The protective titer levels are unknown. Protection was demonstrated following vaccination with an OspA/OspC bacterin at a 1-year tick challenge despite low titers,[289,294] but in another study, vaccine failure occurred in the face of positive titers.[300] Production of OspA and OspC antibody levels is highest with recombinant vaccines (rOspA and crLyme, respectively),[307,308] but even these vaccines may not yield full protection, therefore tick control is still recommended.

In the presence of complement, host antibodies to OspA cause an arrest of growth and prevention of salivary gland invasion in the ticks that feed on previously vaccinated animals.[89,302] Vaccination of an already infected animal does not clear infection.[303] Variable efficacy (50%–100%) has been noted for the commercial rOspA vaccine.[301,302,311] In a field study, infection rate was 25% in vaccinates versus 63% in non-vaccinates with a preventive fraction of 60.3%.[304]

TABLE 69.5 Vaccination for Prevention of Lyme Borreliosis: Pros and Cons

Pros	Cons
Tick control does not always work due to lack of compliance and misuse or failure of the product. Vaccines are an additional safety net when tick control fails.	Tick control is recommended anyway in endemic areas due to other tick-borne diseases. When used properly, tick control may be more efficacious than vaccination.
In endemic areas, 5%–10% is still a very high number of affected dogs.	The vast majority (90%–95%) of seropositive dogs do not become ill.
Histopathologic evidence of chronic arthritis may be an additive factor to arthritis later in life, although this is unproven.	Lyme arthritis is self-limiting or responds quickly to antibiotics.
Even though there is no experimental model for Lyme nephritis to study this question, evidence for postvaccinal sensitization or aggravation of Lyme nephritis is lacking or anecdotal at best. Decreasing exposure and infection will decrease the number of carriers with circulating immune complexes and perhaps lessen the opportunity for glomerular deposition.	There is no experimental model for Lyme nephritis, an immune-mediated illness. We do not know if Lyme vaccine prevents, aggravates, or may sensitize for it. OspA is an inflammatory protein. Other Lyme antigens may have molecular mimicry with cardiolipin, myelin, myosin, etc. The most severe cases of Lyme disease are immune-mediated and theoretically vaccination may sensitize for it.
Giving an extra booster vaccine at 6 months of age will help to increase protection. Vaccines can be given every 6–12 months, especially just before tick season.	Vaccines have inconsistent efficacy and duration of immunity.
Use of C_6 and OspF serologic tests can differentiate between vaccinal and natural antibodies.	Vaccination can interfere with interpretation of some serologic diagnostic test results.
Correctly applied vaccination aids in the prevention of *B. burgdorferi* infection.	Vaccine expense and possible adverse events in genetically predisposed individuals.

In another study, dogs were given the rOspA vaccine at 0 and 3 weeks, again at 6 months and then annually.[295] Using C_6 ELISA, 99% of seropositive dogs in that clinic were non-vaccinated, incompletely vaccinated, or previously seropositive dogs. However, this percentage decreased over a 33-month follow-up period in those dogs that received the complete vaccination series. In humans, immunity was often much stronger after a third vaccine was added to the series.[305,306] Regardless of the product used, when a third dose was given to dogs, a higher antibody titer was induced compared to the titer in dogs immunized only twice at the beginning of the vaccination schedule.[291] Therefore, extra-label recommendations in highly endemic areas might be to use a third immunization 6 months after the two initial doses. There was no consensus reached about the need to administer Lyme borreliosis vaccines on a 6-monthly basis among consensus statement panelists.[104]

OspC antigens are present, in lower levels than those of OspA, in all whole cell bacterins.[233,307] Monovalent bacterin studies showed a 78% preventive fraction for illness[308] and 90%–92% preventive fraction for seroconversion[304,309]; however field studies did not control for use of tick prevention measures. In a parenteral challenge study in mice, protection was not afforded by previous immunization with vaccines based on OspC, whereas it was with an OspA product.[310] However, in dogs, addition of a bacterin strain that induced antibodies to OspC offered protection even when OspA antibodies were not identified.[289,294,311] Use of a bivalent bacterin in dogs that stimulated both OspA and OspC borreliacidal antibodies protected dogs, after an infected tick-feeding challenge, against clinical illness and serologic or PCR evidence of infection.[289,294] Although OspC is highly immunogenic, considerable variation in OspC among strains of *B. burgdorferi* and other species such as *B. afzelii* makes heterologous protection with this antigen difficult.[271,319–321] This is the rationale for the development of the chimeric recombinant OspA-OspC vaccine (Vanguard crLyme, Zoetis, Parsippany, NJ, USA) available at the time of wrting. This vaccine consists of a chimeric OspC construct comprised of seven different OspC peptides. Whether inclusion of OspC in vaccines increases protection remains unknown, especially as more contemporary studies have suggested that expression of OspA is present throughout the bloodmeal, and OspA is only down-regulated after the spirochete enters the host.[92]

In one study, after vaccination with each of three vaccine types (Recombitek, Nobivac, and LymeVax), dogs were challenged with infected ticks.[300] Six of 18 vaccinated dogs became infected (based on DNA amplification of skin biopsies at the tick bite site and seroconversion against C_6, OspC, OspF, p39, and SLP). At the time of tick exposure, three dogs that subsequently became infected had evidence of vaccine-induced OspA-specific antibodies and one dog had both OspA- and OspC-specific antibodies. Not included in this study was the chimeric recombinant vaccine (Vanguard crLyme, Zoetis).[297,304] Dogs vaccinated with this chimeric vaccine were less likely than control dogs to develop serologic evidence of infection after tick challenge at 21 days after vaccination (7/16 dogs versus 14/16 dogs, respectively).[322] A 1-year challenge study is needed.

Since the most serious forms of Lyme borreliosis involve immune-complex deposition, the possibility that vaccination might trigger formation of CICs has raised concern.[323] In a preliminary study, when dogs with positive C_6 antibody titers were vaccinated, those with the highest titers and those given whole cell bacterins had the highest levels of CICs after vaccination compared with those with lower titers or given recombinant OspA vaccine.[136,237,284] These findings require confirmation and their clinical significance is unknown. An additional theoretical concern is the possibility that a hypersensitivity reaction may occur if a whole cell vaccine is given to a dog that harbors large quantities of the spirochete.[216] Although such an organism-specific reaction has not been substantiated, a whole cell *Borrelia* spp. vaccine was more likely to induce vaccine-induced adverse events than any other canine vaccine.[324] Nevertheless, the prevalence rate for such reactions is relatively low[324] and in accordance with that for bacterins in general.

PREVENTION

In humans, a single dose of doxycycline given within 72 hours of identified engorged *I. scapularis* attachment was 87% effective in preventing Lyme borreliosis,[325] although this has been controversial because of concerns that ticks are often misidentified and because the chance of infection even after a known tick bite is extremely low.[326] Regardless, in dogs and cats, high tick exposure rates probably preclude the usefulness of this concept. At the time of writing (2022), a human monoclonal antibody directed against OspA (2217LS) has entered Phase 1 clinical trials for prophylaxis of Lyme disease in humans (Lyme PrEP). The antibody is designed to be administered to at-risk humans just before the onset of the tick season, and like vaccine-induced antibodies, would act within the tick after the tick ingests a blood meal. This intriguing approach has the potential to be associated with a lower risk of adverse effects than vaccination, but whether protective antibody levels can be maintained for an entire tick season remains to be determined.[327]

Vector Control

Products for vector control in pets have included collars, topical powders, shampoos, dips or foams, sprays, spot applications, and new oral products (see Chapters 13 and 109). Amitraz-impregnated tick collars have prevented transmission of *Borrelia* spp. organisms to vector-exposed dogs[328] but are toxic to cats. Topical solutions that control, and in some cases repel, ticks are also available.[329–331] Fipronil may prevent Lyme borreliosis but may not kill ticks fast enough to prevent exposure to other tick-borne pathogens. Oral oxazolines (afoxolaner, fluralaner, lotilaner, sarolaner)[332] do not prevent tick attachment but produce a fast kill (< 8 hours) by binding to insect/tick-specific GABA-gated chloride channels. Even though transmission of *B. burgdorferi* requires at least 24 hours of tick attachment, products should be selected that reduce transmission of co-pathogens such as *A. phagocytophilum*, which can occur more rapidly. Daily examination and combing to remove attached ticks on animals should be done; however, ticks are considerably more difficult to find on animals than on humans.

Vector Control in the Environment

Landscaping techniques help to reduce tick exposure.[333] Application of acaricides to relatively large environmental areas is expensive, logistically difficult, and raises concerns about negative environmental impacts. The 2-year life cycle of *Ixodes* species and the redistribution of ticks by various hosts make it difficult to treat all stages simultaneously.

Removal of leaves and of bordering shrubs and bushes in backyards and gardens reduces the risk of tick exposure because *Ixodes* ticks need a humid, texture-rich environment to quest for prey. The efficacy of a rodent- or deer-targeted acaricide (fipronil) was assessed in various studies.[334,335] Host-targeted intervention was an efficacious, economical, safe, and environment-friendly alternative to area-wide spraying of acaricide to control free-living populations of ticks. However, from a practical management perspective, effective acaricide programs for wildlife are difficult, if not impossible, to implement.

Orally administered vaccines, containing *Escherichia coli* or vaccinia virus expressing OspA, have been used experimentally to protect mice against challenge infection with *B. burgdorferi*.[336–338] When combined in a bait delivery system, such a vaccine might be helpful in disrupting transmission of this infection. Even if effective, vaccination of sufficient numbers of reservoir species would be impossible. Reduction of the deer population might help to decrease the number of ixodid ticks, but other mammalian hosts could still propagate the vectors. Continual depopulation would be required to remove deer migrating back into the area. In the future, the possibility exists that islands in the northeast United States could study the effect of the release of genetically engineered mice (using CRISPR to induce resistance to infection), which may interrupt the transmission cycle.[339]

PUBLIC HEALTH ASPECTS

The case definition of human Lyme borreliosis is: (1) an erythematous rash or one objective sign of musculoskeletal, neurologic, or cardiovascular disease, and (2) laboratory confirmation of infection.[3,137] In the United States in 2015, roughly 30,000 cases were reported from 50 states and the District of Columbia.[340] However, it is estimated that 476,000 cases occur annually.[341] The distribution of endemic infection is limited to certain geographic areas (Northeast/mid-Atlantic/upper Midwest) and 90% of the cases are seen in just 14 states (PA, NY, MA, NJ, CT, WI, MD, MN, VA, ME, RI, VT, NH, and DE).[340] The sylvan cycle in nature appears limited to these areas. However, these regions may be redefined as a result of future climate changes affecting ticks, migration of reservoir hosts, and further investigation of tick-borne illnesses. Errors in reporting disease outside of these regions (other than from host movement) have probably been due to misclassification and overdiagnosis. For example, antibodies to *Borrelia hermsii*, the cause of TBRF in humans, cross-reacted with older whole spirochete antigen tests and likely overestimated the prevalence of Lyme disease.[342–344]

The highest annual incidence of Lyme borreliosis is among children younger than 14 years and adults older than 30 years. Clinical signs usually begin from several days to 1 month after a tick bite. Erythema migrans, an expanding nonpruritic ring-like erythematous lesion of at least 5 cm, may develop in the vicinity of the bite. Fever, myalgia, arthralgia, and headache (influenza-like symptoms) may accompany the lesion. Erythema migrans lesions can be found on individuals in nonendemic regions and may be associated with organisms inoculated by bites of ticks that are not competent vectors of *B. burgdorferi* (e.g., *A. americanum* transmitting *Borrelia lonestari*). These humans have mild constitutional symptoms but have seronegative test results for *B. burgdorferi.* In contrast, humans who become ill from *B. burgdorferi* infection may develop recurrent joint swelling and musculoskeletal soreness. Meningeal signs include pain, sensory loss, behavioral changes, and recurrent headaches. Peripheral neurologic signs can mimic multiple sclerosis. Myocarditis is characterized by development of symptoms characteristic of atrioventricular conduction disturbances. Subclinical infections are also thought to occur.[138] Treatment of Lyme borreliosis in humans is most rewarding during the early phases of illness. In 10%–20% of humans treated that are still ill with chronic Lyme borreliosis (e.g., musculoskeletal or neurocognitive impairments), antimicrobial therapy is no more effective than placebo.[3,137,270,345–349]

The most effective precautions include avoidance of tick habitats, wearing long pants and long-sleeved shirts, taping socks over cuffs, tucking pants into socks, wearing light-colored clothing (to help identify ticks for early removal), and treating clothing and exposed skin with repellents. These may be cumbersome in hot weather.[350,351] Agents that contain DEET repel ticks and can be applied to clothing or exposed skin. Those containing permethrin kill ticks on contact but can only be applied to clothing (caution near cats). Inspection for, and removal of ticks soon after leaving tick-infested areas helps prevent transmission of infection. Studies in animals show that little risk of infection exists within the first 24 hours of attachment, and a maximum rate of infection occurs between 48 and 72 hours of attachment or if the infected tick feeds until engorgement.[352] Prompt tick removal is best,[353] but removal up to 60 hours later may still reduce transmission.[354] The incidence of disease is also greater in humans when ticks are attached for 72 hours or more.[355]

Dogs and cats do not appear to be a source for infection in humans because they do not excrete infectious organisms in their body fluids (including urine) to any appreciable extent.[80] No evidence proves that infected pet dogs or cats pose a direct risk to humans other than that they introduce unfed ticks in various life cycle stages into a household. The ticks do not survive long indoors, and if they are attached to a pet, they do not reattach without molting. Most ticks do not partially feed, and if they are disengaged from their first host during feeding, their mouthparts are usually damaged so that they will not refeed on a second host. As with other tick-borne illnesses, improper handling of ticks resulting in release of midgut or salivary contents onto abraded skin or mucous membranes might allow percutaneous penetration of infectious material, although this has never been reported.

Dogs and cats appear to be sentinel hosts but not reservoir hosts for human infection.[33,40,189,356–358] In the same environment, dogs and cats have a greater risk of exposure than their human counterparts because of their greater likelihood of contacting the tick vector.[339] Even in areas where Lyme borreliosis is endemic, the risk of infection from a recognized ixodid tick bite is so low that prophylactic antimicrobial therapy of exposed humans is not routinely recommended.[326,360] A human rOspA vaccine was marketed in the United States, but its use was limited because of concerns about potential but unproven side effects, and the product was withdrawn from the market in 2002.[3,361] At the time of writing, a recombinant OspA chimeric vaccine is in clinical trials for prevention of Lyme borreliosis in humans; this is a multivalent vaccine that provides protection against OspA types in US and European *Borrelia* species. Future vaccine targets may also include tick salivary proteins required for infection (Salp15) or other antigens.[99,362–367]

TICK-BORNE RELAPSING FEVER (TBRF) BORRELIOSIS

ETIOLOGY AND EPIDEMIOLOGY

Numerous *Borrelia* species comprise the relapsing fever group of vector-borne agents that cause disease in domestic animals and people (see Table 69.1).[15] Except for *Borrelia recurrentis*, which is a louse-borne relapsing fever agent, all others are transmitted by ticks (often the soft tick, *Ornithodoros*, which only feeds for 15–90 minutes, so transmission of these borreliae is quite rapid). *Borrelia lonestari* has been associated with erythema migrans lesions in humans in southeastern and south central United States (Fig. 69.12).[368] The illness has been labeled southern tick-associated rash illness (STARI) although the true cause of this condition remains unknown. *Borrelia lonestari* is thought to be transmitted by *A. americanum* (the lone star tick).[367–371] Differences in strains or species may account for the regional differences in clinical findings that have been reported. White-tailed deer (*Odocoileus virginianus*) became infected experimentally and developed spirochetemia, whereas infections of dogs were unsuccessful, although an increase in their antibody titers was observed.[372] *Borrelia miyamotoi* is an emerging TBRF disease in humans (but not known to occur in pets) in the Northeast and mid-Atlantic regions of the United States.[13–15] It is transmitted by *Ixodes* spp. ticks and can mimic Lyme borreliosis. Differences include spirochetemia, faster transmission of the organism after tick attachment, and transmission by all tick stages, including larvae, since there may be transovarial tick transmission.[62]

Relapsing fever spirochetoses have been found in sick dogs and cats. Microscopically visible spirochetemia accompanied by clinical illness has been observed in dogs in Texas and Florida infected with *B. turicatae*.[7–9,211] Using recombinant ELISA and immunoblot assays, the prevalence of antibodies to *B. turicatae* in 878 dogs from Texas was 2%, with the majority of positive dogs being from southern and central Texas; 2 of 17 seroreactive dogs also seroreacted to *B. burgdorferi*.[373] *Borrelia hermsii* has been identified in sick dogs in northwestern states.[5,6,374] *Borrelia persica* is a TBRF spirochete that is found in southern countries of the former USSR, Iran, Iraq, Syria, Jordan, Turkey, Israel, Egypt, and Cyprus and is transmitted by *Ornithodoros tholozani*. It is known to infect humans, dogs, and cats.[10–12,375–377] *Borrelia hispanica* was detected in two dogs and a cat from Spain with nonspecific clinical illness, thrombocytopenia with or without anemia, and spirochetemia.[378] In Spain, Portugal, Morocco, and Tunisia, TBRF borreliae (especially *B. hispanica*) have been isolated from *Ornithodoros erraticus*, an important vector that feeds on rats, mice, gerbils, and other small mammals.[379] *Borrelia hispanica* can also be transmitted by *Ornithodoros occidentalis*. *Ornithodoros tholozani*, which transmits *B. persica*, inhabits the Middle East, the Balkans, and southern countires of the former USSR. It dwells in man-made shelters and caves while feeding on various wild and domestic animal hosts and humans.

Relapsing fever spirochetes are maintained in nature between susceptible reservoir hosts and competent soft ticks (except for *B. miyamotoi*, which is transmitted by *Ixodes* spp. ticks). Soft (argasid) ticks prefer a variety of burrow-inhabiting mammals as hosts. Thus, relapsing fever borreliae have more restricted geographic ranges and niche vectors than those causing Lyme borreliosis (see Table 69.1). *Borrelia hermsii* is the most common cause of TBRF in North America in humans and involves at least three main vectors. In the western United States and Mexico, *Ornithodoros turicata* infests burrows of rodents, terrapins, and snakes, as well as domestic habitats of people and animals. Also in the western United States, *Ornithodoros hermsi* and *Ornithodoros parkeri* feed on rodents and squirrels and live in dead trees, fallen logs, and in cabins and homes. Unlike the *Ixodes* ticks, *Ornithodoros* ticks harbor spirochetes for extended periods because their life cycle takes years to complete. Mammalian hosts may harbor persistent infections but are only intermittently spirochetemic for 14 to 30 days; thus, the ticks are most responsible for maintaining the infection in nature. TBRF has not been reported east of Texas and Oklahoma; however, sporadic isolations of these spirochetes have been made from ticks and humans outside endemic regions. In the southern United States, *B. lonestari* may be associated with seropositivity to *Borrelia* spp. in humans and animals in areas where *Ixodes* ticks are not found.[380,382] Deer may be reservoir species for this organism. In addition to *B. lonestari*, *A. americanum* can be co-infected with *Ehrlichia ewingii*, *Ehrlichia chaffeensis*, and *Rickettsia* spp., which are all capable of causing disease in humans. With the exception of *E. ewingii*, the clinical significance of these organisms in dogs is unknown.

In the southern hemisphere, a Lyme borreliosis-like disease (Baggio-Yoshinari syndrome), has been discovered in people in Brazil.[382] Symptoms in people include fever, erythema migrans, shifting intermittent lameness, and joint swelling. Visible spirochetemia, more typical of the relapsing fever spirochetoses, is apparent in the peripheral blood of affected humans. Dogs in the region are antibody-positive in *Borrelia* spp. assays; however, the incriminated spirochetes have not been isolated by cultivation or genetically identified in affected humans or seropositive dogs. A relapsing fever-like spirochete (*Borrelia brasiliensis*) has been isolated from the soft tick *Ornithodoros brasiliensis*, which predominantly infests dogs. Further study is needed to determine if it is the cause of this infection.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Borrelia hermsii causes the model spirochetal disease of the relapsing fever group. Unlike other *Ornithodoros* species, *O. hermsi* does not excrete coxal fluid while feeding; it must transmit the organism while biting the host. Whereas *B. burgdorferi* in *Ixodes* ticks migrate from the midgut to the salivary gland, the salivary gland, midgut, and other

Fig. 69.12 Erythematous lesions at the site of *Amblyomma americanum* attachment (southern tick-associated rash illness, STARI). Once thought to be caused by *Borrelia lonestari*, the cause of the rash remains unclear. (From Centers for Disease Control and Prevention.)

tissues of *O. hermsi* are permanently contaminated with *B. hermsii* organisms, which allows for rapid transfer of the spirochetes during the short feeding times (minutes to hours).

In the mammalian host, *B. hermsii* has developed highly adapted mechanisms to evade the immune system.[120,383] Each inoculated spirochete may produce 30 unique antigenic variants, each expressing a major immunodominant protein that defines a specific serotype. In the mammalian host, episodes of cyclic spirochetemia are caused by waves of replicating spirochetes with relatively homogeneous serotypes. As the immune system responds to each new wave of replication, antigenic variation results in clinical relapse. The organism expresses variable major proteins, such as Vsp 33; however, after ingestion by the tick, a new major protein is upregulated on the cell surface and confers the unique serotype. Vsp 33 is homologous to OspC of *B. burgdorferi* and allows the organism to maintain its infectivity within the nonfeeding tick. Similar to the VlsE in *B. burgdorferi* organisms, rearrangement of silent genetic cassettes in the *vmp* gene accounts for antigenic variation and immune evasion.[120,384]

Clinical signs in dogs from Florida and Texas infected with *B. turicatae* included pyrexia, shifting leg lameness, hepatosplenomegaly, visible spirochetemia, anterior uveitis, and thrombocytopenia.[8,9,211] Many of the other relapsing fever spirochetes may infect dogs and cats as incidental hosts in the same way they are known to infect humans (see Table 69.1). The two dogs and cat infected with *B. hispanica* had nonspecific signs of inappetence and thrombocytopenia, with or without anemia.[378] However, co-infecting vector-borne pathogens may have also contributed to clinical signs in these animals.

DIAGNOSIS

As a result of the lack of serologic tests for TBRF, diagnosis is made by visualization of the spirochetes in blood smears using dark-field microscopy, Wright-Giemsa, acridine orange, silver, or Gram stain (Fig. 69.13). The presence of visible spirochetes differentiates relapsing fever from Lyme borreliosis, because the latter rarely, if ever, is associated with visible spirochetemia (except in the case of *B. mayonii* infection). Fresh blood smears are superior to those prepared from EDTA-preserved

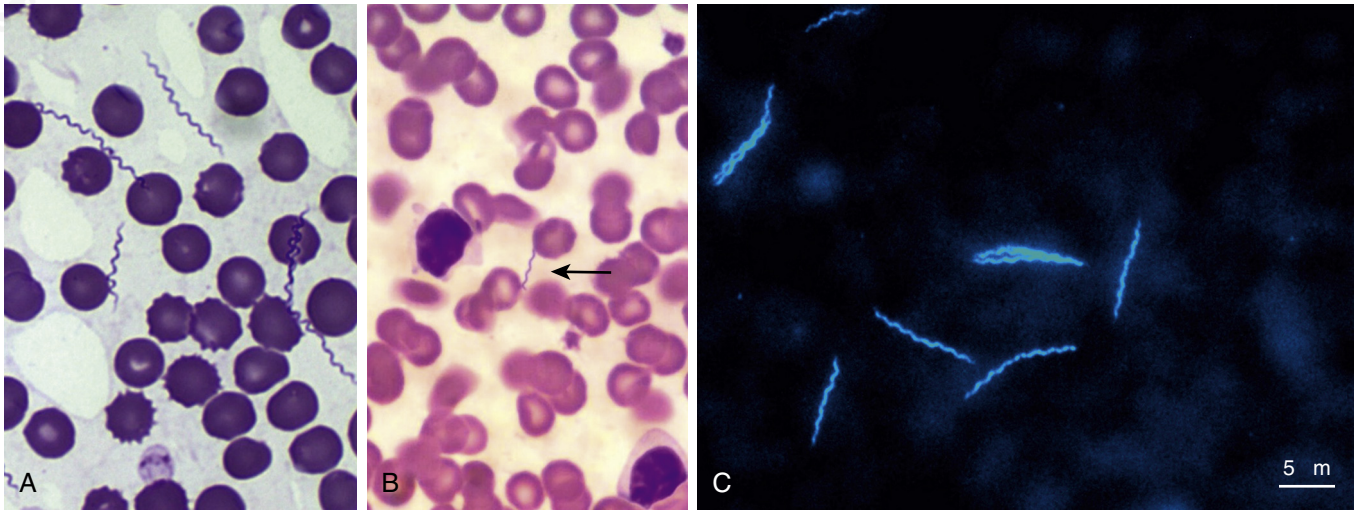

Fig. 69.13 *Borrelia hispanica* spirochetes from two dogs and a cat from Spain. (A) Blood smear from a 6-year-old male hound from Seville, Spain, with lethargy, anemia, and thrombocytopenia (Giemsa stain, 150× magnification). (B) Blood smear from a dog from Valencia, Spain, with anorexia and thrombocytopenia (100× magnification, *arrow* directed at spirochete). (C) 4′,6-diamidino-2-phenylindole (DAPI)-stained spirochetes cultured from the blood of a 1-year-old male cat with cachexia and regenerative anemia. (From Margos G, Pantchev N, Globokar M, et al. First cases of natural infections with *Borrelia hispanica* in two dogs and a cat from Europe. *Microorganisms*. 2020;8:1251.)

blood.[9] Sensitivity can be improved by buffy coat examination or inoculation of the blood into mice and subsequently into spirochete media. PCR-based methods can be used to identify the spirochetes.

TREATMENT AND PREVENTION

Therapy for relapsing fever spirochetosis is similar to that for Lyme borreliosis and involves treatment with doxycycline. The Jarisch-Herxheimer reaction, a severe febrile reaction to released bacterial endotoxins seen in some humans after treatment of TBRF, has not been documented in dogs. Clinical improvement after treatment was noted in most dogs infected by *B. turicatae*.[9,211] Prevention involves fast-kill tick-control since transmission is much faster than for Lyme borreliosis. Vaccines for Lyme disease would not be expected to prevent infection with *B. turicatae* or with other TBRF spirochetes.

CASE EXAMPLE

Signalment

"Dako," a 7-year-old MC Doberman pinscher from Amador County, CA.

History

Dako was evaluated for a 2-day history of lethargy, apparent blindness, inappetence, and inability to walk. He was taken to a local emergency clinic within 24 hours of illness where a neurologic examination was considered abnormal and an intracranial lesion was suspected. He was treated with IV fluids and given a single dose of ampicillin (1 g). The following day his mentation and thoracic limb strength had improved, but he remained unable to walk and had evidence of urinary incontinence. He lived on a farm and had contact with sheep, horses, llamas, chickens, geese, cats, and four other dogs, all of which were currently healthy, although one additional dog had died of acute renal failure 1 month ago. There was no travel history or toxin exposure, but frequent exposure to ticks occurred. Dako's diet consisted of commercial dry dog food, and occasionally pieces of cooked steak and raw goose eggs. He had not received a Lyme vaccine in the past but had been vaccinated regularly for CDV, CAdV, CPV2, and CPI3.

Current Medications

Monthly topical flea and tick preventative (fipronil and s-methoprene), monthly oral heartworm preventative (ivermectin and pyrantel).

Other Medical History

Color dilution alopecia.

Physical Examination

Body weight: 43.1 kg.

General: Quiet, alert, and responsive. Hydrated. Ambulatory on all four limbs but appeared very painful. Temperature = 101.9°F (38.8°C), HR = 78 beats/minute, RR = 24 breaths/minute, mucous membranes pink, CRT = 1 second. BCS = 5/9.

Integument: A thin haircoat with scaling was noted.

Eyes, ears, nose, and throat: Mild episcleral injection was present bilaterally. Moderate dental calculus and gingivitis were also present.

Musculoskeletal: Symmetrically well-muscled. Multiple distal joints were severely swollen and painful on palpation, including both carpi, tarsi, stifle, and elbow joints. The dog appeared painful when rising from recumbency and when walked, with pronounced right pelvic limb lameness.

Cardiovascular: No abnormalities detected.

Respiratory: No abnormalities detected.

GI: No abnormalities detected. Large bladder, actively urinated a large amount during the examination.

Rectal examination: No abnormalities detected.

Lymph nodes: Bilateral popliteal lymphadenomegaly (3 cm in diameter). Remaining peripheral lymph nodes measured 2 cm in diameter. All nodes were soft on palpation.

Neurologic examination: No neurologic abnormalities detected.

Laboratory Findings

CBC: HCT 48.4% (40%–55%), MCV 69.6 fL (65–75 fL), MCHC 34.9 g/dL (33–36 g/dL), WBC 17,100 cells/μL (6,000–13,000 cells/μL), neutrophils 15,561 cells/μL (3,000–10,500 cells/μL), lymphocytes 171 cells/μL (1,000–4,000 cells/μL), monocytes 1,026 cells/μL (150–1,200 cells/μL), eosinophils 342 cells/μL (0–1,500 cells/μL), platelets clumped (150,000–400,000 platelets/μL).

Continued

CASE EXAMPLE—cont'd

Serum chemistry profile: Sodium 148 mmol/L (143–151 mmol/L), potassium 3.5 mmol/L (3.6–4.8 mmol/L), chloride 115 mmol/L (108–116 mmol/L), bicarbonate 20 mmol/L (20–29 mmol/L), phosphorus 3.1 mg/dL (2.6–5.2 mg/dL), calcium 10.0 mg/dL (9.6–11.2 mg/dL), BUN 11 mg/dL (11–33 mg/dL), creatinine 0.8 mg/dL (0.8–1.5 mg/dL), glucose 102 mg/dL (86–118 mg/dL), total protein 6.1 g/dL (5.4–6.9 g/dL), albumin 3.6 g/dL (3.4–4.3 g/dL), globulin 2.5 g/dL (1.7–3.1 g/dL), ALT 17 U/L (21–72 U/L), AST 36 U/L (20–49 U/L), ALP 60 U/L (14–91 U/L), creatine kinase 217 U/L (55–257 U/L), GGT 1 U/L (0–6 U/L), cholesterol 167 mg/dL (139–353 mg/dL), total bilirubin 0.1 mg/dL (0–0.2 mg/dL), magnesium 1.8 mg/dL (1.9–2.5 mg/dL).

Urinalysis: SpG 1.018; pH 8.0, negative protein (SSA), negative bilirubin, negative glucose, 0–1 WBC/HPF, 0–2 RBC/HPF.

Cytology of synovial fluid obtained via arthrocentesis (see table below): Negative for morulae in WBC.

Imaging Findings

Thoracic radiographs: Unremarkable.

Abdominal ultrasound: The liver was diffusely hypoechoic but was normal in size. There was mild bilateral adrenomegaly (0.9 cm). The urinary bladder was very large and was in a pelvic location.

Microbiologic Testing

SNAP 4Dx Plus test (IDEXX Laboratories, ME): Positive for *B. burgdorferi* C_6–specific antibodies; negative for antibodies to *Anaplasma* spp. and *Ehrlichia* spp. and negative for *Dirofilaria immitis* antigen.

Lyme C6 Quant antibody ELISA (IDEXX Laboratories, ME): 153 U/mL (normal, <30 U/mL).

PCR for *B. burgdorferi* on synovial fluid: Negative.

Diagnosis

Immune-mediated polyarthritis; possibly secondary to *B. burgdorferi* infection.

Treatment

Dako was treated with doxycycline (10 mg/kg, PO, q12h) and tramadol (2 mg/kg, PO, q8h) and showed dramatic clinical improvement within 24 hours of initiating treatment. A physical examination was normal 2 weeks later.

Comments

The positive serology and response to doxycycline was suggestive of a diagnosis of Lyme polyarthritis, although it is possible there was some other cause that was not identified and the presence of C_6 antibodies was not related to this dog's illness. It may have been too early in the course of illness for this dog to have seroconverted to other vector-borne pathogens such as *A. phagocytophilum.* Other diagnostic assays that may have been useful in this dog (and in this geographic location) are serology for *Bartonella* spp.; PCR on blood for vector-borne pathogens such as *A. phagocytophilum, Rickettsia* spp., and *Ehrlichia canis*; aerobic bacterial culture of the synovial fluid; and convalescent serology for the vector-borne pathogens above. The negative synovial fluid PCR result does not rule out the possibility of Lyme arthritis because organism numbers within the synovial fluid of animals with Lyme arthritis may be extremely low. Furthermore, the dog had been treated with ampicillin before it was seen, which may have reduced organism numbers further.

	Right carpus	Left carpus	Right tarsus	Left stifle
Cell count (cells/μL)	23,730	29,370	ND	1,020
Neutrophils (%)	85	94	76	12
Small mononuclear cells (%)	2	0	1	41

Bartonellosis

Pedro Paulo V.P. Diniz, Bruno B. Chomel, Lynn Guptill, Edward B. Breitschwerdt

KEY POINTS

- Bartonellosis is an emerging, zoonotic, vector-borne infectious disease of cats, dogs, other animals, and humans.
- Causes: The most common species reported in cats are *Bartonella henselae, Bartonella clarridgeiae,* and *Bartonella koehlerae*, whereas dogs are most often infected with *B. henselae* and *Bartonella vinsonii* subsp. *berkhoffii.*
- Geographic Distribution: Worldwide, with the highest prevalence in humid subtropical and tropical regions.
- Major Mode of Transmission: Fleas (*Ctenocephalides felis*) (through flea fecal contamination of wounds); possibly other flea species (such as *Pulex* spp.) and other vectors such as lice, biting flies, mites, and ticks. Blood transfusion transmission occurs experimentally.
- Clinical Signs: In dogs, signs that relate to infective endocarditis (lethargy, fever, cardiac murmur, cough, tachypnea, lameness, neurologic) are the most frequent and well understood. Cats are commonly healthy carriers; however, *Bartonella* can also cause fever, endocarditis, myocarditis, and transient lymphadenomegaly in cats and may cause (or contribute to) other systemic inflammatory disorders.
- Differential Diagnoses: Dogs: other bacterial causes of endocarditis; other vector-borne diseases such as ehrlichiosis, anaplasmosis, borreliosis, and babesiosis; and immune-mediated inflammatory diseases. Cats: major differential diagnoses are other bacterial causes of endocarditis, other systemic inflammatory diseases, and other causes of lymphadenomegaly.
- Human Health Significance: *Bartonella* causes cat scratch disease and other less common disorders, including endocarditis, in immunocompetent humans as well as vasoproliferative disorders (known as bacillary angiomatosis or peliosis) in immunocompromised humans.

ETIOLOGY AND EPIDEMIOLOGY

Bartonella spp. are fastidious, facultative intracellular gram-negative bacteria that infect a wide range of domestic and wild mammalian host species (Fig. 70.1). Different *Bartonella* species have adapted to specific mammalian reservoir hosts and can infect and occasionally cause disease in the reservoir or in incidental hosts. More than 10 species of *Bartonella* infect cats or dogs worldwide (Table 70.1). Cats are the principal reservoir host for *Bartonella henselae*, the main cause of cat scratch disease (CSD) in humans, and subclinical bacteremia in cats is widespread (8% to 56% of healthy cats worldwide).[1]

There is a wide diversity of *B. henselae* strains and at least two different 16S rRNA genotypes. Genotype I (Houston I) and some subgroups within Genotype II (Marseille) are more likely to be a source of human infection.[2,3] There are other methods of genetically classifying *B. henselae*, including multilocus sequence typing, amplified fragment length polymorphism, and more recently whole-genome sequencing; each identifies great genetic diversity within *B. henselae*.[4] Although additional data are needed, it is possible that the genotypes/strains most frequently isolated from bacteremic cats are relatively less virulent than the genotypes/strains that most often infect humans.[2]

Cat fleas (*Ctenocephalides felis*) play a major role in the transmission of feline *Bartonella* infections.[5] Experimentally, transmission among cats has not occurred in the absence of fleas and it is believed that the presence of cat fleas is essential for the maintenance of *Bartonella* infection within the cat population. *Bartonella henselae* can multiply in the digestive system of the flea and survive several days in flea feces.[6] The main source of infection appears to be flea feces that are inoculated by scratches from contaminated cat claws.[7] *Bartonella* DNA has been detected in cat saliva, possibly due to licking of *Bartonella*-contaminated flea feces or alternatively blood contamination of the oral cavity from dental disease or wounds. However, the transmission of *B. henselae* via cat saliva has not been documented experimentally. Other potential vectors, such as *Pulex* flea species, ticks, lice, mites, bedbugs, and biting flies also harbor *Bartonella* DNA, but vector competence remains to be confirmed. Experimental transmission of *Bartonella birtlesii* has been accomplished with *Ixodes ricinus* ticks,[8] and there is indirect epidemiologic evidence that ticks may transmit *Bartonella* to dogs.[9] Transmission via transfusion has not been documented in a client-owned dog or cat, but was documented experimentally in cats and mice[10–12] and has been suspected in human medicine.[13]

Because *Bartonella* infections are often subclinical in cats and dogs, the full extent to which *Bartonella* spp. cause disease in feline and canine species remains unclear. *Bartonella* spp. have been widely studied for their role in several idiopathic inflammatory disorders of cats, including uveitis, lymphadenopathy, caudal stomatitis, and rhinitis, but definitive evidence of disease causation has been difficult to clarify due to the high serologic and bacteremic prevalence in many cat populations studied. *Bartonella* spp. are important causes of endocarditis in dogs and occasionally cause endocarditis and myocarditis in cats (see Table 70.1).

Epidemiology of *Bartonella* Infection in Cats

Bartonella henselae and *Bartonella clarridgeiae* account for the majority of *Bartonella* spp. isolated from domestic cats in the United States (Fig. 70.2), Europe, the Philippines, the Middle East, and most other regions.[14,15] *Bartonella koehlerae* has been isolated from cats in Israel, the United States, and a few other countries; *Bartonella bovis* and *Bartonella quintana* have also been isolated from, or their DNA detected in, a few healthy domestic cats.[16–18] Domestic cats are considered an

Fig. 70.1 Transmission electron photomicrograph of *Bartonella henselae* organisms in culture media (methanol uranyl acetate and then lead citrate, × 120,000). (Courtesy of Stanley Hayes, Rocky Mountain Laboratories, Hamilton, MT.)

important reservoir and vector for human infections with *B. henselae*, and cats are likely also reservoirs for *B. clarridgeiae and B. koehlerae*. Molecular methods have detected multiple *Bartonella* species in *Ct. felis*, the cat flea, along with other pathogens.[19,20] While these data suggest flea involvement in the transmission of several *Bartonella* species, competence for transmission for some *Bartonella* species by fleas has not yet been verified. Transplacental and transmammary transmissions from queens to kittens have not occurred when tested experimentally.[17,21] In addition to infection via fleas, cats have been infected experimentally via intravenous inoculation, as well as intradermal and oral routes.[5,7,11,22,23] Similar to domestic cats, wild felids, including bobcats, pumas, African lions, and cheetahs, can be infected with various *Bartonella* species.[24–27]

Young cats (≤1 year) are more likely than older cats to be bacteremic, and stray or feral cats infested with fleas are more likely to be bacteremic than pet cats that are not flea-infested.[6,28,29] Older cats are more likely to be seropositive than young cats, which likely reflects the increased chance of exposure over time. The prevalence of *Bartonella* bacteremia in cats is highest in warm, humid climates (e.g., 68% in the Philippines), and is low in colder climates (e.g., 0% in Norway).[3] *Bartonella henselae* type Marseille (type II) was more prevalent among cats in the western United States, western Europe, and Australia; type Houston-1 (type I) was more prevalent in Asia (Japan and the Philippines).[3] Some molecular typing methods reveal an even broader genetic diversity among feline strains, and most of the strains that infect humans cluster in a limited number of groups.[2,3] There is also evidence of genomic variation in *B. henselae* during the course of infection in cats.[30] The genetic diversity of *B. henselae* likely plays a role in the persistence of feline *B. henselae* infections, and has made vaccine development challenging. An improved understanding of genetic diversity among *B. henselae* isolates for cats, dogs, and humans may in turn lead to a better understanding of the differing pathogenicity of these isolates. Cats may be co-infected with multiple *B. henselae* genotypes/strains, and can also be concurrently infected with multiple *Bartonella* species.[31,32] Strain variation has important implications for diagnosis, treatment, and vaccine development to prevent infection in cats.

Epidemiology of *Bartonella* Infection in Dogs

Dogs are most commonly infected with *B. henselae* or *Bartonella vinsonii* subsp. *berkhoffii*; however, the frequency of infected dogs varies widely among regions and countries. Domestic and wild carnivores are thought to be the natural reservoir for *B. vinsonii* subsp. *berkhoffii* and *Bartonella rochalimae*, because these organisms establish prolonged bacteremia in these hosts.[24,33] For example, in California, 76% of coyotes *(Canis latrans)* were seropositive for *B. vinsonii* subsp. *berkhoffii*, with 28% of coyotes found to be bacteremic.[34] At least 14 *Bartonella* species have been detected in dogs, with 11 species capable of infecting both dogs and humans (see Table 70.1).

Because it is often difficult to culture *Bartonella* from domestic dog blood, prevalence studies in dogs have been primarily based on antibody detection. Unfortunately, *Bartonella* spp. seroreactivity correlates poorly with bacteremia and may underestimate the actual prevalence of *Bartonella* in dogs.[35] Also, variable serologic cross-reactivity occurs among *Bartonella* species, so seroprevalence studies cannot always be *Bartonella* species-specific. The prevalence of antibodies to *B. vinsonii* subsp. *berkhoffii* in dogs is highest in tropical or subtropical regions. For example, seroprevalence as high as 47% was detected in stray dogs from Morocco.[36] In the southeastern United States, the prevalence of *B. henselae* and *B. vinsonii* subsp. *berkhoffii* antibodies were 3.8% and 1.5%, respectively, in dogs tested for evidence of vector-borne disease exposure.[37] In another study of 15,451 serology specimens from dogs in North America between 2008 and 2014, 3.3% of dogs were *Bartonella* spp. seroreactive (*B. henselae* 2.1%, *B. koehlerae* 2.4%, and *B. vinsonii* subsp. *berkhoffii* 1.4%).[38] Studies based on enrichment culture coupled with molecular detection may provide a more sensitive indicator of bacteremia in dogs. In one study in the United States, 9.2% of 663 sick dogs were bacteremic for at least one species of *Bartonella*.[39] Risk factors identified in dogs from the southeastern and western United States are tick exposure, exposure to other vector-borne pathogens, residence in a rural environment, roaming, outdoor exposure, intact male sex, being of mixed breed, and being a herding or working dog.[9,38,40,41] The prevalence of *B. henselae* antibodies in sick dogs in the western region of the United States is less than 2%.[40] However, prevalence can be high in free-roaming dogs, as reported in Northern California, where 29% (54/184) of the dogs were seroreactive to *B. vinsonii* subsp. *berkhoffii, B. clarridgeiae,* and/or *B. henselae*.[42]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After infection (Fig. 70.3), *Bartonella* is found in erythrocytes and can also infect endothelial cells and bone marrow progenitor cells.[43] Inhibition of phagocytosis and pyroptosis (a highly inflammatory form of programmed cell death) of macrophages appears to promote *Bartonella* invasion into the bloodstream and potentially through lymphatic circulation.[44] The bacteria then establish a chronic, often subclinical, relapsing bacteremia that can last for weeks, months, or even years, which is likely an evolutionary adaptation that facilitates ongoing transmission by hematophagous arthropods.[1,20] Infection of endothelial cells appears to be necessary for the development of disorders such as vasculoproliferative disease and endocarditis.[15] *Bartonella* is thought to cause vasculoproliferative disease via cytokine-induced stimulation of endothelial cell proliferation and

TABLE 70.1 Comparison of Selected Disease-Producing Members of the Genus *Bartonella*

Common Pathogens for Dogs, Cats, or Humans (Alphabetical Order)

Organism (Classic Disease)	Geographic Occurrence	Confirmed Vector	Potential Vector	Reservoir Host	Incidental Host	Disease Associations
Bartonella bacilliformis (Oroya fever)	Andes Mountains	Sandfly (*Lutzomyia*)	Tick (*Dermacentor andersoni*)	Human	Human	Hemolytic anemia, fever, asymptomatic bacteremia, indolent angiomatous skin lesions (verruga peruana)[15]
Bartonella henselae (cat scratch disease)	Worldwide	Cat flea (*Ctenocephalides felis*), *Ixodes ricinus* ticks	Other ticks (*Ixodes* spp., *Dermacentor* spp., *Rhipicephalus* spp., *Haemaphysalis* spp.), deer keds (*Lipoptena mamazae*),[138] stable fly (*Stomoxys* spp.)[139]	Cat	Dog, human	Dog and human: peliosis hepatis,[71] granulomatous hepatitis,[97] generalized pyogranulomatous lymphadenitis,[140] panniculitis, polyarthritis,[141] endocarditis,[133,142,143] Dog: idiopathic effusions, hyperviscosity syndrome,[103] sielometaplasia,[102] hemangiopericytoma,[53] epistaxis,[86] necrotizing aural margin vasculitis[76] Human: localized tissue infection; angiomatosis, peliosis, granulomatous and pyogenic inflammation, lymphadenitis, endocarditis, neuroretinitis, focal retinochoroiditis, muscle pain, headache, fatigue[119] Cat: fever,[60] lymphadenomegaly,[62] endocarditis, myocarditis, diaphragmatic myositis, uveitis,[54,55] possibly caudal stomatitis,[56–59,62,63] possibly lower urinary tract disease, anemia, mild neurologic signs, and reproductive failure[17,56,59,93]
Bartonella quintana (trench fever)	Worldwide	Body louse (*Pediculus humanus*)	Cat flea (*Ctenocephalides felis*), bed bug (*Cimex lectularius*)[144]	Human, non-human primates (Rhesus macaques)[145]	Human, dog, cat	Dog and human: endocarditis.[96] Human: bacteremia, localized tissue infection, angiomatosis, peliosis, granulomatous and pyogenic inflammation, lymphadenitis[29,119]
Bartonella vinsonii subsp. *berkhoffii*	Worldwide	Likely fleas (*C. felis*)	Brown dog tick (*Rhipicephalus sanguineus*)	Dog, coyote, fox, wolf[146]	Dog, human	Dog: endocarditis,[69,113,142] cardiac arrhythmias, myocarditis, polyarthritis,[141] granulomatous rhinitis, anterior uveitis, chorioretinitis, meningoencephalitis, meningoradiculoneuritis,[147] anemia/thrombocytopenia, bacteremia, seroma,[85] hemangiopericytoma, granulomatous and pyogenic inflammation, panniculitis,[147] bacillary angiomatosis.[72] Human: endocarditis, fever, lymphadenopathy[20,137] Cat: osteomyelitis, systemic reactive angioendotheliomatosis[52,93]

Uncommon Pathogens for Dogs, Cats, or Humans (Alphabetical Order)

Organism (Classic Disease)	Geographic Occurrence	Confirmed Vector	Potential Vector	Reservoir Host	Incidental Host	Disease Associations
Bartonella alsatica	Europe	Rabbit flea (*Spilopsyllus caniculi*)	Unknown	Rabbit	Human	Endocarditis,[131] lymphadenitis[128]
Bartonella bovis (*Bartonella weissii*)	Worldwide	Unknown	Biting flies (*Haematobia* spp., *Hippobosca equina*)[14]	Ruminants (cattle, deer, moose[148])	Dog, cat	Dog: uveitis, hyperglobulinemia[38] Cattle: endocarditis[149]
Bartonella clarridgeiae	Worldwide	Cat flea (*Ctenocephalides felis*)	Unknown	Cat	Dog, human	Dog: endocarditis, chronic lymphocytic hepatitis with copper accumulation (Doberman pinscher)[97] Human: similar to *B. quintana*
Bartonella doshiae	Worldwide	Unknown	Unknown	Rodent	Human	Fatigue, blurred vision, arthralgia[150]

inhibition of endothelial cell apoptosis. Virulence factors characterized in *Bartonella* species include adhesins, heme acquisition mechanisms, type IV secretion systems, effector proteins (*Bartonella* effector proteins [BEPs]), and a low-potency lipopolysaccharide, among others.[15] Host immune status, related to elements such as breed-related immunodeficiency syndromes, other genetic idiosyncrasies, nutritional status, housing conditions, co-infections with other pathogens, immunosuppressive drug treatment or other medications, or defects in normal host barriers (such as congenital valvular disease in dogs with endocarditis), may also influence whether disease ultimately develops in *Bartonella*-infected cats and dogs.

Infected cats and dogs often show no overt clinical signs of illness. In some situations, disease manifestations that occur in *Bartonella*-infected dogs and cats are otherwise uncommon to rare and/or known to be associated with *Bartonella* infection in human patients. In other situations, nonspecific clinical signs are present and it has been impossible to clearly assign a disease causation role to *Bartonella* in an individual patient. Establishing a clear understanding of the role of *Bartonella* in disease causation has also been hindered primarily by limitations in diagnostic tests.

Clinical Manifestations in Cats

Experimental infections of specific pathogen free (SPF) cats with *Bartonella* have shed light on disease processes that can follow natural infection of cats with *Bartonella*. Cats inoculated intradermally with plate-grown *B. henselae* developed a small papule or abscess at the site of inoculation (Fig. 70.4), with concurrent transient fever and accompanying lethargy and inappetence. Lymphadenomegaly of the nodes draining the inoculation site lasted up to 6 weeks.[16–19] Transient mild neurologic signs (including nystagmus, whole body tremors, focal motor seizures, decreased or exaggerated responses to stimuli, and mild behavioral abnormalities) occurred in some cats.[16–19,45] Reproductive disorders, such as failed conception and fetal resorption, were also reported in multiple studies.[17,21,46] Most cats infected with *B. henselae* and/or *B. clarridgeiae* show no clinical signs, and gross lesions are lacking at necropsy. Cats infected with culture-grown *B. koehlerae, B. bovis, B. quintana, B. vinsonii* subsp. *berkhoffii,* or *B. rochalimae* also showed no clinical signs.[47] However, histopathology of cats infected by blood transfusion or culture-grown *B. henselae* or *B. clarridgeiae* showed peripheral or generalized lymph node hyperplasia, splenic follicular hyperplasia, and focal splenic microabscesses, lymphocytic cholangitis/pericholangitis, lymphocytic hepatitis, lymphoplasmacytic myocarditis, and/or interstitial lymphocytic nephritis.[16,18] Myocarditis was also reported in an experimentally infected cat.[48] Collectively, results from experimental infection studies involving cats suggest that the source of inoculum, the route of inoculation, and the virulence characteristics of the *Bartonella* species/strain can influence clinical, hematological, and pathological findings.

Bartonella also causes endocarditis or myocarditis in naturally infected cats, and was associated with feline endomyocarditis-left ventricular endocardial fibrosis complex in 18 of 36 cats evaluated.[49] *Bartonella henselae* DNA was amplified from aortic valvular vegetative lesions of cats, with visualization of the organism in lesions using silver stains.[20,50] Pyogranulomatous myocarditis and diaphragmatic myositis were associated with *B. henselae* infection in two cats, and organisms were detected in lesions with silver stains and IHC (Fig. 70.5).[51] *Bartonella vinsonii* subsp. *berkhoffii* DNA was detected in blood and bone lesions of a cat with carpal and metacarpal osteomyelitis (Fig. 70.6).[52] *Bartonella vinsonii* subsp. *berkhoffii* and *B. henselae* DNA was also PCR amplified and sequenced from cardiac tissues of several cats with systemic reactive angioendotheliomatosis, a vasculoproliferative disorder.[53]

The potential for *Bartonella* to be a contributor to chronic diseases seems likely given the prolonged bacteremia reported, and findings of inflammatory cell infiltrate in many tissues of experimentally infected cats. As a result, *Bartonella* has been investigated for a potential role in several idiopathic conditions of cats (see Table 70.1).[50–52,54–62] These include uveitis,[54–56] gingivostomatitis,[56–59,61,62] fever of unknown origin,[60] lower urinary tract disease,[56,59,63] hyperglobulinemia, anemia, inflammatory polyps, chronic kidney disease,[56,59] high serum pancreatic lipase immunoreactivity,[64] lymphadenopathy,[62] neurologic disease,[56,65,66] plasmacytic pododermatitis,[67] and chronic idiopathic rhinosinusitis.[68] There is currently no convincing and repeatable scientific evidence that *Bartonella* infection causes any of these conditions. Studies have varied in the methodology used to detect infection (serology, culture, and/or PCR assays). The utility of serology for establishing disease associations is limited, and studies that rely on *Bartonella* seroreactivity to evaluate disease association should be interpreted with caution. Finding *Bartonella* in tissues via PCR or culture should be evaluated carefully, as high proportions of cats may be infected with *Bartonella* species, and there may be other etiologies for clinical conditions being investigated. Because of the high prevalence of *Bartonella* exposure in domestic cats, an understanding of the significance of *Bartonella* in these conditions will require carefully controlled, long-term prospective study of large numbers of cats with clearly defined clinical conditions using *Bartonella* culture and/or PCR assays, along with investigation for other etiologies. It is important to consider that many of the conditions investigated likely have multifactorial etiologies, and cats exposed to *Bartonella* are likely exposed to other arthropod-vectored pathogens.

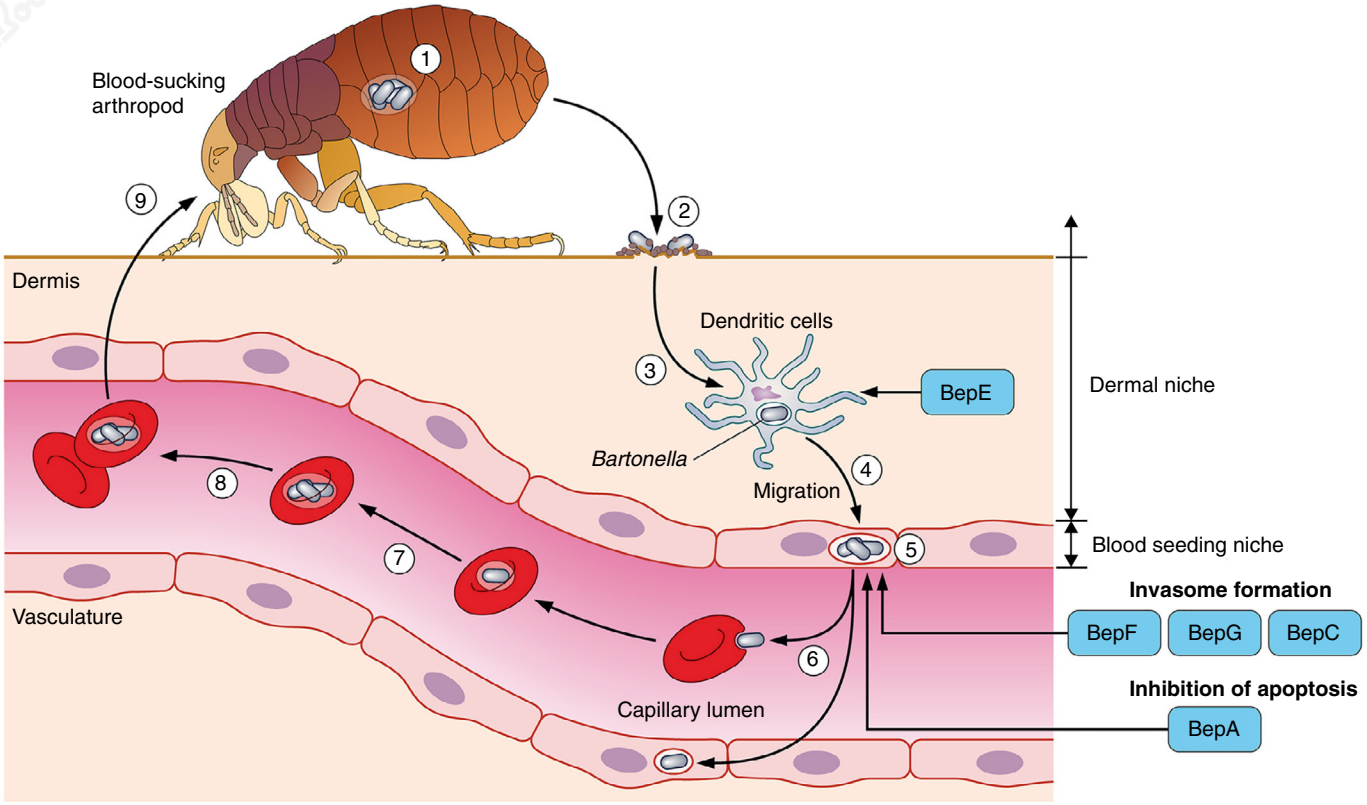

Fig. 70.3 Model of *Bartonella* infection in the reservoir host. (1) *Bartonella* replicate first in the midgut of the arthropod vector and are excreted in the feces. (2) Inoculation of *Bartonella*-containing insect feces into the dermis occurs by scratching. (3) *Bartonella* colonize cells of "dermal niche" such as dendritic cells. *Bartonella*-translocated effector protein E (*BepE*) facilitates the dissemination of *Bartonella* (4), while BepC, BepF, and BepG participate in the engulfment and internalization of the bacterial aggregate (invasome) by the targeted cell and BepA participates in the inhibition of apoptosis (5). *Bartonella* are periodically seeded into the bloodstream where they invade erythrocytes and endothelial cells at different organs (6). After limited replication inside the RBC (7), they persist for the remaining lifespan of the RBC (8) and are thus competent for transmission by a blood-sucking arthropod (9). (From Siamer S, Dehio C. New insights into the role of *Bartonella* effector proteins in pathogenesis. *Curr Opin Microbiol.* 2015;23:80-85.)

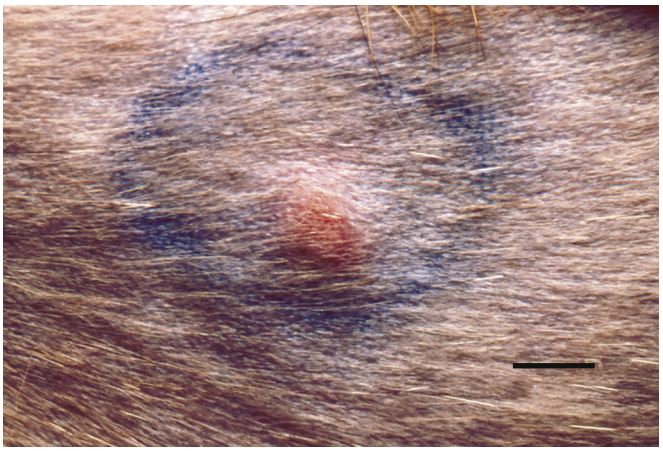

Fig. 70.4 Postinoculation papule 20 days after intradermal inoculation of *Bartonella henselae* in a cat. The size of the papule increased from the time of inoculation and only *B. henselae* was isolated from bacterial culture of an aspirate. (Bar =1 cm.) Clinical Manifestations in Dogs

Bartonella spp. are important causes of blood culture–negative endocarditis in dogs, but they have also been detected within lesions from many other pathologies using culture or PCR (see Table 70.1). Infection with *Bartonella* was identified from 19% to 28% of dogs with culture-negative endocarditis.[45,69] In United States military working dogs, 13 of 18 dogs with histologic diagnoses of culture-negative endocarditis, 3 of 5 dogs with endomyocarditis, and 3 of 3 dogs with endocardiosis tested positive for *Bartonella* using PCR; in contrast, only 1 of 28 control dogs without histologic evidence of cardiac lesions tested positive.[70] Worldwide, the DNA of several *Bartonella* species has been detected in the heart valves of dogs with endocarditis. The most common species identified has been *B. vinsonii* subsp. *berkhoffii*. In dogs, *Bartonella* endocarditis usually involves the aortic valve, although the mitral valve is occasionally affected, so the possibility of bartonellosis should not be ruled out in dogs with mitral valve endocarditis. Dogs with *Bartonella* endocarditis are more likely to be afebrile and more likely to have congestive heart failure than dogs with other causes of endocarditis, and their median survival time is shorter (Fig. 70.7).[45] Complications of *Bartonella* endocarditis include murmur, lameness,

Identification of *Bartonella henselae* in 2 cats with pyogranulomatous myocarditis and diaphragmatic myositis. *Vet Pathol.* 2012;49:608-611.)

weakness, thromboembolic disease, neutrophilic polyarthritis, and collapse.

Bartonella isolates or *Bartonella* DNA have been detected in lesions from dogs with a variety of chronic pyogranulomatous or granulomatous inflammatory and vasculoproliferative diseases (Fig. 70.8). Consequently, the clinical manifestations vary over the time course of illness and in severity according to the organ or tissue most severely affected. *Bartonella henselae* was detected in a dog with peliosis hepatis and *B. vinsonii* subsp. *berkhoffii* in a dog with bacillary angiomatosis, both of which are rare conditions that are strongly associated with *Bartonella* infection in humans.[71–73] Peliosis hepatis and bacillary angiomatosis are vasculoproliferative diseases characterized by the presence of blood-filled proliferation of vascular tissue in the liver and skin, respectively. *Bartonella henselae* was also detected in an SPF beagle research dog that had aural vasculitis, with confirmation of intralesional infection using PCR amplification, DNA sequencing, and confocal immunostaining.[74] Based on case reports and seroprevalence studies, *Bartonella* has been associated with polyarthritis, epistaxis, and thrombocytopenia in dogs.[40] However, these associations could also reflect the presence of other detected or undetected diseases, including co-transmitted vector-borne pathogens that cause these disorders. *Bartonella* has been investigated for its potential role in lymphoma,[75] neurologic diseases,[76] idiopathic cavitary effusion,[77,78] idiopathic rhinitis,[79] and in splenic disorders including lymphoid nodular hyperplasia, hemangiosarcoma,[80] and fibrohistiocytic nodules.[81] *Bartonella* spp. DNA was amplified and sequenced from fresh frozen tissues from 73% of dogs diagnosed with hemangiosarcoma.[80] The clinical relevance of finding *Bartonella* infection in association with a neoplasm requires additional study.

Physical Examination Findings

Among 47 dogs confirmed to be infected with one or more *Bartonella* spp. in the United States, the most frequent signs were fever (40%), lethargy (40%), weight loss (34%), anorexia (32%), lymphadenopathy

Fig. 70.6 Dorsopalmar radiograph of thoracic limbs. (A) Proliferative lesion of the right fifth metacarpal bone and adjacent soft-tissue swelling *(arrow)*. (30%), diarrhea (23%), neurological signs (21%), heart murmurs (21%), respiratory signs (21%), polyuria/polydipsia (21%), lameness (19%), vomiting (15%), and splenomegaly (13%).[82] When compared to dogs suspected of other tick-borne diseases, the presence of weight loss was more frequent in dogs infected with *Bartonella* species.[83] In dogs with *Bartonella* endocarditis, physical examination findings include lethargy, inappetence, and thin body condition; lameness or recumbency due to thromboembolic complications, weakness, or polyarthritis; joint effusion; and, uncommonly, fever (as high as 104.9°F [41°C]). Evidence of cardiac disease and congestive heart failure is often present, including respiratory distress, cough, increased lung sounds, and systolic and/or diastolic heart murmurs, cardiac arrhythmias, and pulse deficits. Neurologic signs such as anisocoria and obtundation can occur in dogs with thromboembolism that involves the CNS. There may also be evidence of flea or tick infestations in some dogs. Other physical examination findings that might be present in dogs with other manifestations of bartonellosis are mass lesions that involve lymph nodes or salivary glands; splenomegaly or hepatomegaly; cavitary effusions; peripheral edema; epistaxis; or nodular skin lesions (Fig. 70.9).[38,77,84–87]

Physical examination findings in cats with *Bartonella* endocarditis or myocarditis have included fever, lethargy, respiratory distress, cardiac murmurs, and arrhythmias.[50,51] Fever and lymphadenomegaly are common findings in experimentally infected cats, and *Bartonella* infection should be on the list of differential diagnoses for cats presenting with fever and/or lymphadenomegaly that cannot be otherwise explained, along with a history compatible with *Bartonella* exposure.

In addition to endocarditis and myocarditis, *Bartonella* may contribute to acute-onset cardiac arrhythmias and sudden death.[49] *Bartonella* spp. DNA was amplified by PCR and sequenced from 18 of 36 cats (50%) with endomyocarditis and 1 of 12 (8.3%) cats with hypertrophic cardiomyopathy, whereas DNA was not amplified from any non-cardiac disease control hearts.

DIAGNOSIS

Most clinical signs or clinical pathologic abnormalities proposed to be attributable to bartonellosis are shared by conditions resulting from many other etiologies. Therefore determining which animals likely have clinical signs resulting from *Bartonella* infection can be difficult. Diagnostic testing should not be focused on *Bartonella* alone but should include evaluation for other potential causes of the clinical condition(s) being evaluated. Diagnosis of bartonellosis is based on the presence of consistent clinical abnormalities (especially endocarditis or myocarditis, but also other systemic inflammatory or vasculoproliferative diseases), a history of exposure to arthropod vectors, histopathologic findings, and positive culture or PCR assay results on blood or affected tissues (Table 70.2). It may be impossible to identify *Bartonella* as the cause of disease if the organism is not detected in the blood by PCR or enrichment blood culture/PCR and if affected tissues (e.g., valvular vegetations) cannot be obtained for analysis. Also, because healthy cats and dogs can be bacteremic, documentation of bacteremia must be viewed in the clinical context of the animal's illness. Similarly, visualizing organisms (or amplifying organism-specific DNA sequences) in tissue may not always confirm causation due to *Bartonella*, as this is distributed throughout many tissues because it is a blood-borne pathogen. Other possible causes of disease must also be investigated, and a response to antibiotic treatment could be evaluated (see Case Example). Finally, disease resolution in association with antibiotic administration may not indicate *Bartonella* as a cause, since other undocumented bacterial pathogens may be treated as a result of antibiotic therapy. Some antibiotics have anti-inflammatory and/or immune-modulating properties that make it difficult to differentiate whether a positive change in patient status is a result of antimicrobial properties of the drug, other properties of the drug, the host immune response having more time to address the pathogen, or a combination of factors.[88] Documentation of seroconversion and seroreversion in conjunction with antibiotic administration can be used to support a diagnosis of bartonellosis.[89] Increased documentation of seroconversion in dogs with an acute-onset illness will be important to better understand the extent to which acute versus chronic infections occur in dogs. In contrast, when dealing with a long-standing illness, serology (if positive) can only be used to implicate *Bartonella* exposure. As *Bartonella* seroprevalence is much lower in dogs compared to cats, positive serology is perhaps more diagnostically useful when evaluating a sick dog.[38] More specifically (and as occurs in humans), dogs with *Bartonella* endocarditis usually have high antibody titers to *Bartonella* spp. Conventional organism detection tests (blood culture and PCR) are insensitive because dogs tend to have very low levels of bacteremia when compared with cats. The sensitivity of *Bartonella* spp. detection has improved with the use of enrichment culture coupled with a highly sensitive PCR, which is the current recommended approach for confirming bacteremia in dogs.[85,90,91] Improved detection of *Bartonella* bacteremia in cats has also been demonstrated using methods combining enrichment culture and PCR assays.[92] Nonetheless, the prevalence rates of *Bartonella* spp. in cats and dogs do not correspond with the low number of reported clinical cases potentially because *Bartonella* infections are underdiagnosed in dogs and cats.[93]

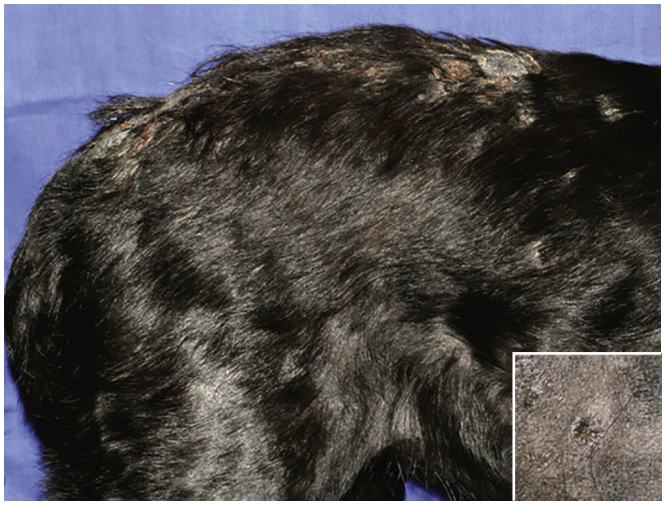

Fig. 70.9 An 8-year-old, spayed female Labrador retriever with panniculitis associated with *Bartonella henselae* infection. Lesions consisted of patchy to complete alopecia containing diffuse, palpable subcutaneous nodules with overlying hemorrhagic crusts. Several of the nodules were ulcerated, scarred, and crateriform in appearance (*inset*). (From Rossi MA, Balakrishnan N, Linder KE, et al. Concurrent *Bartonella henselae* infection in a dog with panniculitis and owner with ulcerated nodular skin lesions. *Vet Dermatol.* 2015;26(1):60-63, e21-62.)

Laboratory Abnormalities

Hematologic and biochemistry abnormalities in dogs and cats with *Bartonella* endocarditis are nonspecific and often mild. Most infected cats have no clinical pathologic abnormalities. Chronically infected dogs may also be hematologically unremarkable or have only mild nonregenerative anemia, neutrophilia, neutropenia, or thrombocytopenia. A few dogs have low to moderate numbers of circulating band neutrophils, lymphocytosis, and/or monocytosis.[94–96] Serum biochemical abnormalities can include azotemia, hypoalbuminemia, hypoglobulinemia, and hyperglobulinemia. Isosthenuria, proteinuria, cylindruria, and slightly increased urine protein-to-creatinine ratios have been present in the urine of some affected dogs. Dogs with hepatic involvement have had moderately increased serum ALT and/or ALP activities.[71,97] In one study from the United States, the most common laboratory abnormalities detected among *Bartonella*-bacteremic dogs were proteinuria (40%), anemia (38%), leukocytosis (36%), thrombocytopenia (34%), elevated liver enzymes (32%), hyperbilirubinemia (30%), hyperglobulinemia (26%), hypoglobulinemia (23%), azotemia (21%), monocytosis (17%), abnormal coagulation panel (PT/PTT) (13%), leukopenia (11%), and lymphocytosis (11%).[82,83] Ineffective erythropoiesis was diagnosed in a dog that failed immunosuppressive drug therapy, but had resolution of the anemia after documentation of *B. henselae* bacteremia, in association with antibiotic administration.[98]

TABLE 70.2 Diagnostic Assays Available for *Bartonella* Infection in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Whole blood, other tissue specimens	*Bartonella* spp.	Confirms infection and allows species identification. Specialized culture conditions required; best performed in laboratories with special expertise. Requires several weeks' incubation. Sensitivity is especially low in dogs because of low-level or intermittent bacteremia. The collection of serial samples and the use of BAPGM enrichment media followed by PCR may increase sensitivity but may increase the chance of false-positive results due to PCR-related contamination. Positive culture results alone do not imply disease causation, because healthy dogs and cats can have *Bartonella* in their tissues. Results must be interpreted in light of the clinical signs and history.
Histopathology with organism detecting using silver stains or IHC	Tissue specimens obtained by biopsy or necropsy	*Bartonella* spp. organisms	Low sensitivity, but supports disease causation when positive and properly performed and interpreted.
Serology	Serum	Antibodies to *Bartonella* spp.	Variable cross-reactivity between *Bartonella* species; species-specific assays are required. Immunofluorescent antibody and ELISA assays are best validated. Results correlate poorly with bacteremia. Positive results do not imply disease causation, because a significant proportion of healthy dogs and cats are seropositive. High positive titers are usually present in dogs and cats with endocarditis.
PCR	Whole blood, splenic or lymph node aspirates, other tissue specimens	*Bartonella* spp. DNA	Confirms active infection more rapidly than culture. Sensitivity and specificity may vary depending on assay design and specimen type; may not necessarily be more sensitive than culture. Positive results alone do not imply disease causation, because healthy dogs and cats can have *Bartonella* in their tissues. Results must be interpreted in light of the clinical signs and history. False-positive results may occur as a result of PCR-related contamination.

BAPGM, *Bartonella* alpha Proteobacteria growth medium.

A 2022 study found no clinically relevant laboratory abnormalities in cats infected with *Bartonella* other than neutrophilia.[99]

Cardiac biomarkers such as troponin I and natriuretic peptide (Nt-ProBNP) may be elevated in sick dogs with *Bartonella* endocarditis or myocarditis. Cardiac troponin I is a highly sensitive marker for myocardial damage, and was elevated (0.28 to 3.05 ng/mL, reference ≤0.11 ng/mL) in three out of eight *Bartonella* spp. infected or exposed dogs, lacking diagnostic indications of endocarditis.[100] Natriuretic peptides are a biomarker for stress or stretching of the myocardium, and are frequently elevated in patients with congestive heart failure, which can be caused by endocarditis or myocarditis.[101]

Diagnostic Imaging

Plain Radiography

Thoracic radiographs in dogs with *Bartonella* endocarditis often show evidence of congestive heart failure, with venous engorgement and pulmonary edema (Fig. 70.10). Lung lobe consolidation and hilar lymphadenopathy were described in a dog with systemic granulomatous disease and sialometaplasia.[102] Bilateral mandibular pyogranulomatous lymphadenitis and pulmonary nodules were found in a dog with *B. henselae* bacteremia.[103]

Abdominal Ultrasound

Ultrasound examination of dogs with systemic granulomatous or pyogranulomatous disease may reveal lymphadenomegaly and organomegaly,[104] and mixed echogenic patterns within the liver.[97] In two distinct reports, dogs with peliosis hepatis had ascites/hemoperitoneum and multiple, small nodular masses and hypoechoic cystic lesions within the liver (Fig. 70.11).[71,73]

Electrocardiography

Arrhythmias and conduction disturbances have been more frequently reported in patients with endocarditis or myocarditis, but occur in dogs without echocardiographic evidence of these disease processes. ECG findings are nonspecific and can vary from atrial, nodal, or ventricular conduction disturbances, including atrioventricular blocks and/or bundle branch blocks. In addition, supraventricular and/or ventricular premature complexes may be observed (Fig. 70.12).

Echocardiography

Echocardiography in dogs and cats with *Bartonella* endocarditis reveals oscillating valvular vegetations or thickened and hyperechoic valve leaflets, which usually involve the aortic valve (Fig. 70.13). There may be evidence of aortic regurgitation or insufficiency and eccentric hypertrophy of the left ventricle or decreased cardiac output.

Microbiologic Tests

Culture

Despite the limitations described earlier, culture of blood or other tissues for *Bartonella* facilitates a definitive diagnosis of infection. However, blood culture requires special techniques and can be insensitive because of the relapsing nature of bacteremia (see Fig. 70.3). Sensitivity can be improved by collecting serial blood samples (e.g., three blood draws within 7 days). Culture has especially low sensitivity in most dog populations because of the low level of bacteremia (especially when dogs are incidental hosts and develop the disease). Blood for culture should be obtained using aseptic collection and placed in EDTA-containing tubes, and then chilled or frozen during shipment. The collection of blood into plastic EDTA tubes allows the tubes to be frozen directly, which releases organisms from erythrocytes after which they are inoculated into optimized liquid growth media. Blood should be sent to laboratories familiar with the culture of these fastidious organisms, and the laboratories should be contacted for instructions regarding specimen collection and submission. Special media (such as fresh chocolate agar, or brain-heart infusion agar enriched with 5% to 10% blood) and culture conditions (5% CO_2, temperatures of 35°C to

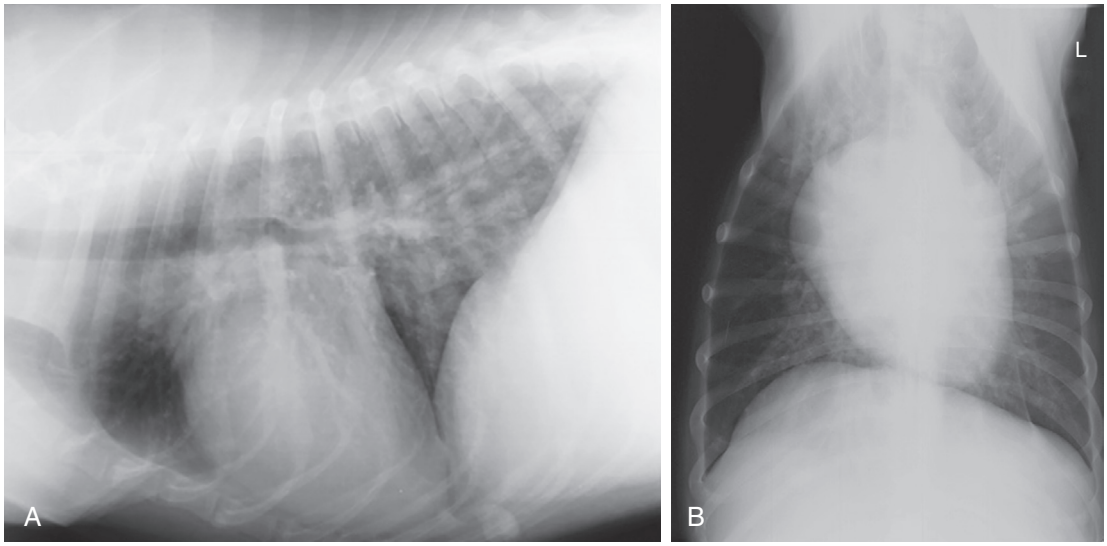

Fig. 70.10 Radiographs from a dog with acute aortic valve infective endocarditis associated with *Bartonella* spp. infection. The dog was evaluated for acute dyspnea. Thoracic radiographs show normal heart size and diffuse interstitial pulmonary infiltrates of the caudal lung lobes. Pulmonary veins were mildly distended. Because of the lack of cardiomegaly, there was debate whether the infiltrates were cardiogenic, and measurement of markedly elevated pulmonary capillary wedge pressure confirmed left heart failure as the cause of the infiltrates. (From MacDonald K. Infective endocarditis in dogs: diagnosis and therapy. *Vet Clin North Am Small Anim Pract*. 2010;40:665-684.)

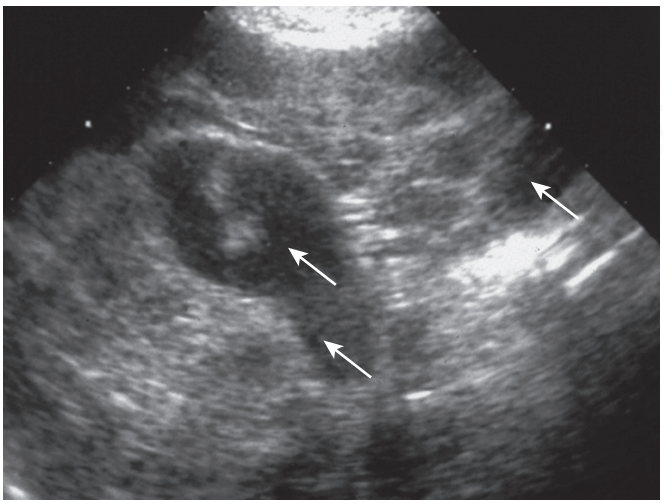

Fig. 70.11 Ultrasonographic appearance of the liver of a dog with peliosis hepatis, associated with *Bartonella henselae* infection showing hypoechoic areas *(arrows)* representing vascular peliosis. (Courtesy of Barbara Kitchell, University of Illinois, Urbana, IL.)

37°C) are used to enhance the likelihood of isolation of *Bartonella*.[75] Extended incubation times of up to 6 to 8 weeks can be required for successful isolation. The use of an insect growth medium (*Bartonella* alpha Proteobacteria growth medium, or BAPGM) that contains multiple micronutrients and defibrinated sheep blood for enrichment culture of blood, cerebrospinal and joint fluid, pathological effusions, and potentially other tissues, followed by PCR testing of the liquid culture at defined time points, in conjunction with sub-inoculation of the liquid culture medium onto agar plates, has enhanced culture sensitivity, compared to conventional microbiological approaches. It also has the potential to yield other fastidious organisms not cultured under routine conditions that may play a role in endocarditis.[105] Liquid culture did not significantly improve the isolation of *Bartonella* spp. in cats.[106]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Many PCR-based assays have been developed for the rapid detection of *Bartonella* DNA in blood or other tissues.[100,107,108] Some veterinary diagnostic laboratories offer real-time PCR assays for the detection of *Bartonella* species as a component of vector-borne PCR panels. Some assays are designed to detect all *Bartonella* spp., whereas other assays are designed to be species-specific. Genetic analysis of PCR products by DNA sequencing or other modalities can be performed to identify the infecting *Bartonella* species. Diagnostic utilization of droplet digital PCR (ddPCR) has substantially improved the detection of *Bartonella* DNA while maintaining exceptional specificity.[109] The clinical performance of many of these assays, when compared among laboratories or compared with culture, has not been well studied. When used directly on blood specimens, PCR assays may be no more sensitive than conventional culture for the detection of *Bartonella*, and detection of DNA does not necessarily equate to the documentation of living organisms. However, the turnaround time for PCR assay results is typically much faster than for culture. False-positive PCR assay results due to laboratory contamination or sample contamination at the time of collection (of particular concern with tissues collected at necropsy) have the potential to occur. False-negative PCR results may occur due to DNA degradation or cross-linking secondary to formalin fixation or other factors. Whenever possible, clinicians should simultaneously collect and freeze tissues for PCR testing at the same time tissues are collected for histopathology. Reputable laboratories with experience in molecular diagnostics are recommended to achieve optimal sensitivity and specificity. Laboratories should be contacted before specimen submission for guidelines for specimen collection and shipment.

Serologic Testing

Immunofluorescent antibody (IFA), ELISA, and Western immunoblot assays are available for the detection of *Bartonella* spp. antibodies. Some degree of cross-reactivity occurs among *Bartonella* species, but multiple species-specific assays still should be performed to increase the chance of antibody detection. Cross-reactivity can be observed for endocarditis

Fig. 70.12 Twelve-lead surface ECG recording of a dog with *Bartonella*-associated inflammatory cardiomyopathy, showing the presence of sinus rhythm conducted with left bundle branch block, interrupted by frequent ventricular ectopic beats with right bundle block morphology *(arrows)*. (From Santilli RA, et al. *Bartonella*-associated inflammatory cardiomyopathy in a dog. *J Vet Cardiol.* 2017;19(1):74-81.)

cases, where antibody titers can be quite high.[20,94] Experimentally, dogs generated a specific antibody response by IFA testing to each *Bartonella* species, without the development of cross-reactivity.[110] *Bartonella henselae* Western immunoblot was more sensitive than *B. henselae* IFA, but there were still infected dogs (PCR+) that were negative by both testing modalities.[111] In addition to the possibility of *Bartonella* spp. transmission by other arthropods, such as ticks, clinicians should be aware that dogs with flea infestations may be exposed to multiple *Bartonella* spp. as a result of a single or sequential flea exposures. Acute and convalescent titers can be used to assess a patient with an acute-onset illness, whereas paired titers are less likely to be valuable for patients with chronic and persistent infection. If serologic testing is performed in dogs, a panel that includes testing for *B. henselae, B. vinsonii* subsp. *berkhoffii, B. rochalimae, B. koehlerae,* and *B. clarridgeiae* would be optimal.[112] In cats, a serologic panel including *B. henselae, B. koehlerae,* and *B. clarridgeiae* should be considered. In the authors' experience, variability in the antigen of *Bartonella* species or strain used for testing may result in different results among laboratories. Measurement of *Bartonella* serum antibodies has a limited ability to help determine whether a sick animal has an active *Bartonella* infection. In both cats and dogs, bacteremia can occur in the absence of detectable antibodies, and seropositive cats and dogs are not always bacteremic. Some dogs that are chronically ill and *Bartonella* spp. nonseroreactive seroconvert after administration of antibiotics, potentially reflecting enhanced antigenic recognition. For example, in one study with 61 naturally infected and sick dogs, only 7 of 19 (36.8%) *B. henselae* and 4 of 10 (40%) *B. vinsonii* subsp. *berkhoffii* infected dogs for which sera were available were seroreactive to *B. henselae* and *B. vinsonii* subsp. *berkhoffii* antigens, respectively. Because of this, serology is not recommended as the sole diagnostic test for canine or feline bartonellosis and should be used and interpreted in conjunction with PCR testing or enrichment culture/PCR.[38]

Pathologic Findings

Gross necropsy of dogs and cats with *Bartonella* endocarditis may reveal evidence of congestive heart failure, with lung congestion and edema. Single or multiple nodules, variably sized, are typically present on the periphery of valvular leaflets, which may be small and firm or large, granular, and friable (Fig. 70.14). White plaques may be found adherent to the adjacent endocardial surfaces. Histopathology reveals chronic inflammation, with fibrous tissue and extensive mineral deposits. The presence of valvular mineralization should raise suspicion for *Bartonella* endocarditis because mineralization is uncommonly associated with endocarditis caused by other bacteria.[45] Small bacilli may be seen within lesions with silver stains or immunohistochemical stains for *B. henselae*.[50,51,72] Silver stains must be interpreted with caution because necrotic debris and nuclear material can mimic positive staining. Gross lesions in the dog with peliosis hepatis consisted of multiple, 0.1- to 0.3-cm cysts in the liver that were filled with cloudy, serosanguineous fluid (Fig. 70.15).[71,72] Nodular granulomatous or pyogranulomatous lesions in the myocardium, kidneys, lymphoid, or other tissues have also been described in animals with bartonellosis (Figs. 70.16 and 70.17),[97,113,114] and nodular pyogranulomatous inflammatory lesions with intralesional bacteria were described in the myocardium and diaphragm of cats with *Bartonella* myocarditis and diaphragmatic myositis (see Fig. 70.5).[51,115]

Cats with acute or chronic experimental *B. henselae* or *B. clarridgeiae* infections had hyperplasia of lymphoid organs, splenic microabscesses,

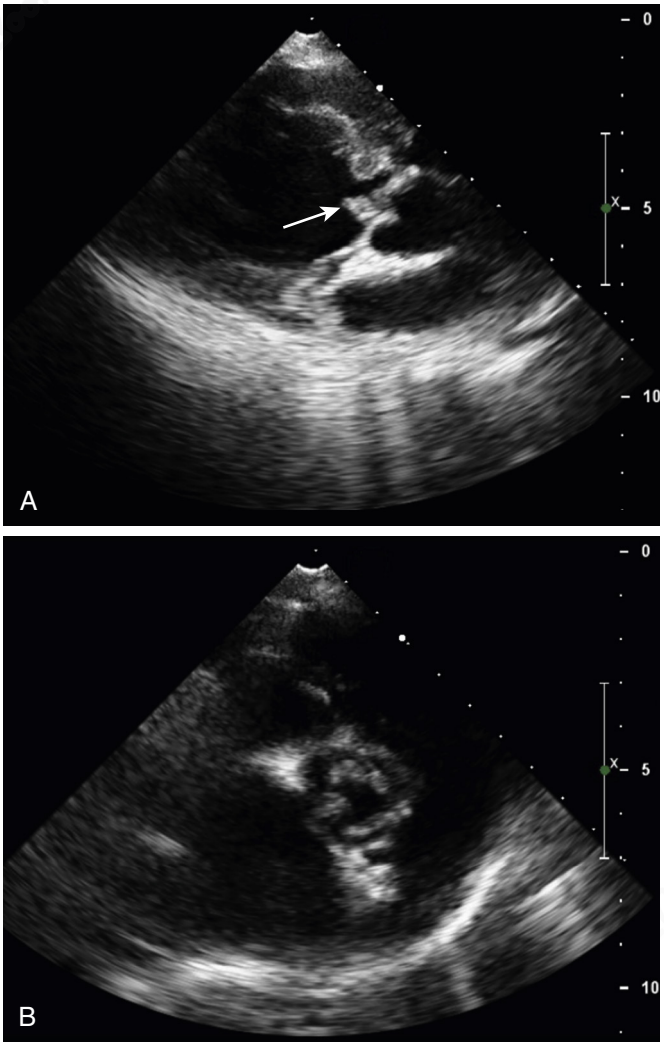

Fig. 70.13 Echocardiogram images from a 13-year-old German shepherd dog with blood culture–negative endocarditis. IFA serology for *Bartonella vinsonii* subsp. *berkhoffii*, *Bartonella clarridgeiae*, and *Bartonella henselae* were positive at titers of 1:512, 1:1024, and 1:128, respectively. On the long-axis view (A) there is an irregular hyperechoic lesion attached to the aortic valve cusps *(arrow),* and the cusps appear thickened. On the short-axis view (B), the normal "Mercedes-Benz" sign has been destroyed by the aortic valvular thickenings. (From Sykes J. *Canine and Feline Infectious Diseases.* Elsevier; 2014.)

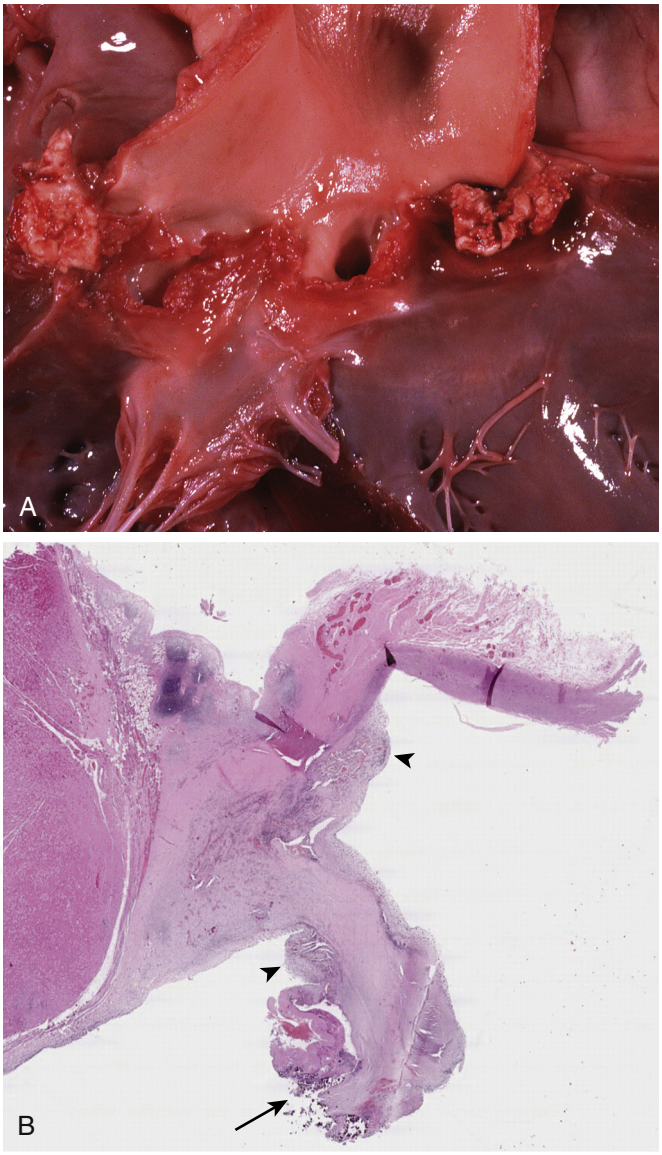

Fig. 70.14 Gross pathologic findings (A) and histopathology (B) of the aortic valve from a dog with *Bartonella* endocarditis. (A) The periphery of the valve is eroded. Variably sized, mineralized nodules expand the valve leaflet. There are multifocal, slightly raised, dull white plaques on the surface of the adjacent aorta and ventricular endocardium. (B) Aortic valve, aorta, and ventricular septum. The distal leaflet is fragmented and contains mineral deposits *(arrow)* and hemorrhage. At the base of the valve, the endothelial surface is lifted and there are broad bands of loose connective tissue, small vessels, and endothelial-lined clefts *(arrowheads).* Hematoxylin and eosin stain, bar = 180 μm. (Reprinted from Pesavento PA, Chomel BB, Kasten RW, et al. Pathology of *Bartonella* endocarditis in six dogs. *Vet Pathol.* 2005;3:370-373.)

necrotizing granulomatous lesions in lymph nodes, and small foci of pyogranulomatous, neutrophilic, or lymphocytic inflammation in many tissues (including lung, liver, kidney, heart, and spleen) (Figs. 70.18 and 70.19).[16,22]

TREATMENT AND PROGNOSIS

Efficacy has not been established for any antimicrobial for the elimination of *Bartonella* infections in cats or dogs. In humans, the 2015 American and European guidelines for the management of infective endocarditis recommend the use of doxycycline combined with gentamicin for treatment of *Bartonella* infection,[116,117] but clinical improvement has been reported after the use of other antibiotics. A recommendation has been made to avoid the use of fluoroquinolones alone for treatment in humans.[118] Valve replacement is often indicated. Overall, treatment protocols for human *Bartonella* infections vary with clinical presentation and patient immune status.[107,119]

The prognosis for *Bartonella* endocarditis in dogs and cats is generally poor. Only a single case of successful treatment of suspected *B. henselae* endocarditis in a cat has been reported at the time of writing, where marbofloxacin and azithromycin were used for 6 weeks.[120] Supportive care and medications to manage congestive heart failure are often required. *Bartonella* spp. antibiotic resistance or treatment failures have been reported in association with the single use of azithromycin, doxycycline, and fluoroquinolones in dogs,[77,85,118] therefore monotherapy with these antimicrobials is no longer recommended. As bacterial isolation of *Bartonella* spp. is extremely difficult to achieve,

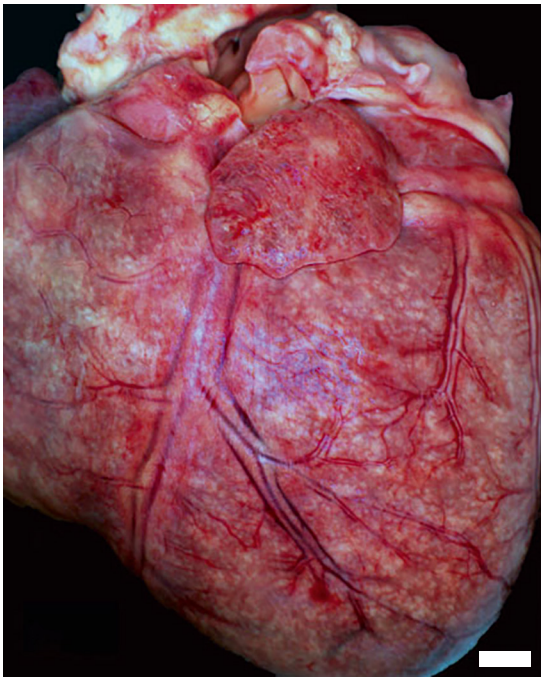

Fig. 70.16 Pyogranumolatous pancarditis associated with *Bartonella henselae* infection in a 6-year-old female spayed American pit bull terrier. Multifocal to coalescing white nodular foci are visible from the epicardium of the right and left ventricles and atria of a dog. Bar = 5 mm. (From Donovan TA, et al. Pyogranulomatous pancarditis with intramyocardial *Bartonella henselae* San Antonio 2 (Bh SA2) in a dog. *J Vet Intern Med*. 2017;31:142-148.)

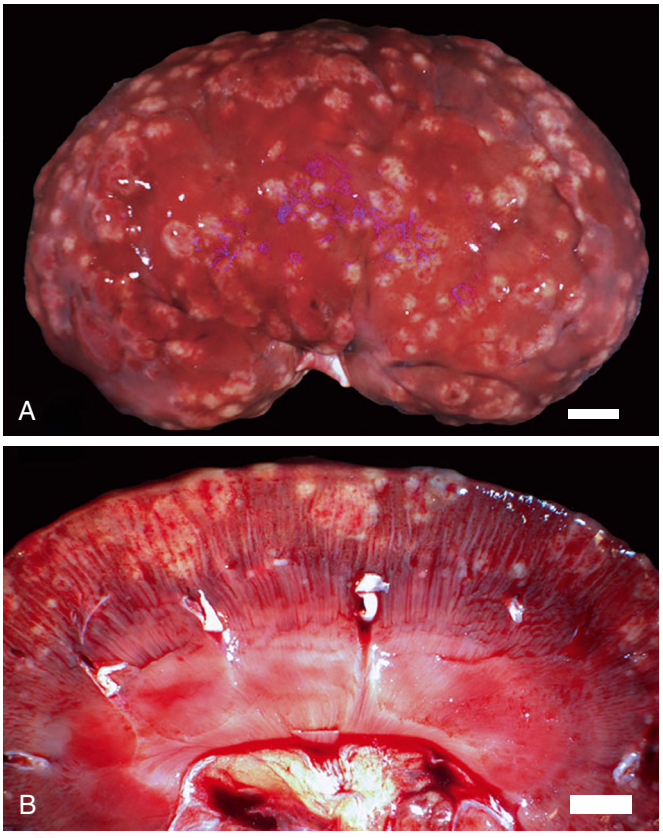

Fig. 70.17 Pyogranulomatous nephritis associated with *Bartonella henselae* infection in a 6-year-old female spayed American pit bull terrier. Visible from the renal cortex are dozens of multifocal to coalescing, tan nodular foci, which range from pinpoint to 1 cm in diameter. Bar = 5 mm. (From Donovan TA, et al. Pyogranulomatous pancarditis with intramyocardial *Bartonella henselae* San Antonio 2 (Bh SA2) in a dog. *J Vet Intern Med*. 2017;31:142-148.)

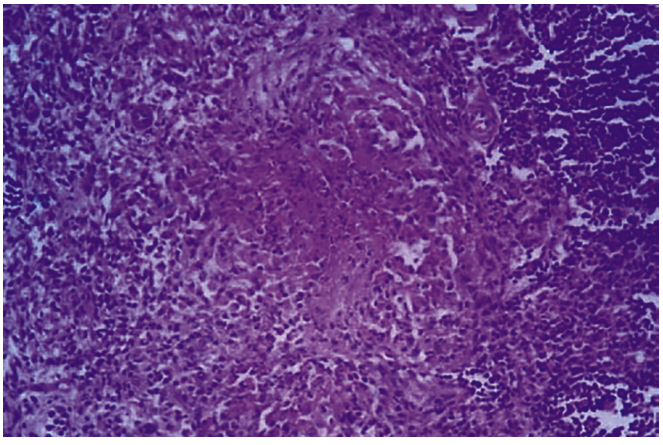

Fig. 70.18 Necrotizing granuloma in the lymph node of a cat infected with *Bartonella henselae*, 56 days following inoculation (hematoxylin and eosin stain, × 200). (Courtesy of Lynn Guptill, Purdue University, West Lafayette, IN.)

determining antibiotic resistance patterns is often not possible. This greatly limits our ability to determine the mechanism(s) that are responsible for treatment failures. Oral antimicrobial alternatives for stable animals include high-dose doxycycline in combination with rifampin or fluoroquinolones, alone or in combination with amoxicillin (Table 70.3).[121] To avoid a shock-like reaction (Jarisch-Herxheimer reaction) caused by the sudden release of bacterial endotoxins/antigens during the first days of antimicrobial treatment, it is recommended that antibiotics are not started concomitantly. Instead, the second antibiotic should be introduced at least 5 to 7 days after the first one.[121] Dogs with CNS signs have been empirically treated with

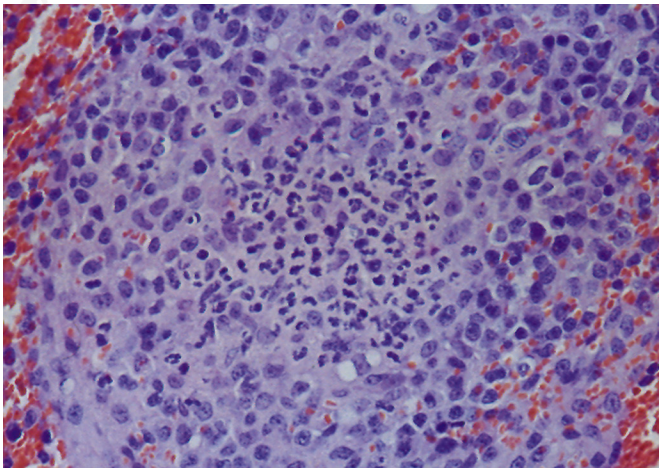

Fig. 70.19 Histologic section of feline spleen showing a microabscess 14 days following inoculation with *Bartonella henselae* (hematoxylin and eosin stain, × 400). (Courtesy of Lynn Guptill, Purdue University, West Lafayette, IN.)

doxycycline and rifampin; however, the use of rifampin in cats should be avoided if other alternatives are available.

Data from experimentally or naturally infected cats indicate that a high dose of doxycycline may be necessary to treat *Bartonella* infection in cats. There is no consensus regarding the best treatment for ill, infected cats, and data from randomized clinical trials are lacking. Initial treatment with doxycycline may be appropriate, with the addition of another antibiotic if this treatment does not appear to be effective. Antibiotic treatment may induce resistant strains of *Bartonella* and other resident microflora, therefore treatment should be reserved for use only in *Bartonella*-positive cats showing clinical signs. While antibiotic treatment reportedly decreases the level of bacteremia in cats, there is no evidence that treatment will decrease the probability of transmission of *Bartonella* to arthropod vectors, other cats, or humans. Care should be taken to avoid scratches or bites when administering drugs to bacteremic cats. Client education is necessary regarding the uncertainty of treatment efficacy, the advisability of long-term follow-up, and the chance for reinfection following treatment. The importance of flea control and other means of preventing transmission (see Prevention) should be strongly emphasized.

IMMUNITY AND VACCINATION

There are no vaccines available for the prevention of bartonellosis in cats or dogs. *Bartonella* evades the host immune system and establishes a persistent intracellular infection. Dogs and cats can be co-infected with multiple different *Bartonella* species, strains, or genotypes. Developing a vaccine is challenging because vaccination and challenge with the same or different *Bartonella* species/strains result in variable protection, and protection is generally specific to the infecting species or even the genotype.[122–124]

PREVENTION

Prevention of *Bartonella* infections in cats and dogs is best accomplished by avoiding exposure to arthropod vectors and infected animals. Vector control measures, such as the use of ectoparasiticides, can interrupt transmission of *B. henselae* among cats and should be maintained year-round for cats and dogs.[48,88] Housing cats indoors may also reduce exposure to fleas. To the extent possible, animal-to-animal contact should be restricted in shows and other group events.[125] *Bartonella* spp. can be transmitted by blood inoculation to cats and dogs, therefore blood donors should be screened for infection. The 2016 ACVIM guidelines on canine and feline blood donor screening recommend the optimal standard as to use dogs and cats that are seronegative and PCR assay or culture negative (Table 70.4). Because of the poor correlation between positive serology and bacteremia, and the high seroprevalence rates in cats, the minimal standard recommended by the ACVIM panel is to use a *Bartonella* spp. PCR-negative donor, regardless of the serology results.[10] However, because *Bartonella* spp. may reside within a healthy animal without evidence of bacteremia, it is important to remember that no currently available screening test can rule out *Bartonella* infection. It is not known how many *Bartonella* seropositive cats that have negative culture as well as PCR test results may be harboring *Bartonella* species. Therefore the most conservative protocol would be to avoid the use of any seropositive animal as a blood donor, even if PCR or BAPGM results are negative.

TABLE 70.3 Treatment Options for Sick Dogs and Cats with Suspected Bartonellosis

Antibiotic Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration (Estimated)[a]
Doxycycline[b]	5–15 (dogs and cats)	PO	12	6 weeks
Amikacin[c]	15–30 (dogs), 10–14 (cats)	IM/IV/SC	24	7–21 days
Rifampin[d]	5 (dogs and cats)	PO	12	4–6 weeks
Enrofloxacin[e]	5 (cats), 5–20 (dogs)	PO	12–24	6 weeks
Pradofloxacin[f]	5–7.5 (cats, oral suspension) 3 (dogs and cats, tablets)	PO	12–24	6 weeks

[a]Longer duration of treatment may be required.
[b]Monotherapy is not recommended at doses below 10 mg/kg every 12h due to the risk of treatment failure. Recommended in combination with enrofloxacin or rifampin. See text for details.
[c]Use in combination with ampicillin (at 10–20 mg/kg every 6–8h) for the initial treatment of endocarditis. Monitor urine and renal values during treatment.
[d]Use in combination with doxycycline; do not treat with rifampin alone because of the likelihood of rapid selection for resistant bacteria. May cause GI adverse effects.
[e]Other fluoroquinolones are preferred in cats due to the higher risk of retinal toxicity with enrofloxacin. A dose of 5 mg/kg every 24h should never be exceeded in cats.
[f]Use in combination with doxycycline. Shorter interval (12h) is recommended. Tablet formulations are approved for dogs outside the United States. See Table 10.7 for details.
IM; intramuscular; IV; intravenous; PO, oral; SC, subcutaneous.

TABLE 70.4 2016 ACVIM Guidelines for *Bartonella* Screening of Blood Donors

Donor Species	Optimal Standard	Minimal Standard	Comments
Dog	Seronegative and BAPGM culture PCR-negative dogs[a]	PCR- negative dogs[a]	Serology results should not be used alone. Instead, they should be combined with PCR results if BAPGM culture is not practical. Conventional culture is not recommended due to poor sensitivity in dogs.
Cat	Seronegative and PCR- or culture-negative cats[a]	PCR- negative cats[a]	If a seronegative cat is difficult to find, a seropositive but PCR-negative cat may be used. Conventional culture can be used in cats.

[a]A broad PCR panel for multiple *Bartonella* spp. is recommended. The minimal standard is to test cats for *B. henselae* and dogs for *B. henselae* and *B. vinsonii* subsp. *berkhoffii*.
BAPGM, *Bartonella* alpha Proteobacteria growth medium.

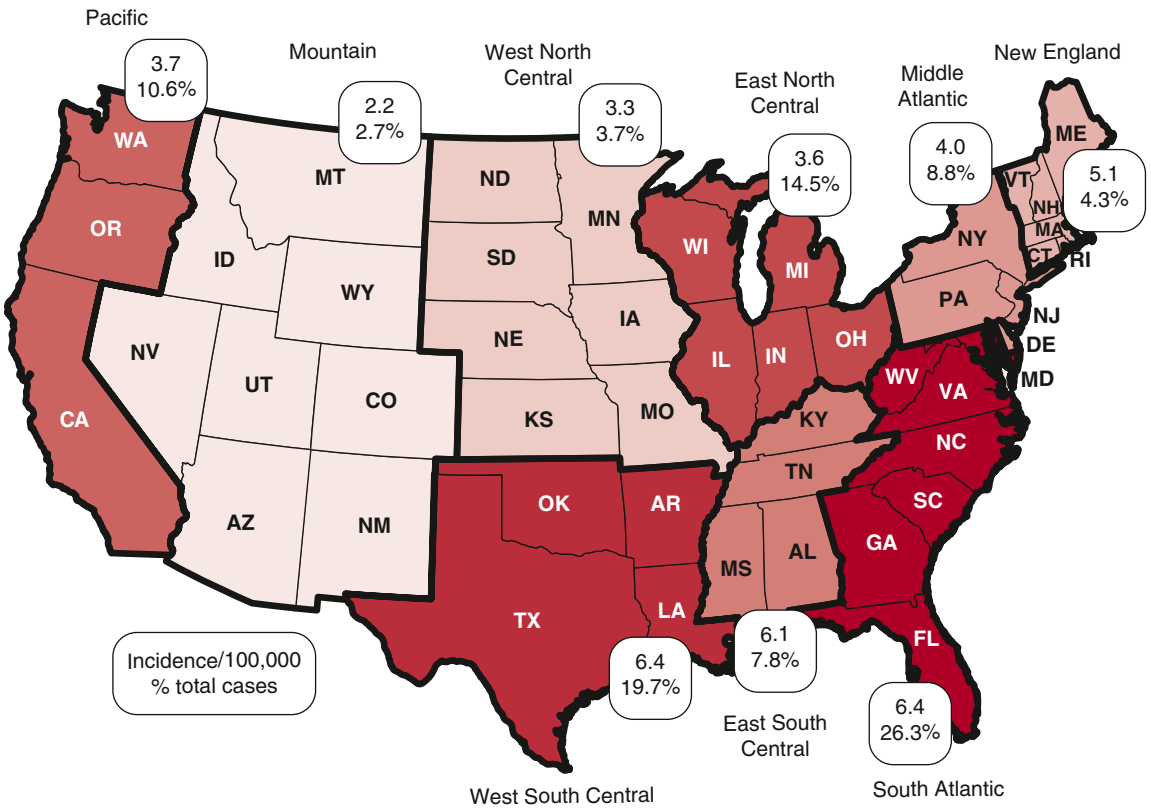

Fig. 70.20 Geographic distribution of cat scratch disease by US census division, United States, 2005–2013. Rates are reported as average incidence per 100,000 population per year. During the study period, there were <10 cases in Alaska and <10 cases in Hawaii. (Modified from Nelson CA, et al. Cat scratch disease in the United States, 2005-2013. *Emerg Infect Dis*. 2016;22:1741-1746.)

PUBLIC HEALTH ASPECTS

Dogs and cats are reservoirs for several zoonotic *Bartonella* species. Cats are a major reservoir for *B. henselae*, the principal cause of CSD in immunocompetent humans, and also serve as a vector for transmission. The average annual incidence of CSD in the United States is 4.5 outpatient diagnoses/100,000 population, with a higher incidence in the southern United States (Fig. 70.20).[126] CSD is characterized by the formation of a papule at the site of inoculation (a cat scratch) within 14 days, followed by the development of local lymphadenopathy (Fig. 70.21) and malaise 1 to 3 weeks after the scratch (or bite), which can persist for weeks to months. Most cases of CSD are self-limiting after several months and respond minimally to antimicrobial drug treatment. Occasionally, CSD is complicated by other disorders such as encephalopathy, relapsing bacteremia, osteomyelitis, neuroretinitis, endocarditis, glomerulonephritis, and other conditions, some of which require antimicrobial drug treatment.[29,116,127–132] Vasculoproliferative diseases such as bacillary peliosis (e.g., peliosis hepatis) and bacillary angiomatosis (Fig. 70.22) are among the most common complications in immunocompromised humans.[15,133] Children from 5 to 9 years of age have the highest incidence for outpatients and inpatients in the US.[126] Young cats are most often implicated in transmission to humans because young cats are more likely to be highly bacteremic than older cats. Dogs are less likely to act as vectors for *Bartonella* spp. when compared with cats, because the prevalence of *Bartonella* infection and the magnitude of bacteremia in dogs are lower than that in cats. Nevertheless, dogs have occasionally

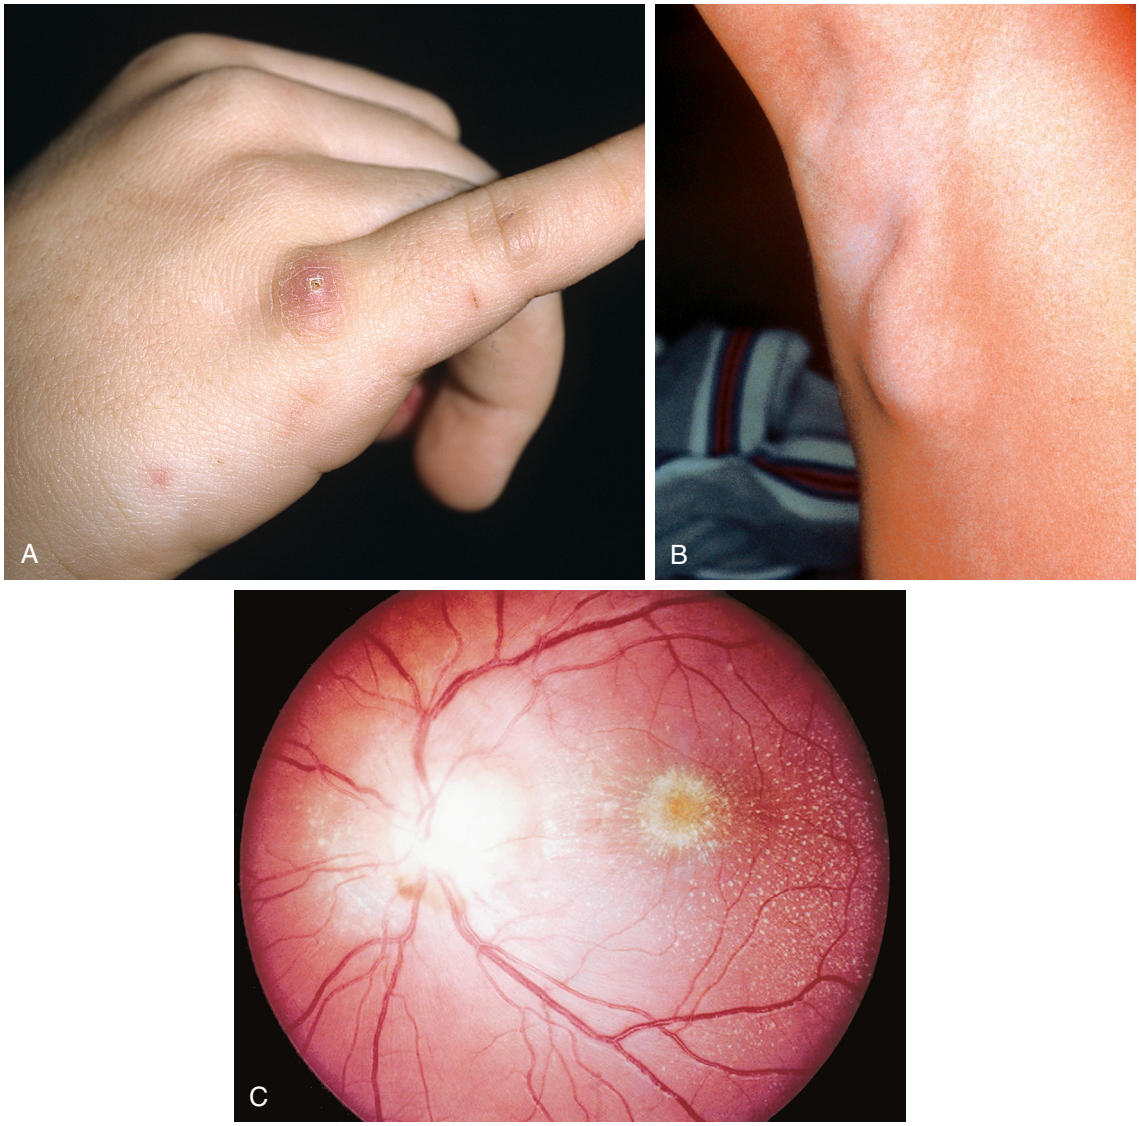

Fig. 70.21 Clinical features of cat scratch disease. (A) Cutaneous lesion at the site of inoculation in an immunocompetent host (7–10 days after a cat scratch and before the onset of local lymphadenopathy). (B) Regional lymphadenopathy in an immunocompetent host. (C) Cat scratch disease neuroretinitis. (A, From Dinulos J. *Habif's Clinical Dermatology: A Color Guide to Diagnosis And Therapy.* 7th ed. Philadelphia, PA: Elsevier; 2021. B, From Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology: A Textbook of Skin Disorders of Childhood and Adolescence.* 6th Ed. Philadelphia, PA: Elsevier; 2020. C, From Bennett JE, Dolin R, Nlaser MJ. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases.* 9th Ed. Philadelphia, PA: Elsevier, 2020.)

been suspected as the source of transmission of *Bartonella* to humans through bite wounds or scratches, and to date, all *Bartonella* species identified in sick dogs are also pathogenic or potentially pathogenic in humans. Immunocompromised people should preferably choose healthy adult, well-socialized cats and dogs that have known health histories as pets over kittens and puppies, and should be properly educated in regard to the need for vector control. Cats' claws should be trimmed regularly, but there is no evidence that declawing prevents transmission. Animal scratches or bites should be avoided, and if they occur, the wounds should be washed thoroughly with soap and water, after which prompt medical attention should be sought. Children should be closely supervised when interacting with pet animals (see Chapter 75). The 2022 guidelines for preventing opportunistic infections among HIV-infected persons from the CDC, National Institutes of Health, and Infectious Diseases Society of America state: "No evidence indicates any benefits to cats or their owners from routine culture or serologic testing of the pet for *Bartonella* infection or from antibiotic treatment of healthy, serologically positive cats."[134] Because there is no antimicrobial drug treatment that is proven to reliably eliminate *Bartonella* infections from cats or dogs, treatment of healthy infected animals is not recommended. The administration of antimicrobial drugs to pets may cause a false sense of security and result in unnecessary bites or scratches. Owners should wear gloves when medicating sick pets. The pros and cons of the testing of healthy cats for *Bartonella* infection are shown in Box 70.1.[88]

Veterinarians and veterinary staff members are at risk for *Bartonella* exposure and infection.[135] *Bartonella* has the potential to be transmitted to veterinarians and staff as a result of scratches, less likely bite wounds as well as needle-stick injuries.[136,137] Veterinarians should avoid these injuries (consider the use of sedation whenever possible), wear gloves when handling any animal with fleas, thoroughly wash wounds that

Fig. 70.22 Cutaneous bacillary angiomatosis lesions on the elbow of an AIDS patient. All lesions involuted with doxycycline treatment. (From Slater LN, Welch DF. *Bartonella,* including cat scratch disease. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*, 7th ed. Philadelphia, PA: Churchill Livingstone Elsevier; 2010:2995-3009.)

occur, and seek medical attention early if necessary. Gloves should also be worn if skin contact with animal blood or saliva is anticipated, and hand hygiene performed after all animal encounters.

Pet owners should receive printed information that provides a summary of the potential clinical conditions that *Bartonella* may cause in pet dogs and cats and common sense ways to avoid zoonotic transmission. A clear statement of the uncertainty of efficacy of antimicrobial treatment for *Bartonella*, the potential for reinfection of pets with *Bartonella* following treatment, and the need for excellent vector control should be included.

Although cats and dogs are important reservoirs of *Bartonella*, humans can also develop bartonellosis through other routes of transmission, such as via other arthropods and possibly through blood transfusions.[13] Human body lice primarily transmit *B. quintana* among humans (especially the homeless), which causes relapsing fever (trench fever) and endocarditis.[15]

BOX 70.1 Advantages and Disadvantages of Routine Testing of Healthy Cats for *Bartonella* spp. Infection

Advantages

Cats with positive *Bartonella* test results can be eliminated as blood donors or breeding animals.

Compliance with client physician orders.

Disadvantages

Bartonella serology and PCR can be falsely positive or negative.

Some cats with positive serologic test results may have eliminated the infection.

Cats with negative test results may still be bacteremic, or become bacteremic within the near future.

Detection of positive *Bartonella* spp. test results in some situations may lead to needless administration of antibiotics or euthanasia.

A focus on testing may lead to lesser use of effective prevention methods such as flea control.

No treatment reliably eliminates bacteremia in healthy cats.

Antimicrobial drug treatment of cats has not been shown to prevent human infection or benefit healthy infected animals.

Treatment of positive cats may lead to unnecessary life-threatening adverse drug reactions, esophageal strictures (doxycycline), or blindness (fluoroquinolones).

The use of antimicrobials to treat healthy positive cats is likely to lead to increased antimicrobial resistance not just of *Bartonella*, but other microbes exposed to the administered antibiotics.

CASE EXAMPLE

Signalment

"Piper," a 4-year-old neutered male domestic shorthair cat from north-central Indiana.

History

Piper was evaluated at the Purdue University Veterinary Teaching Hospital for ocular abnormalities, lethargy, decreased appetite, and occasional cough and sneezing over 1 week. Piper was obtained one year previously and had been a specific pathogen-free cat prior to adoption. Piper had shown signs of intermittent idiopathic cystitis and two instances of lower urinary tract obstruction/struvite crystalluria, for which he had been treated with catheterization to relieve the lower urethral obstruction, and was fed a prescription diet. Between episodes, he appeared healthy with no other clinical abnormalities. Piper had been housed indoors since adoption. He was neutered at 3 years of age without complication, just before adoption. Five weeks before evaluation, the family had acquired another cat from a pet store; this cat had fleas at the time of acquisition, but was otherwise healthy (Fig. 70.23). Piper was up to date on vaccinations for respiratory viruses, panleukopenia virus, and rabies. He was receiving heartworm preventative monthly and no other medications.

Fig. 70.23 Piper (left) shown in close contact with the newly acquired cat.

CASE EXAMPLE—cont'd

Physical Examination

Body weight: 5.1 kg.

Quiet, alert, responsive, and approximately 5% dehydrated. T = 103.8°F (39.5°C), HR = 160 beats/min, RR = 60 breaths/minute, mildly tacky and pink mucous membranes, CRT <2 s.

Body condition score 5.5/9, ambulatory, adequate muscle mass.

Marked chemosis with erythema, blepharospasm, and serous to mucoid discharge OU. Moderate gingivitis was noted with marked dental tartar. There was no evidence of nasal discharge or abnormal nasal airflow.

Ophthalmologic examination: Positive fluorescein-staining OS with small (1–2 mm) superficial ulcer; negative OD.

Laboratory Findings

CBC: Total protein 8.3 g/dL (6.0–8.0 g/dL), HCT 34% (30%–45%), MCV 41 fL (40–55 fL), MCHC 36 g/dL (30–36 g/dL), WBC 20,500 cells/μL (6000–18,000 cells/μL), neutrophils 18,040 cells/μL (3000–12,000 cells/μL), lymphocytes 1230 cells/μL (1500–7000 cells/μL), monocytes 410 cells/μL (50–850 cells/μL), eosinophils 820 cells/μL (100–1500 cells/μL), basophils 0 cells/μL (0–100 cells/μL), platelets 533,000 cells/μL (300,000–700,000 cells/μL)

Morphology: Enlarged platelets noted.

Treatment

Piper was discharged with oxytetracycline hydrochloride (5 mg/g)/polymyxin B sulfate (10,000 units/g) ophthalmic ointment, to be administered to the eyes q8h, and was treated with subcutaneous fluids.

Follow-Up

Two weeks later, Piper was evaluated again on an emergency basis in the evening for progressive lethargy and decreased appetite since the previous visit.

Physical examination findings were similar to the previous visit except that his eyes were markedly improved. He was more lethargic and was assessed as mildly dehydrated. Temperature was 104.0°F (40°C), pulse was 180 beats/minute, and respiratory rate was 40 breaths/minute. A fluorescein stain was negative OU. Piper received subcutaneous fluids and was discharged with oral amoxicillin, 20 mg/kg q8h, and returned the following day for reevaluation. His physical examination was unchanged (temperature, 104.3°F [40°C], pulse 170 beats/minute, respiratory rate: 20 breaths/minute).

A CBC at that time showed: Total protein 7.2 g/dL (6.0–8.0 g/dL), HCT 25% (30%–45%), MCV 42 fL (40–55 fL), MCHC 34 g/dL (30–36 g/dL), WBC 10,800 cells/μL (6000–18,000 cells/μL), neutrophils 10,040 cells/μL (3000–12,000 cells/μL), lymphocytes 320 cells/μL (1500–7000 cells/μL), monocytes 110 cells/μL (50–850 cells/μL), eosinophils 220 cells/μL (100–1500 cells/μL), basophils 110 cells/μL (0–100 cells/μL), platelets 351,000 cells/μL (300,000–700,000 cells/μL).

Morphology: Anisocytosis 1+, Dohle bodies 1+.

Piper's oral medication was empirically changed to doxycycline, 5 mg/kg PO q12h with water, to be given for 3 weeks, and the ophthalmic ointment was continued.

Piper improved initially, and his CBC results all were within reference ranges 1 week later. Doxycycline and the ophthalmic ointment were continued for the full 3 weeks. Piper did well until clinical signs reoccurred 6 weeks later and he was examined again.

Physical examination at that time showed: T = 104.6°F (40.3°C), pulse = 210 beats/min, RR = 40 breaths/min. Pale mucous membranes, CRT = 2 s. Enlarged popliteal lymph nodes, blood glucose 87 mg/dL via glucometer.

A CBC was repeated and showed: Total protein 7.2 g/dL (6.0–8.0 g/dL), HCT 30% (30%–45%), MCV 42 fL (40–55 fL), MCHC 33 g/dL (30–36 g/dL), WBC 19,600 cells/μL (6000–18,000 cells/μL), neutrophils 16,270 cells/μL (3000–12,000 cells/μL), lymphocytes 2350 cells/μL (1500–7000 cells/μL), monocytes 390 cells/μL (50–850 cells/μL), eosinophils 590 cells/μL (100–1500 cells/μL), basophils 0 cells/μL (0–100 cells/μL).

Platelets were too clumped to count; pathologist review showed adequate platelets, enlarged platelets.

Other morphology: Anisocytosis 1+, poikilocytosis 2+, Heinz bodies 2+, toxic neutrophils 1+, reactive lymphocytes noted; few with 1+ toxicity.

POC FeLV antigen and FIV antibody assay: Negative.

Because of the history of the onset of the febrile illness closely following the introduction of a new cat with fleas into the household, and the recurrence of fever following resolution of the ophthalmologic clinical signs, blood was collected for *Bartonella* culture, PCR, and serology, and doxycycline (5 mg/kg PO q12h, immediately followed by a bolus of water) was prescribed. Infection with *B. henselae* was confirmed by blood culture and PCR of blood. Piper was also seroreactive to *B. henselae*.

Outcome

Piper was evaluated again 2 weeks later and had improved, was no longer febrile or lethargic, and was eating well. Treatment was continued for 6 weeks, and a follow-up CBC showed all results within reference ranges.

Diagnosis

B. henselae bacteremia, likely a result of exposure to fleas from the newly introduced cat, was suspected to be the cause of the recurrent fever and peripheral lymphadenomegaly following resolution of the upper respiratory signs. The upper respiratory signs were suspected to be a result of feline upper respiratory disease, and could have been associated with pathogens such as FCV, FHV-1, *Mycoplasma*, and/or *Chlamydia*, but specific testing was not done for these infectious agents.

Comments

Bartonella infection in this cat was suspected because of fever and lethargy that occurred after the introduction of a new cat that had fleas. Whether the treatment with doxycycline contributed to the resolution of clinical signs cannot be determined. Cats that are experimentally infected with *Bartonella* show fever with lethargy approximately 2 to 4 weeks after inoculation, and this resolves without any treatment.

The owner was educated about the transmission of *Bartonella*, including the zoonotic potential, and the importance of treating flea infestations. Both cats were treated for fleas including preventive medications. The owners were advised to continue to keep the cats indoors, and to use flea preventative medications in the future if the cats' lifestyle changed.

Canine Brucellosis

Autumn P. Davidson, Jane E. Sykes

KEY POINTS

- First Described: *Brucella canis* was first isolated from dogs by Leland Carmichael in 1966 (United States).[1]
- Causes: Most commonly *Brucella canis*; rarely *Brucella abortus, Brucella suis,* or *Brucella melitensis. Brucella* organisms are small (1.0 to 1.5 µm), gram-negative, non–spore-forming aerobic coccobacilli.
- Affected Hosts: The *Brucella* genus is composed of 12 classical species based on host preference, phenotypic characteristics, and genetic analysis: *B. abortus* (cattle), *B. canis* (dogs), *B. melitensis* (goats, sheep), *Brucella neotomae* (rodents), *Brucella ovis* (sheep), *Brucella pinnipedialis* (seals), *Brucella ceti* (porpoises, dolphins, whale), *Brucella microti* (voles), *Brucella inopinata* (unknown host), *Brucella papionis* (baboons), *Brucella vulpis* (foxes), and *B. suis* and its biovars (pigs, cattle, hares, rodents, and wild ungulates). Although most *Brucella*, with the exception of the biovars of *B. suis*, show host preference, they can also infect other host species. *Brucella canis* has a limited host range; only dogs and wild Canidae have been found to be susceptible. Rural dogs are susceptible to clinical infection with *B. abortus*, *B. suis*, and *B. melitensis.*
- Geographic Distribution: Worldwide, but infections are most often reported from the southwestern United States, Central and South America, China, and Japan. Sporadic reports have occurred in Canada and throughout Europe. Australia and New Zealand appear to be free of the disease.
- Route of Transmission: Direct mucosal exposure (oral, nasal, conjunctival, venereal) to contaminated body fluids (semen, vaginal discharge, urine, aborted fetuses, and their placentas).
- Major Clinical Signs: Most commonly infertility, abortion, scrotal enlargement secondary to epididymitis/orchitis, scrotal dermatitis, eventual testicular atrophy, lymphadenomegaly, splenomegaly, signs related to discospondylitis (spinal pain, pelvic limb paresis, or paralysis), uveitis, chorioretinitis, rarely osteomyelitis and meningoencephalitis. No signs may be present.
- Differential Diagnoses: Herpesvirus infection, bartonellosis, mycobacterial infections, chronic vector-borne diseases associated with splenomegaly such as ehrlichiosis and babesiosis, coxiellosis, other bacterial and fungal causes of metritis, orchitis/epididymitis, and discospondylitis, intervertebral disc disease, hemic neoplasia (such as lymphoma or multiple myeloma). Additional differential diagnoses for dogs with ophthalmitis include deep mycoses, rickettsial diseases, leptospirosis, and toxoplasmosis.
- Human Health Significance: *Brucella canis* can be transmitted to humans and most often causes mild, influenza-like illness.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Canine brucellosis is most commonly caused by *Brucella canis*, a small, gram-negative, non–spore-forming aerobic coccobacillus. The genus *Brucella* is named after Major General Sir David Bruce (1855–1931), an Australian-born British microbiologist. David Bruce discovered *Trypanosoma brucei* and worked in the Army Medical Service and the Royal Army Medical Corps. The *Brucella* genus is composed of 12 classical species based on host preference, virulence, phenotypic characteristics, and genetic analysis: *Brucella abortus* (cattle), *B. canis* (dogs), *Brucella melitensis* (goats, sheep), *Brucella neotomae* (rodents), *Brucella ovis* (sheep), *Brucella pinnipedialis* (seals), *Brucella ceti* (porpoises, dolphins, whale), *Brucella microti* (voles), *Brucella inopinata* (unknown host), *Brucella papionis* (baboons), *Brucella vulpis* (foxes), and *Brucella suis* and its biovars (pigs, cattle, hares, rodents, and wild ungulates).[2,3] Factors that define host preference are unknown despite remarkable (~97%) similarity at the genome level.

Members of the Canidae family are the natural hosts of *B. canis*. *Brucella abortus*, *B. suis*, and *B. melitensis* occasionally cause canine infections but are comparatively rare.[4–7] Even an attenuated vaccine strain of *B. melitensis* or *B. abortus*[8] can infect dogs. Cats can be infected experimentally with *B. canis*, with transient bacteremia, but are relatively resistant. Rabbits and nonhuman primates also have been found to be susceptible to experimental infections. No other animal species has developed significant agglutination titers.[9] Natural infection with non–*B. canis* species is thought to occur after ingestion of contaminated placentas and aborted fetuses from livestock; farm dogs may be predisposed.[10] In recent years, infection of dogs with *B. suis* has been associated with hunting activity and the feeding of raw meat diets[11–13]; a dog in the Netherlands became infected after being fed raw hare meat imported from Argentina. Dogs usually harbor the organisms in the lymph nodes of their GI tracts for extended periods. Dogs are not believed to be as important in the spread and maintenance of these non–*B. canis* infections as their respective farm animal or wildlife reservoirs. However, testing and removal of affected dogs from infected farms, in addition to affected livestock, have been considered the optimal preventive measures for eradication. *Brucella canis* infections are zoonotic, but other species of *Brucella* usually present a greater risk to human health (see Public Health Aspects).[2,14]

Brucellosis caused by *B. canis* is the primary contagious infectious venereal disease of concern in canine reproduction. *Brucella canis* causes reproductive failure in both male and female dogs. Screening for *B. canis* infection is an important part of the pre-breeding and pre-purchase evaluation of any dog (male or female) and should be included in the initial diagnostics in any case of canine abortion, orchitis, epididymitis, and apparent infertility in dogs (failure to conceive, change in semen quality). Because the incidence of canine brucellosis is low in many geographic locations, breeder compliance with regular

screening can wane, which makes continued veterinarian vigilance important.[15] Notably, neutered and maiden or virgin dogs can also be infected. Interstate and international shipment of semen as well as dogs can result in brucellosis outside of its endemic regions.[16,17]

Brucella canis can cause systemic disease (often manifested as discospondylitis) in dogs not used for reproduction due to age or neutering status. Dogs with *B. canis* discospondylitis are typically medium- to large-breed dogs, with body weights that range from 14 to 64 kg; dogs have ranged in age from 1 to 8 years, with a median of 4 years in one study.[18,19] Of 22 dogs with *B. canis* discospondylitis known to the authors, 18 (82%) were intact male dogs, 3 (14%) were female spayed, and 1 (4%) was male neutered.[20] Three dogs described in the literature with *B. canis* ophthalmitis did not fit this signalment; one dog was a Pomeranian and none were intact males.[21]

Natural transmission of canine brucellosis occurs by several routes. Transmission of *B. canis* occurs through direct exposure to body fluids that contain sufficient numbers of the bacteria to cause infection (the minimum oral infectious dose for dogs is approximately 10^6 organisms, and the conjunctival dose is 10^4 to 10^5 organisms), most often in semen, lochia, aborted fetuses/placentas, urine, and, to a lesser extent, milk.[9] Mucosal transmission is therefore primarily oral, nasal, or conjunctival and secondarily venereal. Oronasal and conjunctival exposure follows the ingestion or aerosolization of infectious materials. The aerosol route is especially important in crowded kennel or benched dog show conditions.[22]

Infected bitches transmit *B. canis* during proestrus and estrus, at breeding, or after abortion through oronasal contact with vaginal discharges. Transmission is most common by oronasal contact with aborted materials because they contain up to 10^{10} organisms/mL. Shedding of *B. canis* may occur for periods up to 6 weeks after an abortion. Seminal fluid and urine have been incriminated as sources of infection from males that harbor organisms in the prostate and epididymides. The rate of isolation of *B. canis* from the semen of infected dogs is usually high for the first 6 to 8 weeks post inoculation (PI). Intermittent shedding of the organism in low numbers has been noted for up to 60 weeks PI and may continue for at least 2 years. Urinary excretion begins between 4 to 8 weeks after the onset of bacteremia and continues for at least 3 months. Concentrations of 10^3 to 10^6 organisms/mL of urine have been found in males, with lesser numbers of bacteria in the urine of females.[9] At one time, urine of infected males was thought to contain too few organisms to be infectious by the oronasal route; however, studies have demonstrated that *B. canis* can be transmitted from infected to uninfected mature male dogs after several weeks or months of close contact with infected dogs.[23,24] The propensity of males to shed the organism in the urine is probably related to the localization of *Brucella* in the prostate and epididymis, which are in close association with the urinary bladder. Neutering helps reduce this risk to a large extent but does not prevent shedding. Alternative means of transmission occur less frequently under natural circumstances; low numbers of organisms have been found in feces, nasal, and ocular secretions. Brucellae are stable in the environment for up to 2 months in the presence of cooler temperatures and organic debris.[9]

Transplacental transmission and direct cutaneous inoculation can also occur.[25] Although fomite-associated transmission can occur under appropriate circumstances (transmission has been reported after vaginoscopy), *B. canis* is short-lived outside the host and is readily inactivated by common disinfectants, including quaternary ammonium compounds, 1% sodium hypochlorite, 70% ethanol, iodine/alcohol solutions, and accelerated hydrogen peroxide.[9]

Canine brucellosis occurs most commonly as outbreaks in large commercial kennels, and less commonly in privately owned and housed dogs, although exceptions exist.[26–28] Determination of seroprevalence is strongly influenced by the method of testing used and its interpretation. The disease is endemic in the Americas, Africa, and Asia. Although the geographic distribution of canine brucellosis is not fully understood, increased incidence has been seen in the southern-most United States and commonly in Mexico, Central and South America, the People's Republic of China, and Japan.[29,30] These patterns may be associated with an increase in free-roaming, intact dogs. Among breeds in this region, beagles and Labrador retrievers have a higher prevalence of infection, as do feral dogs. Seroprevalence in an Indian reservation in South Dakota was 6.8%, with a gradual decrease in the prevalence over time.[31] Older dogs were more likely to be seropositive than younger dogs. Of 943 dogs entering a Minnesota shelter, 3.5% of owner-surrendered and 3.1% of strays were positive using the 2-mercaptoethanol rapid slide agglutination test (ME-RSAT) assay,[32] but only one positive dog, a dog from Texas, was also positive on AGID. Among Mississippi shelters, the seroprevalence using RSAT followed by ME-RSAT ranged from 0% to 8.6%.[33] In Michigan, prevalence of infection was low in dogs from noncommercial breeders, but infection appeared to be endemic in dogs being produced for pet ownership by commercial facilities.[34] Using a multilocus variable number of tandem repeats (VNTR) analysis (MLVA-13Bc method), 229 isolates of *B. canis* from the United States were grouped into three major clusters and 10 genotype groups.[35] Cluster A mainly contained genotype groups 1 and 2, with some 3 isolates; Cluster B contained group 6 isolates; and the remaining isolates were in Cluster C. Molecular typing methods such as VNTR and MLST are increasingly being applied to investigations of *B. canis* infections in dogs worldwide.[36,37]

There are sporadic reports of canine brucellosis in Canada and throughout continental Europe and the United Kingdom.[17,37–45] Australia and New Zealand appear to be free of the disease and have strict importation requirements in hopes of avoiding establishment of the disease.[46] Evidence of exposure to *B. suis* was detected in one in 10 eastern Australian dogs that had cointact with feral swine.[47] However, because infection with *B. canis* is chronic and subclinical, the organism can readily be imported into regions where the prevalence of disease is low through the movement of subclinically infected dogs. The increased practice and success of canine semen processing for exportation (chilling and cryopreservation) for the purpose of artificial insemination now makes canine brucellosis a concern worldwide, as direct mucosal contact among dogs is no longer necessary for transmission.[16]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The general sequence of events after infection by *Brucella* is summarized in Fig. 71.1. *Brucella* organisms attach to and penetrate mucous membranes; the severity of disease resulting is proportional to the infectious dose. Because they contain the highest concentration of organisms, vaginal discharge and semen of infected dogs are the most likely sources for infection by mucosal contamination. *Brucella* organisms have the ability to replicate intracellularly and be transmitted to new individuals, maintaining infection within the population of their respective reservoir host. Bacteria are phagocytized at contaminated mucosal sites by tissue macrophages and other phagocytic cells and transported to lymphatic and genital tract tissues where they multiply. After replication in regional lymph nodes, bacteremia occurs within 7 to 30 days after exposure and can persist up to 64 months. *Brucella canis* has a predilection for steroid-dependent (reproductive) tissues; subsequent dissemination to reticuloendothelial cells, the prostate, gravid uterus, testes, epididymides, and placenta occurs. The organism survives facultatively within monocytes and macrophages of the reticuloendothelial system, avoiding or suppressing host bactericidal

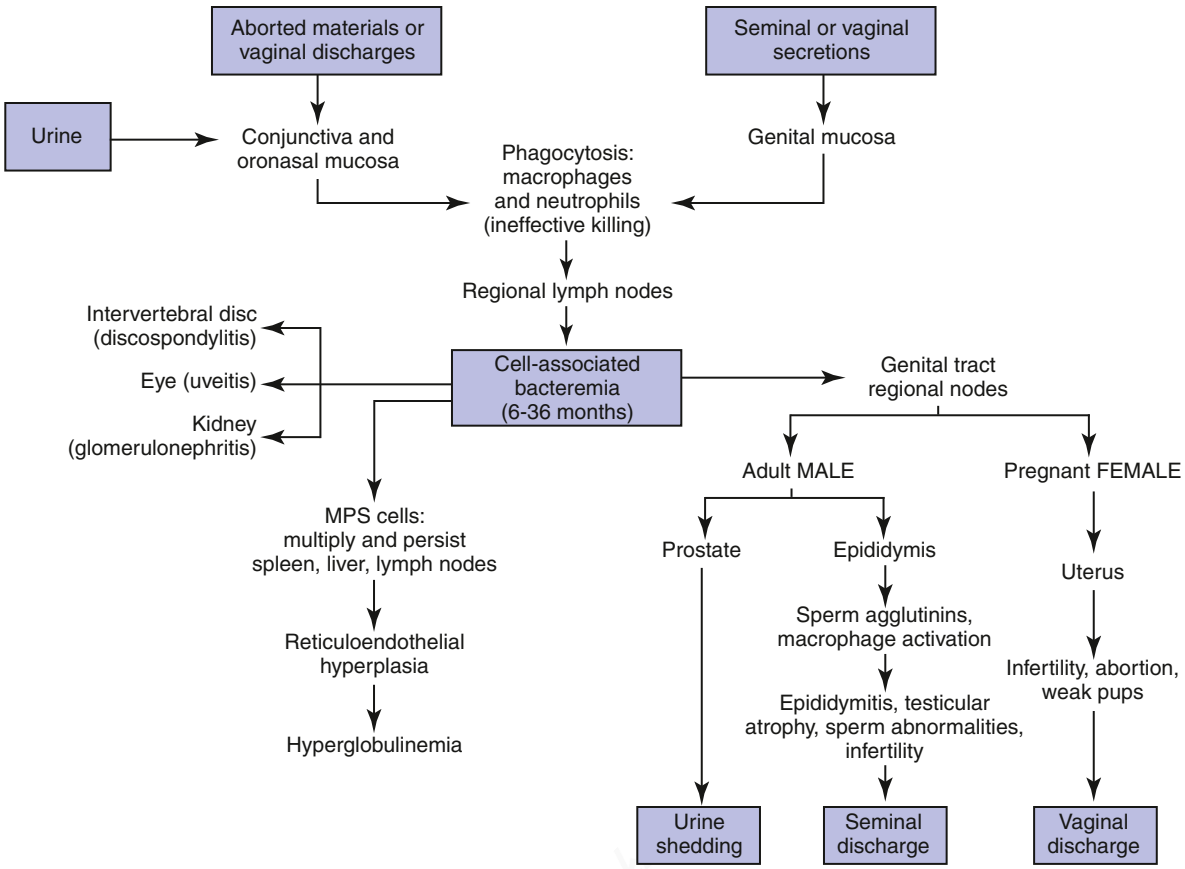

Fig. 71.1 Sequential pathogenesis of canine brucellosis. *MPS,* mononuclear phagocyte system.

mechanisms. *Brucella* organisms survive and multiply in reticuloendothelial cells because they inhibit the bactericidal myeloperoxidase-peroxide-halide system through the release of 5′-guanosine and adenine. The organism inhibits TNF-α, disrupting the bactericidal activity of natural killer cells and macrophages.[48] Early in infection, polymorphonuclear cells and macrophages kill intracellular *B. canis* relatively ineffectually. Generalized lymphoreticular hyperplasia (Fig. 71.2A) and hyperglobulinemia occur during the course of infection. As with other intracellular parasites, CMI is probably the most important defense mechanism against *B. canis*. Persistent, nonprotective antibody titers are characteristic of such infections and appear to have little influence on the level of bacteremia or number of organisms in tissues. The greatest numbers of *B. canis* organisms are found in the lymph nodes, spleen, and tissues of gonadal steroid dependency. Although usually confined to mononuclear phagocytes, they may enter other cells such as placental epithelium.

Brucella organisms can be found in the rough endoplasmic reticulum of placental trophoblastic giant cells in an infected dam's gravid uterus. Severe necrotizing placentitis with infarction of the labyrinth region, coagulation necrosis of the chorionic villi, and necrotizing arteritis result in fetal death. Embryonic death may occur as early as 20 days after mating. The organism can be found in the gastric contents of aborted fetuses. The uterus is not a favored site of growth in the nongravid or diestrual female.

The primary target of *Brucella* in the male dog are the portions of the reproductive tract that participate in the maturation, transport, and storage of spermatozoa. Pyospermia develops 3 to 4 months post infection. Necrotizing vasculitis and granulomatous inflammation results in epididymal and subsequent testicular pathology.[49,50] Microscopic epididymal inflammation usually develops beginning 5 weeks after infection (Fig. 71.2B). Granulomatous inflammation of the epididymides and testes in males causes sperm leakage, which provokes the immune system to produce a complex of anti-sperm agglutinating antibodies and DTH reactions against sperm that are unrelated to the antibodies against *B. canis*. The immune responses produced against spermatozoa further contribute to the epididymitis and orchitis resulting in eventual spermatogenic arrest and testicular atrophy seen in most infected males. Epididymitis and orchitis usually progress despite treatment because of their immunodestructive pathogenesis. The organism can be found in the prostate gland and urethra and is shed intermittently in the urine. The prostate gland may be a site of *Brucella* persistence in intact males for months to years.

Brucella canis, similar to other bloodborne bacteria, may localize in nonreproductive tissues such as the end-arterial circulation of the intervertebral disc, causing discospondylitis (see Chapter 121). Concurrent sacroiliitis was described in one dog.[51] Other tissues that filter bloodborne organisms or immune complexes may become involved, including the eye (anterior uveitis), kidney (glomerulopathy), and meninges (meningoencephalitis).

Spontaneous recovery from infection may occur within 1 to more than 5 years post infection; however, dogs with intervertebral disc or ocular infections, both sequestered from the immune system, usually develop progression of the disease unless it is treated. Antibacterial therapy may accelerate the clinical recovery of all dogs. Some dogs may have persistent bacteremia throughout this time, whereas others can harbor bacteria in tissues for several months after the bacteremia ceases. Despite tissue persistence, when *B. canis* is no longer detected in the blood, serum agglutination titers decrease (see Diagnosis).[52] Dogs that recover naturally have low or negative agglutination titers and yet are immune to reinfection, suggesting that protective immunity is cell

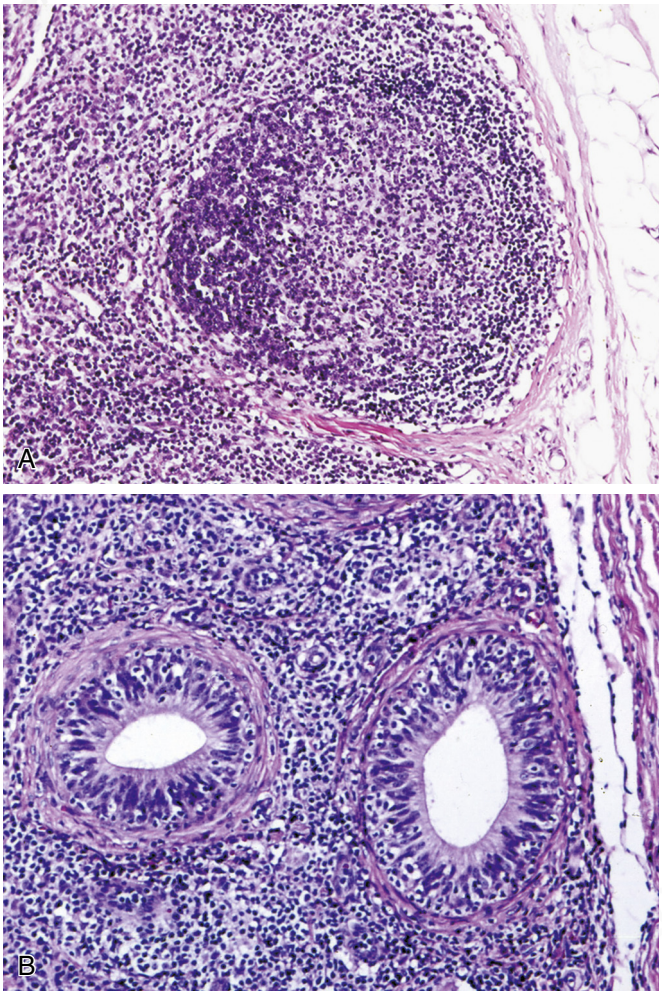

Fig. 71.2 (A) Follicular hyperplasia in the lymph node from a dog with chronic *Brucella canis* infection (hematoxylin and eosin stain, ×40). mediated. Recovered dogs that were challenged orally or IV as long as 4 years after spontaneous recovery from experimental infection were immune.[53] However, chronically infected dogs that were successfully treated with antibacterials were susceptible to oronasal challenge 12 weeks after treatment had been halted. Immunosuppression with glucocorticoids and antilymphocyte serum appears to increase the susceptibility of dogs to initial infection, but it does not augment the severity of the disease or alter the course of infection in experimentally infected dogs.[9]

Despite generalized systemic infection with *B. canis*, adult dogs rarely are seriously ill. The clinical systemic signs are often subtle or absent. Owners of working dogs have occasionally reported dry, lusterless coats, loss of vigor, and suboptimal athletic performance. Nongravid females show no signs of disease other than lymphadenomegaly (pharyngeal if orally acquired, inguinal and pelvic if venereally acquired), which occurs in both sexes. Ocular abnormalities and discospondylitis are frequently present in the absence of other systemic signs of illness. For unknown reasons, ocular abnormalities are often unilateral and include uveitis and multifocal granulomatous chorioretinitis. The most common finding in dogs with discospondylitis is episodic spinal pain resulting in gait abnormalities and lethargy. Meningoencephalitis may result in behavioral changes and neurologic deficits. Chronic multifocal pyogranulomatous dermatitis that resembled lick granuloma lesions has also been reported in an infected dog, but a direct causal relationship was not established.[54] Osteomyelitis or polyarthritis of the appendicular skeleton causes lameness of the affected limb. Infection of the bone that surrounded a total hip replacement was described in two dogs, 9 and 12 months after surgery.

Overt clinical signs usually involve reproductive disturbances in sexually mature animals. The primary clinical sign of canine brucellosis in the breeding bitch is pregnancy loss. Bitches usually abort dead pups between 45 and 60 days of gestation but show no other clinical signs. Pups are usually partially autolyzed, with subcutaneous edema and congestion and hemorrhage of the abdominal subcutaneous region. Moderate quantities of serosanguinous peritoneal effusions are found. Their appearance suggests fetal death *in utero* some time before abortion (Fig. 71.3). Decomposed fetuses are not usually found because the bitch ingests them. Abortion is typically followed by a brown or greenish-gray vaginal discharge that lasts for 1 to 6 weeks. Brucellosis should be suspected under any circumstance when apparently healthy bitches abort 2 weeks before term. Less commonly, bitches may carry infected puppies to term and whelp both live and dead puppies within a single litter. Most pups that are born alive will die within a few hours or days, but those that survive or that are infected as neonates usually have generalized peripheral lymphadenomegaly as the primary clinical manifestation of disease until they reach sexual maturity. Such puppies usually have persistent hyperglobulinemia, and some may have transient fever, leukocytosis, or seizures as the systemic manifestations of their infections.[9]

Although abortion of dead puppies is the primary clinical sign of reproductive failure reported with brucellosis, conception failures can occur at any time after breeding. Embryonic death may occur as early as 20 days after mating. Bitches with pregnancy loss early in gestation (resorption) can appear to be infertile (failure to conceive) unless early ultrasonographic pregnancy evaluation was performed to identify pregnancy. As with brucellosis in other species, infections with *B. canis* do not interfere with normal estrous cycles. A high proportion of

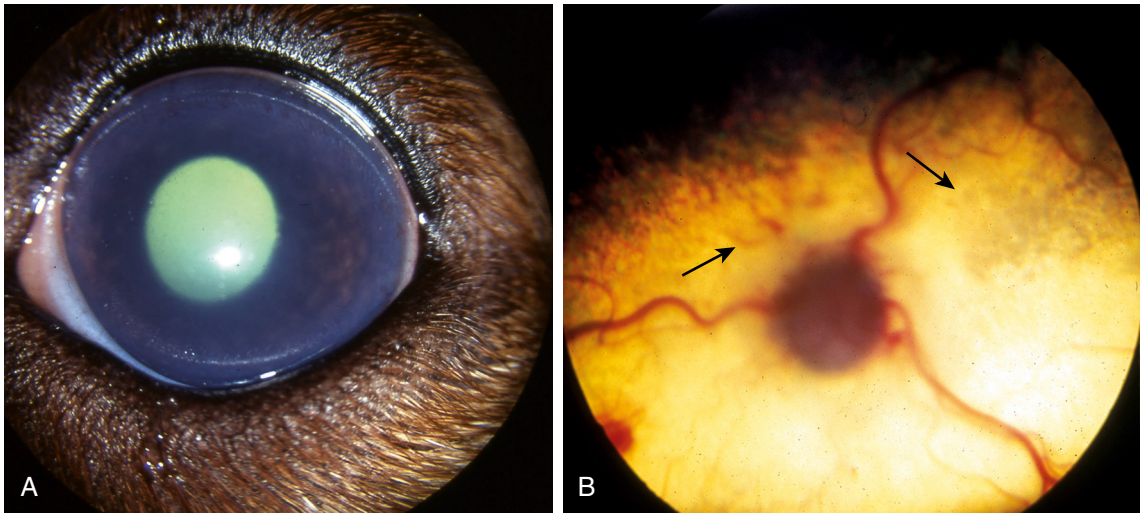

Fig. 71.4 (A) Uveitis and (B) healed chorioretinal lesions *(arrows)* from a dog with brucellosis. (Courtesy of Leland Carmichael, Cornell University, Ithaca, NY and University of Georgia, Athens, GA.)

bitches that abort may have normal litters subsequently. However, even after having normal litters, some infected bitches experience intermittent reproductive failures and remain infectious to their offspring.[55,56]

In male dogs, a variable degree of subfertility progressing to infertility exists in all cases. Small litter size or failure to produce pregnancy can be reported. Libido can be reduced and pain can be associated with ejaculation. A decreased volume of ejaculate is usually present. Clients are often unaware of the physical abnormalities of the epididymides or testes; in contrast, scrotal dermatitis is usually recognized because it causes self-excoriation.

Physical Examination Findings

Fever is uncommon and, with the exception of males, which commonly have physical changes to the external genitalia, most infections will not be diagnosed by routine history or physical examination. Generalized peripheral lymphadenomegaly can be present and splenomegaly may be detected on abdominal palpation. Dogs with meningoencephalitis can exhibit behavioral changes, anisocoria, ataxia, hyperesthesia, head tilt, and circling. Dogs with discospondylitis initially exhibit spinal pain and later paresis and ataxia if spinal cord compression develops. Delayed placing reactions, pelvic limb hyperreflexia, and, uncommonly, pelvic limb paresis or tetraparesis can occur. The presence of splenomegaly or abdominal lymphadenomegaly in dogs with discospondylitis should raise suspicion for *B. canis* infection.

Signs of ocular involvement include blepharospasm, conjunctival hyperemia, evidence of uveitis such as aqueous flare, iris hyperpigmentation, loss of the normal contour of the iris surface, hypopyon, posterior synechiae, and secondary glaucoma. Corneal edema, vitreous opacities, swelling and hyperemia of the optic disc, and evidence of multifocal granulomatous chorioretinitis have also been described (Fig. 71.4).[21,57] Polyarthritis secondary to immune stimulation can be evidenced by joint pain on palpation, decreased range of motion, or lameness.

Affected bitches in diestrus or anestrus can have normal physical examination findings. Because of the prominent testicular abnormalities, male dogs are presented for examination more often than are females. Males otherwise appear to be in good health. Affected dogs commonly have scrotal enlargement early in the course of disease due to epididymitis with or without orchitis (Fig. 71.5). Serosanguinous scrotal edema can be present, as well as scrotal erythema secondary to dermatitis from excoriation or a secondary bacterial dermatopathy (Fig. 71.6). Testicular atrophy and asymmetry are common chronic sequelae.[58]

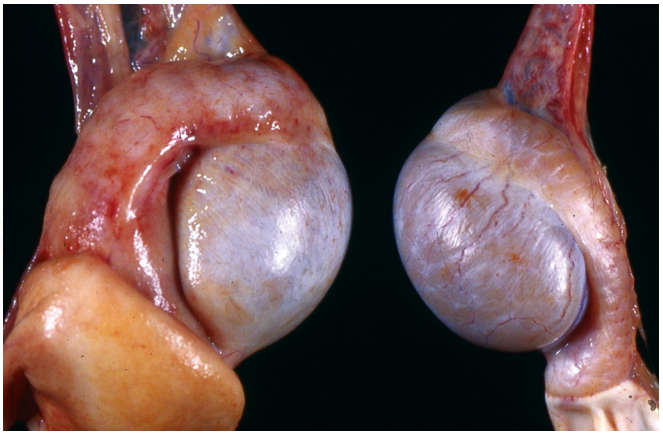

Fig. 71.5 Gross specimens; enlargement of the tail of the epididymis on the testicle from an experimentally infected dog 60 weeks post inoculation *(left)* compared with that of a noninfected dog. (Courtesy of Leland Carmichael, Cornell University, Ithaca, NY.)

DIAGNOSIS (TABLE 71.1)

Laboratory Abnormalities

Hematologic and biochemical values are either unaltered or nonspecific in canine brucellosis.

Complete Blood Count

The CBC may show leukocytosis due to a neutrophilia. Degenerate left shifts, monocytosis, and/or lymphopenia have been uncommonly reported. An increased incidence of positive Coombs' test findings in the absence of anemia has been reported.[9]

Serum Chemistry Profile

The chemistry panel is often normal, but hyperglobulinemia (β and γ) and hypoalbuminemia may be present, especially in chronically infected dogs.

Fig. 71.6 Testicular enlargement and scrotal dermatitis in an experimentally infected dog 35 weeks post inoculation. (Courtesy of Leland Carmichael, Cornell University, Ithaca, NY.)

Urinalysis

The urinalysis is generally within normal limits, even when *B. canis* bacteriuria is present.

Diagnostic Imaging

Plain Radiography

Abdominal radiographs can show splenomegaly in dogs with systemic brucellosis. Plain radiography of the spine can show evidence of either multifocal or focal discospondylitis (Fig. 71.7). Advanced imaging (CT or MRI) may be more sensitive than plain radiography for detection of endplate lucency (Fig. 71.8); see also Chapter 121).

Sonographic Findings

Abdominal ultrasound examination of dogs with brucellosis can show no abnormalities, or abdominal lymphadenomegaly and splenomegaly can be present (Fig. 71.9A and B). Ultrasound of the prostate may reveal prostatic irregularity, hyperechogenicity, and parenchymal cysts typical of intact males. Ultrasound of the scrotum and scrotal contents can confirm the presence of edema of the tunics, epididymal enlargement with hyperechogenicity, testicular enlargement and hyperechogenicity, or atrophy and loss of parenchymal detail (Fig. 71.10).[59]

Microbiologic Tests

Cytologic Diagnosis

Aspirates of the spleen or lymph nodes of dogs with brucellosis reveal lymphoid reactivity on cytologic examination, sometimes with plasmacytosis. Scrotal edema is serosanguinous. Prostatic aspirates in one dog with prostatitis showed granulomatous inflammation with intracellular gram-negative coccobacilli.[42]

CSF analysis in dogs with *Brucella* discospondylitis is usually unremarkable. Pleocytosis, primarily consisting of neutrophils, and increased protein concentration can occur with meningoencephalitis, but they are unremarkable when discospondylitis alone is present.[8] Aspirates of ocular fluids (aqueous or vitreous humor) from a dog with panophthalmitis revealed pyogranulomatous inflammation with extracellular and intracellular small gram-negative cocci.[25]

Semen Examination

Sperm morphology should always be evaluated in dogs with infertility because of the obvious abnormalities that occur with brucellosis. Clinicians should keep in mind the potential infectious nature of semen during collection and evaluation. Semen abnormalities, evident by 5 weeks post infection, become pronounced by 8 weeks. Diminished sperm counts (oligospermia), poor motility (asthenospermia), and increased morphologic abnormalities (teratospermia) are characteristic of semen in dogs infected with *Brucella*, but are not specific for the disease. Detached sperm heads, proximal and distal cytoplasmic droplets, and acrosomal deformities are the most common morphologic abnormalities (Fig. 71.11). By week 15 post infection, sperm head-to-head agglutination suggests the presence of anti-sperm antibodies. Large aggregates of inflammatory cells, usually consisting of neutrophils, surround adherent macrophages containing phagocytized sperm. More than 90% of the sperm are abnormal by 20 weeks post infection. A lack of sperm cells (azoopermia) without inflammatory cells corresponds with the development of bilateral testicular atrophy.

Bacterial Isolation and Identification

Despite improvements in serologic diagnostic methods, blood cultures are still indicated to confirm infection if possible when brucellosis is suspected.[52] A positive *B. canis* culture has been advocated as the best diagnostic test in the first 2 months of the disease; however, dogs can be abacteremic 27 to 64 months after disease onset despite active infection. Isolation of *B. canis* is time consuming but not difficult because the organism grows well aerobically on conventional media used for other *Brucella* spp.. Only a positive result is definitive, because there are numerous reasons for isolation failure. Of the *Brucella* spp. that infect dogs or humans, *B. canis* is the only one with a consistent mucoid (rough) colonial morphology because its cell wall contains truncated LPS moieties. Isolation of the organism from blood, the most practical fluid for isolating the organism, is the most definitive diagnostic procedure. Blood culture should not be the sole test used to diagnose infection because bacteremia, although generally sustained, may be absent or intermittent in more chronically infected animals. Antibacterial administration may interfere with successful isolation of the organism. Blood culture can be helpful if serologic tests are ambiguous. Whole blood must be taken for culture because the organisms are associated with the leukocyte fraction. Bacteremia is detected 2 to 4 weeks after oronasal infection and, if untreated, persists for long periods (1 to 2 years or more). Urine culture is positive in some dogs, especially males, when blood culture is negative; however, unless cystocentesis is performed, urinary isolation of *B. canis* may be difficult because of overgrowth by urethral contaminants. However, urine collected via the urethra may have greater levels of semen, which is a predominant source of *B. canis* organisms. Collection of semen by ejaculation is valuable for culture during the first 3 months of infection, when the concentration of organisms is greatest. With discospondylitis, culture of disc or bone specimens removed at surgery, or material from needle aspiration of the disc space, may also be cultured. Of dogs with *Brucella* discospondylitis or ophthalmitis, 6 of 15 dogs tested positive by blood culture, 3 of 13 by urine culture, and 4 of 6 by culture of disc material or bone chips from the intervertebral disc space obtained at surgery.[19,49]

Brucella canis can be isolated from tissue specimens collected at surgery or necropsy. The lymph nodes, spleen, liver, bone marrow, and male reproductive organs are the most common sources even though gross lesions are seldom present in these organs. In the dam, post-abortion uterus, fetuses, placentas, and vaginal or uterine

TABLE 71.1 Diagnostic Tests Available for *Brucella* Infection in Dogs

Assay	Specimen Type	Target	Performance
Culture	Whole blood, urine, semen, disc aspirates or bone fragments (discospondylitis, osteomyelitis), tissue specimens obtained at laparotomy or necropsy (e.g., spleen, uterus, prostate, testes/epididymides), aborted fetuses and placental tissue	*Brucella* spp. organisms	Confirms infection but is insensitive. Antibiotic treatment can lead to false-negative results. Earliest positive at 2–4 weeks PI.
Histopathology with organism detection using IHC	Tissue specimens above obtained by surgical biopsy or at necropsy	*Brucella* spp. organisms	IHC may have low sensitivity depending on the tissue examined, but supports disease causation when positive and properly performed and interpreted. Earliest at 2–4 weeks PI.
Serology, rapid slide agglutination test (RSAT), and mercaptoethanol (ME-RSAT)	Serum	Antibodies to *Brucella* spp.	Rapid and inexpensive. False positives are common as a result of cross-reactivity with other bacterial species and require confirmation with an alternative test. Positive results do not imply active infection. False-negative results with RSAT can occur in dogs with sequestered infection; e.g., discospondylitis. The sensitivity of the RSAT may be higher than that of the ME-RSAT. ME-RSAT false-negatives 1%. Earliest at 3–4 weeks PI.
Serology, tube agglutination test (TAT), and mercaptoethanol (ME-TAT)	Serum	Antibodies to *Brucella* spp.	See RSAT. Usually positive by 3-6 weeks PI. Semi-quantitative. Titers ≥ 1:200 tend to correlate with bacteremia. ME-TAT usually positive by 5-8 weeks PI, somewhat increased specificity.
Serology, agar gel immunodiffusion (AGID); cell wall/somatic (AGID); internal cytoplasmic	Serum	Antibodies to *Brucella* spp.	Least sensitive for very early infection; very sensitive later. Detects chronic cases well, but can remain positive after recovery. Requires special expertise and is time-consuming to perform. AGID cell wall positive 5–10 weeks PI; cytoplasmic positive 8–12 weeks PI. Cytoplasmic antigen assays are more specific for *Brucella* spp. antigens.
Serology, indirect immunofluorescent antibody (IFA)	Serum	Antibodies to *Brucella* spp.	Requires expertise to perform and interpret. May have lower specificity and sensitivity when compared with TAT or ELISA assays.
Serology, ELISA	Serum	Antibodies to *Brucella* spp.	Has the potential to be sensitive and specific, but assays vary in performance. A standard, accepted assay is not currently available.
PCR	Whole blood, splenic or lymph node aspirates, disc aspirates, tissue specimens obtained at surgery or necropsy, vaginal swabs in proestrus/estrus or when aborting, semen, urine, placental materials, or fetuses.	*Brucella* spp. DNA	Confirms active infection and has the potential to be more sensitive than culture. Sensitivity and specificity may vary depending on assay design, specimen type, and quality assurance practices in the laboratory. Results should be interpreted with caution and in light of the clinical picture and the results of serologic tests and/or culture.

ELISA, enzyme-linked immunosorbent assay; *IHC,* immunohistochemistry; *PCR,* polymerase chain reaction; *PI,* post infection.

fluids most consistently yield positive cultures. False-negative results may occur in chronically infected animals because of extremely low numbers of organisms present. Centrifugation lysis methods may be advantageous under these circumstances because they increase the ability to culture intracellular pathogens.[39] Growth of *Brucella* can be identified on the basis of rough (as opposed to smooth) colony morphology, staining characteristics, and slide agglutination with anti-*Brucella* serum. Identification to the species level is best done by an experienced laboratory. Differentiation between *B. canis* and *B. suis* can be difficult. Recently, MALDI-TOF MS has been useful in assisting with rapid identification of *B. canis*.[60] In the United States, the New York State Diagnostic Laboratory at Cornell University, the Tifton Veterinary Diagnostic and Investigational Laboratory in Georgia, and the University of Florida are recognized to be reliable for definitive testing made necessary by positive *B. canis* screening tests in dogs intended for breeding, or for clinically affected dogs undergoing evaluation for infertility or abortion, or when outbreaks are being managed. Susceptibility testing can be performed, but *in vitro* test results may not correlate well with the *in vivo* treatment response.

Fig. 71.7 Thoracic radiograph of *Brucella* discospondylitis at the T7-T8 junction with ventral spondylosis and collapse of the intervertebral disc space. (Courtesy of Anna Park, DVM, and James Lavely, DVM, DACVIM [Neurology].)

Serologic Diagnosis

Serologic testing is the most frequently used diagnostic method for detecting canine brucellosis. There are two reasons to perform serologic tests for brucellosis in dogs: (1) as part of a routine screening program in breeding kennels, whereby healthy dogs are screened for infection, and (2) for the initial diagnostics in sick dogs that are suspected to have brucellosis because of infertility, pregnancy loss, epididymitis/orchitis, discospondylitis, ophthalmitis or unexplained lymphadenopathy/splenomegaly.

Assays used for screening purposes are usually rapid and inexpensive, but can suffer from low specificity due to strong cross-reactivity between surface LPS antigens of *B. canis* and those of other less or nonpathogenic infectious agents. Up to 50% to 60% of dogs can have false-positive test results because of cross-reacting antibodies to microorganisms such as *Bordetella, Pseudomonas, Escherichia coli,* and *Moraxella* spp. All sera should be free of hemolysis because hemoglobin causes false-positive agglutination of the tube test antigen.

Even when antibodies detected truly represent anti-*Brucella* antibodies, the presence of these antibodies does not indicate active infection with *Brucella* because dogs can remain seropositive for months after they clear the infection. Antibodies to *Brucella* do not become detectable until 2 to 12 weeks after infection despite the presence of bacteremia at 2 weeks, so a window of time exists in which an infected dog eludes serologic diagnosis with any assay used. For this reason, newly acquired animals should be tested sequentially at least twice at 30-day intervals before introduction into a breeding kennel. Low or intermediate titers may reflect previous or very recent infection, and testing should be repeated, or attempts made to detect the organism by blood culutre or PCR.[60] Males may harbor the organism in the prostate glands and epididymides for extended periods after bacteremia ceases. In such instances, agglutination titers may decline naturally or as a result of treatment, yielding false-negative test results. Beyond the first 3 months of infection, the sensitivity of screening assays is generally believed to be high.

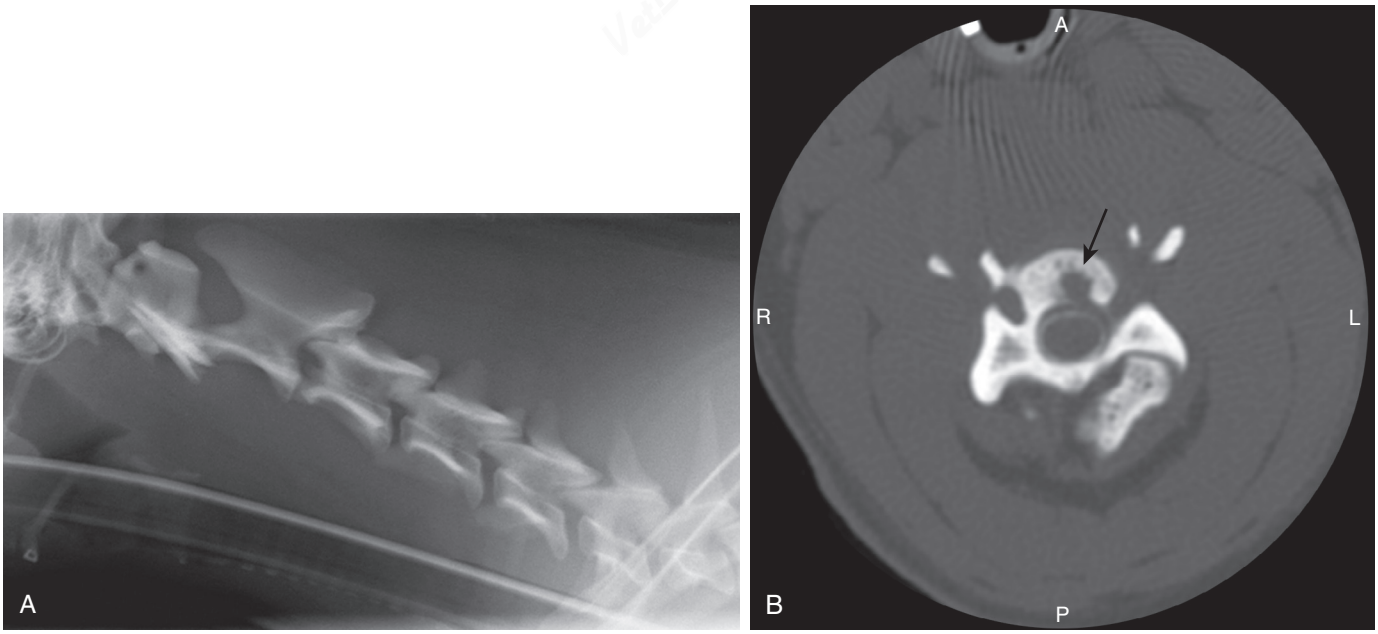

Fig. 71.8 Diagnostic images of a 1-year-old female spayed labradoodle with *Brucella canis* discospondylitis that was initially evaluated for cervical pain. Cerebrospinal fluid (CSF) analysis revealed a CSF protein concentration of 31 g/dL, with 3 nucleated cells/μL, 89% of which were small mononuclear cells and 11% of which were large mononuclear cells (marginal lymphocytic pleocytosis). *Brucella canis* was isolated from five of five blood culture specimens. Urine culture was negative. Of significance, a *B. canis* rapid slide agglutination test was negative. The dog was treated successfully with antimicrobial drugs (doxycycline and clavulanic acid–amoxicillin) and lesions resolved radiographically. (A) Plain lateral radiograph of the cervical spine; with endplate lucency associated with cranial endplate of C3 at the C2-3 articulation. The C2-3 disc space appears narrowed. (B) Computed tomography image; central lysis of the end plates at C2-3 is present *(arrow),* compatible with discospondylitis at C2-3.

Examples of screening assays include the RSAT; the semiquantitative ME-RSAT; the semiquantitative tube agglutination test (TAT); AGID assays; and indirect IFA or ELISA assays. Veterinarians need to understand the limitations of the assays available to them through local veterinary diagnostic laboratories or in-house test kits. The RSAT uses *B. ovis* as the antigen, whereas the ME-RSAT uses *B. canis* antigen, which may improve specificity. However, in one study, the sensitivity of the ME-RSAT was only 32%, when compared with 71% for the RSAT, so the RSAT may be preferable for screening.[61] In the TAT, a titer of more than 1:200 correlates well with positive blood cultures, but lower titers are more difficult to interpret. The performance of AGID assays requires trained laboratory personnel and special media. Two AGID assays are available: an assay that uses cell wall antigens as the substrate (cell wall AGID assay) and an assay that uses cytoplasmic antigens of *Brucella* as the substrate (cytoplasmic AGID assay). The cell wall assay has the same low specificity as other assays that detect antibodies to *Brucella* LPS, and the sensitivity may be lower than that of the RSAT.[62] In contrast, the cytoplasmic assay is specific for antibodies to *Brucella*, so, when available, it is a useful confirmatory assay for dogs that test positive with other rapid serologic assays (Fig. 71.12).[63] Indirect IFA has lower sensitivity than many other serologic assays. A number of ELISA assays have been developed to overcome difficulties that relate to the low specificity of serologic assays for *B. canis* and the limited availability of other assays. The performance of these ELISA assays has varied, but sensitive and specific ELISA assays and a lateral flow immunoassay have been developed that may prove useful for rapid serologic testing in the future.[64]

In practice, for screening purposes, healthy bitches are tested at least 1 month before a planned breeding with a serologic assay of low specificity such as the RSAT because these assays are rapid, readily available, and inexpensive. Healthy, fertile stud dogs should be tested at least annually with the RSAT (and require that all bitches be screened and negative before contact breedings). A single high agglutination titer to *B. canis* usually indicates active infection, but this should be substantiated by additional tests. Dogs that are subclinical but have positive results on

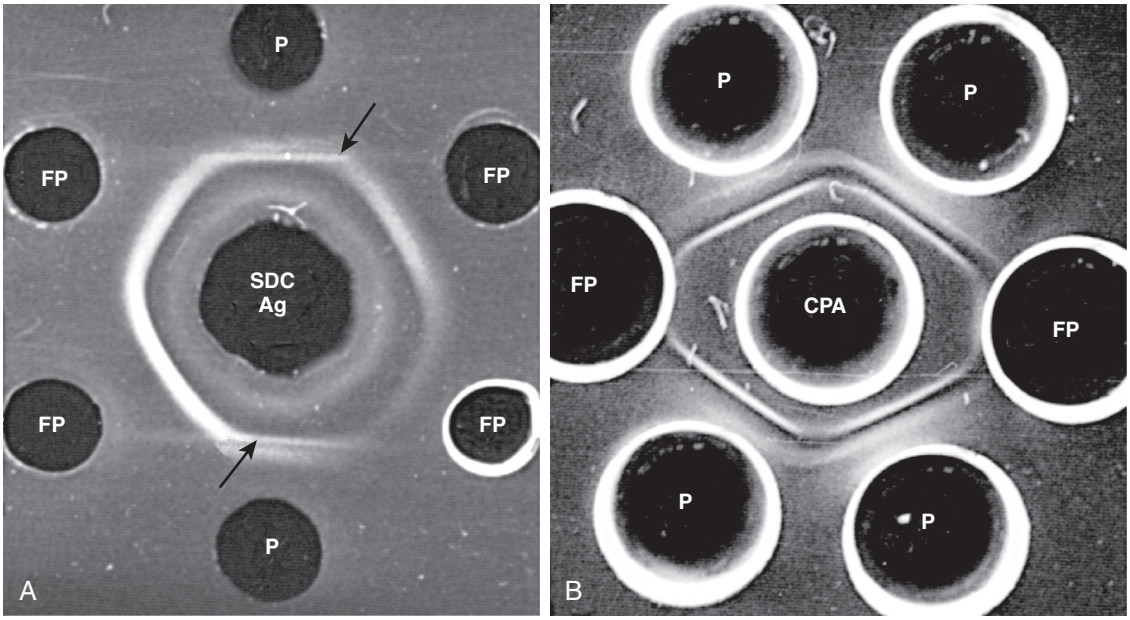

Fig. 71.12 Agar gel immunodiffusion patterns using sodium desoxycholate *(SDC)*-extracted somatic (lipopolysaccharide) antigens reacted with positive *(P)* and false-positive *(FP)* sera. (A) Cross-reactions are evident. *Arrows* indicate *Brucella canis*–specific precipitin line. (B) Cytoplasmic protein antigen *(CPA)*. Precipitin lines occur only with sera from *Brucella*-infected dogs using CPA.

agglutination procedures should never be condemned as infected until blood culture results or the more specific cytoplasmic protein antigen (CPAg) AGID or PCR test results confirm the positive findings.

In cases of subfertility or if recent exposure is suspected and the RSAT result is negative, a second test is performed a month later to assess for seroconversion (which would be expected if the dog was early in the course of infection when first tested); the dog should not be used for breeding in the interim. If the test result is then positive, a confirmatory assay should be performed. This could include the TAT or a more specific assay, such as the cytoplasmic AGID assay, a specific ELISA assay, blood or semen culture (although blood culture can lack sensitivity), or a nucleic acid-detection assay. The use of multiple assays may be required to confirm the diagnosis.

Chronically infected dams may have diagnostically equivocal antibody titers and negative blood cultures. In females, recrudescence of bacteremia and increased antibody titers develop during proestrus, estrus, pregnancy, or abortion. These are the most reliable times to screen subfertile or infertile dams for infection.

Serologic tests should be evaluated in light of clinical findings in the dog being evaluated (Fig. 71.13). Antibacterial therapy may suppress bacteremia and the associated serologic response, possibly contributing to false-negative serologic test results and failure to isolate the organism from infected dogs. Antibacterials should not be given until diagnostic testing has been completed.

Molecular Diagnosis Using Nucleic Acid–Based Testing

A variety of PCR assays have been developed for detection of *B. canis* DNA in clinical specimens. In one study, PCR on whole blood was more sensitive than blood culture or serology for detection of canine infection.[61] PCR assays have been used to successfully identify *B. canis* in semen from dogs with negative culture results, which suggests that this may ultimately be the most sensitive method of testing as part of the male dog pre-breeding evaluation, especially in cases where management of an outbreak is the concern. PCR testing of vaginal swab specimens was more sensitive than blood culture or blood PCR in dams suspected to be infected with *B. canis*.[62] PCR assays were also used to detect *B. canis* in the aqueous humor of dogs with endophthalmitis, and in lymph node aspirates.[21,58] *Brucella canis* DNA has also been detected in multiple tissues from stillborn fetuses and neonates at necropsy. Assays have been designed that differentiate among *Brucella* species.[57] A real-time PCR assay was used to detect *B. canis* in tissue specimens, urine, buffy coat, and intervertebral disc material of a dog with discospondylitis when culture of intervertebral disc material, blood, and urine was negative.[9]

Positive serologic test results in dogs with discospondylitis or other disease manifestations suggestive of brucellosis should be confirmed using culture or a NAAT whenever possible. Although uncommon, false-negative serologic test results can occur in dogs with discospondylitis, so attempts should also be made to detect the organism with culture or NAATs. Of various dogs with *B. canis* discospondylitis or ophthalmitis, 15 of 18 were positive with the RSAT, 16 of 16 were positive with the TAT, and 6 of 7 were positive with AGID assays. The three dogs that were negative with the RSAT had discospondylitis. One was positive by blood culture, and the other two dogs tested positive with the TAT at a later date.[19,21]

Further studies are needed in dogs to determine if PCR methods can be used as a predictor of successful eradication of the organism. Several veterinary diagnostic laboratories in the United States as well as veterinary academic laboratories now offer real-time PCR assays for detection of *B. canis* on a commercial basis.

Pathologic Findings

Gross Pathologic Findings

Macroscopic changes in adults or surviving pups are usually confined to lymphadenomegaly and splenomegaly.

Histopathologic Findings

Lymph node enlargement is the result of diffuse lymphoreticular hyperplasia. In dogs with chronic bacteremia, lymph node sinusoids and the spleen are filled with plasma cells and macrophages containing phagocytized bacteria. Diffuse submucosal lymphocytic infiltration occurs in

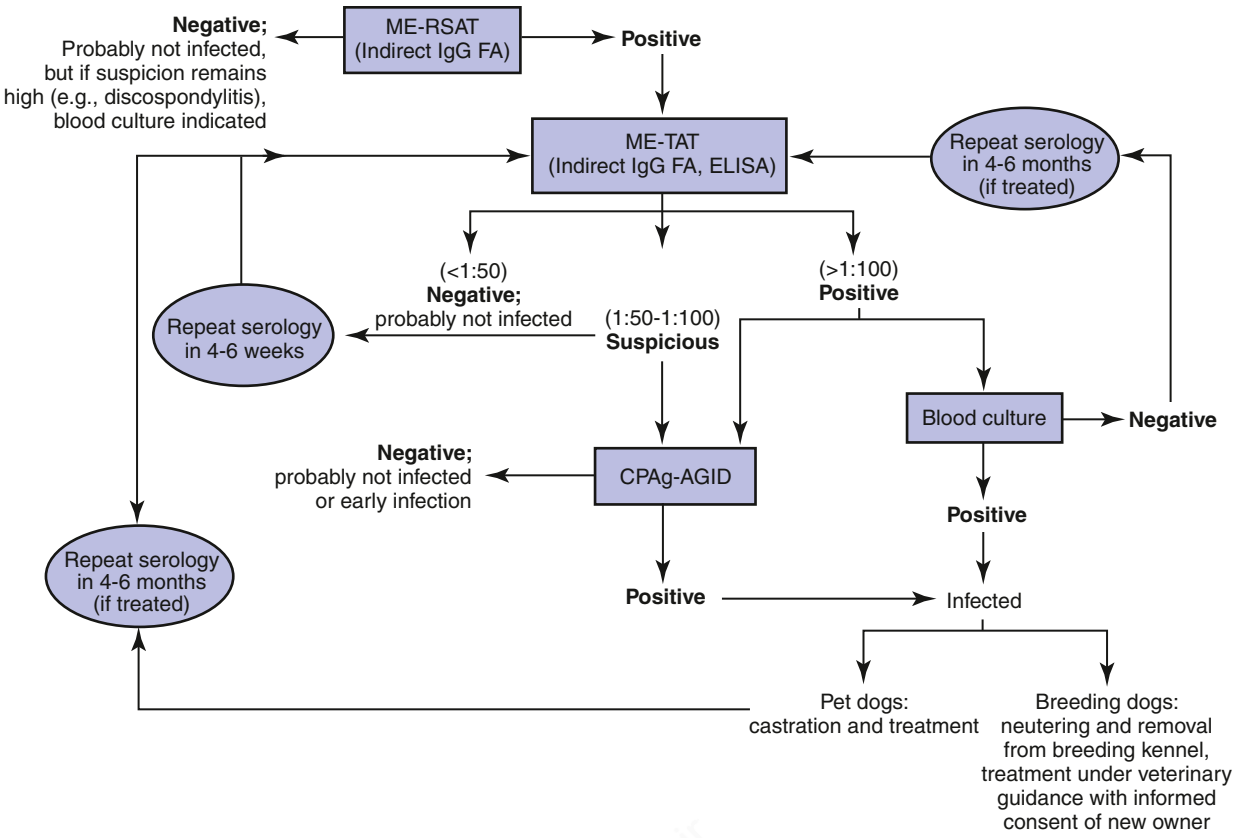

Fig. 71.13 Diagnostic algorithm for canine brucellosis. The indirect fluorescent antibody (*FA*) and enzyme-linked immunosorbent assay (*ELISA*) tests are alternative screening tests when there is unavailability of 2-mercaptoethanol rapid slide agglutination test (*ME-RSAT*) and 2-mercaptoethanol tube agglutination test (*ME-TAT*) antigens. Polymerase chain reaction (*PCR*) can be used as confirmation at various steps where uncertainty exists. See text for rationale in making these decisions. *CPAg-AGID,* cytoplasmic protein antigen-agar gel immunodiffusion.

all genitourinary organs. A necrotizing vasculitis occurs in the target tissues of gonadal steroids, including the prostate, scrotum, sheath, or vulva. Lesions are most prominent in the prostate, epididymides, and uterus, whereas milder changes are observed in the renal pelvis, testes, ductus deferens, urinary bladder, and ureters. Extensive necrosis of the prostatic parenchyma and seminiferous tubules is caused by inflammatory cell infiltration, which eventually results in atrophy or fibrosis. A chronic to subacute endometritis can be seen in the uterus, with glandular hyperplasia and reticular cell nodules (Fig. 71.14). Focal hepatic necrosis, myocarditis, and meningoencephalitis also have been described. Vertebral osteomyelitis and discospondylitis may be present in dogs with discospondylitis. Renal abnormalities occur in some dogs and consist of hyaline thickening of the basement membrane of glomeruli with minimal cellular infiltration or proliferation. A mild interstitial nephritis has been noted. Ocular disease includes granulomatous iridocyclitis and exudative retinitis, with diffuse infiltration by lymphocytes, plasmacytes, and neutrophils. Corneal endothelium has vacuolated cytoplasm with variable plasma cell infiltration; exudates with leukocytes are present in the anterior chamber. Placental trophoblasts can contain large numbers of gram-negative bacteria, and coagulative necrosis may be present. In male dogs, lesions are more likely to be restricted to the reproductive system. Special stains (e.g., Brown-Brenn stain) must be used to detect intracellular organisms. IHC has been used to confirm the presence of *Brucella* spp. in placental tissues (Fig. 71.15).

Tissue distribution and cell tropism of *Brucella canis* in naturally infected canine foetuses and neonates. *Sci Rep.* 2018;8:7203.)

TREATMENT AND PROGNOSIS

In certain jurisdictions, brucellosis is a reportable disease in dogs or in humans; once a diagnosis is confirmed, proper authorities should be notified. Any dog in contact with the confirmed case should be quarantined and carefully evaluated for infection over a 60-day period. Infected dogs should be isolated from further contact with other dogs until they are less likely to be contagious. In breeding kennels, the infected dog should never be used for breeding again and should be removed from the breeding program. Infected males are very unlikely ever to regain fertility and should be neutered to reduce shedding. Infected females can regain fertility, but infection can persist. This means that they represent a source of infection for other dogs and that they are at risk for future loss of offspring; they also should be neutered. Eradication of the disease in breeding kennel situations has not been successful without removal of all current or historically infected dogs. Carrier dogs are important in maintaining *B. canis* infection in the dog population because its survival outside the host is short lived. Application of routine hospital disinfectants can inactivate the bacterium. The risk of infecting males when breeding with previously infected females can be minimized by judicious artificial insemination. Breeding of such animals should be done only under exceptional circumstances when it is considered essential (e.g., to prevent the loss of a valuable blood line) and after the risk is explained to an owner.

Because of the zoonotic potential of the disease and difficulty in eradicating the infection, euthanasia of affected dogs has been recommended; this is an unacceptable decision for many private breeders/hobby kennels or pet owners, leading to requests for therapy. Neutering is always indicated. Neutering decreases the number of organisms shed in semen, urine, and vaginal discharge, but does not eradicate infection.

Antibiotic therapy for treatment of brucellosis has historically not been rewarding, likely because the organism is intracellular and bacteremia is periodic. Antimicrobial drug treatment can reduce antibody titers without clearing infection. Relapses are common. Bacteremia often recurs days to months after treatment is discontinued, making

TABLE 71.2 Medications That Could Be Used To Treat Brucellosis in Dogs

Drug	Dose (mg/kg)	Route	Interval/Duration
Doxycycline or minocycline[a]	5–10	PO	q12h for 4 weeks
Streptomycin	5	IM or SC	q24h on weeks 1 and 4
Gentamicin sulfate	5	PO	q12h for 4 weeks
Enrofloxacin	10	PO	q24h for 4 weeks
Rifampin	5	PO	q24h

[a]Use in combination with one of the other drugs listed. Combinations of drugs are preferred for treatment where possible.

follow-up evaluation essential because animals can still sequester infection in tissues. Antibody titers can persist when infection has been cleared, making interpretation difficult. The organism is susceptible to several antibacterials, but the ineffectiveness of *in vivo* therapy commonly leads to failures or relapses. None of the treatment regimens is 100% successful. For greatest efficacy, dogs with brucellosis should *not* be treated with a *single* antibacterial regimen; in *all* cases, combination therapy should be used.

Combination therapy should be used whenever possible, preferably with tetracyclines (high-dose doxycycline or minocycline) for at least 1 to 2 months and an aminoglycoside (streptomycin or gentamicin) for the first 1 to 2 weeks of treatment (Table 71.2). Some also advocate use of two 1-week courses of aminoglycoside treatment spaced 1 month apart, or treatment with streptomycin every other week for 4–8 weeks. Combination therapy with tetracyclines and streptomycin is thought to be the most successful treatment, but unavailability of streptomycin, nephrotoxicity, parenteral therapy requirements, and expense may be problematic.[38,42,44] In addition, aminoglycosides do not provide adequate ocular or CNS penetration for dogs with ophthalmitis or meningitis. A combination of doxycycline and rifampin has been used to treat human brucellosis but may not be well tolerated by dogs because of GI adverse effects. The use of three or four drugs in combination (e.g., streptomycin, enrofloxacin, doxycycline with or without rifampin) was efficacious for treatment of ophthalmitis in dogs. Topical 1% prednisolone acetate and atropine ointment may be required for management of uveitis.[65–67]

One study reported a possible benefit of therapy with enrofloxacin (5 mg/kg, q12h, PO for 4 weeks, often for multiple courses) in a small group of infected dogs. Enrofloxacin did not completely eliminate *B. canis*, but it maintained fertility and avoided the recurrence of abortions, transmission of the disease to subsequently whelped puppies, and dissemination of microorganisms during parturition. Ultimately, however, most treated dogs remained culture positive. Clinical reproductive illness may have been prevented; however, confirmation of eradication of the organism could not be confirmed.[28] Combinations of enrofloxacin and doxycycline may be a more effective alternative for dogs unable to tolerate aminoglycoside or rifampin treatment and for dogs that have ocular or CNS involvement, but studies are lacking. Localized infections in hard-to-reach areas such as in the intervertebral disc should be treated with at least two or more sequential or intermittent 4-week courses of antimicrobial therapy after neutering. Treatment for 6 weeks or longer may be necessary and should be based on clinical, radiographic, and serologic monitoring.[22] Doxycycline and aminoglycoside combination is recommended for this treatment. Surgical intervention is rarely needed unless the diagnostic workup requires obtaining intervertebral tissues for culture. Decompressive surgery should be avoided in paraparetic dogs when possible by first evaluating the clinical response to antimicrobial therapy. Sequential radiography and titers at 3- to 6-month intervals are used to monitor progress. Serologic monitoring should be done with quantitative methods so that relative changes can be detected. Endophthalmitis with *B. canis* has been exceedingly difficult to treat and requires long courses of therapy with potent three- or four-drug combinations. There are few reports of successful elimination of ocular infection in dogs. The organism enters the eye,[68] and the ocular tissues are difficult to penetrate, especially with aminoglycosides. Enucleation is required if the eye has been severely damaged, because vision will never return and the eye acts as a persistent nidus for the organism. Even use of two antimicrobials is associated with relapse rates of ocular inflammation of 6% to 21%. Multiple-drug combination therapy with doxycycline, gentamicin, enrofloxacin, and subsequent addition of rifampin was successful in eliminating the ocular inflammation in one infected dog.[69] As with other CNS infections, therapy with antimicrobials must be at maximal levels to obtain reasonable drug concentrations at the site of infection. Furthermore, as the blood–CNS barrier heals, concentrations will be much more difficult to achieve. Aminoglycosides are of little use in clearing infections from the CNS.

Follow-up is always required after any course of antimicrobial therapy. Antimicrobial regimens must be repeated should the results indicate that infection has not been eliminated. Cures of brucellosis must not be assumed because bacteremia may recur weeks or months after antibacterials are discontinued. Attempted culture of bacteria or serologic testing immediately after treatment is halted is deceiving. Reports of successful cures should be viewed with caution unless subsequent cultures and serology and PCR have been performed for at least 6 months. Use of quantitative ME-TAT titers is the best means of monitoring successful elimination of the organism. Testing should be performed at 6- to 9-month intervals after a treatment regimen. Titer values should decrease if therapy is effective. Titers below 100 should be reached or else additional courses of treatment are indicated. Corresponding AGID titers results should also become negative. Persistence of increased (greater than 100) titers should evoke suspicion that the infection still exists.

Large commercial kennels (puppy mills) present the most challenging scenario. Owners are usually willing to euthanize confirmed positive cases but less willing to go through the expense and time required to eradicate the disease from the facility. Difficulties are compounded if antibacterial therapy is instituted when brucellosis is suspected but not confirmed, because isolation of *B. canis* becomes uncertain and serologic tests results are questionable. A kennel should be quarantined as soon as the diagnosis of *B. canis* is ascertained, and infected animals should be promptly eliminated. Appropriate disinfection procedures should be implemented to arrest the spread of infection via fomites. Persons working with infected dogs and their discharges or secretions should wear gloves until serotesting can be done to determine the extent of the infection. Animals should not be admitted to or released from the kennel until the disease is eradicated. Movement of dogs within a colony also should be restricted to removal of proven and suspect cases to isolation quarters. New additions are at high risk for infection, especially if dogs are not individually penned, which also increases the number of animals requiring repeated testing during the eradication process. Animals must not be released for sale or any other purpose because they may spread the disease. All dogs in an infected kennel should be serotested for at least 3 months after seronegative status is achieved, especially before each breeding, even if artificial insemination is used. If animals are retained as pets or working dogs, or if treatment is contemplated, they should be neutered and moved to separate housing. Although determining the origin of infections is important, this has proved difficult because of the reluctance of owners to reveal actual or suspected sources.

Preventive measures are particularly important in large breeding kennels or wherever a large number of dogs are kept, but no legally mandated control measures exist, and in the United States, canine brucellosis is not a reportable disease in most states. Prevention is accomplished by quarantine of all new acquisitions until two serotest results at a 1-month interval are negative. Animals from kennels known to have had breeding problems should be rejected unless test results are negative.[70] Animals with any clinical sign of canine brucellosis should be rejected. Animals used for breeding should be tested 3 to 4 weeks before each mating to allow time for test results to be reported. Dams should not be mated to stud dogs unless they have been tested and certified negative. If dogs leave a colony, they should be tested before readmission. All canine blood donors should be screened for brucellosis using serology because of the potential for transmission through transfusion of contaminated blood products.[71]

IMMUNITY AND VACCINATION

Serum agglutinating antibodies do not protect against infection in the dog as immunity likely depends on CMI. Presently, the development of a vaccine is considered undesirable because *Brucella* vaccines evaluated have offered only moderate protection, and immunized dogs develop antibodies that confound serodiagnosis. A promising vaccine candidate based on a *B. ovis* mutant was able to protect dogs against challenge with *B. canis*; dogs developed antibodies to rough *Brucella* spp.[72] Such a vaccine may be useful if the serologic response can be differentiated from that to *B. canis* through diagnostic test design.

PREVENTION

Prevention of infection and elimination of infected dogs should be the principal control strategy in kennels. Prevention requires at least yearly testing of all breeding stock and testing of all dogs to be introduced into a kennel. Ideally, two negative screening tests performed at least a month apart should occur before a dog or bitch is introduced into a breeding facility. *Confirmed* positive dogs should be isolated (euthanasia is advised by some), neutered, treated, and tested monthly (AGID, blood culture, or PCR assay on blood) until two consecutive negative tests occur, although occult infection can still be present.

Private breeders should require serologic screening of all female dogs offered for breeding. Should positive test results occur on screening, breeders should not accept dogs unless follow-up testing with confirmatory assays is negative. Artificial insemination without dog-to-dam contact should be used if any concern exists. Stud dogs should be screened at least annually. Because of the potential for non-venereal transmission, screening of maiden dogs and bitches before breeding is also recommended.[15,22]

Prevention of brucellosis in dogs caused by other species of *Brucella* involves avoidance of raw meat diets, hunting activities, and consumption of products of livestock parturition on farms.[11–13]

PUBLIC HEALTH ASPECTS

Humans can become infected with *B. canis*,[73,74] although they are relatively resistant to infection and other *Brucella* species account for the majority of human disease, especially *B. melitensis* (Fig. 71.16). The majority of human brucellosis cases in the United States caused by all

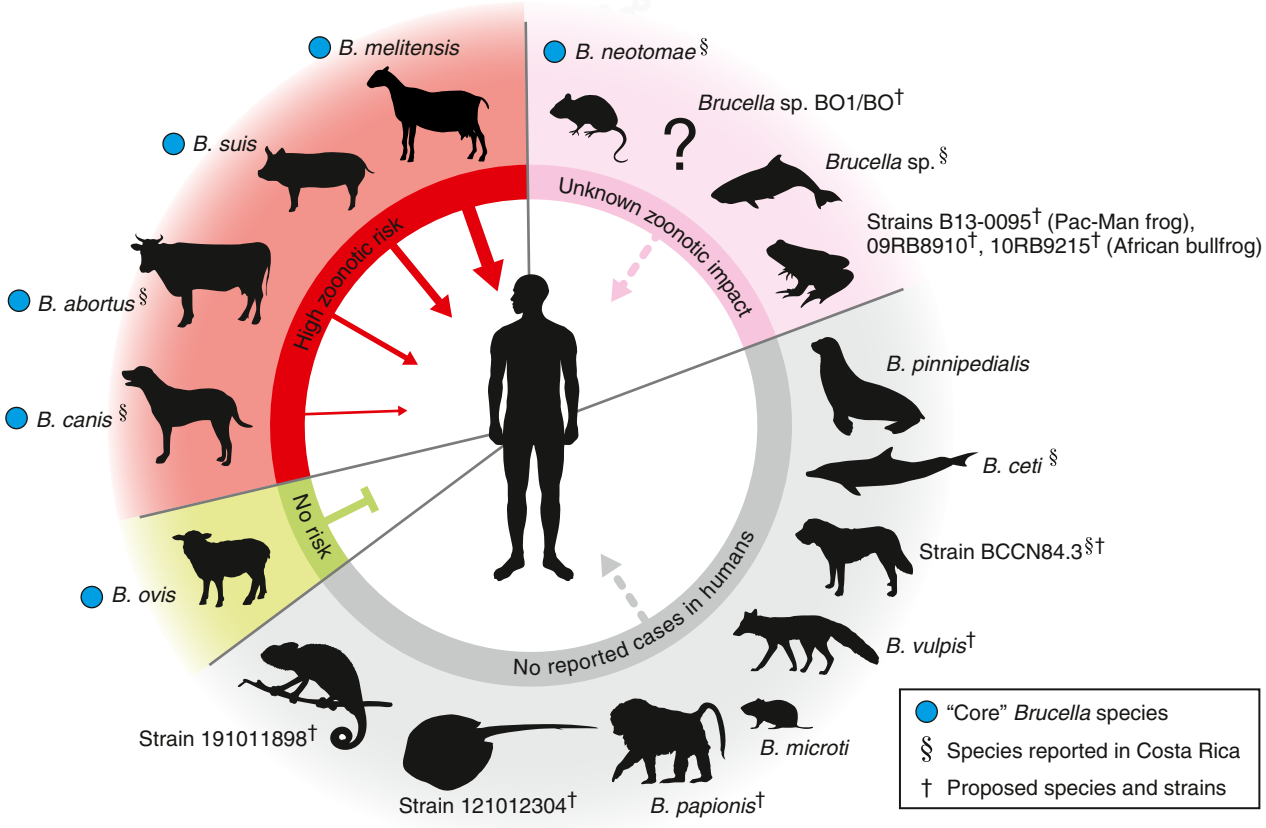

Fig. 71.16 Zoonotic potential of various *Brucella* species. The colors and arrow sizes represent the zoonotic risk displayed by each species isolated from its preferred host. (Modified from Suarez-Esquivel M, Chaves-Olarte E, Moreno E, et al. *Brucella* genomics: macro and micro evolution. *Int J Mol Sci.* 2020;21:7749.)

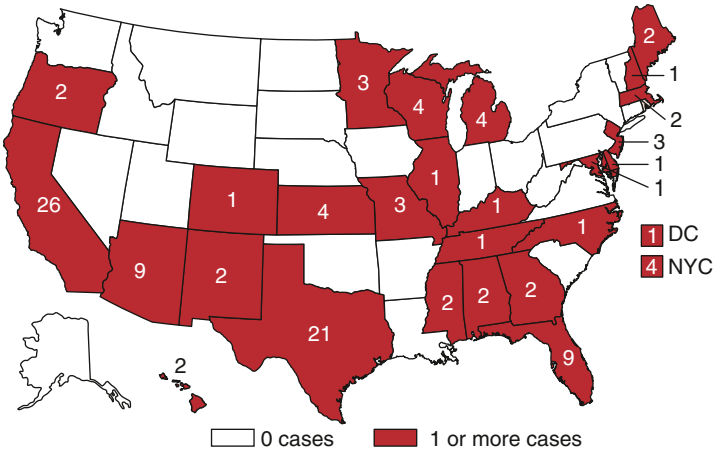

Fig. 71.17 Geographic distribution of reported human cases of brucellosis in 2010. Numbers represent the number of cases reported to the Centers for Disease Control and Prevention. DC, Washington DC; NYC, New York City (Modified from https://www.cdc.gov/brucellosis/resources/surveillance.html.)

species of *Brucella* are reported from California, Texas, Arizona, and Florida (Fig. 71.17). Approximately 40 cases of human infection with *B. canis* have been reported worldwide; however, the actual number is unknown, and the close contact that exists between humans and dogs increases the significance of the zoonotic risk posed. Brucellosis is the most commonly reported laboratory-acquired infection.[75] Serologic assays used for diagnosis of brucellosis in humans often do not detect antibodies to *B. canis*, so the disease may be overlooked. Transmission to humans most commonly occurs through contact with an infected dog's semen, vulvar discharge from an infected bitch, aborted fetuses or placentas, or through direct, accidental laboratory exposure. Thus, disease is more likely to occur in people who are in contact with breeding dogs, but disease occasionally occurs in the owners of pet dogs with discospondylitis. Immunocompromised humans, children, and those who are pregnant may be at greater risk for development of disease. Infection of humans with *B. canis* typically results in nonspecific, persistent clinical signs of fever, muscle aches, night sweats, and general malaise. Rarely, granulomatous hepatitis, hepatosplenomegaly, osteomyelitis, pulmonary disease, and endocarditis have been reported. In one case report, disease occurred in an HIV-infected dachshund dog breeder who reported infertility in one of the dogs, which had been tested by a veterinarian and was seropositive with a screening assay. Confirmatory testing with AGID performed at a university veterinary diagnostic laboratory yielded a negative result, so brucellosis was not thought to be present. However, subsequent blood culture of all the dogs in the household was positive in one other dog.[48,76] Affected humans are typically treated successfully with combinations of doxycycline and either aminoglycosides (for the first week) or rifampin, but monotherapy has been associated with unacceptable rates of relapse.

Prevention of human disease involves eradication of the disease in dog kennels; precautions such as the wearing of gloves and protective clothing when in contact with aborted material; and hand washing after handling dogs and before eating. Although it is preferable that immunocompromised individuals do not participate in dog breeding activities, if necessary, these individuals should take special care if they interact with breeding dogs. Contact with dogs with reproductive problems or their secretions should be avoided whenever possible, and if aborted material must be handled, gloves, gowns, and face protection should be worn, all protective wear should be disposed of properly, and hands should be washed thoroughly.[75,77,78–80]

CASE EXAMPLE

Signalment

"Sadie," a 6-year-old female spayed border collie mix from northern California (Fig. 71.18).

History

Sadie was brought to her local veterinarian for listlessness and reluctance to jump noted during the previous 48 hours. She had been adopted from a local humane shelter and had been ovariohysterectomized at 11 months of age. She lived in a rural agricultural area in northern California and was the only dog in the household; however, she was used for sheep herding with several other dogs.

Current Medications

Sadie was not on any medications.

Physical Examination

Sadie's vital signs were within normal limits, mucous membrane color was pink, and she was quiet and alert on physical examination. Body weight was 25 kg. Mild dental

Fig. 71.18 Six-year-old female spayed border collie mix with brucellosis.

CASE EXAMPLE—cont'd

tartar was evident. Thoracic auscultation and abdominal palpation were unremarkable, pulses were synchronous, and no peripheral lymphadenomegaly was evident. Palpable dorsal thoracolumbar pain was demonstrated. She was reluctant to rise but was ambulatory. The neurologic examination including a funduscopic examination was normal.

Laboratory Findings

A CBC, chemistry panel, and urinalysis with aerobic culture were performed. Mild neutropenia (2,958 cells/μL; reference range, 3,000–11,500 cells/μL) was found; the chemistries and urinalysis were within normal limits with no proteinuria.

Imaging Findings

Radiographs of the spine revealed evidence of disc space collapse, spondylosis, and probable discospondylitis at the T7-T8 disc space (see Fig. 71.7).

Microbiologic Testing

A SNAP 4Dx Plus test (IDEXX Laboratories) for antigen of *Dirofilaria immitis* and antibodies to *Ehrlichia canis, Anaplasma phagocytophilum,* and *Borrelia (Borreliella* [incertae sedis]*) burgdorferi* was negative. Aerobic bacterial urine culture was negative. Serum was submitted for a *B. canis* IFA, which was positive at a titer of 1:200. A *B. canis* AGID was submitted and was also positive.

Treatment

Sadie was treated with tramadol (1–2 mg/kg, PO, q8h) and carprofen (3 mg/kg, PO, q12h). Once the serologic test results were available, a tentative diagnosis of *B. canis* discospondylitis was made, and she was treated with enrofloxacin (5.5 mg/kg, PO, q12h). Clinical improvement was reported in 2 weeks, and repeat radiographs were performed in 1 and 5 months. Equivocal change was reported in the appearance of T7-T8 at 1 month, but the 5-month radiograph showed no progression, suggesting the lesion was no longer active. The owners were advised of the zoonotic potential of this disease and the potential hazard of transmission to other dogs. The potential need for lifelong intermittent antibiotic therapy with risk of relapses was also discussed. Repeat AGID testing post therapy was advised. It was also advised that dogs in contact with Sadie be screened for brucellosis.

Comments

Dogs with *Brucella* discospondylitis frequently are brought to their veterinarian for clinical signs of spinal pain or lameness that resemble common musculoskeletal injuries such as intervertebral disc disease or rupture of the cranial cruciate ligament. Although not typical, this case illustrates the fact that *B. canis* disease can occur in a neutered female dog without any breeding history, and often occurs in the absence of fever or significant abnormalities on routine laboratory testing. A diagnosis of *Brucella* discospondylitis was strongly suspected based on positive serologic test results with multiple assays. Blood culture was not performed, but a urine culture was negative. Monotherapy with fluoroquinolones has been associated with high rates of relapse in human patients once antimicrobial drug treatment has been discontinued, so it is generally not recommended. Nevertheless, it can occasionally be successful.

Tetanus and Botulism

Jane E. Sykes, Jamie M. Burkitt Creedon

KEY POINTS

- First Described: The etiology of tetanus was identified in the late 1800s in Germany (Nicolaier).[1] *Clostridium botulinum* and its toxin were first described in Belgium in 1897 (van Ermengem).[2] Prior to that, descriptions of both tetanus and botulism had been recorded; tetanus was described by Hippocrates more than 2000 years ago.
- Causes: Tetanospasmin neurotoxin of *Clostridium tetani* (tetanus); and botulinal neurotoxin of *C. botulinum*, *Clostridium baratii*, or *Clostridium butyricum* (botulism).
- Affected Hosts: Both diseases affect humans and domestic animals, including dogs and cats.
- Geographic Distribution: Both are ubiquitous organisms that affect the worldwide population.
- Primary Mode of Transmission: Inoculation of spores into a wound (tetanus) or ingestion of preformed toxin (botulism).
- Major Clinical Signs: Spastic rigidity (tetanus) or flaccid paralysis (botulism).
- Differential Diagnoses: Differential diagnoses for tetanus include strychnine toxicosis, hypocalcemia, and masticatory muscle myositis. Differential diagnoses for botulism include causes of acute lower motor neuron disease such as idiopathic polyradiculoneuritis (coonhound paralysis), tick paralysis, coral snake envenomation, myasthenia gravis, ionophore toxicosis, and paralytic rabies.
- Human Health Significance: Botulism and tetanus are not directly transmissible from animals to humans, but care should be taken when handling specimens from animals with botulism.

ETIOLOGY: TETANUS AND BOTULISM

Tetanus and botulism are neurologic diseases caused by the toxins of *Clostridium tetani* and *Clostridium botulinum*, respectively. These environmentally ubiquitous organisms are gram-positive, anaerobic, spore-forming, rod-shaped bacteria, with worldwide distributions. The spores of *C. tetani* and *C. botulinum* are extremely hardy in the environment and resist boiling and disinfection with alcohol or formalin.

The vegetative form of *C. tetani* produces the two toxins *tetanospasmin* and *tetanolysin*. Botulism is caused by botulinal neurotoxins (BoNTs), which comprise a family of seven antigenically distinct toxins produced by *C. botulinum* (which produces all seven BoNT types A–G), *Clostridium butyricum* (type E only), and *Clostridium baratii* (type F only). Although these seven neurotoxins are produced by a variety of clostridial organisms and are themselves different, they have identical toxicologic effects, and are thus considered together. BoNT is produced by the sporulated or vegetative clostridial organism under anaerobic conditions. Species susceptibility to BoNT serotypes varies. For instance, most human cases of botulism are caused by BoNT types A, B, or E. All reported clinical feline[3] and most canine[4–10] cases of botulism have been caused by BoNT type C. Rare cases of botulism caused by BoNT type D,[11] one likely caused by type A,[7] and one caused by type B[12] have been reported in dogs.

Tetanospasmin and BoNT have similar structures and mechanisms of action even though they cause diseases that contrast sharply with one another. Both toxins are among the most potent toxins known with an LD_{50} of ≤ 1–5 ng/kg.[13,14] The toxins consist of two polypeptide chains, a heavy (H) chain and a light (L) chain, joined by a disulfide bond (Fig. 72.1). The H chain attaches to presynaptic nerve terminal membrane receptors, although the precise receptors have not been identified because of the extremely low concentrations at which these toxins act. Variation in receptor binding affinities may explain differences in species susceptibility to clostridial neurotoxins. The toxin is then internalized via receptor-mediated endocytosis into the presynaptic nerve terminal, where it has a local impact on nerve cell function (BoNT) or travels by retrograde axonal transport to the nerve cell body and diffuses into inhibitory interneurons, where it impacts CNS inhibitory interneuron function (tetanospasmin). The L chain, a zinc-dependent matrix metalloproteinase, is released from the vesicle and subsequently cleaves one or more *docking proteins*. These proteins are critical for the release of neurotransmitters from synaptic vesicles into the synaptic cleft and are located on the membrane of synaptic vesicles *(synaptobrevin)* or the presynaptic cell membrane (*syntaxin* and *SNAP-25*). Synaptobrevin binds to the docking proteins located on the presynaptic membrane. The resulting complex (the SNARE complex) docks the synaptic vesicle at the proper location for fusion and exocytosis of neurotransmitter molecules into the synaptic space (Fig. 72.2). Tetanospasmin cleaves synaptobrevin, whereas botulinum neurotoxin C cleaves syntaxin; other botulinum neurotoxins cleave synaptobrevin or SNAP-25. The process of recovery involves the sprouting of new presynaptic terminals, followed by recovery of the original synapse, after which new terminal outgrowths retract.[15]

TETANUS

EPIDEMIOLOGY

Humans and horses are most susceptible to tetanus, and so widespread vaccination against the disease is performed in these species. Disease occurs occasionally in dogs and is rare in cats. The development of tetanus in dogs and cats usually follows introduction of environmental spores into a penetrating wound, but more than one third of affected

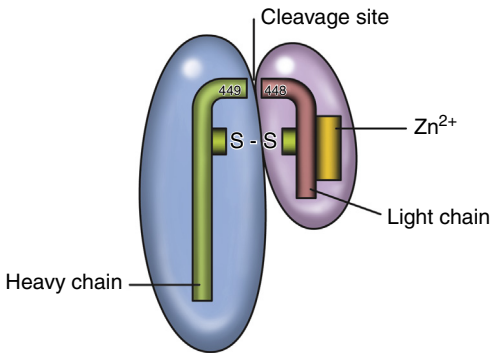

Fig. 72.1 Schematic of the structure of *Clostridium tetani* and *Clostridium botulinum* toxins.

dogs have no known wound history (*cryptogenic tetanus*)[16]; a similar prevalence of cryptogenic tetanus has been reported in humans.[17] Traumatic wounds of the feet, claws, or head; draining tracts associated with grass awn migration; animal bite wounds; tick bite wounds; bleeding claw trim wounds; wounds that result from chronic protozoal or fungal infections of the skin; teething wounds in dogs; and surgical wounds (particularly ovariohysterectomy and castration) have all been implicated.[16,18–20] One study in dogs suggests that tetanus occurs seasonally in the winter in England, though seasonality was not found in dogs in California.[21,22] Although dogs of any age, breed, or sex can develop tetanus, disease occurs most often in young, large-breed, active, intact male dogs.[16,18,19] Disease is seen in puppies as young as 8 weeks of age. Some studies describe a significant proportion of affected dogs as less than 1 year of age. Disease may be more severe in young than in mature dogs[16]; high mortality rates have been reported in the youngest people as well.[23] Cats are often young animals with outdoor access,[24] but cats of any age have been affected.[25]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Clostridium tetani spores are introduced into tissues where they germinate, replicate locally, and produce tetanospasmin toxin in anaerobic conditions. Ingestion is not a route of transmission because tetanospasmin is destroyed by GI secretions. Tetanolysin appears to promote local tissue degradation at the site of inoculation, which may optimize the tissue environment for organism growth. The toxin is produced as a single polyprotein that is cleaved extracellularly by a bacterial protease into the L and H chains, which remain connected by the disulfide bond. It then binds to presynaptic terminals of lower motor neurons and is internalized, travels up axons by retrograde axonal flow, and enters inhibitory interneurons in the brain and spinal cord, where it interferes with the release of inhibitory neurotransmitters γ-aminobutyric acid (GABA) and glycine (see Fig. 72.2). Toxin can also spread hematogenously to the CNS from the wound site. The result is unhindered excitation of motor neurons, spastic rigidity, and dysfunction of the sympathetic and parasympathetic nervous systems. Clinical signs occur 3 days to 3 weeks after a wound in both dogs and cats. Shorter incubation periods occur when the inoculation site is nearer the CNS and when a large amount of toxin is present. Paralysis may initially be localized to the wound site but can then generalize. Involvement of the head is common in dogs, and often owners of dogs with tetanus first notice an unusual appearance to their dog's eyes, a "swollen" face, or evidence of dysphagia.[16] Regurgitation or vomiting of food occurs in less than 20% of affected dogs, and a voice change or dysuria may be noted. Abnormal activity during sleep (twitching, running, vocalization) was documented in at least 46% of 50 surviving dogs with tetanus in the United Kingdom; these signs resolved in approximately half of these dogs within 6 months.[26] Death occurs in severely affected dogs due to paralysis of respiratory muscles; infectious complications such as pneumonia; upper airway obstruction; the development of severe hyperthermia with DIC, multiple organ failure, and/or pulmonary thromboembolism; and cardiac arrhythmias.[16,18,19] Hiatal hernia and coxofemoral joint luxations have also been described as complications of tetanus in dogs.[16,18,27,28] Disease in cats is usually localized to the limbs, but generalized tetanus can occur.[24,25,29–35] Many affected cats have an initial history of disappearance or a recognized wound, after which rigid lameness is noted.

Physical Examination Findings

Tetanus causes spastic muscle rigidity. *Generalized tetanus* involves spastic rigidity of all four limbs in addition to muscles of the head. *Localized tetanus* involves spasm in a single limb or region of the body. Like humans, dogs more often experience generalized tetanus; cats more often have localized tetanus, probably due to the feline species' relative resistance to tetanospasmin. Both species can experience either type. The cephalic form of tetanus is localized to the head secondary to a head wound; *cephalic tetanus* is seen in humans and involves flaccid facial paralysis that usually precedes generalized tetanus with spastic rigidity[36]; cephalic tetanus has not been described in dogs or cats.

Dogs and cats with *generalized tetanus* experience rigidly extended limbs. The tail is often held erect, or curved dorsally. Dogs that are ambulatory walk slowly with a stiff, stilted gait and can have a wide-based or "sawhorse" stance; voluntary movement of the head may occur slowly or appear difficult. Reflexes may be exaggerated or difficult to elicit due to excessive extensor tone. When muscles of the head are involved, tetanus causes globe retraction and thus third eyelid elevation, a wrinkled forehead and erect pinnae, retracted lips (*risus sardonicus*), and trismus—spasms of masticatory muscles that make it difficult to open the mouth (Fig. 72.3A). Cats with generalized tetanus may not have increased jaw tone.[33–35] Miosis may be present. Laryngeal spasm and hypersalivation occur in approximately half of affected dogs.[18,19]

Severely affected dogs are anxious and hypersensitive, develop opisthotonus, vocalize, or tremble, or can experience generalized seizures when stimulated. Patients are often hyperthermic due to increased muscle activity (up to 111°F [43.9°C]).[34] Moderate to severe obtundation can result. Abdominal palpation may reveal an enlarged bladder that is difficult to express, or palpation may be difficult because of abdominal muscle spasm. Tetanic spasms can lead to dyspnea and hypoventilation.[16,18] At least a third of dogs with generalized tetanus in a referral environment are bradycardic or have bradyarrhythmias (which include atrioventricular block or sinus arrest), with heart rates that range from 40 to 60 beats/minute; another one third of dogs are tachycardic (>150 beats/minute) or have variable heart rates, which may reflect autonomic dysfunction or pain.[16] The inciting wound that allowed introduction of *C. tetani* may or may not be found, particularly in dogs. In cats with tetanus, a wound is often identified.[29–33,37,38] Animals with generalized tetanus usually have a prolonged clinical course and require hospitalization for 1–2 weeks or more; median hospital stay for dogs has been reported to be 13–17 days.[18,19]

Localized tetanus usually involves rigid extension of the limb nearest or affected by the inoculating wound. Dogs with localized thoracic limb tetanus have caudal retraction of the limb with extension of both the elbow and carpus.[25] When a cat's thoracic limb is affected, spasm of the triceps muscle results in caudal extension of the limb with carpal flexion (in contrast to dogs) and elbow extension (Fig. 72.3B).[24,30] The head and neck may deviate toward the affected limb.[25] Localized tetanus can progress to generalized disease.

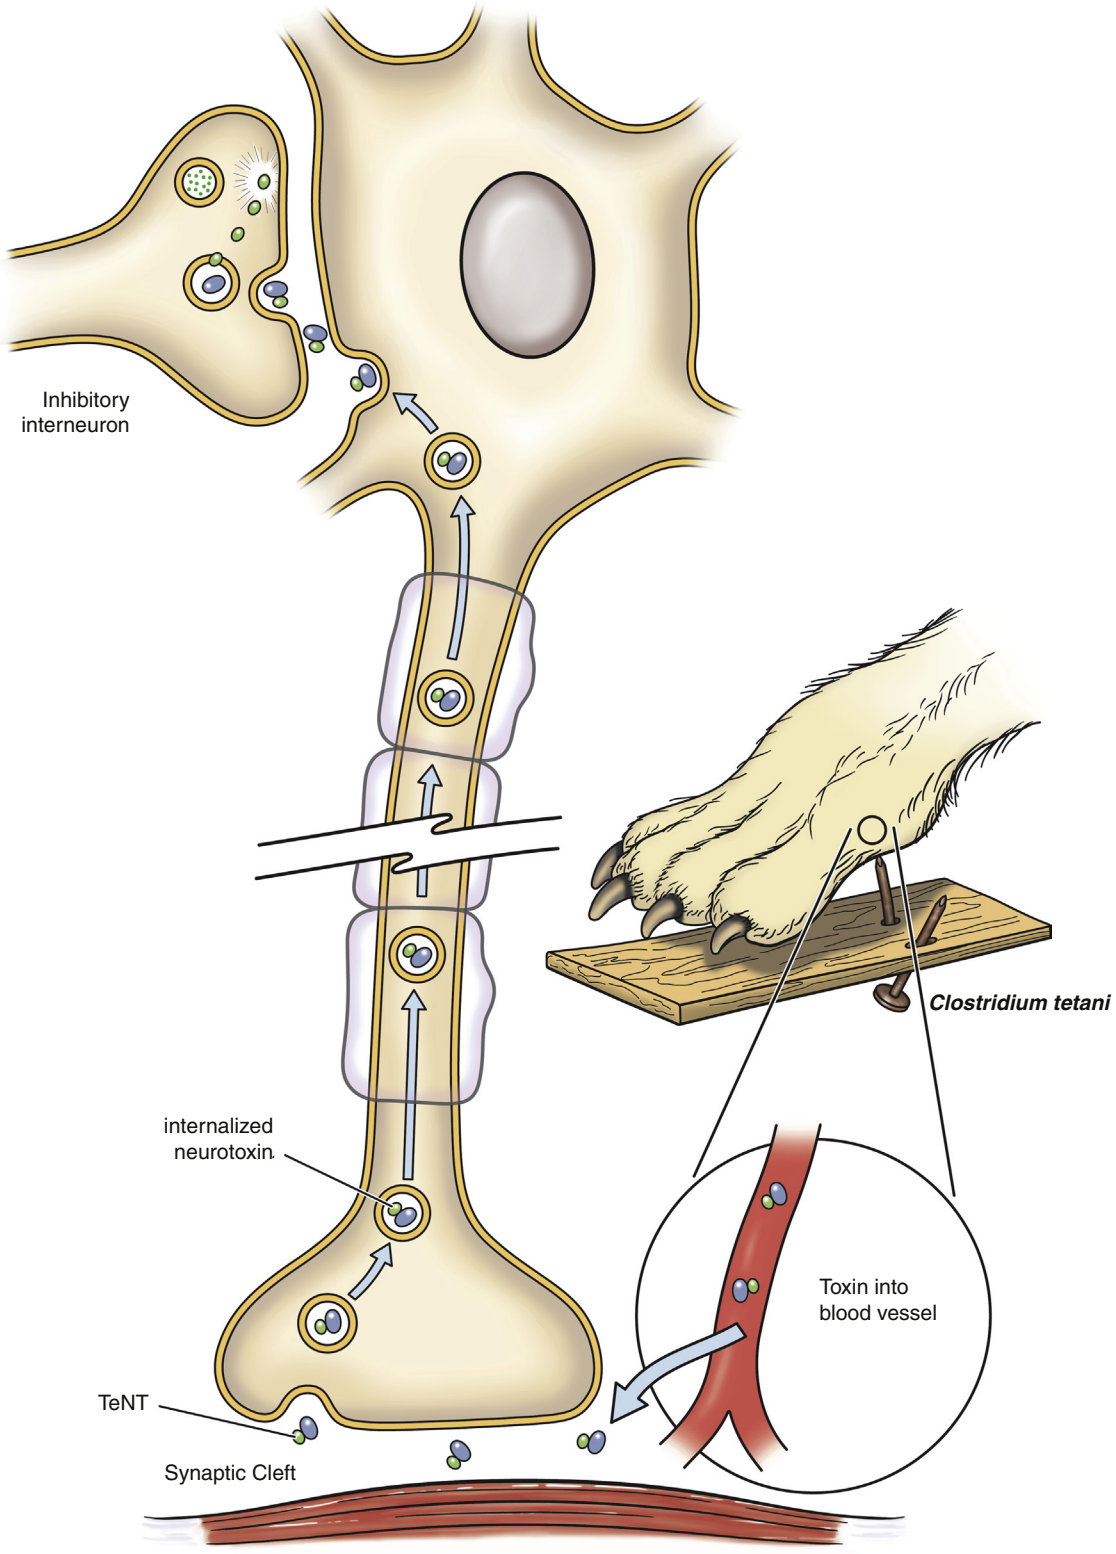

Fig. 72.2 Mechanism of action of tetanospasmin.

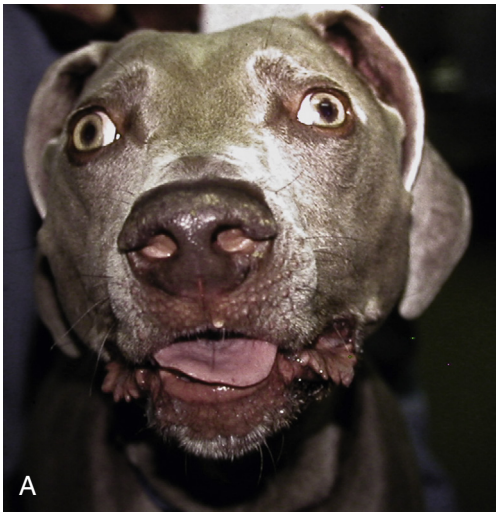
DIAGNOSIS

Tetanus is a clinical diagnosis in all species. That is, there is no clinicopathologic, microbiologic, serologic, imaging, or other diagnostic test that is definitive for the disease; diagnosis is based on history and physical examination, and the exclusion of other rule-outs for the problem. The main rule-outs for generalized tetanus are hypocalcemic tetany, which is ruled out by a normal serum ionized calcium concentration, and strychnine toxicosis. Strychnine was historically used as a pesticide to kill small mammals, but has largely been replaced in the western world by other toxins. Thus, strychnine toxicosis is probably a less common clinical problem today than tetanus.



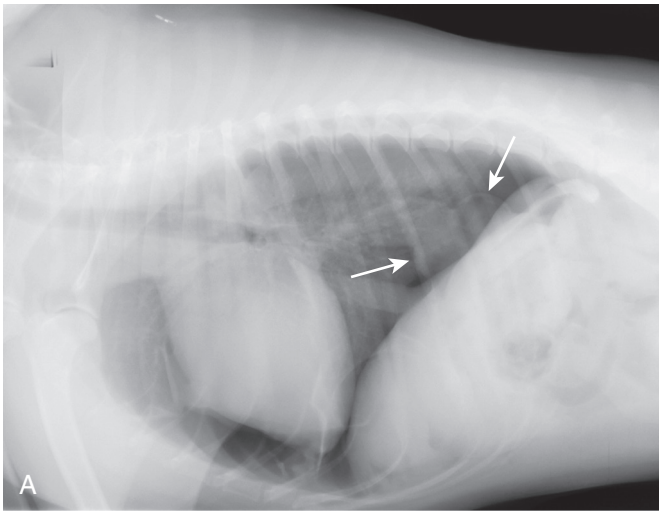


Fig. 72.3 (A) Weimaraner with generalized tetanus. The dog walked with a stiff gait and was salivating profusely. Risus sardonicus is evident. (B) A 3-year-old female domestic shorthair cat with localized tetanus that was seen for a 3-day history of right thoracic limb lameness. Extension of the shoulder and elbow and partial flexion of the carpal joint are present. (From Langner KFA, Schenk HC, Leithaeuser C, et al. Localised tetanus in a cat. *Vet Rec.* 2011;169:126.)

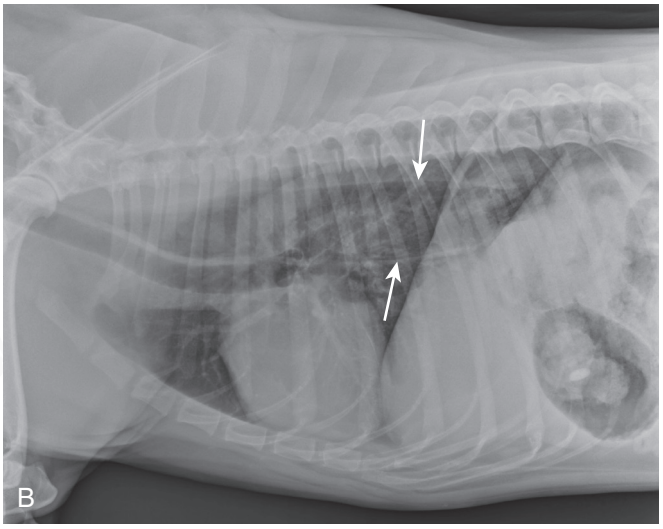

Fig. 72.4 Radiographic findings in dogs with tetanus (A) and botulism (B). (A) Lateral thoracic radiograph from a 3-year-old female spayed English springer spaniel with tetanus that was seen for vomiting, dysuria, respiratory distress, and a stiff gait. Pneumothorax and a hiatal hernia *(arrows)* can be appreciated. Before the radiographs were taken, an exploratory laparotomy had been performed because a foreign body was suspected. The pneumothorax developed postoperatively for reasons that were unclear. A foxtail wound was later found on the left distal pelvic limb between the digits. The dog was hospitalized for 19 days, during which time all radiographic abnormalities resolved. (B) Lateral thoracic radiograph from a 6-year-old female spayed Labrador retriever with botulism. Megaesophagus is present. The arrows delineate the dorsal and ventral esophageal wall.

The primary differential diagnosis for the facial signs of tetanus is masticatory muscle myositis, which is ruled out if nonfacial musculature is involved and by serologic testing for type 2M antibodies. A history of a traumatic event, surgical procedure, or other wound in the preceding 3 weeks, or of a period of disappearance, should raise suspicion for tetanus.

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Routine laboratory test results in animals with tetanus are often normal, but stress hyperglycemia, mild to severe increases in the activity of serum creatine kinase (usually < 20,000 U/L but sometimes > 200,000 U/L, reference range: 46–320 U/L), mildly increased AST activity, and myoglobinuria may be present.[16,18] Dehydration may result in hemoconcentration or prerenal azotemia. Animals with wounds or aspiration pneumonia may have an inflammatory leukogram. Severe hyperthermia in dogs with tetanus may lead to laboratory evidence of multiple organ dysfunction, with azotemia, increased liver enzyme activities, or hyperbilirubinemia. Thrombocytopenia and coagulation test abnormalities consistent with DIC may also be present in these dogs.

Cerebrospinal Fluid Analysis

CSF analysis in dogs and cats with tetanus is typically normal.

Diagnostic Imaging

Thoracic radiographs in animals with tetanus may reveal aspiration pneumonia.[16,18,19] Occasionally, dogs with generalized tetanus have evidence of a hiatal hernia on thoracic radiography,[16,27,39,40] which appears as a soft tissue mass in the caudal thorax (Fig. 72.4A). Abdominal ultrasound and advanced imaging modalities are generally noncontributory.

Electrodiagnostic Tests

Electrodiagnostic testing is not usually performed in animals with tetanus since the diagnosis can generally be made without it, and because electrodiagnostic findings in the disease are nonspecific.

Electromyography (EMG) evaluates the electrical activity in muscle while nerve conduction studies evaluate the quality and speed of nerve responses following stimulation. Animals with tetanus have had normal electrodiagnostic measurements[18] in some cases, and persistent electrical motor unit discharges in others.[24,41]

Microbiologic Tests

Isolation and Identification

Attempts to culture *C. tetani* from wounds are not recommended because the presence of *C. tetani* in a wound does not necessarily imply toxin production. In addition, culture for this organism is insensitive.[17]

Serologic Diagnosis

Serologic testing is not performed in cases of tetanus because it is a clinical diagnosis with so few rule-outs that it is a nearly pathognomonic presentation. Antibodies are produced to the toxin during natural infection,[42] but serology is generally neither available nor necessary for diagnosis.

Pathologic Findings

There are no specific gross or histopathologic findings associated with tetanus. Evidence of complications such as aspiration pneumonia, pulmonary thromboembolism, or DIC may be seen on necropsy in patients that die of severe cases.

TREATMENT AND PROGNOSIS

Specific Treatment

Tetanus antitoxin is widely available and should be administered as a single dose IV (equine antitoxin) or IM (human antitoxin) after an initial intradermal test dose to evaluate for an allergic reaction (Table 72.1). Dogs that react to the test dose can be premedicated with diphenhydramine and a low dose of dexamethasone. Adverse reactions to antitoxin include vomiting, retching, or tachypnea and may occur even in premedicated dogs.[16] Reduction in the rate of antitoxin administration or discontinuation of treatment leads to resolution of clinical signs. Administration of antitoxin does not reverse existing signs because it does not enter nerve terminals, but it may neutralize free toxin. A small amount of antitoxin can be administered locally if a wound is identified. The efficacy of tetanus antitoxin is controversial, and the optimal dose is not known. In one study, earlier IV administration of equine tetanus antitoxin did not influence disease progression or mortality as opposed to administration later in the course of disease.[16] Antitoxin administration may prevent localized tetanus from generalizing.

For animals with tetanus, treatment with antimicrobials that have activity against *C. tetani* is recommended. Appropriate antimicrobials for treatment of tetanus include IV metronidazole or penicillin G. Metronidazole is preferred because of its improved penetration into purulent material and the fact that penicillin can antagonize GABA. Studies in human patients have also shown improved outcome with metronidazole as opposed to procaine penicillin.[43] Once antitoxin has been administered and spasms are controlled (see Supportive Care), wounds should be managed appropriately. Earlier, appropriate antimicrobial treatment and wound debridement were not shown to influence progression or mortality in one small veterinary study in dogs.[16] However, early, definitive management with antitoxin, wound management, and appropriate antimicrobial therapy is a cornerstone of treatment in humans with tetanus,[44] and common sense suggests that veterinary patients would benefit from that same level of care.

Supportive Care

Supportive care is an essential part of management for patients with tetanus. The extent of care required depends on the severity of illness. IV fluids, soft bedding, frequent turning to prevent decubital ulcers, application of ocular lubricant to prevent corneal ulceration, bladder expression or urethral catheterization (ideally intermittent), enemas to relieve constipation, and nutritional support in the form of hand feeding, feeding tubes, or parenteral nutrition may be required. Force feeding is not recommended because it is unlikely to satisfy caloric needs and can contribute to the development of aspiration pneumonia.

To help minimize spasms, dogs or cats with generalized tetanus should be placed in a quiet, dimly lit environment away from excessive visual or auditory stimuli. Cotton balls can be used as earplugs. Sedatives and/or muscle relaxants such as acepromazine, benzodiazepines, dantrolene, or baclofen may be useful. Severely affected animals may require a constant-rate infusion of drugs such as pentobarbital, phenobarbital, or propofol. Barbiturates are no longer recommended for treatment of tetanus in humans, in whom benzodiazepines are the mainstay for sedation and relaxation.[45,46] If human disease is severe, drugs that cause neuromuscular blockade such as vecuronium are used, but this necessitates mechanical ventilation. Methocarbamol often appears ineffective and requires frequent administration,[16,19] and thus its use is not recommended because it may delay administration of more effective medications. Also, benzodiazepines are preferred to methocarbamol because they are GABA agonists and provide some sedation. Successful control of muscle spasms relieves pain and hyperthermia. If used, opioids should be administered with caution because they may contribute to constipation or GI adverse effects. Administration of magnesium sulfate infusions has also been associated with improvement in clinical signs; a dose of 70 mg/kg over 30 minutes followed by an initial CRI of 100 mg/kg/day has been recommended. Oral magnesium aspartate (12 mg/kg q12h) orally can be continued for 14 days once this is feasible.[47]

Fans and room temperature fluids may be beneficial for dogs with tetanus-induced heat injury. Administration of atropine may be required for animals with bradyarrhythmias (in dogs, HR < 60 beats/minute; in cats, HR < 120 beats/minute). Rarely, bradyarrhythmias have required temporary pacemaker placement.[16] Occasionally (< 10% of dogs with generalized tetanus in a referral population), mechanical ventilation is required to support respiration.[16] Temporary

TABLE 72.1 Suggested Dosages of Medication for Specific Treatment of Tetanus

Drug	Dose	Route	Interval (hours)	Duration (days)
Metronidazole	15 mg/kg	IV, PO	12	10
Tetanus equine antitoxin	100–1000 units/kg 500 units	IV, IM[a] SC near wound site	NA	Once
Human tetanus immune globulin	500 units	IM near wound if found	NA	Once

[a]IV use is preferred. Administer 0.1 mL intradermally as a test dose before infusion. The full dose should then be given slowly over 10 minutes. The maximum dose is 20,000 units/kg.

IM, intramuscular; *IV,* intravenous; *NA,* not applicable; *PO,* oral; *SC,* subcutaneous.

tracheostomy may be required to bypass the larynx in cases of severe upper airway obstruction.[18]

Prognosis

Provided complications do not occur, prognosis is generally good for animals with generalized tetanus. The overall 28-day survival rate for dogs with generalized tetanus in one study was around 80%,[16] whereas in another study of 20 dogs it was only 50%.[19] A classification system has been developed to assess the severity of tetanus in dogs for the purpose of prognostication (Table 72.2).[16] The survival rate for dogs that progressed to tetanus severity class I or II was 100%, but it dropped to 60% for dogs that progressed to tetanus severity class III or IV.[16] However, at the time of initial evaluation, only 11% of 37 dogs were in class III or IV, and dogs progressed to higher classes unpredictably, with 47% of the dogs categorized in class III or IV when the highest recorded class was assigned. Dogs with severe tetanus are more likely to develop complications such as aspiration pneumonia or multiple organ dysfunction than dogs with mild tetanus. In a few dogs that recover (< 10% of dogs that develop generalized tetanus), intermittent localized muscle spasm continues to occur for many months, which may be noticed by the owner during activities such as sleeping or eating.[16]

The prognosis for animals with localized tetanus is excellent with supportive care of wound management and antimicrobial treatment.

IMMUNITY AND VACCINATION

Given the relative rarity of tetanus in dogs and cats, vaccination is not recommended in these species. Recurrent tetanus has been documented in people, so recovery from natural disease does not necessarily result in protection from future episodes.[44] Thus, preventative measures should be discussed with owners of pets that recover from tetanus.

PREVENTION

Control of: (1) roaming, (2) exposure to plant awns, and (3) aggressive interactions with other animals may reduce the chance that wounds develop. If wounds are noticed, they should be cleaned promptly with soap and water. Surgical instruments should always be sterilized properly before use so that tetanus spores are inactivated, and needles should never be reused. Tetanus spores can be inactivated with iodine, glutaraldehyde, hydrogen peroxide, or autoclaving at 121°C and 15 psi for 15 minutes.

PUBLIC HEALTH ASPECTS

Animals with tetanus cannot transmit it directly to people who handle them. The main risk that dogs with tetanus pose to humans is through bite wounds, which can occur when owners attempt to administer oral medications to animals with increased jaw tone or spasm.

Tetanus in humans is rare in developed countries because most children are vaccinated against the disease. When it occurs, it is most often in people older than 65 years because of waning immunity, and in injection drug users.[48] Worldwide, the vast majority of cases occur in neonates from developing nations because of lack of immunization.

TABLE 72.2 Tetanus Severity Classification System for Dogs

Class	Clinical Signs
I	Absence of class II, III or IV signs *and* any or all of: • Miosis, enophthalmos, risus sardonicus, erect ears, or trismus • Hypersensitivity to noise, light or touch • Ambulatory
II	Absence of class III or IV signs *and* any or all of: • Dysphagia • Stiff gait, sawhorse stance, erect tail • Ambulatory
III	Class I or class II signs, absence of class IV signs, *and* any or all of: • Recumbency • Muscle fasciculations or spasms • Seizures
IV	Class I, II, or III signs *and* any or all of: • Bradycardia (HR ≤ 60 beats/minute) or bradyarrhythmia • Sinus tachycardia (HR ≥140 beats/minute) or tachyarrhythmia • Labile hypertension or hypotension (mean arterial blood pressure ≤60 mmHg or ≥ 130 mmHg, or systolic arterial blood pressure ≤ 80 mmHg or ≥150 mmHg) • Periods of apnea or respiratory arrest

Modified from Burkitt JM, Sturges BK, Jandrey KE, et al. Risk factors associated with outcome in dogs with tetanus: 38 cases (1987-2005). *J Am Vet Med Assoc.* 2007;230:76–83.

BOTULISM

EPIDEMIOLOGY

Botulism is rare in dogs and even rarer in cats. Clinical disease in dogs and cats follows ingestion of carrion that contains preformed neurotoxin. Botulism outbreaks in dogs have been reported in hunting foxhounds that have eaten domestic mammal or wild animal carcasses.[4,49] Maggots can vector *C. botulinum* and BoNT between bird carcasses,[50] and some cases of canine botulism have followed ingestion of bird carrion.[5,8,9,51] At least one case was associated with a botulism outbreak in waterfowl.[10] Most dogs reported have been medium- to large-breed, intact male or intact female dogs that vary in age; this finding is likely because the vast majority of botulism cases in dogs have been reported in foxhound packs. The only report of botulism in cats was an outbreak of disease that occurred after several cats were fed pelican carrion.[3] The relative resistance of dogs and cats to botulism has been hypothesized to reflect an adaptive response to a carnivorous lifestyle.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Clostridium botulinum spores germinate in anaerobic conditions and produce toxin. They grow best in temperatures that range from 30°C to 37°C, so carrion in warm conditions is ideal for BoNT production. The toxin is ingested, survives the acid stomach conditions, and is absorbed into the bloodstream from the small intestine. It then travels to peripheral cholinergic synapses, which include the neuromuscular junction and autonomic synapses, and inhibits release of acetylcholine (ACh) (Fig. 72.5). This leads to ascending, symmetrical flaccid paralysis, development of megaesophagus, and signs of autonomic dysfunction. Clinical signs usually occur within 12 to 72 hours after ingestion of botulinum toxin and may be complicated by signs from dietary indiscretion, although GI signs may also reflect the presence of autonomic derangement. Disease progresses rapidly over 1 or 2 days,

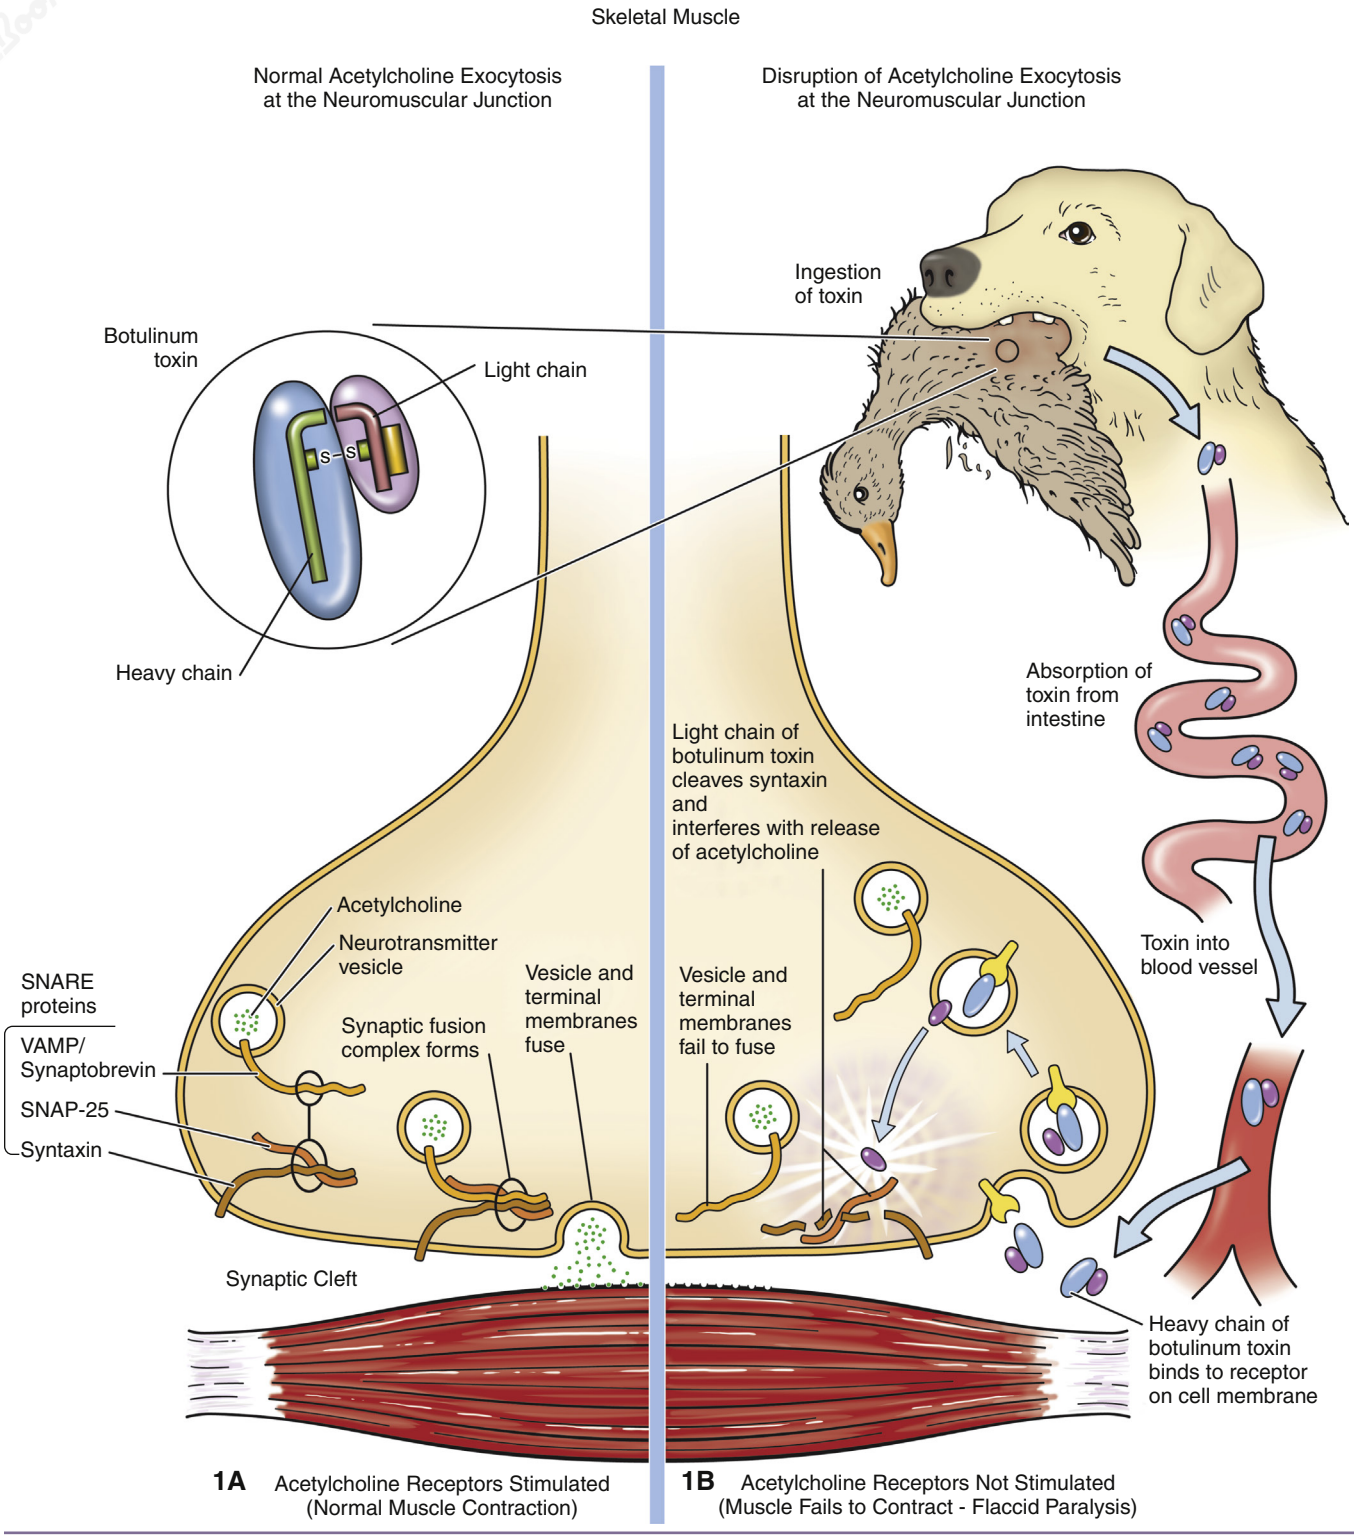

Fig. 72.5 Mechanism of action of botulinum toxin

and then begins to resolve with supportive care. Rapid development of signs after carrion ingestion is generally associated with a more severe course of disease. Death can result from respiratory muscle paralysis or aspiration of GI contents. Abnormalities in affected cats were ascending flaccid paralysis, lethargy, hypothermia, tachypnea, dehydration, and urinary incontinence.[3]

Physical Examination Findings

Botulism causes an acutely progressive, ascending, bilaterally symmetrical flaccid paralysis. Physical examination findings depend on the severity of intoxication. Fever is absent unless aspiration pneumonia has developed. Mildly affected animals show only ataxia or pelvic limb paresis, whereas those with severe intoxication are quadriplegic with

TABLE 72.3 Diagnostic Assays Available for Diagnosis of Botulism

Assay	Specimen Type	Target	Performance
Mouse inoculation bioassay	Feces, vomitus, intestinal contents, serum, foodstuffs	Botulinum toxin	Gold standard for diagnosis. False negatives can occur if toxin degradation occurs. Slow turnaround time means diagnosis is generally retrospective. Laborious and requires the use of laboratory animals.
ELISA toxin assays	Feces, vomitus, intestinal contents, serum, foodstuffs	Botulinum toxin	Rapid and inexpensive. Standard ELISA toxin assays have a lower sensitivity than the mouse inoculation assay.
ELISA assays that detect the antibody response to botulinum toxin	Serum	Anti–botulinum toxin antibodies	Negative antibody titers occur early in the course of disease, so acute and convalescent titers must be performed. Thus, diagnosis is retrospective.

absent voluntary motor activity and are unable to rise from lateral recumbency. The ability to wag the tail is often retained in dogs.[4,10,51] Segmental reflexes are generally decreased or absent, and pain perception is preserved. Patients usually experience constipation, and an "overflow" bladder due to lower motor neuron dysfunction may be present. Cranial nerve examination can reveal decreased function, especially facial nerve function and a decreased gag reflex, sometimes accompanied by ptyalism.[4,5,51,52] Dysphonia is common. Decreased blinking can result in corneal ulceration,[5,6] and concomitant keratoconjunctivitis sicca has been reported.[9] Mydriasis with sluggish pupillary light reflexes has been described.[4,52]

Occasionally tachycardia and tachypnea are present. Tachypnea may result from diaphragmatic muscle weakness or secondary aspiration pneumonia. Increased breath sounds may also be present on thoracic auscultation of dogs with secondary aspiration pneumonia. Physical examination findings in one affected cat consisted of hypothermia, lethargy, dehydration, quadriplegia, and decreased segmental reflexes.[3] In general, the sooner the onset of clinical signs after ingestion of toxin, the more severe and long-lasting the course of disease. Most cases worsen over the first 1–2 days of clinical signs and are markedly improved in less than a week.

DIAGNOSIS

Diagnosis of botulism is most often based on a history of recent exposure to carrion, clinical signs, and exclusion of the few other rule-outs; sometimes electrodiagnostic testing is performed. The primary differential diagnoses for botulism are acute idiopathic polyradiculoneuritis (coonhound paralysis), tick paralysis, acute fulminant myasthenia gravis, coral snake envenomation, ionophore toxicosis, and paralytic rabies. The intermediate syndrome of organophosphate intoxication and organophosphate-induced delayed neuropathy are also possible, though these syndromes are exceptionally rare in veterinary medicine. A full history should be obtained for vaccination status and possible exposure to organophosphate pesticides or ionophore antimicrobial agents, and a close examination should be performed for engorged ticks. An ACh receptor antibody assay can be performed to rule out fulminant myasthenia gravis. Serologic assays have been used to detect an antibody response to BoNT. Finally, specific assays that detect BoNT in serum, GI contents, or food can be performed (Table 72.3).

Laboratory Abnormalities

Complete Blood Count, Serum Biochemical Tests, and Urinalysis

Routine laboratory test results in animals with botulism are often normal. Dehydration may result in hemoconcentration or prerenal azotemia. Animals with aspiration pneumonia may have leukogram changes.

Cerebrospinal Fluid Analysis

CSF analysis in dogs and cats with botulism is typically normal.

Diagnostic Imaging

Thoracic radiographs in dogs with botulism may be unremarkable, or megaesophagus may be present (see Fig. 72.4B).[6,9,52] Aspiration pneumonia may occur.[4,9,52] Carrion bones are occasionally present in the GI tract. Abdominal ultrasonographic examination may be normal, or mild abdominal lymphadenopathy may be identified.

Electrodiagnostic Tests

EMG and nerve conduction studies can be useful to support a diagnosis of botulism (Table 72.4). Sedation or anesthesia for electrophysiologic testing is generally not advisable in dogs with megaesophagus and aspiration pneumonia, although this testing has been performed without anesthesia in some cases.[4] EMG evaluates the electrical activity in muscle. Using EMG, the primary finding in dogs with botulism is prolonged or increased insertional activity.[4,52] Fibrillation potentials and positive sharp waves have also been noted.[4,9]

Nerve conduction studies evaluate the quality and speed of nerve responses following stimulation. Nerve conduction findings in dogs with botulism include normal F waves (late waves that decrease in magnitude or disappear in acute polyradiculoneuritis, and thus distinguish the two diseases) and decreased magnitude of the compound muscle action potential.[4,9,52] Repetitive nerve stimulation at low frequencies can result in decremental responses, but repetitive nerve stimulation at high frequencies in dogs with botulism has no effect on the muscle response.[52] Motor nerve conduction velocity is normal[52] or decreased.[4]

Microbiologic Tests

Isolation and Identification

Detection of *C. botulinum*, *C. butyricum*, or *C. baratii* bacteria in source material,[3,6] or in the stomach contents,[3] vomitus, or feces[5,51] of affected animals helps support the diagnosis of botulism, but is neither sensitive nor specific for clinical disease.

Serologic Diagnosis

ELISA assays that detect the antibody response to botulinum neurotoxin are available and were used to confirm a diagnosis of botulism in one dog.[5] A convalescent specimen collected 3 weeks after the onset of illness was positive, but specimens collected at the time the dog was first evaluated and 10 days into the course of disease were negative. Thus, the diagnosis is generally retrospective with this method because most dogs have recovered by the time seroconversion occurs.

Toxin Detection

Botulinum toxin can be detected in feces,[4,7,9,51] vomitus,[8] GI contents collected at necropsy, source material (carrion),[3,9] or serum.[4,8–10,12,51]

TABLE 72.4 Pathophysiologic, Clinical, and Electrophysiologic Features of Botulism, Polyradiculoneuritis, and Myasthenia Gravis

	Pathophysiology	Neurologic Signs	Electrodiagnostic Findings	Time Course
Botulism	Botulinum toxin-induced inhibition of acetylcholine release	Ascending flaccid tetraparesis, autonomic signs (Mydriasis with incomplete/absent PLR, neurogenic KCS, urinary retention), dysphonia, decreased reflexes, respiratory muscle paralysis, facial nerve paralysis, megaesophagus, constipation, normal pain perception	EMG: prolonged or increased insertional activity; fibrillation potentials and positive sharp waves possible NCS: normal F waves, decreased magnitude of CMAP. Normal MNCV. Decremental response to repetitive nerve stimulation at low frequencies	Progresses over 1 to 2 days, then usually markedly improved within a week
Acute Canine Polyradiculoneuropathy	Lymphocytic radiculoneuritis and nerve root demyelination, mechanism unclear	Ascending flaccid tetraparesis, dysphonia, ventroflexion of the neck, variable hyperesthesia of distal limbs	EMG: Increased insertional activity, fibrillation potentials and positive sharp waves, complex repetitive discharges. Normal to decreased magnitude of CMAP with temporal disperson. Normal MNCV. (I think many cases have demyelination and reduced MNCV – most published cases report reduced MNCV and this is my personal experience). F waves may not be recordable or will be prolonged. Sensory nerve conduction and repetitive nerve stimulation normal.	Rapid progression over a few days, but progression may continue for 10 days. Time course to recovery weeks to months.
Acquired Myasthenia Gravis	Anti-acetylcholine receptor antibodies at the neuromuscular junction	Muscle weakness, exercise intolerance, regurgitation due to megaesophagus, rare facial nerve paralysis, normal reflexes	EMG: Normal CMAP, but with repetitive nerve stimulation, decremental CMAP response with improvement upon intravenous administration of edrophonium chloride (maybe – we don't routinely test post-edrophonium). Diagnosis is made by >10% decrement. Normal MNCV.	Variable progression, with acute fulminant and focal forms of disease.

CMAP, compound muscle action potential; *MNCV,* motor nerve conduction velocity.

Specimens should be held at 4°C, marked with a warning label, and shipped immediately to the laboratory. The most sensitive assay is a mouse inoculation assay, in which untreated mice and mice treated with serotype-specific antitoxin are inoculated with the specimen to determine if the antitoxin is protective.[53] However, several days are required to run this assay and it involves the sacrifice of laboratory animals. Toxin type-specific ELISA assays are available for rapid detection of BoNT C, but standard ELISA assays lack sensitivity when compared with mouse inoculation. Research efforts have been focused on the development of a variety of novel, rapid, highly sensitive, and inexpensive diagnostic assays that detect minute quantities of botulinum toxins.[53]

Pathologic Findings

There are no specific gross or histopathologic findings associated with botulism.

TREATMENT AND PROGNOSIS

Specific Treatment

There is no readily available specific treatment for botulism in dogs. In the United States, heptavalent equine antitoxin is available from the CDC for treatment of human botulism. However, its availability is tightly controlled, so it may be impossible to obtain for treatment of dogs and cats.[54] Antimicrobials are not indicated for the treatment of botulism, because the disease is due to the ingestion of preformed toxin.

Supportive Care

Supportive care is an essential part of management. The extent of care required depends on the severity of illness. IV fluids, soft bedding, frequent turning to prevent decubital ulcers, application of ocular lubricant to prevent corneal ulceration, bladder expression, enemas to relieve constipation, and nutritional support in the form of hand feeding, feeding tubes, or total parenteral nutrition may be required. Force feeding is not recommended because it is unlikely to satisfy caloric needs and can contribute to the development of aspiration pneumonia. Occasionally, intermittent positive pressure ventilation may be required to support ventilation. Antimicrobial drugs should only be used if secondary infection develops (e.g., bacterial pneumonia or UTI). Aminoglycosides should be avoided because they may contribute to neuromuscular blockade.

Prognosis

Provided complications do not occur, prognosis is generally good for animals with botulism. Most animals are markedly improved within a week of onset of clinical signs.

IMMUNITY AND VACCINATION

Botulism is so rare in dogs and cats that vaccination against it is considered unwarranted. Vaccination has been successful in other species,

and BoNT vaccine development is an active area of research due to concerns about the toxin being used in bioterrorism.[55]

PREVENTION

Prevention of botulism involves limiting access to carrion and feeding heat-processed commercial diets that are unspoiled. Although BoNT can be denatured through boiling, spores can survive this treatment. Thus, cooked food should not be allowed to stand for long periods before it is fed to pets. The spores of *C. botulinum* are inactivated by pressure-cooking foods.

PUBLIC HEALTH ASPECTS

Animals with botulism cannot transmit the condition directly to people. Nevertheless, feces, tissues, or body fluids from animals with botulism should be handled with care and marked with warning labels before they are submitted to the laboratory because the toxin may be present in these items and only minute quantities are required to cause severe disease.

Three forms of botulism occur in people: infant botulism, wound botulism, and food botulism. Infant botulism occurs as a result of local production of botulinum toxin within the intestinal tract by *C. botulinum* in the absence of the competing intestinal microflora that are normally found in adults. Wound botulism occurs almost exclusively as a result of injection of contaminated heroin by IV drug users. Botulinum toxin preparations are used to treat conditions such as strabismus, esophageal achalasia, cervical dystonia, axillary hyperhydrosis (excessive sweating), or blepharospasm. There are rare reports of iatrogenic botulism after such use.[56,57] Life-threatening iatrogenic botulism has occurred after use of botulinum preparations that were unlicensed for cosmetic treatment of wrinkles.[58] Significant concerns have been raised about the possible use of botulinum toxin as an agent of bioterrorism. This has stimulated considerable research on the disease, which is otherwise very rare.

CASE EXAMPLE

Signalment

"Jenny," a 6-year-old female spayed Labrador retriever from Winters in northern California.

History

Jenny was brought to the University of California, Davis veterinary emergency service early in the morning for a 2-hour history of inability to stand. Her owners awoke to find her in another room, unable to get up for her morning walk. She appeared anxious and was breathing with increased effort, but was still wagging her tail. She also did not want to eat breakfast. There had been no known history of travel, toxins, trauma, or tick exposure. Over the past 2 months, she had been treated with prednisone (1 mg/kg, PO, daily for 5 days, followed by 0.74 mg/kg, PO, daily thereafter) for allergic dermatitis. Three weeks before the onset of illness, she was treated with a short course of cephalexin after an aural hematoma was repaired. Jenny had been regularly vaccinated with rabies, distemper, hepatitis, and parvovirus vaccines.

Physical Examination

Body weight: 27.2 kg.

General: Bright, alert, responsive, and hydrated. Laterally recumbent and anxious. T = 101.0°F, HR = 140 beats/minute, panting.

Integument, eyes, ears, nose, and throat: Sutures were present on the pinna of the right ear from the recent aural hematoma repair. Moderate dental calculus and gingivitis were present. There were no other abnormalities noted.

Musculoskeletal: BCS 5/9. The dog was unable to use the pelvic limbs to bear weight.

Cardiovascular, respiratory, GI, genitourinary, and lymph nodes: No clinically significant abnormalities were present.

Neurologic Examination

Mentation: Appropriate, anxious.

Gait/Posture: The dog was non-ambulatory, but voluntary movement was present in all four limbs. She was unable to stand and support weight, but could crawl and shuffle. She attempted to bear weight on her thoracic limbs and could maintain sternal recumbency. When supported to stand, the pelvic limbs collapsed and the thoracic limbs were minimally able to bear weight.

Cranial nerves: Slightly reduced palpebral reflexes and gag reflex. Absent corneal reflexes. No other deficits were noted.

Postural reactions: These were difficult to assess because of the dog's inability to stand, but appeared decreased.

Segmental reflexes: Reduced muscle tone was present in the thoracic limbs. Triceps, patella, and gastrocnemius reflexes were decreased. Reduced thoracic limb withdrawal reflexes were noted, but pelvic limb withdrawal reflexes were intact. Panniculus and perineal reflexes were also intact. Pain perception remained intact.

Spinal palpation: No apparent pain was present on palpation or cervical manipulation.

Neuroanatomic localization: Neuromuscular disease.

Laboratory Findings

CBC: HCT 41.0% (40%–55%), MCV 69 fL (65–75 fL), MCHC 36.6 g/dL (33–36 g/dL), WBC 5,800 cells/μL (6,000–13,000 cells/μL), neutrophils 3,671 cells/μL (3,000–10,500 cells/μL), lymphocytes 1,769 cells/μL (1,000–4,000 cells/μL), monocytes 197 cells/μL (150–1,200 cells/μL), eosinophils 145 cells/μL (0–1,500 cells/μL), platelets clumped but adequate (150,000–400,000 platelets/μL).

Serum biochemistry profile: Sodium 146 mmol/L (145–154 mmol/L), potassium 3.9 mmol/L (3.6–5.3 mmol/L), chloride 107 mmol/L (108–118 mmol/L), bicarbonate 21 mmol/L (16–26 mmol/L), phosphorus 2.3 mg/dL (3.0–6.2 mg/dL), calcium 11.4 mg/dL (9.7–11.5 mg/dL), BUN 15 mg/dL (5–21 mg/dL), creatinine 0.9 mg/dL (0.3–1.2 mg/dL), glucose 105 mg/dL (64–123 mg/dL), total protein 7.1 g/dL (5.4–7.6 g/dL), albumin 4.2 g/dL (3.0–4.4 g/dL), globulin 2.9 g/dL (1.8–3.9 g/dL), ALT 64 U/L (19–67 U/L), AST 25 U/L (19–42 U/L), ALP 129 U/L (21–170 U/L), creatine kinase 57 U/L (51–399 U/L), GGT 4 U/L (0–6 U/L), cholesterol 204 mg/dL (135–361 mg/dL), total bilirubin 0.2 mg/dL (0–0.2 mg/dL).

Urinalysis: SpG 1.025; pH 7.0, trace protein (SSA), 1+ bilirubin, no hemoprotein, glucose, ketones, WBC/HPF, RBC/HPF, bacteria or crystals in the sediment. Many lipid droplets were present.

Imaging Findings

Thoracic radiographs: The cardiopulmonary structures were within normal limits. There were mineralized opacities within the stomach. There was a small amount of gas in the midthoracic esophagus.

Abdominal ultrasound examination: Mild mesenteric lymphadenomegaly was identified. No other abnormalities were present.

Neuromuscular Testing

Edrophonium response test for myasthenia gravis: Negative.

Treatment

Jenny was admitted to the intensive care unit and treated with supportive care that included IV fluids (lactated Ringer's solution with 20 mEq/L KCl at 75 mL/hour),

CASE EXAMPLE—cont'd

soft bedding, intermittent manual bladder expression, physical therapy (massage and passive ROM exercises), and frequent turning. Treatment with prednisone was discontinued. Respiratory function was monitored continuously by observation, serial examination, and serial venous pCO_2 measurements. After repeated inspections for ticks, topical fipronil was applied in case the signs resulted from tick paralysis. Serum was submitted for an ACh receptor antibody titer, and feces were submitted for a botulinum toxin assay. Over the subsequent 12 to 18 hours, Jenny became anxious after she was fed canned food and began to retch and hypersalivate. Thoracic radiographs were repeated and showed megaesophagus (see Fig. 72.4B). Severe tachycardia also developed (HR = 210 beats/minute). An ECG showed ventricular tachycardia followed by supraventricular tachycardia. Systolic blood pressure was 145 mmHg. Acepromazine was administered (0.01 mg/kg, IV, once), after which her HR decreased to 90 beats/minute, with a normal sinus rhythm. A second neurologic examination showed progression of disease with reduced cervical tone and an inability to hold up the head, tetraplegia with absence of all segmental reflexes, and a reduced tail wag. The owners were warned that mechanical ventilation may be needed should the disease progress. Over the course of the next day, dysphonia and a mild cough developed, and Jenny regurgitated several times. Gastrostomy or jejunostomy tube feeding or parenteral nutrition were offered to the owner, but were declined. Four days after admission, improvement in the triceps reflex was noted, and on day 5, some voluntary movement was noted in the pelvic and thoracic limbs. At that time Jenny was successfully fed meatballs of canned dog food by hand. She was kept in sternal recumbency for 30 minutes after eating to minimize aspiration. On day 7, the ACh receptor antibody and botulinum toxin assay results became available.

Serum acetylcholine receptor antibody titer: 0.05 nmol/L (reference interval, < 0.6 nmol/L)

Botulinum toxin C mouse bioassay (fecal specimen): Positive for type C botulinum toxin. An extract from the fecal specimen was lethal in the bioassay. The effects were eliminated by heating the extract at 80°C for 10 minutes, which indicated that the toxic effects were due to a heat-labile toxin. Mice were also protected from the effects by anti–type C botulinum antisera but not by anti–type A botulinum antisera.

Diagnosis

Botulism.

Outcome

On day 8 after hospitalization, thoracic radiographs showed resolution of megaesophagus and no evidence of pneumonia. By day 10, Jenny began to shuffle along the floor. All segmental reflexes had returned but remained reduced. The dog was discharged from the hospital with instructions for continued care in the home environment. By day 15, Jenny's owners reported that her normal bark had returned, and she could walk 20 steps and defecate and urinate unassisted. A month after discharge she was re-examined and no abnormalities were detected.

Comments

The main differential diagnoses considered for this dog were myasthenia gravis and botulism. Initially, polyradiculoneuritis was also considered, but the subsequent development of megaesophagus was not consistent with this disorder. Ultimately, a diagnosis of botulism was confirmed through assay of the stool for botulinum toxin. A history of carrion ingestion was not known, but the dog lived in a semirural area, and the presence of mineralized stomach contents suggested that it had occurred. Prednisone administration may have contributed to polyphagia and ingestion of carrion by this dog.

Yersinia pestis (Plague) and Other Yersinioses

Bruno B. Chomel, Jane E. Sykes

KEY POINTS

- First Described: Descriptions of plague date back to around 1300 BC. The causative agent was isolated in 1894, in Hong Kong by Alexandre Yersin.[1,2]
- Cause: *Yersinia pestis*, a gram-negative coccobacillus (family Enterobacterales).
- Affected Hosts: *Yersinia pestis* causes disease in rodents, rabbits, wild carnivores, domestic dogs and cats, and humans. Wild felids (such as mountain lions or bobcats), goats, deer, antelope, camelids, and nonhuman primates can also develop illness.
- Geographic Distribution: USA: Southwestern United States; foci also exist in South East Asia, Africa (including the island of Madagascar), and South America (Peru, Brazil, Bolivia, and Ecuador).
- Major Mode of Transmission: Flea-borne, via an enormous variety of rodent flea species; ingestion of infected rodents or rabbits by cats and dogs. Human contamination reported by sleeping with flea-infested pets.
- Major Clinical Signs: Fever, lethargy, inappetence, lymphadenopathy, subcutaneous abscesses, hemoptysis (dogs).
- Differential Diagnoses: Tularemia, cat bite abscesses, *Streptococcus* spp. infections, feline infectious peritonitis, leptospirosis (dogs), aspiration or foreign body pneumonia (dogs).
- Human Health Significance: A small percentage (10%) of human plague cases result from exposure to infected cats, through bites, scratches, or respiratory droplet inhalation from cats with pneumonic plague. Dogs and cats can also expose humans through the carriage of infected fleas into households (especially when sleeping with owners).

ETIOLOGY AND EPIDEMIOLOGY

The genus *Yersinia* includes 11 different species, three of which are pathogenic in humans, cats, and dogs: *Yersinia pestis*, the agent of plague, and the two enteropathogenic species *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*. Only *Y. pestis* is transmitted by arthropod vectors. Plague is caused by *Y. pestis*, a coccobacillus of the family Enterobacterales. It is a nonmotile, non–spore-forming, facultative anaerobic, gram-negative, bipolar-staining bacterium. The bacterium is non-saprophytic and sensitive to desiccation and temperatures ≥ 40°C. However, it can survive for several weeks to months in organic material such as infected carcasses, and survival in contaminated soil has been confirmed in natural conditions for at least 24 days and in experimental conditions for up to 40 weeks.[2,3] Cold temperatures or freezing may prolong the viability of this organism for years. The organism grows slowly in culture even at its optimum temperature (28°C on blood agar or MacConkey agar), so cultures should be held for at least 48 hours before being discarded. Colonies are much smaller than those of other Enterobacterales and may be overlooked. As recently as 1500 to 20,000 years ago, *Y. pestis* evolved from *Y. pseudotuberculosis*, a relatively benign enteric bacterium that is transmitted through contact with contaminated food and water.[3] As part of its transition from an enteric to vector-borne pathogen, *Y. pestis* has acquired two unique plasmids (pPla and pMT1), possesses genes required for persistence outside the vertebrate or vector, and gained apparently new functions for several chromosomal genes. *Yersinia pestis* produces a lipopolysaccharide endotoxin and a capsular envelope containing the antiphagocytic principal fraction I antigen. Three geographic variants of *Y. pestis* (*orientalis, antiqua*, and *mediaevalis*) have been distinguished biochemically but have identical virulence.

Yersinia pestis is maintained in wild burrowing rodents in rural regions of Asia (including the Middle East), Africa, and the Americas (Fig. 73.1). There is no plague in the Australian continent and New Zealand, Oceania, Japan, Taiwan, the Philippines, and Indonesia. The last case of plague in Europe was reported after World War II. The organism is transmitted between rodents by rodent fleas; humans, dogs, and cats are usually accidental and "dead-end" hosts (although direct transmission can occur through aerosols in humans and cats with pneumonic disease). Fleas become infected when they feed on heavily bacteremic rodents. The organism replicates in the flea gastrointestinal tract and creates in some flea species, such as *Xenopsylla cheopis*, the Oriental rat flea, a blockage of the proventriculus, located prior to the flea stomach, which causes the "starved" flea to repeatedly and aggressively feed and regurgitate bacteria into the bite site of a new host.[4,5] Infection is maintained by an obligatory flea-rodent-flea cycle involving bacteremic rodent hosts and their resident fleas (Fig. 73.2). More than 80 flea species have been found to be naturally infected with *Y. pestis*, and at least 28 flea species occurring in North America have been experimentally confirmed as vectors.[6] A large number of flea species can transmit *Y. pestis*, but some flea species, such as the Oriental rat flea *(X. cheopis)* worldwide and the ground squirrel flea *(Oropsylla montana)* in the western United States are particularly efficient vectors. Although nowhere near as efficient as these two fleas as a vector, the cat flea *(Ctenocephalides felis)*, for which the proventriculus blockage is usually absent, can infest rodent reservoirs and also has the potential to transmit *Y. pestis*.[7] However, the rapid transit of *Y. pestis* in the cat flea digestive tract makes the cat flea a poor plague vector. *Yersinia pestis* attains very high concentrations in rodent blood (108 organisms/mL) before the death of the rodent occurs, which allows fleas to acquire sufficient numbers of bacteria for efficient transmission to other rodents.[8] Fleas can remain infected for more than a year, which permits transmission long after the death of an infected rodent. Efficient transmission between rodents is enhanced by the fact that rodent fleas, which

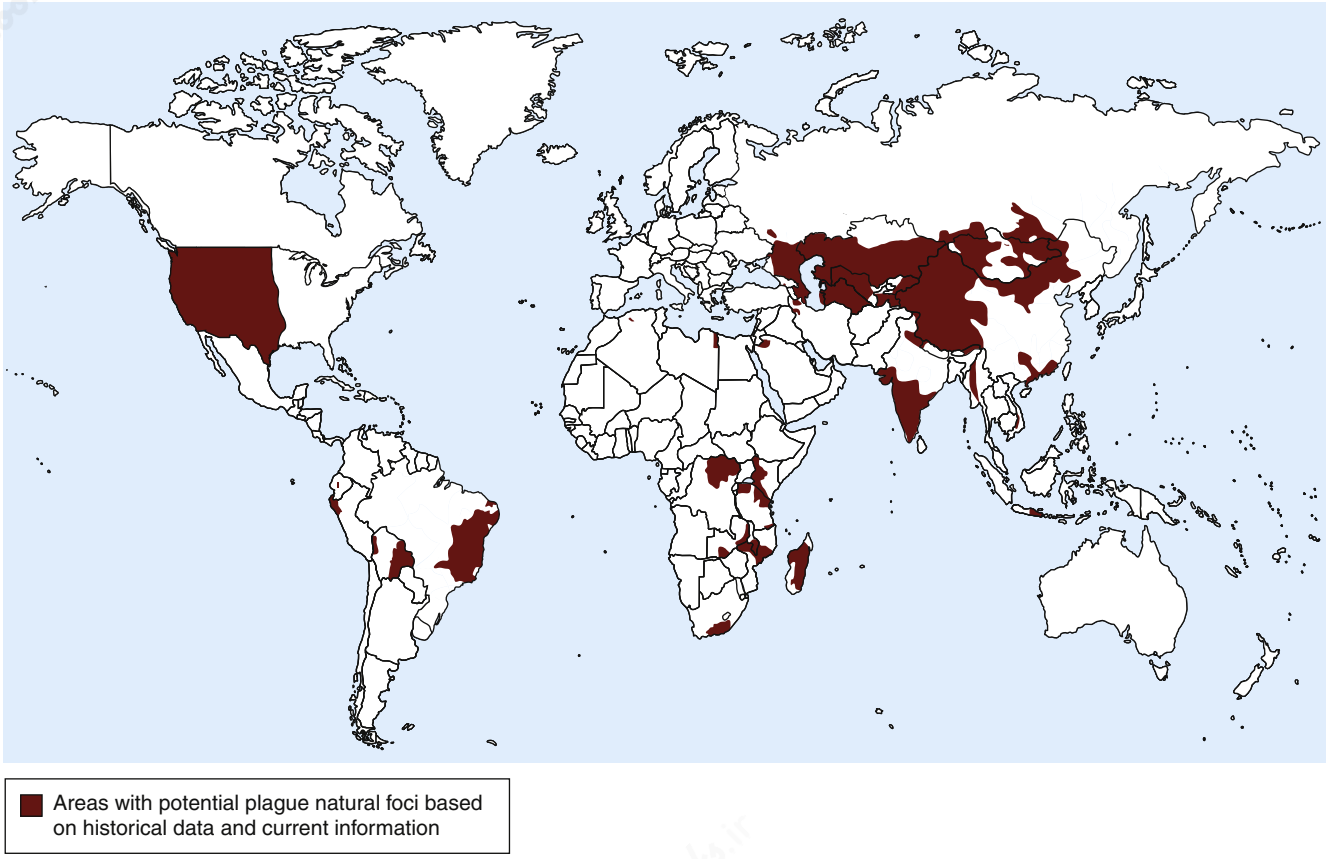

Fig. 73.1 Worldwide distribution of plague endemic areas. Data compiled from the World Health Organization, Centers for Disease Control and Prevention, and other sources. (From Centers of Disease Control and Prevention. Prevention of plague: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep.* 1996;45:1-15. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases,* 7th ed. Philadelphia, PA: Churchill Livingstone, Elsevier; 2011.)

are temperature sensitive, will search for a new warm-blooded host when their rodent host dies.

In the United States, plague foci are located throughout an area bounded on the east by the Rocky Mountains, with some incursions in the great Midwest plains, and on the west by the Pacific Ocean (Fig. 73.3). In North American carnivores, seroprevalence is highest in mustelids; intermediate in ursids (bears), felids, and canids; and lowest in procyonids.[9] Plague is transmitted to cats or dogs when they ingest or come into close contact with infected mammals (especially rodents or rabbits) or less commonly, after the bite of a rodent flea. Lesions of cats infected orally under experimental conditions were consistent with those in naturally infected cats. This corroborates the contention that cats most commonly contract plague through consumption of *Y. pestis*–infected rodents and not as a result of a flea bite. The histopathology of *Y. pestis* disease in these cats was comparable to that described for human plague.[10] Of 60 cats diagnosed with plague in one study, 75% had hunted rodents.[11]

Humans are infected by: (1) the bite of an infected flea (most common); (2) direct contact with contaminated tissues (such as handling dead rodents, rabbits, or other dead wild mammalian carnivores); or less frequently (3) inhalation of respiratory secretions by infected animals, especially cats (see Fig. 73.2). Death of a rodent from plague can cause the rodent's fleas to bite humans and other animals in a search for an alternative blood meal.

In the United States, plague in humans, dogs, and cats is now uncommon, although it is likely under-recognized in dogs and cats, and early recognition requires a high index of suspicion for the disease in endemic regions, because of the nonspecific nature of clinical signs.[12] Cats are more susceptible to disease than dogs. Affected dogs and cats can be of any age, breed, and sex, with a mean age of 3 years in one feline case series,[11] and 4 years in another.[13] Most plague cases in humans and cats occur in the southwestern United States, particularly northern New Mexico, but also southern Colorado, northern Arizona, and to a lesser extent California, southern Oregon, and western Nevada (especially in the Sierra Mountain ranges) (see Fig. 73.3). In 2016, plague was identified in six cats from Idaho; five were from southwestern Idaho, where dead ground squirrels with plague had been identified, and one was from eastern Idaho.[13] The probability of an area in the United States being a high-risk plague habitat increases with elevation up to 2300 meters and declines as elevation increases thereafter.[14]

Rodent or rabbit species associated with human cases include white-tailed antelope squirrels, ground squirrels, rock squirrels, cottontail rabbits, jack rabbits, prairie dogs, deer mice, Colorado chipmunks, and wood rats.[5] The prevalence of antibodies to *Y. pestis* in a survey of 4115 pet dogs and 466 pet cats from California in the mid-1990s was less than 5% in both species.[15]

In general, plague has a seasonal distribution that correlates with the timing of epizootics that lead to a die-off of susceptible rodents. In the United States, most plague cases occur from February through August, when rodents and their fleas are most active and humans and their companion animals are more likely to be outdoors. However, cases also occur outside these months, and so plague should not be

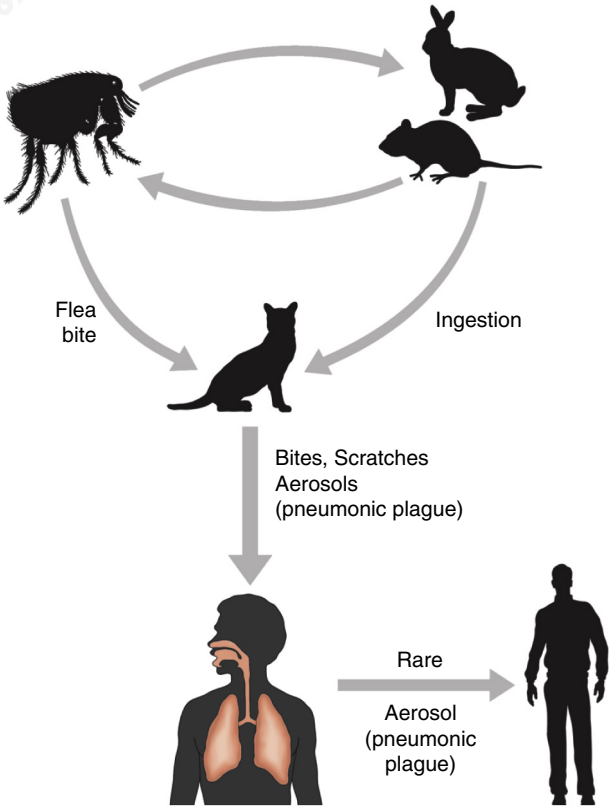

Fig. 73.2 The role of the cat in transmission of *Yersinia pestis* to humans. Most humans are infected by direct contact with wildlife reservoir hosts or a bite from an infected flea, but infections can also occur as a result of cat bites or direct exposure to cats that have pneumonic plague. Dogs can also be infected but are less susceptible than cats to disease and shedding. Direct aerosol transmission from one human to another is rare and only occurs in humans that have terminal pneumonic plague.

ruled out based on season. Interannual variability of plague incidence in endemic regions can be influenced by annual precipitation.[16] Summer soil moisture favors flea survival and vegetation growth for rodent populations. Global climate warming will likely influence the distribution of plague, with an expected shift of endemic regions away from the Equator.[17]

In general, the organism does not survive well in the environment outside infected hosts, with survival less than 72 hours on hard surfaces.[18] However, *Y. pestis* survived at least 24 days in blood-contaminated soil that was protected from UV light.[19] The extent to which environmental survival of *Y. pestis* contributes to the geographic distribution and epidemiology of the disease requires further clarification.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

After inoculation into the mammalian host by fleas, *Y. pestis* is taken up by mononuclear cells, in which it survives, replicates, and produces F1 capsular envelope antigen. The envelope allows it to further resist phagocytosis, and a number of other virulence determinants including the *Yersinia* outer membrane proteins (Yomps), the Psa fimbriae antigen, and a broad-range protease known as Pla allow it to evade the immune system.[20] Cats and dogs usually become infected after they ingest or come into close contact with bacteremic rodents or other wildlife species that may have died of plague. In this situation, the organism has already produced a capsule and disseminates more rapidly than occurs after flea-borne transmission. Organisms are carried by lymphatics to regional lymph nodes. In more than half of affected cats, this results in an intense neutrophilic inflammatory response, variable fever, prostration, inappetence, and formation of the *bubo*, which is an enlarged and tender lymph node that occasionally forms an abscess and drains purulent material. This form of disease is known as *bubonic plague* and is the least fatal form of the disease. The location of

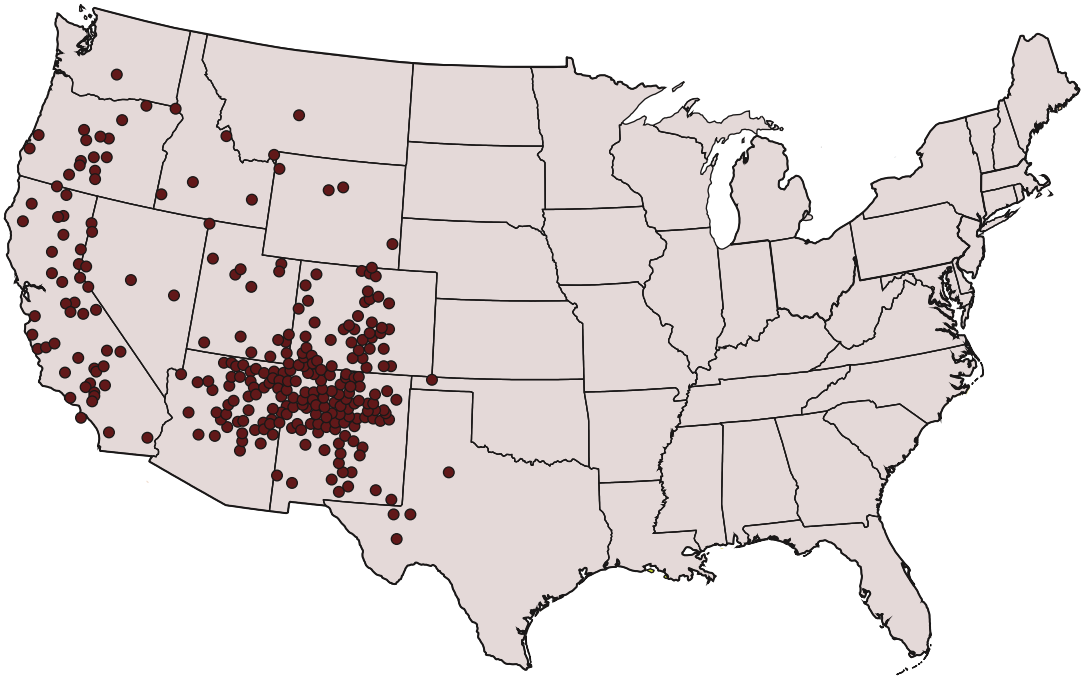

Fig. 73.3 Approximate distribution of human plague cases in western United States, 1970 to 2020. Each dot represents a case, with the dot placed randomly in the county of exposure. (Modified from Mead PS. *Yersinia* species (including plague). In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases,* 8th ed. Philadelphia, PA: Elsevier Saunders, 2015. Data from 2007-2020 collated from ProMed-Mail reports, http://www.promedmail.org/.)

the bubo(es) depends on the initial site of infection. In cats that ingest infected rodents, the mandibular or retropharyngeal lymph nodes are usually involved, and affected cats shed bacteria from the oropharynx. Less often (around 20% of cats with bubonic plague), other peripheral lymph nodes are involved; this may follow flea-borne transmission that occurs at sites distant to the head.[11]

In some cats, bubo formation is accompanied by bacteremia, with associated endotoxemia and sepsis, and formation of hemorrhagic, neutrophilic, and necrotizing lesions in many organs. Disseminated intravascular coagulation and multiple organ failure can then ensue. Signs of severe sepsis or septic shock in affected cats include tachypnea, vomiting, tachycardia or bradycardia, and weak pulse quality. In some situations, bacteremia and multiple organ involvement occurs in the absence of identifiable buboes (*septicemic form*), which has a high mortality rate. *Pneumonic plague* occurs in about 10% of affected cats as a result of hematogenous spread of bacteria to the lungs or, less often, by inhalation of organisms and can result in dyspnea and cough. It has also been described in dogs.[12] The incubation period for plague is estimated to be 1 to 6 days, with shorter incubation periods after ingestion or inhalation of the organism, and death can occur within 2 to 3 days in the absence of appropriate treatment; occasionally the clinical course extends for 2 to 3 weeks. Some (<20%) cats show no signs of illness, or there may be transient fever, decreased appetite, and recovery. Transient febrile illness is also common in dogs.

Physical Examination Findings

Physical examination in cats with plague reveals lethargy (82% of cats), fever (71% of cats; mean rectal temperature of 40.5°C [105.1°F]), dehydration, a thin body condition, and lymphadenopathy. Lymphadenopathy most often involves the mandibular nodes. In one case series, 33% of 67 cats with bubonic plague had bilateral lymphadenopathy, 32% had left-sided lymphadenopathy, and 13% had right-sided lymphadenopathy; in the remainder of cats, the location was not known.[11] Bilateral disease occurred only when the mandibular and cervical nodes were involved. Lymph nodes may be markedly enlarged (up to 8 cm, with a mean of around 4 cm); may be edematous, abscessed, and painful on palpation; and may drain purulent material. Drainage was reported in 6 (15%) of 40 cats with bubonic plague. Dyspnea or tachypnea can be present in cats with pulmonary involvement or possibly as a result of painful lymphadenopathy. Other reported physical examination abnormalities in cats with plague include ocular or nasal discharge (14% of cats) and abscesses that involve sites other than the lymph nodes, such as the sublingual region or the tongue, oral cavity, face, limbs, or trunk. Physical examination findings in dogs suspected to have plague have included fever, lethargy, mandibular or cervical bubo formation, oral ulceration and ptyalism, tachypnea, and cough, sometimes with hemoptysis.[12,21] In a report that described plague in 62 dogs from New Mexico, clinical signs included fever (100%), lethargy (97%), anorexia (77%), lymphadenopathy (23%), vomiting (13%), diarrhea (8%), and abscesses (2%).[22]

DIAGNOSIS

Diagnosis of plague is based on a history of residence in an endemic area as well as contact with, or predation of, wild mammals (especially rodents or lagomorphs). Duration of illness, physical examination findings, and lymph node aspirate cytology also support the diagnosis. Clinicians should not exclude plague as a diagnosis based on season.[12] There is a relative lack of information available on laboratory abnormalities in dogs and cats with plague because the disease is rare. Ultimately, a diagnosis of plague can only be confirmed by culture, direct fluorescent antibody testing, and/or serologic testing. Confirmation of the diagnosis may ultimately take weeks, so a high level of suspicion for the disease is needed in endemic areas.

Laboratory Abnormalities

Hematologic abnormalities in naturally infected cats most often consist of mild to moderate neutrophilia, usually with a mild to moderate left shift, and occasionally lymphopenia and monocytopenia.[11,12] Leukopenia with a left shift can also occur in cats and dogs with pneumonic plague. Platelet counts have not been widely reported in naturally infected cats but may be low in cats with severe sepsis; thrombocytopenia has also been reported in dogs with pneumonic plague.[12] The serum biochemistry panel may show hypoalbuminemia, hyperglycemia, azotemia, electrolyte abnormalities, hyperbilirubinemia, and increased liver enzyme activities.[12,23] In the canine case series from New Mexico, a CBC was performed for 31 dogs; of these, 27 (87%) had a high WBC count and 18 (58%) had neutrophilia. The median WBC count was 21.6 × 10^3 WBCs/μL (range, 5.5 × 10^3 WBCs/μL to 38.1 × 10^3 WBCs/μL); median absolute neutrophil count was 16.5 × 10^3 neutrophils/μL (range, 1.8 × 10^3 neutrophils/μL to 24.5 × 10^3 neutrophils/μL).[22]

Diagnostic Imaging

Plain Radiography

Findings on thoracic radiography in cats with pneumonic plague have not been described in detail, but include diffuse interstitial, alveolar, and often nodular lung opacities. Findings in dogs with pneumonic plague have included lobar consolidation as well as patchy alveolar opacities.[12] Similar findings have been described in humans with pneumonic plague.[24]

Sonographic Findings

Abdominal ultrasound findings in cats with plague have not been reported. Based on pathologic findings, they might include abdominal lymphadenomegaly, splenomegaly, and hepatomegaly.

Computed Tomography

Computed tomography findings were reported for a dog with plague and consisted of unusual findings of unilateral lung lobe consolidation, small foci of parenchymal density in other lobes, and intrathoracic lymphadenomegaly (Fig. 73.4).[25] These were considered atypical for pneumonic plague, but are typical for human pneumonic plague.[24]

Microbiologic Tests

Diagnostic assays currently available for plague in dogs and cats are described in Table 73.1.

Cytologic Demonstration of Bacteria

Yersina pestis is usually found in large numbers in tissues. If plague is suspected, aspirates of buboes or other affected tissues should be collected and smears prepared in isolation while wearing protective clothing, including eye protection and properly fitted high-density (N95) face masks (see Chapter 15). The smears should be heat fixed or immediately immersed in fixative solution to inactivate any organisms present. Cytologic examination shows massive numbers of neutrophils and a monomorphic population of coccobacilli with bipolar staining (Fig. 73.5). This is in contrast to cat bite abscesses, where a mixture of bacteria is usually present.

Direct Immunofluorescent Antibody and Antigen ELISA Assays

Heat-fixed slides prepared from lymph node aspirates can be submitted to approved testing facilities for application of immunofluorescent

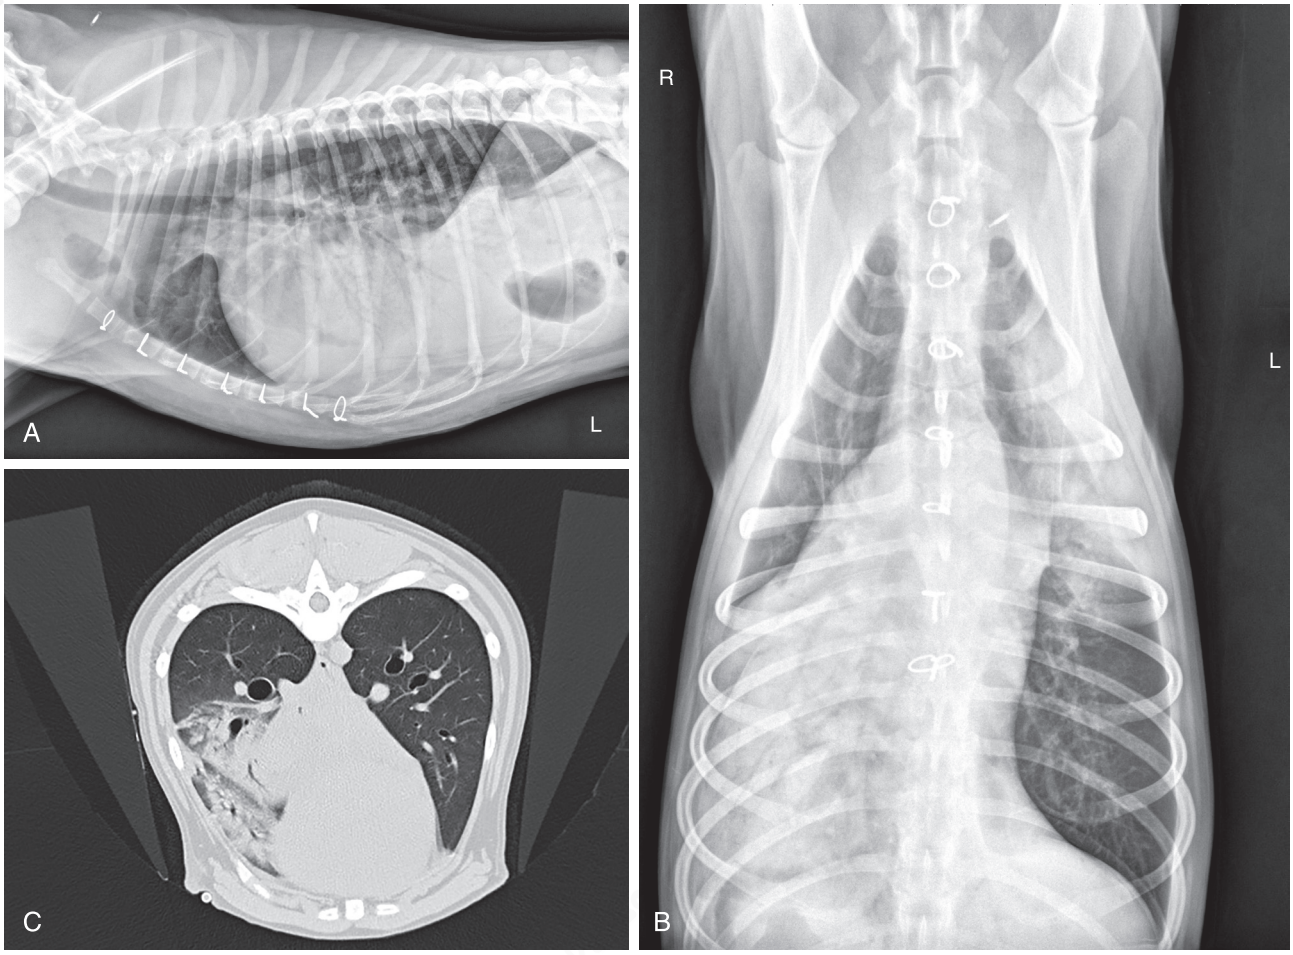

Fig. 73.4 Lateral (A) and ventrodorsal (B) thoracic radiographs and computed tomography scan (C) from a dog with plague showing severe lung consolidation and alveolar infiltrates. (A and B, from Schaffer PA, Hershkowitz CS, Dowers KL, et al. Delayed diagnosis of fatal pneumonic canine plague: clinical and pathologic features in two naturally infected Colorado dogs. *BMC Vet Res*. 2020;16(1):160. Published 2020 May 25. doi:10.1186/s12917-020-02361-z. C, from Schaffer PA, Brault SA, Hershkowitz C, et al. Pneumonic plague in a dog and widespread potential human exposure in a veterinary hospital, United States. *Emerg Infect Dis*. 2019;25:800-803.)

TABLE 73.1 Diagnostic Assays Available for Plague in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture	Lymph node aspirates, blood, tissues collected at necropsy	*Yersinia pestis*	Recent antibiotic treatment may cause false-negative results. May take 48 hours for colonies to appear. Hazardous to laboratory personnel and should be sent to laboratories with appropriate expertise when possible. MALDI-TOF may not accurately distinguish between *Y. pestis* and *Y. pseudotuberculosis*
Cytology	Lymph node aspirates	*Y. pestis* organisms (bipolar-staining bacilli)	Low sensitivity. Recent antibiotic treatment may cause false-negative results
Direct IFA	Lymph node aspirates, tissues collected at necropsy	*Y. pestis* F1 antigen	Increases sensitivity for detection of *Y. pestis* over cytology alone, but false negatives can still occur. Recent antibiotic treatment may cause false-negative results. Must be performed by laboratories with expertise in plague diagnosis
Serology	Serum	Antibodies to *Y. pestis*	Acute and convalescent serology is required for diagnosis of acute infection, because initial results may be negative, and positive results may reflect previous exposure rather than active infection
PCR-based assays	Lymph node aspirates, blood, tissues	*Y. pestis* DNA	Assays have not been validated in dogs and cats but several assays exist for diagnosis of human plague

antibody (direct IFA) against the F1 envelope antigen. Local public health authorities should be contacted for information on recommended testing facilities if direct IFA testing is required. IFA can also be applied to impression smears from tissues obtained at necropsy. Negative direct IFA results do not rule out plague, so culture and serology should also be considered.[11] A recombinant F1 antigen assay has been developed and offers advantages of lower biosafety requirements when compared to assays that use conventional F1

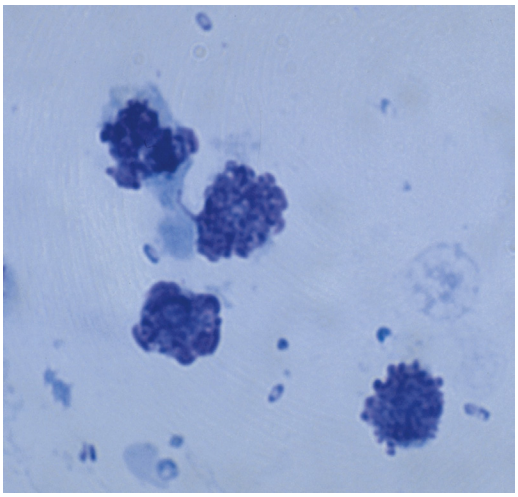

Fig. 73.5 Lymph node aspirate cytology from a cat with bubonic plague. Bipolar rods are scattered throughout the field. (From Nelson RW, Couto CG, eds. *Small Animal Internal Medicine,* 4th ed. St. Louis, MO: Mosby; 2009.)

antigen.[26] A lateral-flow dipstick assay has been described for rapid (within 15 minutes), sensitive, and specific POC diagnosis of plague in human patients, although false negatives may still occur.[27,28] This assay detects F1 antigen in body fluids such as sputum, lymph node aspirates, serum, and urine and has an estimated shelf life of about 2 years at room temperature. It has not been validated for diagnosis of plague in cats.

Isolation and Identification

Yersinia pestis can be grown from clinical specimens on routine media used for isolation of organisms that belong to the Enterobacterales. The organism grows slowly, and colonies are smaller than those of other Enterobacterales, so cultures must be held for at least 48 hours. If plague is suspected, specimens should never be shipped to routine veterinary diagnostic laboratories. Instead, local public health authorities should be contacted immediately for instructions regarding how and where to submit specimens for culture of *Y. pestis*. MALDI-TOF has been used to identify *Y. pestis*, but in the report that described the dog seen with plague at Colorado State University, the organism was incorrectly identified as *Y. pseudotuberculosis* with a high confidence score.[25] Because of concerns that the signs were not typical for *Y. pseudotuberculosis*, a PCR assay was done the following day (5 days after admission) that identified the organism as *Y. pestis*.

Serology

Acute and convalescent serology is required for serologic diagnosis of plague in cats and dogs. The most widely used serologic test is a passive hemagglutination inhibition (HI) assay (see Chapter 2), which is available through public health laboratories approved for plague diagnosis. Because of the extremely short incubation period, a significant proportion of affected cats and dogs may have negative titers when they first are brought to the veterinarian, so convalescent serum should be submitted at least 10 to 14 days after the initial titer request. Some cats may die before a rise in antibody titer occurs.[23] A fourfold increase in titer together with consistent clinical abnormalities confirms the diagnosis of plague. Titers in affected cats in one study ranged from less than 1:4 for acute specimens to 1:8192 for convalescent specimens.[11] In the case series of dogs from New Mexico, 54 plague cases had paired serologic samples tested, with 53 (98%) having positive test results on one or both samples, but only 2 (4%) dogs having positive results for the first serologic test. The median number of days between acute and convalescent serologic sample collection was 18 days, with a range of 10 to 54 days. Median convalescent antibody titer was 512 (range, 32 to 4,096).[22]

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays have been described for detection of *Y. pestis* DNA and are an attractive means of diagnosis because of their sensitivity and rapid turnaround time. In addition, the organism can be deliberately inactivated before specimens are submitted to the laboratory for PCR testing, which reduces the risk of laboratory-acquired infection. Real-time PCR assays have been validated for use on clinical specimens from humans,[28] but to date assays have not been validated for diagnosis of the disease in cats or dogs. The real-time PCR assay used to diagnose plague in a dog seen at Colorado State University was based on a CDC laboratory response network protocol (https://www.epa.gov/homeland-security-research/sam-and-us-centers-disease-control-and-prevention-cdc-laboratory-response).[25] Complex assays have been described that are able to accurately identify small sequence differences between *Y. pestis* and *Y. pseudotuberculosis*.[29] Real-time PCR was considerably more sensitive for diagnosis of human plague in Africa than the lateral-flow dipstick antigen assay or culture. A sensitive and specific isothermal amplification assay for rapid detection of *Y. pestis* has also been developed that could be used in field situations in highly endemic regions.[30]

Pathologic Findings

Gross pathologic findings in cats with plague include enlarged lymph nodes or abscesses with associated edema and hemorrhage, focal (up to 1 cm) lung lesions, and hemorrhages in a variety of organs. Histopathology in dogs and cats reveals hemorrhage, necrosis, neutrophilic infiltrates, fibrinopurulent pleuritis, and often very large numbers of small coccobacilli in tissues (although these are not always present) (Fig. 73.6).[12]

TREATMENT AND PROGNOSIS

Treatment of cats and dogs with plague involves supportive care, abscess drainage, and antimicrobial drug administration (Table 73.2). Animals suspected to have plague should be housed in isolation at least for the first 72 hours of antimicrobial drug therapy and handled by as few individuals as possible. Thoracic radiographs should be taken to assess for pulmonary involvement. Public health authorities should be notified immediately. Gowns, gloves, and suitable face protection (eye protection and a properly fitted high-density [N95] surgical mask) should be worn, and protective wear should be properly removed and disposed of after handling affected cats. Cats and dogs with plague should also be treated for fleas. Abscesses should be lanced and flushed with chlorhexidine solution. Any biohazardous waste should be double bagged and disposed of correctly. Routine disinfectants can be used to inactivate the organism in the environment. Antimicrobials with activity against most isolates of *Y. pestis* are aminoglycosides, tetracyclines such as doxycycline, chloramphenicol, and fluoroquinolones. In the New Mexico study, most plague-case dogs received enrofloxacin or doxycycline.[22,31-33] Trimethoprim-sulfamethoxazole and chloramphenicol also have activity against *Y. pestis*. Parenteral aminoglycosides such as gentamicin are preferred for seriously ill animals. Mortality rates in naturally infected cats that are not treated with antimicrobial drugs can reach 75%, but most (>90%) cats treated with antimicrobial drugs survive.[11] The time between antimicrobial drug treatment and recovery of affected cats ranged from 1 to 10 days in one study (mean, 4.4 days).[11]

TABLE 73.2 Suggested Antimicrobial Drugs for Treatment of Plague in Cats and Dogs

Drug	Species	Dose (mg/kg)	Route	Interval (Hours)	Duration
Doxycycline	D, C	10	IV or PO*	24	10 days
Gentamicin	C	5–8	IV, IM, SC	24	10 days
	D	9–14	IV, IM, SC		
Enrofloxacin	D, C**	5	IV, IM, or PO	24	10 days

*Oral administration should be avoided for at least the first 72 hours of treatment to minimize exposure of the caregiver to *Y. pestis*. For IV doxycycline administration, dilute in 100 mL of lactated Ringer's saline and administer over 2 hours; if fluid overload is a concern, consider parenteral tetracycline or use of an aminoglycoside.

**The use of enrofloxacin to treat cats is controversial because of the potential for irreversible retinal toxicity and blindness. Do not exceed a dose of 5 mg/kg in cats. The use of alternative fluoroquinolones such as marbofloxacin, orbifloxacin, or pradofloxacin should be considered for cats.

IMMUNITY AND VACCINATION

There are no plague vaccines for dogs and cats. Although vaccines have been used to prevent plague in highly at-risk humans, these did not protect against pneumonic plague. Vaccine development for humans is continuing; for example, a vaccine based on a *Y. pseudotuberculosis* strain that produces an F1 pseudocapsule protected mice against both bubonic and pneumonic plague.[34] Currently there are no vaccines approved for use in the United States. Because *Y. pestis* is a potential agent of bioterrorism, efforts have been focused on development of subunit vaccines. However, *Y. pestis* has also been considered an unlikely agent of bioterrorism because in general it does not survive well in the environment, and person-to-person transmission requires close contact (1 m or less [3 feet]) with a dying person, usually on the last day of life.[5,22]

PREVENTION

Prevention of plague in dogs and cats involves housing cats indoors in endemic areas and discouragement of predation or exposure to/consumption of wild animals. Dogs should not be allowed to dig in endemic areas where rodent burrows exist. Flea preventatives should reduce the chance that dogs and cats will carry infected fleas into the house. Rodent control in the environment (e.g., removal of garbage and food scraps) should also be performed.

PUBLIC HEALTH ASPECTS

The clinical course of plague in humans closely resembles that in cats (Fig. 73.7). Three major pandemics of plague have occurred in humans: Justinian plague, which occurred in the Mediterranean basin during the sixth century Byzantine era; the "Black Death," which began in 1347 and spread throughout Europe; and modern plague, which began in China in the 1860s and was subsequently spread by rat-infested steamships to all continents inhabited by humans.[35] Interesting parallels have been drawn between the Black Death and the COVID-19 pandemic.[35] Currently, more than 80% of human plague cases reported to the WHO originate from sub-Saharan Africa and Madagascar. In the 1970s, Vietnam was the country reporting most human cases. From 1900 (when it first appeared) to 2015, 1036 cases were reported in the United States (www.cdc.gov). Between 2000 and 2019, 107 cases were reported to CDC with 11 deaths. The overall death rate in the United States for humans treated for plague is 15% to 22%. In endemic regions, humans who have close contact with rodents or their canine or feline predators are at risk. Most humans are infected as a result of contact with rodent fleas. Human disease has also been reported after skinning of rabbits or contact with wild carnivores (Fig. 73.8).[24,36] Fewer than 10% of human plague cases result from exposure to cats, with infection transmitted from cats to humans after a bite, scratch, or inhalation of respiratory droplets from cats with pneumonic plague.[37-39] However, exposure to cats often results in pneumonic plague, which has the worst prognosis and can progress to death within as little as 24 hours after the onset of symptoms. From 1977 to 1998, the CDC confirmed

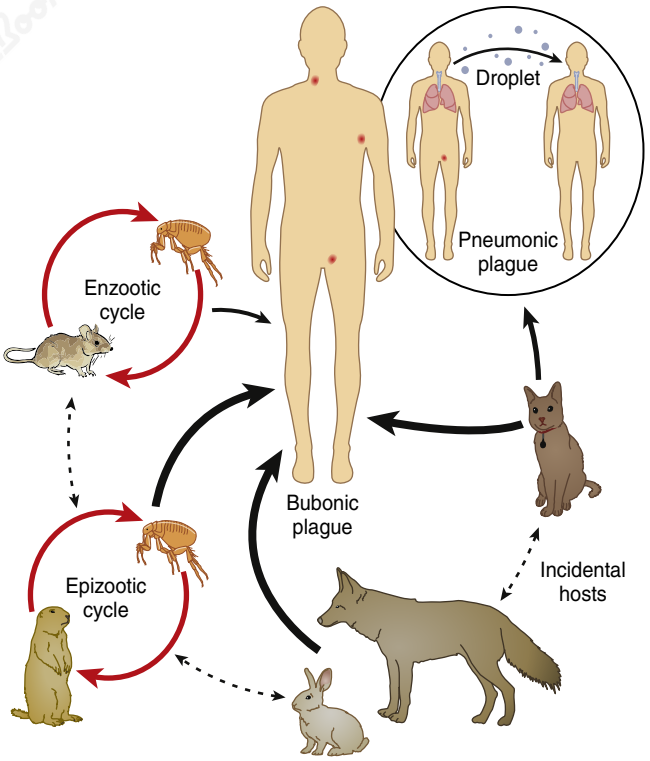

Fig. 73.8 Ecology and transmission of plague to humans. Red circles indicate zoonotic cycles. Wide solid arrows indicate common routes and thin arrows indicate uncommon routes of transmission to humans. (From Mead PS. Plague *(Yersinia pestis).* In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell Douglas and Bennett's Principles and Practice of Infectious Diseases,* 9th ed. Philadelphia, PA: Elsevier, 2019:2781, Fig. 229A.3)

23 human plague infections acquired through inhalation of *Y. pestis*–infected droplets expelled from cats with secondary plague pneumonia.[40] Approximately one-fifth of those infected died, and one-fourth of those infected were veterinarians or their technicians. The remaining three-fourths of those infected were owners of or humans caring for sick cats. Approximately three-fourths of the humans developed bubonic plague, one person developed septicemic plague, and the remainder developed a pneumonic infection.[41] During 1926 to 2012, six (43%) of all primary pneumonic cases of human plague that occurred in the United States had contact with domestic cats.[42]

Occasionally, dogs or cats carry rodent fleas into the house, which may then transmit the infection to humans. Sleeping with a dog may also increase the risk of infection, and transmission of *Y. pestis* through contact with dogs has been increasingly recognized in recent years.[25,36,43,44] Exposure to infected fleas carried into a household by a dog was suspected in a report of two affected humans in Oregon, one of whom slept in the same bed with the pet dog during the 2 weeks before onset of illness.[43] The dog seroconverted to *Y. pestis*. Widespread exposure of 116 veterinary personnel at Colorado State University was reported in 2017 when a dog that had sniffed a dead prairie dog was seen for lethargy, fever, and hemoptysis.[25] In that dog, plague was initially not thought to be likely because the animal was a dog (rather than a cat), the season, a lack of peripheral lymphadenomegaly, and a radiographic imaging pattern suggestive of a foreign body. From 1970 to 2017, the proportion of plague cases associated with animal exposure in the United States increased over time, and 154 of 258 patients with animal exposure had contact with domestic animals before illness, including 121 with dogs and 102 with cats. Of those 154 patients, 42% had exposure to a domestic animal that brought wild animals into the house; 20% reported co-sleeping with their pet.[36] Most patients were reported from New Mexico (52%), followed by Colorado (14%) and Arizona (13%). Of those that had wild animal contact before development of plague, 40% reported skinning, 24% reported handling a sick or dead animal, and 22% reported casual handling or touching a wild animal.[36] Of six pneumonic plague cases associated with occupational exposure, five were veterinarians or veterinary technicians who were caring for animals with plague.

Pet flea control and reduction of exposure to rodents also serve to reduce plague in humans. Pet owners should be made aware that pets can carry fleas (and ticks) into the house and that flea control may reduce the chance of arthropod-transmitted human disease. Adoption of wild animals should be discouraged. In the veterinary hospital situation, plague can be prevented if there is a high index of suspicion for the disease and appropriate precautions are taken (see Treatment and Prognosis). Owners of pets suspected to have plague should be advised to contact their physicians without delay. Humans with exposure to affected animals are generally treated with prophylactic doxycycline or levofloxacin for 7 days.[24]

OTHER YERSINIOSES

Yersinia pseudotuberculosis and *Y. enterocolitica* are enteropathogenic bacteria that are distributed worldwide. They are classified into serotypes based on their O antigens, with different classification systems used for the two pathogens. Enteropathogenic yersiniae are maintained in a variety of food animals and wild animal reservoirs and are well-known causes of food-borne febrile gastrointestinal illness in humans; reactive arthritis may be a complication of infection in 15% of patients.[24] Pigs are a major reservoir for *Y. enterocolitica,* and outbreaks have primarily followed consumption of undercooked pork products.[24] *Yersinia enterocolitica* can also grow in food held at refrigeration temperatures. Affected human patients frequently exhibit right lower abdominal pain due to mesenteric adenitis or ileitis, which can mimic appendicitis. A small proportion of patients develop complications such as secondary polyarthritis and erythema nodosum (panniculitis).[24] Children are most susceptible. Immunocompromised humans (such as those with diabetes mellitus, malignancy, or immunosuppressive drug therapy) can occasionally develop bacteremia with systemic spread and abscesses in a variety of different organs. The mortality rate in this situation is at least 50%.[24] Dogs and cats can shed *Y. enterocolitica* and *Y. pseudotuberculosis* in their feces in the absence of clinical signs.[45,46] *Yersinia enterocolitica* was also isolated from 19% of 144 tonsils from stray dogs in Ireland.[47] Strains found in dogs can resemble those implicated in human disease,[48] and in several reports, dogs were suspected as a source for human infection and disease. *Yersinia enterocolitica* infection was associated with hepatitis in a 2-year-old Pekingese dog from Korea[49] and hepatitis and myocarditis in a 4-month-old Rottweiler.[47] It has also been isolated from young dogs with hemorrhagic diarrhea. There have been several reports of *Y. pseudotuberculosis* infection in cats, with microabscess formation in a variety of abdominal organs.[50-53] One cat from the United Kingdom was seen for acute-onset neurological signs, fever, increased serum liver enzyme activities, and leukopenia. Histopathology of liver biopsies showed severe necrotizing and pyogranulomatous hepatitis with intralesional gram-negative bacterial microcolonies.[53] A 7-year-old Labrador retriever search-and-rescue dog that was evaluated at the authors' hospital for hemoptysis, fever, and left cranial lung consolidation had pulmonary

Y. pseudotuberculosis infection; the clinical findings resembled those described for the dogs seen at Colorado State University for plague. Cases of human transmission from pets have also been reported, such as a diarrheic puppy dog which likely transmitted the infection to a 1-year-old girl.[54]

Enteropathogenic *Yersinia* species are usually susceptible to doxycycline, trimethoprim-sulfamethoxazole, chloramphenicol, aminoglycosides, and fluoroquinolones. Some organisms produce β-lactamase enzymes. Of concern, the mortality rate in *Y. pseudotuberculosis* bacteremia has been reported as 75% despite antimicrobial treatment.[24]

In dogs and cats, prevention of enteropathogenic yersiniosis involves feeding properly cooked foods and preventing predation. Other measures to reduce zoonotic transmission include hand washing after handling dogs and cats (especially before eating), wearing gloves when contact with saliva or feces is anticipated, and preventing dogs from licking the face or open wounds.

CASE EXAMPLE

Signalment

"Sam," a 5-year-old male neutered domestic shorthair cat from Woodland, CA.

History

Sam was brought to the UC Davis VMTH emergency service for evaluation of fever and inappetence. The owner first noticed he was ill 4 days previously, when he regurgitated a small amount of pink fluid about 1 hour after eating. The following day he was not eating, lethargic, and his water consumption was reduced. On day 3, he was taken to a local veterinary clinic where he was found to be febrile (105°F [40.5°C]), icteric, and had a mass on the left side of his neck. He was treated with enrofloxacin (1 mL SC, once), ketoprofen (0.1 mL SC), and clavulanic acid-amoxicillin (1 mL PO q12h), and blood was sent out for laboratory analysis. The results of a CBC showed a mild neutrophilia (13,083 cells/μL; reference range, 2,500–12,500 cells/μL) with slightly toxic neutrophils and a mild lymphopenia (1,176 cells/μL; reference range, 1,500–7,000 cells/μL). A biochemistry panel showed hyponatremia (133 mEq/L; reference range, 147–156 mEq/L), hypochloremia (99 mEq/L; reference range, 111–125 mEq/L), hypokalemia (3.4 mEq/L; reference range, 3.9–5.3 mEq/L), hyperglycemia (214 mg/dL; reference range, 70–150 mg/dL), hyperbilirubinemia (3.7 mg/dL; reference range, 0–0.4 mg/dL), increased serum CK activity (1858 U/L; reference range, 64–440 U/L), and a mild metabolic acidosis (bicarbonate 12 mEq/L; reference range, 13–25 mEq/L). ELISA serology for FeLV antigen and FIV antibody and IFA serology for FCoV antibody were negative. On receipt of the laboratory test results, the local veterinarian recommended referral.

Sam had been fed commercial dry and canned cat food and was treated monthly with fipronil. He was acquired at 6 weeks of age, at which time he was neutered. He had been vaccinated annually by the owner for feline herpesvirus-1, feline calicivirus, and feline panleukopenia virus, and was vaccinated for rabies for the first time 4 months ago. He had a history of intermittent inappropriate urination. He lived with three other cats, three dogs, and two rabbits, and the owner had brought home a wild mouse from the Lake Tahoe (Sierras) region several weeks ago. The rabbits were acquired by the owner 6 months ago, are kept indoors, and did not receive flea control. The owner fostered cats and occasionally dogs for the local animal shelter and cared for a colony of feral cats, which did not interact with the household cats. The household cats lived harmoniously indoors.

Physical Examination

Body weight: 5.4 kg

General: Lethargic but responsive. Resents handling. T = 105.9°F [41.1°C], R = 60 breaths/min, P = 176 beats/min, CRT < 2 s.

Integument: Mild scaling was present throughout the haircoat but no ectoparasites were visible.

Eyes, ears, nose, and throat: No significant clinical abnormalities. A small amount of dental calculus was present.

Musculoskeletal: Body condition score 6/9. There was a 2 × 2 × 6 cm firm subcutaneous mass alongside the trachea on the left side.

Cardiovascular: There were no murmurs or arrhythmias detected on cardiac auscultation. Pulses were strong and synchronous.

Respiratory: Tachypnea with a shallow respiratory pattern. Normal bronchovesicular sounds were present in all lung fields.

Abdominal palpation: No clinically significant abnormalities. Bladder palpable but small.

Lymph nodes: Left mandibular lymph node enlarged, 2 cm. All other lymph nodes appeared to be within normal limits.

Laboratory Findings

CBC: HCT 20.3% (30–50%), MCV 42.9 fL (42–53 fL), MCHC 33.0 g/dL (30–33.5 g/dL), reticulocytes 9,500 cells/μL (7,000–60,000 cells/μL), WBC 23,120 cells/μL (4,500–14,000 cells/μL), neutrophils 18,958 cells/μL (2,000–9,000 cells/μL), band neutrophils 3,699 cells/μL, lymphocytes 231 cells/μL (1,000–7,000 cells/μL), monocytes 231 cells/μL (50–600 cells/μL), eosinophils 0 cells/μL (150–1,100 cells/μL), basophils 0 cells/μL (0–50 cells/μL), platelets 102,000/μL (180,000–500,000 platelets/μL).

Serum chemistry profile: anion gap 18 mmol/L (13–27 mmol/L), sodium 143 mmol/L (151–158 mmol/L), potassium 3.2 mmol/L (3.6–4.9 mmol/L), chloride 110 mmol/L (117–126 mmol/L), bicarbonate 18 mmol/L (15–21 mmol/L), phosphorus 3.0 mg/dL (3.2–6.3 mg/dL), calcium 8.8 mg/dL (9.0–10.9 mg/dL), BUN 15 mg/dL (18–33 mg/dL), creatinine 0.8 mg/dL (1.1–2.2 mg/dL), glucose 151 mg/dL (63–118 mg/dL), total protein 6.6 g/dL (6.6–8.4 g/dL), albumin 2.5 g/dL (2.2–4.6 g/dL), globulin 4.1 g/dL (2.8–5.4 g/dL), ALT 30 U/L (27–101 U/L), AST 39 U/L (17–58 U/L), ALP 5 U/L (14–71 U/L), GGT < 3 U/L (0–4 U/L), cholesterol 134 mg/dL (89–258 mg/dL), total bilirubin 2.1 mg/dL (0–0.2 mg/dL), magnesium 2.0 mg/dL (1.5–2.5 mg/dL), creatine kinase 586 U/L (73–260 U/L).

Urinalysis: SpG 1.014; pH 8.0, trace protein (SSA), 1+ bilirubin, 2+ hemoprotein, 2+ glucose, rare WBC/HPF, 7–12 RBC/HPF, few lipid droplets.

Imaging Findings

Thoracic radiographs: No clinically significant abnormalities were present.

Abdominal ultrasound: No clinically significant abnormalities were present.

Neck ultrasound: There was moderate to severe enlargement of the retropharyngeal lymph nodes bilaterally and of the left mandibular salivary gland.

Microbiologic Testing

Cytologic examination of lymph node aspirates (mandibular and retropharyngeal): A slightly bloody background is admixed with markedly increased numbers of variably degenerate neutrophils. Low numbers of a mixed population of lymphocytes and scattered macrophages are also observed.

Interpretation: Marked suppurative inflammation.

Comments: Although no intracellular bacteria were seen, the number of neutrophils and their variably degenerate nature suggested sepsis as the primary differential diagnosis. The ability to observe bacteria cytologically and the results of bacterial culture may have been affected by recent antibiotic treatment.

Aerobic and anaerobic bacterial culture and susceptibility (lymph node aspirate): No growth.

PCR for *Francisella tularensis* DNA (lymph node aspirate): Negative.

Diagnosis

Severe suppurative lymphadenitis and fever, suspect plague or tularemia.

Treatment

Sam was transferred to isolation, during which time he bit a clinician, and was treated with intravenous fluids (lactated Ringer's solution and 20 mEq/L at 15 mL/h IV) and antimicrobial drugs (ampicillin, 20 mg/kg IV q8h and gentamicin, 5 mg/kg IV

Continued

CASE EXAMPLE—cont'd

q24h). Public health officials were contacted. The cat's rectal temperature initially increased to 107°F (41.6°C) and a bag of ice was placed beneath the cat's bedding; dark brown diarrhea was also noted. On the second day of hospitalization, Sam's rectal temperature was 105°F (40.5°C) and by day 3 it had normalized and Sam began to eat. It increased again to 103.9°F (40.0°C) the following day and the right mandibular and retropharyngeal lymph nodes became palpably enlarged. Subsequently the cat's rectal temperature normalized, laboratory abnormalities were improved, and the lymph nodes decreased in size and were soft on palpation. The cat was discharged with instructions to continue treatment with oral amoxicillin and subcutaneous gentamicin for 7 days, with a recheck planned at that time for an examination and convalescent *Y. pestis* and *F. tularensis* serology. The owner did not bring Sam back for a recheck examination, but a follow-up telephone conversation indicated that Sam had recovered completely.

Comments

A diagnosis of plague or tularemia was never confirmed in this cat although strongly suspected based on the history of wild rodent and rabbit exposure (with the rodent adopted from a plague endemic region) and the clinical abnormalities that were present. The findings of hyperbilirubinemia, thrombocytopenia, and increased serum CK activity were perhaps more suggestive of tularemia than plague, although hyperbilirubinemia and thrombocytopenia can occur in human plague. The history of antibiotic treatment may have contributed to the negative cytology, culture, and PCR results. Culture was requested on site shortly after admission because plague and tularemia were initially overlooked as likely diagnoses. Once these diseases were considered, an attempt was made to send specimens out to a public health laboratory for additional testing but this was complicated by concerns relating to the hazardous nature of the specimens. Handling of the cat was limited to as few individuals as possible and was difficult because the cat was aggressive. The clinician who was bitten by the cat immediately saw her physician who prescribed doxycycline for 7 days. Rabies quarantine was instituted because the cat was incompletely vaccinated for rabies. The owner was also educated about the possibility of plague or tularemia and the implications for human health. Although flea control was used, not all of the animals had flea prevention and there was significant turnover of a variety of wild and domestic animal species in the household. Continued adoption of wild animals by the owner was discouraged.

Tularemia

Jane E. Sykes, Bruno B. Chomel, Anne B. Nordstoga

KEY POINTS

- First Described: 1911, Tulare County, California.[1]
- Cause: Virulent strains of *Francisella tularensis*, a gram-negative coccobacillus (family Francisellaceae).
- Main Modes of Transmission: Inoculation, skin/mucosal contact, aerosol inhalation, ingestion, vector transmission.
- Major Vectors: Ticks (especially *Dermacentor andersoni, Dermacentor variabilis,* and *Amblyomma americanum* (eastern United States); and *Dermacentor reticulatus*, *Haemaphysalis concinna*, and *Ixodes ricinus* (Europe); biting flies (western United States); mosquitoes (Scandinavia).
- Affected Hosts: More than 300 animal species, which include rodents, rabbits, wild carnivores, domestic dogs and cats, sheep, horses, nonhuman primates, and humans.
- Geographic Distribution: Northern hemisphere between 30 degrees and 71 degrees of latitude; most severe disease cases in humans is reported from North America, especially the United States, where virulent strains are most prevalent.
- Major Clinical Signs: Fever, lethargy, inappetence, lymphadenopathy, subcutaneous abscesses, splenomegaly, hepatomegaly, GI signs such as vomiting and abdominal pain.
- Differential Diagnoses: Plague, cat bite abscess, *Streptococcus* spp. infections, feline infectious peritonitis, mycobacterial infections, lymphoma, sepsis caused by other gram-negative bacteria.
- Human Health Significance: Cats and less commonly dogs and wild canids (i.e., coyotes) can transmit tularemia to humans after they are exposed to infected rodents or rabbits. Cat bites are most commonly implicated.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Tularemia (also known as rabbit fever, hare fever, deerfly fever, and lemming fever) is an extremely infectious but uncommon zoonotic disease caused by *Francisella tularensis,* a small (0.2 × 0.2 × 0.7 μm), non-motile, aerobic, facultative intracellular gram-negative coccobacillus. The name "tularemia" comes from the first isolation of the organism from sick ground squirrels in Tulare County, California, in 1911 by McCoy and Chapin.[2] The first isolate from a human being was obtained in 1914 by Wherry and Lamb (OH, United States). Edward Francis extensively described the clinical, epidemiological, and diagnostic aspects of tularemia in the early 20th century.[3]

There are four subspecies of *F. tularensis: tularensis, holarctica, novicida,* and *mediasiatica*. Subspecies *tularensis* (also known as type A) and *holarctica* (type B) cause most disease in humans.[3] Subspecies *mediasiatica* is only found in Asia and the former Soviet Union. Subspecies *novicida* can cause illness in severely immunosuppressed humans and is widely studied as a model for tularemia because of its low virulence to laboratory workers.

Francisella tularensis subsp. *tularensis* has the greatest degree of virulence (for humans) and predominates in North America, whereas the less virulent subspecies *holarctica* predominates in Europe but is also present in North America. Additional genetic variation within type A and type B subpopulations of *F. tularensis* correlates with geographic distribution of cases and the severity of disease.[4] Molecular subtyping has further divided type A into subpopulations A1a, A1b, A2a, and A2b. The highest mortality rate (24%) in humans results from infections by A1b.[5] *Francisella tularensis* subsp. *holarctica* strains are typically separated into three biovars. Biovar 1 (erythromycin sensitive) is reported in western Europe and biovar 2 (naturally erythromycin resistant) is found in eastern European countries, although these strains overlap in their geographical spread. Biovar japonica (which ferments glycerol) is mainly found in Japan, but was also reported in China and Turkey, and more recently from Australia.[3,6]

Tularemia occurs primarily in the Northern Hemisphere, especially between 30 degrees and 71 degrees of latitude (Fig. 74.1). Human disease caused by a subsp. *novicida*–like organism was reported from the Northern Territory in Australia in 2003,[7] and subsp. *holarctica* was reported as the cause of disease in a woman from Tasmania, Australia after she was bitten by a ringtail possum.[8]

Even in North America, where *F. tularensis* subsp. *tularensis* predominates, tularemia is a rare disease, and most human cases occur in the central and north-central United States, especially Arkansas, Missouri, Kansas, South Dakota, and Oklahoma, with an additional focus in Massachusetts (especially Martha's Vineyard) (Fig. 74.2). Cases also occur in California. Type A1 is found in the central states endemic region and is the most virulent and invasive subtype, while type A2 is observed in the western United States and is less virulent. Type B is associated with water bodies especially the upper Mississippi and Missouri Rivers, high rainfall areas, rodents and ticks, whereas type A1 is associated with lagomorphs, cats, and ticks.[9] Despite its rarity, tularemia is a reportable disease in the United States because *F. tularensis* is considered a potential agent of bioterrorism. In Europe, *F. tularensis* subsp. *holarctica* is endemic in many countries ranging from Eastern to Western Europe. In Scandinavian countries, outbreaks in humans involving tens to hundreds of patients occur on a regular basis. Tularemia is considered a re-emerging zoonosis, with increasing numbers of reported cases in humans, in countries like Germany, France, Italy, and Spain.[3,10,11] Tularemia has been absent from the United Kingdom, with the exception of travel-related disease. It also occurs in Russia and Japan.[12]

Disease in cats and dogs due to *F. tularensis* has mainly been reported from the United States. Young adult cats and dogs are usually affected. As with plague, cats are more susceptible than

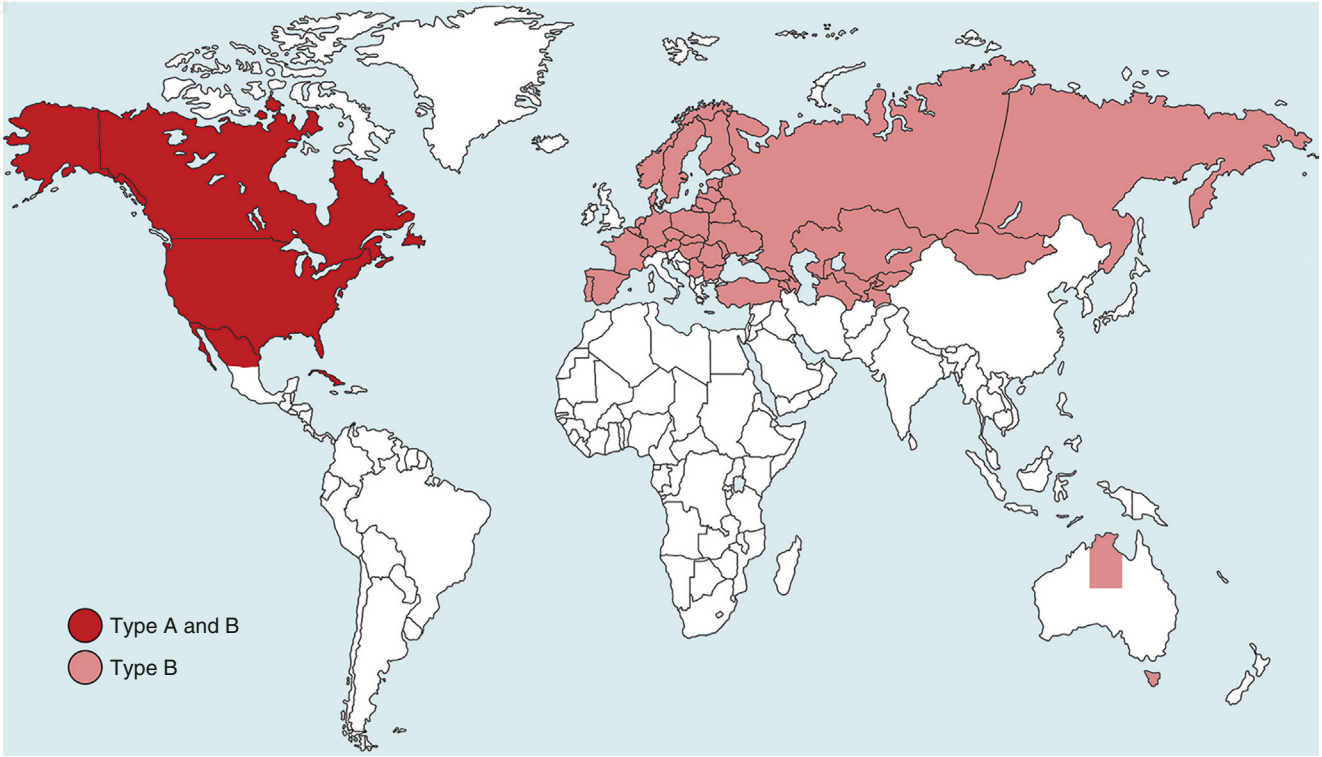

Fig. 74.1 Global distribution of tularemia. (Modified from Centers for Disease Control and Prevention).

dogs. Cases have been reported from Oklahoma[13-15] and Kansas,[16] but also from other locations that include Montana,[17] Missouri,[18] Massachusetts,[19] central Virginia,[20] and eastern Oregon,[21] which mirrors the distribution in humans. A case series of 88 dogs with tularemia was also described from New Mexico.[22] The median age of affected dogs in that study was 4 years and 8 months (range, 3 months to 14 years); 52% were neutered females, 33% were castrated male dogs, and 71% were medium- to large-breed dogs. Cases occurred every month of the year except December. In Oklahoma, feline tularemia has seasonal incidence peaks that occur from March to June and September to November.[8] In a review of 106 *F. tularensis* isolates collected mainly from Nebraska between 1998 and 2012, a strikingly high percentage (48%) were cat associated.[23] The highest number of feline-derived tularemia cases occurred in a city known to have multiple feral cat colonies and during a year with extended warm weather and extreme drought conditions.

Tularemia is likely underdiagnosed in cats and dogs because clinical signs are nonspecific. Many cats are diagnosed with tularemia at necropsy.[13,16] The seroprevalence in pet cats from Connecticut and New York state was 12%.[24] Feline tularemia seems to be mainly associated with *F. tularensis* subsp. *tularensis*, but *F. tularensis* subsp. *holarctica* is also found in cats.[13,15,25,26] However, in these studies, the focus has mainly been on zoonotic potential, and little is known about clinical disease in cats with *F. tularensis* subsp. *holarctica* infection. Tularemia was reported in a dog from Norway after hunting a mountain hare infected with *F. tularensis* subsp. *holarctica*.[27] Several additional cases of tularemia in dogs have been recognized in Norway and the United States in recent years.

Francisella tularensis is maintained in the environment by a huge variety of terrestrial and aquatic mammals, which include rabbits, hares, ground squirrels, prairie dogs, lemmings, voles, beavers, muskrats, water rats, ring tail possums, and other rodents.[12] It often causes severe disease in these species, although subclinical carriage may also occur. It can be transmitted by arthropod bites, inhalation or ingestion of the organism, and direct skin contact with infected tissues (probably when there are minute breaks in the skin) (Fig. 74.3). Inhalation of as few as 10 organisms can cause human disease, whereas larger numbers of organisms (10^8) must be ingested for disease to occur. Cats and dogs become infected when they hunt rodents or lagomorphs; a history of rabbit ingestion is most often described in association with reported feline and canine cases.[13-15,22,27] In a Norwegian study, antibodies to *F. tularensis* were found in 13 of 23 dogs exposed to lemmings, while all 10 dogs without exposure to hares or lemmings were seronegative.[27] The organism can also survive for years in frozen rabbit meat.

In the western United States (Utah, Nevada, and California), the most common arthropod vectors are biting flies, whereas ticks (especially *Dermacentor* spp. and *Amblyomma americanum*) are the most common vectors east of the Rocky Mountains.[28] In Europe, *Dermacentor* ticks and *Ixodes ricinus* are the main tick vectors; mosquitoes are important vectors in Scandinavia.[29] In Sweden, transstadial maintenance in mosquitoes and transmission to susceptible mammals have been documented.[29,30]

Francisella tularensis is well known for its ability to survive up to several months in fresh water sources, and survival in brackish water has also been demonstrated.[31] While *F. tularensis* contamination of water wells have resulted in several human outbreaks of oropharyngeal tularemia, transmission by vectors generally results in the ulceroglandular form.[32] Survival and replication of *F. tularensis* within free-living amebae such as *Hartmannella vermiformis* may contribute to the organism's ability to persist in water sources.[33]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The clinical manifestations of tularemia depend on the virulence of the infecting strain, the route of inoculation, and host immunity.

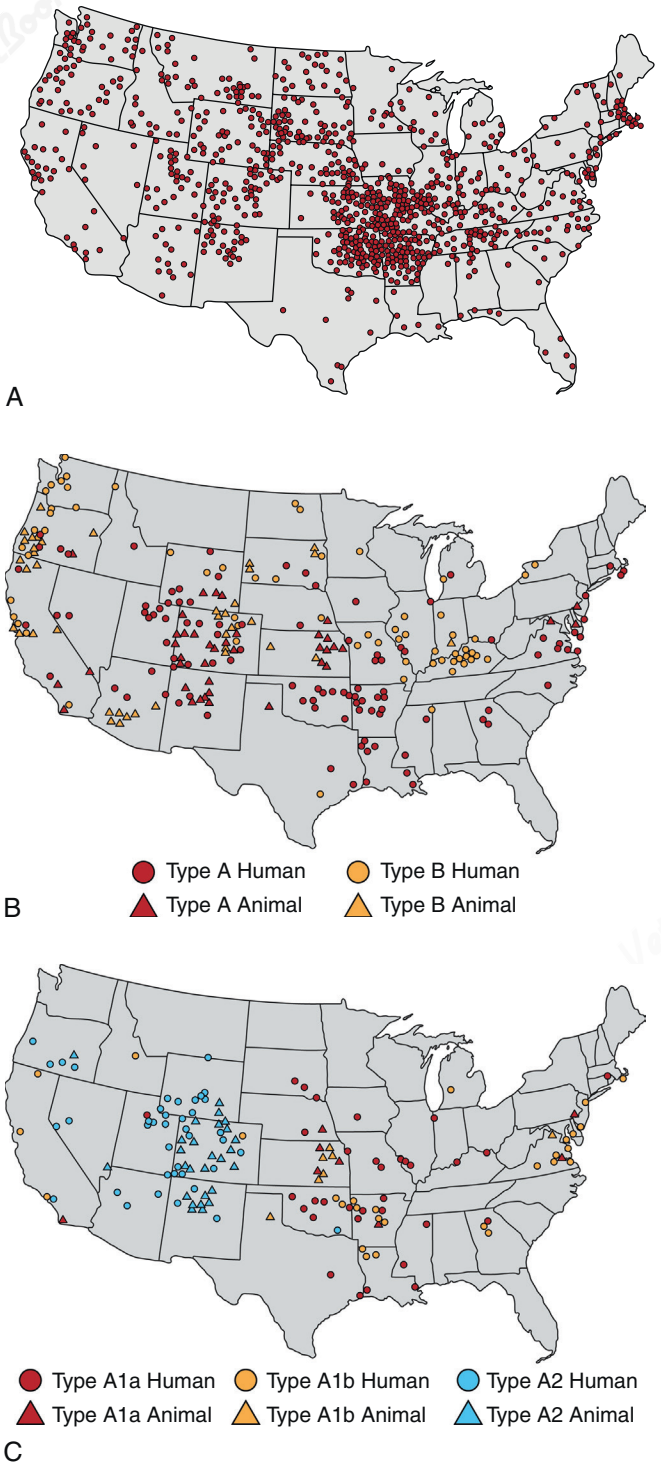

Fig. 74.2 Approximate geographic distribution of tularemia cases in the USA. Compare this with the geographic distribution of plague (Fig. 73.3). (A) Overall distribution of human tularemia cases. (B) Distribution of type A and type B isolates from humans and animals. (C) Distribution of isolates from humans and animals by molecular subtype. Note that the geographic distribution of human type A cases follows the distribution of subtype A1, the most virulent subtype being A1b. (A, compiled from data available from Kugeler et al.[5] and the Centers for Disease Control and Prevention through 2018; B, modified from Kugeler et al.[5])

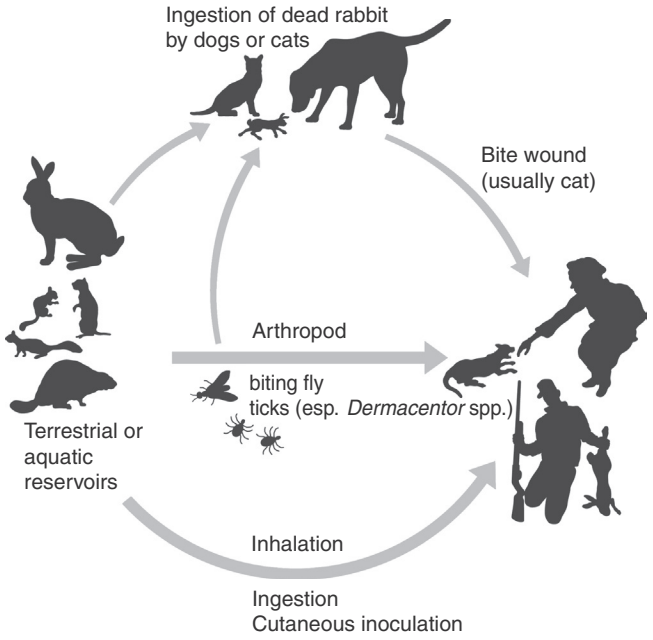

Fig. 74.3 Transmission cycle for *Francisella tularensis*.

Although tularemia may rapidly progress to death in cats, protracted illness has also been described.[21] Milder disease occurs in dogs when compared with cats.[22]

Francisella tularensis survives in macrophages through evasion of cellular destruction by phagosomes and inhibition of the respiratory burst. Several different virulence factors of *F. tularensis* have been identified, which include bacterial LPS, pili, a capsule, and a series of acid phosphatase enzymes. The endotoxic activity of the LPS of *F. tularensis* is 1000-fold less than that of *Escherichia coli*.[34,35] Production of acid phosphatase enzymes may be key to the organism's ability to inhibit the respiratory burst and survive in macrophages.[36] Many stages of the organism's intracellular lifestyle depend on a pathogenicity island (group of virulence genes) known as the *Francisella* pathogenicity island, which encodes a type VI–like secretion system associated with bacterial virulence.

For the first few days after cutaneous inoculation, *F. tularensis* replicates locally and can produce a papule that may then ulcerate. It then disseminates to local lymph nodes, which may be followed by bacteremia and sepsis, with infection of systemic, primarily reticuloendothelial tissues. The organism invades not only macrophages but also nonphagocytic cells such as hepatocytes and alveolar epithelial cells,[37] with induction of a profound inflammatory response and necrosis. Incubation periods that range from 1 to 5 days have been suspected in naturally occurring tularemia in dogs and cats, but longer incubation periods (up to 21 days) can occur in humans. Clinical signs typically manifest as a sudden onset of fever, lethargy, and inappetence. Other manifestations in affected cats have included a thin body condition, icterus, hepatomegaly, vomiting, dehydration, peripheral and/or abdominal lymphadenomegaly, splenomegaly, and oral and/or lingual ulceration. Hypothermia and bradycardia can occur in moribund cats;[13] one cat had seizures and was nonresponsive.[20] A single cat with localized cutaneous tularemia had a chronic (1-year duration) draining skin lesion in the region of (but not involving) the mandibular lymph nodes, in the absence of systemic signs.[21] Infection in dogs results in disease that is either subclinical or mild.[22,27] In reports of naturally affected dogs, clinical signs have included fever, lethargy,

anorexia, and peripheral lymphadenopathy.[14,22,27,38] Other signs have included vomiting, diarrhea, respiratory signs, oculonasal discharge, and tonsillitis.[14,22,38]

Physical Examination Findings

Physical examination in cats with tularemia may reveal lethargy, fever (up to 40.5°C [105.1°F]) or hypothermia, a thin body condition, and dehydration.[13,15,17-19] Ulceration of the oral mucous membranes or tongue may be present.[13,19] Icterus may also occur.[36] Moribund cats may be hypothermic and bradycardic and may have weak pulse quality. Mild to marked peripheral lymphadenopathy is present in most but not all cats. Lymphadenopathy may be restricted to the lymph nodes of the head and neck[19] or may be generalized.[13,15] Abdominal palpation may reveal hepatomegaly or splenomegaly, or abdominal lymph nodes may be palpable. One or more signs of fever (up to 41.4°C [106.5°F]), lethargy, peripheral lymphadenopathy, mucoid ocular discharge, and tonsillitis may be present in dogs.[14,22,27,38]

DIAGNOSIS

Tularemia should be considered in cats and dogs with lymphadenopathy and fever that have a history of residence in or recent travel to an endemic area, as well as contact with or predation of wild mammals (especially lagomorphs). Plague is the major differential diagnosis of zoonotic importance in the southwestern United States (Table 74.1). Ultimately, the diagnosis can be confirmed by culture, PCR, and/or serologic testing. Access to approved laboratories that practice BSL 3 procedures is required to perform bacterial culture when tularemia is suspected. Local public health authorities should be contacted to report suspicion for the disease and for information on recommended testing facilities.

Laboratory Abnormalities

Complete Blood Count, Biochemistry Profile, and Urinalysis

Leukocyte counts in a limited number of cats with tularemia have been normal, decreased (as low as 1300 cells/μL), or increased with evidence of neutrophil toxicity.[13,15,19,20] Moderate to marked bandemia may be present.[15,19] Thrombocytopenia is a common finding (as low as 41,000 platelets/μL).[13,15] The serum biochemistry panel may show hypoglycemia, azotemia, and electrolyte abnormalities, increased liver enzyme activities, and hyperbilirubinemia (up to 7.6 mg/dL).[13,15,20] Bilirubinuria and hemoglobinuria may be present.[13] Leukocytosis due to a neutrophilia (just over 50% of dogs) and thrombocytopenia (38% of dogs) have been reported in infected dogs.[14,22]

Cytologic Examination of Lymph Node Aspirates

Cytologic examination of lymph node aspirates in cats with tularemia may reveal lymph node hyperplasia.[15] Lymph nodes may also contain necrotic debris and increased numbers of macrophages and/or degenerate neutrophils.[13,19] Because *F. tularensis* is tiny and stains only faintly, organisms are less likely to be visualized than those of *Yersinia pestis* (see Chapter 73).

Diagnostic Imaging

Plain Radiography

Findings on thoracic radiography in cats with tularemia have not been well described; one cat had normal thoracic radiographs.[15] Findings on abdominal radiography have included hepatomegaly and fluid-filled intestinal loops.[15]

TABLE 74.1 Differences and Similarities between Plague and Tularemia in Cats and Dogs in the United States

	Plague	Tularemia
Organism	Gram-negative bacillus (Enterobacterales). Survives relatively poorly in the environment. Grows on routine culture media used for gram-negative bacteria	Gram-negative coccobacillus (Francisellaceae). Can persist in the environment and water sources for months. Fastidious growth in culture; often requires special media and prolonged incubation
Major arthropod vectors	Diverse variety of rodent and rabbit fleas	*Dermacentor* spp. and *Amblyomma americanum* ticks
Geographic location	Southwestern United States	Western, southwestern, central, and eastern United States
Affected hosts	Cats > dogs	Cats > dogs
Usual history	Rodent contact or exposure to rodent fleas	Rodent and especially rabbit contact; ingestion often reported
Clinical signs	Acute disease with high fever and lymphadenopathy, most often of the mandibular and/or retropharyngeal lymph nodes. Hyperbilirubinemia and icterus do not appear to be common in affected cats	Acute or more chronic disease (sometimes associated with a thin body condition) with oral ulceration, lymphadenopathy of the mandibular and/or retropharyngeal lymph nodes, or generalized lymphadenopathy and abdominal organomegaly. Hyperbilirubinemia is frequent in affected cats, and icterus has been described
Lymph node aspirate cytology	Neutrophilic inflammation; monomorphic population of bipolar staining bacilli often present	Lymphoid reactivity or neutrophilic to pyogranulomatous inflammation and necrosis; bacteria often not visualized
Antimicrobial drugs	Aminoglycosides, doxycycline, chloramphenicol, trimethoprim-sulfamethoxazole	Aminoglycosides are the treatment of choice. Doxycycline, chloramphenicol, and fluoroquinolones may be effective but may be followed by relapse
Zoonotic potential	Exposure to cats with pneumonic plague can lead to human infection through aerosols; bites and scratches have also been implicated. Human pneumonic plague usually results from exposure to infected cats and can progress to death within a few days. Exposed humans may require prophylaxis with doxycycline	Most often follows bites from affected cats, less often scratches. Course of disease longer and mortality may be lower than occurs with pneumonic plague. Medical attention should be sought if bites or scratches occur

TABLE 74.2 Diagnostic Assays Currently Available for Tularemia in Dogs and Cats

Assay	Specimen Type	Target	Performance
Culture (not recommended)	Lymph node aspirates, blood, tissues collected at necropsy	*Francisella tularensis*	Recent antibiotic treatment may cause false-negative results. May require special media and takes at least 48 hours for colonies to appear. *Hazardous to laboratory personnel* and should be sent to laboratories with appropriate expertise when possible
Direct immunofluorescent antibody	Lymph node aspirates, tissues collected at necropsy	*F. tularensis* antigen	May be positive when culture is negative. False negatives can still occur. Recent antibiotic treatment may cause false-negative results
Serology	Serum	Antibodies to *F. tularensis*	Acute and convalescent serology is required for diagnosis, because initial results may be negative, and positive results may reflect previous exposure rather than active infection. Seroconversion may take up to 3 weeks
PCR	As for culture	*F. tularensis* DNA	Recent antibiotic treatment may cause false-negative results

Sonographic Findings

Abdominal ultrasound findings could include abdominal lymphadenomegaly, splenomegaly, and/or hepatomegaly. Abdominal lymphadenomegaly has been described in both a cat[15] and a dog.[27]

Microbiologic Tests

Diagnostic assays currently available for tularemia in dogs and cats are described in Table 74.2.

Direct Detection

Heat-fixed slides can be submitted to experienced laboratories for direct immunofluorescent antibody (IFA) staining for *F. tularensis*. Alternatively, IFA or immunoperoxidase stains can be applied to tissues obtained at necropsy.[16] Negative results do not rule out tularemia, but in some cases IFA may detect the organism when culture is negative.[39] Fluorescence in situ hybridization (FISH) has also been used to detect *F. tularensis* in tissues and differentiate between subspecies.[40] As for plague, lateral-flow assays have been described for rapid detection of *F. tularensis* LPS antigen in clinical specimens such as urine.[41] The use of these assays in dogs and cats has not been described.

Isolation and Identification

Francisella tularensis can be grown from clinical specimens, but it is very fastidious, grows slowly, is hazardous to laboratory personnel, and does not always grow on media used for routine isolation of gram-negative bacteria such as MacConkey agar (in contrast to *Y. pestis*). The use of cysteine-supplemented media (such as cysteine heart agar) and incubation in a CO_2-supplemented environment enhances recovery of the organism. Growth generally occurs 48 to 72 hours after inoculation, but cultures must be held for 7 to 10 days. Characteristic dewdrop colonies are isolated. Overgrowth of contaminating bacteria can occur unless the media is supplemented with antibiotics that inactivate these organisms. *Francisella tularensis* may grow from blood specimens after inoculation of routine blood culture media. Confirmation of the identity of the organism can be achieved with molecular methods. Whole-cell MALDI-TOF mass spectrometry has also been used for identification of *F. tularensis* isolates to the subspecies level (see Chapter 3).[42]

Serology

As for plague, acute and convalescent serology, with demonstration of a fourfold increase in titer, is required for serodiagnosis of tularemia in affected dogs and cats and is less hazardous to human health than culture. Tube agglutination and microagglutination assays are the standard methods for serodiagnosis, but ELISA assays have also been developed. Because of the extremely short incubation period, affected cats and dogs may have negative titers when they are first brought to the veterinarian, so convalescent serum should be submitted at least 2 to 3 weeks after the initial titer if the animal survives. Some cats die from the disease before a rise in antibody titer occurs. In addition, high titers may persist after recovery from infection, so a single positive titer is not diagnostic for tularemia.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR assays that detect *F. tularensis* DNA represent an attractive means of diagnosis because of their sensitivity, rapid turnaround time, low risk to laboratory personnel, and the ability to differentiate between subspecies and genotypes of *F. tularensis*.[43,44] PCR assays have been used to detect *F. tularensis* in tissues at necropsy in cats.[18,45] A number of real-time PCR assays have been used to detect *F. tularensis* in human clinical specimens. Despite the sensitivity of PCR assays, false negatives can still occur. Real-time PCR assays for *F. tularensis* are offered on a commercial basis by some veterinary diagnostic laboratories in the United States.

Pathologic Findings

Gross pathologic findings in cats with tularemia include icterus, oral ulceration, lymphadenomegaly, splenomegaly, and hepatomegaly. Multifocal to coalescing irregular yellow, gray, or white foci (usually 1 to 5 mm in diameter) are present in these organs, and sometimes other organs such as the lung and myocardium.[13,18,19] When examined using histopathology, the nodules represent well-circumscribed but non-encapsulated masses of caseous necrosis, with abundant cellular debris, surrounded by infiltrates of degenerate neutrophils, macrophages, and/or fibroblasts. Lesions are centered on the splenic white pulp and cortical lymphoid follicles within lymph nodes. Necrosis and hemorrhage of lymphoid follicles within the GI tract may be present.[13,17] Organisms may be discernible with silver staining as tiny coccobacilli[17] or can be demonstrated with immunoperoxidase or immunofluorescence methods.[16,39]

TREATMENT AND PROGNOSIS

No substantial reports have been made on antimicrobial therapy of canine or feline tularemia. Treatment involves supportive care and antimicrobial drug administration (Table 74.3). As for plague, animals suspected to have tularemia should be housed in isolation at

TABLE 74.3 Suggested Antimicrobial Drugs for Treatment of Tularemia in Cats and Dogs

Drug	Dose (mg/kg)	Route	Interval (Hours)	Duration
Gentamicin	5–8	IV, IM, SC	24	14 days
Doxycycline	5	PO	12	2–3 weeks
Marbofloxacin	2.75–5.5	PO[a]	24	2–3 weeks

[a]Parenteral aminoglycosides are preferred for at least the first 72 hours of treatment to minimize exposure of the caregiver to *F. tularensis* during treatment.

least for the first 72 hours of antimicrobial drug therapy and handled by as few individuals as possible. Public health authorities should be notified. Gowns, gloves, and suitable face protection (eye protection and a properly fitted high-density surgical mask) should be worn, and protective wear should be properly removed and disposed of after handling affected animals. Any biohazardous waste should be double bagged and disposed of correctly. Routine disinfectants should be used to inactivate the organism in the environment. The drug of choice for initial treatment of tularemia in humans is a parenteral aminoglycoside such as streptomycin, with gentamicin as an alternative. Doxycycline can also be used but is associated with a higher relapse rate in humans than occurs with aminoglycosides.[44] Fluoroquinolones have the highest activity against *F. tularensis in vitro*,[46] but like tetracyclines, they may be associated with relapse *in vivo*.[44,47] Extension of the course of treatment from 2 weeks to 3 weeks when fluoroquinolones or doxycycline is used has been effective for treatment of human tularemia.[48] Other drugs with *in vitro* activity against *F. tularensis* include chloramphenicol and macrolides.[46]

IMMUNITY AND VACCINATION

Natural infection by *F. tularensis* is followed by protection against reinfection. Because *F. tularensis* is facultatively intracellular, cell-mediated immune responses are required for pathogen clearance, although humoral immunity is also important.[37] As a result, inactivated vaccines have not been effective for prevention of tularemia, because they primarily induce humoral immunity. An attenuated live vaccine that contained *F. tularensis* subsp. *holarctica* (live vaccine strain, or LVS) has been available for prevention of serious disease in people at high risk of exposure. However, this remains unlicensed because of concerns regarding efficacy and the route of administration, which was by scarification.[49] Since then there has been strong interest in vaccine development for prevention of human tularemia, because of concerns that the organism will be used as a weapon of bioterrorism.[37] Vaccines are not commercially available for dogs and cats given the rarity of disease in these species and the minor role that they play in transmission of disease to humans.

PREVENTION

Prevention of tularemia in dogs and cats involves housing cats indoors and discouragement of predation or exposure to dead wild rodents and rabbits. Use of tick preventatives also reduces the chance that dogs and cats will carry infected ticks into the house. Rodent control in the environment (e.g., removal of garbage) should also be performed.

Fig. 74.4 Papule undergoing central necrosis with desquamation on the thigh of a middle-aged man infected with *Francisella tularensis*. (Courtesy of Dr. Joseph A. Bocchini, Louisiana State University Health Sciences Center, Shreveport, LA. In: Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases*, 7th ed, Philadelphia, PA: Churchill Livingstone; 2010:2927-2937.)

PUBLIC HEALTH ASPECTS

In the United States, humans are most commonly infected by *F. tularensis* after arthropod bites (approximately half of the cases follow tick bites)[28] or handling infected wild animals. Common biological vectors are ticks, and in endemic areas in Sweden and Finland, mosquitoes play an important role in transmitting the bacteria.

Occupations associated with an increased risk of tularemia include farming, hunting, landscaping, meat handling, working with sheep, veterinary practice, and laboratory work. Severe illness is most often reported in young children (5 to 9 years) and the aged (>75 years). Men are more likely to be affected than women.[44]

Several overlapping forms of disease have been described in humans, the development of which depends on the route of inoculation and the virulence of the infecting strain: ulceroglandular, glandular, oculoglandular, oropharyngeal, typhoidal, and pneumonic.[44] Ulceroglandular tularemia results from cutaneous inoculation, oropharyngeal disease follows ingestion, and pneumonic tularemia can result from aerosol inhalation. Pneumonic tularemia has been described in people after activities such as lawn mowing or brush cutting in tick-infested areas. Infection of humans from cats and dogs (or wild canids, such as coyotes) can occur after these animals carry *F. tularensis* in their mouths after ingestion of wild prey.[50-52] Human-to-human transmission does not seem to occur.

Clinical signs in humans consist of acute onset of a flu-like illness, with fever, chills, and malaise after an average incubation period of 3 to 5 days. Sore throat, abdominal pain, vomiting, diarrhea, lymphadenopathy, rash, and a cough may also occur. Laboratory abnormalities include thrombocytopenia, elevated serum transaminase activities, increased serum creatine kinase activity, myoglobinuria, and pyuria.[44]

Infection with less virulent strains may result in transient flu-like illness followed by recovery. Without treatment, clinical signs can persist for several months, with chronic lymphadenopathy, weight loss, and debilitation.[44] Disease in chronically affected humans can resemble cat scratch disease.

Ulceroglandular tularemia is the most common form of human tularemia. It consists of a red and painful papule at the site of skin infection, with associated lymphadenopathy (Fig. 74.4). The papule then undergoes necrosis, forming an ulcer, which can take weeks to heal. In some individuals, lymph nodes may suppurate and become fluctuant. Multiple lesions can occur on the hands when infected

animals have been handled, whereas tick bites typically result in single lesions elsewhere on the body.[44] Only lymphadenopathy may be present if the ulcer heals before the time of evaluation *(glandular tularemia)*. *Oculoglandular tularemia* occurs when organisms gain access through the conjunctiva and is characterized by conjunctivitis, conjunctival ulceration, lacrimation, and associated lymphadenopathy.[44] *Oropharyngeal tularemia* is characterized by fever and severe throat pain; tonsillitis, oral ulceration, and associated lymphadenopathy may be present, which resembles the disease described in dogs and cats (which usually acquire infection via ingestion). Oropharyngeal tularemia tends to occur in children who ingest contaminated food or water and can resemble streptococcal pharyngitis (strep throat). *Typhoidal tularemia* is a febrile illness in the absence of prominent lymphadenopathy and may be associated with sore throat, abdominal pain, diarrhea, vomiting, icterus, and, with more chronic illness, hepatomegaly and splenomegaly. *Pneumonic tularemia* is the most severe form and results from inhalation of the organism or hematogenous spread of the organism to the lung, with clinical signs such as cough, chest pain, and hemoptysis. Thoracic radiographs can reveal lobar infiltrates, hilar lymphadenopathy, pleural effusion, and miliary infiltrates.[44] Changes resemble those seen in other chronic pneumonias, such as tuberculosis or fungal disease.

Although not the most common route of infection for humans, cat- and dog-bite–associated tularemia has been described (including among veterinary staff), and cats that live in rural endemic areas are important vectors of the most virulent strain of *F. tularensis*, type A1b.[48,52] Less commonly, human disease follows cat scratches or casual contact with cats.[39] In some cases, cats had recent contact with or ingested wild rabbits or rodents. Both apparently healthy and sick cats have been involved. Aerosol exposure to organisms on the coats of dogs (such as occurs when dogs shake their coats after contact with infected rabbits) has rarely been suspected in clusters of human disease.[51,53,54] In summary, tularemia should especially be considered in humans who develop illness in endemic areas within 3 weeks after a bite from a cat or dog that is a stray or that has had a recent history of wild rabbit or rodent contact. Following known exposure, prophylaxis with doxycycline has been used.[45] Disease in humans can mimic *Pasteurella multocida* cellulitis, the most common bacterial infection after a cat bite, but treatment with amoxicillin or clavulanic acid–amoxicillin is ineffective. It can also resemble cat scratch disease, and antibodies for *F. tularensis* may cross-react with *Bartonella* antigens, leading to diagnostic confusion.[2]

CASE EXAMPLE

Signalment

"Fido," an 8-month-old intact female, mixed-breed dog.

History

Fido was referred to Fredrikstad Small Animal Hospital, in the southeastern part of Norway, from a local animal clinic. Two days after a mountain hike, the dog became ill with lethargy and diarrhea. The owner had observed the dog eating lemmings. Over the next 3 days, the dog's condition worsened, with development of inappetence and vomiting 3 to 5 times daily.

On the day of the examination at Fredrikstad Small Animal Hospital, the dog had also developed hemorrhagic diarrhea; weight loss of 2 kg over a 1-week period was documented. The dog had been vaccinated for canine distemper, infectious canine hepatitis, parvovirus, and canine parainfluenza virus at 12 weeks of age, and had no previous history of illness.

Physical Examination

Body weight: 20 kg

General: Lethargic but responsive. T = 39.6°C [103.3°F], RR = 60 breaths/min, HR = 100 beats/min, CRT: 2 s.

Musculoskeletal: Body condition score 4/9.

Cardiovascular: No murmurs or arrhythmias were detected. Pulse quality was strong and synchronous.

Respiratory: No clinically significant findings.

Abdominal palpation: Mildly tense abdomen.

Lymph nodes: All peripheral lymph nodes appeared to be within normal limits.

Laboratory Findings

CBC: HCT 43.1% (37%–55%), MCV 61 fL (60–77 fL), MCHC 33.0 g/dL (30.0–37.5 g/dL), WBC 4140 cells/μL (5500–16,900 cells/μL), neutrophils 3060 cells/μL (2000–12,000 cells/μL), lymphocytes 640 cells/μL (500–4900 cells/μL), monocytes 310 cells/μL (300–2000 cells/μL), platelets 167,000 platelets/μL (175,000–500,000 platelets/μL).

Serum chemistry profile: Sodium 149 mmol/L (144–160 mmol/L), potassium 4.1 mmol/L (3.5–5.8 mmol/L), chloride 106 mmol/L (109–122 mmol/L), phosphorus 1.87 mmol/L (0.81–2.20 mmol/L), calcium 2.28 mmol/L (1.98–3.00 mmol/L), BUN 4.0 mmol/L (2.5–9.6 mmol/L), creatinine 68 μmol/L (44–159 μmol/L), glucose 5.83 mmol/L (4.11–7.95 mmol/L), total protein 70 g/L (52–82 g/L), albumin 27 g/L (23–40 g/L), globulin 43 g/L (25–45 g/dL), ALT 65 U/L (10–125 U/L), ALP 116 U/L (23–212 U/L), GGT 0 U/L (0–11 U/L), cholesterol 6.96 mmol/L (2.84–8.26 mmol/L), total bilirubin 6 μmol/L (0–15 μmol/L), amylase 330 U/L (500–1500 U/L).

Imaging Findings

Thoracic and abdominal radiographs: All structures appeared within normal limits.

Abdominal ultrasound: The mesenteric and iliac lymph nodes were enlarged and hypoechogenic, and measured up to 19 mm in diameter. Cytologic examination of fine-needle aspirate from an enlarged mesenteric lymph node showed mostly mature lymphocytes, with a few neutrophils and macrophages. Erythrocytes were present in moderate numbers. No bacteria or other infectious agents were seen in the aspirate. Conclusion: reactive lymphadenopathy.

Microbiologic testing:

PCR for *Francisella tularensis* DNA (swab specimen from the tonsils): negative.

Parvovirus antigen SNAP test (IDEXX Laboratories, Portland, ME): negative.

Fecal flotation: no parasites detected.

Serologic testing: Paired serum samples demonstrated a significant increase in antibody titer as determined using microagglutination test (MAT), from 1:20 on day 4 after exposure to lemmings to 1:640 on day 18.

Diagnosis

Tularemia.

Treatment

The dog was treated with IV fluids (128 mL/hour). Because of the high CRP, fever, lethargy, leukopenia, and bloody diarrhea, a decision to treat with antimicrobials was made (ampicillin, 20 mg/kg, IV, q8h). Two days later the dog had recovered, and had no diarrhea, no dehydration, or fever. Oral amoxicillin was continued for 3 more days.

Comments

In this case, a decision to pursue diagnostic testing for tularemia was made because of the history of exposure to lemmings, fever, and abdominal lymphadenopathy. The choice of antimicrobials was not optimal for treatment of tularemia but was initiated because of the concern for bacterial infection in light of the clinical findings. Most isolates of *F. tularensis* have shown *in vitro* resistance to penicillins,[46] so this dog likely recovered despite lack of specific antimicrobial therapy.

Bite and Scratch Wound Infections

Jane E. Sykes, Ellie J.C. Goldstein

KEY POINTS

- Causes: A variety of aerobic and anaerobic bacteria that include mycoplasmas and mycobacterial species. *Pasteurella* spp. are commonly isolated.
- Geographic Distribution: Worldwide.
- Major Clinical Signs: Fever, lethargy, hyperesthesia, puncture wounds, cutaneous swellings, lacerations, tissue avulsions, and signs that relate to damage and/or infection of other structures (such as the thorax, abdomen, and brain and spinal cord).
- Differential Diagnoses: Other traumatic injuries, cutaneous neoplasia, sterile nodular panniculitis (dogs), plague, tularemia.
- Human Health Significance: Cat and dog bite wound infections are common in humans and may be life-threatening in the immunocompromised. They also can be associated with transmission of potentially serious bloodborne bacterial pathogens such as *Bartonella*, *Francisella tularensis*, *Pasteurella multocida,* and *Capnocytophaga canimorsus.*

ETIOLOGY AND EPIDEMIOLOGY

Bite wounds are one of the most common reasons that dogs or cats are brought to veterinary hospitals for care. Despite this, there is surprisingly little information available on their epidemiology in comparison to the plethora of publications on animal bite wounds in people (see Public Health Aspects). Bite wounds often result in bacterial infection, but can also result in systemic viral infection (especially in the case of bitten cats), and less often, fungal or bloodborne protozoal infections such as babesiosis (Table 75.1).

Bacterial pathogens that cause bite wound infections are usually members of the normal oral cavity flora of the biting animal species, but organisms in the environment can also contaminate bite or scratch wounds (e.g., *Clostridium tetani, Mycobacterium* spp., *Nocardia* spp., *Bartonella* spp.). Bite wounds are instantly contaminated with a plethora of bacterial species from the oral cavity, but only a small proportion of these species possess virulence properties that allow them to proliferate within the wound and cause disease. The degree to which proliferation occurs also depends on host factors such as underlying immunocompromise. Although there are similarities that relate to the oral flora of the biting animal, the bacterial species that cause bite wound infections in dogs and cats can differ from those that cause dog or cat bite wound infections in human patients, so data from human studies should not be extrapolated to dog or cat bite wound infections.

Dogs

Bite wounds in dogs most often result from aggressive dog-dog interactions. The dog breeds affected depend on regional variation in dog breed popularity. Younger adult, male dogs and especially intact male dogs appear to be predisposed, but studies that compare affected dogs to a control (or "background") population have not been reported.[1–3] Bite wounds in dogs can also result from the bites of other domestic and wild animal species, but the epidemiology of infections that result from these wounds is not well described. One study described 154 dogs from southern California with coyote bite wounds; dogs < 10 kg were more likely to have wounds involving multiple body parts and abdominal penetrating wounds, and rib fractures were associated with mortality.[4]

Approximately 20% of dog-dog bite wounds become *infected*, as opposed to *contaminated*. The likelihood that a wound becomes infected increases with the time lag between the aggressive interaction and when veterinary attention is sought.[2,3] Infection develops 8 to 24 hours after the bite occurs and is less likely to develop if the wound is limited to the dermis.[3] The distribution of bacterial species involved varies from one study to another and may be influenced by whether infected or only contaminated wounds were evaluated. The most common bacterial species isolated from dog-dog bite wounds are *Staphylococcus pseudintermedius, Enterococcus* spp., *Pasteurella* spp., streptococci, and *Escherichia coli.*[1–3,5] *Staphylococcus aureus* and *Capnocytophaga canimorsus,* which are important pathogens in humans that are bitten by dogs, are rarely isolated from bitten dogs,[2,3] although the prevalence of *C. canimorsus* is probably underestimated because it is very difficult to grow in culture. In the author's hospital, *Pasteurella* spp. accounted for 17% of 41 bacterial species cultured from 33 dog bite wounds, followed by a variety of staphylococci (some methicillin-resistant) (15%), *E. coli* (12%), *Enterococcus* spp. (7%), and *Bacteroides* spp. (7%). Other organisms were *Peptostreptococcus* spp., *Clostridium* spp., and *Pseudomonas aeruginosa* (each 5%); and *Streptococcus viridans, Actinomyces* spp., *Acinetobacter* spp., *Serratia marcescens, Klebsiella pneumoniae, Myroides* spp., *Prevotella* spp., *Fusobacterium* spp., *Aeromonas* spp., *Mycobacterium smegmatis,* and *Mycoplasma* spp. (one isolate each or 2%). Obligate anaerobes were isolated from five dogs (15%), and in all five of these dogs, multiple bacterial species were isolated.

Cats

Most bite wounds in cats result from aggressive interactions with other cats, but nonfatal dog bite wounds can also occur. Occasionally, cats are bitten by a variety of other small wildlife species that vary geographically based on the local fauna present. In contrast to dogs, which often crush and tear tissues with their teeth, cats deliver deep puncture wounds that create an environment where obligate and facultative anaerobes flourish. Thus, anaerobic bacterial infections are more prevalent in cat bite abscesses than in dog bite wounds, and accordingly, polymicrobial infections are present more often in closed cat bite abscesses

TABLE 75.1 Pathogens that Cause Local or Systemic Infections in Dogs and Cats as a Consequence of Bite or Scratch Wounds from the Same or Another Animal Species[a]

Organism Class	Dogs	Cats
Viruses	Rabies	Rabies FeLV FIV
Mycoplasmas	Hemotropic mycoplasmas?	Nonhemotropic mycoplasmas Hemotropic mycoplasmas?
Gram-negative aerobes[b]	*Aeromonas* *Acinetobacter* *Capnocytophaga canimorsus* *Enterobacter* spp. *Escherichia coli* *Neissera (N. dumasiana)* *Pasteurella* *Proteus* *Pseudomonas aeruginosa* *Serratia marcescens*	*Escherichia coli* *Pasteurella*
Gram-positive aerobes[a]	*Actinomyces* *Corynebacterium* *Enterococcus* *Staphylococcus*, especially *S. pseudintermedius* *Streptococcus*	*Actinomyces* *Corynebacterium* *Enterococcus* *Lactobacillus* *Nocardia* *Streptococcus*

[a]When only a genus name is listed, multiple species from that genus have been isolated.
[b]The term "aerobe" refers to facultative anaerobes and obligate aerobes.

than in dog bite wounds. In a study of 36 closed cat bite abscesses, 168 bacterial strains were isolated, of which 72% were obligate anaerobes and 28% were facultative anaerobes.[6] The most prevalent anaerobes isolated from cat bite abscesses include *Porphyromonas, Bacteroides, Prevotella, Peptostreptococcus,* and *Fusobacterium*. *Pasteurella multocida,* a commensal of the oral cavity of virtually all cats, is the most common facultative anaerobe present.[6–8] *Porphyromonas* spp. appear to be particularly prevalent; in one study of 15 abscesses in Australian cats, they accounted for 92% to 99% of all the facultative and obligate anaerobes present.[9] Less often *Actinomyces,* β-hemolytic streptococci, lactobacilli, and *Propionibacterium* spp. have been isolated.

CLINICAL FEATURES

Dogs

Among dogs, dog bite wounds consist of abrasions, lacerations, avulsions (i.e., skin flaps), crushing injuries, and deep puncture wounds (Fig. 75.1). Abscesses can also develop. Dog bite wounds may also penetrate body cavities and cause pneumothorax, rib fractures, lung contusions or damage the esophagus, vertebral column, or GI tract. Pyothorax or bacterial peritonitis can also occur. Most dogs have between one and five wounds. Rarely, more than 10 wounds are present.[1–3] The majority of bite wounds occur cranial to the diaphragm, especially on the head and neck (Fig. 75.2). The location of the bite wounds also depends on the size of the bitten dog; large-breed dogs are more likely to have wounds on the neck and face, but small-breed dogs often have wounds on their dorsum or thorax. Injury to underlying tissue is frequently dramatically more severe than is apparent on the surface. Classification systems have been used to describe the severity of dog-dog bite wounds based on the type of injury (laceration vs. puncture wound) and the presence or absence of dead space or abscessation.[1–3] Abscessation is rarely associated with dog bite wounds as compared with cat bite wounds.[3] The presence of pus, fever, erythema, subcutaneous emphysema, and/or a foul odor suggests that infection has occurred. Uncommonly, hematogenous spread of bacteria leads to signs of severe sepsis or septic shock (see Chapter 123).

Cats

In cats, cat bite wounds may be difficult to identify on the surface or be undetectable, but infection can extend to penetrate bone, joints, tendon, and muscle.[8,10] Cat bite wounds are most often located on the thoracic limbs, lateral aspect of the face, and near the base of the tail (Fig. 75.3).[11] In contrast, scratches are often found on the bridge of the nose, pinna, and inguinal region. Cat bite abscesses are characterized by the presence of firm or fluctuant subcutaneous swellings or masses, with or without fever, lethargy, inappetence, and hyperesthesia. Some cats are brought to the veterinarian solely because of lethargy, and a careful physical examination is required before an abscess or cellulitis is detected. One or more scabs may be found on top of the abscess, or the overlying skin may lack hair and have a gray, necrotic appearance. If the abscess ruptures, cream-colored or red-brown purulent material may be identified on the haircoat, sometimes in association with a foul odor (Fig. 75.4). Alternatively, the haircoat may be matted over the site. Lameness may be apparent if the limbs are involved, and especially if there is extension to the bone or a joint. Involvement of the thoracic cavity may be associated with fever, lethargy, tachypnea, and decreased lung sounds due to pyothorax (see Chapter 124).[10] Bite wounds to the calvarium can result in neurologic signs such as circling, disorientation, head pressing, mental obtundation, delayed or absent placing reactions, tetraparesis, anisocoria, absent menace responses, and seizures.[12] Penetration of the caudal vertebral column and spinal cord can lead to vertebral fractures, osteomyelitis, bacterial meningitis, and signs of pelvic limb paralysis (Fig. 75.5). As in dogs, progression to severe sepsis or septic shock can occur, but most cat bite abscesses rupture and resolve spontaneously.

Fig. 75.1 Dog bite wounds. (A) Multiple puncture wounds, abrasions, and lacerations to the abdomen of a 10-year-old female spayed mixed-breed dog. A portion of the jejunum had perforated and had herniated into the subcutaneous tissue. The dog developed cardiac arrest after 2 days of aggressive treatment that included surgery and was euthanized. (B) Five-year-old male neutered Pomeranian dog with a bite wound to the lateral cervical region from a pit bull terrier dog that resulted in tissue avulsion. (C) Inguinal region of a 6-year-old intact male German shepherd dog with severe bite wounds and tissue avulsion that resulted in extensive exposure of muscle and bone. The dog had been attacked by four other dogs. The dog survived with aggressive medical treatment and surgery that included amputation of the right pelvic limb. (Courtesy of the University of California, Davis Veterinary Emergency and Critical Care Service.)

Cats with dog bite wounds often have life-threatening injuries.[10] Fractures, severe hemorrhage, and hypovolemic shock can dominate the clinical picture. Penetrating injury of cervical structures, the thorax, abdominal organs, brain, or spinal cord can occur (Fig. 75.6).[10] Thoracic wounds have been associated with a higher risk of mortality (27% in one study).[10] Death most often results from trauma rather than infection, but occasionally deep-seated infections or bacteremia develops if the cat survives the initial traumatic episode.

DIAGNOSIS

A diagnosis of bite wound infections is based on history of a fight or bite and physical examination findings that suggest that infection has developed. Cytologic examination of a wound may also assist in diagnosis of infection. The veterinarian should record whether the wound was provoked or unprovoked and note the time and location that the wound occurred and the biting animal species involved. Depending on the extent and location of bite wounds, radiographs of the affected region should be considered to assess for underlying damage to bone or body cavities. All cats with cat fight wounds should be tested for FeLV and FIV infection, and the test should be repeated 2 months later because transmission may have occurred at the time of the fight wound (see Chapters 32 and 33).

Laboratory Abnormalities

Laboratory abnormalities in cats or dogs with wound infections are variable and depend on the degree of tissue trauma, the underlying organs involved (if any), and the severity and type of infection. The CBC may show nonregenerative or regenerative anemia, neutrophilia with bandemia, toxic neutrophils, monocytosis, and lymphopenia or lymphocytosis. Animals with severe sepsis or septic shock may be thrombocytopenic. Findings on the chemistry panel include hypoalbuminemia and evidence of muscle damage (increased activities of CK, AST, and sometimes mild increases in serum ALT activity). Increased muscle enzyme activities may be a clue to an underlying cat bite wound in cats with fever of unknown origin. Prolongations of the PT and/or APTT may be present in animals with septic shock and disseminated intravascular coagulation.

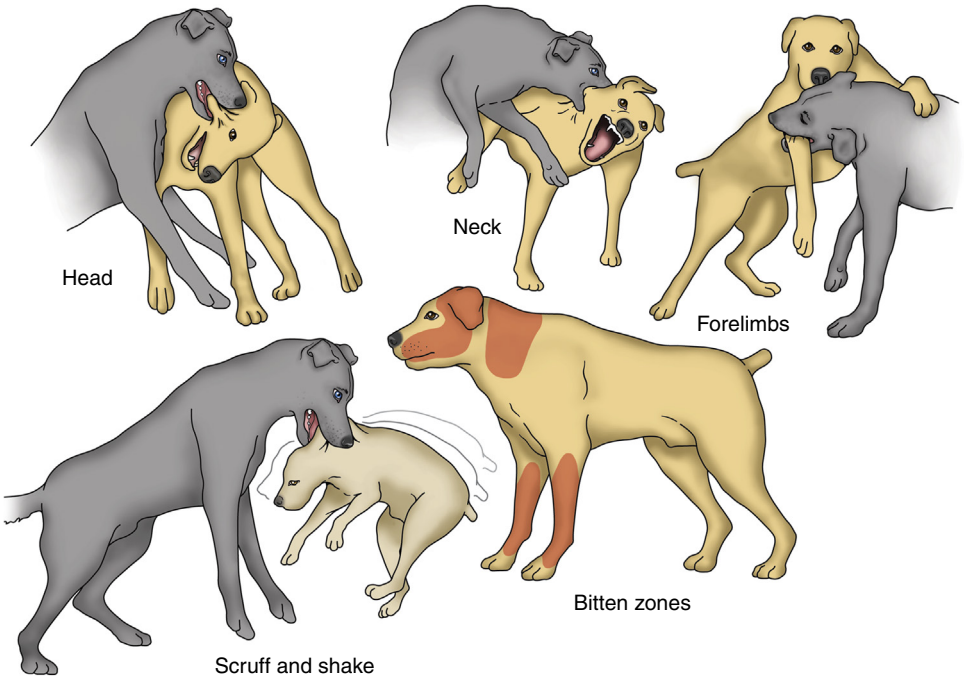

Fig. 75.2 Common anatomic distribution of dog-to-dog bite and fight wounds.

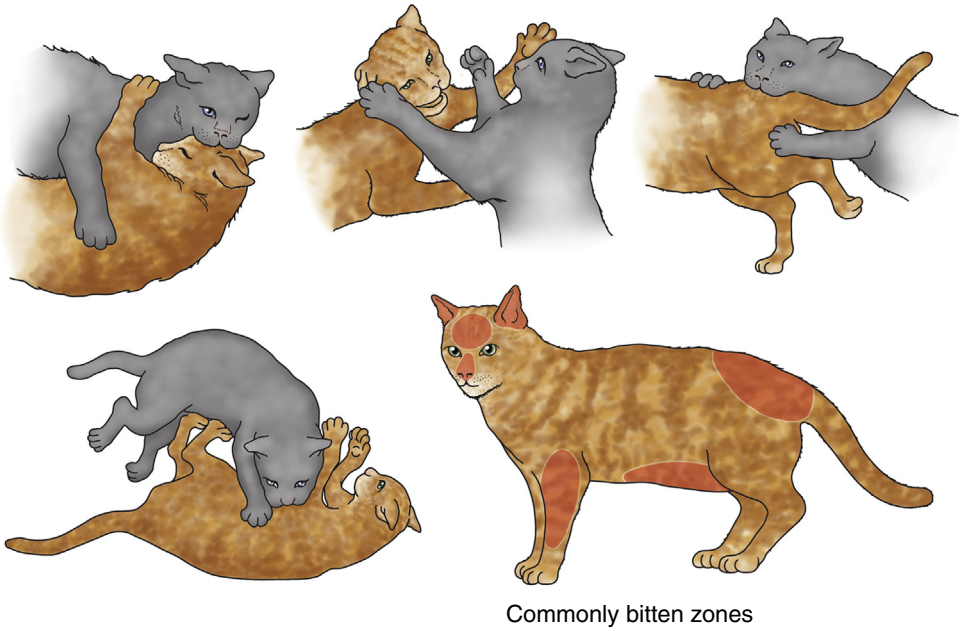

Fig. 75.3 Common anatomic distribution of cat-to-cat bite and fight wounds ("wound cat"). (Adapted from Malik R, Norris J, White J, et al. Wound cat. *J Feline Med Surg.* 2006;8:135-140.)

Diagnostic Imaging

Plain Radiography

Radiographs of the thorax in dogs or cats with bite wounds may show fractured ribs, pneumothorax, evidence of pulmonary contusions, mediastinal emphysema, diaphragmatic herniation, or pleural effusion due to hemothorax or pyothorax. Abdominal radiographs may show a lack of serosal detail due to hemoabdomen or bacterial peritonitis. Radiographs of the axial or appendicular skeleton may reveal fractures or tooth foreign bodies. In more chronic bite wound infections, evidence of osteomyelitis or septic arthritis may be present, with soft-tissue swelling and bony lysis (see also Chapter 121).

Sonographic Findings

Ultrasound of soft tissues can be useful to assess the extent of bite wound infections. Abdominal ultrasound is indicated for animals with bite wounds to the abdomen to assess for evidence of peritonitis or trauma to abdominal organs. Findings in dogs or cats with peritonitis include a hyperechoic mesentery with an irregular outline and free peritoneal fluid, which is typically echogenic (see Chapter 125).

Advanced Imaging

Findings on MRI in cats with brain abscesses secondary to cat bite wounds include space-occupying lesions with well-defined margins

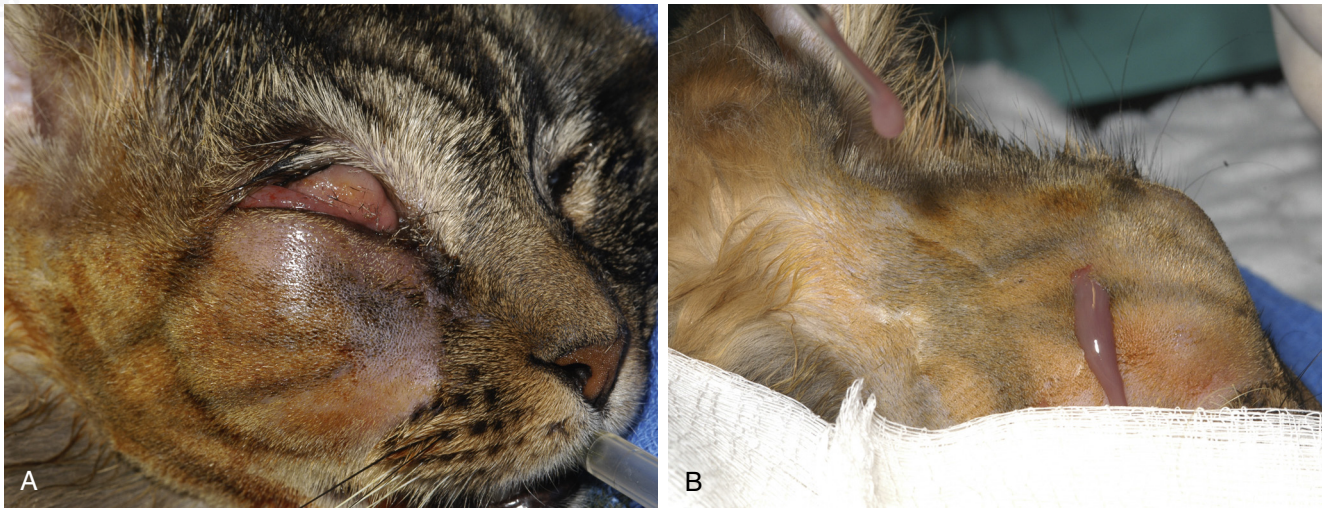

Fig. 75.4 (A) Six-year-old female spayed domestic shorthair cat with a cat bite abscess adjacent to the right eye that was associated with marked chemosis and periocular swelling. (B) Purulent material discharged from the abscess when it was drained surgically. (Images courtesy University of California, Davis Veterinary Ophthalmology service.)

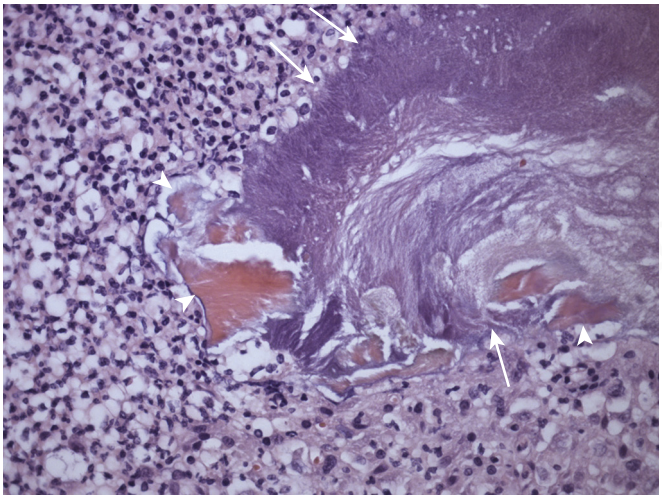

Fig. 75.5 Histopathology of the vertebral column of a young adult, male domestic shorthair that was found with a bite wound to the base of the tail that drained purulent material and pelvic limb paralysis with absent deep pain sensation. Multiple fractures of caudal vertebrae 4 and 5 were present in association with suppurative osteomyelitis *(arrowheads),* cellulitis, ascending meningitis, and masses of intralesional bacteria *(arrows).* Multiple anaerobes were cultured from the lesion. Hematoxylin and eosin stain.

that are hyperintense on T2-weighted images, and hypointense T1-weighted images.[12] Marked ring enhancement is usually present. Evidence of brain herniation may be detected.[12]

Cytologic Examination

Cytologic examination of swab or fluid specimens collected from infected wounds typically reveals large numbers of degenerate neutrophils with intracellular bacteria, which may include cocci, rods, or long, filamentous organisms (which are usually anaerobes).

Microbiologic Tests

Isolation and Identification

Dogs. Aerobic bacterial culture and susceptibility and anaerobic bacterial culture are indicated whenever possible from dogs that are suspected to have infected bite wounds. Routine culture lacks sensitivity for detection of anaerobes, and anaerobic bacterial infections respond predictably to treatment, so anaerobic culture could be considered optional if client finances are limited (see Chapter 54).

The skin around the wound should be clipped and cleaned with chlorhexidine solution, and an aspirate, swab, or devitalized tissue specimen should be collected from as deep within the wound as possible while the animal is sedated or anesthetized. When pockets of purulent material extend subcutaneously away from an open wound, collection of aspirates percutaneously with a needle and syringe can avoid contamination by surface bacteria. Because a positive culture from a wound does not imply infection, results must be interpreted in light of the physical examination and laboratory findings. Susceptibility test results for isolated bacteria can then be used to guide antimicrobial drug treatment. Blood cultures should be considered for dogs with evidence of severe sepsis or septic shock.

Cats. In general, culture of cat bite abscesses in cats is not routinely performed because they almost always respond to drainage with or without systemic antibacterial drug treatment. Cytologic examination and culture are indicated for cat bite abscesses/cellulitis if clinical signs of infection are persistent or recurrent in the face of treatment, or if severe infections that involve underlying bones, joints, or body cavities occur. Culture is also recommended for draining skin lesions in the inguinal region, which may result from infection with rapid-growing mycobacteria (see Chapter 61). Blood cultures are indicated for cats with signs of severe sepsis or septic shock.

TREATMENT

Surgical Management

Dogs

Dogs with dog bite wounds should be muzzled and the wound(s) covered with a clean, dry bandage immediately after the injury occurs to prevent further contamination of the wound until the animal's condition can be stabilized if necessary. If possible, the dog should then be sedated or anesthetized and a wide area of skin around the wound clipped in order to determine the extent of injury and prepare for surgery. Frequently, this leads to detection of additional full-thickness puncture wounds or lacerations. The skin around the wound should be scrubbed with chlorhexidine or povidone-iodine

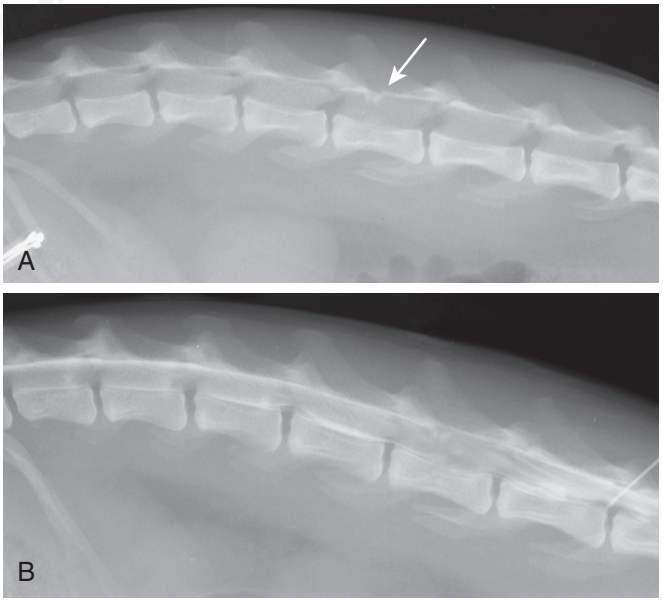

Fig. 75.6 (A) Lateral radiograph of the lumbar spine of a 3-year-old female Siamese cat with a dog bite wound to the lumbar spine. The cat was unable to stand and had absent placing reactions in the pelvic limbs. Patellar reflexes were also absent. Two osseous densities are superimposed at the level of the dorsal spinal canal at the level of the fourth lumbar vertebra (L4) *(arrow).* The dorsoventral view showed deviation of the spinous process of L4 (not shown). CSF analysis revealed mild suppurative inflammation. (B) Myelogram. A spinal needle is inserted at L5-6 for injection of contrast agent. Spinal cord widening with associated thinning of the contrast column circumferentially is identified over the body of L4. Dorsal deviation and splitting of the ventral contrast column is present over L2-3 as a result of disc protrusion in this region. A decompressive hemilaminectomy over L4 to L6 was performed and a bone fragment was removed; the cat ultimately recovered.

solution. Full-thickness punctures and lacerations should then be explored, debris and devitalized tissue removed, and specimens collected for culture if infection is suspected. If the abdominal or thoracic cavity has been penetrated, surgical exploration of these cavities is typically required to identify and treat damaged viscera. Wounds should be lavaged extensively with copious quantities of sterile saline or lactated Ringer's solution under moderate pressure (such as using a 60-mL syringe attached to an 18-gauge needle). The use of antibiotics or antiseptics to lavage the wound is not generally recommended, as they can be toxic to tissue and provide minimal benefit for treatment of established wound infections. If used, 0.05% chlorhexidine diacetate (1 part 2% chlorhexidine to 39 parts water) is preferred because it has antibacterial activity in the presence of organic debris, residual antibacterial activity, and minimal systemic absorption and toxicity.

In general, infected wounds that are limited to the subcutaneous tissues and muscle are subsequently managed as open wounds in order to optimize drainage and debridement. Closure of infected wounds can lead to dehiscence and persistence of infection. Whenever possible, the wound is covered with bandages that absorb fluid, reduce dead space, prevent movement and contamination of the wound, and assist in debridement. Hydrophilic bandages are often used for the first 3 to 5 days. Wound closure is generally recommended for noninfected wounds that are in the "golden period" (first 6 to 8 hours after injury). The reader is referred to small animal surgical texts for more detailed information on surgical management of bite wound infections, including debridement, closure, reconstructive techniques, dressings, and bandaging (see Suggested Readings).[13]

TABLE 75.2 Suitable Antimicrobial Drugs for the Treatment of Bite Wound Infections in Dogs and Cats[a]

Drug	Species	Dose (mg/kg)	Interval (hours)	Route
Amoxicillin-clavulanic acid	D, C	12.5–20	8–12	PO
Ampicillin-sulbactam	D, C	10–20[b]	8	IV, IM
Pradofloxacin[c]	D C	3 5–7.5	24 24	PO PO
Enrofloxacin	D	5–20	24	IV, IM, PO
Marbofloxacin	D	2.75–5.5	24	PO
Gentamicin	D	9–14	24	IV, IM
Amikacin	D	15–30	24	IV, IM
Metronidazole	D, C	10	8	PO, IV

[a]Doses of antimicrobial drugs that have activity primarily against gram-negative aerobes are listed for dogs, because isolation of gram-negative aerobes from cat bite abscesses is very rare.
[b]Dose according to ampicillin component.
[c]The pradofloxacin dose for dogs is for the tablet formulation available in Europe. The dose for cats is for the oral suspension. The use of pradofloxacin in dogs may be associated with myelosuppression and is off-label in some countries.
C, cat; *D,* dog.

Cats

As for open dog bite wounds, a wide area of skin around cat bite abscesses should be clipped and scrubbed. The abscess should then be lanced and specimens collected for culture if desired. The abscess cavity should then be lavaged, necrotic tissue debrided, and a placement of a drain should be considered to optimize drainage and prevent early wound closure. Whenever possible, the wound and drain should then be covered with a bandage. The drain is removed in 3 to 5 days. For cats with pyothorax, placement of chest tubes with or without surgical exploration may be required (see Chapter 124 and Suggested Readings for this chapter).[14] Cats with abscesses that involve the CNS have the potential to recover with craniectomy, drainage of purulent material within the abscess, removal of any tooth fragments present, and closure of subcutaneous tissue and the skin.[12]

Antimicrobial Treatment

Contaminated Wounds (First 8 Hours After Injury)

The need for antimicrobial treatment in contaminated, noninfected wounds is controversial, because there is no evidence that it prevents infection of the wound and it may select for infection with bacteria that are resistant to the antimicrobial drug used. Proper wound cleaning and debridement are likely to have the greatest impact on whether infection subsequently develops. Antimicrobial treatment could be considered for deep punctures or large, dirty wounds that require extensive debridement. If deemed necessary, the drug of choice for contaminated wounds is amoxicillin-clavulanic acid, because it has efficacy against most oral cavity commensals of the dog and cat mouth such as *Pasteurella* spp. and a variety of anaerobes, including those that produce β-lactamase enzymes.

Infected Wounds

For severely infected dog bite wounds, initial treatment should consist of parenteral antimicrobial drugs that have activity against gram-negative and gram-positive aerobic and anaerobic bacteria, which includes methicillin-resistant staphylococci (in regions where methicillin-resistant *S. pseudintermedius* is prevalent). Appropriate

combinations include ampicillin-sulbactam and an aminoglycoside, or a combination of ampicillin, metronidazole, and an aminoglycoside (Table 75.2). Where methicillin-resistant *S. pseudintermedius* is not prevalent, a fluoroquinolone could be substituted for the aminoglycoside. Subsequent treatment should be based on the results of culture and susceptibility. Amoxicillin or amoxicillin-clavulanic acid are appropriate choices for treatment of cat bite abscesses once drainage has been established (although many cat bite abscesses will likely heal with drainage alone). Because *Pasteurella* spp. are not susceptible to clindamycin or first-generation cephalosporins, monotherapy with these drugs should be avoided. Pradofloxacin is also a suitable choice, because it has activity against anaerobes as well as a variety of aerobic bacterial species.

Antimicrobial drug treatment of infected bite wounds that are localized to the skin, subcutaneous tissue, and muscle should continue for 3 to 5 days after signs of infection are no longer evident. The reader is referred to Chapters 121, 124, and 125 for information on the management of osteomyelitis, septic arthritis, pyothorax, and peritonitis.

Rabies Prophylaxis

In regions where rabies occurs, bite wounds may need to be reported to local public health authorities. If the biting animal has an unknown vaccination history, or the bite was from a wild animal that was unavailable for testing, a rabies booster should be administered and the animal monitored for 45 days. If the bitten animal is unvaccinated or has a lapsed vaccination status, additional quarantine or euthanasia may be required (see Chapter 21).

PROGNOSIS

The odds of mortality for dogs that had bite wounds to the thorax were 23.4-fold higher when a positive bacterial culture was made and 12.1-fold higher when pleural effusion was present.[5] Mortality rate for cats with thoracic dog bite wounds was 27% at the same institution,[10] approximately double that for dogs. The prognosis for bite wound infections depends on the severity and extent of injury, the immune status of the host, and the organisms involved. Recurrent infections may result from underlying osteomyelitis, foreign bodies, immunodeficiency, or the presence of atypical organisms such as *Mycobacterium* spp., *Nocardia* spp., or *Mycoplasma* spp. (which do not respond to β-lactam drugs). Failure to respond to appropriate treatment should prompt a thorough physical examination; testing for retroviruses in cats; imaging of the affected area; and culture for aerobic and anaerobic bacteria and mycoplasmas. If the clinical picture is suggestive, culture for mycobacteria may also be indicated.

PREVENTION

Prevention of bite wounds involves education of pet owners with regard to housing cats indoors and use of secure collars and leashes for walking dogs (Box 75.1). Intact male dogs should be neutered if they are not to be used for breeding. Proper handling and socialization of puppies as well as behavior training should be encouraged. Pet owners should be instructed to avoid or closely supervise interactions between their dogs and unfamiliar dogs that are breeds of known aggressive tendency, such as American pit bull terriers, rottweilers, German shepherds, blue heelers, chow chows, and Jack Russell terriers, although mixed-breed dogs have also been identified in association with increased risk of bite injury.[15] Special caution is warranted for small-breed dogs, which may provoke larger breed dogs and are more likely to develop life-threatening injuries. Dogs that are unfamiliar with one another or dogs with a history of fighting with one another should never be left together without proper supervision.

BOX 75.1 Strategies to Prevent Dog Bites[24]

- Always supervise an infant or child who is near a dog (even your own or another known dog). Any dog can bite.
- Do not disturb any dog caring for puppies, eating, or sleeping.
- Never reach through or over a fence to pet a dog.
- Do not run past or from a dog.
- Teach children to move slowly around dogs.
- Do not encourage aggressive or rough play with any dog.
- Always ask permission from a dog's owner before petting a dog. Always let the dog sniff your hand before petting a dog.
- Never approach any unfamiliar dog. If an unfamiliar dog approaches, stand still with your arms to the side.
- Keep your dog healthy and provide routine veterinary care.
- Socialize and train your dog.

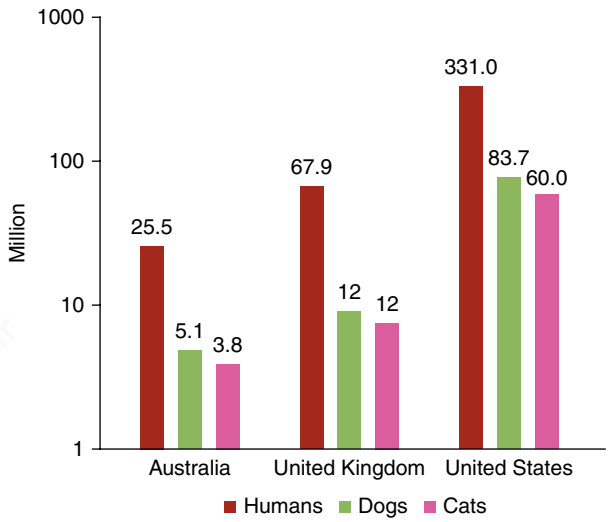

Fig. 75.7 Estimated absolute numbers of humans and owned dogs and cats in Australia, the United Kingdom, and the United States in 2020–2021 (data expressed in millions with a logarithmic scale on the y-axis).[16–18]

PUBLIC HEALTH ASPECTS

Epidemiology of Dog and Cat Bite Wounds

In 2021, the AVMA reported that in 2020, there were 83.7 million dogs and 60 million cats; 45% of households owned at least one dog and 26% of households owned cats.[16] This amounts to more dogs and cats than the combined human population in the United Kingdom and Australia in 2019 (Fig. 75.7). In the United Kingdom, the Pet Food Manufacturers' Association estimated that around 33% of households owned a dog and 27% owned a cat in 2021, with 59% of households owning pets.[17] In Australia in 2019, 40% of households owned dogs and 27% owned cats; the total pet population was estimated at 29 million, more than the estimated human population of 25 million.[18] Based on a survey conducted in 2018, fewer households in Japan owned dogs (11.5%) and cats (10.1%).[19] In the United States, German shepherds, rottweilers, and Jack Russell terriers are among the top 10 dog breeds owned. Dog and cat bite wounds account for approximately 1% of emergency department visits by humans in the United States, and similar numbers are reported in Europe. Dog bites accounted for more than 70% and cat bites accounted for 13% of animal bite visits to emergency rooms in New York City.[20] The median age of bitten people in one study was 15 years, in another study it was 28 years, and in a third study of facial dog bites from the Massachusetts General Hospital over a 20-year period (1997–2018) it was 29.5 years.[21–23]. Many bites occur

in children, especially boys aged 5 to 9 years.[21,22,24–27] Children often have dog bites to the face, neck, and head.[28,29] Women and the elderly are at risk for cat bite injuries almost always to the hands. Patients who seek medical attention more than 8 hours after injury usually have infected wounds.

Dog Bite Infections

In the United States in 2018, dog bites accounted for 340,000 emergency department visits per year (900/day), and over 40% of those bitten were children or adolescents.[30] An analysis of police reports over an 8-year period in Detroit revealed that 83% of dog bite incidents were caused by a neighborhood dog, and most often occurred in the victim's yard by dogs that were found wandering-at-large or had escaped from their own yard.[31] Stay-at-home orders related to the COVID-19 pandemic have led to increased contact between children and their dogs, and one pediatric emergency department in Colorado reported a 3-fold rise in visit rates for dog bites (Fig. 75.8). In the case series of facial dog bites in Massachusetts, 88% of dogs were known, and provocation was reported in 65% of cases; pit bulls were responsible for most bites (8.5%). Behaviors described before the bite were playing with a dog, feeding a dog, or placing the face close to the dog. Pit bulls were also associated with most bites (36%) in case series of children and adolescents from central Texas[28] and people with orthopedic bite wound injuries in Fresno, California (50%).[32] A Canadian study found an association between dangerousness and increased body weight; entire male dogs were most dangerous despite absence in differences in body weight between neutered and non-neutered male dogs. In this study, dangerousness was categorized based on severity of injury and the appropriateness of aggressive behavior given the context.[33]

Between 3% and 20% of dog bite wounds in humans become infected.[34–36] The infecting organisms generally reflect the flora of the canine oral cavity, but may also derive from the environment or the bitten person's skin or oral cavity. Many infections are polymicrobial, but the organism that most often contributes to dog bite wound infections is *Pasteurella* spp., which is found in 50% of wounds (Table 75.3).[21,37–45] The most common species is *Pasteurella canis*, but *P. multocida* (subspecies *multocida*, *septica*, and *gallicida*), *Pasteurella stomatis*, and *Pasteurella dagmatis* may also be present.[46] Other common isolates from dog bite wounds include streptococci (especially the α-streptococcus *Streptococcus mitis* and *Streptococcus pyogenes*; *Streptococcus canis* is rarely isolated), staphylococci, *Corynebacterium* spp., *Neisseria* spp., and anaerobes.[37] Of the staphylococci, *S. aureus* is isolated most often (20% of infections). Infections with *S. pseudintermedius* occur rarely. Anaerobes are present in approximately 70% of infections and are almost always present in combination with other anaerobes and aerobic bacteria. Lethal outcomes of bite wound infections are rare but have been reported following infection by *C. canimorsus* and *P. multocida*.[47,48] *Pasteurella multocida* subsp. *septica* may have a greater predisposition to infect the CNS when compared with other *P. multocida* subspecies.[49]

Cat Bite Infections

Although cat bite wounds are less traumatic to tissue, they are more likely to become infected and progress to infection more rapidly than dog bite wounds.[14] Infection rates in children can be up to 50%.[34] The upper extremities are often affected. Most infections are polymicrobial. As in dog bite wounds, *Pasteurella* spp. are the most common organisms isolated and are present in 75% of wounds.[21,37] The predominant species are *P. multocida* subsp. *multocida* and *P. multocida* subsp. *septica*. Streptococci (including *S. pyogenes*) and staphylococci are also often present, but *S. aureus* is isolated less frequently from cat bite wounds than dog bite wounds. *Neisseria* and *Moraxella* are also often isolated from cat bite wounds (see Table 75.3). The prevalence of infection with anaerobes in cat bite wounds is similar to that in dog bite wounds.[21]

Clinical Manifestations of Human Infections

Infection of bite wounds in humans most often results in localized cellulitis, pain, purulent discharge, a black to gray appearance, and, less often, fever and local lymphadenopathy. Extension to underlying bones

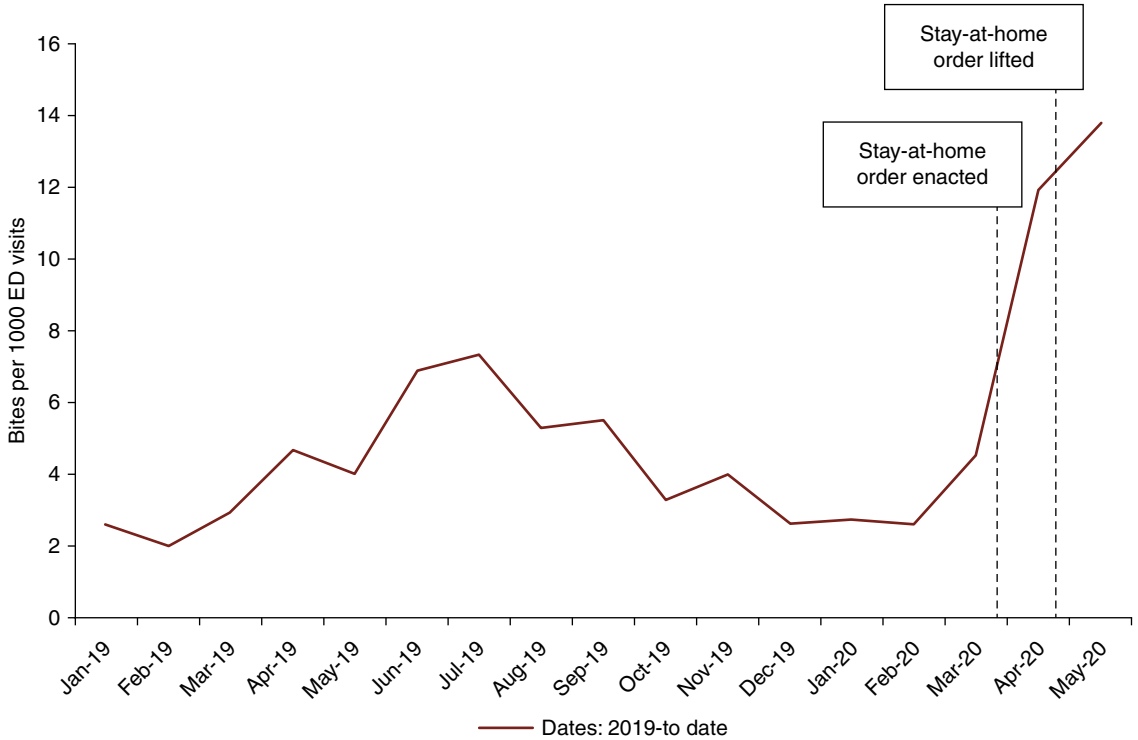

Fig. 75.8 Dog bite incidence before and after the COVID-19 pandemic. (Modified from Dixon CA, Mistry RD. Dog bites in children surge during coronavirus disease-2019: a case for enhanced prevention. *J Pediatr* 2020;225:231-232)

or joints can lead to osteomyelitis or septic arthritis, which is especially likely to occur after penetrating cat bite wounds to the hand (Fig. 75.9). Tenosynovitis is also common. Rarely, necrotizing fasciitis, bacteremia, meningitis, endocarditis, peritonitis, or brain abscesses develop.[28,50]

Most of the serious consequences of dog or cat bite wound infections occur in immunocompromised humans and involve *P. multocida* or *C. canimorsus*. Severe disease manifestations have also occurred after exposure of wounds to dog or cat saliva through licking, or after invasive medical supplies (such as dialysis tubing) were chewed or licked by a pet.[51] In a few cases, patients have had a history of contact with animals but no known bite or scratch wound.[52–57] Life-threatening infections with *P. multocida* tend to occur in infants, pregnant women with animal contact, patients on chronic glucocorticoid therapy, HIV-infected people, organ-transplant recipients, and patients with chronic liver disease.[50]

Capnocytophaga canimorsus is a capnophilic (carbon dioxide–loving), facultatively anaerobic, filamentous gram-negative bacterial rod that is found in the oral cavity of dogs and cats.[58] Although rarely reported as a cause of illness in dogs or cats, this organism can cause cellulitis, gangrene, bacteremia, meningitis, and endocarditis in humans.[50,58,59] *Capnocytophaga canimorsus* bacteremia is rare, but humans who are immunocompromised, especially those with chronic alcoholism, cirrhosis, or a history of splenectomy, are at risk for life-threatening *C. canimorsus* infections that progress rapidly, with a mortality of over 30%. However, severe infections have also been described in apparently immunocompetent humans.[60] The virulence factors that contribute to these severe infections are not well understood. The organism does not cause endotoxemia but appears to evade recognition by the immune system and resist phagocytosis.[50] In one series of humans with *C. canimorsus* sepsis, 56% of cases followed a dog bite and 10% of cases followed exposure of a wound to dog saliva by licking.[61] Veterinarians have also developed corneal infections with *C. canimorsus* when dog tooth fragments have struck them in the eye during dental extractions.[62,63] Most affected humans are older than 40 years of age. Clinical manifestations of *C. canimorsus* sepsis include fever, myalgia, and a petechial rash that involves the skin and mucous membranes, which may progress from purpura *(purpura fulminans)* to gangrene over a period of several days. Because *C. canimorsus* is very difficult to grow, early diagnosis and successful treatment require clinical suspicion and early treatment with effective antimicrobial drugs, such as β-lactam/β-lactamase inhibitor combinations, which are also active against *Pasteurella* spp.

Prevention of Bite Wounds in Humans

Veterinarians play an important role in educating the public about prevention of cat and dog bite wounds. Provision of information to clients who intend to purchase a new dog about dog breeds, puppy socialization, dog behavior training, and how to prevent and manage aggression and avoid bites or scratches (to themselves and to others) is encouraged. Dog owners should be instructed to always supervise children and infants when near a dog. Dog owners may have difficulty finding homeowners insurance if their dog bites someone. Many insurance companies will not insure a homeowner with certain breeds of dogs.

Veterinarians can also engage in community activities (especially in schools) where young children can be educated about pet ownership and how to avoid wounds and wound infections from their own or someone else's dog or cat. One report described a decrease in the severity of dog bite injury in children following implementation of an educational safety program for primary school children.[64] Immunocompromised individuals should be educated about the potential benefits and risks of pet ownership and precautions that can be taken to minimize infections. During 2015, 181 Los Angeles letter carriers were involved in dog attacks. Finally, care should be taken in the veterinary practice situation

to avoid bites or scratches to veterinary staff. Veterinary staff should be educated about the types of infections that can occur in the workplace; likelihood of these infections; risk factors for infection; appropriate preventative measures; and protocols to follow should a bite or scratch wound occur.[65] Immediate treatment of animal bite injuries has been shown to reduce complications and shorten hospitalization.[66] In general, antimicrobial preemptive treatment with activity against *Pasteurella* (i.e., not first-generation cephalosporins, dicloxacillin, erythromycin, clindamycin, or metronidazole unless in combination with antimicrobials active against *Pasteurella*, such as amoxicillin-clavulanic acid) is recommended for 3 to 5 days even in the first 24 hours after injury for moderate to severe bites, especially those to the hand or face, when a joint could be involved, when there is edema, or in an immunocompromised patient.[49] Primary closure is not recommended unless there are cosmetic or functional reasons that primary closure might be necessary. Routine hand-washing practices should be enforced, and licking by dogs or cats should be discouraged. Face protection should be worn by veterinary staff when dental procedures are performed. Bites and scratches may need to be reported to public health authorities, and all staff should be educated about the need to ensure that tetanus and rabies immunizations are not overdue.

Fig. 75.9 Cat bite wounds to the base of the thumb of a veterinarian with associated cellulitis. Penetrating cat bite wounds of the hand have a tendency to extend to underlying bones and joints.

CASE EXAMPLE

Signalment

"Murphy," a 5-year-old intact male boxer dog from Vacaville in northern California.

History

Murphy was evaluated by the University of California, Davis Veterinary Emergency and Critical Care service for dog bite injuries after a fight with another dog in the household. The owner had returned home a few hours earlier to find Murphy bleeding from the neck. The other dog, a 5-year-old male neutered boxer mix, was found hiding and unable to stand with several "scratches" on his body. Murphy had a history of fights with other dogs. Both dogs in the household were fully vaccinated for CDV, parvovirus, adenovirus, and rabies. There was no other pertinent medical history.

Initial Physical Examination

Body weight: 46.2 kg.
General: Quiet, alert, responsive, and hydrated. T = 102.1°F (38.9°C), HR = 110, panting, pink and moist mucous membranes, CRT = 1 s.
Integument: The haircoat was full, thick, and dirty. There was a 1-cm superficial laceration on the ventral aspect of the pinna, and approximately 10 puncture wounds on the left ventral cervical region. A 2-cm superficial laceration was present at the cranial aspect of the dorsal midline, and a 5-cm superficial laceration was present on the left flank. No ectoparasites were seen.
Eyes, ears, nose, and throat: Bilateral conjunctival hyperemia and a mucoid ocular discharge were present. No other significant abnormalities were noted.
Musculoskeletal: BCS 6/9, ambulatory
Other systems: No clinically significant abnormalities were detected. Cranial nerve examination was unremarkable. A full neurologic examination was not performed.

Initial Treatment

Murphy was sedated with hydromorphone and dexmedetomidine. The left neck was clipped with a no. 40 clipper blade from the midpoint of the dorsal aspect of the head to the ventral aspect of the left ear and the thorax. The skin was cleaned with 0.05% chlorhexidine solution, and all puncture sites were probed and flushed with sterile saline. The sites were found to be relatively superficial. Drain sites were created with a no. 11 scalpel blade for three wounds, and a 3 × 0.75 inch Penrose drain was placed across a wound site that had the greatest amount of dead space and secured with a single interrupted suture. The dog was sent home with instructions for the owner to administer amoxicillin-clavulanic acid (16 mg/kg PO q12h) and tramadol (2.4 mg/kg PO q8-12h), to monitor the wound for development of excessive discharge, bleeding, swelling, or redness, and to keep the area clean with a washcloth soaked in warm water. Instructions were provided to return in 3 days to have the wound reevaluated and the drain removed.

The owners returned 7 days later for drain removal. At that time, they reported that Murphy had been eating normally, but had been drinking more than usual. His activity level had been normal, but they believed his neck had become swollen and tender. They had been administering the medications as directed.

CASE EXAMPLE—cont'd

Physical Examination (Day 7)

Body weight: 46.2 kg.

General: Quiet, alert, responsive, and hydrated but anxious. T = 103.1°F (39.5°C), HR = 114, RR = 36, pink and moist mucous membranes, CRT = 1 s.

Integument: There were marked crusts and scabs on the left lateral and ventral aspect of the neck. The Penrose drain was present with minimal amounts of discharge. Serous to purulent discharge was draining from the ventral puncture wounds. There was moderate crusting of the dorsal aspect of the left pinna.

Other systems: No change from the previous examination.

Treatment (Day 7)

The dog was again sedated and purulent material was collected for culture and susceptibility. The eschars were gently removed with forceps and the skin scrubbed with 0.05% chlorhexidine and water. Ultrasound of the neck region revealed pockets of hypoechoic material beneath the skin, and surgical debridement of the area under general anesthesia was recommended. Subsequently, Murphy was anesthetized and the wound was explored. No abscesses were found. The devitalized tissue was excised, the wounds flushed vigorously, and two Penrose drains were placed. The neck was bandaged initially, but this interfered with the dog's ability to breathe comfortably, so the bandage was removed. The dog was hospitalized overnight and treated with hydromorphone (0.05 mg/kg IV q4h) and warm compresses to the neck (q6h for 5 minutes). He was then sent home with instructions to administer tramadol as previously prescribed, clindamycin (20 mg/kg PO q12h), and enrofloxacin (10 mg/kg PO q24h), and to warm compress the neck every 4 to 6 hours for the next 3 days. They were also instructed to return in 3 to 5 days for reevaluation and drain removal.

Microbiologic Testing

Direct mear and Gram stain: Rare numbers of gram-positive cocci

Aerobic and anaerobic culture and susceptibility (swab from wound):

Isolate 1: Methicillin-resistant *Staphylococcus aureus,* resistant to all β-lactams and clindamycin; susceptible to amikacin (≤4 μg/mL), chloramphenicol (8 μg/mL), doxycycline (≤2 μg/mL), enrofloxacin (≤0.25 μg/mL), gentamicin (≤1 μg/mL), marbofloxacin (≤0.25 μg/mL), rifampin (≤1 μg/mL), and trimethoprim-sulfamethoxazole (≤0.50 μg/mL).

Isolate 2: *Enterococcus faecium* (intrinsic resistance to low-level aminoglycosides, cephalosporins, clindamycin, fluoroquinolones, trimethoprim-sulfamethoxazole), resistant to chloramphenicol and rifampin. Intermediate susceptibility to doxycycline (8 μg/mL), erythromycin (1 μg/mL), ticarcillin (64 μg/mL), and ticarcillin-clavulanate (64 μg/mL). Susceptible to ampicillin (1 μg/mL), clavulanic acid-amoxicillin (≤4 μg/mL), penicillin (4 μg/mL), and imipenem (≤1 μg/mL).

Isolate 3: *Pseudomonas aeruginosa,* resistant to ampicillin, amoxicillin-clavulanic acid, all cephalosporins tested, chloramphenicol, and doxycycline. Susceptibility to clindamycin was not reported because this species is usually resistant. Susceptible only to amikacin (≤4 μg/mL), gentamicin (2 μg/mL), enrofloxacin (0.50 μg/mL), imipenem (≤1 μg/mL), ticarcillin (16 μg/mL), ticarcillin-clavulanic acid (16 μg/mL). The MICs for trimethoprim-sulfamethoxazole and marbofloxacin were 2 μg/mL and ≤0.25 μg/mL, respectively.

Anaerobic culture: Moderate numbers of mixed growth that included *Bacteroides ureolyticus* group (β-lactamase negative), *Peptostreptococcus anaerobius,* and *Bacteroides* spp./*Prevotella* spp. (β-lactamase negative).

Diagnosis

Polymicrobial bite wound infection with anaerobes and multiple drug-resistant aerobic gram-positive and gram-negative bacteria.

Outcome

On receipt of the culture and susceptibility test results, the clindamycin was substituted with amoxicillin-clavulanic acid (16 mg/kg PO q12h). Treatment with enrofloxacin was continued and the owners were educated with regard to the public health significance of the infection and the need to wear gloves when handling the wound and for scrupulous hand-washing practices. The dog returned 4 days after surgery for drain removal. The owners reported that the drains had been producing considerable amounts of purulent material and that Murphy was doing well. He was afebrile and the wound was unchanged in appearance. He was again sedated, the area was scrubbed, and crusts were removed. The drains were removed. Murphy recovered uneventfully and the sutures were removed 10 days later at a local veterinary clinic. Five months later he was seen again for multiple bite wounds to the thoracic limbs and right thorax.

Comments

In this dog, bite wound injuries were complicated by infection with multiple gram-negative and gram-positive drug-resistant aerobic bacteria as well as anaerobes. The *S. aureus* and *P. aeruginosa* were resistant to amoxicillin-clavulanic acid, which had been used to prevent infection when the dog was first seen. In contrast, the anaerobes and the *E. faecium* were susceptible to amoxicillin-clavulanic acid, but presumably were able to proliferate and persist in the face of antimicrobial drug treatment as a result of the presence of the other drug-resistant bacteria, purulent material, and dead space. Bite wounds to the neck can be a challenge to manage because of the mobility of this area, which contributes to the maintenance of the dead space. The use of a bandage can reduce dead space, avoid further contamination, and reduce exposure to multidrug-resistant bacteria, but attempts to bandage the wound were not tolerated by this dog. Client education was an important part of management. The owners were instructed to separate the dogs when unattended to avoid further fights. Neutering may also have been of benefit.

Surgical and Traumatic Wound Infections

J. Scott Weese, Ameet Singh

KEY POINTS

- Cause: Infection (typically bacterial) associated with breaches in normal host defenses, which are inherent risks with any surgical procedure.
- Geographic Distribution: Worldwide.
- Route of Transmission: Bacterial contamination can occur pre-, intra- or postoperatively. Contamination can come from the patient's microbiota, veterinary personnel, equipment, the environment (hospital and community), or owners.
- Major Clinical Signs: Most often, infections are superficial and are characterized by signs of inflammation at the superficial surgical site. Cardinal signs of inflammation and purulent discharge are typically present. Systemic signs of infection/inflammation are uncommon but can occur from deep or organ/space infections, or from bacterial translocation from an infected site.
- Differential Diagnoses: Surgical site inflammation is the main differential diagnosis.
- Human Health Significance: Some pathogens may pose a zoonotic risk, particularly methicillin-resistant *Staphylococcus aureus* (MRSA).

ETIOLOGY AND EPIDEMIOLOGY

The skin is a complex organ that serves as a barrier to the vast commensal and external microbiotas, which harbor a large collection of opportunistic pathogens. The skin microbiota has only recently been explored in detail in dogs and cats,[1–3] and it is still poorly understood. It contains a large and diverse population of bacteria, with smaller numbers of fungi, encompassing transient organisms from the environment or other individuals, and a more established resident population. Included in this is a range of harmless commensals and opportunistic pathogens, and it is reasonable to assume that all patients harbor multiple potential opportunistic pathogens on their skin and mucosal surfaces at any given time. Any traumatic injury to skin creates a potential portal for infection from those sites, other body sites (e.g., the GI tract), the environment, veterinary personnel, and owners. Factors such as wound size, depth, degree of contamination, presence of foreign material, degree of tissue damage, and compromise of vascular supply all play a role in whether infection develops.

A key concept in SSI prevention is consideration of the "period of risk." This is greatest during the time from first incision until some point at which healing of the surgical wound has formed an effective barrier. The starting point is the point at which the skin or mucosal barriers are breached. The end point is harder to discern. It presumably decreases greatly by the time of surgical wound closure, but is not complete until sometime (perhaps hours) after that, as an effective seal is created through the healing process.

While surgery is ideally performed in well-designed surgical suites, a sterile environment is not achievable. Risk from aerosolized bacteria and fungi exist in the best designed and maintained operating theatres, from pathogens in the environment, on surgical personnel, or on the patient. Surgical instruments are the main area where sterility can truly be achieved, yet these can carry pathogens into the wound once they are exposed to the external environment or patient.

Various studies have evaluated SSI rates in different patient populations, using different approaches. The use of active (e.g., patient examination, telephoning owners) versus passive (medical record review) approaches, and varying (or undescribed) definitions for SSI hamper comparisons between studies. Nevertheless, while the actual rates vary between and within procedures, the key aspect is that SSIs are uncommon on a percentage basis, but given the large number of surgical procedures that are performed, the impact of SSIs on the patient, owner, and clinician can be substantial.

Risk factors for SSIs have been studied in differing dog and cat populations, and results are somewhat inconsistent (Table 76.1). Various patient (e.g., breed, hypotension), procedure (e.g., dirty, procedures with implants), and surgeon (e.g., experience) risk factors have been reported, examples of which are presented in Table 76.2.

In humans, surgical wounds are classified as clean, clean contaminated, contaminated, and dirty.[4] This classification system also is commonly used in veterinary medicine, and while study of the impact of these categories on SSI risk has been limited, there is an association with increasing surgical risk class and SSI incidence.[5,6] Consideration of surgical wound category is useful when making decisions about antimicrobial prophylaxis, owner consultation about risk, and for surveillance purposes, albeit with some limitations (Table 76.3).

Clean surgical wounds are surgical incision sites with no prior trauma or inflammation; no breaks in sterile technique during surgery; and no contact with mucosal surfaces such as the respiratory, genitourinary, or GI tracts.

Clean contaminated surgical wounds are defined when there are minor breaks in surgical technique (such as a torn glove); contact with normal mucosae of the GI tract without spillage of visceral contents; or contact with uninfected genitourinary, biliary, or respiratory tracts. They also include otherwise clean procedures involving drain placement.

Contaminated surgical wounds have accidental GI tract spillage from penetration of an infected viscus or tissue, foreign bodies, devitalized tissue, or pus; or involve a break in sterile technique. Bacterial contamination is suspected, but purulent discharge is absent. Clean lacerations of the skin or subcutaneous tissues that are not already infected are often categorized as contaminated.

TABLE 76.1 Examples of Surgical Site Infections Surveillance Studies in Dogs and Cats

Population	n	SSI Rate
Dogs, TPLO[38]	437	2.3%
Dogs, TPLO[39]	134	14%
Dogs, TPLO[40]	145	8.4%
Dogs, TPLO[40]	155	7.1%
Dogs, TPLO[33]	549	6.7%
Dogs, TPLO[32]	226	13.3%
Dogs, TPLO[41]	242	10.8%
Dogs, TPLO[30]	902	6.1%
Dogs, TPLO[29]	1000	6.6%
Dogs, various procedures[6]	846	3%
Dogs and cats, various procedures[5]	1010	3%
Dogs and cats, various procedures[19]	1255	5.5%
Dogs, cranial crucial ligament rupture procedures[42]	811	3.2%
Dogs, hemilaminectomy[43]	154	0.6%
Dogs, laparoscopic ovariectomy or ovariohysterectomy[44]	224	1.3%
Dogs and cats, various procedures[7]	1143 dogs, 102 cats	2.8%
Dogs > 50 kg, TPLO and TTA[31]	91 TTA, 54 TPLO	TTA: 15.4% TPLO: 26%
Dogs, orthopedic implant procedures[45]	389	4.3%
Dogs, TTA[46]	224	5.3%
Dogs, TTA[47]	624	7.6%
Dogs, TTA[48]	1613	6.1%
Dogs, orthopedic implant procedures[34]	97	12.9%
Dogs, elbow arthroscopy[49]	750	0.2%
Dogs and cats, minimally invasive abdominal or thoracic procedures[50]	179	1.7%
Dogs and cats, open thoracic or abdominal procedures[50]	1255	5.5%
Dogs, total hip replacement[51]	100	1%

TPLO, tibial plateau levelling osteotomy; *TTA,* tibial tuberosity advancement.

Dirty surgical or traumatic wound infections are surgical wounds or nonsurgical defects that are already infected or have breaks in the skin associated with blunt trauma. Devitalized tissues, foreign bodies, or purulent discharges are often observed. Examples of dirty wounds include previously perforated viscera, devitalized wounds, compound fractures, foreign bodies, pus pockets, and acute cellulitis. Traumatic wounds are assumed to be contaminated and have a high risk of infection because microbes bypass the anatomic and immunologic barriers of the host. These wounds possess the highest risk of postoperative infection.

As indicated earlier, a variety of pathogens can cause SSIs, and these can originate in the patient's microbiota (e.g., *Staphylococcus pseudintermedius,* enterococci, Enterobacterales), the microbiota of veterinary personnel and owners (e.g., *S. aureus*), and the environment (e.g., Enterobacterales, *Serratia, Pseudomonas*). While a large number of pathogens can cause SSIs, a few species account for most infections. The most common tend to be coagulase-positive staphylococci, particularly *S. pseudintermedius,* which accounts for the majority of SSIs in many situations, and Enterobacterales (e.g., *Escherichia coli, Klebsiella, Enterobacter*).[6,7] The rise in methicillin-resistant staphylococci and extended-spectrum beta-lactamase (ESBL)–producing Enterobacterales, as well as frequent inherent and acquired resistance in other pathogens such as *Pseudomonas,* complicate treatment. *Streptococcus* spp. are sometimes involved, most commonly *Streptococcus canis*. This species is of particular relevance because of its potential to cause necrotizing fasciitis, most often as a consequence of enrofloxacin treatment.[8] Some bacteria are commonly identified but often of no or questionable clinical relevance, such as many coagulase-negative staphylococci and enterococci. Uncommon but important pathogens include *Serratia, Acinetobacter, Proteus, Actinomyces,* and *Stenotrophomonas.*[5–7]

Surveillance

Surveillance is an important component of SSI prevention. One cannot identify and define "abnormal" levels of infection without knowing "normal" levels. While large outbreaks are usually readily apparent, more subtle changes or rates that are higher than in comparable facilities may not be as obvious, leading to missed opportunities to intervene.

Identification of SSIs requires an understanding of SSI definitions, differentiation of inflammation and infection, and consistent assessment. Standard criteria for SSI identification in human surgery[4] are likely applicable to veterinary patients (Table 76.4). Consistent application of a definition for an SSI is critical because variable rigor can lead to spurious changes in apparent rates. Beyond definitions, the next important component is how SSIs are being investigated. SSI surveillance can involve review of medical records, prospective recording of complications as patients are identified with SSI at recheck examinations, or active surveillance through contacting owners at specific timepoints after surgery. These vary in their sensitivity and extent, and in general, the most active the approach, the more accurate the information. Reliance on medical records can markedly underestimate the true SSI rate,[6,7] particularly in referral facilities where patients with SSIs may be managed by a referring veterinarian and not reported to the surgical facility. Active methods such as direct examination or contact with owners at set timepoints can provide more accurate data but are more time-consuming.

Centralized reporting of SSIs within a facility is important, particularly in large facilities with many personnel. Reporting SSIs to a single person (e.g., infection control practitioner) or use of a centralized line-listing or similar document can help ensure that all SSIs are recorded and that changes in rates can be detected as early as possible. Determination of SSI rates is needed to put cases (numerators) into context. This requires an ability to determine the number of procedures (the denominator), something that can range from simple to almost impossible, depending on the records system. Ideally, there is an ability to readily report numerator and denominator, both overall and broken down by procedure, body system, or various other categories.

TABLE 76.2 Examples of Reported Risk Factors for Surgical Site Infection in Dogs

Population	Risk Factor	Odds Ratio
Dogs, TPLO[38]	Increasing weight	1.03
Dogs, TPLO[33]	MRSP carriage Bulldogs	6.7 11.1
Dogs, TPLO[41]	Increasing body weight	1.05 per 1kg
Dogs, TPLO[32]	Anesthesia time	1.01 per minute
Dogs, TPLO[29]	Intact male Increased body weight	1.85 1.02 per increased kg
Dogs, TPLO[40]	German shepherd Meniscectomy Attending surgeon having performed <20 procedures	9.7 2.5 3.0
Dogs, elbow dysplasia surgery[52]	Labrador retriever Rottweiler German shepherd Staffordshire bull terrier	5.7 5.6 3.3 3.1
Dogs undergoing surgery for cranial cruciate ligament disease[52]	Rottweiler	3.96
Dogs, various procedures[6]	Hypotension Surgical classification (compared to clean) Use of an implant	27.7 Dirty: 14.6 Clean contaminated: 2.2 5.6
Dogs, TTA[45]	Surgical time Anesthesia time	1.07 per minute increase 1.04 per minute increase
Dogs, orthopedic implant procedures[34]	Anesthesia time	1.02 per minute increase
Dogs and cats, abdominal and thoracic procedures[50]	Clipping >4h prior to surgery Surgical time	4.0 2.1 per every 90 minutes
Dogs and cats, various procedures[5]	Duration of surgery Number of personnel in the operating room Dirty wound	per minute 1.3 5.6
Dogs and cats, various procedures[19]	Clipping surgical site before induction Duration of surgery	3.0

MRSP, methicillin-resistant *Staphylococcus pseudintermedius; TPLO*, tibial plateau leveling osteotomy; *TTA*, tibial tuberosity advancement.

TABLE 76.3 Classification of Surgical Wounds and Indications for Prophylaxis

Clean	Contaminated
1. Wound from elective surgery 2. Nontraumatic 3. No entry into mucosal surface 4. No break in asepsis 5. No inflammation or drainage encountered	1. Fresh traumatic wound, infection likely 2. Break in sterile technique 3. Spillage from GI or urinary surface 4. Acute inflammation 5. Dental prophylaxis 6. Mucosal surgery
Clean Contaminated	**Infected (Dirty)**
1. Bacterial entry into GI, genitourinary, or respiratory tract mucosae with minimal spillage or simple laceration 2. No unusual contamination, no suppurative inflammation 3. Minor break in asepsis 4. Clean wound with drain placement	1. Abscessed or foreign material present 2. Viscus perforated or fecal contamination 3. Older (>4 hour) traumatic wound 4. Suppuration or necrotic tissue 5. Major break in asepsis

Some potentially biasing factors that must be considered when assessing SSI rates include:

- changes in caseload (e.g., increase or decrease in patient susceptibility, increased or decreased emergency procedures)
- changes in surgical procedures (e.g., addition of new procedures that have higher or lower inherent SSI rates)
- changes in personnel identifying or reporting SSIs
- surveillance bias when more attention is paid to SSIs and their documentation
- surveillance bias through introduction of active rather than just passive surveillance
- surveillance bias through change in SSI definition
- changes in apparent rates because of new records systems that allow for better data recovery.

Bacterial culture is important for diagnosis of SSI and determining optimal patient care, but is absolutely critical for SSI investigation. Knowing whether an increase is due to infections by the same organism or by different organisms can help infer the pathophysiology. For example, an increased rate by the same apparent organism (same species +/- same antibiogram) suggests a point source of infection. A clonal outbreak cannot be proven without additional testing (e.g., strain typing), something that is not often available, but knowing

TABLE 76.4 Definition of a Surgical Site Infection[4]

Surgical Site Infection	Criterion
Superficial incisional	Date of event for infection occurs within 30 days after any operative procedure *AND* involves only skin and subcutaneous tissue of the incision *AND* patient has at least ***one*** of the following: A. Purulent drainage from the superficial incision. B. Organisms identified from an aseptically obtained specimen from the superficial incision or subcutaneous tissue by a culture- or nonculture-based microbiologic testing method which is performed for purposes of clinical diagnosis or treatment. C. Superficial incision that is deliberately opened by a surgeon, attending physician, or other designee and culture- or nonculture-based testing is not performed *AND* patient has at least one of the following signs: pain or tenderness; localized swelling; erythema; or heat. D. Diagnosis of a superficial incisional SSI by the surgeon or attending physician or other designee.
Deep incisional	Date of event for infection occurs within 30 or 90 days after the operative procedure *AND* involves deep soft tissues of the incision (e.g., fascial and muscle layers) *AND* patient has at least ***one*** of the following: A. Purulent drainage from the deep incision. B. Deep incision that spontaneously dehisces, or is deliberately opened or aspirated by a surgeon, attending physician, or other designee *AND* organism is identified by a culture- or nonculture-based microbiologic testing method which is performed for purposes of clinical diagnosis or treatment or culture- or nonculture-based microbiologic testing method is not performed *AND* patient has at least ***one*** of the following signs: fever (>38°C); localized pain or tenderness. A culture- or nonculture-based test that has a negative finding does not meet this criterion. C. An abscess or other evidence of infection involving the deep incision that is detected on gross anatomical or histopathologic examination, or imaging test.
Organ/space	Date of event for infection occurs within 30 or 90 days after the operative procedure *AND* infection involves any part of the body deeper than the fascial/muscle layers that is opened or manipulated during the operative procedure. *AND* patient has at least ***one*** of the following: A. Purulent drainage from a drain that is placed into the organ/space (e.g., closed suction drainage system, open drain, T-tube, drain, CT-guided drainage). B. Organisms are identified from fluid or tissue in the organ/space by a culture- or nonculture-based microbiologic testing method that is performed for purposes of clinical diagnosis or treatment. C. An abscess or other evidence of infection involving the organ/space that is detected on gross anatomical or histopathologic examination, or imaging test evidence suggestive of infection. *AND* meets at least ***one*** criterion for a specific organ/space infection site listed in the Surveillance Definitions for Specific Types of Infections.

https://www.cdc.gov/nhsn/pdfs/pscmanual/17pscnosinfdef_current.pdf
SSI, surgical site infection.

whether the same or different organisms are involved can help target the investigation. The bacterial species involved in an outbreak can also be used to identify likely causes. For example, *S. aureus* is a largely human-associated organism, and a cluster of *S. aureus* (especially MRSA) infections would suggest a human source in the clinic and a need to investigate hygiene practices and postoperative wound care. As a common canine commensal, *S. pseudintermedius* exposure is exceedingly common, and clusters of infections can relate to various factors such as excessive skin trauma (e.g., clipper burn, excessive scrubbing), postoperative trauma or licks of the surgical wound by the patient, inadequate bandaging, and similar factors that allow for infection by a commensal organism. Enterobacterales (e.g., *E. coli, Klebsiella, Enterobacter*) are less common causes of SSI and a cluster of infections suggests a point source, which could involve personnel-based transmission from an index patient, inadequate cleaning and disinfection, and compromises in wound care. Organisms such as *Serratia, Acinetobacter, Pseudomonas,* and *Stenotrophomonas* are water-loving organisms that can persist in the environment and contaminate water sources, biocide solutions (e.g., pre-made surgical prep gauzes), endoscopy equipment, cold sterile solutions, and other clinic sites.[9–13] Identification of these should lead to a prompt investigation of the environment, cleaning and disinfection practices, biocide handling,

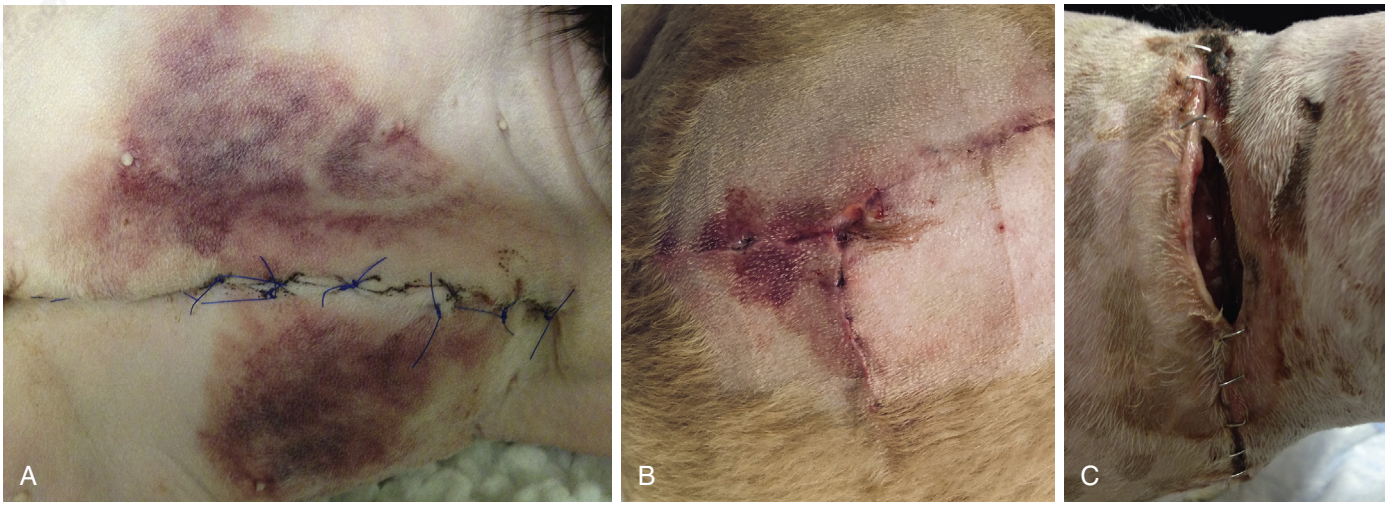

Fig. 76.1 (A) Surgical site undergoing normal healing. (B) Surgical site infection in a mixed-breed dog following internal plate fixation of a pelvic fracture. The dog was lame and the incision was red and draining purulent fluid. A methicillin-susceptible *Staphylococcus pseudintermedius* was cultured from the wound. (C) Severe surgical site infection in a dog; there is evidence of dehiscence and tissue necrosis. (B, Courtesy University of California-Davis Orthopedic Surgery Service.)

and equipment processing. Identification of even one infection caused by these should be of concern (as opposed to the more common staphylococcal SSIs) and more than one infection should be considered an outbreak until proven otherwise. These are just examples of how bacterial identification can be used to tailor the initial investigation.

CLINICAL FINDINGS

SSIs can range from readily apparent to occult. Most infections are superficial and are therefore readily identified by veterinary personnel or owners. The degree of discharge, pain, and systemic signs may be highly variable, and the onset may be gradual or peracute. Most often, initial signs relate to discharge from the surgical site. Changes in patient behavior, such as attempting to lick, scratch, or chew at the site may be noted. Those can also be normal responses to healing (and likely risk factors for inciting an infection), as inflammation is an inevitable response to surgery. Differentiation of SSI from surgical site inflammation is important, because the clinical implications, treatment plan, and infection control aspects of infection versus inflammation are different (Fig. 76.1). This is not always straightforward, and there may be situations where it is debatable whether mild infection or noninfectious inflammation are present. The use of standard definitions of classification of SSIs (see Table 76.4) is useful to facilitate proper diagnosis and differentiate infection and inflammation, as much as possible. Standard definitions also foster consistency between individuals and facilities.

Deep and organ/space SSIs may not be as readily apparent. Severe deep or organ/space infections can be present with little or no superficial component. Gross observation of the surgical site cannot be used to rule out an SSI. Signs of infection can also be masked in the traumatized patient and patients with important comorbidities, so complicating infection should be considered when any clinical signs worsen. Fever and leukocyte changes are not always predictive of infection. Some local inflammation or serous discharge should be expected at the incision site of any surgical procedure. Additional signs that may be associated with systemic infections are respiratory distress, hyperglycemia or hypoglycemia, acute kidney injury, thrombocytopenia, icterus, and mental obtundation. Any clinical abnormality developing in the postoperative period should prompt consideration of (and potentially investigation of) an SSI. Most SSIs develop within the first week or two postoperatively, but complications can develop later, particularly with implants. Current guidelines for human medicine recommend monitoring until 90 days postoperatively for certain procedures involving implants (https://www.cdc.gov/nhsn/pdfs/pscmanual/9pscssicurrent.pdf). Specific guidance for veterinary medicine is lacking but while infections occurring more than 30 days after the procedure are uncommon, infections linked to implant-associated procedures can be encountered months, or even years, after surgery. Whether this reflects a very slowly developing infection associated with the time of surgery or subsequent infection of the surgical site from later bacteremia or dispersion of biofilm-embedded bacteria is unknown. However, history of surgical implants is important to know, even well beyond the immediate postoperative period.

DIAGNOSIS

Clinically, diagnosis of SSI is usually straightforward, particularly superficial SSIs, where changes are grossly apparent. However, infection involving deep tissues without superficial involvement may not be obvious. Systemic manifestations of infection, such as rectal temperature elevations and leukocytosis or bandemia on a CBC, are more indicative of infection but are neither highly sensitive nor specific for SSI. A correlation has been made between elevation of rectal temperature 24 hours postoperatively and increased duration of surgical procedure.[14] However, an elevation of the rectal temperature the day after surgery does not always indicate the development of wound infection. With deeper wounds, diagnostic imaging (radiography, ultrasound, CT) may reveal deeper tissue damage, soft tissue swelling, or gas formation. With chronic orthopedic infections, bony lysis, bone proliferation, or sequestra may be observed.

Biomarkers such as CRP and postoperative neutrophil/lymphocyte ratio have been used in human medicine to distinguish between SSI and inflammation that is not associated with infection. A study of dogs undergoing tibial plateau leveling osteotomy (TPLO) used serum CRP and amyloid A concentrations to investigate early identification of SSI.[15] Significantly elevated concentrations of both markers at day 6

in dogs with SSI when compared to dogs with uncomplicated recovery were identified. However, whether this will be useful for clinical diagnosis and differentiation of infectious and noninfectious inflammation remains to be determined.

Diagnostic specimens should be collected in virtually all cases of suspected SSI, but there are situations where samples and testing are more important or more prone to error. In general, the more superficial the infection, the lower the value of culture because of the greater likelihood of contamination and the lesser need for systemic antimicrobial treatment. Culture is particularly important with severe infections, infections involving invasive devices, infections that are poorly responsive to antibiotics or developed during antibiotic treatment, and in other situations where resistant pathogens are more likely. In humans, culture of superficial wounds or draining tracts is not generally recommended because those specimens do not necessarily reflect the deeper, true component (see Chapter 3 and https://www.cdc.gov/antibiotic-use/healthcare/implementation/clinicianguide.html). There is no reason to think recommendations should be different in animals.

The main approaches to specimen collection for detection of SSIs are tissue biopsy, fine-needle aspirate, and swab. Properly collected tissue biopsy specimens are likely the most sensitive and specific, but they are uncommonly obtained because of invasiveness, time, and cost. If biopsy specimens are collected, they should be taken from viable tissue, not necrotic tissue. Fine-needle aspirates can obtain material from deep sites and limit contamination with superficial bacteria. Aspirates should be collected from affected areas, avoiding necrotic foci. Sampling from an abscess can be performed. Adequate material should be obtained for both cytology and culture. Multiple aspirates should be collected, when possible.

Swabs are most commonly obtained, as a cheap, easy, and generally effective approach. However, there are some limitations and the relative performance of swabs versus tissue specimens or aspirates is unknown. Swabs only sample surface organisms, not necessarily infected tissue. This can result in detection of secondary colonizers, missing the primary cause. The goal must be to limit the amount of surface contamination, to avoid sampling of obviously contaminated sites, and to carefully interpret results from swabs, considering the site and expected resident microbiota. In humans, the Levine technique is considered preferable to other methods (Box 76.1).[16,17]

Cytology is a cost-effective, easy, and overlooked diagnostic tool. It can provide rapid information to help make a diagnosis, to guide empirical therapy, to help assess unusual results (e.g., evidence of rods with a culture report indicating gram-negative rods such as *E. coli* from a site where staphylococcal infections dominate), and to presumptively identify organisms that may be difficult to culture (e.g. *Actinomyces, Nocardia, Mycobacterium*). Cytological specimens need to be collected with care, trying to obtain the most representative sample, but they are not subject to the same potential for contamination compared to culture because slight contamination from the commensal microbiota is less likely to be evident cytologically. Cytology can also help confirm the presence of a likely infectious disease and identify some noninfectious causes (e.g., neoplasia). Cytologic examination should be considered every time a diagnostic sample is obtained.

TREATMENT

Treatment of SSIs is highly variable and depends on the wound (e.g., location and severity of the infection), patient (e.g., comorbidities, allergies), and the offending pathogen (e.g., antimicrobial susceptibility). Superficial infections may be amenable to local therapy with cleaning and application of biocides (e.g., chlorhexidine) or topical antimicrobials (e.g., silver sulfadiazine, mupirocin, fusidic acid, bacitracin/neomycin/polymyxin B) or other therapies (e.g., honey). Suture removal may be indicated to remove a nidus of infection and to facilitate drainage. Deeper infections almost invariably require systemic antimicrobial therapy, which should be chosen based on culture and susceptibility testing, with exception of focal abscesses not accompanied by cellulitis or systemic signs such as fever.

BOX 76.1 Levine Technique for Wound Sampling

Clean wound with normal saline
Debride nonviable tissue
Wait 2–5 minutes
Moisten the swab with saline if site is dry
Culture the healthiest-looking tissue in the wound bed
Do not culture exudate, pus, eschar, or heavy fibrous tissue
Rotate the end of the swab over a 1 cm^2 area for 5 seconds
Apply sufficient pressure for tissue fluid to be expressed

When antimicrobials are indicated, empirical therapy is usually needed while awaiting culture and susceptibility results. The location of infection can indicate the most likely pathogens. Staphylococci are the most common causes of superficial infections and orthopedic infections, while Enterobacterales are more common in procedures associated with the gastrointestinal or urogenital tracts. Cytology can facilitate empirical therapy when an abundance of cocci (most commonly staphylococci), rods (most commonly Enterobacterales), or filamentous bacteria (e.g., *Actinomyces, Nocardia*) are observed. The use of a hospital antibiogram (see Chapter 8) can also assist with selection of appropriate empirical antimicrobials. Empirical therapy with a first-generation cephalosporin (e.g., cephalexin, cefazolin) or amoxicillin-clavulanic acid is commonly used for superficial infections. With more severe disease, where sepsis is of concern, broad-spectrum therapy (e.g., either amoxicillin/ampicillin or clindamycin, combined with a fluoroquinolone) is reasonable, with a plan to de-escalate once culture results are available.

Extensive debridement or surgical drainage of wounds may be required to prevent wound infection and reduce extensive swelling or abscess formation (Fig. 76.2). Wounds should be covered to prevent extensive drying of devitalized tissues, and drainage should be encouraged by incomplete closure or drain placement. Occlusive dressings containing adequate absorbent material should be changed whenever drainage is present. To encourage formation of sufficient granulation tissue, limbs should be immobilized or supported. Chronic nonhealing scar tissue should be resected from the wound. Surgical drains, intravenous catheters, and intubations in trauma patients also increase the risk of infections. See the Suggested Readings list for more information on the surgical approach to wound management following development of an SSI.

Systemic antimicrobials alone may be inadequate for treatment of many SSIs when they are complicated by bacterial biofilm formation, antimicrobial resistance, or difficulty delivering antimicrobials to the infection site at adequate levels. A variety of adjunct approaches may be required. These include surgical intervention to establish drainage, lavage, debride infected tissue, or to remove foreign material (e.g., implants, suture); surgical placement of antimicrobial-impregnated materials (e.g., beads, collagen sponges; see Chapter 121); injection of antimicrobial-impregnated gels; or intra-articular or regional limb perfusion as means of removing infectious foci and delivering high concentrations of antimicrobials to the site. The ability to deliver high antimicrobial concentrations with some approaches can potentially be effective for bacteria reported as resistant, as the determination of

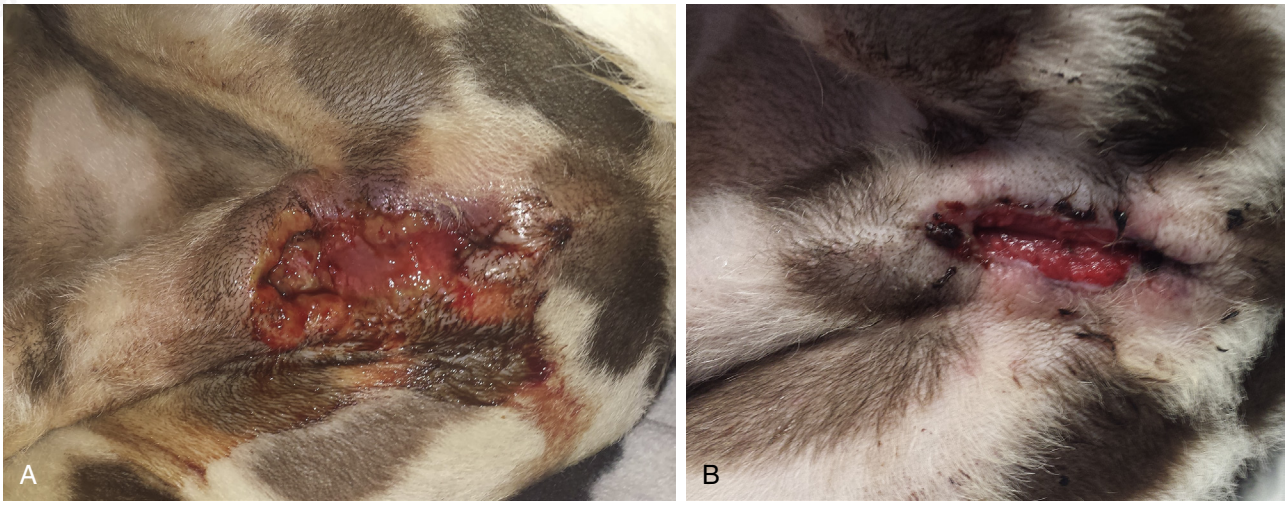

Fig. 76.2 (A) Scrotal urethrostomy site infection in a Dalmatian with dehiscence and devitalized tissue. A severely MDR, methicillin-resistant *S. pseudintermedius* (susceptible only to aminoglycosides) and small numbers of *Fusobacterium* spp. were cultured from the wound. (B) The wound healed with extensive debridement and lavage; a large hematoma was removed from a subcutaneous pocket at the left cranial aspect of the urethrostomy site. Resistance of the *S. pseudintermedius* to the empirically selected antimicrobial was predicted by susceptibility testing. However, because healing was progressing well, antimicrobial therapy was not adjusted. (Images courtesy University of California-Davis Soft Tissue Surgery Service.)

susceptibility or resistance is based on anticipated serum drug levels. If higher concentrations can be achieved (and sustained) at the site of infection, drugs to which the bacterial isolate is reported as resistant may be effective. Typically, antimicrobials used for these approaches are concentration-dependent drugs with long half-lives, such as aminoglycosides.

PREVENTION

Absolute prevention of SSIs is impossible. The nature of surgery will always predispose to some risk of infection. Accordingly, the key is to implement optimal practices to reduce the incidence and severity of SSIs. This is a complex area and one with a paucity of objective data; however, reasonable recommendations can be made based on data from human medicine, limited veterinary data, and general principles of surgery and infection control.

Surgical Site Antisepsis

Basic surgical aseptic technique is the cornerstone of SSI prevention.[18] At a fundamental level, SSI prevention can be thought of as a series of tools to reduce bacterial contamination, reduce tissue trauma, minimize surgical time, and prudently use foreign materials, while minimizing local (e.g., skin barrier damage) and systemic compromise (e.g., immunosuppression, hypoglycemia, hypotension, hypothermia).

Bacterial dose is a key determinant of the risk of infection, and measures to reduce bacterial contamination of the surgical site are a critical tool. The animal's hair should always be clipped (not shaved) and its skin prepared for surgery before it enters the operating room, as close to the time of surgery as is practical. Clipping before anesthesia was a risk factor in one study,[19] something that probably relates more to the ability to atraumatically clip an anesthetized animal. Care should be taken not to injure the skin during the clipping procedure, as skin integrity is probably one of the most important factors for SSI prevention. The goal is not to remove every remnant of hair. Rather, it is to reduce the impact of the hair coat on subsequent skin preparation and the surgical procedure. Leaving some remnants of hair is preferable to skin trauma from excessive clipping. Antisepsis of the skin at the incision site is designed to reduce the microbial burden, not sterilize the skin. A variety of approaches can be used, including the traditional three-step (chlorhexidine or iodine soap, alcohol, tincture of chlorhexidine or iodine) to one-step paint-on products. As with clipping, excessive scrubbing should be avoided in order to maintain skin integrity.

The two main perioperative and wound-care biocides are chlorhexidine and iodophors. Concentration is essential as higher concentrations result in more damage to host cells, while lower concentrations can limit antimicrobial efficacy. The relative efficacy of povidone iodine versus chlorhexidine is still somewhat unclear as conflicting data are available. The WHO has recommended alcohol-based chlorhexidine for surgical preparation,[18] but this recommendation has been challenged.[20] Chlorhexidine should be avoided when preparing sites around the eyes or ears because of ocular and ototoxicity concerns. In humans, it is also recommended to avoid chlorhexidine in the genital region because it can cause mucosal irritation. It is commonly stated that chlorhexidine may be preferable because of residual activity; however, the presence of a true residual effect in vivo has been challenged[21] and convincing evidence of a clinically relevant residual effect is lacking. The efficacy of chlorhexidine may be less impacted by organic debris such as blood. Chlorhexidine resistance has been identified;[22,23] however, there is little evidence that this currently poses a clinical risk as concentrations required to inhibit bacterial strains carrying resistance genes are still well below concentrations used clinically.

Disinfection and Sterilization

The sterilization of surgical instruments and facilities is an essential part of the operative procedure (see Chapter 15 for a review of hospital and equipment disinfection procedures). Surgical equipment should be appropriately sterilized using steam autoclaves or ethylene oxide, with appropriate quality-control practices, including routine use of biological indicators. Cold sterilization *should not* be used for any instruments that can undergo other forms of sterilization. Cold sterilization should be considered high-level disinfection at best, not sterilization as bacterial contamination of cold sterilization solutions is common.[24]

Procedure Factors

Use of proper surgical technique is perhaps the single most important factor in preventing postoperative infections. The risk of tissue infection is directly proportional to the increased amount of tissue handling, desiccation, and trauma. Foreign material and blood clots allow for adherence and replication of microorganisms and facilitate formation of biofilms. Bacterial contamination can lead to risk of infection in the immediate postoperative period or more insidious problems through colonization of implants.

The duration of the surgical procedure and anesthesia time are well established as risk factors for SSIs in both animals and humans. Surgical time should not be decreased at the expense of proper technique, but there are various measures that can be used to reduce anesthesia and surgical time, particularly those that relate to coordination and organization, to limit waiting time. There should be no delays between anesthetic induction and completion of the procedure. Proper coordination, including use of a surgical checklist,[25] can help reduce unnecessary delays.

Antimicrobial Prophylaxis

Perioperative antimicrobial administration can reduce the incidence of postoperative infection in certain procedures; however, objective evidence in small animal surgery is sparse and somewhat conflicting. Perioperative antimicrobials are most important for procedures where contamination is at increased risk of occurring or is unavoidable (e.g., dirty procedures), and potentially with procedures where the implications of an SSI can be devastating. Antimicrobials are not likely indicated for clean procedures that do not involve surgical implants.

When antimicrobials are indicated, the key concept is maintenance of therapeutic drug levels throughout the period of risk. This is typically achieved by administering the first dose intravenously 30 to 60 minutes prior to the first incision, with intraoperative dosing every 2 half-lives of the antimicrobial as long as the surgery is underway. For example, cefazolin is a commonly used antimicrobial and it has a half-life of 37 to 57 minutes,[26,27] meaning intraoperative redosing is indicated every 75 to 120 minutes.

Once the period of risk has ended, antimicrobials are presumably not indicated. Continuation of antimicrobials after surgery is rarely required. In humans, recommendations for most procedures are to not continue antimicrobials for longer than 24 hours after surgery.[28] In some situations, postoperative prophylaxis is continued, yet this rarely extends beyond 24 hours, a time at which it is reasonable to assume that any bacterial contaminants have been killed or are resistant and a relatively effective barrier to the outside microbiota has been established. In veterinary medicine, most of the available data pertain to TPLO, a procedure that is typically associated with a high infection rate. Numerous studies have reported a protective effect of postoperative antimicrobials for TPLO,[29–33] and another study of clean orthopedic implant procedures that was dominated by TPLOs also reported efficacy of postoperative antimicrobials.[34] However, what constitutes "postoperative" has not been adequately investigated. It is possible that antimicrobials only need to be continued for 24 hours postoperatively, as with most human procedures, but further study is required to determine the optimal regimen. There are no corresponding data supporting postoperative antimicrobial prophylaxis for other surgical procedures, and results from TPLO studies should not be extrapolated to other surgical procedures.

Wound Lavage

Contaminated cutaneous or soft tissue wounds should be lavaged with copious amounts of prewarmed saline, lactated Ringer's solution, or tap water. Pressure can be delivered with a 35-mL syringe and 18-gauge needle or similar size catheter or via a commercial device. Lavage without pressure is not as effective. It is debatable whether biocides are necessary in flush solutions versus sterile saline or running tap water, as physical flushing is more important in contaminated traumatic injuries or infected wounds to reduce bacterial levels. Lactated Ringer's solution has been reported to be less traumatic than normal saline or tap water to canine connective tissues *in vitro*,[35] so it might be the most desirable flush solution to preserve tissue healing. However, whether that corresponds to clinical wound lavage is debatable. When a biocide is desired, aqueous (as opposed to alcohol-based) formulations must be used and concentrations are typically lower than those used for intact skin, such as 0.05% for chlorhexidine.[36]

Engineered Devices

A variety of new approaches have been investigated to reduce the incidence of SSIs. There are abundant options in human medicine, some that have been explored in veterinary medicine, and many other potential options based on *in vitro* testing. These include approaches such as antimicrobial- or biocide-impregnated suture and devices (e.g., implants) coated with biocides, heavy metals, or other substances to inhibit bacteria. Results have been mixed and typically when an impact has been identified, it has been relatively modest. In companion animal veterinary medicine, limited data are available. Triclosan-impregnated suture had no discernable impact of TPLO SSI in one study.[37] However, it is a challenge to perform clinical SSI studies with sufficient statistical power to detect a difference, particularly if that difference is modest. Accordingly, this may be a scenario where it is better considered "absence of evidence of efficacy" versus "evidence of absence of efficacy." Despite the lack of good current efficacy data, there may be effective future options as new materials and approaches are studied.

CASE EXAMPLE

Signalment

"Edith," a 5-year-old female spayed bichon frise from Ontario, Canada.

History

Edith was brought for veterinary evaluation 5 days after a cystotomy to remove uroliths. The surgery was uneventful and normal recovery occurred. The dog was treated with preoperative cephazolin and discharged with instructions for exercise restriction and to ensure that an E-collar was worn at all times. The E-collar compliance was sporadic. The owner noticed the patient licking at the incision site the day before evaluation.

Current medications: None.

Other medical history: Nothing relevant.

Physical Examination

Body weight: 4.7 kg.

General: Unremarkable physical examination apart from the surgical site. Vital parameters and other physical examination findings were normal.

Surgical site: The suture line was intact but was inflamed, with a small amount of purulent debris and crusted material. The dog resented palpation of the site and a small amount of pus was expressed from the cranial aspect of the suture line.

Specimen collection: Two sutures were removed from the cranial aspect of the incision, where pus was expressed. The area was cleaned with sterile saline, and residual fluid was removed using sterile gauze. Avoiding contact with surrounding tissue, a sterile swab was pressed against the affected

Continued

CASE EXAMPLE—cont'd

subcutaneous tissues and rubbed back and forth for 5 seconds, to try to express fluid from the site. This was done twice to collect specimens for cytology and culture.

Cytology findings

Cytologic examination revealed suppurative inflammation, with approximately 90% neutrophils. Occasional intracellular cocci were evident.

Diagnosis

Superficial SSI, likely caused by self-trauma or licking the wound.

Treatment

Cephalexin, 26 mg/kg (125 mg) PO q12h for 5 days.

Strict compliance with E-collar use was emphasized.

Local treatment of the wound was considered but not deemed necessary based on the small size of the wound and relatively minor infection.

Comments

The diagnosis was straightforward given the clinical signs and recent surgery. Other antimicrobial options were considered initially, including amoxicillin-clavulanic acid and clindamycin. The cytology results allowed for confidence in targeting gram-positive bacteria, leading to a choice of cephalexin over the broader-potentiated penicillin. Clindamycin would have been an equivalent option to cephalexin in a gram-positive soft tissue infection such as this. *Staphylococcus pseudintermedius* that was susceptible to cephalexin, clindamycin, and amoxicillin-clavulanic acid was isolated from the specimen. The patient recovered uneventfully.

Miscellaneous Bacterial Infections

Carolyn R. O'Brien, Jane E. Sykes

KEY POINTS

Dermatophilosis

- First Described: 1915 in cattle from the Belgian Congo (Van Saceghem).[1]
- Cause: *Dermatophilus congolensis*, family Dermatophilaceae.
- Affected Hosts: Skin commensals on cattle, horses, small ruminants. Secondary hosts: humans, dogs, cats, platypus.
- Geographic Distribution: Worldwide, but infections are more common in humid environments.
- Primary Mode of Transmission: May be acquired by dogs and cats through contact with affected primary hosts or from contaminated fomites or soil.
- Major Clinical Signs: Exudative dermatitis (dogs), deep soft-tissue abscesses with fistulation (cats).
- Differential Diagnoses: Dogs: superficial pyoderma, mycobacteriosis, allergic dermatoses, immune-mediated dermatoses, drug eruptions, thermal or caustic skin damage. Cats: mycobacteriosis, nocardiosis, fungal infections, cutaneous neoplasia.
- Human Health Significance: Humans often develop infection as a result of contact with colonized or infected animals (especially horses, cattle, and elephants), although infections are very rare. No cases have been reported in association with contact with a dog or cat.

Melioidosis and Glanders

- First Described: *Burkholderia pseudomallei* was first described by Whitmore and Krishnaswami in 1912[2] in Burma. Glanders (*B. mallei*) was reported in ancient Greece by Hippocrates, c.450 BC; 100 years later Aristotle named the disease "meles." The organism was isolated for the first time by Loeffler and Schuetz in 1882.[3]
- Causes: *Burkholderia pseudomallei* (melioidosis) and *Burkholderia mallei* (glanders/farcy), gram-negative, aerobic, rod-shaped bacteria that belong to the family Burkholderiaceae.
- Affected Hosts: *Burkholderia pseudomallei*: Humans, non-human primates, captive marine mammals (e.g., dolphins, whales, sea lions), birds, reptiles, sheep, goats, cattle, alpaca, pigs, horses, mules, cats, dogs, and other wildlife (kangaroos, meerkats). *Burkholderia mallei*: Donkeys, mules, horses, camels, humans, cats, dogs, large carnivores (wolves, bears, lions, tigers, leopards, jackals, and hyenas).
- Geographic Distribution: *Burkholderia pseudomallei*: Tropics and subtropics. *Burkholderia mallei*: South America (Brazil), northern Africa, China, Iraq, Pakistan, India, Mongolia, Turkey, and United Arab Emirates.
- Primary Mode of Transmission: *Burkholderia pseudomallei*: Cutaneous inoculation via breaches in the integument; inhalation/aspiration of aerosols or muddy water, respectively; ingestion. *Burkholderia mallei*: Inhalation of aerosols, ingestion of contaminated water or feed, or via contact with fomites in solipeds, especially in situations where husbandry is substandard, and ingestion of infected meat in carnivores.
- Major Clinical Signs: Range from minor skin lesions, subacute to chronic pneumonia, to fulminant sepsis (*B. pseudomallei*).
- Differential Diagnoses: Mycobacteriosis, neoplasia, other saprophytic gram-negative infections, for example, *Chromobacterium violaceum.*
- Human Health Significance: *Burkholderia pseudomallei* is estimated to clinically affect approximately 165,000 people per year, 10% to 40% fatally. Both *B. pseudomallei* and *B. mallei* are classified as a Tier 1 Select biothreat agents by the United States CDC.

Chromobacteriosis

- First Described: Schroeter 1872.[4]
- Cause: *Chromobacterium violaceum*.
- Affected Hosts: Humans, pigs, cattle, dogs, non-human primates, water buffalo, Macquarie turtle, red panda, horse.
- Geographic Distribution: Worldwide but mostly tropical and subtropical regions.
- Primary Mode of Transmission: Cutaneous inoculation after exposure of wounds to contaminated water or soil.
- Major Clinical Signs: Localized cutaneous and regional lymph nodes, multi-systemic abscessation, pneumonia, and sepsis.
- Differential Diagnoses: *Burkholderia pseudomallei* infection, and other causes of gram-negative sepsis.
- Human Health Significance: Infections are acquired from the environment and are not transmitted between animals and humans. Infections in humans are often fatal.

DERMATOPHILOSIS

ETIOLOGY AND EPIDEMIOLOGY

Dermatophilus congolensis is a gram-positive, facultative anaerobic, branching filamentous, spore-forming actinomycete. The organism dimorphically exists as either a hyphal form or motile, flagellated cocci. During growth, hyphae branch, then undergo transverse and longitudinal division to produce packets of zoospores, consisting microscopically of three to eight paired rows of cocci. The organism is a normal component of the skin flora of cattle, horses, sheep, and goats. Numerous terrestrial and aquatic mammalian and reptilian host species can develop disease when infected as accidental hosts. Outbreaks in livestock can be associated with serious economic losses. Infections have been very rarely described in dogs,[5–7] cats,[8–14] and humans.[15] The prevalence of the disease in primary host species is increased by high environmental moisture levels (rainfall, humidity), and ambient temperatures, the presence of biting vectors and/or other causes of disruption of the dermis (e.g., thorns), as well as the presence of carrier animals.[16] The increased incidence in wet conditions can be attributed to two factors: (1) enhanced spread of infective zoospores and (2) compromise to the epidermal barrier.[17] Immunosuppressive therapy or concurrent illness may predispose animals to infection. There is also some evidence to suggest that host susceptibility may vary genetically.[17]

Dermatophilus congolensis is possibly a saprophyte, although attempts to culture it from the environment have proved unsuccessful and its environmental niche remains a mystery; in general, soil is not thought to be an important source of infection because the organism is not thought to survive long periods in the ground.[18] Spread between animals may occur due to direct contact, contact with contaminated fomites (e.g., horse rugs, brushes), or the environment (e.g., sheep dips, etc.). Chronic carrier animals are assumed to be the primary reservoir.[19] Arthropods such as fleas, ticks, and biting flies have been incriminated as possible mechanical vectors, but their role is not clear.

Dermatophilosis is variably or colloquially known as streptothricosis, "lumpy wool disease," "fleece rot," "strawberry foot rot," "mud fever," "rain-scald," "snuffleupagosis," and proliferative dermatitis, depending on the host species affected and the clinical picture. Experimental infection after inoculation onto damaged skin of dogs[20] and a kitten, and subcutaneous injection of an adult cat have been reported.[10]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Dermatophilus congolensis is an opportunistic pathogen that invades skin that has been compromised by minor trauma (e.g., the bites of vectors) or maceration from prolonged contact with moisture. Once the infection becomes established, the exudative process results in separation of the epidermal layers, which allows filamentous hyphae to infiltrate tissues and flagellated cocci to migrate. Alternating layers of keratinized epidermis, vesicles containing exudate, pyogranulomatous inflammation, and bacteria result in development of scabs that are considered characteristic for the disease. Infected scabs can then flake off and become a potential source of infection for other animals and people. Cats develop nodular lesions with draining fistulas, usually with concurrent fever, anorexia, and lethargy. Oral[13,14] and urinary bladder[13] infections have also been reported in cats.

Physical Examination Findings

Dermatophilosis is typically confined to the skin in dogs and manifests as a non-pruritic, crusting dermatitis. Dry scabs are adherent to the hair in affected regions and underlying skin is ulcerated and erythematous. Systemic signs are typically minimal, unless the disease is associated with a comorbid, immunosuppressive condition. Cats may develop subcutaneous nodules[9] or deep abscesses, involving contiguous structures such as the subcutis, muscle, and lymph nodes, particularly in the popliteal region.[8–10]

DIAGNOSIS

Microbiologic Tests

Cytologic Diagnosis

Dermatophilus congolensis has a distinct appearance when examined using light microscopy of Romanowsky-stained preparations made from emulsified crusts or via impression smears collected from the base of freshly removed crusts.

Isolation and Identification

Dermatophilus congolensis grows best in microaerophilic culture conditions with 5% to 10% CO_2 on blood agar at 37°C. Inoculae derived from the underside of freshly removed crusts provide the best results. The organism forms small, grayish, wrinkled, raised colonies that exhibit β-hemolysis on blood agar (Fig. 77.1).[21] Due to the relatively slow growth of *D. congolensis,* culture of specimens contaminated with other skin bacteria can result in rapid overgrowth of the organism. Special techniques such as the use of selective media, 0.45 µm membrane filtration of material derived from the emulsion of crusts with distilled water, or

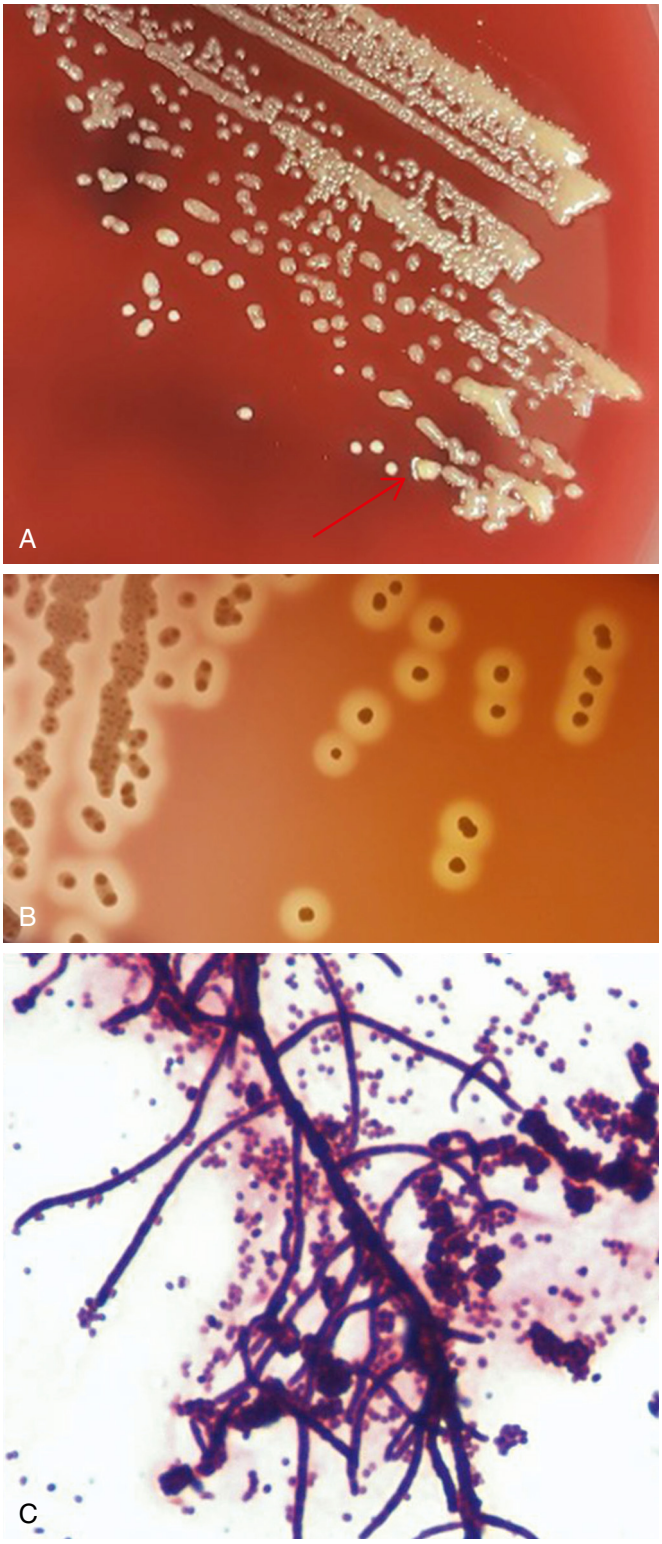

Fig. 77.1 *Dermatophilus congolensis* colonies on 5% sheep blood agar. Note pitting of the agar (A; *arrow*) by colonies and complete hemolysis of sheep erythrocytes (B). (C) Gram stain showing cocci individually and in paired rows ("railroad tracks") which are most commonly observed in patient specimens (see Fig. 77.2). (A and B, courtesy of Dr. Barbara Byrne, University of California-Davis Veterinary Microbiology Laboratory. C, from Alejo-Cancho I, Bosch J, Vergara A, et al. Dermatitis by *Dermatophilus congolensis*. *Clin Microbiol Infect*. 2015;21:e73-74.)

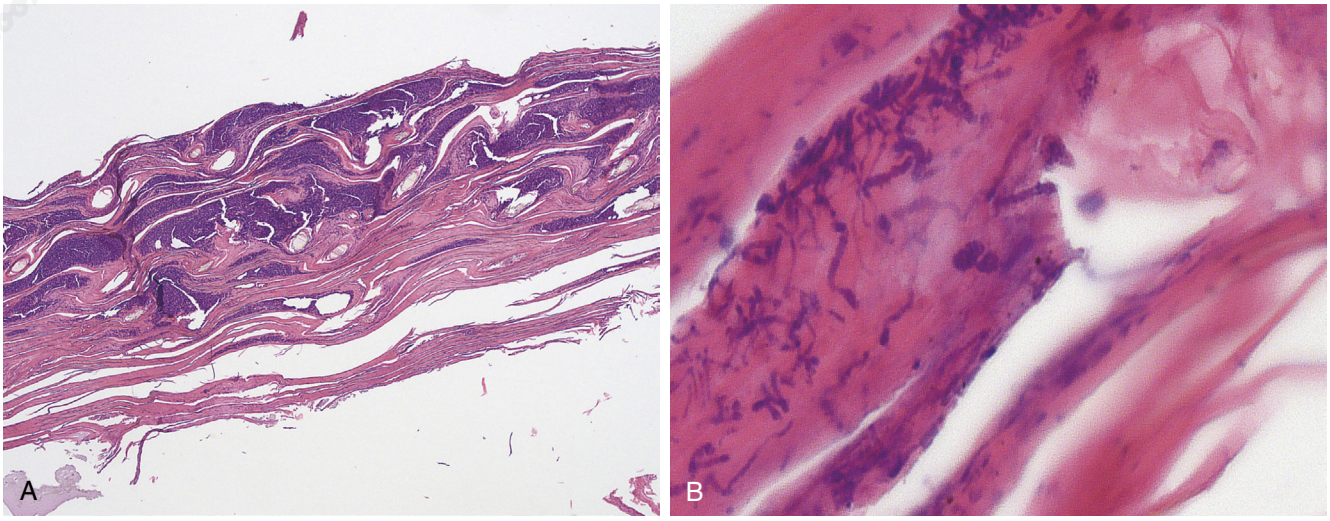

Fig. 77.2 Biopsy specimen showing many chains of *Dermatophilus congolensis* within a parakeratotic layer of dermis (A, 20× magnification; B, 600× magnification). Hematoxylin and eosin stain. (Courtesy of Dr. Verena Affolter, University of California-Davis, Anatomic Pathology Service.)

Haalstra's method (which monopolizes the chemoattractive effects of a carbon dioxide–rich environment on the motile cocci) may be employed to enhance the success of culture. MALDI-TOF mass spectrometry has been successfully used to rapidly identify *D. congolensis*.[21]

Molecular Diagnosis Using Nucleic Acid–Based Testing

Due to its economic importance, and the challenges associated with culture of this organism, several endpoint (conventional) and real-time PCR assays have been developed and used for diagnosis of dermatophilosis.[22–25] Infection in one cat from Illinois was identified by amplification and sequencing of 16S–23S rRNA gene DNA.[9]

Pathologic Findings

Histopathologic findings in dogs with dermatophilosis include exudative, suppurative hyperkeratotic dermatitis, with subcorneal abscessation, and dermal edema and hemorrhage. The parakeratotic layer typically contains branching hyphae containing characteristic coccoid zoospores (Fig. 77.2). Cats tend to have deeper pyogranulomatous lesions in subcutaneous or superficial lymphoid tissue. Immunostaining has been used to identify *D. congolensis* in tissue specimens.

TREATMENT

There are no widely established treatment protocols for any species, and a combination of systemic antimicrobials (typically oxytetracycline in ruminants and penicillin/streptomycin in horses) and topical therapy are utilized. Control of biting insects is also recommended, including isolation of affected animals. Some animal infections have been observed to heal spontaneously, and human infections are generally considered self-limiting, unless the skin remains macerated for longer than 10 to 16 hours a day.[18] Lesions should be kept clean and dry. Removal of adherent crusts via bathing with medicated shampoos (containing chlorhexidine or povidone iodine) is advocated and should be continued for at least 2 weeks. Lime sulfur dips (2%) may also be helpful in animals with superficial infections. The use of topical ointments is discouraged, as this promotes the moist, microaerophilic environment that the bacteria favors.

There are reports of successful treatment of dermatophilosis with a combination of penicillin and streptomycin in a dog[5] and ampicillin in a cat.[11] One cat was also successfully treated with doxycycline, where the organism was not susceptible to penicillin.[8] As there may be regional variations in drug susceptibility patterns, particularly to penicillins and fluoroquinolones, it is recommended that treatment be based on individual antibiogram data should culture be successful.[26,27]

PUBLIC HEALTH ASPECTS

Human dermatophilosis is rare and is, typically, but not always, associated with contact with animals (particularly cattle, horses, and elephants).[18,21,28] Affected humans often reside in or have a travel history to tropical locales (especially Africa, Australia, and Thailand). However, one case described lesions on the inner thigh in a 15-year-old girl who had been horseback riding in Michigan,[18] one case was described in an 8-year-old boy in Wisconsin without known animal contact,[29] and the first human cases ever reported were in four people from Orange County, NY who developed furunculosis after handling an infected deer in a wildlife reserve (1961).[30] Previous skin lesions are often reported (e.g., cuts, abrasions, psoriasis). There is a tendency for the legs of young women to be affected, and it has been proposed that shaving of the skin may lead to micro-abrasions that facilitate entry of the organism into the skin.[31] The handling of infected carcasses has also been associated with human infection. Most human cases have involved superficial cutaneous infections, manifesting as exudative pustular dermatitis, folliculitis, pitted keratolysis of the soles of the feet, subcutaneous nodules, or onycholysis; however, there are isolated reports of oral[32] and esophageal infections,[33] and one case of necrotizing granulomatous lymphadenopathy in an immunocompromised child. There are no reports of human infection secondary to contact with affected dogs or cats; however, precautions such as the wearing of personal protective equipment (e.g., disposable gowns and gloves) during handling of infected animals is recommended, including thorough hand washing after contact.

MELIOIDOSIS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Melioidosis is an infection caused by the facultative aerobic, gram-negative, motile, non-spore-forming beta-proteobacterium, *Burkholderia pseudomallei*. The bacterium is soil and water borne, and is mostly restricted to latitudes within 25 degrees north or south of the equator.[34] *Burkholderia pseudomallei* is estimated to cause disease in approximately 165,000 people

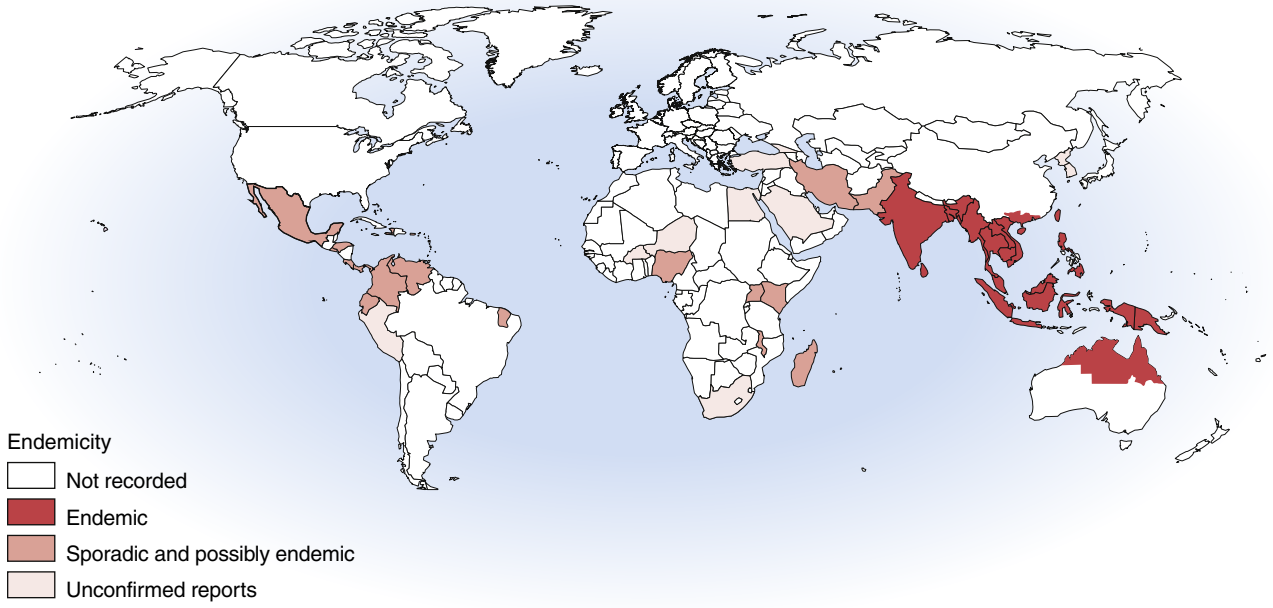

Fig. 77.3 The known geographic distribution of melioidosis. (From Currie BJ. *Burkholderia pseudomallei* and *Burkholderia mallei*: melioidosis and glanders. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:2707-2717.)

each year, with a mortality rate of 10% to 40%.[35] Most human cases are reported from Southeast Asia (particularly northeastern Thailand[36]) and Northern Australia (the "Top End" of the Northern Territory[37]), especially during the wet/monsoon seasons (Fig. 77.3).[38] Sporadic autochthonous cases are also reported outside of the area of high endemicity, including the Carribean,[39] Central and South America,[40] Africa,[41,42] the Indian subcontinent,[43] and the Middle East. Occasional cases of melioidosis have been reported in people from the southwestern United States, with no recent travel history to endemic regions.[44,45] Genetic analysis of strains involved has suggested that the organism may be present in the soil in Texas. Some of the affected individuals had histories of travel to endemic regions decades earlier, so it was felt that until the organism was isolated from the environment, it cannot be said that *B. pseudomallei* is endemic in the United States. Genetic analysis of worldwide strains implicates Australia as a likely geographical origin of the species with spread to Southeast Asia, thence to East Asia.[46,47] South American strains appear to have originated in Africa.[46]

Burkholderia pseudomallei can be isolated most reliably from moist clay soils and pooled surface water from endemic areas. Human infection numbers increase after heavy monsoonal rains and winds, presumably because of inhalation of organism-laden aerosols. Infection is thought to occur via cutaneous inoculation through open wounds contaminated with soil; bites of arthropod vectors; inhalation of dust, aerosols, or aspiration of muddy water (such as that occurs with near drowning); or ingestion of soil, contaminated infected carcasses, contaminated drinking water, or milk (following infection of the mammary gland). Because of the risks of inhalation or ingestion, the bacterium has been labeled as a biological weapon, and has been classified as a Tier 1 Select Agent by the CDC,[48] although its true potential in this scenario is unclear.

Burkholderia pseudomallei generally has a low propensity to cause disease in clinically healthy hosts, and infection mostly results in subclinical seroconversion. In humans, severe disease is almost always seen in individuals with compromised innate immunity, particularly those with impaired neutrophil function, such as with diabetes mellitus, alcohol abuse, chronic kidney or pulmonary disease, thalassemia, and cancer.[47,49] Smoking and/or glucocorticoid use are also associated with an increased risk of infection in people.[50] Major impairment of adaptive CMI, such as that seen in advanced HIV infection, does not appear to be a risk factor for disease in people.[51] Likewise, a high antibody titer does not protect against either primary infection or relapse.[52,53]

Geographical differences exist with regard to clinical manifestation and mortality, which is thought to be due to both regional access to adequate healthcare and, also host and bacterial genetics. The infecting dose, route of infection (particularly inhalation), and the duration of clinical signs prior to treatment also influence the severity of clinical disease.

Most cases in humans are acute infections that occur after short incubation periods (mean 9 days, range 1 to 21 days).[47] Although relatively uncommon, the infection may remain subclinical for long periods, with the sudden appearance of disease after many years of dormancy, like that seen with tuberculosis. The longest recorded incubation period was in a United States veteran of the Pacific theater of World War II, who was diagnosed 62 years after presumed exposure.[54] Because of concerns relating to reactivation of infection in soldiers returning from Vietnam, the disease was referred to as the "Vietnamese Time."[55,56]

Melioidosis is considered an emerging disease in humans and it has been proposed that the incidence of the disease in people is greatly under-reported in the developing world. This is likely to be even more the case for animal disease.

CLINICAL FEATURES

Pathogenesis, Clinical Signs, and Physical Examination Findings

Burkholderia pseudomallei is a facultative opportunistic intracellular organism, capable of replication within the cytosol of host cells

(neutrophils, macrophages, and epithelial cells).[44] The bacteria are able to move within the cell to form protrusions of the cell membrane and result in cell-to-cell spread.[57] This may also be facilitated by promotion of multinucleated giant cell formation.[47,58,59] A detailed review of the pathogenesis of infection and the role of a vast array of virulence factors produced by *B. pseudomallei* (e.g., capsular polysaccharide, LPS, flagella, pili, T3SS, T6SS, proteases, lipases, phospholipases) is provided in the Suggested Reading list.[47]

Melioidosis is known as "the great mimicker" in human medicine because of the range of clinical syndromes it can produce.[60] These include: (1) mild or inapparent infection; (2) local skin ulcers (Fig. 77.4A); (3) chronic abscess and granuloma formation in subcutaneous tissues or internal organs (often liver and/or spleen, but may also include prostate in men), arthritis, and osteomyelitis (Fig. 77.4B); (4) chronic pneumonia or; (5) acute, fulminant bacteremia with resultant pneumonia and/or encephalomyelitis (Fig. 77.4C).

Reports of canine and feline melioidosis are uncommon in the literature.[61–66] Seven military dogs stationed in Vietnam developed fever, myalgia, and abscess formation of multiple organs, including the dermis, lung, liver, kidneys, spleen, epididymis, and testis, and an Australian dog developed disseminated cutaneous melioidosis after ingesting offal from a goat that had died of the disease. A dog in Thailand that had been trapped in a barbed wire fence developed severe cutaneous wounds, splenic abscessation, and bacteremia.[62] In 2016, *B. pseudomallei* was identified in a 4-year-old mixed-breed dog that had been admitted to a shelter in New York after spending 21 months in a dog shelter in Thailand. The dog was evaluated at the Cornell University Hospital for Animals for apparent spinal trauma, and during the clinical workup, *B. pseudomallei* was isolated from the dog's urine.[61] Of the six cats reported with melioidosis, three were presumed to have acquired the infection in Malaysia,[63] with the remaining three cases domiciled in Northern Australia.[63] Multifocal abscesses, lymphadenomegaly, hepatomegaly, and splenomegaly were most common in the affected cats.[63,65,66] Two cats had unilateral panophthalmitis and retrobulbar abscessation.[64]

DIAGNOSIS

The index of suspicion for melioidosis should be increased in animals that are domiciled in or have a travel history from areas of endemicity, especially Northern Australia and Thailand.

Microbiologic Tests

Cytologic Diagnosis

Thorough cytologic examination of Gram-stained smears of pus from lesions can sometimes reveal small numbers of bipolar-staining gram-negative rods (often described as having a "safety-pin" appearance); this should increase suspicion of the infection in endemic areas (Fig. 77.5). Immunofluorescent antibody staining is available in Thailand,[67] but access to this technique may be limited elsewhere.

Isolation and Identification

Although culture of the organism is considered the gold standard for diagnosis, results may take up to 7 days. This delay may contribute significantly to the high mortality rate in fulminant cases. Also, culture may have a low sensitivity.[68] Bacteremia occurs in between 38% and 73% of human cases, and blood culture systems typically result in successful isolation of the organism within 48 hours of incubation.[47] The isolate may also be erroneously identified as *Pseudomonas*, or dismissed as a contaminant in laboratories unfamiliar with the agent. Generally, *B. pseudomallei* is grown on routine bacteriologic media (blood, MacConkey), although selective media such as modified

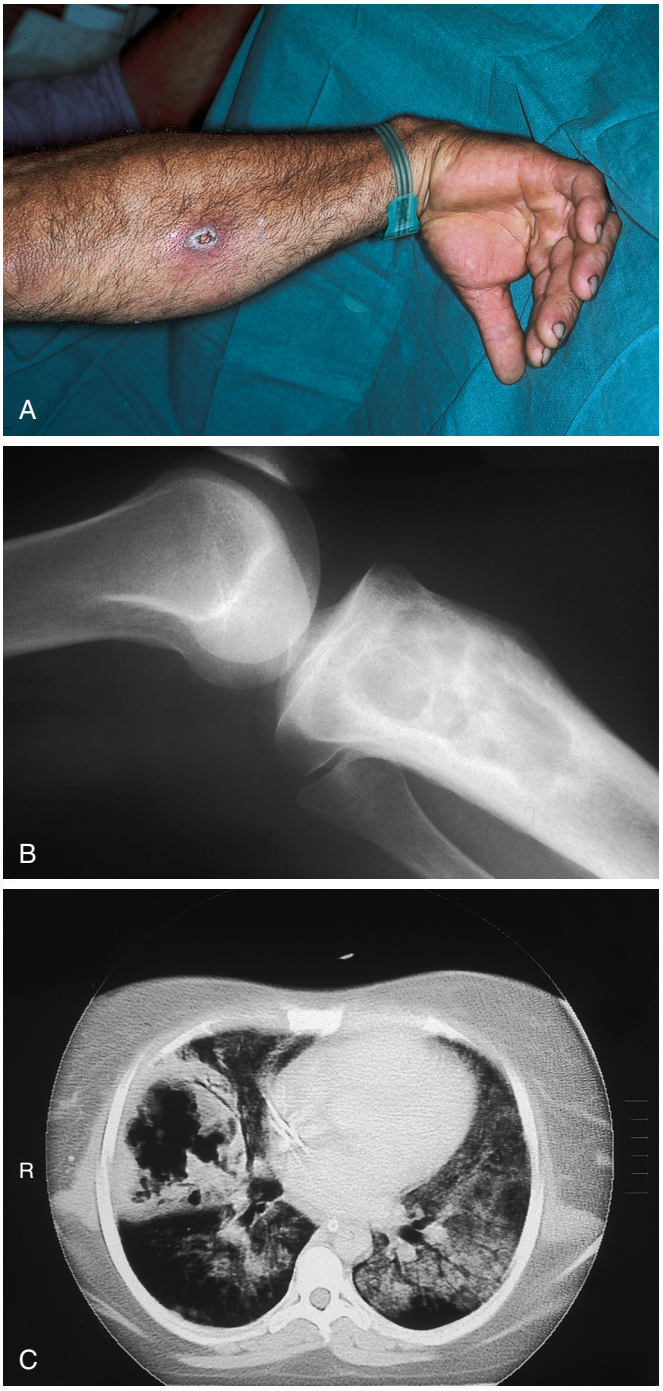

Fig. 77.4 (A) Cutaneous melioidosis on the right forearm of a 50-year-old man. (B) Radiograph of large radiolucency in the proximal tibia of a 43-year-old man with *Burkholderia pseudomallei* osteomyelitis. (C) CT scan of the thorax of a 26-year-old woman with fatal melioidosis, showing a large pulmonary abscess. (From Currie BJ. *Burkholderia pseudomallei* and *Burkholderia mallei*: melioidosis and glanders. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:2707-2717.)

Ashdown's agar[69] incubated for 96 hours may be needed to isolate the organism from sites where contaminating microorganisms are present. *Burkholderia pseudomallei* may also be misidentified as less virulent *Burkholderia* species or as *Chromobacterium violaceum* with commercial bacterial identification kits.[70] The use of MALDI-TOF

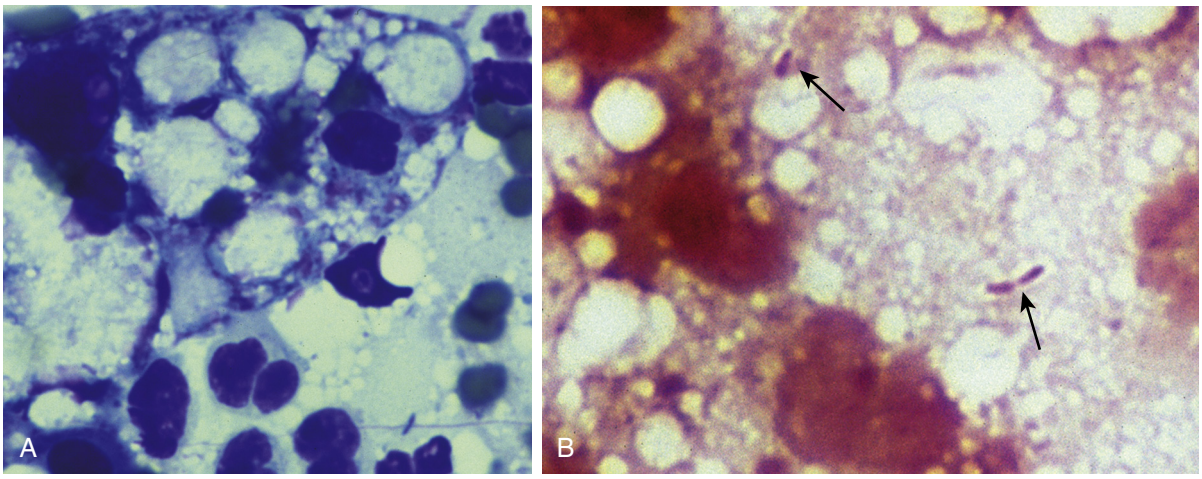

Fig. 77.5 Squash preparation of liver lesion from a cat with disseminated melioidosis obtained at necropsy. (A) Note the suppurative inflammation (Diff-Quik; original magnification ×330). (B) Extracellular gram-negative bacilli are present *(arrows)* (Burke's modification of the Gram stain; original magnification ×330). (From O'Brien CR et al. Disseminated melioidosis in two cats. *J Feline Med Surg.* 2003; 5:83-89; with permission from European Association of Feline Medicine.)

mass spectrometry by laboratories has allowed more rapid and accurate identification of *B. pseudomallei*.[47]

Serologic Diagnosis

Although indirect hemagglutination and enzyme-linked immunosorbent assays have been developed, they are of little clinical use, due to the high level of exposure in endemic areas. No serostudies have been published for dogs and cats to date.

Molecular Diagnosis Using Nucleic Acid–Based Testing

PCR and isothermal amplification assays can detect *B. pseudomallei* DNA in patient specimens; however, some of these assays have been found to have poor specificity and/or sensitivity.[71,72] Amplification and sequencing of the 16S rRNA gene is problematic as it does not reliably distinguish between *B. pseudomallei* and *Burkholderia thailandensis*.[73] The sequencing of the *groEL* gene may more reliably differentiate these two species.[74] A real-time PCR targeting the TTS1 gene cluster may also be used to identify the organism from culture systems[75]; however, the use of real-time assays on clinical samples has shown disappointing sensitivity.[76,77]

Antigen-Detection ELISA

A rapid, POC lateral-flow immunoassay has been developed to detect the presence of *B. pseudomallei* capsular antigen in sputum or pus.[76] It is not as sensitive as blood culture for detection of circulating organisms.

Pathologic Findings

Pathologic findings are microabscesses in affected organs and draining lymph nodes (Fig. 77.6). Immunohistochemical methods can detect the organism in affected tissues.[26]

TREATMENT AND PROGNOSIS

In people, treatment of melioidosis may be prolonged, is often unsuccessful, and relapses may occur. *Burkholderia pseudomallei* is resistant to many antimicrobial drugs, and successful treatment typically requires multidrug therapy for 12 to 20 weeks. There are few reports of successful treatment in animals and only one report of successful treatment of dogs and cats—the dog from Thailand that had been trapped in the barbed wire fence.[62] The dog introduced into New York was incontinent as a result of its spinal condition, and euthanasia was recommended because of public health concerns.[61] Surgical drainage of large abscesses may be required in conjunction with antimicrobial therapy. Antibacterial treatment is recommended for small or disseminated lesions.

The organism tends to be susceptible *in vitro* to trimethoprim-sulfonamides, amoxicillin-clavulanate, ticarcillin-clavulanate, some third-generation cephalosporins, tetracyclines, chloramphenicol, some fluoroquinolones, and carbapenems. It is generally resistant to penicillin G, aminopenicillins, first- and second-generation cephalosporins, most aminoglycosides (including gentamicin), most macrolides, quinolones, and rifampin.[79]

Current recommendations for treatment of acute melioidosis in human patients are an "intensive phase" of high doses of IV ceftazidime (+/− trimethoprim-sulfonamide) or meropenem (preferred if the patient has neurological involvement) for at least 10 to 14 days, and up to 4 to 6 weeks in patients with complicated pneumonia, deep organ abscesses, neurological, musculoskeletal, genitourinary, and/or extensive skin and soft-tissue involvement. This is followed by an "eradication" drug regimen of orally administered, high doses of trimethoprim-sulfonamide (plus folic acid supplementation) for 3 to 6 months.[47] Amoxicillin-clavulanate may be an alternative to trimethoprim-sulfonamide; however, acquired resistance is documented.[80] Following a response to treatment, affected animals should be closely monitored for signs of relapse. Melioidosis has a high rate of mortality in humans, with one study showing that 74% of patients with blood cultures that were positive after 24 hours of incubation died during their admission.[47] The dog from Thailand was treated with 2 weeks of meropenem (20 mg/kg IV q12h) followed by trimethoprim-sulfamethoxazole (25 mg/kg PO q12h) for 20 weeks.[62]

PUBLIC HEALTH ASPECTS

Generally, people in endemic areas become infected from the environment, as do animals. The organism has survived in a parenteral anesthetic solution and possibly an antiseptic cleaning agent containing cetrimide (3%) and chlorhexidine (0.3%). Zoonotic transmission is thought to be extremely rare, although anecdotal reports of animal-to-human transfer have been documented.[81] Identification of *B.*

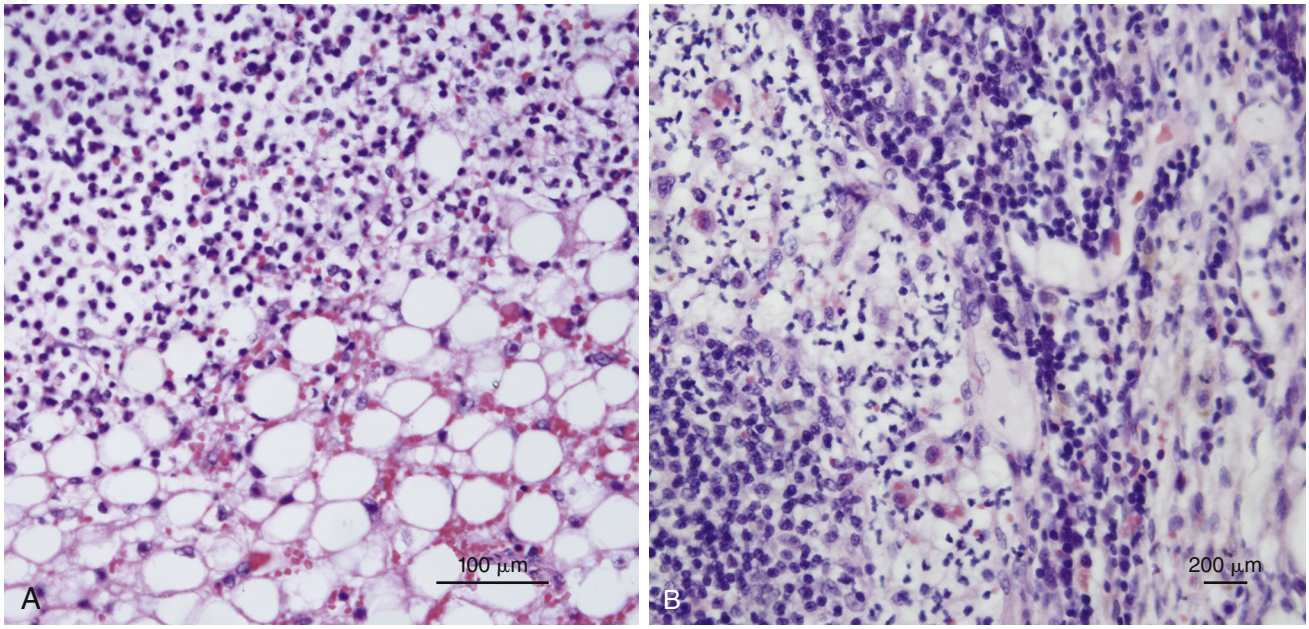

Fig. 77.6 (A) Histopathology of liver microabscesses from a 5-year-old domestic shorthair cat with melioidosis. Note the relatively well-circumscribed aggregation of the neutrophilic aggregation and the surrounding fatty degeneration of hepatocytes (hematoxylin and eosin stain, bar = 100 μm).(B) Histopathology of sternal lymph node from the same case. Note the neutrophilic exudate present in the cortical sinus. Involvement of the sternal lymph node was presumed secondary to the hepatitis observed in this case (hematoxylin and eosin stain, bar = 200 μm). (Courtesy of Mark Krockenberger, University of Sydney, Sydney, Australia.)

pseudomallei infection in companion animals in non-endemic regions should be reported to public health authorities. In the case of the dog introduced into the New York shelter, extensive contact tracing was performed, and it was recommended that highly exposed individuals be treated with prophylactic trimethoprim-sulfamethoxazole for 3 weeks.[61] Baseline and follow-up serologic testing indicated no significant evidence of human infection.

GLANDERS

ETIOLOGY AND EPIDEMIOLOGY

The causative agent of glanders, *Burkholderia mallei* (formerly *Pseudomonas mallei*), is a gram-negative, non-motile, non-spore-forming obligate intracellular bacterium. *Burkholderia mallei* has never been isolated from the environment,[82] instead being adapted to an equine host. It is estimated that approximately 3.5 million years ago, *B. mallei* evolved from the saprophytic organism *B. pseudomallei* through reductive evolution to become a specialist mammalian pathogen.[83,84]

Burkholderia mallei is susceptible to inactivation outside the host with heat (≥55°C/131°F for 10 min), ultraviolet light, and common disinfectants, although there have been reports of survival in tepid water for up to 1 month.

Glanders primarily affects solipeds (horses, donkeys, and mules) and these species are considered the natural reservoir of the organism, although it has been reported to occasionally occur in people and other animals, including dogs[85] and cats.[86] The disease is now very rare in the developed world; control programs eradicated it from Australasia in 1891, and the United States, Canada, and western Europe in 1965. It is now generally restricted to South America (Brazil), northern Africa, China, Iraq, Pakistan, India, Mongolia, Turkey, and United Arab Emirates.

Glanders is primarily transmitted from horse to horse via the inhalation of aerosols, ingestion of contaminated water or feed, or via contact with fomites, especially in situations where husbandry is substandard.[87] Transmission to non-equine species may occur via consumption of contaminated horsemeat, cutaneous inoculation, or inhalation. *Burkholderia mallei* has been used as a bioagent in numerous combat settings, being historically used to incapacitate warhorses in World War I and II, and more recently in the Afghan War.[88] The bacterium is classified as a Tier 1 Select Agent by the CDC,[48] and is also listed as a notifiable disease by the World Organization for Animal Health (OIE).

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The organism may cause localized cutaneous disease (farcy) or acute bacteremia and pneumonia in both animals and people. After ingestion of infected horsemeat, cats were reported to develop nodules on the nasal mucosae and conjunctiva, as well as nasal discharge. The cats eventually developed dyspnea secondary to obstructive lymphadenopathy.[86] The affected dog, domiciled in Turkey and possibly fed infected horsemeat, was reported to have a non-healing cutaneous wound of the right gluteal region of approximately 18 months' duration.[85]

DIAGNOSIS

Diagnosis of glanders can be made via isolation and identification of the organism from lesions or exudates using routine laboratory techniques. MALDI-TOF mass spectrometry has been used to differentiate *B. mallei* from *B. pseudomallei*,[89] but incorrect identifications can still occur.[90] A variety of molecular assays (e.g., PCR and isothermal assays)[91,92] have also been developed for specific diagnosis of *B. mallei* infection that allow it to be differentiated from other *Burkholderia* species.

TREATMENT AND PROGNOSIS

Due to the risk of zoonotic transmission and the potential for ongoing subclinical infection and shedding despite antibiotic therapy, treatment of affected animals is often not advised. No documented treatment of cats or dogs exists.

Like *B. pseudomallei*, *B. mallei* is intrinsically resistant to many antibiotics. In consideration of treating infection in other hosts, *B. mallei* is susceptible *in vitro* to aminoglycosides, azithromycin, carbapenems, trimethoprim-sulfonamides, ceftazidime, doxycycline, amoxicillin-clavulanic acid, chloramphenicol, and piperacillin.[93,94] Treatment regimens recommended for people with glanders are virtually identical to those advocated for the management of melioidosis.[95]

PUBLIC HEALTH ASPECTS

Glanders can be transmitted directly to people from infected solipeds. Glanders is considered to be more zoonotic than melioidosis, and the risk of laboratory-acquired infections also appears to be higher with *B. mallei* infections.[55] For microbiology laboratory personnel, horse abattoir workers, veterinarians, and equine handlers in endemic regions, exposure to the organism may be a significant occupational hazard, and appropriate protective measures should be implemented if exposure is possible. In the laboratory, biosafety level 3 containment is recommended.

BURKHOLDERIA CEPACIA COMPLEX INFECTION

The *Burkholderia cepacia* complex (Bcc) is an emerging cause of opportunistic infections in dogs and cats. Organisms that belong to this complex are widely distributed in the environment and can be isolated from soil and aquatic environments, including drinking water. Infections by Bcc organisms are identified much more commonly than those with *B. pseudomallei* and *B. mallei*, and in human medicine they are known for their ability to cause disease in humans with cystic fibrosis.[56] The Bcc has been reported to cause deep pyoderma in dogs as well as sepsis in dogs on immunosuppressive drug treatment, especially cyclosporine, but oclacitinib in one dog.[96,97] In one study, four of six affected dogs were West Highland white terriers.[96] Physical examination findings have revealed multifocal irregular, erythematous to hemorrhagic alopecic papules, plaques, and nodules, with extensive crusting, draining tracts, and ulceration. These have been confined to the trunk and proximal limbs.

Skin biopsies from affected dogs have revealed neutrophilic to pyogranulomatous inflammation with intralesional gram-negative rod-shaped bacteria that stain with Warthin-Starry (silver) stain. Treatment with systemic fluoroquinolones, doxycycline, or trimethoprim-sulfamethoxazole, along with withdrawal of immunosuppressive drugs when possible, has been successful in almost all dogs, but one dog died as a result of *B. cepacia* sepsis.[96]

Between 1990 and 2020 at one of the authors' institutions (JS), *B. cepacia* was identified in one dog with cutaneous furunculosis that was being treated with cyclosporine for immune-mediated polyarthritis (IMPA), a male neutered miniature poodle (see Case Example). It was identified using culture as a secondary invader in six dogs with neoplasia that disrupted normal cutaneous and mucosal host defenses (cervical SCC, corneal SCC, osteosarcoma of the zygomatic arch and secondary otitis externa, nasal adenocarcinoma, and cutaneous T-cell lymphoma), and one dog with nasal aspergillosis. It was also isolated from the urine from one dog with atypical hypoadrenocorticism and a possible UTI; and a bronchoalveolar lavage specimen from a dog with bronchiectasis and secondary bacterial pneumonia. Treatment with enrofloxacin was generally used and resulted in elimination of the infection, but dogs continued to show clinical signs as a result of their underlying condition.

CHROMOBACTERIOSIS

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Chromobacterium violaceum is a long, gram-negative, motile, facultatively anaerobic, non-spore-forming bacillus that belongs to the order Neisseriales. It exists as a saprophyte of soil and water in the tropics and subtropics, generally between latitudes 35 degrees north and south of the equator, although the geographical range may be expanding because of climate change.[98] In culture it is variably hemolytic, and produces the violet pigment, violacein, from the condensation of two tryptophan molecules.

Chromobacterium violaceum is a rare cause of disease in people and animals and infection is mostly acquired via inoculation of cutaneous wounds, although ingestion of contaminated water may be a possible source.[99,100] Fewer than 200 cases have been reported worldwide, with most cases coming from Southeast Asia; over 35 cases have been reported from the United States, mainly from Florida.[101] Most humans that develop disease are children or immunosuppressed adults, but some are apparently immunocompetent. Approximately 8% of the reported human cases have concurrent chronic granulomatous disease (CGD), a primary immune disorder in which neutrophils have an impaired respiratory burst due to defects in NADPH oxidase.[102] Glucose-6-phosphate deficiency also appears to predispose to the infection. A predisposition in young males was observed in one study,[98] possibly related to the mainly X-linked inheritance pattern of CGD.[102]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Cases often begin with localized skin or lymph node involvement and then may progress to widespread multi-systemic disease and fulminant bacteremia. Disease typically appears 1 day to 2 months after exposure. Infected people and animals are afflicted with abdominal organ and CNS abscessation, pneumonia, osteomyelitis, and necrotizing fasciitis.[98,103,104] A 60% mortality has been reported in affected humans in the United States.[101]

Four dogs have been reported with chromobacteriosis, including a dog from New South Wales, Australia with possible parvovirus infection[105]; two dogs from Florida,[106] and one from Poland.[107] One of the dogs from Florida (a 9-year-old beagle) was seen with signs of right-sided heart failure and evidence of pericarditis; culture of abdominal effusion yielded a heavy growth of *C. violaceum.* The dog's condition deteriorated, and after a subtotal pericardiectomy the dog developed cardiac arrest. Necropsy confirmed constrictive, effusive pericarditis but *C. violaceum* could no longer be isolated; the dog had been treated aggressively with parenteral antimicrobials during hospitalization (initially enrofloxacin and ampicillin followed by imipenem-cilastatin). The second dog from Florida was a 9-month-old Labrador retriever that developed necrotizing fasciitis at a surgical site after routine castration; the dog swam in a lake at a local park the night before the operation. The disease in this case was associated with a degenerative left shift, thrombocytopenia, hypoalbuminemia, mild hyperbilirubinemia and severe edema, and extensive necrosis and sloughing of the inguinal skin. *Chromobacterium violaceum* was isolated from the blood. Both of the dogs from Florida were afebrile at the time of initial evaluation. The dog from Poland also had a history of swimming in a lake, and

was diagnosed with chronic bilateral otitis externa, from which *C. violaceum* was cultured.

DIAGNOSIS

Chromobacterium violaceum is readily cultured on MacConkey agar at 37°C, and is relatively easy to identify due to the characteristic violet-pigmented colonies (Fig. 77.7).[101,104] Not all isolates are pigmented, however, which may cause some confusion.[99] Because of the typically fulminant clinical progression, antemortem diagnosis hinges on a high index of suspicion and timely culture of blood, tissue, or exudates. Molecular identification via both single-target and multiplex PCR[108] have been reported.

TREATMENT AND PROGNOSIS

Most isolates are susceptible to fluoroquinolones, aminoglycosides, trimethoprim-sulfonamides, carbapenems, and tetracyclines.[98,109] The organism appears to be resistant to a relatively wide range of antibiotics including β-lactams, second-generation cephalosporins, rifampin, and vancomycin.[98] Because the infection is so rare, there are no firm guidelines to inform therapy. Therefore treatment should primarily be based on the results of antibacterial susceptibility data, although empiric therapy based on clinical suspicion, for example treatment with a fluoroquinolone, pending these results would be appropriate.[98,106]

The prognosis for the disease in people is historically poor, with approximately 60% mortality rates reported[98]; however, more recent studies describe a much more favorable outcome (7.1% mortality).[103] The authors of the latter study speculated that improved patient outcomes were possibly due to the early use of meropenem in cases managed at their institution.

Of the dogs with systemic infections, two succumbed to bacteremia.[105,106] The dog from Florida with necrotizing fasciitis and bacteremia was treated with aggressive supportive care, parenteral then oral enrofloxacin and amoxicillin-clavulanic acid, and multiple surgeries for debridement and drainage of the affected skin; on day 112 after initial admission, the wound had healed. The dog with otitis externa was treated successfully with a 2-week course of systemic enrofloxacin and a topical aural preparation containing marbofloxacin, clotrimazole, and dexamethasone acetate, applied deep into both ear canals once daily.[107]

Relapses have been reported in the human literature,[98] thus it would seem prudent to treat systemically affected animals with an oral drug regimen for an extended period (e.g., at least 1–2 months past resolution of illness), with close monitoring for any evidence of recrudescence.

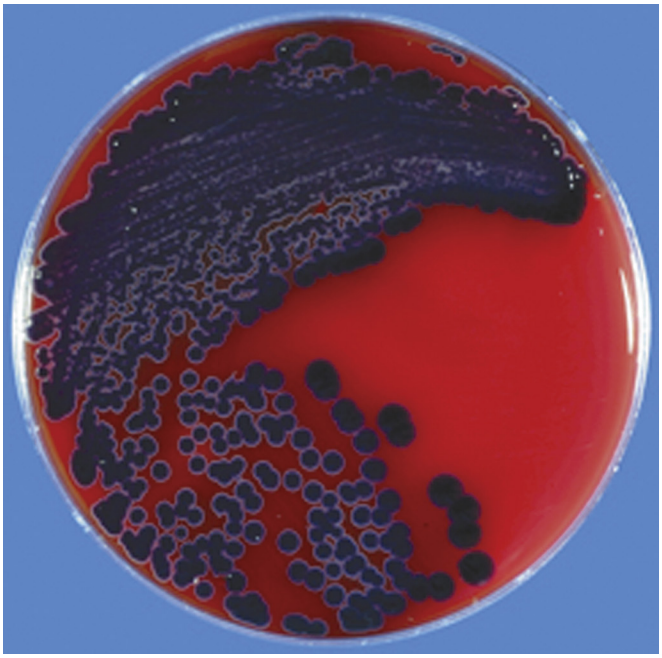

Fig. 77.7 Violet-black colonies of *Chromobacterium violaceum* from production of the pigment violacein. (From Steinberg JP, Lutgring JD, Burd EM. Other gram-negative and gram-variable bacilli. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandelll and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:2847-2864.)

OTHER UNUSUAL BACTERIAL INFECTIONS

Streptomyces spp. and *Streptobacillus* spp. are filamentous bacteria that belong to the Actinomycetales and Leptotrichiaceae, respectively. *Streptomyces* spp. are gram-positive soil saprophytes that have rarely been reported as a cause of pyogranulomatous dermatitis and cellulitis in cats, with poor response to aggressive medical and surgical treatment.[110,111] *Streptobacillus moniliformis* is a gram-negative bacillus that is the cause of rat bite fever in humans, a rare but potentially lethal zoonosis that occurs worldwide, typically following the bite of a rat.[112] There is a single case report from 1961 of systemic disease associated with an organism resembling *S. moniliformis* in a dog from Canada.[113] The organism has also been detected in the oral cavity of healthy dogs, raising concern that humans may develop rat bite fever after a bite wound from a dog.[114] A *Streptobacillus* species was isolated from the lungs of a cat with pneumonia and characterized as *Streptobacillus felis* sp. nov. using molecular methods and mass spectrometry.[115]

CASE EXAMPLE

Signalment

"Jojo," an 8-year-old male neutered miniature poodle from Walnut Creek, California, USA.

History

Jojo was seen at a follow-up visit for IMPA, which had been diagnosed 16 months previously and treated with a tapering course of prednisone and cyclosporine. The owners reported that Jojo still occasionally exhibited lameness of the right thoracic limb, but otherwise was doing well at home and appeared to be bright and appetent. Two weeks before the examination, the owners noted that Jojo was developing some skin nodules on the dorsal aspect of his lumbar region. He was also showing some signs of pruritis in association with the lesions. They began treating him with topical mupirocin and cefpodoxime, which were left over from a previous episode of inguinal pyoderma. No improvement in the skin condition was noted.

Current Medications

Prednisone (0.25 mg/kg PO q48h), cyclosporine (5 mg/kg PO in the morning and 2.5 mg/kg in the evening), cefpodoxime 5 mg/kg PO q24h, cyclosporine ointment OU q24h, neomycin/polymyxin B/dexamethasone eye drops for keratoconjunctivitis sicca (KCS), monthly flea prevention (imidacloprid/pyriproxyfen topical), and heartworm prevention (monthly ivermectin).

CASE EXAMPLE—cont'd

Jojo had been diagnosed with KCS several years ago, which was adequately controlled with the topical ocular medications. Before he was diagnosed with IMPA, he had a history of recurrent superficial pyoderma and *Malassezia* infections that were secondary to allergic dermatitis. This had been managed with frequent bathing with topical shampoos, flea preventatives, mupirocin ointment, cefpodoxime, and fluconazole. He was fed a commercial chicken and rice dry diet.

Physical Examination

Body weight: 10 kg.

General: Bright, alert, responsive, and hydrated. T = 101.7°F, P = 96, mucous membranes pink, CRT < 1.5 s, panting, and very active in the examination room.

Integument: Short, clean haircoat with no evidence of ectoparasites. There were 10 to 15 prominent papules with crusting, scattered across the dorsum, with most lesions being present in the caudal dorsal region. The dermis beneath the papules appeared thickened in some areas.

Eyes, ears, nose, and throat: Mild bilateral nuclear sclerosis, mild bilateral mucoid ocular discharge, moderate generalized periodontal disease. No other clinically significant findings.

Musculoskeletal: Body condition score 5/9, with symmetrical musculature and no evidence of joint effusion, pain on palpation, or lameness.

Cardiovascular, respiratory, GI, and genitourinary: No clinically significant findings.

Lymph nodes: No lymphadenopathy evident.

Biopsy Findings

Multiple 0.5-cm punch biopsies were collected and submitted for histopathology and culture. Histopathology revealed severe, chronic, diffuse plasmacytic and neutrophilic dermatitis and folliculitis with furunculosis. Occasional gram-negative rods were observed within neutrophils and macrophages. A diffuse inflammatory infiltrate, composed of dense aggregates of primarily plasma cells and neutrophils, with fewer numbers of lymphocytes, macrophages, and mast cells, spanned the superficial to deep dermis of all sections. A nodular inflammatory infiltrate was present in the deep dermis to the subcutis of two sections. Multifocally scattered lymphocytes and neutrophils infiltrated the follicular epithelium, and there was focal rupture of the mid-portion of a hair follicle and the ruptured segment was surrounded by neutrophils (furunculosis). Rare neutrophils and macrophages contained intracellular clusters of intracytoplasmic bacterial rods measuring approximately 2 μm in length. The superficial dermis was edematous. Aggregates of neutrophils multifocally infiltrated the epidermis and there was multifocal epidermal ulceration. Gram staining highlighted the presence of clusters of intracellular gram-negative bacterial rods within occasional neutrophils and macrophages.

Aerobic and anaerobic bacterial culture: Culture of a macerated skin biopsy specimen yielded small numbers of *Burkholderia cepacia*. The isolate was susceptible to amikacin, amoxicillin-clavulanic acid, doxycycline, enrofloxacin, gentamicin, imipenem, and trimethoprim-sulfamethoxazole; and resistant to cefazolin, cefovecin, cefoxitin, cefpodoxime, erythromycin, and chloramphenicol.

Diagnosis

Burkholderia cepacia deep pyoderma.

Treatment and Outcome

Enrofloxacin, 10 mg/kg PO q12h for 4 weeks was prescribed. The owners were told to cease bathing/grooming during treatment. At a recheck examination 2 months later, no change in the skin lesions was identified. Another course of enrofloxacin was prescribed, and 2 weeks later the owners reported mild improvement in the skin lesions. Arthrocentesis was performed and cytologic examination of synovial fluid from the right carpus and tarsus showed no abnormalities. The cyclosporine dose was reduced to 2.5 mg/kg PO q12h. One month later, the skin lesions had reduced in size and Jojo was less pruritic. There had been no signs of lameness. Enrofloxacin treatment was continued for another month until the lesions had resolved. At a recheck examination 2 months later (5 months after diagnosis), there was no evidence of the skin lesions.

Comments

This dog had similar lesions to those reported in case series of dogs with *B. cepacia* furunculosis reported in the literature, which were also receiving cyclosporine treatment.[96,97] Ultimately, prolonged antimicrobial treatment was required, together with a reduction in the dose of cyclosporine. The organism was resistant to all cephalosporins tested, which explained the initial failure of the condition to respond to cefpodoxime. Fortunately, Jojo's polyarthritis remained in remission after the cyclosporine dose was reduced.

SECTION 3

Fungal Diseases

Jane E. Sykes

Fungal diseases can be divided into superficial mycoses and deep mycoses. Superficial mycoses typically involve the skin and subcutis or mucosal surfaces, but rarely internal structures. Superficial mycoses include the most common fungal infections of dogs and cats such as dermatophytosis and *Malassezia* infections, which are addressed in this section in Chapters 78 and 79. Deep mycoses include the endemic mycoses caused by *Histoplasma* spp., *Blastomyces* spp., and *Coccidioides* spp.; cryptococcosis; sporotrichosis; and systemic mold infections.

For those with an interest in taxonomy, there have been significant changes in fungal nomenclature since the last edition, with the identification of new species of *Blastomyces* spp. in dogs, the proposed (and controversial) renaming of *Cryptococcus* spp. molecular types as separate species, the formal ("One Fungus, One Name") effort to use one name for mold pathogens rather than separate names for anamorphs and teleomorphs, and new names for *Pneumocystis* species. The chapter on sporotrichosis describes a major outbreak of zoonotic disease caused by *Sporothrix brasiliensis* in cats, dogs, and humans in Brazil, which involved thousands of cats and over 4,000 humans, the largest epidemic of this mycosis in the form of a zoonosis.

Although diagnosis and treatment of systemic mold infections used to be rare, with more widespread use of potent immunosuppressive drugs, veterinary practitioners are recognizing these infections more commonly. Many of these molds are resistant to commonly used antifungal drug treatments and have the potential to cause life-threatening disease. Other systemic fungal and algal infections that can be devastating if not recognized and treated early are candidiasis, oomycete infections (pythiosis and lagenidiosis), mucormycosis and entomophthoromycosis, and protothecosis. This section also includes chapters on organisms with unique classification, such as the "odd" fungus *Pneumocystis carinii* f. sp. *canis*, the aquatic protistan parasite (mesomycete) *Rhinosporidium seeberi*, and the mostly-fungus-somewhat-protozoan (microsporidian) parasite *Encephalitozoon cuniculi*.

Recent years have seen advancement in diagnostic testing capabilities for fungal infections, with an explosion in antigen detection tests, including point-of-care tests such as those for detection of cryptococcal polysaccharide antigen. Although the pace of advances in antifungal treatment has not been quite as fast, there is now more widespread use of newer azoles such as posaconazole and voriconazole, as well as improved understanding of the pharmacokinetics of azoles in dogs and cats. This has resulted in safer and more efficacious antifungal treatment regimens for dogs and cats. New azoles such as isavuconazole and antifungal drugs with novel mechanisms of action such as olorofim are now being used to treat refractory fungal infections in humans. We can look forward to further drug development activities and safety and pharmacokinetic studies so that similar drugs can be used to help companion animals in the future.

Dermatophytosis

Karen A. Moriello, Kimberly Coyner

KEY POINTS

- First Described: Clinical signs of dermatophytosis date back to the ancient Greek times.[1] One of the earliest texts describing the disease in animals was published in 1905.[2]
- Cause: There are over 30 species of dermatophytic fungi, but the most common dermatophytes that cause disease in dogs and cats are *Microsporum canis*, *Nannizzia gypsea* (previously *Microsporum gypseum*), *Trichophyton mentagrophytes*, and occasionally *Microsporum persicolor*. Most are zoophilic (and zoonotic) dermatophytes adapted for growth on keratinized structures of animals such as fur, skin cells, and toenails.
- Affected Hosts: *Microsporum canis* affects primarily dogs and cats, *T. mentagrophytes* commonly affects rodents, rabbits, and hedgehogs, and *M. persicolor* has been described in voles, but all dermatophyte species can infect any host. *Nannizzia gypsea* is a geophilic dermatophyte species which is usually found in decomposing fur/feathers present in the soil, but can infect living animals after contact with contaminated soil.
- Geographic Distribution: Dermatophytosis is present worldwide and is most common in warm climates.
- Route of Transmission: Exposure to spores is needed; dermatophytes are not part of the normal fungal biome. Dermatophytes are most commonly transmitted by direct contact between an infected and uninfected animal; fomite transmission via traumatic inoculation can occur via grooming equipment, bedding, collars, ectoparasites, and exposure to a contaminated environment. Successful fomite infection requires microtrauma to the skin in association with spore exposure.
- Major Clinical Signs: Clinical signs can be quite variable depending on animal and dermatophyte species involved, and chronicity and location of infection. Lesions commonly found include asymmetrical areas of papules, pustules, crusts, scaling, comedones, and alopecia. Erythema, hyperpigmentation, draining tracts, and nodular dermatitis can occur; as well as onychogryphosis. Pruritus is usually minimal but can sometimes be severe. Lesions can occur anywhere on the body but in cats tend to occur commonly on the face, ears, and paws, and then spread to other areas.
- Differential Diagnoses: Other causes for follicular infection including bacterial folliculitis and demodicosis, other ectoparasites, pemphigus foliaceus (in cases of severe facial or generalized crusting), and (in cases of nodular dermatitis), neoplasia, deep fungal infection, or mycobacterial granulomas. Dermatophytosis is most common in young animals, animals housed intensely, and/or animals under physiological stress.
- Human Health Significance: All dermatophytes are potentially zoonotic; *Microsporum canis* is the species most commonly transmitted from infected animals to humans. People handing infected animals should wear gloves. This is a low-level zoonotic disease and causes skin lesions in people; it is curable and infection is not life-threatening. Complications of animal-origin infections are rare, and when infection occurs in immunosuppressed people the most common potential adverse effects are those associated with prolonged treatment.[3-5] Most serious dermatophyte infections in people are of human origin and involve human pathogens.[3-5]

ETIOLOGIC AGENT AND EPIDEMIOLOGY

There are more than 30 species of dermatophytic fungal organisms; the dermatophytoses of veterinary importance are fungi in the genera *Microsporum* and *Trichophyton*.[6] Zoophilic dermatophyte species are adapted to living animal hosts; the most common species that affect dogs and cats are *Microsporum canis* and *Trichophyton mentagrophytes* (Table 78.1). Geophilic dermatophyte species such as *Nannizzia gypsea* (previously *Microsporum gypseum*) are usually found in fur, feathers, and horn present in the soil after the keratin products have been shed from the living animal. *Nannizzia gypsea* can also infect animals and humans after contact with contaminated soil. Anthropophilic dermatophytes species are adapted to humans and rarely infect dogs and cats; these include *Microsporum audouinii, Trichophyton tonsurans*, and *Epidermophyton floccosum*.

The classification of *Trichophyton* spp. and *Microsporum* spp. is evolving and species are being reclassified and renamed based on differing reproductive strategies.[7-9] There is a general consensus to move to a "one fungus-one name" classification system based on molecular typing; increasingly, clinicians will see the genus *Arthroderma* being used. Dermatophyte species can reproduce asexually (anamorphs) or sexually (teleomorphs, classified in the teleomorphic genus *Arthroderma*, phylum Ascomycota). The teleomorphic state of *Microsporum canis* is *Arthroderma otae*. The anamorphic species *Trichophyton mentagrophytes* can occur as a teleomorphic complex which includes *Arthroderma benhamiae* and *Arthroderma vanbreuseghemii*. Similarly, *N. gypsea* is now known to be a complex of the anamorphic phase *N. gypsea* and the teleomorphic *Arthroderma gypseum* and *Arthroderma incurvatum*. Risk factors for dermatophytosis include warm, humid environments, young age and group housing (such as shelters or catteries).[10-21] In a study of cats entering a northwestern animal shelter in the United States, owner-surrendered cats were half as likely to be diagnosed with *M. canis* dermatophytosis than transported cats.[21] Dermatophytosis is more common in cats than in dogs, but is still an uncommon disease even in cats; in one study of 1407 cats evaluated for skin disease, only 2.4% were diagnosed with dermatophytosis, far lower than the more common diagnoses of allergies/atopy (26%), bacterial skin infections (10%), ear mite infestation (6.1%), and flea infestation (5.2%).[22] Prevalence literature does

TABLE 78.1 Common Dermatophyte Species that Infect Dogs and Cats

Dermatophyte Species	Classification	Main Source
Microsporum canis (teleomorph *Arthroderma otae*)	Zoophilic	Cats, dogs, horses
Nannizzia gypsea (previously *Microsporum gypseum*) (teleomorphs *Arthroderma gypseum* and *A. incurvatum*)	Geophilic	Soil
Microsporum persicolor	Zoophilic	Voles, field mice
Trichophyton mentagrophytes (teleomorphs *Arthroderma benhamiae* and *A. vanbreuseghemii*)	Zoophilic	Rodents
Trichophyton verrucosum	Zoophilic	Cattle, other ruminants
Trichophyton erinacei	Zoophilic	Hedgehogs

not support the anecdotal comment that "it is ringworm until proven otherwise in cats." Infection with FeLV or FIV has not been shown to make cats more likely to develop dermatophytosis, but dermatophytosis has been described in cats and dogs with other immunosuppressive comorbidities.[23-26] There may be a genetic or breed predilection in some cases, as Persian cats and Yorkshire terriers are predisposed to dermatophytosis.[11,27-31] Terriers and hunting dogs are also over-represented for infection by *N. gypsea* and *M. persicolor*, likely due to skin abrasions and subsequent infection from contaminated soil while digging or hunting[32,33] (Fig. 78.1).

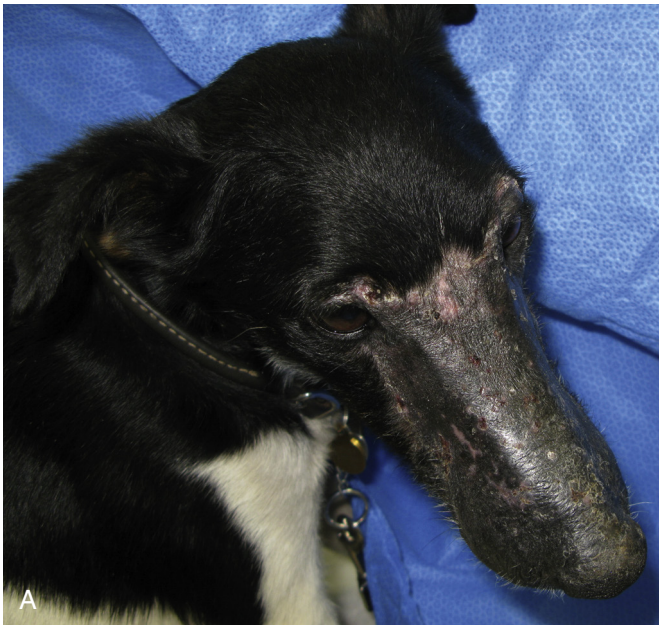

Fig. 78.1 Chronic *Trichophyton mentagrophytes* infections. There is alopecia, crusting, hyperpigmentation, and ulceration of the muzzle and periocular skin. CLINICAL FEATURES

Pathogenesis and Clinical Signs

Dermatophyte infections are transmitted among animals or to people primarily through direct contact with infected hair, scale, and/or crusts. Concurrent microtrauma is needed to establish an active infection from contact with a contaminated environment. The infective form of the organism is the arthrospore, a very small spore formed from the segmentation and fragmentation of fungal hyphae in infected hair and keratin. The dose or quantity of naturally infective material needed to establish spontaneous infection is unknown; in an experimental model, 100 macroconidia spores from a culture plate were able to cause a lesion but only when coupled with microtrauma and occlusion for >72 hours.[34] *Microsporum canis* infections typically follow contact with an infected cat, while most *Trichophyton* infections are suspected to be due to contact with infected rodents or their nests. *Nannizzia gypsea* infections are contracted when the animals dig in contaminated soil.

Arthrospores adhere very strongly to keratin in skin cells, hairs, and toenails. A requirement for dermatophyte infection is damage to normal skin defense factors, which include fungistatic fatty acids in sebum and an intact epidermis. Microtrauma to the skin from pruritus or self-trauma, humidity, and ectoparasites all contribute to conditions optimal for dermatophyte infection.[34,35]

The infection process has three stages: 1) adhesion of arthroconidia to corneocytes, which occurs within 2 to 6 hours of exposure and is likely mediated by carbohydrate-specific adhesins expressed on the surface of arthroconidia as well as dermatophyte-secreted proteases such as subtilisins; 2) conidial germination, which occurs within 24 hours of infection and in which germ tubes emerge from the arthroconidia and penetrate the stratum corneum; and 3) fungal invasion of the keratin network.[36-39] Other proteolytic enzymes (keratinase, elastase, and collagenase) have been isolated from dermatophyte fungi and are likely involved in all three stages of the establishment and progression of an infection.[39,40] By 7 days of incubation, hyphae begin to form arthroconidia, completing the fungal life cycle. Lesions typically appear 1 to 3 weeks after exposure.[34]

Dermatophytes can counter the host immune response in a number of ways, including lymphocyte inhibition by fungal cell wall mannans, macrophage function alteration, and altered/slowed keratinocyte turnover.[37,41] Both humoral (Th2) and cellular (Th1) immune responses occur in dermatophyte-infected animals; however, clinical cure and protection against reinfection depends on a strong CMI response involving macrophages and cytokines such as IFN-γ.[37,42]

Dermatophytosis is primarily a follicular disease, and thus the most common clinical signs include asymmetrical hair loss, scaling, crusting, papules, comedones, and variable pruritus. Some patients develop a classic ring-like lesion with central healing with or without hyperpigmentation and fine follicular papules on the periphery

Fig. 78.2 (A) Jack Russell terrier puppy with multifocal classic well-circumscribed lesions caused by infection by *Microsporum canis.* (B) On questioning, the owner of the affected litter of puppies revealed that she also had a lesion on her arm. (Courtesy Dr. Terry Nagle.)

(Fig. 78.2). Generally, however, clinical signs are highly variable and depend on the degree of inflammation and hair shaft destruction. In cats, lesions tend to occur most commonly on the face, ears, and muzzle and then progress to paws and other body areas. Multifocal and diffuse lesions are most commonly seen in animals with concurrent immunosuppressive disease and/or physiological stress such as overcrowding. Hunting dogs often develop lesions on the muzzle and paws. Onychogryphosis may occur, which may involve one to multiple digits. Pustular dermatophytosis can histologically mimic pemphigus foliaceus. Both dogs and cats can develop nodular dermatophyte infections; Persian cats and Yorkshire terrier dogs are predisposed to such lesions. These include kerions (localized, raised, nodular, exudative inflammatory lesions), pseudomycetomas, and mycetomas (subcutaneous masses) and present as nodules that fistulate, ulcerate, and drain serous to purulent exudate. Mycetomas are characterized by the presence of: 1) tumefaction, 2) draining sinus tracts, and 3) tissue grains or granules. In contrast to true mycetomas (eumycetomas), which are localized lesions containing dense clusters of organisms, pseudomycetomas (also known as dermatophytic mycetomas) lack draining tracts, and consist of loosely compacted clusters of hyphae.

Fig. 78.3 Adult cat with pruritus and multifocal areas of hair loss, scales, and crusts associated with *Microsporum canis* infection.

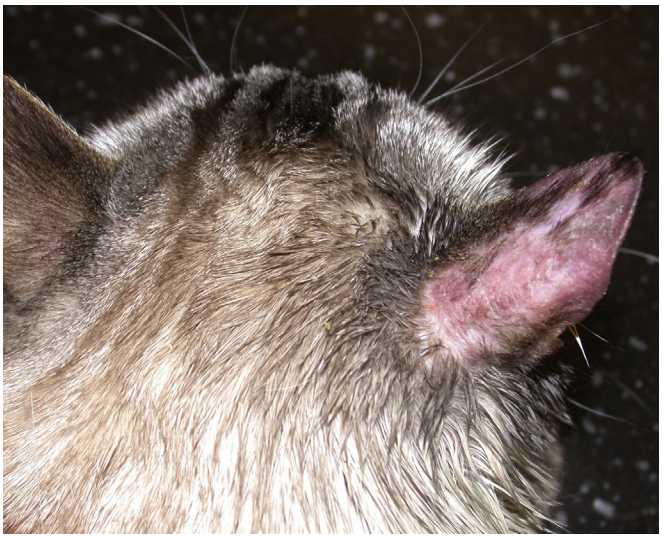

Fig. 78.4 Adult cat with unilateral otitis and hair loss on the ear pinnae associated with *Microsporum canis* infection.

Physical Examination Findings

Cats

Cats with dermatophytosis may develop focal to multifocal to extensive regional to generalized alopecia with variable crusting, scaling, erythema, follicular cast formation, comedones, and hyperpigmentation. Pruritus may range from none to severe, and in some cases miliary dermatitis, symmetrical alopecia, and eosinophilic plaques may develop. These lesions can resemble hypersensitivity dermatitis (Fig. 78.3). Lesions are commonly first noted on the face and limbs but can occur in any area. Alopecia, scaling, or crusting of one or both outer pinnae can occur (Fig. 78.4), as can chin dermatitis similar to feline acne. Uncommonly, lesions similar to pemphigus foliaceus such as bilaterally symmetrical facial, pinnal, nailbed, and footpad lesions can be seen. Dermatophyte

Fig. 78.5 Face of a 14-year-old dog infected with *Trichophyton mentagrophytes* (see Case Example).

Fig. 78.6 A 5-year-old male neutered mixed-breed dog with a history of an acute development of a nodular lesion on the muzzle. The diagnosis was kerion reaction associated with *Microsporum canis* infection.

pseudomycetomas are uncommon and are characterized by dermal to subcutaneous granulomatous masses which can fistulate, ulcerate, and drain.

Dogs

Dogs most often develop focal to multifocal areas of alopecia with variable scaling, crusting, papules, and hyperpigmentation. These signs are clinically indistinguishable from more common causes of alopecia, bacterial pyoderma, and demodicosis. Crusting of the facial and muzzle skin (Fig. 78.5) and furunculosis can mimic immune-mediated diseases. Dermatophyte kerions (Fig. 78.6) are most commonly caused by *Trichophyton* spp. and *N. gypsea*, and dermatophyte pseudomycetomas have rarely been reported. Paw and claw involvement can be characterized by onychogryphosis involving one to multiple toenails, and occasionally all may be affected (Figs. 78.7 and 78.8).

Fig. 78.7 Paw of a 14-year-old dog with *Trichophyton mentagrophytes* dermatophytosis (see Case *Example*).

Fig. 78.8 Foot of a 9-year-old intact male terrier mix with dermatophytosis caused by *Nannizzia gypsea* (previously *Microsporum gypseum*). The dog competed in rodent hunting events that occurred in underground tunnels. Severe, chronic dermatitis with ulceration and alopecia that involved multiple distal limbs and claws was present. The claws were irregular and discolored. (Courtesy University of California, Davis, Veterinary Dermatology Service.)

DIAGNOSIS

The diagnosis of dermatophytosis relies not on any one single diagnostic test, but rather by clinical acumen and assimilation of available information. It is commonly stated that fungal culture is the "gold standard" diagnostic test; however, if the criterion is to demonstrate *infection*, that is invasion of the hair and skin by a dermatophyte, then the only tests that demonstrate this are direct examination of hairs and histological examination of skin biopsy specimens. The objectives of this section are to provide the clinician with recommendations for

TABLE 78.2 Diagnostic Tests Used for Dermatophytosis

Test	Type	Specimen/Purpose	Tool	Comments
Dermoscopy	POC tool	Identifies hairs for direct examination or culture. When used with direct examination can confirm infection	Handheld dermoscope	Provides excellent magnification of hairs; look for broken "comma" shaped hairs; pluck hairs for direct examination and/or culture
Wood's lamp examination	POC tool	Identifies hairs for direct examination and/or culture through detection of apple green fluorescence on hair shafts. When used in conjunction with direct examination can confirm infection	Plug-in Wood's lamp only, best with built-in magnification (e.g., Burton Wood lamp)	Reliably identifies hairs for direct examination and/or culture; over 90% of untreated *M. canis*–infected cats have positive fluorescence; requires good equipment and technique. Can be used to monitor response to treatment; loss of fluorescence at base of hair shaft indicates good response to treatment. *Nannizzia gypsea* and *Trichophyton* spp. do NOT fluoresce
Direct examination (cytologic examination)	POC	Identifies infected hairs to select for dermatophyte culture and species ID; confirm infection	Mineral oil, skin scraping-spatula, forceps	Permits identification of both *Microsporum* and *Trichophyton* infections. Entire edge and center of infected lesion should be scraped
Fungal culture	POC or commercial diagnostic laboratory	Hairs and/or scales	Dermatophyte test medium, toothbrushes, skin-scraping spatulas	Detects fungal spores on the haircoat; must be used in conjunction with clinical examination to confirm infection. False-positive tests can occur due to fomite contamination, false-negative tests occur due to poor sample selection. Test of choice for monitoring treatment
Skin biopsy	Diagnostic laboratory	Tissue; excisional biopsy specimen or deep wedge biopsy specimen from nodule, 6–8 mm skin biopsy specimen from other skin specimens	Skin biopsy punch, other surgical instruments/materials as appropriate	Surface pathology is important for diagnosis, do not scrub or prepare the skin before specimen collection. Special stains required to identify the dermatophytes, important to alert pathologist of differential diagnosis, cannot identify species unless specimen is submitted for tissue PCR
Molecular testing: real-time PCR	Diagnostic laboratory	Hairs, scales, and crusts	Large amounts of hair and/or crusts needed to ensure adequate specimen for testing	Negative test is suggestive that dermatophytosis is not present. Will detect viable and nonviable fungal DNA, false positives are common if fomite contamination is a possibility; cannot yet be used to monitor for mycological cure

POC, point of care.

what test(s) are most likely *to confirm the presence of disease* and what test(s) are most likely *to confirm the absence of an active infection in a treated animal* (i.e., cured, not a risk).

Diagnostic assays for dermatophytosis are divided into two major categories: point of care (POC) and commercial diagnostic laboratory assays (Table 78.2). POC diagnostics include dermoscopy, Wood's lamp examination, hair trichograms and skin scrapings, and in-house fungal culture. Diagnostic laboratory testing includes diagnostic laboratory fungal culture, nucleic acid amplification tests (PCR), and histopathology. CBCs, serum chemistry panels, urinalysis, and diagnostic imaging are not helpful for confirming either the presence or absence of dermatophytosis. These tests are helpful and indicated when concurrent illness is suspected to have predisposed an animal to widespread severe dermatophytosis.

Point-of-Care Diagnostic Assays and Tools

Dermoscopy

Dermoscopy is a POC tool used to identify hairs for direct examination and/or fungal culture. A dermascope is a noninvasive handheld tool that allows for illuminated magnification of the skin and hair. There are several studies in the veterinary literature describing normal cat skin and hair and dermoscopic examination of cats with dermatophytosis.[43-45] Infected hairs are opaque, slightly curved, or broken with a homogenous thickness. These infected hairs have been called "comma hairs" because of their appearance. Microscopic examination of hairs shows hyphae and spores. Dermoscopes vary in cost and their primary advantage is magnified illumination of broken hairs for the purpose of specimen collection for direct examination and fungal culture. Dermoscopes can be used with or without a Wood's lamp.

Wood's Lamp Examination

A Wood's lamp is a POC diagnostic tool used to identify hairs that are suitable for direct examination and/or fungal culture (Box 78.1). This is an ultraviolet light (320 to 400 nm wavelength, optimum 365 nm) that can detect microbial organisms that produce phosphors as a result of their growth on skin and/or hairs.[46] It is different from a "black light" which comprises a clear glass that filters medium- and short-wave ultraviolet light and emits a large amount of blue visible light. In veterinary medicine the primary pathogen of importance that fluoresces is *M. canis*. The characteristic green fluorescence of *M. canis*–infected hairs is due to a water-soluble pigment located within the cortex or medulla of the hair.[47-49] The fluorescence is the result of a chemical interaction that occurs as a result of the infection and is not associated with spores or infective material. *Nannizzia gypsea, M. persicolor*, and *Trichophyton* spp. do *not* fluoresce.

BOX 78.1 Practice Tips for Wood's Lamp Examination

1. Use a medical-grade, plug-in Wood's lamp with built-in magnification.[a] Handheld battery-operated devices should not be used. The lamp does not need to warm up before use.
2. Be sure the room is dark and that the animal can be safely restrained.
3. Allow adequate time for the examiner's eyes to adapt to darkness. To ensure this is the case, use a "positive" control if possible. A positive control can be prepared by mounting infected hairs between two glass slides. Fluorescence will remain positive for years.
4. Hold the lamp close to the skin (2 to 4 cm) and move very slowly over the haircoat. This greatly decreases false-positive findings from dust. Holding the lamp too far away is one of the most common mistakes made, and leads to false-negative results.
5. Start at the head and carefully inspect the haircoat. Infected hairs are often obscured by scale and crusts; it is important to gently lift crusts and scales and look under the crusts.
6. Fluorescence is present only on the hair shafts and not on skin, crusts, scales, or nail and is green in color (Fig. 78.9). One of the most common things mistaken for fluorescence is hair sebum which usually appears "yellow."
7. Clear acetate tape can be pressed against the skin and gently lifted off the skin and then mounted on a glass slide. This technique can be helpful to visualize short hairs that cannot be plucked easily. Alternatively, lesions can be gently scraped to collect hair, which is then mounted in mineral oil, cover-slipped, and then examined. A Wood's lamp can be held over this to identify fragments of fluorescing hairs, which then identifies areas to initiate microscopic examination. Do not use clearing agents such as KOH, as this will destroy the fluorescence and are not helpful in visualizing infected hairs.

[a] The authors recommend Burton UV light model UV 502 (https://www.burtonmedical.com/).

Fig. 78.9 Positive Wood's lamp examination on a kitten in a shelter. The kitten is being viewed through the magnifying glass of a medical-grade Wood's lamp from 18 inches away. The Wood's lamp bulbs can be seen on the top and bottom of the picture. This demonstrates the usefulness of a strong Wood's lamp coupled with magnification.

BOX 78.2 Practice Tips For Direct (Microscopic) Examination

1. Use both hair pluckings and skin scrapings.
2. Use mineral oil as a mounting medium; no studies show that clearing agents are superior to mineral oil. Clearing agents such as KOH can induce artifacts and damage the microscope lens.
3. Mineral oil does not destroy fluorescence on *M. canis*–infected hairs; a Wood's lamp can be held over the glass microscope slide to help locate hairs for examination.
4. Use a glass coverslip to enhance visualization of the specimen.
5. Examine the specimen at 4× and 10× magnification for abnormal hairs, which appear wider and paler than normal hairs even at low power (Fig. 78.10).
6. The addition of lactophenol cotton blue stain to the mineral oil can help visualize infected hairs.
7. Follicular casts (circumferential accumulations of keratin around the hairs) are common artifacts, which appear on focal areas of the shaft or around the hair root.

An evidence-based review found that commonly held beliefs about the usefulness of Wood's lamp examination are inaccurate.[50] Statements such as "less than 50% of strains fluoresce" are based upon retrospective studies of random-source diagnostic specimens.[11,51-53] When data from 30 experimental infection studies and spontaneous disease studies were examined, results were surprisingly different.[50] Experimental dermatophyte infection studies reported 100% fluorescence in cats, and studies involving spontaneous disease in untreated animals reported 91 to 100% fluorescence. In studies that reported on *M. canis* fluorescence in cats that previously received treatment (predominantly longhaired cats), the prevalence of fluorescence varied from 39% to 53%. Fluorescence disappears with successful treatment. In addition, baths and lime sulfur or enilconazole dips were not associated with any loss of fluorescence when used to monitor response to treatment. In small animal practice, Wood's lamp examination is likely to be positive in most animals with *M. canis* dermatophytosis. This also has been the experience of one of the authors (KAM) in animal shelters (Fig. 78.9). Fluorescing hairs are most likely to be found in untreated infections; fluorescence may be more difficult to identify in treated animals. False-positive and false-negative results are commonly due to inadequate equipment, lack of magnification, patient compliance, poor technique, or lack of training.[50] Wood's lamp examinations can be an important POC examination tool in shelters to screen cats for dermatophytosis. In one report of management of *M. canis* dermatophytosis in a shelter, 1226 cats were surrendered to the shelter in a 7-month period.[54] Of these cats, 273 (22.3%) were culture-positive; but only 60 of 273 had lesions, were positive on Wood's lamp, and were positive using direct (light microscopic) examination. The 213 remaining culture-positive cats lacked lesions and were Wood's lamp negative; these cats were determined to be fomite carriers. Infection from fomite carrier cats was not introduced into the facility as cats were housed in cages at intake until repeat fungal cultures were negative. The only intervention was allowing the cat to groom. The use of a Wood's lamp at intake allowed for rapid identification of infected cats (50 of 60 being kittens), and prevention of reintroduction of the contagion to the facility.

Direct Examination of Hairs and Scale

Direct (light microscopic) examination of hair and scale can confirm dermatophyte infection in the examination room (Box 78.2). Material can be collected with the aid of a dermoscope, Wood's lamp, or via a combination of skin scraping and plucking of hairs. The optimal way to collect specimens is by both superficial skin scraping and plucking of hairs from lesions. Use of this combined technique yielded positive results in 87.5% of cases in one study.[55] In this study, a Wood's lamp was not used and the authors confirmed *M. canis*, *Trichophyton*, and

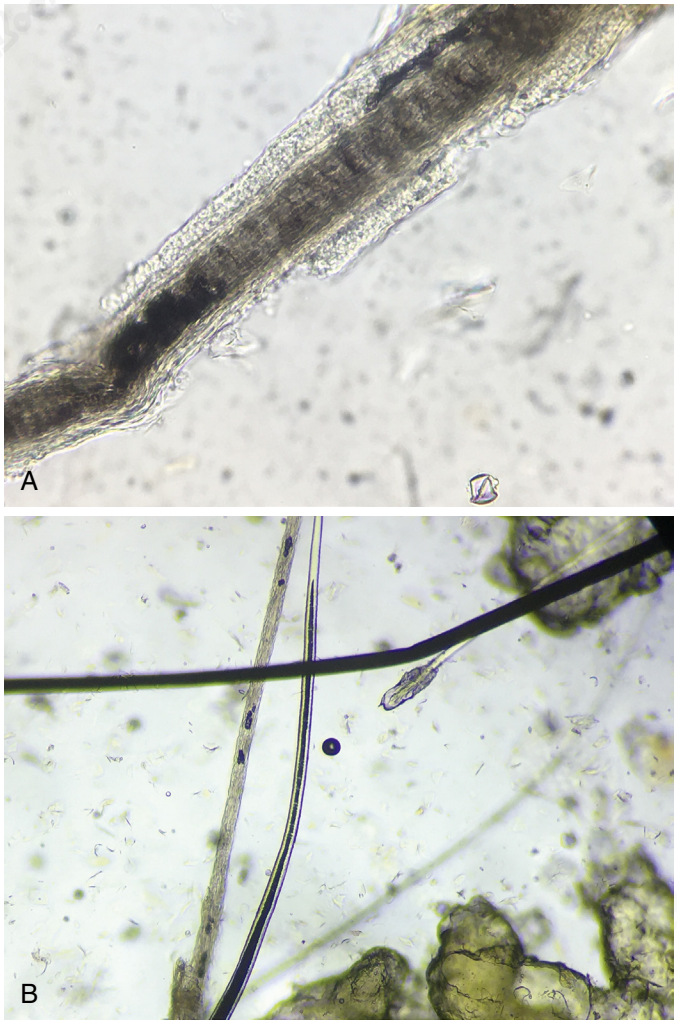

Fig. 78.10 (A) The infected hair is pale and shows disruption of the corticomedullary junction; dermatophyte arthroconidia are present encasing the cuticle of the hair (40x magnification). (B) In this trichogram cytology, the pale, fuzzy infected hair on the left side contrasts sharply with the normal hair in the center of the image (10x magnification).

N. gypsea based on culture of hairs determined to be infected on direct examination. Mounting specimens in mineral oil is time and cost-effective as it allows for concurrent microscopic examination for mites.

Dermatophyte Culture

Despite increased availability of molecular testing, fungal culture is still the most common method used to confirm a diagnosis of dermatophytosis and to identify the causative species (Box 78.3). It is also the only medical-legal test used to identify the fungal species. Fungal cultures may be performed as a POC in-clinic test or at a commercial diagnostic laboratory. A recent study revealed good correlation between POC cultures and diagnostic laboratories when both gross colony morphology along with microscopic features were used to identify colonies.[56] Importantly, there was a high error rate when culture media color change alone was used for diagnosis.

The POC procedure employs dermatophyte test medium (DTM), which consists of a nutrient medium, inhibitors of bacterial and saprophytic growth, and phenol red as a pH indicator. Several variations are available, some of which claim to speed growth of the culture, but this has not been found to be clinically significant and commercial media all appear to perform similarly.[57] Plates that have a large volume of medium and are easy to inoculate should be purchased. Plates are

BOX 78.3 Procedure for Point-of-Care Culture of Dermatophytes

1. Use a fungal culture medium that can easily be inoculated and allow it to warm to room temperature before inoculation.
2. Do not clean lesions with alcohol before specimen collection as this can result in a false-negative culture.
3. Collect specimens using a toothbrush. A new unopened toothbrush is mycologically sterile. Comb the target lesion approximately 20 times, or until the bristles are filled with hair. If lesions are not clearly visible, comb the entire haircoat. If lesions are heavily crusted, forceps or hemostats can be used to collect crusts and hairs for culture.
4. Stab bristles onto the surface of the plate with just enough pressure to turn the ends of the bristles yellow. Do no not pluck individual hairs from within toothbrush bristles for culture as this can lead to false-negative results. To inoculate hairs and/or crusts plucked directly from the lesions, press the hairs firmly onto the surface of the fungal culture plate. Do not embed them.
5. Store plates in clear plastic bags to keep media hydrated and prevent cross-contamination. It is not necessary to store plates in the dark.
6. Incubate at 25°C to 30°C (77°F to 86°F).
7. Examine the plates daily by holding the plate up to light to look for growth.
8. Colonies have pale, never heavily pigmented, colony growth and a red color change in the medium around them as they grow (Fig. 78.11). Red color change alone is never diagnostic. Microscopic confirmation is always required to confirm the presence of dermatophytes.
9. Make a clear acetate tape preparation using lactophenol cotton phenol blue stain and wait 15 minutes before microscopic examination to allow the stain to be absorbed by conidia and hyphae.[a] New methylene blue or Diff-Quik II solution (basophilic thiazine dye) can be used but may not be as effectively taken up by cells.
10. Key differentiating features of *Microsporum canis*, *Nannizzia gypsea*, and *Trichophyton* on cytologic examination using light microscopy are shown in Figures 78.12 to 78.15. If a suspected dermatophyte cannot be identified on in-house cytologic examination, submit the culture plate to a commercial diagnostic laboratory for definitive fungal identification.

[a] Lactophenol cotton blue stain can be purchased online.

preferable to vials because they permit inoculation with a toothbrush. For incubation, DTM containers should be loosely covered or capped at room temperature and protected from desiccation. Placement of individual cultures in a plastic self-closing bag will help prevent desiccation, cross-contamination, and mite infestation of the culture medium. Dermatophyte colonies appear as soon as 5 to 7 days after inoculation. In cultures of human dermatophyte infections, 98.5% of fungal cultures were positive before day 17.[58] When veterinary specimens were examined, 98.2% of fungal cultures for *M. canis* were positive by day 14 of incubation.[59] In a study of 202 diagnostic DTM plates from *M. canis*–infected shelter cats from a Pacific northwestern shelter, all had recognizable colony growth by day 7 (median 4 days), and 19 of 19 fomite carrier cat cultures exhibited growth by day 12.[21] A fungal culture can be considered negative if no pathogen has been isolated by day 14. Plates should be inspected daily for growth by holding the plate up to the light to look for colony growth. This avoids opening of culture plates until it is appropriate to do microscopic confirmation. Dermatophyte colonies are never green, gray, brown, or black. Pathogens are white, light tan, or buff in color and have a powdery to cottony mycelial growth. The red color change is caused by a change in the pH of the medium and is not diagnostic for dermatophytosis; it merely identifies colonies for microscopic sampling. The color change usually occurs at the time the colony is first visible, but may develop

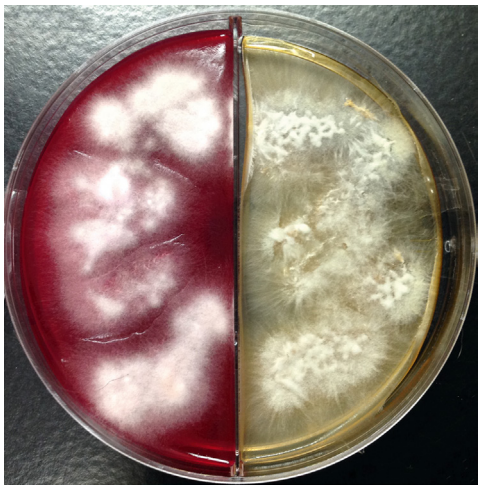

Fig. 78.11 Typical growth of *Microsporum canis* on DTM *(red)* and Sabouraud dextrose agar on dual growth plate. Note the pale colony growth. Dual plates are a good choice because they provide the "red flag" aid of the color indicator in DTM with a growth medium (Sabouraud). The phenol red in DTM can sometimes result in changes to the gross and microscopic features of dermatophytes, making in-clinic identification more difficult. This is avoided if dual plates are used, as this does not occur with Sabouraud medium.

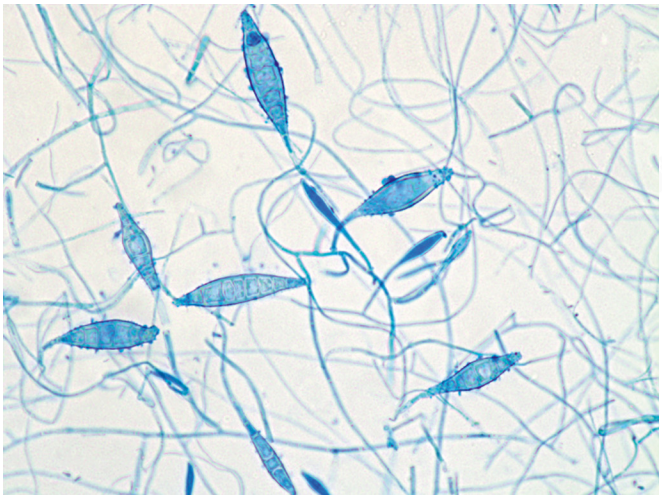

Fig. 78.12 *Microsporum canis* macroconidia stained with lactophenol cotton blue (40× magnification). The specimen was allowed to stand for 15 minutes before being examined. The stain has been absorbed intracellularly making the macroconidia more visible. Key characteristics are thick walls, tapered ends, rough walls and large amounts of hyphae and relatively few macroconidia compared to *N. gypsea*.

within 12 to 24 hours of fungal growth. Growth of any pathogenic or non-pathogenic fungus will eventually produce a red media color change after the colony has grown for several days to a week.

Unless there is a specimen collection error such as collection of only a few hairs rather than using a toothbrush for sampling lesions, large numbers of colonies of the dermatophyte will appear on the plate if dermatophytosis is present. The number of colonies decreases as the infection resolves spontaneously or with successful treatment. One of the most common problems with in-house culture is the lack of sporulation or growth, or both, of *M. canis* on DTM. A common cause of this is over-inoculation of the culture plates. This results in rapid swarming of the plate with fluffy colony growth but only unsporulated hyphae are noted on microscopic examination. Toothbrush

Fig. 78.13 *Nannizzia gypsea* macroconidia (40× magnification). Note the wider and blunted appearance compared to *Microsporum canis*, together with thin walls. A key differentiating feature on cytological examination is that *N. gypsea* produces large numbers of macroconidia that are easily found and hyphae are not commonly found.

Fig. 78.14 Macroconidia of *Trichophyton* spp. The specimen appears pale; it was examined immediately after staining.

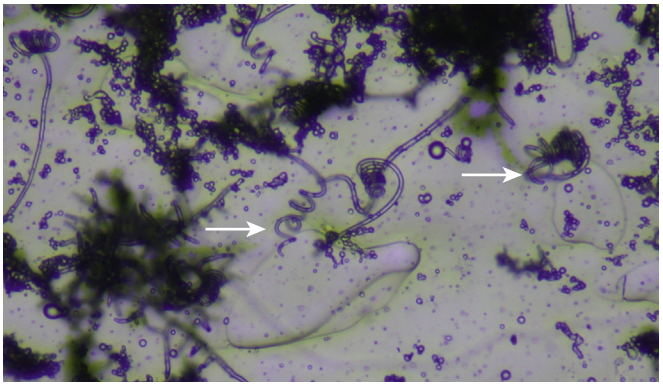

Fig. 78.15 Spiral hyphae most typical of *Trichophyton* spp. *(arrows)*. Note the large numbers of microconidia. Spiral hyphae are highly suggestive of *Trichophyton* spp.

specimens should be directly inoculated onto the surface of a plate to avoid overgrowth of contaminants. In one study that compared direct inoculation to the plucking of hairs from bristles that were then inoculated onto a plate, the latter technique resulted in marked contaminant growth.[60] The number of toothbrush inoculations on the plate should be limited to four to six, and individual impressions should be

clearly visible and not cover the entire plate surface. If the plate has been over-inoculated, a subculture can be performed to identify the pathogen. When evaluating fungal cultures in *treated* animals: 1) colony growth may be slower; cultures negative for growth at day 14 should be considered negative, 2) gross and microscopic fungal colony morphologies may appear abnormal, and 3) as dermatophytosis resolves, the number of dermatophyte CFU per plate should dramatically decrease, so this feature can be used to monitor response to treatment (see Box 78.3). If toothbrush specimens are sent to a human or veterinary diagnostic laboratory, clinicians should contact the laboratory to ensure they are familiar with toothbrush inoculation techniques and request weekly updates on growth. Quantification (CFU/plate) is important and should be reported as a 1-–10 count. MALDI-TOF mass spectrometry (see Chapter 3) has been used to successfully identify dermatophytes to the genus level; reliable species-level identification has been more challenging but shows promise as libraries improve.[61]

Skin Biopsy

Histological examination of skin biopsy specimens is indicated in three clinical situations in order to confirm the presence of true disease. The first is in the evaluation of nonhealing wounds or nodular lesions, because kerions and pseudomycetomas (dermatophytic mycetomas) often yield negative fungal cultures. The second is in the evaluation of dogs or cats with facial lesions where extensive crusting is present and/or if pemphigus foliaceus is suspected. In rare cases, dermatophytes can produce pustular histologic lesions with acantholysis. The third is in the workup of an animal with unusual skin disease not easily attributed to other causes. In all cases it is important to alert the pathologist that dermatophytes are suspected, because routine stains (i.e., H&E) are not as sensitive as PAS or Gomori's methenamine silver (GMS) for detection of fungal elements in tissue.

Specimen collection. The skin should not be prepared or disinfected before biopsy, as key diagnostic findings are present in the superficial crusts. It is critical to collect multiple (4–6) skin biopsy specimens no less than 6 mm in diameter, as tissue specimens shrink by 30% to 50% when placed in formalin. Deep wedge samples or excisional biopsies are preferred for nodular lesions. It is not uncommon for organisms to be scant in tissues, hence the need for multiple sections to increase the chance of making a diagnosis. Histopathology does not permit identification of the dermatophyte species present, and molecular testing on paraffin-embedded specimens is not widely available. In nodular lesions, submission of a wedge of tissue in sterile saline for a macerated fungal culture is ideal for identification of dermatophyte species present. Histological examination of skin biopsy specimens is not recommended as a basis to determine mycological cure.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Reports on the use of PCR for the diagnosis of dermatophytosis in spontaneous skin disease are still relatively uncommon in the veterinary literature. One study reported 100% concordant results between PCR and culture for the diagnosis of nodular lesions in cats caused by *M. canis*.[62] A second study reported correct identification of *Trichophyton* infections in dogs (n = 7) and *M. canis* infections in cats (n = 8) in 15 specimens from animals with a diagnosis confirmed via both fungal culture and direct examination of hair.[63] In another study, 183 hair specimens from dogs and cats with suspected dermatophytosis were tested by PCR and fungal culture.[64] Fungal culture confirmed the diagnosis in 59 of 183 specimens, and endpoint (conventional) one-step PCR and nested PCR (see Chapter 6) were positive in 49 and 63 of 183 specimens, respectively. In this study, there were notable differences in the sensitivity and specificity of molecular assays used between dogs and cats. One-step testing was highly accurate for dogs (AUC > 90) but only mildly accurate for cats (AUC = 78.6). Nested PCR was accurate for cats (AUC = 93.6) and had a specificity and sensitivity of 94.4% and 94.9%, respectively, for both species.[64] Use of nested PCR is no longer recommended for routine molecular diagnosis because of its potential for false-positive test results due to contamination. In a field study of 132 cats, 21% of which were culture-positive for *M. canis*, there were no false-negative real-time PCR results.[65] False-positive real-time PCR results were common primarily from fomite carriage and real-time PCR was found to be inferior to fungal culture for determination of mycologic cure. PCR-based molecular methods have also been used to study the epidemiology of dermatophytosis and trace the source of human infections to animals; in one report, microsatellite-primed PCR fingerprinting was used to identify a carrier cat as a possible source of *M. canis* infection.[66]

In untreated animals, real-time PCR can be used to evaluate suspect skin lesions, and a negative test is highly suggestive that dermatophytosis is not present unless specimens of suboptimal quality are submitted. PCR assays, like toothbrush fungal cultures, cannot differentiate fomite carriers from truly infected animals, but with a toothbrush fungal culture, quantitative reporting (CFU/plate) helps to distinguish fomite carriage from active infection. Because PCR detects DNA from both viable and nonviable fungi, cured animals may have positive test results. A negative PCR test in an animal with apparent clinical cure also suggests mycological cure. However, if the PCR test is positive then a dermatophyte culture needs to be performed to determine if the PCR detected viable or nonviable fungal DNA. Pending the results of dermatophyte culture, topical antifungal therapy should be continued.

Specimen collection. Specimen quality is important for fungal PCR testing. The active infection is present in the hair follicle, making it important to submit a specimen that contains hair bulbs. A Wood's lamp or dermoscope can be used to identify suspect lesions or hairs. If crusted lesions are present, the crust should be gently lifted, taking care not to dislodge hairs. Hairs can be plucked with forceps and transferred to a sterile container. Alternatively, a target lesion can be aggressively combed with a toothbrush and then the entire toothbrush is submitted.

TREATMENT AND PROGNOSIS

Although dermatophytosis is a self-limiting disease in immunocompetent animals, treatment is recommended to shorten the course of infection because it is a contagious and zoonotic disease. Optimum treatment involves the use of a systemic antifungal drug to eradicate the infection in the hair follicle, topical therapy to disinfect the haircoat, and routine cleaning of the environment. The primary purpose of the environmental cleaning is to minimize problems associated with positive fungal cultures due to environmental contamination and not true disease during the treatment period. Recent treatment consensus guidelines state that "confinement needs to be used with care and for the shortest time possible". Dermatophytosis is a curable disease, but behavior problems and socialization problems can be lifelong if the young or newly adopted animals are not socialized properly. Veterinarians need to consider animal welfare and quality of life when making this recommendation.[50] Treatment is continued until there is both clinical and mycological cure.

Topical Antifungal Drug Treatment

Topical antifungal therapy is an equally important part of the treatment of dermatophytosis and is used in conjunction with a systemic antifungal drug (Box 78.4). Topical therapy removes dermatophytes from the haircoat, which is the source of infection for other animals and people. Topical therapy minimizes shedding of spores in the environment, minimizing the potential for false-positive fungal cultures and unnecessarily prolonged treatment. Haircoat disinfection is critical for mycological cure. The most common cause of a "persistent positive culture" in an animal that is otherwise clinically normal is a nidus

BOX 78.4 General Recommendations for Topical Antifungal Therapy

Clipping of haircoat not always indicated or possible; if done, use blunt-ended metal-tipped scissors.

Topical therapy should be continued until mycological cure is documented, even if systemic therapy has been completed.

Topical therapy with antifungal shampoos can be used on exposed but unaffected household pets.

Whole-body topical therapy is indicated to treat the haircoat; adjuvant focal therapy is recommended for hard-to-treat areas that might be inadequately treated by a client with a rinse or shampoo.

Whole-body topical therapy should be used concurrently with systemic antifungal therapy.

Whole-body therapy (twice weekly, wear gloves)

Leave-on rinses:

- Lime sulfur: 8 ounces (237 mL) in 120 ounces (3.55 L) of warm water for proper dilution. This is a 1:16 dilution and must be prepared just before use.[a]
- Enilconazole 100mg/mL (Imaverol, Austrazole): Dilute 1:50 or 20mL enilconazole with 1L water to make a 0.2% solution

Shampoo (no residual activity):

- Miconazole/chlorhexidine formulations are synergistic and recommended. Chlorhexidine alone is ineffective.
- Miconazole, ketoconazole, climbazole formulations are options.
- 3 to 10 minutes contact time, rinse coat thoroughly.

Adjuvant local therapy

For lesions and hard-to-treat areas such as face, periocular areas, or ears:

Apply once daily, wear gloves

1% terbinafine, 1 to 2% miconazole, 1% ketoconazole applied twice daily

1 to 2% vaginal miconazole can be used on periocular lesions

For ears, consider antibacterial drug-free otic preparations that contain ketoconazole or miconazole

Special cases

Shampoos can be used to treat the haircoat of exposed but unaffected housemates.

Leave-on mousse formulations can be used on pets initially if wetting is not possible.

[a] Lime sulfur veterinary products and lime sulfur agricultural products may be labeled differently. Agricultural products may list the active ingredient as 23% calcium polysulfide or 23% sulfur sulfide. These formulations are identical to veterinary-labeled products and should be diluted no differently, i.e., 1:16. It is very important to thoroughly shake lime sulfur containers as the ingredients will settle.

of infection on the face and/or in the ears. Maximum protection from exposure to spores is provided from products with residual activity, namely lime sulfur or enilconazole.

In general, clipping the entire haircoat is not recommended, as this may worsen clinical signs and spread infection. The use of electric clippers is strongly discouraged, as clippers can overheat and cause thermal injury. Electric clipper blades require meticulous gross decontamination before being sterilized. Disposal of electric clipper blades is an option, albeit an expensive one. Clipping of focal lesions or the whole haircoat should be performed with metal round-tipped children's scissors ("scissor clipping"). Animals should be clipped on newspaper to allow for easy disposal of infective material. Pretreatment with one or two lime sulfur rinses before clipping can minimize contamination of the environment. Longhaired adult cats and/or Yorkshire terriers may need to be clipped if the infection is not easily eradicated, recurrent, and/or if matted or thick fur make it difficult to thoroughly soak the haircoat and the surface of the skin.

Twice-weekly whole-body rinses or antifungal shampoos are recommended for the duration of therapy of infected animals. Additionally, topical whole-body rinses or antifungal shampoo treatments can be used to treat exposed uninfected animals and/or to minimize the risk of transmission to other animals in a household. A recent extensive evidence-based review of topical antifungal therapies found that products with documented clinical efficacy included lime sulfur dips (4–8 oz/gal or 15–30 mL/L), 0.2% enilconazole rinses (available in Canada and Europe), and combination miconazole/chlorhexidine shampoos.[50,67-72] *In vitro*, antifungal shampoos containing miconazole, ketoconazole, climbazole, or accelerated hydrogen peroxide are antifungal when used with a minimum of a 3-minute contact time.[73] Lime sulfur and enilconazole are fungicidal on contact and are leave-on, whole-body solutions with residual activity. Lime sulfur veterinary products and lime sulfur agricultural products may be labeled differently. Agricultural products may list the active ingredient as 23% calcium polysulfide or 23% sulfur sulfide. These formulations are identical to veterinary-labeled products and should be diluted no differently, that is, to 1:16. It is important to thoroughly shake lime sulfur containers prior to dilution as the ingredients will settle, and to freshly dilute the dip for each treatment.

Antifungal shampoos do not have any residual activity and so are a second-line treatment option to dips. In one author's experience (KAM), a leave-on climbazole mousse was effective as topical therapy in several situations where animals could not be wetted.

Local antifungal therapy (once or twice daily) with a topical azole or terbinafine cream as an adjunct therapy to whole-body rinses or shampoos is recommended for lesions in areas on the face and/or ears. Vaginal miconazole cream is a common ophthalmologic treatment for fungal keratitis and can be safely used to treat lesions around the eyes. Topical otic preparations containing miconazole, clotrimazole, or ketoconazole can be used daily to disinfect hairs within the ear.

TABLE 78.3 Systemic Antifungal Drugs for the Treatment of Dermatophytosis

Drug	Dose (mg/kg)	Route	Interval (Hours)	Comments
Itraconazole	5	PO	Cats: Alternating weekly schedule for three cycles Dogs: 24	Cycle may need to be repeated in cats with severe infections
Terbinafine	30–40	PO	24	
Ketoconazole	5	PO	Dogs: 24	Do not use in cats
Griseofulvin microsize	25–50	PO	24	Give with a fatty meal
Griseofulvin ultramicrosize	15	PO	q24h	Give with a fatty meal

Systemic Antifungal Drug Treatment

Systemic antifungal therapy eradicates the fungal infection within the hair follicle and is used in conjunction with topical antifungal therapy and environmental cleaning (Table 78.3). It is generally indicated in all animals with dermatophytosis as it is the only therapy that eradicates the infection within the hair follicle. Until infection is eradicated from within the hair follicle, the haircoat will be reseeded with spores.

Itraconazole is the drug of choice for the treatment of dermatophytosis. In cats, it is labeled for use at 5 mg/kg q24h on an alternating week-on/week-off treatment schedule for three cycles or until mycological cure. Similar studies have not been conducted in dogs. Itraconazole concentrates in the adipose tissue, sebaceous glands, and hair for weeks after administration.[74] The human brand name or generic 100 mg itraconazole capsules can be used at 5 mg/kg; however, capsules need to be reformulated. Compounded itraconazole in both dogs and cats has poor bioavailability and should not be used.[75,76] When 12 studies involving 316 animals treated with itraconazole for dermatophytosis were reviewed, adverse effects were rare and included salivation, mild anorexia, and vomiting.[50] No deaths were reported. In target animal safety studies in which cats were given 5, 15, and 25 mg/kg itraconazole q48h for 7 days for 17 weeks with an 8-week recovery period, the most common abnormal clinical observations noted were dose-related hypersalivation, vomiting, and loose stool, which were mild to moderate and self-resolving.[77] Elevations in the activity of serum hepatic enzymes above baseline were sporadic, dose related, and rarely above the reference range. In an extensive review of the literature, reports of severe adverse effects of itraconazole were in dogs or cats traced to studies where animals were treated for long periods with high doses for systemic fungal diseases, not dermatophytosis.[50] Itraconazole is safe in kittens as young as 10 days old.[74] Terbinafine has the lowest MIC for *Microsporum* and *Trichophyton* when compared to itraconazole, fluconazole, ketoconazole, or griseofulvin.[78-80] Terbinafine has been used to successfully treat *M. canis* dermatophytosis in experimentally induced infections and infections in laboratory cats, shelter cats, and pet cats.[54,81-85] Like itraconazole, terbinafine is highly concentrated in the hair of cats for several weeks after 14 days of continuous therapy[86]; however, similar studies have not been conducted on dog hair. In some countries, including the United States, terbinafine is available as a generic formulation, making it a cost-effective alternative to itraconazole for treatment of dermatophytosis. Doses of terbinafine in the literature range widely from 5 to 40 mg/kg per day; however, doses of 30–40 mg/kg have been reported to be most effective clinically. When 10 studies that included 284 animals treated with terbinafine were reviewed, the most common adverse effects associated with terbinafine treatment were occasional vomiting, diarrhea, and soft stools.[50] No deaths were reported. With the widespread availability of itraconazole and terbinafine, ketoconazole is not a first-choice systemic antifungal drug. The drug is not well tolerated in cats and more frequently causes vomiting, diarrhea, anorexia, and, with prolonged use, weight loss.[87] Griseofulvin was the first oral systemic antifungal drug for the treatment of dermatophytosis and for decades was the drug of choice. With respect to MIC, it is more active than fluconazole, similar to ketoconazole but less active than terbinafine or itraconazole.[78-80] It is only available in a human formulation. It is a known teratogen and should not be used in pregnant animals. It needs to be administered with a fatty meal to enhance absorption. Vomiting and diarrhea have consistently been reported as the most common adverse effects associated with administration. The most serious potential adverse effect is idiosyncratic bone marrow suppression.[88] Fluconazole has poor efficacy against dermatophytes and the highest MIC compared to itraconazole, terbinafine, ketoconazole, and griseofulvin for both *Microsporum* spp. and *Trichophyton* spp., so it should not be used for treatment of dermatophytosis.[78-80] Well-controlled *in vivo* studies have shown that lufenuron has no efficacy in the treatment of dermatophytosis and should not be used.[89-91]

BOX 78.5 Recommendations for Environmental Disinfection

Key Client Education Points

Dispel "Urban Myths"

Fungal spores do not multiply in the environment.

Fungal spores do not invade homes; they can grow in actively growing hairs and in skin.

Fungal spores do not cause respiratory disease; if they do cause disease it is a skin lesion.

Fungal spores are not "living" structures, it is a dormant stage of the life cycle.

Dermatophyte spores are present in many day-to-day environments.

Key Disinfection Points

If it can be washed, it can be disinfected.

Target areas are easy to detect, look for pet hair.

Mechanical cleaning and scrubbing with detergent are most important and often all that is needed.

Over-the-counter ready-to-use bathroom disinfectants labeled as active against *Trichophyton* spp. are active against animal pathogens. Products containing accelerated hydrogen peroxide are recommended.

Pre-moistened disinfectant wipes, such as accelerated hydrogen peroxide wipes, can be used on surfaces.

Avoid bleach as a disinfectant as it has no detergent properties, easily degrades, and is a human and animal health hazard.

Environmental sampling is not recommended unless there is concern that lack of a cure is due to false-positive fungal culture/PCR results.

Topical therapy on infected pets twice weekly minimizes contamination of the environment with spores.

Confine pet to easily cleaned areas of home.

General Recommendation

Clean as if "company is coming." Cleaning should be performed twice a week and clutter minimized. This is a good general recommendation for any situation where an infectious disease is present.

Specific Recommendations

Soft surfaces (laundry): Wash laundry until no pet hair is visible (1–2 washes); do not over-fill the laundry machine, use the longest agitation cycle available, hot water and/or bleach do not enhance disinfection.

Soft surfaces (carpet or upholstery): Keep pets off the carpet, vacuum daily to remove pet hair, disinfect using beater brush carpet scrubber with two washings. Pretreatment can be performed with an antifungal disinfectant, or an antifungal shampoo can be used as a carpet detergent. Disinfection is possible with hot water extraction.

Smaller hard surfaces (e.g., bowls, kitty litter boxes): Remove visible debris, wash repeatedly in detergent until clean, rinse. This may be all that is needed. Only use ready-to-use household disinfectants, spray surface thoroughly.

Larger hard surfaces (e.g., floor): Mechanically remove debris, especially hair (such as with disposable dust cloths), wash surface with a detergent until visibly clean, rinse, and remove excess water, use disinfectant to remove any remaining spores.

Hard surface furniture: Use commercial electrostatic dusting clothes to remove dust.

Discard disposable items such as collars, cloth or braided leashes, brushes, "clothing," doggie or kitty beds, soft toys.

Environmental Control

For more information on decontamination for dermatophytosis, the reader is referred to the Suggested Readings.[50,92] Cleaning and treatment recommendations are summarized in Box 78.5. Evidence-based studies on environmental decontamination have now shown that it is much easier to decontaminate an environment than past literature suggests and/or what clients may find on internet resources. In a study of 70 homes exposed to cats infected with *M. canis*, 69 of 70 were decontaminated with routine cleaning measures.[93] One home was not decontaminated due to admitted noncompliance with cleaning recommendations. Dermatophyte spores can only live and reproduce in keratin, hence they do not multiply in the environment. Dermatophyte spores are not the same as mildew or mold that overgrows in homes after water damage. Clients will report reading that "ringworm lives" in the environment up to 24 months. This comment stems from a laboratory study where specimens (n = 25 total) were stored and sampled at various time points. In that study, three of six specimens stored between 13 and 24 months were viable on fungal culture medium.[94] However, this study did not document that stored specimens were able to cause disease. In a different study, stored specimens were only viable for 13 months and it was not possible to induce infection in kittens.[95] Severely contaminated environments, such as might be present in hoarding situations, do represent a risk factor for infection in animals under physiological stress or animals that are predisposed to skin microtrauma (such as through flea infestation), or to people working in these types of environments without proper personal protective equipment. In a home, the major risk is false-positive fungal cultures that will lead to prolonged treatment.

The primary purpose of cleaning is to remove infective material from the environment and minimize the potential for false-positive fungal cultures that confound interpretation of post-treatment monitoring using fungal culture or PCR. The focus should be on mechanical cleaning and removal of debris, coupled with washing of the target surface until visibly clean. The surface needs to be rinsed of detergent as this will inactivate many disinfectants. In addition, the surface needs to be free of any excess water as this will dilute disinfectants. A recent study showed that household bathroom cleaners labeled as active against *Trichophyton* spp. are also active against *M. canis*.[96] In addition to systemic antifungal therapy, the most important additional aspect of treatment is to use topical antifungal therapy to disinfect the haircoat. In a recent study, proper cleaning combined with topical therapy removed infective material from homes within 1 week of treatment initiation.[97] The reader is referred to Suggested Readings for information on management and investigation of suspected outbreaks of dermatophytosis.[54,98,99]

Duration of Treatment

Treatment duration depends on the overall health of the patient. Simple infections in otherwise healthy animals resolve quickly. Complicated infections are those that occur in animals under physiological stress. These include more severe infections and infections in animals with comorbidities that necessitate modifications of treatment. Cats that are culture positive but lesion free at the time of sampling can also be considered "complicated" cases because they could represent simple fomite carriage or early infections that were not identified on initial examination. In studies of shelter cats that were intensely monitored via physical examinations, Wood's lamp examinations, and weekly fungal cultures treated with itraconazole (5–10 mg/kg q24h PO) for 21 days and concurrent twice-weekly lime sulfur rinses, found that the time to cure varied from 10 to 49 days in cats with simple infections and 23 to 80 in cats with more complicated infections.[67,100] The recommendation of two negative fungal cultures at 2-week intervals was based on a 1959 study using oral griseofulvin and no topical therapy or environmental disinfection in the treatment of Persian cats with dermatophytosis.[101] A recent study of 371

BOX 78.6 Recommendations for Monitoring Treatment of Dermatophytosis

1. Clinical cure will precede mycological cure and the first post-treatment examination should occur within 4 weeks. If new lesions develop, client compliance with treatment should be reviewed. Topical antifungal therapy should be performed the day before the examination.
2. In animals with *M. canis* infections, examinations should include a careful Wood's lamp examination, especially of sites where lesions were present and then ears, face, and fold areas (e.g., interdigital areas).
3. Treatment should be continued until the animal is culture-negative or is PCR-negative. In animals with simple infections, one negative culture should be sufficient. In animals with complicated infections, two negative fungal cultures may be needed, especially for long-haired animals. Topical therapy should be continued pending fungal culture or PCR results.
4. Animals can be considered mycologically cured if a PCR test is negative. If PCR is positive, fungal culture should be performed to determine if the test was detecting viable spores or nonviable fungal DNA.
5. Quantitative fungal culture is important in interpretation of response to treatment (Box 78.7). Simple results such as "positive" or "negative" are not adequate to determine cure.

BOX 78.7 Use of Quantitative Dermatophyte Culture to Monitor Treatment Success

A fungal culture plate that allows for toothbrush inoculation and easy visualization of colonies should be used. Standard Petri dish fungal culture plates or dual compartment plates are recommended.

Inoculate the plate with 4 to 7 stabs such that the bristles make a pattern on the plate; this ensures enough pressure was used.

Incubate plates in a plastic bag to retain moisture and minimize cross-contamination. Incubate plates at 25°C to 30°C.

No growth can be reported at 14 days.

Examine plates daily by holding them up the light to look for growth.

Record growth twice weekly as NG (no growth); C (contaminant growth, bacterial or fungal); S (suspect growth [early growth of a pale colony or early growth of pale colony with a red color change]); or Pathogen (requires microscopic identification).

In treated animals, the red color change may lag behind the colony growth, especially as the animal approaches cure.

The number of CFUs per plate can be used to monitor response to therapy, designated as a P or "pathogen score."

P3: ≥10 CFU/plate (often too numerous to count): high-risk pet, active infection

P2: 5–9 CFU/plate: continue treatment

P1: 1–4 CFU/plate: most consistent with fomite exposure or exposure to another infected animal. Continue topical therapy, clean the environment, consider the possibility of exposure to an infected animal.

In most cases, animals with severe infections have a P3 score. As treatment progresses, the P score lowers. Cured animals have NG or C scores.

Treated pets that are exposed to fomite contamination commonly have cultures that fluctuate from negative to P1. When this pattern is seen, the owner should be instructed to address hygiene in the home. As fomite contamination is removed, fungal cultures become negative. In addition to identification of fomite exposure, this system rapidly alerts the clinician to animals that are failing therapy or are relapsing for one reason or another. Lack of response to therapy will be evident by a persistently high P score. Relapses will be represented by a sudden increase in CFU/plate.

shelter cats found that the first negative fungal culture was predictive of mycological cure in otherwise healthy cats where there has been good compliance with treatment recommendations[102] (Box 78.6).

Prognosis

Dermatophytosis is not a life-threatening or life-altering disease. It will spontaneously resolve without treatment, though resolution can take weeks to months. However, treatment is strongly recommended to shorten the course of the infection and prevent transmission to other susceptible animals and people. Spontaneous recovery will eradicate active infection in the hair follicle and clinical lesions, but infective spores will remain on the haircoat until removed via shedding of the hair or grooming. In otherwise healthy animals, the prognosis for rapid and complete recovery is good with treatment. This includes kerion reactions in hunting or working dogs. In 23 published cases of kerion reactions in dogs, all dogs recovered and there was no transmission to people. In dogs and cats with pseudomycetomas or mycetomas, prognosis is difficult to predict based upon published studies. Some animals responded to surgical excision with concurrent long courses of systemic antifungal treatment and others did not, relapsed, or were euthanized. The prognosis for resolution of dermatophytosis in animals with irreversible underlying illnesses or in immunocompromised animals is harder to determine and clients should be advised to expect longer treatment periods.

IMMUNITY AND VACCINATION

In cats, as in other species, recovery from dermatophyte infection is dependent upon the development of CMI, not of humoral immunity.[42,103-105] Any factors that impair CMI need to be mitigated. In a clinical situation, this means all aspects of pet health must be addressed (nutrition, parasite control, vaccination, etc.). Immunity from reinfection has been studied in an experimental infection model.[42] Five cats previously recovered from *M. canis* infection were rechallenged and only one cat was reinfected. This required clipping of the haircoat, scarification of the skin, and repeated (n = 3) direct applications of 1.5 mL of harvested *M. canis* macroconidia and hyphae to the scarified site of the skin. The lesion that developed was more inflammatory and of shorter duration than lesions in the control cats that were dermatophyte-naïve. This infection model was robust and not representative of natural infections. As with other infectious agents, recovery results in immunity but under extreme exposure and/or compromise of the host reinfection is possible. If reinfection of a previously treated and recovered animal is suspected, it should first be established that this is not due to fomite carriage. Studies in dogs and cats on the use of fungal vaccines have shown that vaccination is not protective against challenge exposure.[106,107] This makes sense, since recovery from infection is dependent upon cell-mediated immunity and not humoral immunity.

PREVENTION

As with most contagious diseases, prevention relies on avoiding contact with the infectious agent. In hunting and working dogs, it is impossible to prevent exposure to geophilic dermatophytes (*N. gypsea*) in the soil, or pathogens that are transmitted via rodents (e.g., *Trichophyton* spp.). It is not possible to prevent exposure of dogs and cats to dermatophytes of large animals if there is regular exposure. Risk factors for exposure of pet dogs include exposure to other infected dogs at "doggie day care," dog parks, behavior or activity classes, grooming facilities, and boarding facilities. All animals should receive year-round flea and tick preventatives, because skin microtrauma predisposes animals to many skin infections, one of which is dermatophytosis. In addition, dogs could be bathed in an antimicrobial shampoo containing chlorhexidine and miconazole or ketoconazole. This also minimizes the development of secondary bacterial infections which could be misdiagnosed as dermatophytosis.

The greatest risk for introduction of dermatophytosis into a home with an established pet population is the temporary or permanent introduction of a new animal. This includes not only dogs and cats but also small mammals. Any new addition to an established pet population should be isolated from other pets until that pet is examined by a veterinarian to rule out contagious disease. Pending this examination, the pet could be bathed in an antifungal shampoo to remove any fomite carriage of dermatophytes. Careful examination of the skin for lesions and examination with a Wood's lamp is especially important in animals adopted from shelters or rescue operations. Many shelters now have screening protocols in place, so adoptable animals may have already been screened for lesions and/or have had a toothbrush fungal culture. In any situation where there is a pending fungal culture, bathing two to three times weekly with an antifungal shampoo is recommended until fungal culture or PCR results are available.

In veterinary clinics, disease transmission is prevented through use of the same measures for any animal with a known or suspected contagious disease. Animals with known or suspect infectious diseases should remain out of the general waiting area until they can be transported directly to an examination room. During the visit, all procedures should be confined to the examination room to limit the areas hospital staff members need to clean and disinfect. If hospitalization is needed, animals with suspected or confirmed dermatophytosis should be housed in isolation. Antifungal therapy should be continued if possible, but at a minimum, topical therapy with an antifungal leave-on rinse or foam should be administered.

PUBLIC HEALTH ASPECTS

The word "tinea" refers to dermatophytosis in human medicine. The term is commonly used in conjunction with a modifier that designates its anatomic location. For example, "tinea pedis" means dermatophytosis of the feet. Tinea does not refer to any one particular species of dermatophyte; the predominant pathogen of people depends upon clinical localization and geographic area. The most commonly isolated pathogen from people is *Trichophyton rubrum.*[108] The classic dermatophyte lesion of people is commonly described as an erythematous, circular lesion with a raised crusted margin with variable pruritus. This lesion tends to be limited to the glabrous skin. Infections of feet, nails, hair, beards, inguinal areas, and hands have variable clinical presentations.

Dermatophyte species that cause disease in dogs and cats have the potential to cause human disease. *Microsporum canis* is the most common zoophilic dermatophyte. In general, zoophilic and geophilic (*N. gypsea*) species evoke a more profound inflammatory response than anthropophilic dermatophytes; the latter tend to cause more chronic infections in people.

Dermatophytosis is a common skin disease in immunocompromised people; however, the primary pathogen of concern is *T. rubrum*, not *M. canis*. Reports of *M. canis* infection are limited to single case reports of tinea capitis, pseudomycetoma, or mycetoma and were summarized in three reviews.[3-5] Two of the studies were reviews of humans with *M. canis* infections and of 21 cases, animal contact was confirmed in only 7 cases. None of the patients died from the dermatophyte infection and the disease was treatable, but required prolonged therapy. In another more extensive review on severe dermatophytosis and acquired or innate immunodeficiency in 84 patients, the most common pathogen was *T. rubrum* and only a few infections were due to *M. canis*. The most common underlying conditions associated with severe dermatophytosis were solid organ transplantation (n = 28), CARD9 (caspase recruitment domain-containing protein 9) deficiency (n = 19) (a rare immunodeficiency disorder), and HIV infection (n = 9).

People that handle infected animals should wear gloves and protective clothing. In confirmed cases, it is important to educate clients

that the only way to treat the haircoat is via topical antifungal therapy. The topical therapy of choice for pets in homes with children and immunocompromised people is lime sulfur or enilconazole rinse applied two to three times weekly. Lime sulfur and enilconazole are immediately fungicidal and provide residual protection, unlike antifungal shampoos.

In the United States and in Europe, there are no regulations regarding isolation of children with tinea capitis. As a general recommendation, children infected by zoophilic dermatophytes may return to childcare facilities and/or school immediately after initiation of topical and systemic antifungal treatment. The recommendation for anthropophilic dermatophytes that are more contagious is at most a 1-week isolation at home.[109]

CASE EXAMPLE

Signalment
"Herman," a 14-year-old neutered male terrier cross dog from Tacoma, WA.

History
Herman had a 5-month history of progressive pruritic hair loss and crusting on three paws and the muzzle extending to the periocular region (see Fig. 78.5). Lesions persisted despite several courses of topical and oral antibacterial drug therapy, various combination topical corticosteroid/antibacterial ointments, and oral oclacitinib. The owner reported seeing scratches on the dog's nose that first appeared after the dog was seen to be digging in the woodbox. These were followed by the development of progressive crusting and hair loss on the muzzle followed by similar lesions on three of four paws (see Fig. 78.7). The dog required an Elizabethan collar to prevent self-trauma. Several other dogs and the owners were reportedly unaffected. The dog had not traveled out of the region. His vaccinations were current and included vaccines for distemper, canine infectious hepatitis, parvovirosis, and rabies.

Current Medications
Levothyroxine (0.02 mg/kg PO q12h), oclacitinib (0.5 mg/kg PO q24h), enrofloxacin (5 mg/kg PO q24h).

Other Medical History
The dog had received thyroid supplementation for the past 5 years with adequate serum post-pill T4 concentrations. The dog had a heart murmur, and was polyuric, polydipsic, and frequently incontinent for the past year. There has been a 1.4-kg weight loss in the past year. Laboratory work performed 2 years before examination was unremarkable.

Physical Examination
Body weight: 7.8 kg

General: Normal mentation. Ambulatory on all four limbs. Temperature = 100.2°F (37.9°C), heart rate = 140 beats/min, respiratory rate = 60 breaths/min, mucous membranes pink, CRT = 1 s.

Integument: Physical examination revealed alopecia, silvery adherent scaling, and crusting, which were present on both pelvic limb paws and the right front paw, with extension to the metatarsi and carpi (see Fig. 78.7). Similar alopecia and crusting were present on the dorsal and lateral aspects of the muzzle with extension to the periocular areas. The right side of the muzzle was more severely affected than the left side, and there was a thin ring of erythema and crusting with easily epilated hair on the periphery of the facial lesions (see Fig. 78.5). There were several spreading erythematous circular lesions on the inguinal area and medial aspect of the thighs.

Eyes, ears, nose, and throat: There was mild crusting present on the frontal and dorsal nasal planum, and the right side was more severely affected than the left side. The right upper and lower eyelids and periocular areas were alopecic, erythematous, patchily hyperpigmented, and mildly crusted. A mild amount of brown waxy debris was present within both ear canals.

Musculoskeletal: A body condition score of 4/9 with mild generalized muscle wasting was noted.

Cardiovascular: Strong femoral pulses were noted. A Grade III/VI left-sided systolic murmur was detected on thoracic auscultation.

Respiratory: No abnormalities were noted.

Gastrointestinal and genitourinary: Abdominal palpation revealed mild hepatomegaly.

Lymph nodes: Both popliteal and the right superficial cervical lymph nodes were mildly enlarged.

Laboratory Findings
CBC: HCT 45.0% (36–60%), MCV 74 fL (58–79 fL), MCHC 33 g/dL (30–38 g/dL), WBC 10,500 cells/μL (4000–15,500 cells/μL), neutrophils 8085 cells/μL (2060–10,600 cells/μL), lymphocytes 945 cells/μL (690–4500 cells/μL), monocytes 1155 cells/μL (0–840 cells/μL), platelets 213,000 platelets/μL (170,000–400,000 platelets/μL).

Serum chemistry profile: BUN 31 mg/dL (6–31 mg/dL), creatinine 0.7 mg/dL (0.5–1.6 mg/dL), glucose 109 mg/dL (70–138 mg/dL), total protein 7.0 g/dL (5.0–7.4 g/dL), albumin 2.8 g/dL (2.7–4.4 g/dL), globulin 4.2 g/dL (1.6–3.6 g/dL), ALT 69 U/L (12–118 U/L), ALP 186 U/L (5–131 U/L).

Urinalysis: SpG 1.012; pH 67.5, 3+ protein (SSA), negative bilirubin, glucose, ketones, WBC, casts, crystals, bacteria, 0–1 RBC/HPF, 2–3 fat droplets/HPF.

Dermatologic Diagnostics
Wood's lamp examination: Negative.

Trichogram for fungal organisms: Negative.

Skin scrapings for mites: Negative.

Cytology of crusted skin lesions: RBCs, neutrophils, macrophages, plasma cells, epithelial cells, scattered fungal hyphae.

Dermatophyte Culture
By day 7 after inoculation of dermatophyte culture, there were innumerable, small, raised, white, fluffy fungal colonies present with concurrent red media color change; microscopic examination of a tape preparation of fungal colonies showed hyphae and numerous small round microconidia. Repeat cytologic examination of fungal colonies on days 10 and 14 showed hyphae and microconidia but no macroconidia (which aid in species identification). Nevertheless, numerous spiral hyphae were noted that were consistent with *Trichophyton* hyphae (see Fig. 78.15). The dermatophyte culture was submitted to a commercial diagnostic laboratory for fungal identification, which confirmed the presence of *Trichophyton mentagrophytes*.

Diagnosis
Dermatophytosis caused by *T. mentagrophytes* and concurrent metabolic disease.

Treatment
Enrofloxacin and oclacitinib were discontinued and topical antifungal therapy was prescribed pending laboratory results based on the cytological findings. Specifically, twice-weekly lime sulfur dips and twice daily terbinafine cream were applied to paw and facial lesions. Environmental decontamination measures were discussed with the owner. The contagious and zoonotic nature of the infection was also discussed.

Once laboratory findings results were available, systemic antifungal therapy was prescribed (terbinafine 30 mg/kg PO q24h). Topical therapy and environmental cleaning were continued until repeat fungal culture (DTM) was negative.

Comments
Other diagnostic tests that were recommended but declined by the owner due to financial constraints included urine protein:creatinine ratio to quantitate proteinuria, a urine cortisol:creatinine ratio to evaluate for hyperadrenocorticism, and an abdominal ultrasound to screen for occult neoplasia if metabolic workup was unrevealing. The owner also declined 14-day dermatophyte recheck cultures but agreed to monthly cultures. At 4 and 8 weeks after treatment initiation the clinical signs were much improved, with resolved crusting/erythema and persistent scarring alopecia on the face and paws. Pruritus had improved to minor paw licking. Dermatophyte cultures at 4 and 8 weeks after treatment initiation were negative. Antifungal therapy was discontinued upon the second negative culture result with no relapse of dermatophytosis.

Malassezia Dermatitis

Ross Bond

KEY POINTS

- First Described: *Malassezia pachydermatis* was first described in 1925 by Weidman in the skin scales of an Indian rhinoceros (*Rhinoceros unicornis*) with a generalized exfoliative dermatitis, kept in a zoological collection in Philadelphia, USA.[1]
- Causes: Dogs: *Malassezia pachydermatis.* Cats: *Malassezia pachydermatis*, occasionally other strictly lipid-dependent species.
- Affected Hosts: Mammals and birds.
- Geographic Distribution: Worldwide.
- Primary Mode of Transmission: Horizontal and vertical (at birth).
- Major Clinical Signs: *Malassezia* spp. invade opportunistically and cause a pruritic, greasy, malodorous, erythematous dermatitis commonly centered on folds or intertriginous areas.
- Differential Diagnoses: Hypersensitivity disorders, bacterial overgrowth and pyoderma, primary defects of cornification.
- Human Health Significance: *Malassezia pachydermatis* is a potential cause of fungemia in neonates in intensive care facilities. Other strictly lipid-dependent *Malassezia* spp. are commensal fungi of human skin that are implicated in various human skin diseases, including seborrheic dermatitis, pityriasis versicolor, and the "head-neck" form of atopic dermatitis.

ETIOLOGY AND EPIDEMIOLOGY

Malassezia spp. (previously *Pityrosporum* spp.) are lipophilic yeasts that reproduce asexually by monopolar or sympodial budding. These yeasts, classified within the class Malasseziomycetes in the subphylum Ustilaginomycotina of the phylum Basidiomycota, are most often isolated from the skin and mucosal sites of clinically healthy mammals and birds. The genus was traditionally divided into two groups based on their lipid dependency in culture media. *Malassezia pachydermatis* has long been regarded as unique within the genus in that it can be cultivated routinely on Sabouraud's dextrose agar without lipid supplementation (hence "lipophilic" but not "lipid-dependent"). *Malassezia pachydermatis* has remarkable genetic diversity.[2] This is apparently linked to evolutionary adaptation to the variety of its animal hosts, variation in distribution within those hosts,[3] and variable expression of putative virulence factors.[4]

The application of molecular biological techniques has led to substantial taxonomic revision amongst *Malassezia* spp., and 18 species are now recognized, namely *Malassezia furfur, Malassezia pachydermatis, Malassezia sympodialis, Malassezia globosa, Malassezia obtusa, Malassezia restricta, Malassezia slooffiae, Malassezia dermatis, Malassezia japonica, Malassezia yamatoensis, Malassezia nana, Malassezia caprae, Malassezia equina, Malassezia cuniculi, Malassezia arunalokei, Malassezia brasiliensis, Malassezia psittaci*, and *Malassezia verspertilionis*[5–9] (Table 79.1). Lipid dependence has recently been attributed to lack of the fatty acid synthase gene in the genome of all 14 species whose genome has been sequenced, including *M. pachydermatis.*[10–12] It is now clear that *M. pachydermatis* should be reconsidered as "lipid-dependent"; the ability to grow on Sabouraud's dextrose agar reflects a markedly enhanced ability to metabolize trace lipids derived from the peptone content of the Sabouraud's medium,[12] although this is somewhat academic given the widespread use of Sabouraud's medium in diagnostic veterinary laboratories.

In studies of the mycobiota of normal canine and feline skin, *Malassezia* spp. comprise a surprisingly small percentage of the fungal population[13,14]; instead, environmental molds such as *Alternaria* predominate. Dogs are very frequently colonized by *M. pachydermatis* but very rarely colonized by strictly lipid-dependent *Malassezia* spp.[15,16] Healthy cats are often colonized by *M. pachydermatis* and occasionally by strictly lipid-dependent species, including *M. sympodialis, M. globosa*, *M. furfur, M. slooffiae,* and *M. nana.*[17–20] *Malassezia nana* is the most common strictly lipid-dependent *Malassezia* sp. isolated from cats' ears. *Malassezia slooffiae* has been isolated from the claw folds of cats with seborrheic dermatitis.[21] The pathogenic potential of lipid-dependent *Malassezia* spp. in feline skin disease requires further assessment. Strictly lipid-dependent species are frequently isolated from human skin and are associated with a number of diseases,[22] but isolation of *M. pachydermatis* is rare.

In dogs, *M. pachydermatis* is frequently isolated from the haired skin of the chin and lips, interdigital skin, and external ear canal and less often from other intertriginous areas such as the axilla and groin.[23] Concentrations of organisms in healthy dogs are generally low but are markedly increased, often up to 10,000-fold, in many cases of *Malassezia* dermatitis, although overlap in organism densities can be found between some clinically healthy and affected dogs. The anatomic sites most often colonized in clinically healthy animals correlate with regions most often affected in dogs with skin disease caused by the yeast.

Malassezia dermatitis may be the only disease recognized in some dogs, but in others, concurrent disorders such as allergies, especially atopic disease, keratinization defects, endocrinopathies, and the presence of skin folds may be important in favoring proliferation of the yeast. *Malassezia pachydermatis* infection in dogs is an important "flare factor" for canine atopic dermatitis.[24] Breed predilections vary between geographic regions but may include basset hounds, West Highland white terriers, cocker spaniels, toy and miniature poodles, dachshunds, boxers, Cavalier King Charles spaniels, shih tzus, Australian silky terriers, and German shepherd dogs. Bull terriers with lethal acrodermatitis are known to have impaired immune function, and they harbor large numbers of *Malassezia* on their skin; *Candida albicans* co-infection may be partly responsible for lesions in the nails and footpads of these dogs. A seasonal increase in case numbers may

TABLE 79.1 Summary of the (2018) Taxonomy and Ecology of the Genus *Malassezia*

Species	Identified	Former Designations	Usual Source

be observed in geographic regions where a noticeable change to warm, humid climatic conditions is present.

Affected cats also may have underlying allergic and metabolic diseases, but immunosuppressive viruses such as FeLV and FIV, and paraneoplastic disorders (pancreatic paraneoplastic alopecia, exfoliative dermatitis with thymoma), may also favor infection. Devon Rex and Sphynx cats are predisposed to a seborrheic dermatitis associated with high *Malassezia* populations; Rex cats respond well to systemic therapy with itraconazole.[21,25–27] Molecular analysis of species colonizing Devon Rex cats showed a preponderance of *M. restricta* and *M. globosa*.[28]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

The interactions between *Malassezia* yeasts and the skin of their mammalian hosts, and the factors which influence transition from commensal to pathogen, are the subject of intensive scientific endeavor, especially pertaining to the common skin pathogens of humans (*M. globosa, M. sympodialis, M. restricta*).[29] Adhesion of *Malassezia* cells to keratinocytes has the potential to modulate the expression of an array of cytokines, chemokines, and antimicrobial peptides, the outcome of which may be immune-stimulatory (as may occur in disease states) or immune-suppressive (promoting commensal carriage).[30] A change in host immunity, altered skin microclimate, or disruption in epidermal physiology associated with the diseases mentioned previously may predispose animals to clinical disease. Co-proliferation of staphylococci in the same lesions may exacerbate clinical signs and necessitates concurrent antibacterial therapy in some cases (Fig. 79.1).

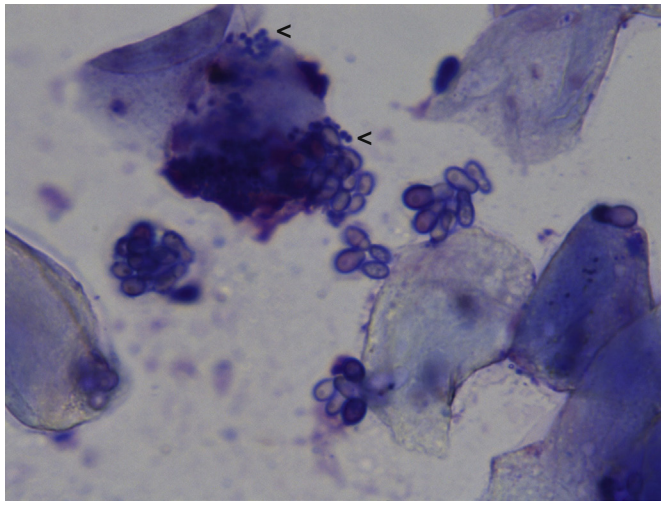

Fig. 79.1 Tape-strip cytologic specimen obtained from the ventral neck of a 4-year-old entire male basset hound with *Malassezia* dermatitis. Numerous aggregates of monopolar-budding yeasts with the typical morphology of *Malassezia pachydermatis* lying amongst or adherent to stratum corneum cells (squames) are accompanied by smaller numbers of coccoid bacteria *(black arrowheads)*. Diff-Quik stain, ×3000.

Comparative studies following the recent sequencing of 14 *Malassezia* species' genomes have significantly advanced opportunities for understanding of the adaption of the genus to its limited ecologic niches (mainly skin), elucidation of virulence factors necessary for colonization and infection, and identification of novel interventional targets for therapy.[12] The genus' evolution to lipid-dependency is associated with a wide expansion of lipase and phospholipase genes, and loss of carbohydrate metabolism genes. Lipases are highly expressed in the skin of human patients with seborrheic dermatitis and likely damage the epidermal barrier directly and by hydrolysis of triglycerides.[22,31] Phospholipase activity, modulated by the endogenous opioid peptide β endorphin,[32] was significantly higher amongst *M. pachydermatis* isolates derived from the dogs with otitis externa[33] or skin lesions[34] when compared with those obtained from the dogs with healthy external ears, or nonlesional skin, respectively. Other enzymes from *Malassezia* spp. such as aspartyl proteases and acid sphingomyelinases may also influence host-yeast inactions.

Malassezia spp. from human skin synthesize an array of indoles that act as potent ligands for the aryl hydrocarbon receptor (AhR), a nuclear receptor and transcriptional regulator with pleiotropic effects that include down-regulation of immune stimulation, modification of melanogenesis and epidermal cell function, and inhibition of antagonistic microbes.[22,35]

The *M. sympodialis* genome has a relative lack of genes encoding cell wall proteins that mediate adhesion.[36] However, *M. pachydermatis* can form biofilms *in vitro* and on catheters,[37] characterized by layers of adhering blastoconidia embedded in variable quantities of extracellular matrix.[38] This may reduce *in vivo* susceptibility to azole antifungal drugs[39] and act in synergism with phospholipase production to contribute to skin lesions in susceptible dogs.[38]

Whilst IgG serologic responses have been evaluated in dogs with *Malassezia*-associated skin diseases,[30] hypersensitivity responses to *Malassezia*-derived antigens are of greatest relevance to the clinician. Immediate, IgE-mediated reactivity to *M. pachydermatis,* identified by either intradermal or serologic testing,[40] may explain the marked exacerbation of the signs associated with yeast proliferation in sensitized dogs with underlying canine atopic dermatitis, and the associated clinical improvement when antifungal therapy is initiated.[24] Studies

of the effectiveness of *Malassezia* allergen–specific immunotherapy with *Malassezia* allergens in atopic dogs with yeast sensitization are required. By contrast, basset hounds with *Malassezia* dermatitis usually show delayed rather than immediate intradermal test reactivity to *Malassezia* antigens,[41] although contact sensitization, as demonstrated by patch test reactivity, more closely correlates with disease status in this breed.[42] These data indicate that a spectrum of immunologic hyper-responsiveness is present in dogs with *Malassezia* dermatitis (none, immediate, delayed, contact), but since similar serologic and skin test reactivity is also seen in a proportion of unaffected dogs, these immunologic tests must be assessed in the context of clinical and cytologic data, and not used as stand-alone "diagnostic" tests.[40]

Dogs

Malassezia dermatitis lesions may be localized or generalized. In dogs, the disease is most often seen at anatomic sites that create a relatively warm, moist skin environment. Thus the interdigital skin, ventral neck, lip region, ear canal, axilla, groin, and folded areas are most often affected. Pruritus is normally reported and ranges in degree from mild to severe. Erythema accompanied by greasy exudation is commonly observed, especially in intertriginous areas where a brown exudate may mat the lower portion of the hair; malodor may be noted with extensive exudative lesions (Figs. 79.2 and 79.3). Traumatic alopecia, lichenification, and hyperpigmentation may develop in dogs with marked pruritus. *Malassezia* otitis externa is often characterized by brown cerumen, with varying levels of associated inflammation. Paronychia (nail-fold inflammation) associated with *M. pachydermatis* may lead to pedal pruritus accompanied by reddish-brown discoloration of the claw and or exudation in the nail fold. Dogs with frenzied facial pruritus associated with *M. pachydermatis* overgrowth of muzzle skin or lip-folds may be misdiagnosed as having neurologic disease. *Malassezia pachydermatis* is occasionally implicated as a cause of keratomycosis in dogs.[43,44]

Fig. 79.2 A 4-year-old neutered male West Highland white terrier with severe *Malassezia* dermatitis. Lesions comprise intense erythema of the ventral neck, axillae, and medial aspect of the forelimbs with a rather demarcated and symmetric distribution. The hair overlying folded ridges of intensely inflamed and thickened skin is matted in a yellow, greasy, malodorous exudate. Focal areas of lichenification and hyperpigmentation are developing in the alopecic regions of the ventral neck.

Cats

Malassezia pachydermatis appears to be a relatively infrequent pathogen in cats, at least when compared with dogs. This finding may reflect the lower carriage rates of the yeast in the skin and ears of healthy cats. Ceruminous otitis externa responsive to topic otic antifungal medication is the most common clinical feature of *M. pachydermatis*–associated skin disease in cats, but occasional cases of localized or generalized *M. pachydermatis*–associated dermatitis have been described. Exfoliative erythroderma, greasy exudation, and varying degrees of pruritus may be seen. In Devon Rex cats with seborrheic dermatitis caused by *Malassezia* spp., greasy, tightly adherent, brown exudate on the claws or in the claw folds is often accompanied by a dark, greasy exudate that mats the hairs on the interdigital skin, axilla, and groin (Figs. 79.4 and 79.5). Cats with exfoliative dermatitis associated with thymoma and paraneoplastic alopecia may have concurrent proliferations of *Malassezia*.

DIAGNOSIS

The clinical signs of *Malassezia* dermatitis are not pathognomonic, and the disease should be routinely suspected in dogs with inflammatory skin diseases, especially those with erythema or greasy exudation as a dominant sign. *Malassezia* dermatitis may mimic or complicate both food-induced and nonfood-induced canine atopic dermatitis. Seborrheic presentations and fold-associated diseases should also prompt an evaluation of the presence and numbers of the yeast. The diagnosis is based on clinical signs, presence of elevated numbers of the yeast in lesional skin, *and* a clinical and mycologic response to antifungal therapy; it is important to recognize that high populations of *M. pachydermatis* can occur in clinically normal skin.

Microbiologic Tests

Cytologic Diagnosis

In clinical practice, yeast numbers are most usefully assessed by cytologic examination. Impression smears can be made directly onto glass slides, or exudate can be transferred to the slide using swabs. However, the author prefers the tape-strip method; clear cellophane tape is pressed on the surface of the skin, thus collecting the stratum corneum cells and any superficial microbes.[45] Unlike direct impressions, tape

Fig. 79.3 A 2-year-old entire female basset hound with severe *Malassezia* dermatitis. Lesions comprise intense erythema and lichenification of the axillae, sternum, and ventral neck. The brown, greasy, malodorous exudate adherent to the lower portion of the hair shafts is clinically suggestive of microbial overgrowth (rather than an uncomplicated allergic dermatitis), most commonly associated with *Malassezia pachydermatis*, but also occasionally with bacterial overgrowth.

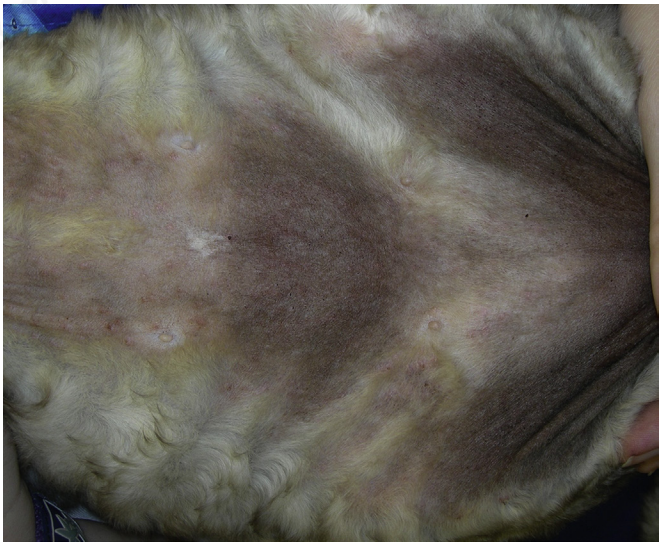

Fig. 79.4 *Malassezia* dermatitis in a 10-year-old female Devon Rex cat is manifest by alopecia, erythema, and demarcated, symmetric areas of brown discoloration of the skin of the ventral abdomen and medial thighs.

Fig. 79.5 *Malassezia* dermatitis in a 10-year-old female Devon Rex cat is manifest by a marked accumulation of a copious dark exudate adherent to the hairs of the palmar interdigital skin.

stripping can be used effectively in most anatomic sites and in dry or greasy lesions. The tape is stained, usually with a modified Wright stain, and examined using the light microscope (see Fig. 79.1). Characteristic peanut-shaped *Malassezia* spp. yeast cells are rarely seen in healthy skin but are usually readily identified in specimens from affected individuals. The use of swabs for cytology is best restricted to the ear canal.[23]

Although some authors have proposed guidelines on the number of yeasts needed for significance (e.g., one or more yeast per high-power field), this approach does not accommodate the overlap seen in yeast population densities in skin specimens from clinically healthy and diseased dogs. In addition, there are important breed and anatomic site differences in yeast population sizes in healthy dogs. In addition, hypersensitivity responses to yeast-derived allergens might enable a relatively small number of organisms to generate skin disease in sensitized individuals. Thus, a therapeutic trial is an important component in the diagnostic evaluation of *Malassezia* dermatitis. Treatment should be recommended whenever the yeast is readily identified in cytologic specimens obtained from consistent lesions.[23]

Culture

Culture of swab specimens is of limited diagnostic value because it merely confirms or refutes the presence of a commensal yeast. Cellophane tape-strip sampling just described for cytology can also be used to transfer cells to the surface of culture plates, although the potential for an antimicrobial effect of the adhesive tape should be considered. *Malassezia pachydermatis* can be isolated using Sabouraud's dextrose agar, modified Dixon's agar, or Leeming's medium, with optimal growth at temperatures between 32°C and 37°C. Lipid-supplemented media should be used when specimens are taken from cats because strictly lipid-dependent species may be present (Fig. 79.6); species identification of these yeasts is specialized and most reliably accomplished by molecular methods. The application of MALDI-TOF MS has led to improved and more rapid identification of *Malassezia* spp. following culture.[46–48]

Concerns have been raised about the increasing prevalence of antifungal drug resistance among pathogenic fungi. Treatment failures in human patients with *M. furfur* fungemia have suggested the possibility that resistance exists[49]; around the time of writing, multi-azole–resistant strains of *M. pachydermatis* have been isolated from dogs with refractory *Malassezia* dermatitis in Japan and Italy.[50,51] Genetic studies suggested that resistance in the isolate from the dog in Japan was due to overexpression of genes that encode ABC transporter proteins or mutations in *ERG11*. Unfortunately, susceptibility testing methods for *Malassezia* have not been standardized, and currently interpretive breakpoints for antifungal susceptibility testing of *Malassezia* species are not available. E-testing and broth microdilution methods have been used in the literature, and suspicion for resistance has been based on very high MICs (e.g., > 32) when compared with control isolates.

Molecular Diagnosis Using Nucleic Acid–Based Testing

At this time, molecular methods based on PCR are not in widespread use for diagnosis of *Malassezia* spp. infections in dogs and cats. However, a multiplex PCR method has been described for the detection of 11 *Malassezia* species in both samples obtained directly from skin and colonies in conventional culture systems.[52] A quantitative real-time PCR assay based on the β-tubulin gene appeared to be accurate and potentially more sensitive than cytologic examination when applied to swabs from dogs with otitis externa, which also has the potential to be used to monitor treatment response.[53] Molecular typing methods such as MLST, random amplified polymorphic DNA (RAPD), PFGE, and next-generation sequencing have been used as powerful tools for epidemiologic studies (see Chapter 7).[23]

Pathologic Findings

Skin biopsy specimens from animals with *Malassezia* spp. infections typically show marked irregular epidermal hyperplasia of the skin surface but extending to follicular infundibula, variable hyperkeratosis and parakeratosis, spongiosis especially of the deep one third of the epidermis, and a superficial perivascular or interstitial infiltrate of mononuclear cells, with focal accumulations of neutrophils, eosinophils, and mast cells (Fig. 79.7). Yeast cells may be seen in the stratum corneum, but the disruption of this layer that occurs during routine tissue processing may lead to an absence of the yeast; biopsy has a low sensitivity

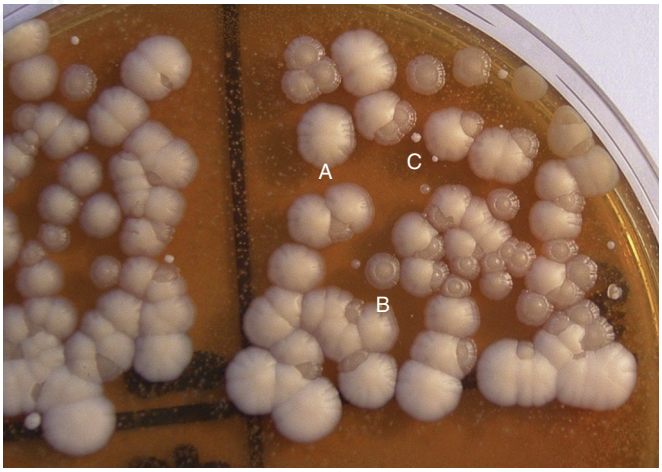

Fig. 79.6 Modified Dixon's agar plate inoculated with a swab from the claw fold of a 10-year-old female seborrhoeic Devon Rex cat. Two colony types of *Malassezia pachydermatis* are represented; large, domed, entire yellow colonies (above *A*) and smaller, buff-colored, domed or umbonate colonies (above *B*). The smaller yellow colonies are examples of *Malassezia slooffiae* (above *C*).

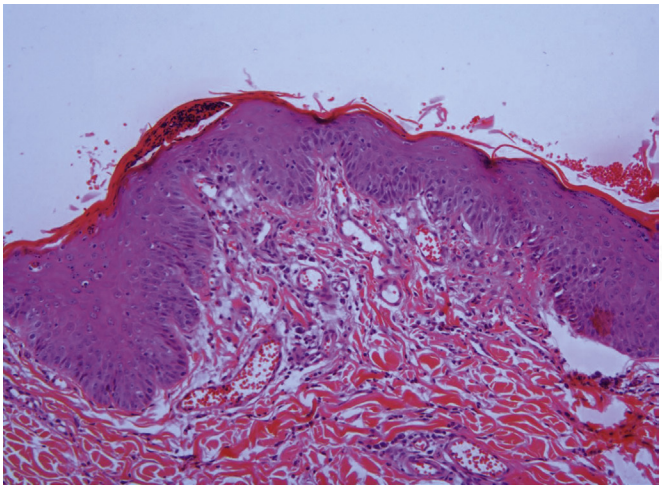

Fig. 79.7 Skin biopsy specimen from the axilla of a 6-year-old neutered female West Highland white terrier with *Malassezia* dermatitis. There is moderate-severe epidermal hyperplasia with "scalloping" and spongiosis of the deeper portion of the epidermis, along with an intra-corneal pustule. Dilation of the superficial dermal vasculature is accompanied by a moderate, predominately mononuclear cell, interstitial infiltrate. Hematoxylin and eosin, ×20.

for yeast detection when compared with cytologic examination (Fig. 79.8). The inflammatory pattern seen in *Malassezia* dermatitis is also commonly encountered in chronic allergic dermatitis.

TREATMENT

Treatment of *Malassezia* dermatitis is based on the use of topical and systemic antifungal treatments (Table 79.2), together with specific therapy for concurrent diseases that favor proliferation of the yeast, where possible.

Topical Therapy

Malassezia yeasts are located in the stratum corneum, and so topical therapy alone can be successful when potent antifungal agents are correctly applied. This approach depends on good compliance and

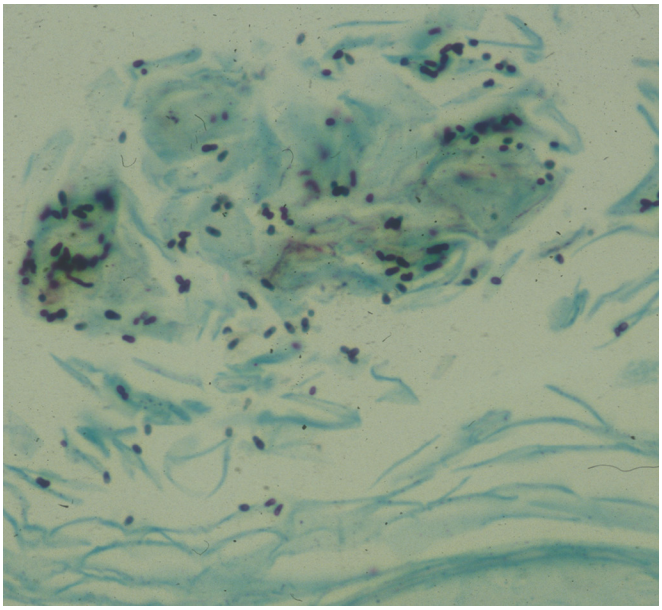

Fig. 79.8 Skin biopsy specimen from a dog with *Malassezia* dermatitis. Abundant *Malassezia pachydermatis* cells are evident within the stratum corneum, illustrating why topical therapy alone can be clinically effective in compliant dogs. Cytology, however, is generally superior to histopathology for the detection of the yeast in clinical cases. Methenamine silver, ×1000.

availability of effective products. Topical therapy avoids the expense and potential toxicity of systemic azole drugs but is more labor intensive for the owner. Evidence-based systematic reviews of antifungal treatments for *Malassezia* dermatitis in dogs support the recommendation of a 2% miconazole and 2% chlorhexidine shampoo twice weekly for 3 weeks as the sole treatment.[23,54,55] A prospective, randomized, and blinded field clinical trial showed that the clinical and cytologic efficacy of a 3% chlorhexidine shampoo was comparable to the miconazole–chlorhexidine product.[56] Maintenance treatment may be needed if an underlying cause cannot be identified and corrected. The anti-staphylococcal properties of shampoos containing miconazole and/or chlorhexidine[57] may also be advantageous in the event of concurrent bacterial overgrowth.

Clinical evidence that supports the use of a number of topical treatments with *in vitro* activity against *M. pachydermatis*, including acetic + boric acid, benzoyl peroxide, and other azoles is lacking.[55] Wipes that contain chlorhexidine, climbazole, and Tris-EDTA had clinical and mycological activity against *M. pachydermatis* in a small open study.[58] The use of wipes may be convenient for the local treatment of body folds and interdigital areas.

Reported efficacy of other topical substances for treatment of canine *Malassezia* dermatitis[59] and otitis externa[60] require further evaluation in blinded studies. These include honey-based gels, a variety of plant-derived essential oils, povidone-iodine, and agents used to treat human dandruff and seborrheic dermatitis (e.g., selenium sulfide).[23,61] A killer decapeptide (KP) engineered from the variable region of a single-chain recombinant anti-idiotypic antibody and representing the internal image of a yeast killer toxin (KT) with broad-spectrum antifungal activity was reportedly safe and effective in *Malassezia* otitis externa in four dogs over 8 days; with development, this approach may represent an alternative to current therapies.[62]

Systemic Therapy

There is fair evidence for use of ketoconazole (10 mg/kg, PO, q24h), and itraconazole (5 mg/kg, PO, q24h) for 3 weeks to treat *Malassezia*

TABLE 79.2 Recommended Treatments for *Malassezia* Dermatitis in Dogs and Cats

Species	Route	Product	Dose
Dog	Topical	2% miconazole + 2% chlorhexidine	Shampoo every 3 days
	Topical	3% chlorhexidine	Shampoo two-three times per week
	Systemic	Itraconazole	5 mg/kg q24h PO or 2 days on–5 days off for 21 days
Cat	Systemic	Itraconazole	5 mg/kg q24h PO or 7 days on–7 days off for 21 days

dermatitis in dogs.[54] Marketing authorization for oral ketoconazole in humans was suspended in Europe in 2013. Itraconazole is less toxic and has better tissue penetration than ketoconazole. A pulse-therapy regimen of itraconazole (5 mg/kg, PO, q24h) for 2 successive days each week has been described as an alternative to daily dosing.[63] Itraconazole has also been used to treat cats with *Malassezia* spp. overgrowth (5 mg/kg, PO, q24h),[64] or at 5 mg/kg on a 1 week on/1 week off pulse basis.[25] Reduced susceptibility to fluconazole *in vitro* is common in *M. pachydermatis*,[65,66] and clinical trial data for fluconazole is very limited.

While pilot studies have shown a potential role for daily or pulse oral dosing with terbinafine for treatment of canine *Malassezia* dermatitis (30 mg/kg, PO, q24h),[67–69] concentrations achieved in sebum and stratum corneum of dogs treated barely exceeded the MIC_{90} of field strains of *M. pachydermatis*, so further clinical and pharmacologic studies are required before use of this drug could be recommended for this indication.

Typically, the response to glucocorticoid therapy is poor. Griseofulvin is *not* effective in *Malassezia* infections. The reader is referred to Chapter 11 for detailed information on these antifungal drugs.

PREVENTION

Failure to identify and correct concurrent diseases may result in relapse of *Malassezia* infection. Intermittent or continuous maintenance therapy is often necessary in animals that experience relapsing disease, particularly in dogs with poorly controlled allergic disease or in dogs in which the reason for disease susceptibility cannot be identified. Although *Malassezia* allergens are now often included in intradermal allergen tests and IgE serology, at the time of writing there is little evidence to support the value of allergen-specific immunotherapy for prevention of *M. pachydermatis* hypersensitivity in dogs.[70]

PUBLIC HEALTH ASPECTS

A variety of *Malassezia* species have been associated with disease in humans, especially *M. restricta*, *M. furfur*, *M. globosa*, and *M. sympodialis*.[49] Yeast proliferation can lead to *Malassezia* folliculitis, seborrheic dermatitis, catheter-related fungemia, and a variety of other invasive infections.[71] Administration of lipid-containing total parenteral nutrition solutions are a risk factor for disseminated infections in humans, which often occur in neonates.[72,73]

Malassezia pachydermatis is rarely associated with diseases in humans. Owners of dogs (which are natural reservoirs for this yeast) with inflamed skin had a high rate of carriage of the organism.[74] A potentially fatal *M. pachydermatis* fungemia has been reported in premature babies and less often in immunocompromised adults.[75,76] Most of the affected neonates have been premature, had concurrent serious underlying disease, had central or peripheral catheters placed, and in some cases were receiving lipid emulsions as a component of parenteral nutrition. In some outbreaks, *M. pachydermatis* was thought to have been transmitted from neonate to neonate on the hands of health care workers; the original source of the yeast was not identified, but transfer from pet dogs has been suspected. These observations highlight the importance of hand washing by health care workers in the control of nosocomial infections.

CASE EXAMPLE

Signalment

"Basil," a 4-year-old neutered male West Highland white terrier from Hertfordshire, UK (see Fig. 79.2).

History

Basil's owner reported that skin disease had first developed at 12 months of age and had been continuous (unless treated) since then. Initial signs were foot-chewing (fore and hind feet), followed by progression to ventral and pinnal erythema, and bilateral erythema-ceruminous otitis externa. The dorsolumbar area had never been affected. These signs persisted in the face of routine ectoparasite control measures comprising monthly application of a spot-on formulation of imidacloprid and moxidectin, and annual spraying of the house with an insect growth regulator (pyriproxyfen). Parasites had never been seen by the owner and Basil was the only pet. Systemic antibiotic therapy was reportedly ineffective, but oral prednisolone rapidly and reproducibly resolved the lesions and pruritus. Signs were controlled for several years using prednisolone, usually at 0.25–0.5 mg/kg on an alternate day basis. Over the last few months, this regimen was no longer effective despite an increased daily dose of prednisolone, and progressive erythema, skin thickening and malodor had developed in parallel with intense pruritus. Apart from the skin disease, Basil was judged to be in good general health.

Current Medications

Prednisolone: 1.0 mg/kg, q24h, PO.
Cephalexin: 15 mg/kg, q12h, PO.
Imidacloprid: 100 mg/moxidectin 25 mg spot-on monthly.

Other Medical History

Dog lived indoors with daily exercise in the local park. Owners were not affected by skin disease. The dog had never travelled beyond the local area.

Physical Examination

Body weight: 10 kg.
General: Bright, alert and responsive.
Integument: Lesions comprised intense erythema of the ventral neck, axillae, and medial aspect of the forelimbs with a rather demarcated and symmetrical distribution. The hair overlying folded ridges of intensely inflamed and thickened skin was matted in a yellow, greasy, malodorous exudate. Focal areas of lichenification and hyperpigmentation were evident in the alopecic regions of the ventral neck. There was bilateral erythemato-ceruminous otitis externa with erythema, hyperpigmentation, and lichenification on the medial aspect of the pinnae, although pinnal margins were unaffected. Interdigital skin was intensely erythematous and brown exudate matted the lower portions of the hair. External parasites were not observed.
Lymph nodes: Moderate peripheral lymphadenopathy affecting superficial cervical and popliteal nodes.
Other organ systems: No abnormalities detected.

Continued

CASE EXAMPLE—cont'd

Laboratory Findings

Microscopy for parasites: Microscopic examination of coat brushings, hair plucks, and skin scrapings showed no pathogens.

Cytology findings: Cytologic examination of smears of ear wax from both ears showed squames and moderate numbers of *Malassezia* spp. yeasts. Tape-strip specimens from inflamed skin of the ventral neck, axillae, and interdigital skin showed large numbers of *Malassezia* spp. yeasts amongst squames, along with rare coccoid bacteria.

Working Diagnosis

Malassezia dermatitis secondary to canine atopic dermatitis.

Treatment

A 2% miconazole and 2% chlorhexidine shampoo was applied every 3 days (10-minute contact time with lather) to treat the *Malassezia* infection of the skin. A combination of miconazole, polymixin B, and prednisolone was applied to both ears twice daily for the *Malassezia* otitis externa. Cephalexin was withdrawn due to lack of cytologic and clinical evidence of pyoderma, but prednisolone was maintained on an alternate day basis in view of the severity of inflammation.

Follow-up

On re-examination after 4 weeks, an excellent response to therapy was observed, with resolution of erythema, malodor, and pruritus. The skin was much less thickened and hair regrowth was evident, and otitis externa had resolved. Cytologic examination showed only rare yeasts in skin and ear samples. Subsequent weekly use of the miconazole/chlorhexidine shampoo was sufficient to prevent relapse of the *Malassezia* dermatitis. Further investigation of the allergic phenotype by diet trialing with a commercial hydrolyzed soy and cornstarch product exclusively for 8 weeks did not influence the ongoing need for low alternate-day doses of prednisolone.

Final Diagnosis

The typical clinical signs and abundance of *Malassezia* yeasts at the first assessment, and subsequent excellent clinical and cytologic response to topical therapy fulfill the diagnostic criteria for *Malassezia* dermatitis.

Previous glucocorticoid responsive allergic skin disease starting before 3 years of age in an indoor dog with lesions affecting front feet and ears, with nonaffected ear margins and dorsolumbar skin, that persisted despite antimicrobial and antiparasitic measures and diet trialing also convincingly fulfill the diagnostic criteria developed[77] for underlying nonfood-induced canine atopic dermatitis. Owners declined IgE testing and allergen-specific therapy, preferring medical therapy alone.

Comments

Development of *Malassezia* dermatitis led to a dramatic progression of previously controlled allergic skin disease, illustrating the potential importance of this disease as a flare factor in canine atopic dermatitis. Topical therapy alone was sufficient in the hands of very motivated owners with a compliant pet. This case illustrates the importance of: (1) evaluating for underlying skin diseases in dogs and cats with infections caused by this commensal yeast, and (2) the need to consider potential complicating factors (primarily microbial infection and ectoparasitic infestation) in the management of allergic dogs.

Blastomycosis

Alyssa C. Mourning, Jane E. Sykes

KEY POINTS

- First Described: Blastomycosis was first described in the United States in 1894 by Thomas Casper Gilchrist.[1]
- Cause: *Blastomyces dermatitidis* and *Blastomyces gilchristii* are the main species that cause disease in humans and dogs in North America (family Ajellomycetaceae). *Blastomyces helices* was recently described in humans, dogs, and cats from western Canada and a variety of regions within the United States. Other species such as *Blastomyces percursus* cause disease in humans outside North America.
- Affected Hosts: Primarily humans and dogs, but also a variety of other domestic and wildlife mammalian species, including cats.
- Geographic Distribution: Blastomycosis is principally a disease of North America, but has been identified in Africa, the Middle East, India, Europe, and Central America. In North America, the endemic distribution includes the Mississippi, Missouri, and Ohio River valleys, the mid-Atlantic states, a small area of northeastern United States, as well as the Canadian provinces that border the Great Lakes (Quebec, Manitoba, and Ontario), Saskatchewan, and southeastern Canada near the St. Lawrence River.
- Primary Mode of Transmission: Inhalation of conidia from the environment. The spores enter the terminal airway and establish a primary infection in the lungs as a yeast form. In rare circumstances, cutaneous inoculation may occur. In most cases, cutaneous blastomycosis in the dog should be considered a manifestation of disseminated disease.
- Major Clinical Signs: Blastomycosis is often associated with fever, inappetence, weight loss, cough, tachypnea, respiratory difficulty, and nodular or ulcerative cutaneous lesions. Ocular lesions, lameness, and neurologic signs are also common.
- Differential Diagnosis: These include neoplasia, other deep mycoses, protothecosis, mycobacterial infections, systemic protozoal infections (leishmaniosis, toxoplasmosis, neosporosis), aspiration or foreign body pneumonia.
- Human Health Significance: *Blastomyces dermatitidis*, *B. gilchristii*, and *Blastomyces helicus* cause disease in humans, but direct transmission from animals to humans does not typically occur. There have been rare cases of transmission of infection after direct inoculation through bite wounds. Dogs are considered a sentinel for human exposure. At the time of writing, blastomycosis is reportable in Arizona, Louisiana, Michigan, Minnesota, and Wisconsin.

ETIOLOGY AND EPIDEMIOLOGY

Blastomycosis is a pulmonary or disseminated disease that is primarily caused by the dimorphic fungi *Blastomyces dermatitidis* and *Blastomyces gilchristii*. Humans and dogs appear to be most susceptible to disease, with rare disease reported in cats. Other mammalian species can also be affected, including cats, horses,[2,3] ferrets,[4] sea lions,[5] lemurs,[6] rhesus monkeys,[7] wolves,[8] foxes,[9] black bears,[10] as well as lions and other captive nondomestic felines such as tigers, cheetahs, and snow leopards.[11] *Blastomyces dermatitidis* and *B. gilchristii* are phenotypically identical but have been differentiated based on the use of genetic typing methods (microsatellite analysis).[12] It has been suggested that in humans, *B. gilchristii* may be less likely to disseminate from the lungs than *B. dermatitidis*, but infections with *B. gilchristii* may be more severe and more likely to present with acute lung disease that results in hospitalization.[13] Nevertheless, both species appear to be capable of causing pulmonary and disseminated disease, and the presence of certain alleles within each species may be associated with a greater likelihood of dissemination or mortality. Studies of the relative prevalence of these species in dogs and association with virulence are required. *Blastomyces helicus* was more recently recognized in dogs and cats from western Canada and the United States.[14]

Blastomycosis is principally a disease of North America, but has been identified in Africa, the Middle East, India, Europe, and Central America.[15–18] *Blastomyces dermatitidis* and *B. gilchristii* have overlapping distributions primarily in the Midwestern parts of the United States, especially around the Great Lakes, along the Ohio and Mississippi river valleys, and in the southeastern states (Fig. 80.1).[19–21] Another focus of endemicity exists in the St. Lawrence river region in the northeast, which extends up into Ontario, Canada.[22,23] Disease may also be seen in parts of Canada around the Great Lakes and has also been reported in dogs and humans from Saskatchewan.[24,25,26] An increase in pulmonary blastomycosis in humans has been reported over the last decade from upstate New York.[27] Occasionally, disease appears in nontraveled dogs that reside in nonendemic parts of the United States, such as in Wyoming, Colorado, and South Dakota.[28,29,30] Disease in humans associated with infection with *B. helicus* has been described in western Canada (Saskatchewan, Alberta) and in two dogs, two cats, and seven humans from scattered regions within the United States (human cases: Texas, northern California, Idaho, Utah, Nebraska; dogs and cats: Fort Collins, Colorado; Helena, Montana; and Atascadero, California).[14] Disease in humans was associated with underlying immunocompromise. A dog from Colorado was known to dig in prairie dog burrows, and one of the cats that was an indoor/outdoor cat from the mountains

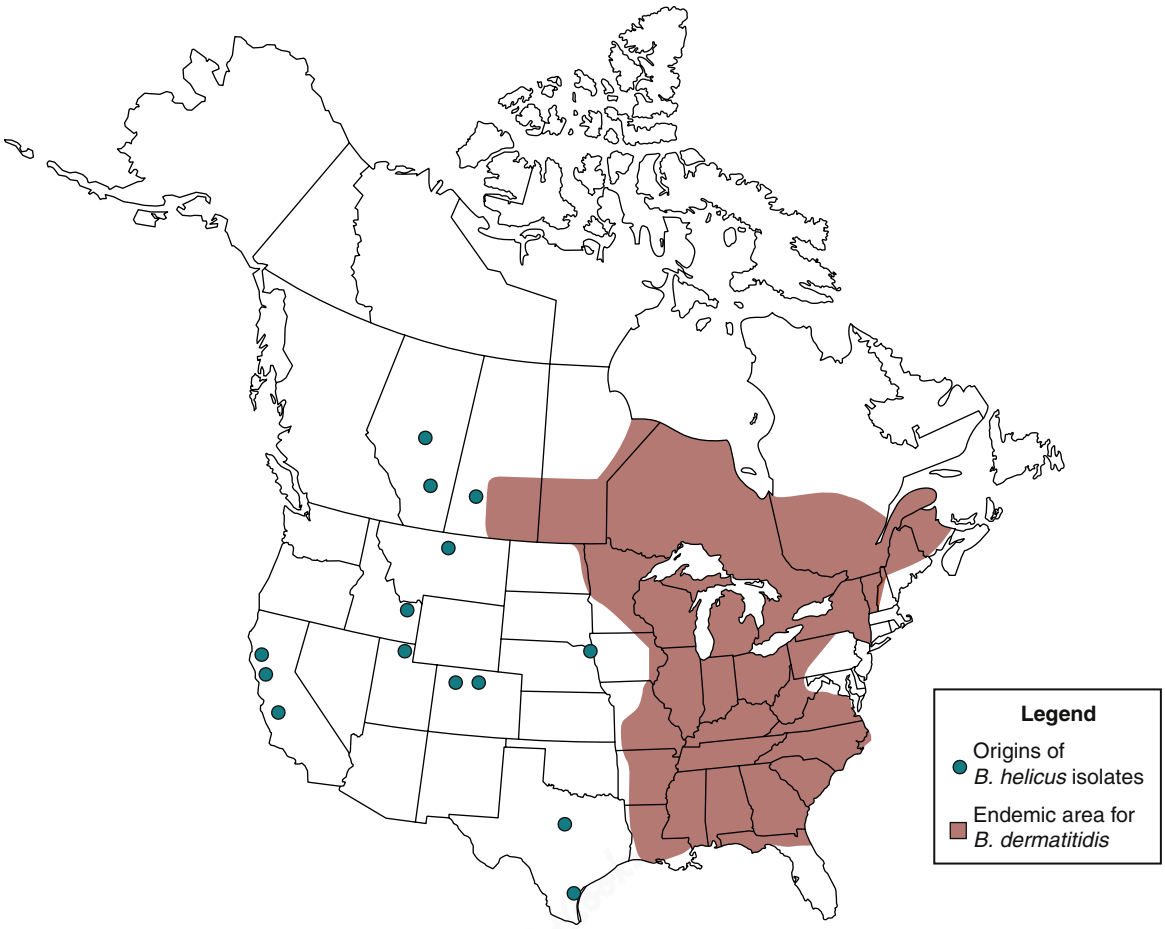

Fig. 80.1 Geographic distribution of blastomycosis in North America. The red shaded area represents the approximate distribution of *Blastomyces dermatitidis* and *Blastomyces gilchristii*. The blue dots represent reported cases of *Blastomyces helicus* in humans (southern Saskatchewan and Alberta, central and southern Texas, eastern Nebraska, southern Idaho, northern Utah, northern California); dogs (central Colorado, central coastal California); and cats (central Colorado, northern Montana).

west of Fort Collins was observed to play with potted plant soil. Canine blastomycosis has also been reported in India.[18] Human blastomycosis occurs in Africa, but reports of canine disease from Africa are absent from the literature. Species described in humans from Africa include *B. dermatitidis*, *B. gilchristii*, *Blastomyces percursus*, and *Blastomyces emzantsi* sp. nov.[21,31] Blastomycosis was described in Europe in a dog with a travel history to the United States.[16] However, travel-related disease occurs less often than other endemic mycoses that have longer incubation periods or more chronic, insidious disease courses, such as coccidioidomycosis.[32,33]

In the environment, *Blastomyces* grows in a saprophytic mycelial form that produces infective spores (conidia) that are 2–10 µm in diameter. The conidia are thought to be aerosolized and inhaled by the host. At body temperature (37°C) and in body tissues, the organism transforms into the yeast form and replicates asexually. Budding yeasts are 5–20 µm in diameter and have a thick, refractile double-contoured cell wall. The ecologic niche of *Blastomyces* spp. appears to be warm, moist, sandy soil that is rich in organic debris such as decaying vegetation and animal waste.[34] However, this has not been thoroughly defined because the fungus is difficult to isolate from the environment. No consistent seasonality has been linked to disease.

Living near a waterway is a risk factor for blastomycosis.[35] In Wisconsin studies, 95% of dogs with blastomycosis lived within 400 m (1,312 ft) of a body of water at altitudes less than 500 m (1,640 ft) above sea level.[36,37] Residence less than 400 m from a body of water increased the risk of blastomycosis by a factor of 10 in one study from Louisiana.[38] *Blastomyces dermatitidis* has been isolated from a woodpile near the Wisconsin River; over 14 years, four of nine dogs housed in a kennel close to the woodpile developed blastomycosis.[39] A study conducted in an endemic area of Tennessee also recognized the association of disease in dogs with proximity to water but did not find an association with soil type, soil pH, or amount of organic matter in the soil.[40] Although proximity to water is a risk factor, exposure to the outside environment is not necessary because blastomycosis can occur in strictly indoor dogs and cats.[38,41–43]

Rain or heavy dew appears to facilitate the release of infectious spores. In one study of 219 infected dogs over an 18-year period, increased rainfall and warmer temperatures preceded the highest incidence periods of infection.[44] The seasonal distribution rates of the cases were winter (24%), spring (18%), summer (36%), and fall (22%). No seasonal differences in disease are found in Tennessee, but more cases occur from late spring through late fall in Wisconsin.[45] In Louisiana, more cases were reported in August, September, October, and January than in the rest of the year.[38] Access to sites that have been excavated also increases the risk for infection because of exposure to organisms deep in the soil.[36] In humans, involvement in dirt-moving activities significantly increased the risk of developing blastomycosis.[43] In 1999, a large outbreak in humans and dogs in St. Louis county,

Minnesota, was associated with wet weather and an excavation site for a new neighborhood.[46]

Even within endemic regions, *Blastomyces* species are not widely distributed. Most humans and dogs living in such areas show no serologic or skin test evidence of exposure. A point source of exposure within an enzootic area is more likely. It is not unusual to find neighborhoods in which numerous dogs with blastomycosis are identified in a short time. In 14% of households in which blastomycosis has been diagnosed in humans or dogs, another case is diagnosed in the same household in the next several years.[41] Exposure of dogs and humans to a common source of infection while engaged in duck and raccoon hunting has been reported.[47,48] A study from Michigan showed that most dogs with blastomycosis were from the eastern half of the Upper Peninsula or the northern Lower Peninsula, and travel or residence north of the 45th parallel was a strong risk factor for infection.[20] The south-central portion of the state was a low-risk area. Hot spots for human blastomycosis have also been identified in northwestern Ontario, Canada, where disease incidence was over 12 times higher than for other regions in the province.[49]

Dogs appear to be more susceptible to infection than humans; in enzootic areas of Arkansas and Wisconsin, the incidence of blastomycosis is 10 times higher in dogs than in humans.[36] This may relate to greater exposure to the organism rather than a true genetic predisposition. The incidence in dogs was 1,420 per 100,000 dogs per year. Young age and proximity to a shoreline were risk factors.[50] Most affected dogs are immunocompetent. Blastomycosis is rarely reported in cats. A 5-year survey of the Veterinary Medical Data Program identified three infected cats, whereas 324 dogs with blastomycosis were found.[51] However, reports of multiple cases of blastomycosis in cats suggest that it may be more common than previously appreciated and possibly underdiagnosed.[42,52] As with other soil-borne mycoses such as histoplasmosis and cryptococcosis, blastomycosis can occur in cats that have been housed entirely indoors.[42,53] In one study, 10% of 41 cats affected with blastomycosis tested positive for FeLV antigen.[54]

Young adult, large-breed (>15 kg) dogs are predisposed, and a slight male predisposition has been identified in some studies, but not others.[20,29] Overrepresented breeds include coonhounds, pointers, Weimaraners, Labrador retrievers, golden retrievers, and Doberman pinschers.[29,38] This may reflect the increased likelihood of exposure of these dog types to organisms in the environment because they are more likely to be used in outdoor activities such as hunting.[20] Blastomycosis has also been diagnosed in strictly indoor dogs and cats.[41–43,53] Dogs younger than 6 months of age and as old as 17 years may be affected, but dogs in the 2- to 4-year age group have the highest risk of infection with the 4- to 6-year age group a close second.[29,38] No breed, age, or sex predisposition for blastomycosis has been recognized in the cat.

CLINICAL FEATURES

Pathogenesis and Clinical Signs

Blastomyces infection most often results from inhalation of conidia in the environment. Direct inoculation of organisms followed by localized cutaneous disease and/or osteomyelitis (inoculation blastomycosis) occurs rarely in dogs and humans.[33,55–57] After infection becomes established in the lungs, organisms may then disseminate systemically (Fig. 80.2). Dissemination is thought to occur via vascular and lymphatic routes. Although organisms enter the lung in almost all cases, lung lesions may resolve by the time the sites of disseminated infection become apparent. Occasionally, a focal lesion develops from a puncture wound,[55,56] but generally a solitary lesion should be considered part of a systemic process. *Blastomyces* spp. could not be isolated from the nares of any of 110 healthy dogs in a highly endemic region in

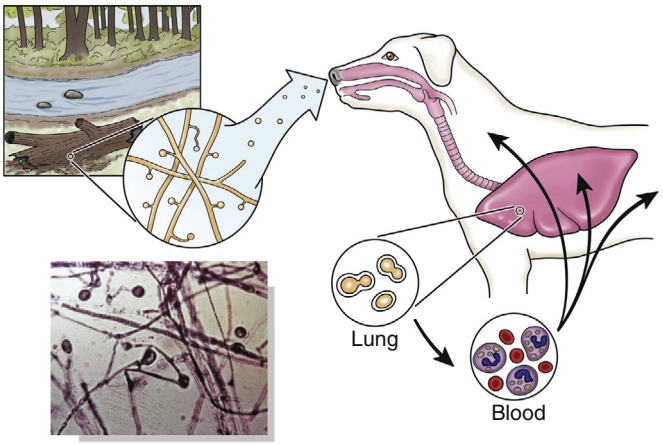

Fig. 80.2 Life cycle of *Blastomyces dermatitidis*. From the lung, the organism can disseminate to a variety of tissues, but especially the eye, lymph nodes, skin, and bones. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Wisconsin; of the 98 dogs with follow-up, one dog developed blastomycosis one month after culture was performed, 6 dogs died of other causes, and 91 dogs were healthy 3 years later.[58]

Blastomycosis may have a shorter incubation period in dogs than in humans.[47] Dogs may inhale a larger inoculum of organisms than humans because they are closer to the ground and actively sniffing the environment. Larger doses of inoculum may be associated with more rapid progression and earlier mortality.[59]

Once within the host, the conidia transform into yeasts that can resist destruction by neutrophils. The yeasts trigger a pyogranulomatous inflammatory response. Important virulence factors include a cell surface glycoprotein known as BAD-1 (previously known as WI-1), and other cell wall components such as α-1,3-glucan and possibly melanin.[60–62] The BAD-1 antigen is an adhesin that binds to host cell receptors on macrophages. It may also contribute to the yeast's ability to evade the host immune response by influencing cytokine secretion and impairing complement activation.[60,63–65] The thick cell wall of the yeast may be antiphagocytic. Melanin production by the yeast may influence the pathogenesis of blastomycosis.[61] In one study, it reduced susceptibility to amphotericin B (AMB), but not to itraconazole or voriconazole.

In some animals, the organism spreads hematogenously from the lungs to associated lymph nodes and other extrapulmonary sites. Extrapulmonary sites of predilection include the skin, eye, bone, lymph nodes, reproductive tissues (prostate and testes), and the CNS. However, virtually any tissue in the body may be affected, and infection has been reported in the mammary glands, nasal or oral cavities, larynx, cardiac tissues (myocardium, endocardium, and pericardium), and very rarely in the kidneys, liver, spleen, peritoneum, GI tract, and urinary bladder.[66–68] Skin involvement is very common with disseminated *B. dermatitidis* and *B. gilchristii* infections, whereas no evidence of skin involvement was noted for humans, dogs, and cats with *B. helicus* infections.[14] In the veterinary cases, organisms were identified in the lungs, but more detailed description of clinical signs was not reported.

Antibodies against the BAD-1 antigen produced no protection against infection in a mouse model,[69] which is consistent with high antibody concentrations specific for *Blastomyces* organisms in dogs with life-threatening, progressive blastomycosis. Many dogs experimentally infected by exposure to contaminated soil recover from blastomycosis without treatment.[70] It is likely that when naturally exposed,

some dogs develop mild respiratory signs and recover spontaneously. Antibodies in 2 of 48 healthy dogs from an endemic area with no history of illness suggest that occasionally dogs do develop a subclinical, self-resolving disease.[71] However, almost all dogs with clinical signs that have warranted veterinary attention have disseminated disease and should be aggressively treated. Dogs[38] and humans[13] occasionally recover from blastomycosis without treatment.

Clinical signs of blastomycosis are variable. Dogs may develop subclinical infections, acute or chronic disease that is localized to the lungs and associated lymph nodes, or severe and progressive signs that result from dissemination of the organism to multiple extrapulmonary sites. The incubation period is variable and not precisely known, but is estimated to range from 5 to 12 weeks.

Nonspecific signs of illness such as lethargy, weakness, fever, inappetence, and weight loss are common. Other common clinical manifestations (between 20% and 50% of affected dogs) include signs of respiratory involvement (such as cough and increased respiratory rate), lymphadenopathy, ocular manifestations, cutaneous lesions, and lameness.[38,72] Lameness may result from fungal osteomyelitis, arthritis, or rarely, hypertrophic osteopathy.[73] GI signs (vomiting, diarrhea, hematemesis, and melena), polyuria or polydipsia, mammary gland masses, laryngeal masses, nasal discharge, sneezing and/or epistaxis, testicular masses, dysuria or hematuria secondary to prostatic involvement, cardiac arrhythmias, and neurologic signs due to meningoencephalitis or ependymitis occur less frequently.[38,68,74–78] Neurologic involvement secondary to extension of intranasal or retrobulbar *Blastomyces* granulomas through the calvarium can also occur.[75,79] Disseminated disease can also affect the brain without extension of granulomas.[80] There have also been reports of meningitis as the primary presentation of blastomycosis, without evidence of involvement outside the CNS.[81] Rarely, thromboembolic disease has been reported.[82]

Signs of disease usually have been present for a few days to a week before evaluation, but may have been apparent for up to a year. In some dogs the disease process seems to plateau; animals show few signs for weeks to months, but then suddenly progresses. Many dogs have a history of antibacterial therapy with minimal or temporary improvement.

Physical Examination Findings

Physical examination abnormalities in dogs with blastomycosis commonly include fever, thin body condition, dehydration, and signs of respiratory involvement. Fever is present in approximately 50% of affected dogs and is usually low grade (103°F to 104°F or 39.4°C to 40.0°C) but occasionally exceeds 106°F (41.1°C).[67,78] Respiratory signs include cough, tachypnea, increased respiratory effort, and increased lung sounds on thoracic auscultation. Other common findings on physical examination are firm cutaneous or subcutaneous masses, draining or ulcerated skin lesions, and peripheral lymphadenomegaly. Careful palpation of the entire skin surface can reveal small skin lesions. Cutaneous and subcutaneous lesions are frequently found on the trunk, limbs, and digits and can also involve the muzzle (Fig. 80.3A and B). Lesions of the tongue, gingiva, or mucocutaneous junctions may also be present (Fig. 80.4). Facial swelling, exophthalmos, or facial deformity has been described in some affected dogs.[75,83] Dogs with nasal cavity involvement can have stertorous respiration, decreased nasal airflow, or nasal discharge. Ocular signs may be unilateral or bilateral and include chorioretinitis (sometimes with retinal detachment) (Fig. 80.5); lesions consistent with optic neuritis; endophthalmitis or panophthalmitis; uveitis with aqueous flare, iris bombé, synechia, and miosis; cataract formation; conjunctivitis; keratitis; and photophobia.[84,85] Severe ocular involvement may result in increased intraocular pressures and/or loss of vision. Dogs with musculoskeletal involvement may be lame, have firm swellings associated with long bones, or exhibit joint swelling, warmth, and/or pain. Dogs with testicular blastomycosis may have scrotal swelling or palpable testicular masses. Neurologic signs are present in fewer than 5% of affected dogs and can include seizures, hypermetria, decreased placing reactions, tetraparesis, circling, ataxia, blindness, decreased or absent menace and/or pupillary light reflexes, nystagmus, and decreased facial sensation (Table 80.1).

Physical examination findings in cats with blastomycosis are similar to those described in dogs. These include fever, thin body condition, peripheral lymphadenopathy, tachypnea, increased or decreased lung sounds, ocular abnormalities (chorioretinitis with retinal detachment, uveitis, panophthalmitis, and secondary glaucoma), nodular or draining skin lesions (Fig. 80.6), and a variety of neurologic signs that include obtundation, ataxia, pelvic limb paresis, circling, hyperesthesia, decreased placing reactions, and blindness.[53,86–89]

DIAGNOSIS

A diagnosis of blastomycosis is usually suspected based on the presence of suspicious clinicopathologic abnormalities in a dog or cat from an endemic area. The diagnosis is usually confirmed through cytologic examination of fine-needle aspirates of affected tissues (especially skin lesions and lymph nodes), impression smears of draining skin lesions, respiratory lavage specimens (transtracheal washes or bronchoalveolar lavage), or body fluids (especially CSF or ocular fluid, but also synovial fluid, diagnostic peritoneal lavage, or urine sediment). Other methods of diagnosis include histopathology (e.g., of bone or tissue biopsies), fungal culture, PCR-based assays, and EIA antigen assays (Table 80.2).

Laboratory Abnormalities

Complete Blood Count

The hemogram of dogs or cats with blastomycosis can be unremarkable. However, a mild, normocytic, normochromic nonregenerative anemia is present in many affected animals likely due to chronic inflammation. Mild to moderate neutrophilia is also present in many dogs and may be accompanied by a mild to moderate bandemia.[38,90] Mild monocytosis, lymphocytosis, or lymphopenia may be detected.

Serum Biochemical Tests

Serum biochemistry findings in animals with blastomycosis include mild to moderate hyperglobulinemia due to a polyclonal gammopathy, hypoalbuminemia, and, uncommonly, mild hypercalcemia.[38,90,91] Hypoalbuminemia was present in 70 of 91 (77%) of dogs in one study, hyperglobulinemia in 58%, and hypercalcemia in 14% of dogs.[38] In one study, 22 dogs with blastomycosis had significantly higher serum ionized calcium concentrations than 35 healthy control dogs.[92] These dogs also had lower serum concentrations of 25-hydroxyvitamin D and parathyroid hormone, as has been described in patients with mycobacteriosis (see Chapter 61).

Urinalysis

The urinalysis is usually unremarkable in animals with blastomycosis, but occasionally proteinuria, pyuria, hematuria, or cylindruria are present. Rarely, *Blastomyces* spp. yeasts are identified in the sediment.

Cerebrospinal Fluid Analysis

CSF analysis in dogs with CNS blastomycosis can reveal increased total nucleated cell counts and increased CSF protein concentration.[93] Nucleated cells typically consist of a mixture of small and large

Fig. 80.3 (A-C) Disseminated blastomycosis in a Labrador retriever. (A) Nodular cutaneous lesions are present on the muzzle. There are also multiple, ulcerated, and draining skin lesions on the distal limbs (B) and digit (C). (D) Granulomatous lesion of nail bed associated with blastomycosis in a dog. mononuclear cells and neutrophils. Although rare, in dogs with brain involvement, organisms may be found on cytological analysis.

Diagnostic Imaging

Plain Radiography

Radiographic patterns in dogs with blastomycosis vary considerably and include unstructured, miliary, or nodular interstitial patterns; a bronchointerstitial pattern; alveolar or mixed alveolar-interstitial patterns; pulmonary mass lesions (>3 cm in diameter); or single or multiple large (0.5 to 2.9 cm) pulmonary nodules that can resemble metastatic pulmonary neoplasia (Fig. 80.7).[38,94,95] Tracheobronchial lymphadenomegaly is present in approximately 25% of dogs.[94] Pleural thickening and mild pleural effusion are uncommonly identified (≤10% of affected dogs). Focal bronchiectasis has also been described. In one study, only 2 of 125 dogs with blastomycosis had no visible abnormalities on thoracic radiography. Findings in affected cats include diffuse miliary or nodular interstitial patterns, lobar consolidation, and/or pleural effusion.[53,86]

Radiographs of affected bone typically show osteolysis, often accompanied by periosteal proliferation and soft tissue swelling. Pathologic fractures may be identified (Fig. 80.8A and B). Evidence of hypertrophic osteopathy was present bilaterally along the humerus, radius, ulna, metacarpi, and phalanges of a dog with a mass lesion in the right middle lung lobe.[73]

Advanced Imaging

CT findings in dogs with CNS blastomycosis include intra-axial, intranasal, or retrobulbar mass lesions that are uniformly or heterogeneously contrast-enhancing.[75] An intra-axial contrast-enhancing mass lesion was also described in a cat.[96] Intranasal or retrobulbar mass lesions can invade the cribriform plate or other parts of the skull, with associated osteolysis. Meningeal or periventricular contrast enhancement may also be present.[75,76] MRI findings have not been extensively described in dogs. One dog had a retrobulbar mass lesion that extended through the calvarium; the lesion was iso- to hypointense on T2-weighted images, slightly hypointense on T1-weighted images, and showed strong homogenous contrast enhancement.[79] In addition to mass lesions, periventricular and meningeal contrast enhancement, as well as ventriculomegaly, have also been described.[97]

Microbiologic Tests

Cytologic Examination

Diagnosis has historically been made by identifying the organism through cytologic or histologic evaluation. Cytologic examination of

Fig. 80.4 Nodular and ulcerated lesions of the tongue in a dog with disseminated blastomycosis. (Courtesy of Dr. Sheila Torres, University of Minnesota.)

TABLE 80.1 Physical Examination Findings in 115 Dogs with Blastomycosis[29]

Clinical Sign	Percent of Dogs
Fever	62
Lymphadenopathy	56
Harsh lung sounds	50
Skin lesions	49
Chorioretinitis	43
Anterior uveitis	42
Cough	32
Emaciation	25
Retinal detachment	23
Cutaneous mass	16
Glaucoma	16
Tachypnea	16
Dehydration	15
Bony mass/swelling	14
Nasal discharge	8
Neurologic signs	6
Prostatomegaly	5
Mammary mass	3
Orchitis	2
Synovial effusion	2

fine-needle aspirates, respiratory wash specimens, or body fluids frequently reveals large numbers of *Blastomyces* spp. yeasts. The yeasts of *B. dermatitidis* and *B. gilchristii* are 8 to 15 µm in diameter, have a thick, refractile cell wall, and exhibit broad-based budding (Fig. 80.9A and B). Daughter cells are nearly as large as the parent cell when they detach. A pyogranulomatous inflammatory response is usually present. Occasionally, organisms are not seen; the sensitivity of transtracheal lavage for diagnosis of pulmonary blastomycosis in two studies of 17 and 39 dogs was 76% and 69%, respectively,[90,95] whereas the sensitivity of FNA of the lung was 46 of 57 (81%).[90] The yeasts of *B. helicus* are smaller than those of *B. dermatitidis* and *B. gilchristii* (2.5 to 6.5 µm in diameter and up to 4 to 9 µm in length) and can exhibit multiple budding with chains of organisms; hyphal forms also have been described.[14] These have the potential to be mistaken for *Candida* spp. and misidentification as *Histoplasma* spp. has been reported.

Serologic Diagnosis

Until recently, AGID was the most widely available antibody assay to detect antibodies to the *Blastomyces* spp. A antigen. Unfortunately, AGID assays have variable and generally unacceptable sensitivity for diagnosis of blastomycosis in dogs and cats, which has ranged from 17% to 91%.[38,71,86,90,98,99] An EIA that used crude mold-phase *Blastomyces* spp. as the antigen had a sensitivity of 76.1%,[99] and a radioimmunoassay designed to detect antibody responses to the BAD-1 antigen had a sensitivity of 92%.[71] The specificity of AGID assay exceeds 95% based on limited studies of healthy dogs or dogs with diagnoses other than blastomycosis.[71,98] Several other antigens have been studied for their potential to be used for antibody detection assays.[100] However, because false-positive test results have the potential to occur as a result of exposure and recovery in endemic areas or as a result of cross-reactivity to other infectious agents, diagnosis based on positive antibody serology alone is not recommended.

Higher sensitivities than AGID were reported with an EIA for antibodies to recombinant *Blastomyces* adhesion-1 repeat antigen (rBAD-1). The sensitivity of the antibody EIA was 95% in dogs versus 65% with the AGID assay. The specificity of the antibody EIA was 95% in healthy dogs, and 100% in dogs with nonfungal pulmonary disease.[101]

An assay that detects *Blastomyces* cell wall galactomannan antigen (MiraVista Diagnostics, Indianapolis, IN, USA) has largely replaced antibody assays for serologic diagnosis of canine blastomycosis. The *Blastomyces* antigen EIA is useful in the diagnosis of blastomycosis

TABLE 80.2 Diagnostic Assays Currently Available for Blastomycosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, body fluids, impression smears of skin lesions	*Blastomyces* spp. yeasts	Organisms are usually present in variable numbers but occasionally may not be visualized. Organisms may appear disrupted after treatment with antifungal drugs.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids	*Blastomyces* spp.	Rarely indicated. Sensitive and specific and may be required for animals when cytologic examination is negative. Risk of laboratory-acquired infections. Slow turnaround time (may require several weeks of incubation).
Antibody serology (gel immunodiffusion)	Serum	Antibodies to *Blastomyces* spp.	When present in conjunction with consistent clinical signs, positive test results usually indicate active infection, but the potential for false positives exists. Negative test results occur commonly in dogs and cats with blastomycosis (low sensitivity).
Antigen assay (ELISA)	Urine, serum	*Blastomyces* spp. antigen	Highly sensitive (>90%) when urine is used as the test specimen. False positives are extremely rare in dogs that lack fungal disease, but cross-reactivity with other fungal pathogens may occur (especially *Histoplasma*), so positive results are not diagnostic for blastomycosis.
Real-time PCR assays	Whole blood	*Blastomyces* spp. DNA	Not yet validated in adequate numbers of dogs or cats with blastomycosis; usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*Blastomyces* spp. yeasts	Sensitive, but yeasts may be difficult to find in some infections. Special stains may assist organism detection.

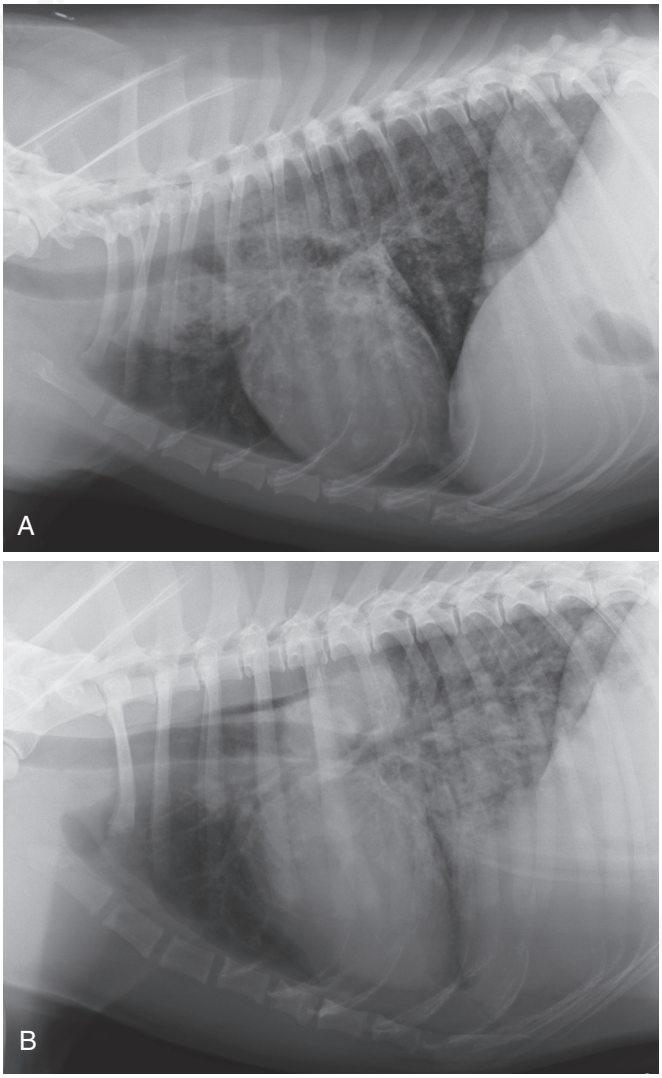

Fig. 80.7 Radiographic patterns in pulmonary blastomycosis. (A) Lateral thoracic radiograph from a 2-year-old female spayed Labrador retriever with a 1-week history of cough and inappetence. A diffuse miliary nodular interstitial pattern is present. (B) Lateral thoracic radiograph from a 5-year-old female spayed German shepherd dog with lethargy and inappetence. An alveolar pattern is present in the caudal lung lobes, along with marked hilar lymphadenopathy. There is also a nodular lesion in the cranial lung lobes just ventral to the trachea. (Courtesy of Daniel Cronk, University of Minnesota.)

(especially in cases lacking cytologic or histologic identification of the organism) and was first reported for use in dogs in 2008.[99] A *Blastomyces* antigen EIA has been available for diagnosis of blastomycosis in humans since 2004 and has since been modified to allow quantification.[102,103] In humans, the overall sensitivity of the quantitative *Blastomyces* antigen EIA was 90%, including 41/46 individuals (89%) with isolated pulmonary blastomycosis, 24/26 (92%) of those with pulmonary and extrapulmonary infection, and 15/17 (88%) of those with extrapulmonary involvement.[103] Equal sensitivity (79%) was reported for *B. dermatitidis* and *B. gilchristii* infections in humans, although there was a trend for antigen concentrations to be higher in *B. dermatitidis* infections.[104] Whether the same is true in dogs is unknown.

The performance of this assay was evaluated in 46 dogs with confirmed blastomycosis.[99] When urine was used, the sensitivity was 93.5%, whereas when serum was assayed, sensitivity was 87%. Only 1 of 43 control dogs without blastomycosis had a positive test result. In another study, 70 dogs with and without blastomycosis were evaluated using the MiraVista antigen EIA. Sensitivity was 100% in serum and urine specimens from dogs with blastomycosis, with specificity of 95% in urine specimens from dogs with nonfungal pulmonary disease and 100% in urine specimens from healthy dogs.[101] Positive test results were also reported for some *B. helicus* infections.[14]

In human patients, the sensitivity of urine galactomannan antigen testing was 90%, and specificity was 99% in patients without fungal infections. However, 96% of humans with histoplasmosis tested positive because of cross-reactivity.[99,103] Positive test results can also occur in dogs and cats that have histoplasmosis. The EIA antibody had 88% specificity when looking at dogs with blastomycosis and histoplasmosis, which indicates it may have a role in distinguishing blastomycosis from histoplasmosis.[101]

Fungal Culture

Blastomyces spp. can be isolated from clinical specimens on routine fungal media in the laboratory. Growth of a white mold typically appears after incubation for 1 to 3 weeks, but occasionally incubation periods of up to 5 weeks are required. The organism is identified based on the morphology of its conidia, which are round to oval and attached to hyphae. *Blastomyces dermatitidis* and *B. gilchristii* are morphologically indistinguishable, and differentiation requires molecular typing. This is typically not done (unless for epidemiologic studies) because of lack of known clinical significance. *Blastomyces helicus* can be identified based on its morphology in culture; unlike *B. dermatitidis*, it does not produce conidia. Because *Blastomyces* spp. grow as a mycelium in the laboratory, culture is a laboratory health hazard and should be performed only if necessary. The laboratory should be warned of the possibility of a dimorphic fungal infection so that appropriate precautions are taken.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays have been developed that rapidly detect *Blastomyces* spp. in clinical specimens from humans,[105,106] but are not currently used routinely for diagnosis in dogs and cats. The sensitivity of one assay was 86% when compared with culture of clinical specimens.[106] PCR assays have not been widely applied to the diagnosis of blastomycosis in dogs and cats.

Pathologic Findings

Gross pathologic findings in dogs with blastomycosis include thin body condition; characteristic skin lesions; bony proliferations that may be accompanied by pathologic fracture; enlargement of the peripheral and/or tracheobronchial lymph nodes; ocular lesions; lung consolidation; and firm, pale, pulmonary nodules or masses that range in size from 1 mm to several centimeters in diameter. Masses may be caseous on cut surface. Animals with CNS involvement may have masses within the brain, secondary hydrocephalus, or retrobulbar or caudal nasal cavity granulomas that may invade the cribriform plate and extend along the optic nerves.[78,93] Rarely, pleural and/or peritoneal effusion and nodular lesions within abdominal viscera have been reported.[67] Testicular and prostatic masses can also be found.[78] Histopathology reveals granulomatous or pyogranulomatous inflammatory infiltrates in a variety of organs, often with intralesional budding yeasts (Fig. 80.10). Multinucleated giant cells, fibroblasts, and large numbers of lymphocytes may also be present. Ocular lesions include uveitis, choroiditis, retinal detachment, retinal degeneration, lens rupture, cataracts, optic neuritis, and vitritis.[78,84] Secondary hepatic and renal amyloidosis was described in one dog.[107]

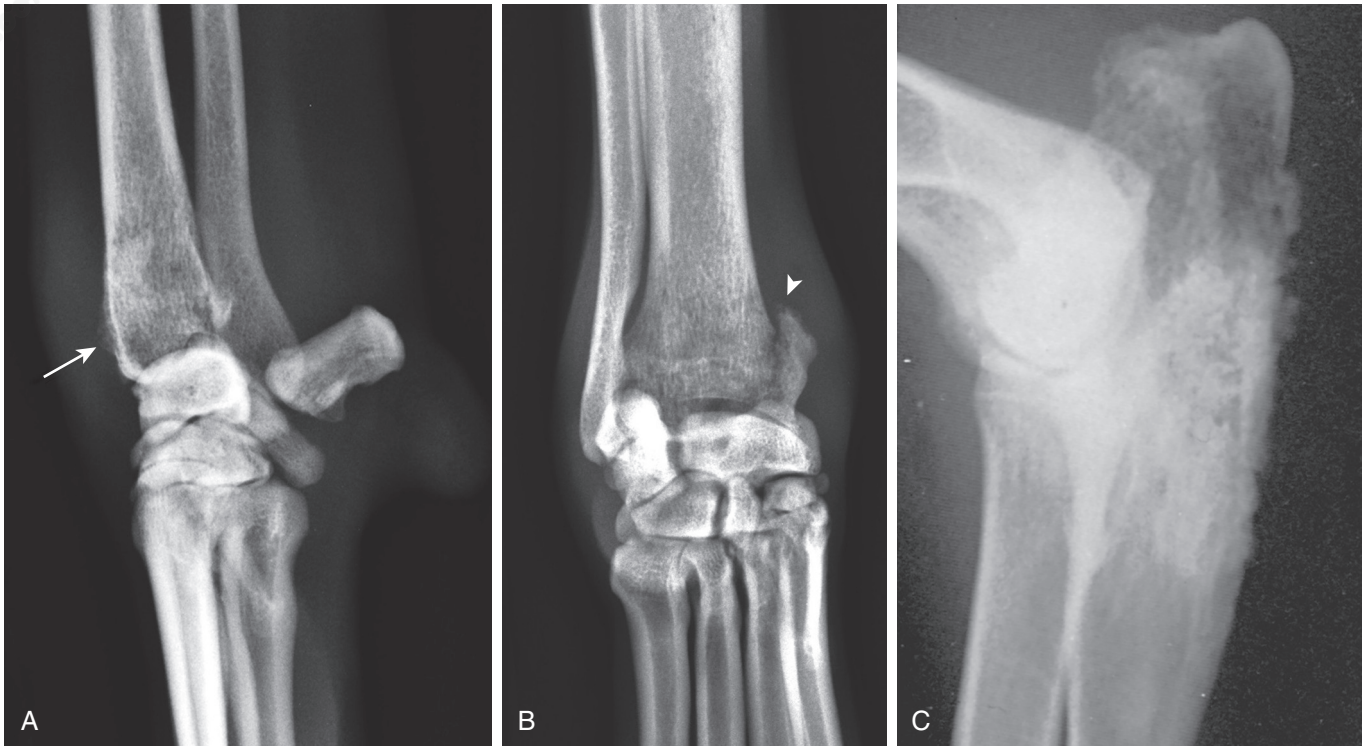

Fig. 80.8 Lateral (A) and anteropalmar (B) radiograph of the right carpus showing an osteolytic and osteoproductive *(arrow)* lesion with a pathologic fracture *(arrowhead)* and associated soft tissue swelling in the distal radius of a 6-year-old male neutered Labrador retriever with disseminated blastomycosis. (C) Semi-aggressive bone lesion characterized by osteolysis and amorphous bone production in the proximal tibia of a dog. (A and B, courtesy of Daniel Cronk, University of Minnesota.)

Organisms are not always detected in lesions, even in untreated dogs. Special stains such as silver stains, PAS, and immunohistochemical stains can assist in the identification of *Blastomyces* spp. yeasts within sections,[84,107,108] but failure to detect yeasts does not rule out blastomycosis.

TREATMENT AND PROGNOSIS

The most widely used treatment for blastomycosis in dogs is itraconazole, which is effective as a single agent in many dogs.[109] Itraconazole has largely replaced the use of ketoconazole for treatment of blastomycosis. The recommended dose of itraconazole for dogs is 5 mg/kg, PO, q24h. This dose has an equivalent efficacy as a dose of 5 mg/kg, PO, q12h and a lower rate of adverse effects such as anorexia.[109]

Seventy-four percent of dogs treated with 5 mg/kg q24h of itraconazole responded to treatment; a 77% response rate was found in a historic control group treated with AMB.[109] Of the dogs that responded initially, 20% of dogs treated with AMB and 20% of dogs treated with itraconazole had recurrence of disease after completing treatment.[109] In another study, 21 of 31 dogs (68%) responded to a 60- to 90-day course of itraconazole. Of those that responded, 5 of 21 dogs (24%) had a recurrence, and 4 of those dogs were successfully retreated with a second course of itraconazole.[38] The mortality rates of itraconazole- and AMB-treated dogs were similar (Table 80.3).

Itraconazole appears to penetrate the eye in dogs with active disease, because the dogs with ocular blastomycosis of the posterior chamber often respond to itraconazole treatment.[110] Twice-daily dosing with 5 mg/kg has been recommended for intraocular infections.[111] The bioavailability of compounded itraconazole is very low; therefore, use of compounded itraconazole is not recommended (see Chapter 11).[112]

The duration of azole treatment should be based on serial monitoring of clinical signs and radiographic lesions (e.g., every 4 to 8 weeks). Most dogs require at least 3 to 6 months of treatment. Some dogs require treatment for more than 1 year, especially those with osteoarticular infections or widespread dissemination. Because fluconazole is less active, its use is not recommended for treatment of human blastomycosis, unless itraconazole is not tolerated.[113–115]

Treatment with deoxycholate AMB or lipid-complexed AMB is also effective and should be considered for dogs with severe disease with widespread dissemination, dogs and cats with CNS involvement, for animals that do not respond to azole monotherapy, or for those that do not tolerate itraconazole.[90,116] Cats with blastomycosis have also been treated with variable success with combinations of AMB and azoles or AMB alone.[53,86] In human patients, the use of deoxycholate or lipid-complexed AMB is recommended for severe pulmonary or disseminated disease, followed by itraconazole therapy after there has been a satisfactory clinical response.[115] Whether protocols that include AMB offer a survival advantage over azole monotherapy for dogs or cats has not been well studied in a prospective fashion. Other drugs that have been used successfully to treat human blastomycosis include voriconazole and posaconazole.[114,117] Because of its ability to penetrate the CNS and eye, voriconazole has been recommended for treatment of human CNS blastomycosis after initial treatment with lipid-complexed AMB.[114,118]

Urine *Blastomyces* galactomannan antigen concentration declines with effective antifungal drug treatment.[99] Urine antigen testing has proven useful not only at the time of diagnosis but also when considering to discontinue treatment as well as documenting poor clinical

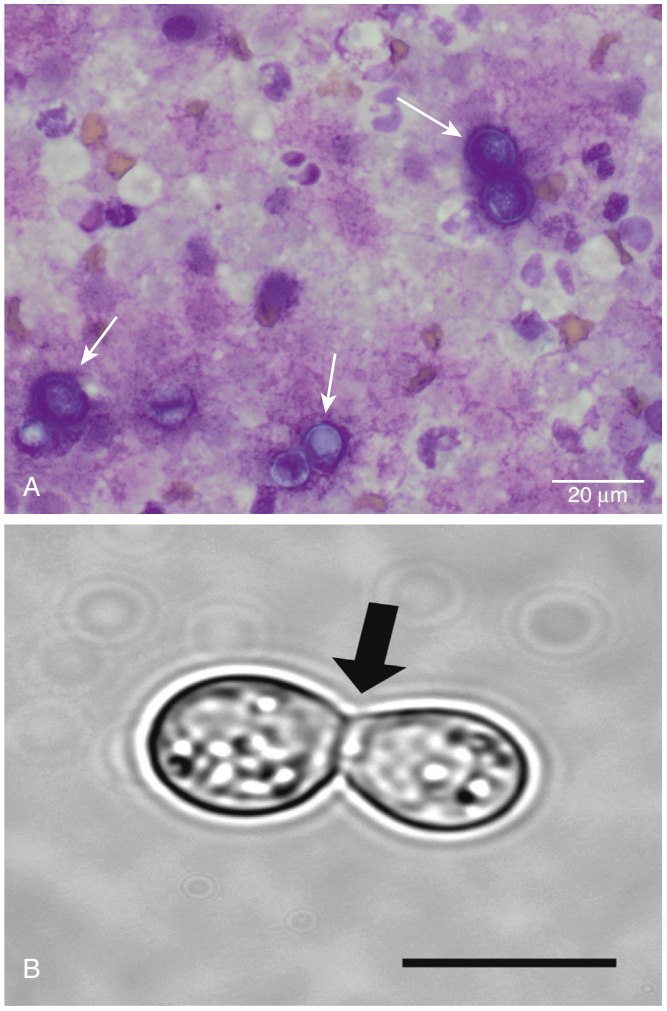

Fig. 80.9 (A) Cytology of a fine-needle aspirate of a skin lesion from a dog with blastomycosis. *Blastomyces* yeasts *(arrows)* have a thick wall and exhibit broad-based budding. A pyogranulomatous inflammatory response is also present. (B) B, *B dermatitidis* yeast. Broad-based budding yeast at 37°C. Arrow points to the broad-based bud between mother and daughter cells. Scale bar is 10 µm. (A, courtesy of Dr. Jed Overmann, University of Minnesota. B, From McBride JA, Gauthier GM, Klein BS. Clinical Manifestations and Treatment of Blastomycosis. *Clin Chest Med* 38 (2017) 435–449. Fig 1. http://dx.doi.org/10.1016/j.ccm.2017.04.006.)

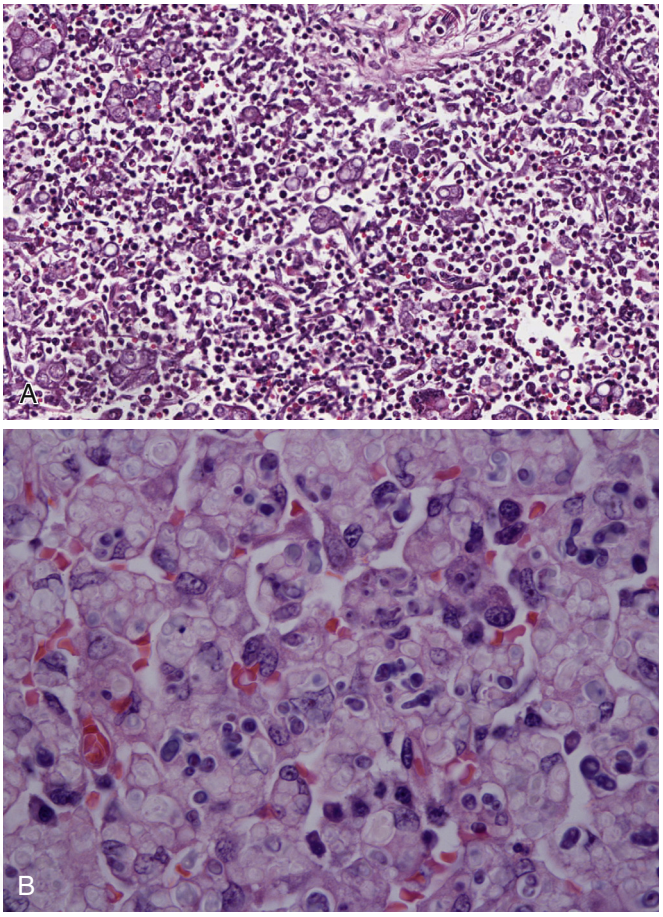

Fig. 80.10 Histopathologic findings in dogs with blastomycosis. (A) Histopathology of the lymph node from a 10-year-old female spayed Australian shepherd dog with blastomycosis. Severe pyogranulomatous lymphadenitis is present with moderate numbers of large yeast organisms. (B) Histopathology of the lung of another Australian shepherd dog that had a pulmonary and a mediastinal abscess due to *Blastomyces* spp. infection. Abundant yeast organisms are present. 1000× oil magnification. (A, courtesy of Dr. Catherine Benson, University of Minnesota. B, courtesy of Dr. Patricia Pesavento, University of California, Davis.)

response or relapse of disease.[119] A low *Blastomyces* galactomannan urine antigen concentration was positively correlated with survival in one retrospective study.[120] A common practice is to continue antifungal therapy until there have been two negative antigen tests at least 3 to 4 weeks apart.

Therapeutic drug monitoring should be considered should the response to treatment be inadequate (see Chapter 11).[109] The dose should be adjusted to achieve serum itraconazole concentrations of 2 µg/mL or greater.

Supportive Care

The severity of lung pathology increased in the initial week of treatment in 23% of dogs.[94] The worsening of signs has been attributed to an inflammatory response to killed yeasts in the lungs. The worsening of infiltrates seen radiographically was not associated with a less favorable outcome.[94] Death usually results from respiratory failure and occurs in 50% of the dogs with severe lung disease during the first 7 days of treatment. Mechanical ventilation was used to treat 5 (4%) of 125 dogs with pulmonary blastomycosis in one report, none of which survived.[90,94]

Dexamethasone (0.25 to 0.5 mg/kg, IV, for 2 to 3 days) can be given to dogs that develop life-threatening respiratory disease after starting antifungal drug treatment. Dogs that receive glucocorticoids for this purpose should be treated for at least 90 days with antifungal drugs.

Other treatments that may be required for treatment of dogs or cats with severe pulmonary blastomycosis are supplemental oxygen, nebulization and coupage, IV fluid therapy, and, in some cases, mechanical ventilation.[90] Dogs with CNS involvement may require treatment with anticonvulsants in order to control seizure activity. The concurrent use of systemic glucocorticoids should also be considered to control brain inflammation and edema, although whether this ultimately improves outcome is not known. For animals that lack CNS involvement, NSAIDs can be used to control pyrexia. Topical anti-inflammatory

TABLE 80.3 Drug Therapy for Blastomycosis

Drug	Species	Dose[a] (mg/kg)	Route	Interval (Hours)	Duration[b] (Days)
Itraconazole	Dog[c]	5	PO	24	60
	Cat	5	PO	12	60
Fluconazole	Dog	5	PO	12	60
Amphotericin B, lipid complex[d]	Dog	1	IV	3 times weekly	Varies[e]
Amphotericin B	Dog	0.5	IV	3 times weekly	Varies[f]
	Cat	0.25	IV	3 times weekly	Varies[g]

[a]Dose per administration at specified interval.
[b]Minimum duration of therapy. Ideally, therapy should continue for at least 1 month beyond the last detection of clinical illness/infection or two negative urine antigen tests at least 4 weeks apart.
[c]Itraconazole is preferred drug and dosage therapy. A 12-hour interval (10 mg/kg/day total dose) is recommended when intraocular involvement is present.[18] Fluconazole may also better penetrate the eye when treating intraocular infections; however, it is not as active as itraconazole. Enucleation may be needed.
[d]Three lipid formulations are available. Efficacy at this dose has been established for ABLC (Abelcet, Enzon Pharmaceuticals, Bridgewater, NJ).
[e]Stop when cumulative dose reaches 12 mg/kg.
[f]Stop when azotemic or cumulative dose reaches 4–6 mg/kg, then start azole, or when cumulative dose is 8–10 mg/kg when given alone.
[g]Stop when azotemic or cumulative dose reaches 4 mg/kg, then use itraconazole.
IV, intravenous; *PO*, oral.

and antiglaucoma agents may be indicated if ocular involvement is present. Enucleation may ultimately be required if endophthalmitis is present to control ocular pain and eliminate infection. Treatment of osteomyelitis or large pulmonary granulomas that are refractory to antifungal chemotherapy may require surgical treatment by amputation or lung lobectomy, respectively.

Cure rates of 50% to 75% have been reported in dogs with blastomycosis.[109,121] An additional 20%–24% of dogs experience relapse of disease after treatment is discontinued.[38,109,121] Recurrence after apparently successful treatment usually occurs in the first 6 months after completion of therapy, but recurrences can occur up to 3 years after completion of therapy.[38,109,121] As mentioned previously, clinical signs and radiographic lesions can worsen in the first few days of treatment in some affected dogs,[94] possibly due to the inflammatory response to dying organisms. The median time for resolution of primary radiographic patterns in dogs with pulmonary blastomycosis in one study was 186 days (range, 4 to >355 days).[94] Significantly longer mean treatment durations were required for radiographic improvement of large pulmonary masses when compared with alveolar and interstitial patterns. The most common radiographic sequela to pulmonary blastomycosis is development of one or more pulmonary bullae. Unstructured interstitial patterns may also persist, presumably as a result of pulmonary fibrosis.[94]

Involvement of the CNS, severe lung disease, and a high band neutrophil count have been identified as negative prognostic factors.[90,109,121] In another study where dogs with blastomycosis were followed for 5 years, serum 25-hydroxyvitamin D concentration and radiographic evidence of pulmonary involvement did not appear to influence prognosis,[92] but increased serum lactate concentration; bone, skin, and lymph node involvement; number of affected sites; and the presence of respiratory signs were associated with survival. In another study, the median band neutrophil count in dogs that did not survive was 1,200 cells/μL (range, 0 to 3,980 cells/μL), whereas that in survivors was 0 cells/μL (range, 0 to 2,380 cells/μL).[90] In that study, 63% of 125 dogs with blastomycosis survived. The prognosis for survival in animals with neurologic involvement is particularly poor. The prognosis for resolution of endophthalmitis is also poor; only 20% of eyes with endophthalmitis respond favorably to antifungal drug treatment.[85] Nevertheless, eyes that do not undergo enucleation can ultimately progress to phthisis bulbi after completion of treatment, without recurrence of systemic infection.[85]

IMMUNITY AND VACCINATION

Immunity to blastomycosis is initially dependent on phagocyte function, especially neutrophils and alveolar macrophages, which can clear conidia. However, once the organisms have transitioned to the yeast form, control of infection also depends on T cells, which stimulate macrophages to kill the yeasts.[115] Humoral immunity is not essential for resolution of infection.

An experimental vaccine that includes a genetically engineered, live-attenuated BAD-1 deletion mutant *B. dermatitidis* strain protected mice from experimental infection. This vaccine was documented as being safe in 25 beagles and 78 foxhounds in a field trial and induced specific immune responses to *B. dermatitidis* antigens.[122,123] Although further study is required, this vaccine holds promise for prevention of blastomycosis in dogs that reside in hyperendemic regions of the United States.

PREVENTION

Avoidance of specific foci of hyperendemicity where other dogs or humans have contracted blastomycosis may prevent blastomycosis, but this is not always possible.

PUBLIC HEALTH ASPECTS

Like dogs, humans acquire *Blastomyces* spp. infection from the environment. Dogs are considered sentinels for human exposure and infection,[47] although whether strains that infect dogs also infect humans requires further study. The incidence of blastomycosis in dogs is approximately eight times that in humans, and disease has been reported in humans and dogs that reside in the same household.[41,47] Approximately 50% of human infections are asymptomatic.[115] When illness develops, it typically occurs 30 to 45 days after exposure and is often a mild, self-limiting influenza-like illness with fever and

cough. Blastomycosis is suspected in endemic areas when respiratory signs persist and fail to respond to treatment with antibacterial drugs. Radiographic abnormalities resemble those in dogs, although hilar lymphadenomegaly is not often seen. Chronic pulmonary blastomycosis can resemble pulmonary neoplasia or tuberculosis. Rarely, blastomycosis-associated ARDS develops, which is associated with a 75% mortality rate.[115,124] Dissemination to extrapulmonary sites similar to those involved in dogs occurs in 20% to 25% of affected humans. Skin lesions are common and are classified as either verrucous or ulcerative (Fig. 80.11A and B); bone involvement is reported in up to one fourth of cases. Although dissemination occurs equally among immunocompromised and immunocompetent humans, more severe infections with higher mortality rates can occur in immunocompromised patients such as those with AIDS, solid organ transplant recipients, and humans treated with TNF-α blockers (used to treat inflammatory diseases such as Crohn's disease, psoriasis, and rheumatoid arthritis).[115,124–127] Overall case fatality rates have ranged from 6% to 22%, and men are predisposed, possibly as a result of increased likelihood of exposure.[46] At the time of writing, blastomycosis is reportable in Arizona, Louisiana, Michigan, Minnesota, and Wisconsin.[128]

Inoculation blastomycosis that involves the skin and underlying bone has been described in veterinary personnel after sharps injuries or bite wounds from dogs with blastomycosis. One involved a needlestick injury after a lung aspirate in a dog with suspected blastomycosis, and another was an accident that occurred during a necropsy.[129,130] Bite wounds from dogs with blastomycosis can result in localized disease; disseminated disease occurred in a renal transplant recipient.[131–133] A veterinary technician developed pulmonary blastomycosis after *Blastomyces* spp. was cultured unexpectedly in a veterinary clinic in-house laboratory.[134] Although these routes of transmission are rare, prevention of sharps injuries, avoidance and proper management of bite wounds, and use of accredited veterinary laboratories for isolation of microorganisms from dogs and cats may reduce the risk of inoculation or laboratory-acquired blastomycosis in veterinary staff. The bandaging of skin lesions has been discouraged because it has the potential to promote transition of the organism to the mold form, but this has not been documented to occur. The body of deceased pets with blastomycosis should be disposed of promptly and by cremation.

Fig. 80.11 Verrucous (A) and ulcerative (B) skin lesions in human patients with disseminated blastomycosis. (A, From Callen JP, Greer KE, Paller AS, Swinyer LJ: Color Atlas of Dermatology, ed 2, Philadelphia, 2000, Saunders. B, From Bradsher RW. Blastomycosis. CASE EXAMPLE

Signalment

"Sam," a 3-year-old male neutered golden retriever from Burlingame in northern California.

History

Sam was evaluated by the Veterinary Emergency and Critical Care Service at the University of California, Davis, for pulmonary blastomycosis, which had been diagnosed at a local veterinary clinic. Sam had a 1-week history of lethargy and inappetence. The day after illness was noted, Sam was taken to a local veterinary clinic. Routine blood work showed only anemia (hematocrit 34%), thrombocytosis (554,000 platelets/μL), and a mildly increased serum ALP activity (199 U/L). Thoracic radiographs showed hilar lymphadenomegaly, a mild diffuse miliary interstitial pattern, and focal alveolar infiltrates in the right cranial and left caudal lung lobe. Cytologic examination of a transtracheal lavage specimen showed pyogranulomatous inflammation with moderate numbers of yeasts that had morphology consistent with *Blastomyces* spp.. Serology (AGIG) for detection of antibodies to *Blastomyces* spp. was negative. Treatment with itraconazole (5 mg/kg, PO, q24h) was commenced, and after 2 days the dose was increased to 10 mg/kg, PO, q24h due to lack of clinical improvement. Subsequently, the dog's rectal temperature increased to 105°F (40.6°C) and a day later, radiographs showed an increase in the severity of the alveolar infiltrates. Treatment with carprofen (2.4 mg/kg, PO, q12h) was initiated, and subcutaneous fluids were administered. This was associated with resolution of pyrexia, but the dog remained lethargic and exercise intolerant, and the owners noted right pelvic limb lameness. The dog was referred for further evaluation.

Approximately 6 weeks before he became ill, Sam had been taken to Georgian Bay in Ontario, Canada, for 1 week. He had also been in the Vermont region for 2 months before that time. Other travel had been limited to various bayside and mountainous parts of northern California. The owner's brother's dog, which had traveled with Sam to Ontario and Vermont, had also been diagnosed with blastomycosis 3 weeks earlier.

Physical Examination

Body weight: 41.5 kg.

General: Quiet, alert, and responsive. T = 103.5°F (39.7°C), HR = 120 beats/minute, panting, CRT < 2 seconds, mucous membranes were moist and slightly cyanotic.

Eyes, ears, nose, and throat: No clinically significant abnormalities were detected. A fundoscopic examination with dilated pupils was unremarkable.

CASE EXAMPLE—cont'd

Musculoskeletal: BCS 4/9; no obvious lameness or pain on palpation was appreciated.

Respiratory: Increased respiratory effort was present. Lung sounds were increased diffusely on thoracic auscultation and partially obscured the heart sounds. Markedly increased respiratory effort was evident when the dog's gait was assessed as part of an orthopedic examination. An intermittent nonproductive cough was also appreciated.

All other systems: No clinically significant abnormalities were detected. No obvious neurologic deficits were noted, but a full neurologic examination was not performed.

Laboratory Findings

Blood oxygen saturation (pulse oximetry) = 91%, improved to 95% with flow-by supplemental oxygen.

CBC: HCT 37.3% (40%–55%), MCV 71.2 fL (65–75 fL), MCHC 35.1 g/dL (33-36 g/dL), WBC 14,640 cells/μL (6,000–13,000 cells/μL), neutrophils 11,273 cells/μL (3,000–10,500 cells/μL), band neutrophils 586 cells/μL, lymphocytes 1,318 cells/μL (1,000–4,000 cells/μL), monocytes 1,318 cells/μL (150–1,200 cells/μL), eosinophils 146 cells/μL (0–1,500 cells/μL), platelets 387,000 platelets/μL (150,000–400,000 platelets/μL).

Rare slight toxicity of band neutrophils was reported.

Serum chemistry profile: Sodium 148 mmol/L (145–154 mmol/L), potassium 5.0 mmol/L (4.1–5.3 mmol/L), chloride 116 mmol/L (105–116 mmol/L), bicarbonate 15 mmol/L (16–26 mmol/L), phosphorus 6.6 mg/dL (3.0–6.2 mg/dL), calcium 9.9 mg/dL (9.9–11.4 mg/dL), BUN 11 mg/dL (8–21 mg/dL), creatinine 0.5 mg/dL (0.5–1.6 mg/dL), glucose 81 mg/dL (60–104 mg/dL), total protein 5.6 g/dL (5.4–7.4 g/dL), albumin 1.8 g/dL (2.9–4.2 g/dL), globulin 3.8 g/dL (2.3–4.4 g/dL), ALT 15 U/L (19–67 U/L), AST 32 U/L (21–54 U/L), ALP 148 U/L (15–127 U/L), GGT 0 U/L (0–6 U/L), cholesterol 318 mg/dL (135–345 mg/dL), total bilirubin 0.4 mg/dL (0–0.4 mg/dL).

Urinalysis: SpG 1.015; pH 5.0, no protein (SSA), 1+ bilirubin, no hemoprotein, no glucose, no WBC, rare RBC/HPF, rare transitional epithelial cells, and a few amorphous crystals were seen.

Imaging Findings

Thoracic radiographs: A nodular soft tissue pattern was present diffusely throughout all lung lobes, which coalesced to alveolar infiltrates in the left caudal lung lobe and right cranial lung lobe (Fig. 80.12). The cardiac silhouette was mildly enlarged. Increased soft tissue opacity was noted in the perihilar region.

Abdominal ultrasound: The spleen was mildly enlarged, and there was mild mesenteric lymphadenopathy.

Diagnosis

Acute, severe pulmonary blastomycosis.

Treatment

Sam was placed in an oxygen cage with an inspired oxygen concentration (FiO_2) of 40% to 60%. An arterial blood gas revealed a pH of 7.301, pCO_2 of 36.6 mmHg, pO_2 of 79.1 mmHg, HCO_3 of 16.8 mmol/L, base deficit of 7.8 mmol/L, and measured O_2 saturation of 92.8%. The dog was also treated with crystalloid fluids (lactated Ringer's solution with 20 mEq/L KCl; 80 mL/hr, IV) and nebulization and coupage (q6h). For the first 24 hours, respiratory rate ranged from 90 to 105 breaths/minute and a nonproductive cough occurred every few hours. The dog drank water, but was inappetent. Treatment with lipid-complexed AMB was initiated (1 mg/kg, IV, on a Monday-Wednesday-Friday basis) and carprofen administration continued. By day 4, Sam was afebrile, eating, and oxygen saturation was 96% with FiO_2 of 46%. However, increased respiratory effort developed when oxygen supplementation was discontinued, and arterial blood gas analysis showed a pH of 7.335, pCO_2 of 27.2 mmHg, pO_2 of 65.8 mmHg, HCO_3 of 13.9 mmol/L, and base deficit of 10.6 mmol/L (room air). By day 5, Sam was playing with toys in the oxygen cage, and his appetite was excellent. Treatment with itraconazole (5 mg/kg, PO, q24h) was resumed in addition to the AMB. By day 8, oxygen saturation was 95% with FiO_2 of 30%. Thoracic radiographs showed persistent radiographic abnormalities, organization of the alveolar infiltrates, and apparent bronchiectasis. Survey radiographs of the appendicular skeleton showed no evidence of osteomyelitis. The dog was discharged after 11 days of hospitalization (cumulative AMB dose of 6 mg/kg). An additional seven treatments of AMB were then administered at the local veterinary clinic. Serial renal panels showed no evidence of nephrotoxicity.

At a recheck 1 month after the date of first evaluation, Sam remained somewhat lethargic and exercise intolerant, but had gained 3 kg. The frequency of cough had decreased from approximately eight times a day to once or twice daily over the previous 2 weeks. An arterial blood gas showed a pO_2 of 93.5

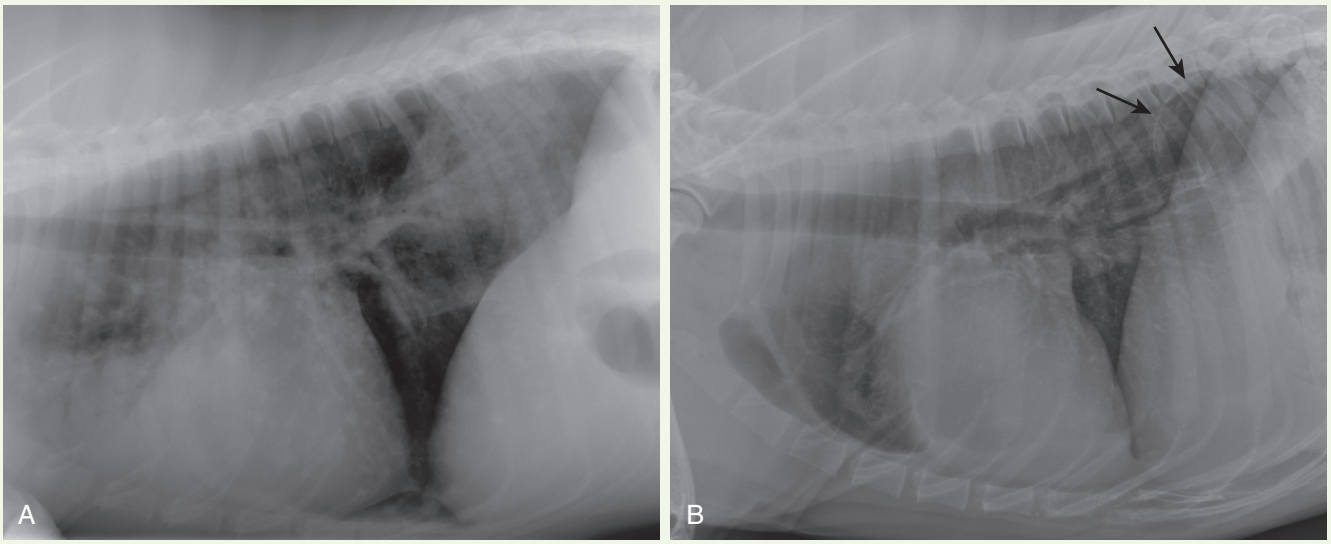

Fig. 80.12 Lateral thoracic radiographs from a young adult male neutered golden retriever with blastomycosis. (A) A nodular soft tissue pattern is present diffusely throughout all lung lobes, which coalesces to alveolar infiltrates in the left caudal lung lobe and right cranial lung lobe. (B) Residual pulmonary infiltrates are present in the right cranial lung lobe after 14 months of itraconazole treatment. There is also a large bulla in the left caudal lung lobe *(arrows)*. (From Sykes JE. *Canine and Feline Infectious Diseases*. Elsevier; 2014.)

Continued

CASE EXAMPLE—cont'd

mmHg, hematocrit was 27.8% with 39,400 reticulocytes/μL, and there was persistent hypoalbuminemia (2.0 mg/dL) and hyperglobulinemia (4.8 mg/dL). There was mild radiographic improvement in the pulmonary lesions. Treatment with itraconazole was continued for an additional 14 months, with serial monitoring of thoracic radiographs at 1, 2, 3, 8, and 14 months. At the 14-month time point, Sam had returned to his normal energetic self, weighed 45 kg, but had persistent mild infiltrates in the right cranial lung lobe on thoracic radiographs and a bulla in the left cranial lung lobe. There was also a mild to moderate generalized interstitial pattern with multiple small soft tissue opaque nodules that had not changed from the previous evaluation. One month after the itraconazole was discontinued, thoracic radiographs remained unchanged. Relapse did not occur. Sam was ultimately euthanized at 8 years of age as a result of an unrelated neoplastic disease.

Comments

This case is an example of acute pulmonary blastomycosis that followed travel to an endemic area. Another dog that traveled to the same area also developed disease. Sam appeared to require more aggressive therapy than itraconazole alone, so AMB was instituted, which was followed by gradual recovery from the infection. Although lipid-complexed AMB was used, treatment with deoxycholate AMB may also have led to cure. No evidence of dissemination was clearly identified. The lameness observed by the client may have represented weakness or exercise intolerance, but it is possible that bone involvement was present but not evident radiographically. The case also illustrates the residual pulmonary lesions that can develop in dogs with pulmonary blastomycosis, and the need for serial radiographic evaluations to assess these lesions. Although not performed in this dog, serial monitoring of antigenuria may also ultimately help determine the most appropriate time to discontinue therapy.

Histoplasmosis

Krystle L. Reagan, Jane E. Sykes

KEY POINTS

- Cause: *Histoplasma capsulatum* (phylum Ascomycetes).
- First Described: 1905, Panama (Samuel Darling), where it was initially mistaken for a protozoal pathogen in a person from Martinique.[1]
- Affected Hosts: Many mammals, including dogs, cats, and humans.
- Geographic Distribution: Worldwide, but especially the Ohio and Mississippi river valleys of the United States, and Latin America.
- Route of Transmission: Inhalation of microconidia in the environment.
- Major Clinical Signs: Cough, tachypnea, organomegaly, GI signs, pallor.
- Differential Diagnoses: Other deep mycoses, mycobacterial infections, hemic neoplasia, leishmaniosis.
- Human Health Significance: *Histoplasma capsulatum* also causes disease in humans, but direct transmission from animals to humans does not occur.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Histoplasma capsulatum is a dimorphic, soil-borne fungus that is found worldwide, but especially in the Mississippi and Ohio river valleys of the United States (Midwest and south-central) as well as in Latin America (Fig. 81.1). Disease has also been diagnosed in cats or dogs from other parts of the United States (northern and southern California, Texas, Colorado), Brazil, Thailand, Italy, Australia (Queensland), Japan, and eastern Canada (New Brunswick).[2–11] At least eight clades of the organism have been identified by genetic analysis: North American classes 1 and 2 (NAm1 and NAm2), Latin American groups A and B (LAmA and LAmB), and one each of Australian, Netherlands, Eurasian, and African, which appear to vary in virulence. A ninth clade, closely related to the North American class 1, was identified in cats with histoplasmosis from California, Texas, and Colorado.[2] Further divergent clades with the Latin American groups have also been described.[12] Three different variants have also been described based on pathogenicity and morphology, *H. capsulatum* var. *capsulatum*, *H. capsulatum* var. *duboisii*, and *H. capsulatum* var. *farciminosum*.[11,13] *Histoplasma capsulatum* var. *duboisii* occurs primarily in Africa and Japan. *Histoplasma capsulatum* var. *farciminosum* infections occur primarily in horses, but have also been reported in humans and dogs.

Histoplasma capsulatum grows best in soil as a mycelium (*Ajellomyces capsulatum*) where temperatures are between 22°C and 29°C, with an annual rainfall of 35 to 50 inches, and a relative humidity of 67% to 87%—conditions typically found between latitudes of 45° north to 30° south.[14] *Histoplasma capsulatum* can be found in the intestinal tract and guano of bats, which constitute the primary reservoir of the organism and serve to disseminate it geographically.[15] Bat caves can maintain perfect conditions for growth of *H. capsulatum*. Although *H. capsulatum* can be found in high concentrations in decaying avian guano (especially around blackbird or starling roosts and chicken coops), it is not found in fresh feces or shed in the feces of birds.

Cats appear to be as susceptible or slightly more susceptible to histoplasmosis than dogs. Affected cats can be as young as 2 months and in some cases, older than 15 years.[16] The mean age of affected cats in reported case series has ranged from 3.9 to 8.8 years.[17,18] For dogs, a mean age of 3 to 4.3 years has been reported,[19,20] and dogs in the 2- to 4-year and 4- to 7-year age groups were more likely to develop histoplasmosis than dogs less than 2 years of age.[21] Sporting or working dogs may be at greater risk of infection as a result of increased likelihood of exposure; in a study that utilized the Veterinary Medical Database, pointers were strongly over-represented.[21] Weimaraners and Brittany spaniels were also at increased risk. Persian cats were slightly over-represented in another study. A sex predisposition has not been clearly identified in dogs or cats, but more female than male dogs were affected in some case series.[18–20,22–24] This contrasts to human histoplasmosis, which tends to affect males. Most affected cats are retrovirus negative, but a significant percentage of cats in two studies (16% and 28%) were co-infected with FeLV.[16,18] A small percentage of affected cats have underlying comorbidities such as lymphoma, FIP, or a history of treatment with glucocorticoids.[16] Comorbidities described in dogs include dirofilariasis[19] and metastatic carcinoma.[11] Disease can occur in animals housed exclusively indoors.[25]

CLINICAL FEATURES

Pathogenesis and Clinical Signs

In the soil, the mycelial phase of *H. capsulatum* forms macroconidia and microconidia (Fig. 81.2), which are environmentally resistant. The microconidia are believed to be the form inhaled by mammalian hosts, because they are small enough (2 to 5 μm) to enter the terminal bronchioles and alveoli. Within the lungs (i.e., at a temperature of 37°C), the microconidia transition to a unicellular yeast phase, which replicates by budding. The incubation period is approximately 2 to 3 weeks.[26] Heat shock proteins on the fungus bind to CD11-CD18 integrins on alveolar macrophages, and receptor-mediated phagocytosis results in fungal entry to pulmonary macrophages.[27,28] The organism then replicates within these cells through control of the phagolysosomal environment by raising the intracellular pH with urease, ammonia, and bicarbonate, and evades the host immune response.[29] The organism further evades detection of the host immune system by altering the cell membrane by synthesizing α-linked glucans to conceal β-glucans. The β-glucans are typically present at high levels within the

fungal cell membrane and are PAMPs that trigger a proinflammatory response from the macrophage.[30,31] The organism ultimately destroys the cells, with subsequent replication in other resident alveolar macrophages and inflammatory phagocytes that are recruited to the lung.[28] Acquisition of iron by the fungus is essential for growth *in vivo*.[32]

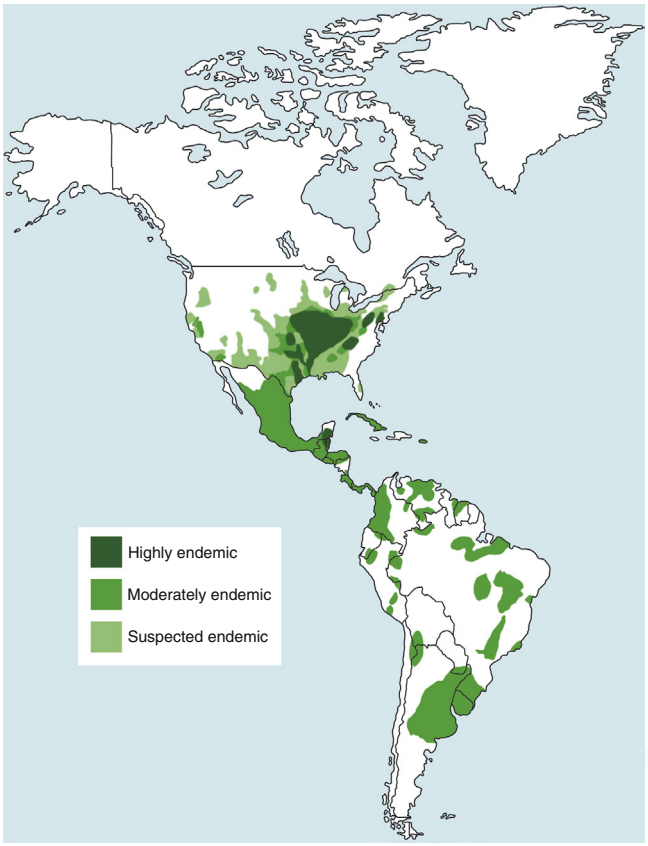

Fig. 81.1 Approximate geographic distribution of histoplasmosis in the Americas.

Cell-mediated immune responses (especially mediated by CD4+ cells, IFN-γ, and TNF-α) lead to the death of infected macrophages and are critical for early control and clearance of infection. There have been several reports of disseminated histoplasmosis in human patients in association with co-infections with HIV infection and COVID-19.[33,34]

Some animals control the initial infection but remain latently infected with small numbers of yeasts. Subsequent immune suppression with medications or secondary to other disease processes such as *Ehrlichia canis* infection or neoplasia can lead to reactivation of infection years later. Thus, the apparent incubation period may be as long as several years.

The clinical manifestations and rate of disease progression depend on the host immune response to infection, which varies both between and within host species (e.g., dog versus cat); the infectious dose; and the *Histoplasma* strain, which can vary geographically. The vast majority of infections are probably subclinical.[35] Replication of the organism leads to a granulomatous inflammatory response in the lungs, which consists primarily of macrophages and variable numbers of lymphocytes. Occasionally, the inflammatory response is followed by the development of fibrosis and scarring. Yeast forms migrate to local lymph nodes (such as the hilar lymph node) and other tissues that contain mononuclear cells, such as the liver and spleen. When CMI is defective or absent, this results in disseminated disease (referred to in human patients as *progressive disseminated histoplasmosis* [PDH]). PDH may be acute, subacute, or chronic.[36] In addition to lymph nodes, liver, and spleen, common sites of dissemination include the bone marrow, small and/or large intestinal tract, the skin, bones, central nervous system, and eye. Dogs with histoplasmosis in the United States appear to be particularly susceptible to intestinal involvement.

Clinical signs in cats are commonly vague and nonspecific, such as weight loss, decreased appetite, weakness, dehydration, and fever.[16–18] Approximately 40% of cats show respiratory signs due to pulmonary involvement such as dyspnea and tachypnea, and to a lesser extent cough and nasal discharge. However, respiratory signs may be absent in some cats with dissemination of infection to nonpulmonary sites. Tachypnea and dyspnea were also described in a cat with a cranial mediastinal mass.[37] Ocular signs occur in approximately one quarter

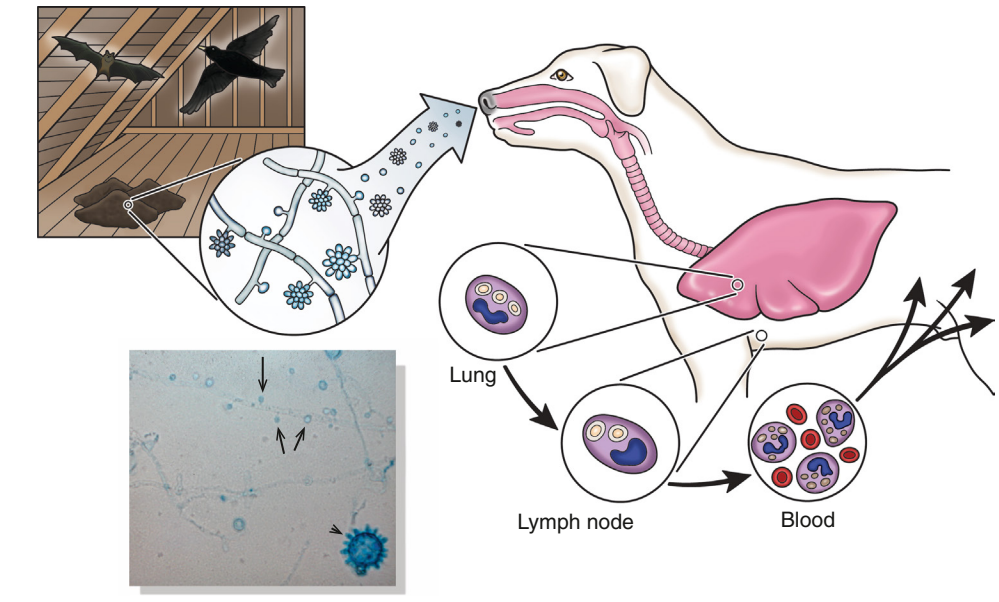

Fig. 81.2 Life cycle of *Histoplasma capsulatum*. In the environment, the organism forms macroconidia *(arrowhead, inset)* and microconidia *(arrows, inset)*. The microconidia are thought to be inhaled into the lungs of mammalian hosts. Within the lung, the organisms transform into yeasts that infect alveolar macrophages and then disseminate to the local lymph nodes and the systemic circulation.

of cats with histoplasmosis. Around 20% of cats have signs of skeletal involvement, usually lameness, which often involves multiple limbs.[16–18,22,38] Skin lesions, peripheral lymphadenopathy, vomiting, diarrhea, oral ulceration, myelopathy, and/or hematuria due to bladder wall involvement have also been reported.[15,17,18,22,39–45] A high proportion of affected cats that were necropsied had evidence of severe disseminated disease.[16]

In dogs, diarrhea, decreased appetite, weight loss, lethargy, fever (up to 40°C or 104°F), and mucosal pallor are the most common clinical signs.[9,10,19,20,23] In addition to decreased appetite, weight loss, and diarrhea, other clinical signs referable to the GI tract include melena, tenesmus, hematochezia, dyschezia, and/or increased frequency of defecation.[10,19,23] Profuse diarrhea may be chronic and may persist for several months. Hilar lymphadenomegaly may be severe and contribute to signs of cough in some dogs. Other signs include respiratory difficulty, icterus, vomiting, hepatomegaly, lymphadenomegaly, nasal discharge, epistaxis, ocular signs, polyuria and polydipsia, lameness due to osteomyelitis, and neurologic signs such as seizures.[10,19,20,46–48] Affected dogs in Japan have had chronic cutaneous or gingival lesions in the absence of pulmonary or GI involvement,[49–52] although disseminated disease has also been described.[11] Skin nodules were also reported in an Australian dog with histoplasmosis.[4] Varied clinical manifestations of histoplasmosis in different parts of the world have also been reported in humans as a result of strain variation in *H. capsulatum.*

Physical Examination Findings

Physical examination findings in affected cats include thin body condition or emaciation; fever; pale and/or rarely icteric mucous membranes; peripheral lymphadenopathy; respiratory signs such as respiratory distress, tachypnea, and increased or decreased lung sounds; single or multiple cutaneous nodules, ulcerations, and/or draining tracts; lameness; and detection of organomegaly, abdominal masses, and/or pain on palpation of the abdomen. Cats with musculoskeletal involvement may have evidence of swelling/effusion in one or more joints, especially the carpus and tarsus.[17] Ocular signs include blindness, masses, or thickening of the conjunctiva or nictating membrane, chorioretinitis, optic neuritis, anterior uveitis, retinal detachment, panophthalmitis, and glaucoma (Fig. 81.3).[53]

In dogs, lethargy, fever, thin body condition, and pale mucous membranes are found most often on physical examination. Other physical examination abnormalities include dehydration, hepatomegaly, icterus, and ascites; tachypnea, increased respiratory effort, and increased lung sounds; lymphadenomegaly that involves one or more peripheral lymph nodes; abnormal stool quality on rectal examination (diarrhea, hematochezia, or melena); nasal and ocular discharge; tachycardia; tongue lesions; and cutaneous nodules, ulceration, or draining tracts.[4,10,19,23,46,54,55] Ocular examination may reveal uveitis, evidence of optic neuritis, or chorioretinitis with retinal detachment.[23,56,57] One dog was seen for lameness, hyperemia, and edema of the left pelvic limb because of a sclerosing pyogranulomatous inflammatory mass in the inguinal region that resulted in venous occlusion.[54] Rarely neurologic signs such as ataxia, obtundation, head tilt, nystagmus, strabismus, seizures, facial paralysis, and tetraparesis may be present on physical examination as a result of hepatic encephalopathy or meningoencephalitis.[57–59]

DIAGNOSIS

Laboratory Abnormalities

Complete Blood Count

The CBC in dogs and cats with histoplasmosis reflects the presence of systemic inflammation, GI hemorrhage, and/or bone marrow infiltration by fungal organisms. In both dogs and cats, anemia is a common abnormality on the CBC, may be mild to severe, and is usually normocytic, normochromic, and nonregenerative.[17–20,22,23,60,61] Increased numbers of nucleated erythrocytes have been reported in some affected dogs.[10,61] The total white cell count or neutrophil count may be normal, increased, or decreased.[19,22,23] Most affected cats have a normal or decreased white cell count,[18,60] but leukocytosis due to neutrophilia and monocytosis may be more common in affected dogs.[19,61] Increased numbers of band neutrophils with toxic neutrophils, lymphopenia, monocytopenia, and thrombocytopenia may be present in some severely affected animals.[17,18,22,23,60,62] Thrombocytopenia may be a result of platelet consumption, sequestration, and/or myelophthisis. Rarely, eosinophilia is present.[63]

Serum Chemistry Profile

Mild to severe hypoalbuminemia is present in most (>75%) of affected dogs and cats.[20] Cats with hepatic involvement may have

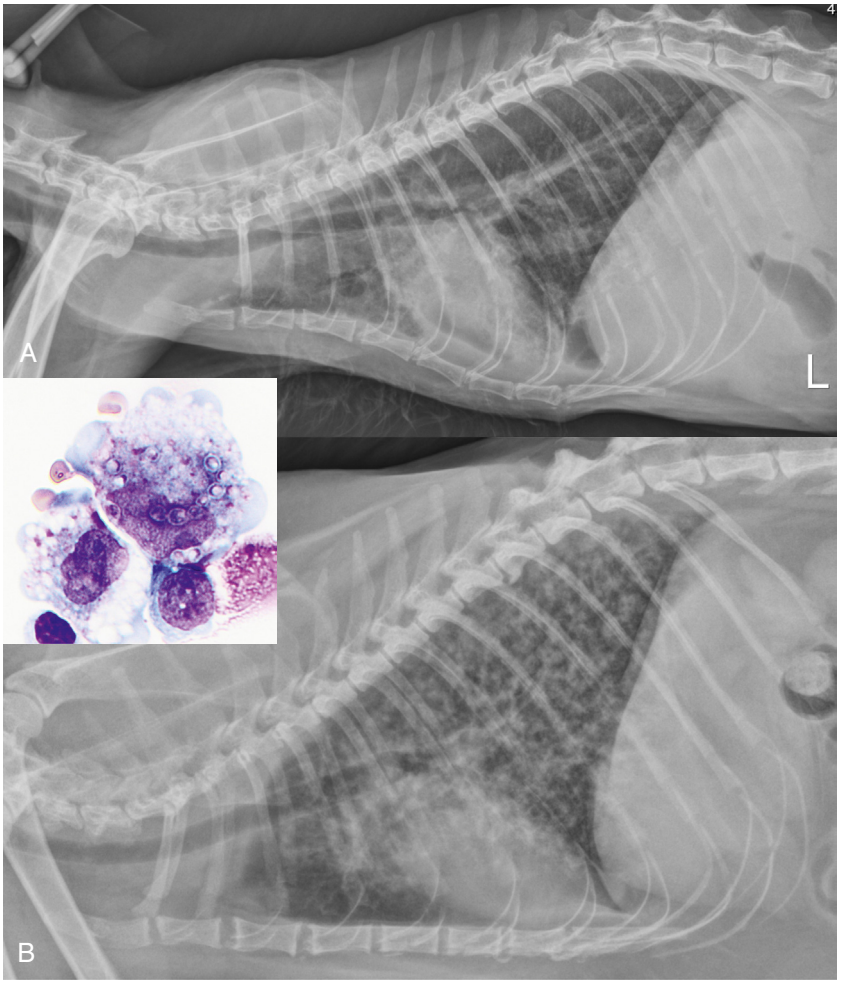

Fig. 81.4 Radiographic abnormalities in feline pulmonary histoplasmosis. (A) Lateral thoracic radiograph from a 12-year-old female spayed domestic longhair cat with disseminated histoplasmosis. There is a diffuse bronchointerstitial pulmonary pattern with an alveolar pattern ventrally, and bicavitary effusion. In the viewable abdomen, hepatomegaly can be appreciated. Cytologic analysis of pleural fluid revealed oval organisms consistent with *Histoplasma* spp. (inset). (B) Lateral thoracic radiograph from a 9-year-old male neutered Siamese cat with disseminated histoplasmosis that was evaluated for lethargy, inappetence, and weight loss of one-month duration. There is a diffuse, severe, nodular interstitial pattern. (Images courtesy University of California-Davis Veterinary Diagnostic Imaging, Small Animal Internal Medicine, and Clinical Pathology Services).

increased activities of serum ALT and AST.[22,60] Hyperbilirubinemia and increased ALP are sometimes reported.[17,22] Hypercalcemia and hyperglobulinemia have been described in a few affected cats.[17,22] Hyperglobulinemia, mild to moderate increases in the activity of serum ALT, AST, ALP, and GGT, and hyperbilirubinemia may be found in dogs.

Urinalysis

Results of urinalysis are usually within normal limits, but low urine specific gravity and bilirubinuria may be present in dogs with hepatic involvement.

Clotting Function

A few dogs with acute PDH have had coagulation abnormalities characterized by increased PT and PTT and fibrin degradation product or D-dimer concentrations.[47,61] Coagulation abnormalities in dogs with histoplasmosis may result from DIC and possibly severe hepatic involvement (see also Case Example).

Diagnostic Imaging

Plain Radiography

In cats, plain thoracic radiographic findings in histoplasmosis usually consist of diffuse, linear, nodular or miliary interstitial patterns, but mixed interstitial-alveolar-bronchial patterns and an absence of abnormal findings have also been described.[17,18,20,24,60,64] Plain thoracic radiographs in dogs may show an alveolar, interstitial, and/or bronchial patterns, tracheobronchial lymphadenomegaly, lung lobe consolidation, and/or rarely pleural effusion (Fig. 81.4).[47,62,64,65] Lesions can sometimes calcify, which does not seem to be the case in cats. Abdominal radiographs may show hepatomegaly, splenomegaly, or decreased serosal detail due to ascites. Radiographic evidence of osteomyelitis (usually osteolytic lesions) or joint involvement

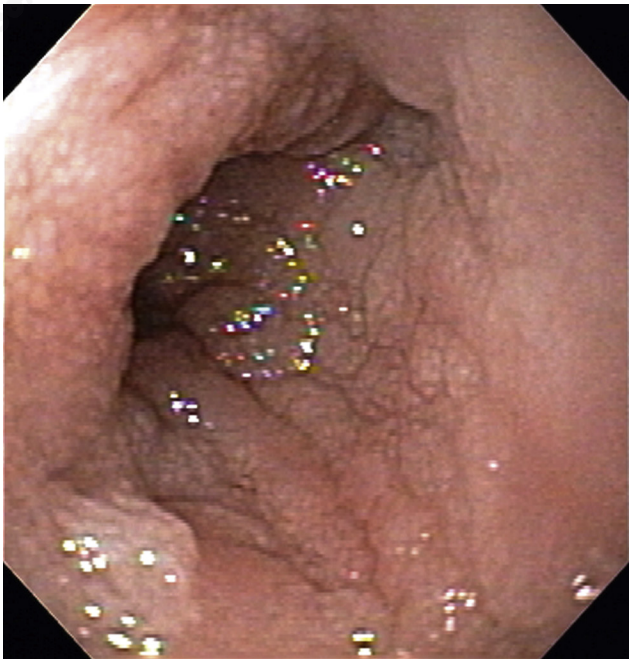

Fig. 81.5 Colonoscopy image from a dog with disseminated histoplasmosis with large intestinal involvement. The mucosa is thickened and granular. (Courtesy Dr. Michael Willard, Texas A&M University.)

(extracapsular and/or extracapsular swelling) may be present in cats, sometimes accompanied by pathologic fractures.[17] Osteomyelitis is rarely described in dogs.[46,48]

Sonographic Findings

Findings on abdominal sonographic examination of dogs with histoplasmosis have included enlargement and hypoechogenicity of the liver, abdominal lymphadenopathy, splenomegaly, and peritoneal effusion.[66] A thickened intestinal wall (most commonly the colon) may be present with disruption of bowel wall architecture.[66] Adrenomegaly, abdominal lymphadenomegaly, splenomegaly, and occasionally renomegaly have also been described in cats.[18,67]

Endoscopy

Colonoscopic findings in dogs with colonic histoplasmosis include irregularity, ulceration, increased granularity, and friability of the colonic wall (Fig. 81.5).

Magnetic Resonance Imaging

MRI may reveal mass lesions that are T1 and T2 isointense with contrast enhancement, as described in a dog with an extradural spinal cord lesion.[68]Although chronic meningitis is the most common manifestation of CNS involvement in humans,[36] ring-enhancing granulomatous mass lesions within the brain (histoplasmomas) have been described in affected people.[69]

Microbiologic Tests (Table 81.1)

Cytologic Examination

Histoplasma yeasts are usually seen extracellularly and intracellularly (usually within mononuclear phagocytes) on staining and cytologic examination of aspirates or impression smears of affected tissues (e.g., fine-needle aspirates of liver, spleen, lymph nodes, lung, bone marrow), rectal scrapings, or cytospin preparations of lung wash specimens or body fluids (e.g., CSF, synovial fluid, ascites, or pleural effusion). The accompanying inflammatory response may be pyogranulomatous, granulomatous, or suppurative. Occasionally one or more organisms are visualized in circulating monocytes, neutrophils, or eosinophils in severely ill animals with disseminated disease. Cytologic evidence of fungemia was detected in nearly 20% of affected cats in one study.[16] The yeasts are 2 to 4 µm in diameter, oval, have a basophilic center, and are surrounded by a clear halo, which results from shrinkage artifact (Fig. 81.6). A variety of stains can be used, such as Diff-Quik and Wright stains. The organism is not encapsulated, even though its name implies the presence of a capsule. Organisms may not be identified within chronic, fibrosing lesions.[54,70]

Serologic Diagnosis

Both antibody and antigen (ELISA) assays are available for serodiagnosis of histoplasmosis. Antibody assays for *H. capsulatum* are based on gel immunodiffusion or complement fixation and have poor diagnostic sensitivity.[16,19,22] False positives reportedly occur in recovered animals, although the specificity of antibody assays in dogs and cats is not well documented. In human patients, acute and convalescent antibody testing is useful for diagnosis of acute pulmonary histoplasmosis, and a single antibody titer is used as an aid for diagnosis of chronic forms of histoplasmosis. In particular, antibody assay of the CSF can be useful for diagnosis of culture-negative chronic *H. capsulatum* meningitis.

An ELISA assay for *H. capsulatum* antigen (MiraVista Diagnostics, Indianapolis, IN, USA) is widely used in human patients for diagnosis of histoplasmosis, and urine is the preferred specimen for testing because it results in a higher sensitivity than when serum is assayed.[70] The use of the antigen assay has been applied for the diagnosis of histoplasmosis in cats and dogs.[54,71] In one study, the urine of 17/18 cats with confirmed histoplasmosis was positive, whereas none of 26 cats with alternate diagnoses tested positive.[71] At the time of diagnosis, the sensitivity of the assay was 93% when urine was used, and 73% when serum was used.[38] There have been several reports of cats with biopsy- or culture-confirmed histoplasmosis with false-negative test results, including cats with ocular, joint, and renal involvement.[17,53,72,73]

The assay has also been used to monitor response to therapy in cats. Elimination of antigen is sensitive (urine 90%, serum 90.4%) for remission, but not specific (urine 64%, serum 52%).[38] Monitoring of antigenemia or antigenuria after discontinuation of treatment can be used to detect early relapse.[38]

In dogs, one study found that urine antigen testing had a sensitivity of 89.5% and specificity of 100%.[74] Two dogs with false-negative test results had disease restricted to the GI tract.[74]

False-positive test results using the *Histoplasma* antigen test occur in human patients with other disseminated mycoses, including blastomycosis, penicilliosis, and coccidioidomycosis,[75,76] so the assay must always be used in conjunction with other diagnostic assays.

An in-house, antibody-based *H. capsulatum* antigen assay (IMMY, Normon, OK) has been investigated for use in cats. This assay was compared to the commercially available ELISA antigen (MiraVista Diagnostics, Indianapolis, IN) on urine specimens. The POC assay has a sensitivity of 77% to 89% and specificity of 80% to 97% depending on the cut-point utilized.[77]

Culture

Histoplasma capsulatum can be isolated from clinical specimens on routine fungal media. There is a risk of laboratory-acquired infection when the organism grows in the mycelial form on artificial media, so culture should only be performed if necessary and the laboratory should be warned of the possibility that infection with a dimorphic fungus may be present so that appropriate precautions are taken. Although most

TABLE 81.1 Diagnostic Assays Available for Histoplasmosis in Dogs and Cats

Assay	Specimen Type	Target	Performance
Cytologic examination	Aspirates of affected tissues, sometimes blood smears or buffy coat preparations, body fluids	*Histoplasma capsulatum* organisms in mononuclear phagocytes and granulocytes	Organisms are usually present but in the absence of experience, they may be confused with protozoa such as *Leishmania* or other fungi such as *Sporothrix schenckii*. False negatives can occur in animals with very chronic clinical manifestations.
Fungal culture	Aspirates or biopsies of affected tissues, body fluids	*H. capsulatum*	Sensitive and specific and may be required for animals with chronic histoplasmosis when cytologic examination is negative. Risk of laboratory-acquired infections. Slow turn-around time (several weeks of incubation may be required).
Antibody serology (CF or gel ID)	Serum	Antibodies to *H. capsulatum*	Positive test results indicate exposure but do not indicate active infection or correlate with clinical disease. Negative test results occur commonly in animals with histoplasmosis (low sensitivity).
Antigen assay (ELISA)	Urine, serum	*H. capsulatum* antigen	Commercial and in-house assays are available, and performance varies between the assays. The commercially available assay appears to be sensitive and specific in cats and dogs, but false-negative results can occur. An increased sensitivity is noted when urine is tested versus serum. Cross-reactivity with other fungal pathogens may occur, so positive results are not diagnostic for histoplasmosis.
Real-time PCR assays	Whole blood	*H. capsulatum* DNA	Not yet validated in adequate numbers of dogs or cats with histoplasmosis, usefulness requires further evaluation.
Histopathology	Biopsy specimens from affected tissues	*H. capsulatum* yeasts	Yeasts can be difficult to find in chronic infections. Special stains may assist organism detection.

CF, complement fixation; *ELISA,* enzyme-linked immunosorbent assay; *ID,* immunodiffusion; *PCR,* polymerase chain reaction.

cultures are positive within 2 or 3 weeks, growth may require up to 6 weeks of incubation. The organism is identified based on morphology.

Molecular Diagnosis Using Nucleic Acid–Based Testing

Real-time PCR assays have been developed for rapid detection of *H. capsulatum* in clinical specimens from affected humans,[78,79] but are not currently used routinely for diagnosis. The sensitivity of one assay was 73% when compared with culture of clinical specimens.[79] PCR assays have not been widely applied to the diagnosis of histoplasmosis in dogs and cats, and so further studies are required to determine their usefulness.

Pathologic Findings

Gross Pathologic Findings

Gross pathologic findings in dogs and cats with histoplasmosis consist of miliary nodules or larger focal lesions in the lungs and other organs, and enlarged lymph nodes, which may be mineralized in dogs with chronic disease. In dogs, the intestinal tract may be thickened and focal or diffuse hemorrhage may be present on the mucosal surface. The liver and spleen may be enlarged with rounded borders, and the liver may be mottled with a reticulated appearance. Pleural and peritoneal effusions are occasionally described.[62]

Histopathologic Findings

Histopathology yields pyogranulomatous or granulomatous inflammation with intralesional yeasts in a variety of organs (Fig. 81.7). Lymphocytes and plasma cells may be present, and in some dogs with chronic histoplasmosis, histologic evidence of fibrosis or calcification is apparent.[54,62] Special stains such as Gomori's methenamine silver or PAS may aid detection of the yeasts in tissues.

TREATMENT AND PROGNOSIS

Antimicrobial Treatment

Antifungal drugs with activity against *H. capsulatum* include the azole antifungal drugs ketoconazole, itraconazole, and fluconazole (see Chapter 11 for more information and dosing for antifungal drugs). Itraconazole and fluconazole are preferred to ketoconazole as they are more effective and less likely to cause toxicity.[22] In one study, remission rates in dogs were not different between those treated with fluconazole (64% remission) and itraconazole (71% remission)[20]; however, in human patients, itraconazole has consistently been more effective than fluconazole. Limited data suggest that posaconazole may be an effective salvage treatment in human patients with histoplasmosis that fails to respond to treatment with other antifungal drugs, which included

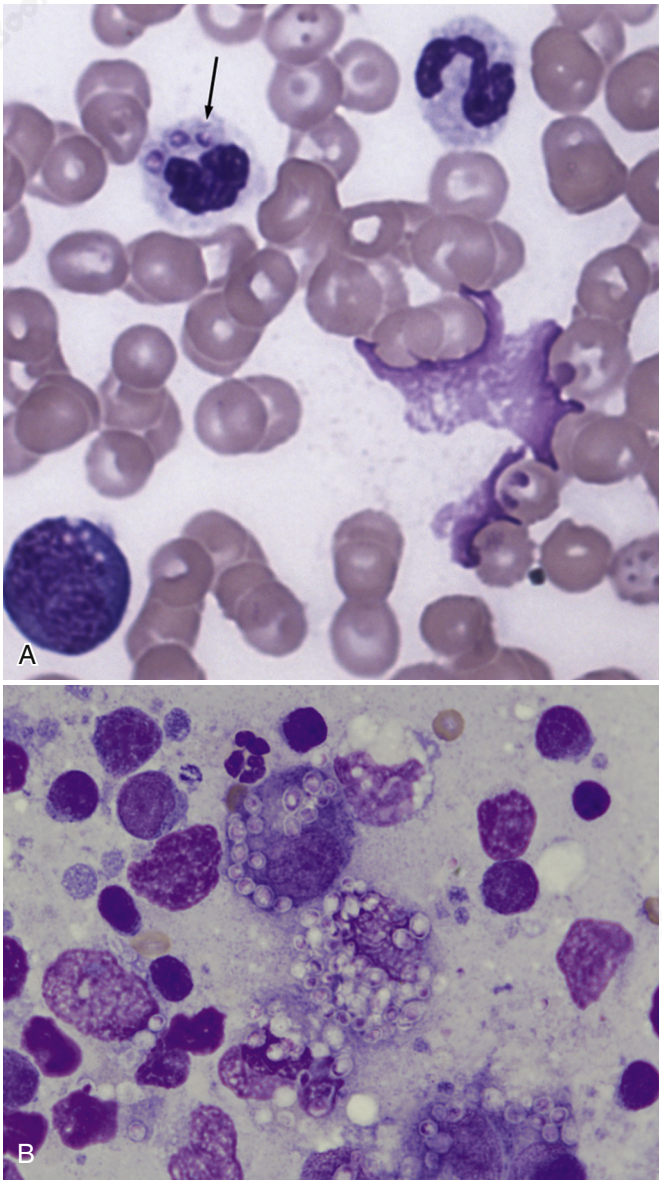

Fig. 81.6 (A) Blood smear from a dog with *Histoplasma capsulatum* fungemia. Three organisms can be seen in a circulating neutrophil *(arrow)*. Wright stain, 1000× magnification. (B) Fine-needle aspirate cytology from the right popliteal lymph node of the cat in Fig. 81.3A. There is pyogranulomatous inflammation with large numbers of intracellular yeast organisms with morphology consistent with that of *H. capsulatum*. Wright stain, 1000× magnification. (Courtesy Angela Royal, Louisiana State University.)

fluconazole, itraconazole, AMB, and voriconazole.[80] Development of resistance to fluconazole has been documented during treatment of cats and human patients with fluconazole.[81,82]

Deoxycholate or lipid AMB should be used initially to treat dogs or cats with severe acute pulmonary, acute disseminated, or CNS disease, after which treatment should be continued with itraconazole. If funds or patient factors do not permit itraconazole treatment, fluconazole can be used as a second-line agent.

The length of treatment and prognosis depends on the severity and chronicity of disease and the immune status of the host. At least 6 months of treatment is generally required. Many animals require treatment for 12 months or longer, and those with more chronic disease may require treatment for more than 2 years. The median duration of therapy for dogs in one study is 125 days for those treated with fluconazole and 182 days for those treated with itraconazole, which are not statistically different.[20] The decision to discontinue treatment should be based on lesion resolution (which may require serial imaging studies); resolution of positive urine antigen titers could also be used to decide when to discontinue treatment.[38] Relapse of disease after discontinuation of treatment is common, occurring in 10% to 40% of patients.[20,25,38]

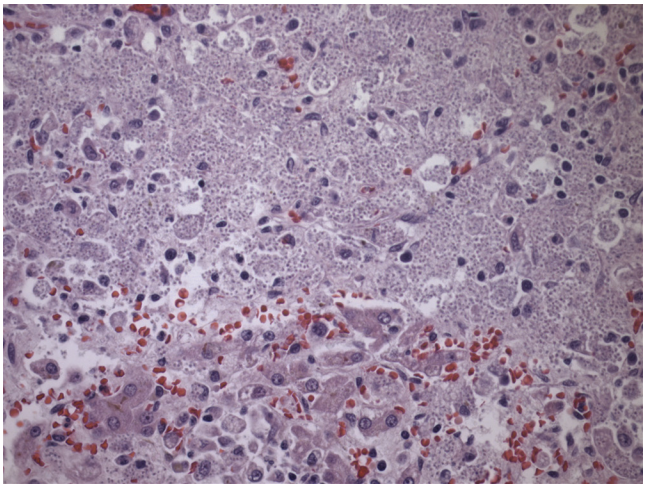

Fig. 81.7 Histopathology of the liver of a 5-month-old intact male redbone coonhound with disseminated histoplasmosis. There is severe granulomatous inflammation with massive numbers of intrahistiocytic yeast organisms.

Survival to hospital discharge for dogs and cats treated for histoplasmosis are 95% and 88% respectively.[20,83] Overall survival in cats treated for histoplasmosis is approximately 67%.[25,83] The need for supplemental oxygen delivery is a negative prognostic indicator in dogs and cats.[20,25] Additional negative prognostic indicators identified in dogs include hyperbilirubinemia, anemia, thrombocytopenia, and hypercalcemia.[20]

Supportive Treatment

Other supportive treatments that may be required depend on the extent of infection and include IV crystalloid fluids, supplemental oxygen, blood transfusions for severely anemic animals, nutritional support, antiemetics, and medications to manage consequences of hepatic failure such as hepatic encephalopathy. Enucleation may be required to manage persistent ocular infection and pain. The role of glucocorticoids for treatment of chronic manifestations of histoplasmosis is controversial, and they are not recommended for treatment of animals with active or disseminated histoplasmosis.

IMMUNITY AND VACCINATION

Immunity to *H. capsulatum* is dependent on a Th1 immune response. Production of IFN-γ and TNF-α activates macrophages to destroy the fungus.[36,84] There is no vaccine for prevention of histoplasmosis, but there is interest in development of a vaccine for at-risk human patients because of increasing incidence of the disease.[36]

PREVENTION

Prevention of histoplasmosis involves avoidance of bat caves and areas previously inhabited by avian species in endemic areas. Nevertheless,

histoplasmosis has occurred in animals housed exclusively indoors, and widespread exposure and recovery likely occurs in endemic areas.

PUBLIC HEALTH ASPECTS

As many as 80% of young adults in endemic areas have been previously infected by *H. capsulatum*, but less than 10% develop symptoms.[36,70] Risk factors identified for human histoplasmosis include exposure to soil disrupted as a result of excavation, exploration of caves inhabited by bats, or renovation of buildings inhabited by birds or bats. Males are predisposed.[36,85] Several forms of the disease have been described, which include acute pulmonary histoplasmosis, chronic pulmonary histoplasmosis (which may be cavitary or noncavitary), and acute or chronic PDH.[36] Complications of pulmonary histoplasmosis include granulomatous mediastinitis (characterized by enlargement and sometimes calcification of mediastinal lymph nodes, with compression of adjacent structures) or mediastinal fibrosis (characterized by fibrosis of caseous mediastinal lymph nodes). The clinical picture of disseminated histoplasmosis is similar to that described in dogs; rare clinical manifestations include meningitis, endocarditis, and vascular infections.[36,70] Humans with AIDS or those treated with immunosuppressive drugs (such as TNF antagonists) are at risk for severe, disseminated disease, and smokers are predisposed to chronic pulmonary histoplasmosis. The overall mortality rate in a 2018 study of 3,409 cases from the United States was 7%, with a hospitalization rate of 57%.[85] Itraconazole prophylaxis is considered for immunosuppressed patients who are at risk of the disease.[36]

Transmission from dogs or cats to humans has not been reported, but disease in dogs and cats may signal the potential for human infection as a result of exposure to the same source of infection in the soil; outbreaks have been described that involved both humans and dogs.[26] The bodies of deceased pets with histoplasmosis should be disposed of promptly and by cremation.

CASE EXAMPLE

Signalment

"Murphy," a 5-month-old intact male redbone coonhound from northern California.

History

Murphy was evaluated at the University of California, Davis Veterinary Medical Teaching Hospital, for a 1-week history of increased respiratory effort, hypersalivation, a single episode of vomiting, and lethargy. He was taken to a local veterinary clinic where he was found to have fever (103.2°F), pale mucous membranes, and a cranial abdominal mass on physical examination. Abdominal radiographs revealed moderate hepatomegaly and mild splenomegaly (available for review). He was treated with vitamin K, a single dose of injectable prednisone (2 mg/kg SC), and cephalexin (20 mg/kg, PO, q8h), and considerable improvement in his mentation was noted. However, after 5 days, anorexia, hypersalivation, vomiting, and liquid diarrhea developed and he returned to the local veterinary clinic where he was hospitalized and treated with IV fluids. The following day, obtundation and facial twitching developed and Murphy was referred for further diagnostics and treatment.

Current Medications

None

Other Medical History

Murphy was coughing 2 weeks ago but this subsequently resolved. He was also treated for a roundworm infection at that time, which was diagnosed by fecal flotation. Murphy was obtained from a breeder in Oklahoma. He had always appeared "slow" to the owner, his appetite had never been very good, and he seemed unthrifty. The other puppies in the litter were apparently healthy and there was no known exposure to toxins. The breeder had administered his first vaccines, and he was revaccinated for distemper, parvovirus, adenovirus, parainfluenza virus, and *Leptospira* by the referring veterinary clinic when he was acquired at 4 months of age.

Physical Examination

Body weight: 12.2 kg.

General: Obtundation was noted, the dog was in lateral recumbency and apparently unaware of his surroundings. Facial twitching occurred throughout the examination. T = 102.2°F, HR =140 beats/minutes, RR = 50 breaths/minute, mucous membranes moist and pink.

Eyes, ears, nose and throat: Moderate conjunctivitis was present. There was a mild bilateral serous nasal discharge. No other abnormalities were detected.

Musculoskeletal: Recumbent, appears small in stature, BCS 3/9.

Cardiovascular: No murmurs or arrhythmias were auscultated, strong pulse quality was present.

Respiratory: No significant abnormalities detected.

Abdominal palpation: Cranial organomegaly was present.

Lymph nodes: All were < 1.5 cm in diameter.

Laboratory Findings

Blood glucose: 70 mg/dL.

Plasma fasting ammonia concentration: 509 μg/dL (0–92 μg/dL).

Canine distemper virus immunofluorescent antibody (urine sediment): negative.

CBC: HCT 30.2% (40%–55%), MCV 61 fL (65–75 fL), MCHC 36.1 g/dL (33–36 g/dL), reticulocytes 49,200/μL (7,000–65,000/μL), WBC 22,000 cells/μL (6,000–13,000 cells/μL), neutrophils 10,340 cells/μL (3,000–10,500 cells/μL), band neutrophils 7,040 cells/μL, metamyelocytes 880 cells/μL, lymphocytes 1,100 cells/μL (1,000–4,000 cells/μL), monocytes 1,100 cells/μL (150–1,200 cells/μL), eosinophils 880 cells/μL (0–1,500 cells/μL), platelets 28,000 platelets/μL (150,000–400,000 platelets/μL). Moderately toxic neutrophils and markedly toxic band neutrophils and metamyelocytes were present. Occasional organisms with morphology consistent with *H. capsulatum* were seen within both neutrophils and monocytes. The myeloid series was shifted to the myelocyte stage with rare progranulocytes noted. Rare nucleated erythrocytes (metarubricytes) were also present. Many lymphocytes were reactive. Numerous macroplatelets were noted.

Serum chemistry profile: Sodium 143 mmol/L (145–154 mmol/L), potassium 4.7 mmol/L (4.1–5.3 mmol/L), chloride 108 mmol/L (105–116 mmol/L), bicarbonate 18 mmol/L (16–26 mmol/L), phosphorus 7.7 mg/dL (3.0–6.2 mg/dL), calcium 10.3 mg/dL (9.9–11.4 mg/dl), BUN 18 mg/dL (8–31 mg/dL), creatinine 0.4 mg/dL (0.8–1.6 mg/dL), glucose 117 mg/dL (70–118 mg/dL), total protein 5.8 g/dL (5.4–7.4 g/dL), albumin 2.1 g/dL (2.9–4.2 g/dL), globulin 3.7 g/dL (2.3–4.4 g/dL), ALT 31 U/L (19–70 U/L), AST 217 U/L (15–43 U/L), ALP 195 U/L (15–127 U/L), GGT 24 U/L (0–6 U/L), cholesterol 363 mg/dL (135–345 mg/dL), total bilirubin 1.1 mg/dL (0–0.4 mg/dL).

Urinalysis (cystocentesis): SpG 1.044; pH 5.0, 1+ bilirubin, no hemoprotein, no glucose, no protein, 0–1 RBC/HPF, rare WBC/HPF; no crystals, casts or bacteria seen.

Coagulation panel: PT 10.7 seconds (7.5–10.5 seconds), PTT 24.4 seconds (9–12 seconds), fibrin degradation products > 40 μg/mL (<10 μg/mL).

Imaging Findings

Thoracic radiographs: There was a diffuse bronchointerstitial pulmonary pattern especially in the region of the cranial right middle lung lobe. The heart and

CASE EXAMPLE—cont'd

pulmonary vasculature were slightly small. In the viewable abdomen, the liver was moderately enlarged.

Abdominal ultrasound: Severe hepatomegaly was present with normal hepatic echogenicity. A large, folded spleen and sublumbar and mesenteric lymphadenomegaly were present.

Microbiologic Testing

Fecal flotation: *Ancylostoma* ova.

Aspiration cytology (liver aspirate): The specimen was bloody and moderately cellular with numerous clusters of platelets and inflammatory cells. Occasional small clusters of hepatocytes were noted, which showed mild to moderate vacuolar degeneration. A few hepatocytes contained intracytoplasmic blue-green pigment consistent with bile. Inflammatory cells consisted primarily of activated macrophages which contained abundant intracellular yeast organisms consistent with *H. capsulatum*. Lower numbers of nondegenerate neutrophils, mixed lymphocytes, and occasional eosinophils and basophils were also found. Interpretation: *H. capsulatum* infection with marked pyogranulomatous inflammation. Mild to moderate hepatic vacuolar degeneration and cholestasis.

CSF analysis (cisternal): The fluid was clear and colorless. The protein concentration was 17 mg/dL (reference range, <25 mg/dL). There were < 1 RBC/μL (reference range, <1,200 RBC/μL) and 25 nucleated cells/μL (reference range, <2 cells/μL). The differential cell count consisted of 1% neutrophils, 6% lymphocytes, and 93% large mononuclear cells. The cytofuge specimen was cellular, and large, foamy macrophage-like cells predominated. Vacuoles within the cytoplasm contained digested debris, but no organisms could be discerned. Low numbers of small lymphocytes were also noted. Interpretation: Mononuclear pleocytosis.

Diagnosis

Acute PDH with suspected *H. capsulatum* meningitis; hookworm infestation.

Treatment

Murphy was hospitalized in the intensive care unit and treated with IV crystalloids (lactated Ringer's solution with 25 mEq/L KCl and 2.5% dextrose, 75 mL/hour), plasma, vitamin K, and heparin (100 U/kg, SC, q8h). The hookworm infection was treated with fenbendazole (50 mg/kg, PO, q24h for 3 days). Seizures were controlled with diazepam as needed and phenobarbital (2 mg/kg, IM, q12h). Hepatic encephalopathy was treated with a warm water enema, followed by a 3 mL/kg lactulose enema, and then oral lactulose (1 mL/kg, PO, q8h). Profuse watery diarrhea ensued. Treatment with lipid AMB was then initiated (2 mg/kg IV, over 2 hours, every other day). Initially, clinical signs improved and Murphy appeared brighter and began eating small amounts of a reduced protein diet. A CBC showed a HCT of 30%, 19,988 neutrophils/μL, 263 band neutrophils/μL with slight toxicity, 2,367 lymphocytes/μL, 2,367 monocytes/μL, 1,315 eosinophils/μL, and 65,000 platelets/μL. No *H. capsulatum* organisms were seen. The results of a biochemistry profile were similar to those reported at hospitalization, but electrolytes and glucose had normalized, and total bilirubin was 2.6 mg/dL.

On day 4 of hospitalization, he developed increased respiratory effort, weakness, and a head tremor. Thoracic radiographs showed a diffuse miliary interstitial infiltrate in the perihilar region and in the region of the right cranial lung lobe, which was slightly more severe that that seen at the time of hospitalization. By day 7 of hospitalization, he remained extremely weak and somewhat inappetent and the owners elected euthanasia due to financial limitations. At necropsy, there was severe hepatomegaly and splenomegaly, and the lungs were firm and mottled dark red to pink, and cut surfaces oozed white froth and blood. Histopathology revealed severe, diffuse, granulomatous inflammation with intrahistiocytic yeasts in the lungs, liver, spleen, bone marrow, sublumbar lymph nodes, and tracheobronchial lymph nodes (see Fig. 81.7). In the kidneys, there was severe, multifocal, granulomatous interstitial nephritis with intrahistiocytic yeasts. Multifocal granulomatous inflammation with intrahistiocytic yeasts was also seen in the pancreas, duodenum, jejunum, thyroid glands, and peritoneal fat. Within the brain there was minimal, focal, granulomatous meningitis.

Comments

In this dog, a diagnosis of disseminated histoplasmosis was straightforward because organisms were seen in a peripheral blood smear. The dog likely acquired infection in Oklahoma where the fungus is endemic. Overwhelming infection suggested a possible underlying immunodeficiency. The dog had evidence of DIC, hepatic encephalopathy, and granulomatous meningitis. Had treatment with AMB and additional supportive care continued, recovery might have occurred, but the costs of this treatment without guaranteed success led the owners to elect euthanasia. Clearly the burden of intact fungal organisms at necropsy was still massive despite several treatments with AMB. Even in human patients, overall cure rates for *H. capsulatum* meningitis are no better than 50%.

Cryptococcosis

Krystle L. Reagan, Mark Krockenberger, Jane E. Sykes

KEY POINTS

- First Described: 1894, in a human patient in Germany (independently by Busse and Buschke).[1]
- Causes: *Cryptococcus gattii* species complex (SC), *Cryptococcus neoformans* SC, and rarely other cryptococcal species. The causative agents are basidiomycetes and usually referred to by their anamorph identification of *Cryptococcus* spp. (with the exception of *Papiliotrema laurentii*, formerly known as *Cryptococcus laurentii*), and the known teleomorphs (filamentous form) are *Filobasidiella* spp.
- Affected Hosts: Cats, dogs, humans, and a variety of other domestic and wild animal species.
- Geographic Distribution: Worldwide.
- Major Mode of Transmission: Inhalation of basidiospores from the environment.
- Major Clinical Signs: Nodular or ulcerative cutaneous lesions, upper respiratory tract signs, chorioretinitis, neurologic signs secondary to meningoencephalitis. In dogs, *Cryptococcus* can disseminate to abdominal organs and cause GI signs such as vomiting, diarrhea, and inappetence.
- Differential Diagnoses: For cats, differential diagnoses for cutaneous lesions include other deep mycoses (especially sporotrichosis), mycobacteriosis, nocardiosis, neoplasia (especially SCC), herpetic dermatitis, and eosinophilic granuloma complex. Differential diagnoses for suspected cryptococcal rhinitis include nasal lymphoma, foreign bodies, sinonasal/sino-orbital aspergillosis, oronasal fistulae, and neutrophilic rhinitis. For ocular and CNS lesions, differential diagnoses include neoplasia (especially lymphoma), toxoplasmosis, FIP, and otogenic bacterial meningitis. For dogs, differential diagnoses include other disseminated mycoses (especially histoplasmosis and blastomycosis), mycobacteriosis, actinomycosis and nocardiosis, other causes of rhinitis (such as foreign bodies, nasal aspergillosis, oronasal fistulas, lymphoplasmacytic rhinitis, and rhinosporidiosis), neoplasia (especially round cell neoplasia), toxoplasmosis, neosporosis, severe inflammatory bowel disease, and pancreatitis.
- Human Health Significance: Human infections occur as a result of exposure to organisms in the environment and are often associated with underlying immune compromise.

ETIOLOGIC AGENT AND EPIDEMIOLOGY

Cryptococcosis is an important fungal infection of humans and animals worldwide and the most common systemic mycosis of cats. The infection is acquired from the environment, and disease transmission from one animal to another has not been reported. Occasional outbreaks of cryptococcosis in humans and animals may result from exposure to common environmental sources.[2,3] Various domestic and native mammals may be infected, which include cats, dogs, ferrets, horses, camelids, goats, sheep, cattle, dolphins, birds, koalas, and other marsupials.[4–10] The incidence of cryptococcosis is eightfold higher in cats than in dogs.[11]

The genus *Cryptococcus* contains at least 37 yeast species. Organisms that belong to the *Cryptococcus neoformans* species complex (SC) and *Cryptococcus gattii* species complex (SC) cause the vast majority of infections in dogs, cats, and humans. *Cryptococcus gattii* SC organisms have emerged as pathogens of immunocompetent humans in temperate regions of North America, in particular on the west coast of the United States and in British Columbia, Canada. Other species, particularly *Papiliotrema laurentii* (previously *Cryptococcus laurentii*)[12] and *Cryptococcus albidus,* rarely cause disease in humans and animals, but may be emerging as a result of immunocompromise.[13–15] *Cryptococcus magnus* was isolated from the external ear canal of a cat with otitis externa,[16] and *Papiliotrema (Cryptococcus) laurentii* has been isolated from the external ear canal of dogs.[17] Molecular methods may be required to accurately identify these species; in one cat where classical phenotypic and biochemical methods led to identification of *C. albidus*, the organism was shown to be *C. neoformans* by 18S rRNA gene sequencing.[18]

Cryptococcus spp. are dimorphic, basidiomycetous fungi. The life cycle of the fungus is thought to involve growth in host tissues as an encapsulated haploid budding yeast, combined with the ability to undergo a transition to a filamentous form (or teleomorph) in the environment. Two mating types of *Cryptococcus* spp. exist, α and **a**. The α mating type is vastly more prevalent in environmental and clinical samples, with **a** mating type rarely found particularly in disease or even in the environment. Under appropriate laboratory conditions, the two mating types fuse and adopt a dikaryotic filamentous state, also known as the *perfect state*. This is followed by production of basidia, which are small, club-shaped structures on which basidiospores form (Fig. 82.1).[19] Cells of the α mating type can also undergo asexual reproduction via a process known as monokaryotic fruiting, which also involves filamentation and spore formation.[19–21] Although they have never been observed in nature, basidiospores (or possibly desiccated yeasts) are thought to be the main form that, when inhaled, gives rise to mammalian disease.[22] In animal tissues, basidiospores convert to the yeast form, which is round to oval with a variably sized capsule. The capsule is primarily (90% to 95%) composed of a polysaccharide known as glucuronoxylomannan (GXM), with smaller amounts of galactoxylomannan. The capsule enlarges after infection of mammalian hosts and protects the fungus from phagocytosis and environmental insults such as desiccation. Within tissues, *Cryptococcus* reproduces by forming one or two daughter cells (buds) that are connected to the parent cell by a narrow base (Fig. 82.2).

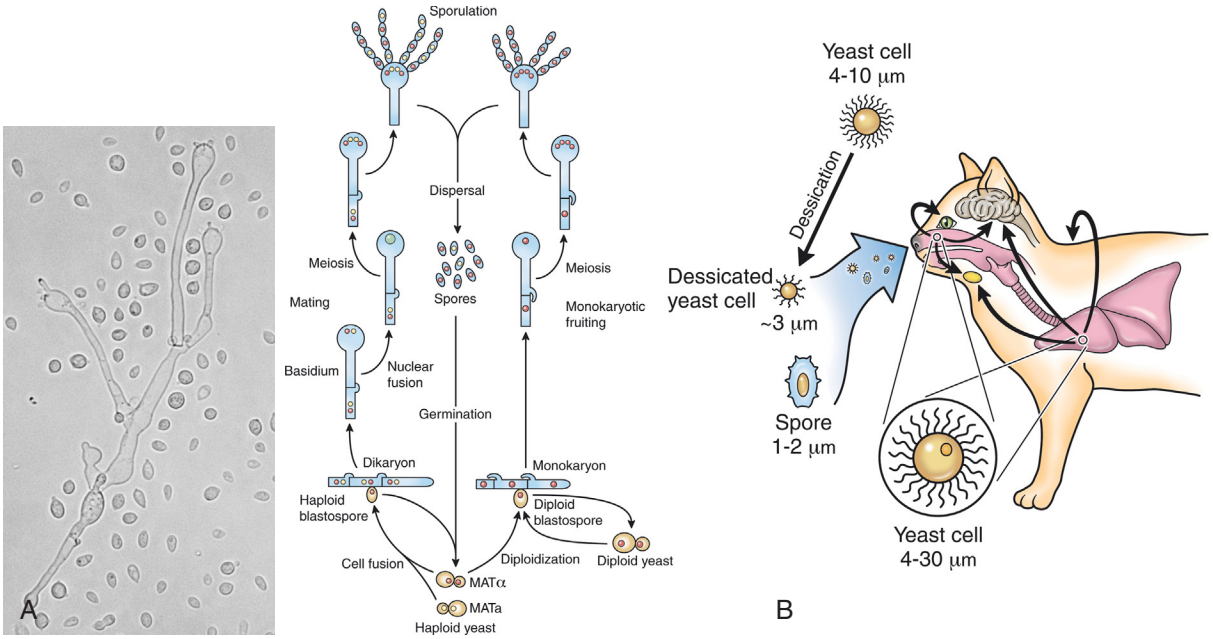

Fig. 82.1 Life cycle of *Cryptococcus* spp. (A) Spores result from either mating between cells of opposite mating types (*MATa* or *MATα*) and subsequent formation of dikaryotic hyphae or unisexual mating of MATα cells (monokaryotic fruiting). In both cases, sexual development within the filamentous form results in meiosis and basidiospore formation. The spores germinate to produce haploid, yeast-like cells that divide by budding. (B) Spores, and potentially desiccated yeast cells, are inhaled. Germination of spores or vegetative growth of yeast cells in the upper or lower respiratory tract results in the proliferation of budding yeasts. Dissemination to a variety of tissues can then occur, but especially to the lymph nodes, nasal cavity, skin, and central nervous system. (Modified from Kronstad JW, Attarian R, Cadieux B, et al. Expanding fungal pathogenesis: *Cryptococcus* breaks out of the opportunistic box. *Nat Rev Microbiol.* 2011;9:193–203. Fig. 82.2 Cerebrospinal fluid cytology from an 8-year-old male neutered domestic shorthair cat with cryptococcal meningitis. Large numbers of budding cryptococcal yeasts are present.

Historically, five serotypes of *Cryptococcus* (A, B, C, D, and AD) were recognized on the basis of antigenic differences in the capsular polysaccharide. Based on the results of molecular typing methods such as PCR fingerprinting, amplified fragment length polymorphism analysis, and restriction fragment length polymorphism analysis of the orotidine monophosphate pyrophosphorylase (URA5) and phospholipase genes, cryptococcal strains from around the world were divided into several major molecular types, some of which have been designated separate species names within *C. neoformans* SC and *C. gattii* SC:[23] VNI and VNII (*C. neoformans*), VNIII (*C. neoformans* × *Cryptococcus deneoformans* hybrid), VNIV (*C. deneoformans*), VGI (*C. gattii* sensu stricto), VGII (*Cryptococcus deuterogattii*), VGIII (*Cryptococcus bacillisporus*), VGIV (*Cryptococcus tetragattii*), and a VGIII/VGIV hybrid (*Cryptococcus decagattii*) (Table 82.1).[23–25] Differences in epidemiology, pathogenicity, clinical features, and drug susceptibility have been associated with each species.[26–29] Designation of separate species names for molecular types has been controversial because of the potential for this to cause confusion among clinicians,[30] but there is increasing use of these separate names in the literature. There will be a differential uptake of this nomenclature by diagnostic laboratories across the world, just as there was at the time that *C. gattii* was distinguished from *C. neoformans*. It emphasizes the need for clinicians to understand some of the history of nomenclature changes, not only when searching the literature for information about the causative organism but also when querying their laboratory about mycology results.
