Clinical signs usually relate to intestinal obstruction or respiratory compromise, but less specific signs of exercise intolerance and weight loss also have been reported.[24,25] A diaphragmatic hernia may also initially be clinically silent if there is minimal pulmonary or bowel compromise. Gastrointestinal clinical signs are variable and depend on the segment and amount of intestine herniated and whether it is simply displaced, incarcerated, or strangulated.[24,25] Frequently reported clinical signs are colic, moderate to severe tachypnea, and endotoxic shock. Respiratory signs of tachypnea can be attributed to pain at the site of injury or gastrointestinal tract, shock, and lung compression and decreased ventilation.[24,25,29,30] Acute tearing of the diaphragm may be associated with hemorrhage into both thoracic and abdominal cavities.

Diagnosis can be challenging, and thoracic radiographs showing gas-filled intestine or abdominal viscera within the thoracic cavity are considered most diagnostic.[24,25,29,30] Ultrasonographic examination may show abdominal organs in the thoracic cavity; however, viscera may not be seen if located away from the thoracic wall and covered by aerated lung.[9] Rectal examination often suggests a relative lack of normal abdominal viscera in horses with extensive migration of abdominal organs into the thoracic cavity. Auscultation of the thorax may reveal gastrointestinal sounds; auscultation usually does not clearly differentiate sounds referred from the abdomen. There may also be an absence of breath sounds ventrally and associated dullness on percussion; however, these findings are not reliable. Abdominal paracentesis is usually normal and can be misleading as the compromised intestine is in the thorax, and thus thoracocentesis may be more representative.[24] Thoracoscopy may also assist visualization of the hernia, but partial deflation of the lungs is necessary to visualize the diaphragm, which may further compromise the patient.[15,28] Because of these difficulties in diagnosis, a definitive diagnosis, in some cases, may be obtained only at the time of surgery or necropsy.

The prognosis for survival is poor, with reports from recent retrospective studies of 16% (7 of 44) and 23% (7 of 31).[25,31] Surgical repair also carries a poor prognosis with complications associated with anesthesia, resection of devitalized bowel, anatomic location and repair of the defect, possible fractured rib repair, and breakdown of the hernia repair site.[24,25,31] Survival in one study was significantly associated with the age of the horse (2 years old), location (ventral) and size (<10 cm) of the diaphragmatic tear, and the amount of compromised viscera at surgery (<50% small intestine).[31] Foals and adult horses that survive can return to their previous level of activity, including those of a broodmare.[25,29,31] In chronic cases with few or no clinical signs, repair does not appear to be necessary, although complications associated with herniated viscera may eventually occur.[26,28]

Pulmonary Edema

Pamela A. Wilkins

Pulmonary edema rarely occurs as a primary event in the horse and, when present, is usually secondary to some other pathologic process. Extravascular fluid accumulates within the lung after events that alter hydrostatic and colloid osmotic interstitial and vascular forces, change the surface area and pore size of the blood-gas barrier, or diminish lymphatic drainage.[1] Pulmonary edema can be classified as cardiogenic or noncardiogenic. Pulmonary capillary pressure can be increased by any increase in left atrial or pulmonary artery pressure. In horses, this can occur secondary to acute renal failure, left heart failure, or very high cardiac output conditions, such as extreme exercise. Increases in microvascular permeability may occur with sepsis, disseminated intravascular coagulation, hypoxic acidosis, allergic responses such as transfusion reactions or primary pulmonary pathology, resulting in the release of mediators of inflammation that increase vascular endothelial or alveolar epithelial permeability. Pulmonary edema associated with airway obstruction has been termed *negative-pressure pulmonary edema* (NPPE) and has been reported in horses.[2-7] NPPE occurs secondary to inspiratory efforts against a closed glottis that result in a precipitous fall in intrathoracic pressure. The large decrease in intrathoracic pressure increases the transmural pressure gradient for all intrathoracic vascular structures, favoring movement of water into the extravascular space. Transient pulmonary obstruction may be a root cause of fatal exercise-induced pulmonary hemorrhage (EIPH) in racehorses and other horses performing at maximal exercise; these horses are predisposed because of already large transmural pulmonary vascular pressures and large intrathoracic pressure swings associated with breathing (Wilkins and Del Piero, unpublished data) (Fig. 31-40).

Diagnosis is based on clinical examination, history of predisposing causes, and radiographs. Horses have a shallow rapid respiratory pattern and may be dyspneic. Arterial blood gas analysis may reveal hypoxemia and hypercapnia. Fine crackles or wheezes may be audible on auscultation. Patients with volume overload (associated with renal failure or, rarely, too-rapid fluid administration) or primary cardiac problems may have an increased central venous pressure with pronounced venous distention. Fluid (clear or slightly yellow or pink-tinged) may drip from the nostrils and can increase in volume without necessarily becoming frothy. Continuous coughing and production of frothy blood-tinged or bloody fluid production warrants a very grave prognosis. Radiographic findings are nonspecific but include peribronchial and perivascular cuffing, increased prominence of vessels, and a hazy reticular interstitial pattern (Fig. 31-41). Underlying pulmonary disease may obscure signs of edema, and radiographs of sufficiently high quality to show relatively subtle changes may not be obtainable in mature horses. Diffuse numerous comet-tail artifacts are seen with thoracic ultrasound examination (Fig. 31-42). Noncardiogenic pulmonary edema (capillary leak) is a component of the definition for VetALI and VetARDS.

Treatment Treatment consists of correcting the cause, reversing hypoxemia, decreasing plasma volume and left atrial pressure, and increasing plasma colloid osmotic pressure. Intranasal oxygen and even positive ventilation may be needed in severe cases. Improvement in oxygenation can be monitored by sequential arterial blood gas analysis or by using transcutaneous oxygen saturation monitoring equipment (pulse oximetry) applied to the nasal mucosa, tongue,

TABLE 31-10

Pharmacologic Treatments for Pulmonary Edema in Horses

Treatment	Reason	Route	Dose/Rate	Comments
Oxygen	Hypoxemia	Intranasal insufflation	5-15 L/min	Aim for PaO_2 > 85 mm Hg, O_2sat > 90%
Furosemide	Diuresis	Intravenous	1 mg/kg	Repeat as needed; monitor acid-base status, hydration, and electrolyte concentrations
Furosemide	Bronchodilation	Nebulization		Will not be effective with concurrent NSAID administration
Bronchodilators (various)	Bronchodilation	Nebulization Oral Intravenous	See section on obstructive pulmonary disease	Many will be effective, described in depth elsewhere in Chapter 31
Flunixin meglumine	Antiinflammatory	Intravenous	1 mg/kg	BID; monitor renal function
Diphenhydramine	Antihistamine	Intravenous	0.1-1 mg/kg	BID; monitor for excessive drowsiness
Epinephrine	Anaphylaxis	Intravenous	3-5 mL IM for 450-kg horse	Use ONLY for treating anaphylaxis

bid, Twice a day; *IM,* intramuscularly; *NSAID,* nonsteroidal antiinflammatory drug; *O_2sat,* percentage oxygen saturation; *PaO_2,* partial arterial oxygen pressure.

or other available nonpigmented mucous membrane. In cases of NPPE, maintaining an adequate, low-resistance airway is very important to prevent further damage, and tracheostomy may be necessary. IV fluid therapy should be guided by the patient's needs and monitored by serial measurement of central venous pressure if necessary. Furosemide may be given intravenously or intramuscularly at a dose of 1 to 2 mg/kg and repeated in 1 hour (Table 31-10). If helpful, the dose can be titrated for each patient. At a dose of 1 mg/kg, approximately 8 L of urine is produced in approximately 1 hour.[8] A few studies have been conducted on the effects of furosemide on pulmonary hemodynamics in the horse.[8-12] Furosemide provides some relief to recurrent airway obstruction (RAO)–affected horses within 20 minutes of administration, increasing dynamic compliance without affecting PaO_2.[13] The beneficial effects appear to be mediated by prostaglandin E_2, derived from either the renal or airway epithelium, resulting in bronchial smooth muscle relaxation. Prior treatment with flunixin meglumine prevents the furosemide-induced bronchodilation.[14] The effect in horses with pulmonary edema has not been reported. Colloid solutions should be administered cautiously or in conjunction with use of diuretics because they can initially increase vascular pressure. Plasma may be safer than other colloid preparations such as dextrans or hetastarch. Colloid solutions may be of little benefit in raising intravascular osmotic pressure in patients with increased microvascular permeability.

Antiprostaglandin drugs (flunixin meglumine, phenylbutazone) and antihistamines may help and are indicated particularly in cases of anaphylactic reaction, as are diphenhydramine and epinephrine (see Table 31-10). Bronchodilators may be of benefit (see Table 31-10). The use of corticosteroids remains controversial; if they are used, antimicrobial coverage is advisable, as pulmonary edema has been shown to impair pulmonary bacterial defense mechanisms.

Smoke Inhalation

Peggy S. Marsh

Smoke inhalation injury is typically associated with exposure to fires, and there are often concurrent problems in other body systems from thermal injury. Extensive or severe burns can magnify the severity of the injuries. Thermal injury, along with smoke inhalation, leads to both local and systemic lesions. Diffuse tissue edema may occur; this is a challenge to manage and can create organ dysfunction. To further complicate the problem, severely affected patients may develop problems, including life-threatening sepsis, hypermetabolism, or both. Depending on the severity of the lesions, smoke and fire injuries often lead to systemic inflammatory response syndrome and, in some cases, multiple organ system failure.[1]

Insult to the respiratory system by smoke inhalation depends on the fuels that burned, the completeness of combustion, and the generated heat intensity. In general, lesions are initiated by three mechanisms. The first is direct thermal injury, which is often limited to the upper respiratory tract by laryngeal reflexes and efficient heat exchange within the nasal passages.[2] Second, toxic chemicals in the smoke can cause damage, both directly and indirectly, through inflammatory mediators. Carbon monoxide intoxication is commonly associated with human injuries from smoke and is a product of incomplete combustion.[3] Finally, with combustion there is consumption of oxygen, and the resulting low PAO_2 can lead to pulmonary vasoconstriction as well as generalized hypoxia.

Three phases of pulmonary dysfunction have been described in the horse.[4,5] The first stage is acute pulmonary insufficiency caused by several mechanisms. Carbon monoxide may be present in sufficiently high concentration to cause toxicity within a short time after exposure. Carbon monoxide combines with hemoglobin to form carboxyhemoglobin. Hemoglobin has a 200 to 250 times greater affinity for carbon monoxide as compared with its affinity for oxygen.[3] High levels of circulating carboxyhemoglobin result in a shift of the oxyhemoglobin dissociation curve to the left, thereby decreasing oxygen release at the tissue level and leading to tissue hypoxia. Other processes occurring during this acute phase include progressive edema and necrosis in the upper respiratory tract, leading to airway obstruction; bronchoconstriction in the lower respiratory tract, caused by the irritating effects of noxious products; and altered pulmonary blood flow.[6]

These insults produce the second stage: formation of pulmonary edema, lower airway obstruction, and pulmonary parenchymal lesions. Within 48 to 72 hours after exposure, driven by pulmonary macrophages, neutrophils are called into the area of insult. They release cytokines, proteolytic enzymes, and oxygen-derived free radicals. Expression of the inflammatory cascade in excess of balance causes microvascular damage, leading to increased extravascular lung water. Local insult also results in the release of tissue factor, initiating the coagulation cascade to produce fibrin. Debris from the inflammatory cascade, along with fibrin and material directly deposited from smoke inhalation, create pseudomembranous casts, which may obstruct the small airways. Widespread plugging of the airways may significantly increase airway pressure, causing barotrauma and alveolar damage.[6] The last stage, bronchopneumonia, occurs as a result of the impaired host immune system, both locally and systemically. This phase may occur up to 1 to 2 weeks after the initial injury.

As the saying goes, "Where there's smoke, there's fire"; it is common for horses with smoke inhalation injury to also have burn injury. A complete description of this process in horses has been

VetBooks.ir

reported.[7] Thermal injury causes a local response that includes microvascular insult and direct tissue coagulation leading to inflammation, local edema, and, finally, necrosis. Extensive local injuries will drive a systemic response. An initial decrease in systemic organ blood flow is followed by the formation of generalized edema. The pathophysiology of edema formation is complex and involves protein shifts, endothelial damage, and alteration of the interstitial architecture, all leading to a net accumulation of fluid in the interstitial spaces.[8] Over time major thermal injury is characterized by high cardiac output, increased oxygen consumption, and protein and fat wasting, all of which may create a hypermetabolic state.[9,10] Loss of skin as a barrier, release of inflammatory mediators, and hypermetabolism play a role in the development of immunosuppression. Other features noted with burn injury in the horse include acute hemolysis, renal failure, laminitis, and myositis.[11]

Horses exposed to fire with smoke will have a variety of clinical signs depending on the duration and type of exposure and the length of time from the insult. The extent of damage to the skin may be very difficult to ascertain initially. Acutely, within the first 6 hours, signs of carbon monoxide toxicity and shock may occur. The patient shows signs of severe hypoxemia and may be depressed, disoriented, irritable, ataxic, or even moribund and comatose. As edema and necrosis progress in the upper respiratory tract, dyspnea and stridor may develop. Auscultation of the thorax may reveal decreased air movement, crackles, or wheezes, but these may not become apparent for 12 to 24 hours. If edema of the airways is sufficiently severe, airflow may be severely restricted. Edema fluid may be visible at the nostrils and, later, may be replaced by inflammatory exudate. Concurrent edema formation may be occurring systemically. Hypoxia and generalized edema may lead to dysfunction of distant organs such as the kidneys and muscles. Signs of infection may be difficult to ascertain from other signs. All that may be noticed is a fever and a worsening of respiratory signs after initial improvement.

Diagnosis is typically based on history and physical examination. A normal initial examination does not rule out exposure because the onset of clinical signs may be delayed several days. Within a short time after exposure, carboxyhemoglobin concentration in venous blood can be measured. A level above 10% is consistent with carbon monoxide toxicity.[3] Various diagnostic tests are useful in determining the extent of respiratory injury. These tests include endoscopy of the upper respiratory tract and tracheobronchial tree, thoracic radiographs, blood gas analysis, hematology, and cytologic evaluation of tracheal aspirates. Any or all of these tests can be performed on a serial basis as prognostic aids. Diagnostic tools for other organ injury include blood pressure monitoring, measurement of central venous pressure, serial hematologic and serum chemistry analyses, and monitoring of urine production.

Treatment depends on stage of injury. Initially, oxygen support is of benefit. It is a treatment for carbon monoxide toxicity and helps reduce hypoxemia.[12] Humidified oxygen can be supplied by nasal insufflation or via transtracheal catheter. Upper respiratory tract obstruction may necessitate a tracheostomy. Attention should be paid to keeping the airways clear, and nebulization may be useful, especially when pseudomembranous casts are suspected. Bronchodilators may be useful in counteracting reflex bronchoconstriction. Decreasing inflammation and pulmonary edema may necessitate the use of diuretics and NSAIDs. Use of corticosteroids is controversial because of the potential for immunosuppression and laminitis.[4] Novel therapies may include use of hyperbaric oxygen chambers and inhalation treatment with medication to inhibit inflammatory mediators, coagulation factors, or oxidative stress.[13]

Secondary complications require attention. Cardiovascular compromise and burn-induced edema may necessitate the judicious use of intravenous fluids. To prevent infection, strict hygiene, meticulous nursing care, and optimal nutritional support should be provided.[1,7,13] Prophylactic antimicrobial use is not recommended in human patients. Documented infection should be treated with appropriate antimicrobial agents based on results of culture and sensitivity patterns.[1,7]

Recurrent Airway Obstruction

Dorothy M. Ainsworth

Definition and Etiology Recurrent airway obstruction (RAO) is an inflammatory condition of the lower respiratory tract of mature horses that is characterized by excessive mucus production, neutrophil accumulation, bronchial hyperreactivity, and (in most cases) reversible bronchospasm. Because etiopathogenesis of the equine disease differs from that of chronic obstructive pulmonary disease (COPD) in humans, it is recommended that the equine disorder no longer be called COPD. The preferred name is RAO or "heaves."[1]

RAO typically develops in adult horses residing in the northeast and midwest regions of the United States and Canada as well as in Great Britain and Switzerland, where the climate is wet and cool and horses are stabled and fed hay. RAO can also occur in horses that are pastured outdoors but fed dusty hay, especially from round bales. RAO rarely occurs in horses maintained in warm, dry climates such as those found in California or in Australia.[2] In North America the prevalence of RAO diagnosed at veterinary teaching hospitals has been positively correlated with rainfall, minimum temperatures, and total pollen and mold counts occurring 1 to 3 months previously.[3] These findings suggest that environmental conditions are integral to the development of the disease in genetically susceptible horses.

RAO is considered to be a hypersensitivity to inhaled molds and organic dusts contained in the feeds, hay, and straw. It is similar to occupational (neutrophilic) asthma that develops in human workers exposed to organic dusts.[4] Identifying the *specific* causative agents within the hay dust that induce the disease has been a challenge, as stable dust contains more than 50 species of molds, large numbers of forage mites, endotoxins, and other inorganic components.[5] Inhalation challenge with endotoxin, a component of hay dust, induces airway neutrophilia but not all of the changes in pulmonary function that are characteristic of RAO.[6,7] Inhalation challenge with aqueous extracts of *Aspergillus fumigatus, Faenia rectivirgula (Micropolyspora faeni),* or *Thermoactinomyces vulgaris* partially induces RAO in susceptible horses.[8-10] Complete experimental induction of RAO in susceptible horses requires inhalation of hay dust particulates either by natural challenge (hay feeding) by nebulization of a hay dust solution or a solution containing fungal spores, endotoxin, and silica microspheres.[11-15]

ROLE OF THE INNATE IMMUNE SYSTEM. Within hours of hay dust exposure, neutrophilia and excessive mucus production are evident endoscopically and cytologically[16,17] and reflect the response of a multitude of pulmonary cell types that initiate innate and adaptive immune responses. Alveolar macrophages isolated from RAO-susceptible horses just 6 hours following nebulization of a hay dust solution[18] exhibit an upregulation in the gene expression of tumor necrosis factor (TNF)–α, interleukin (IL)-1β, and IL-8. Pulmonary intravascular macrophages (PIMs) may also play a pivotal role in airway inflammation, as temporary depletion of PIMs alone in RAO-susceptible horses (by intravenous [IV] gadolinium chloride) significantly reduces airway neutrophilia and airway cell IL-8 and TLR4 gene expression normally induced by moldy hay challenge.[19] The "trigger" for transcription of proinflammatory genes in macrophages (or other pulmonary cells) may reflect activation of Toll-like receptor (TLR) 2 and TLR4, or both, by fungal wall components, endotoxin, or other bacterial cell products leading to nuclear factor κB (NF-κB) activation and gene transcription.[20-22] Recently, hypoxia-inducible factor 1α (HIF-1α) has been proposed to play an essential role in the innate responses of RAO.[23] Although HIF-1α is a known regulator of energy homeostasis and cellular adaptation to hypoxia, it also regulates expression of proinflammatory genes such as TNF-α, IL-8, and vascular endothelial growth factor (VEGF), and engages in cross-talk with the NF-κB pathway.[23] HIF-1α expression in bronchoalveolar lavage fluid (BALF) cells is significantly increased in symptomatic but

VetBooks.ir

not asymptomatic RAO-affected horses or controls.[23] However, the relative importance of these receptors and transcription factors requires further investigation.

The initial upregulation of macrophage-derived proinflammatory genes is transient, with mRNA levels returning to preexposure levels 24 hours after hay dust challenge.[18,24] However, with continuous hay dust exposure, both the protein and the gene expression levels of IL-8 in the airway cells (neutrophils) and bronchial epithelium, as well as the gene expression levels of IL-1β and TNF-α in the BALF cells (probably neutrophils) remains upregulated in chronically affected horses.[25-28] In addition to these chemokines there is evidence that airway neutrophilia in the chronic phase of RAO (disease that has lasted longer than 2 weeks) may also be propagated by IL-17.[28-29] Secreted by lymphocytes and neutrophils, IL-17 promotes maturation, chemotaxis, and activation of neutrophils. IL-17 has the capacity to upregulate the gene expression of IL-8 in the airway epithelium, further promoting the inflammatory cycle, but this remains to be confirmed in horses.[28]

The net effect of proinflammatory cytokine production is to enhance the chemokinetic gradient existing within the airways and to promote neutrophilic extravasation.[25,30] The neutrophil intracellular signaling pathways required for extravasation into the airways involve mitogen-activated protein kinases (MAPKs) and/or phosphoinositide-3-kinase (PI3K): in vitro inhibition of MAPK or PI3K significantly attenuates neutrophil chemokinesis.[30]

ROLE OF THE ADAPTIVE IMMUNE SYSTEM. The role of the adaptive immune system in the development of RAO remains controversial. Data that support the hypothesis that RAO is an IgE-mediated (T-helper type 2 [Th2]) disorder include the findings of elevated allergen-specific IgE concentrations in the serum[31] and in the BALF of RAO-susceptible or affected horses,[32,33] increased numbers of IL-4 and IL-5 (mRNA-positive) BALF cells (detected by in situ hybridization techniques) in RAO-affected horses,[34,35] and the results of genetic studies that suggest a phenotypic association (at least in one family of Swiss warmblood horses) with a locus on equine chromosome 13 that contains the IL-4 receptor gene.[36] Although Th2 disorders are typically characterized by eosinophilic infiltrates, it has been hypothesized that IL-4 activates its receptor on neutrophils to inhibit neutrophil apoptosis, to increase protein synthesis, and to upregulate the expression of the IL-9 receptor.[37] It has been further hypothesized that activation of the IL-9 neutrophil receptor then enhances IL-8 production and neutrophil influx.[37,38] Although the gene expressions of IL-4 and IL-9 receptors are indeed upregulated in peripheral blood neutrophils isolated from RAO-prone and RAO-affected horses, the existence of this pathway, linking the Th2 limb with the development of neutrophilia, requires additional investigation and confirmation.

Other data suggest that RAO is not simply a Th2 immune response. For example, Van der Haegen and colleagues were unable to demonstrate a significant difference in IgE-protein–positive cells in the lung tissue samples of RAO-affected horses compared with control horses.[39] Second, cytokine profiles of BALF cells[26,27] or of pulmonary $CD4^+$ and $CD8^+$ cells[40] isolated from RAO-affected horses during the first 24 or 48 hours after hay dust exposure fail to demonstrate an upregulation of IL-4, IL-5, or IL-13. Furthermore, chronic (3-week) hay dust exposure is associated with an increase in the gene expression of IFN-γ in the BALF cells,[26,27] although in one trial, but not in the second trial, of the same chronically affected horses, the gene expression of IL-4 was upregulated.[26] Fourth, GATA-3, the transcription factor required for IL-4 gene expression, is not upregulated in the bronchial cells of RAO-affected horses.[41] These data *do not* provide unequivocal evidence that RAO is a Th1 immune response because (1) concomitant increases in the gene expression of T-bet, the transcriptional factor for IFN-γ expression in $CD4^+$ cells, is not upregulated concurrently with IFN-γ,[27] and (2) multiple signaling pathways may stimulate the production of IFN-γ. In other species, TLR stimulation leads to the production of proinflammatory factors, including IL-12, and subsequent IFN-γ synthesis.[42,43]

OTHER INFLAMMATORY MEDIATORS. With the accumulation of intraluminal neutrophils and peribronchiolar lymphocytes and with the activation of alveolar macrophages, it is not surprising that numerous other inflammatory mediators are released and may contribute to the inflammatory response of RAO. For example, histamine that is released by degranulated mast cells increases vascular permeability and produces bronchoconstriction. (Although mast cell degranulation is typically attributed to IgE-mediated cross-linking of high-affinity receptors [FceRI] on mast cells, leukotrienes, prostaglandin E, acetylcholine, substance P, endothelin, and peptidoglycan also induce mast cell degranulation.)[44,45] Despite the finding of increased histamine concentrations in the BALF of RAO-affected horses, histamine-1 receptor antagonists provide little therapeutic relief for affected horses; this finding suggests that histamine may not be the predominant mediator responsible for the airway inflammation.[46] The potential role of prostaglandins, with their bronchoconstrictive (PGF_{2a}, PGD_2, TXA_2) and/or bronchodilatory capabilities (PGE_2, PGI_2), has also been examined. In a differential gene expression study of peripheral lung tissue, Lavoie and colleagues[47] reported an upregulation in RAO-affected horses of (1) PGF synthase (an enzyme that reduces PGD_2 and PGH_2 to PGF_{2a}) and (2) PTGDR, a PGD_2 receptor. In diseased horses, increases in BALF, PGE_2, PGF_{2a},[48,49] and serum TXB_2 (a metabolite of TXA_2) are found.[50] However, although administration of a cyclooxygenase inhibitor prevents the increase in the serum TXB_2 in RAO-affected horses, it does not inhibit the development of airway hyperresponsiveness or bronchospasm in susceptible horses; this finding suggests that eicosanoids are not the major contributor to clinical signs.[50] The contribution of lipoxygenase metabolites to the airway disease has also been investigated in RAO-affected horses. In humans, LTB_4, LTC_4, and LTD_4 are considered to be bronchoconstrictors; LTC_4 and LTD_4 are also mucus secretagogues; and LTB_4 (through its action on NF-κB) is a chemotactin, promoting the upregulation of adhesion molecules and cytokines that facilitate neutrophil extravasation.[51] Inhalation of LTB_4 or LTD_4 induces airway neutrophilia and bronchoconstriction, respectively, in normal and RAO-affected horses.[52] BALF cells isolated from RAO-affected horses during the first 48 hours of hay dust exposure and stimulated ex vivo produce increased concentrations of LTB_4 and LTC_4.[51] However, actual BALF concentrations of LTB_4 and LTC_4 are not elevated in chronically affected horses[49] despite the finding that the gene expression of LTA_4 hydrolase (which metabolizes LTA_4 to LTB_4) is upregulated in RAO-affected horses.[47] Pretreatment of RAO-susceptible horses with either a 5-lipoxygenase inhibitor or a LTD_4 receptor antagonist before hay dust exposure does not prevent the development of airway neutrophilia or alterations in lung mechanics.[53,54] Treatment of clinically affected horses with a leukotriene receptor antagonist montelukast (LTC_4, LTD_4, LTE_4 antagonist) also fails to improve pulmonary function test results, clinical scores, or arterial blood gas tensions.[55]

There is increasing evidence that reactive oxygen species, derived from pulmonary macrophages and granulocytes, contribute to the inflammatory process of RAO.[56] Oxidative stress occurs when enzymatic (superoxide dismutase, glutathione peroxidase, glutathione-*S*-transferase) and nonenzymatic antioxidants (glutathione [GSH], ascorbate, α-tocopherol, bilirubin, albumin, and transferrin) are depleted.[57] Evidence of an oxidant stress within the airways of RAO-affected horses is based on the findings of (1) increased levels of oxidized glutathione (GSSG), (2) increased glutathione redox ratios (GSSG/GSSG + GSH), and (3) decreased ascorbic acid concentrations in the pulmonary epithelial lining fluid of RAO-affected horses.[56-58] Tan and colleagues[57] also reported that both red blood cell and white blood cell glutathione peroxidase activities were significantly increased in RAO-affected horses during exacerbation compared with controls, suggesting a systemic response to the pulmonary inflammation.[57] Changes in these indices of oxidant stress are also correlated with lung dysfunction parameters (total lung resistance, dynamic lung compliance, and arterial oxygen tensions) in RAO-susceptible and RAO-affected horses.[59] Although reactive oxygen species are well recognized for their microbicidal activities, they

VetBooks.ir

also upregulate proinflammatory gene expression by activating NF-κB.[60] It is likely that reactive oxygen species generated during the inflammatory process of RAO also contribute to the NF-κB activation in bronchial epithelial cells and in BALF cells of RAO-affected horses.[61,62]

Proteases derived from airway phagocytes, lymphocytes, and epithelial cells may also propagate the inflammatory reaction of RAO. Although many matrix metalloproteinases (MMPs) with gelatinolytic and collagenolytic activities have been identified in the respiratory tract secretions of RAO-affected horses,[63,64] the gelatinase MMP-9 is markedly increased in BALF and in tracheal epithelial lining fluid of diseased horses.[65] It has been suggested that the degradative effect of MMP-9 on the basement membrane and on the extracellular matrix components facilitates the extravascular movement of neutrophils into the airways. In vitro, tetracycline derivatives effectively inhibit MMP activity detected in tracheal epithelial lining fluid,[66] but the efficacy of these compounds in ameliorating or preventing the inflammatory response of RAO-susceptible horses exposed to hay dust remains to be determined.

Epidemiology and Genetics RAO occurs in both ponies and horses, but no gender or breed predisposition has been identified.[67,68] The prevalence of RAO is dependent on the geographic region examined. Bracher reported that 60% to 80% of Swiss horses older than 8 years of age suffer from some degree of this disease. In North America and in Europe the prevalence of RAO is estimated to range from 12% to 50%.[67] Although it has been clearly demonstrated that hay particulates are integral to the development of the disease, the role of a prior viral (or bacterial) infection in inducing susceptibility to hay dust hypersensitivity remains to be established. Furthermore, even though horses with inflammatory airway disease (IAD) share many of the clinical features of RAO,[69] the relationship of IAD to the development of RAO is unknown. Currently there is no evidence that IAD progresses to RAO.[1]

A heritable component of RAO disease susceptibility has long been suspected. Marti and colleagues examined families of RAO-affected warmblood and Lipizanner horses and found that the risk of developing RAO was 3.2 times higher when one parent (dam or sire) had the disease and 4.6 times higher when both parents did.[70] Marti and colleagues concluded that the clinical manifestations of RAO are the result of the interactions of genetic and environmental factors. More recently, results of segregation and genomic analyses performed on two families of Swiss warmblood horses suggest that the mode of inheritance of RAO is characterized by major gene effects but that potential candidate genes differ between the two families.[36,71] In one family of Swiss warmblood horses, RAO was transmitted in an autosomal recessive mode with the major association of microsatellites or single nucleotide polymorphisms and affected cases being found on equine chromosome 13 (ECA 13). In the other family of Swiss warmblood horses, an autosomal dominant mode of inheritance was found with the major association found on equine chromosome 15.[71] Potential candidate genes on ECA 13 include IL-17, IL-4 receptor, and integrin alpha X gene (ITGAX). On ECA 15, a gene of interest is SOCS5 (suppressor of cytokine signaling 5), a gene whose protein product negatively regulates IL-4–dependent pathways and Th2 cell differentiation.[36,71-75] The investigators suggested that the observed genetic heterogeneity between the two families of Swiss warmblood horses may reflect etiologically distinct subgroups of RAO that are not distinguished phenotypically. Although the results are intriguing, it remains to be determined if RAO genetic susceptibility maps to loci on ECA 13 and ECA 15 in other horse breeds.

Clinical Signs and Differential Diagnosis The severity of clinical signs in RAO-affected horses is variable and is exacerbated by stabling; exposure to dusts, hay, and ammonia fumes; and hot, humid weather. In a study of 148 cases of RAO presented for evaluation to a veterinary referral hospital in the United Kingdom, the chief complaints (median duration of which was 7 months) included coughing (84% of cases), bilateral nasal discharge (54%), exercise intolerance (51%), and postexercise breathing difficulty (23%).[76] In a review of 16 cases presented to a veterinary teaching hospital in western Canada, the most common historical complaint (88% of the cases) was coughing,[77] whereas the predominant clinical complaints in 65 cases presented to a veterinary teaching hospital in the northeastern United States were abnormal breathing effort (68%), nasal discharge (50%), and a spontaneous cough (46%).[78]

On physical examination, mildly affected horses are typically afebrile and exhibit a bright demeanor and a normal or slightly accentuated (abdominal) breathing effort, respiratory rate, and heart rate. Nasal discharge may not be evident in all cases, but the horse may be observed to swallow excessively because of expectorated exudate. When the horse is exercised, a thick white nasal discharge and a cough become apparent. The frequency of coughing increases when horses are stabled, often exceeding 10 to 15 coughs per hour.[79] More severely affected horses exhibit tachypnea (respiratory rates > 40 breaths/min), nostril flaring, and a markedly accentuated expiratory effort (heave). The thoracic expiratory component may precede that of the abdominal compartment, producing a "double effort."[80] Abdominal pressure swings may be large enough to cause the anus to protrude with expiration. Paroxysmal coughing, bilateral nasal discharge, anxious facial expression, flatulence during coughing, reluctance to move, inappetence, and weight loss occur in the most severely affected cases.

Although RAO is a diffuse lung disease, auscultation of mild cases may not reveal abnormal lung sounds unless a rebreathing bag is used to induce a hyperpnea. In one survey, thoracic auscultation was abnormal in 47% of the cases, whereas tracheal auscultation was abnormal in 63% of the cases.[76] In the latter, abnormal lung sounds and "mucus clicks" (tracheal exudate) were detected by tracheal auscultation. In mildly affected horses, only regional areas of adventitious lung sounds (crackles or high-pitched expiratory wheezes) may be detected. In contrast, in severely affected horses, wheezes and mucus clicks may be heard at the horse's nostrils without the use of a stethoscope. Depending on the severity of the disease, thoracic percussion may be normal or may reveal expansion of the caudal lung fields beyond the normal line of pleural reflection.

Researchers have developed a clinical scoring system to categorize the severity of RAO. In one system the total clinical score is based on the magnitude of nostril flaring (1 to 4) and the abdominal breathing effort (1 to 4).[81] RAO in horses with a clinical score of 3 or 4, 5 or 6, or 7 or 8 was diagnosed as mild, moderate, or severe, respectively. In moderately to severely affected horses, there is a very good correlation between the clinical signs and alterations in pulmonary resistance or dynamic compliance.[82] For mildly affected horses, clinical scores underestimate the severity of changes in the pulmonary function tests resulting in an underdiagnosis of RAO. Another clinical scoring system—based on the respiratory rate (graded 0 to 2), the respiratory effort (0 to 2), and lung auscultation findings (0 to 2) in affected horses—was found to more closely correlate with histopathologic changes obtained by lung biopsy (and, in particular, the presence of peribronchiolar neutrophil and/or mast cell infiltration) than with the degree of BALF neutrophilia.[77] (Pulmonary function tests were not performed.) However, Tilley and colleagues, in a study of 30 RAO-affected horses and 10 controls, found that the severity of some clinical signs (e.g., cough, nostril flare, and abdominal lift but not breathing frequency, thoracic auscultation, or exercise intolerance) correlated with tracheal mucus scores, BALF neutrophil percentages, and thoracic radiographic evidence of bronchial and tracheal thickening.[83]

In rare cases, horses with long-standing RAO develop cor pulmonale, which is evidenced by jugular distention, pulsation, ventral edema, and tachycardia, in addition to the clinical signs of RAO.[84-85] Although RAO-susceptible horses develop evidence of echocardiographic alterations during acute episodes of RAO (characterized by an increase in pulmonary artery diameter, a decrease in left ventricular diameter [and estimated stroke volume], and an abnormal septal motion), serum troponin measurements remain normal.[86] As the echocardiographic parameters return to normal when horses are in

VetBooks.ir

remission, it is likely that the reversibility of the airway disease reduces the risk of permanent myocardial disease.

Laboratory Aids and Diagnostic Tests The diagnosis of RAO is based on the history, the clinical signs, demonstration of the reversibility of airway obstruction following bronchodilator administration, and the response to therapy. It may be difficult to arrive at a definitive diagnosis in asymptomatic horses or in horses that are exhibiting mild signs at the time of the examination, thus necessitating the use of additional diagnostic tests such as cytologic analysis of lower respiratory tract secretions. During periods of clinical remission, BALF cell populations obtained from RAO-susceptible horses consist predominantly of mononuclear cells (90% macrophages and lymphocytes), and the cell differential counts do not differ from those found in healthy horses.[87] However, when horses develop RAO, aspirates of tracheal and bronchoalveolar fluid contain increased numbers of nondegenerative neutrophils (>25%). The BALF neutrophil percentages may be as great as 90%, far exceeding the normal 5% to 15% found in healthy horses that are stabled and fed hay. The extent of pulmonary neutrophilia alone is not correlated with severity of clinical signs.[88] There also is no regional difference (left versus right lung) in neutrophil percentages in affected horses.[88] In most cases the percentage of eosinophils or mast cells is not increased in affected horses. Therefore cytologic analysis of respiratory secretions in RAO-affected horses reflects a suppurative nonseptic inflammation, distinguishing this disorder from lungworm infections (pulmonary eosinophilia) or pneumonia (degenerative neutrophils, intracellular bacteria). In rare cases, infectious bronchitis may complicate RAO; microbial cultures yield low growth of the bacterial isolate, but the predominant cell type in the tracheal secretions is a nondegenerative neutrophil.

Endoscopic examination of the respiratory tract of RAO-affected horses demonstrates excessive amounts of tracheobronchial secretions that originate from most of the bronchial segments. Distal airways are edematous and inflamed, and airways easily collapse during expiration. Expectorated secretions from the lower respiratory tract coat the pharynx, larynx, and other structures of the upper respiratory tract.

In general, the complete blood cell count, serum biochemistry profile, and serum fibrinogen concentrations are usually normal in RAO-affected horses.[78] In severely stressed horses, a mature neutrophilia and lymphopenia may be evident on the leukogram. Recently, Lavoie-Lamoureux and colleagues reported significant increases in serum haptoglobulin and serum amyloid A concentrations in symptomatic RAO-affected horses, challenging the conventional thinking that RAO is a compartmentalized inflammatory response.[89]

Arterial blood gas analyses are normal in approximately 25% of the cases,[90] but other cases exhibit hypoxemia (Pa_{O_2} < 85 mm Hg) with or without evidence of arterial hypercapnia.[91] In affected horses that are exercised, at a given work effort the arterial oxygen tensions are reduced compared with blood gas values obtained from the same horses during clinical remission.[92] Prognostic value of arterial blood gases in RAO-affected horses has not been examined.

In a study of digital thoracic radiographs of 22 warmblood horses affected with RAO, an unstructured interstitial pattern was found in all cases; a bronchointerstitial pattern occurred in 21 cases, and an alteration in the diaphragmatic silhouette (flattened or concave presumably due to lung hyperinflation) was noted in 10 cases. None of the thoracic radiographs demonstrated evidence of hilar opacity or concavity.[93] Nevertheless, radiographs may be of limited value in diagnosing RAO because the accentuated bronchointerstitial pattern can often be detected in healthy aged horses. Radiographs can be useful in ruling out thoracic neoplastic or infectious (interstitial or bronchopneumonia pneumonia, equine multinodular pulmonary fibrosis) disorders in horses that have clinical signs resembling RAO (cough, nasal discharge, abnormal breathing effort). In severely affected horses with RAO that repeatedly fail to respond to medical interventions, radiographs should be taken to determine if bronchiectasis (dilation or deformation of the bronchi or bronchioles) exists.[94] Bronchiectasis is a relatively uncommon complication of RAO but, when it occurs, it causes irreversible airway obstruction as a result of collapse of the affected airways.

Ultrasound evaluation of RAO-affected horses confirms a shift of the caudal lung border caused by alveolar hyperinflation.[95] However, gas in the large colon (left side) or in the cecum (right side) may preclude complete imaging of the most caudal extent of the lung fields at the sixteenth intercostal space. Thoracic ultrasonography of RAO-affected horses may demonstrate small hypoechoic areas of irregularity on the lung surface, but in general ultrasonography is not useful in detecting airway inflammation. In horses with cor pulmonale, ultrasonography confirms the presence of pulmonary hypertension and right ventricular hypertrophy.[85]

Lung biopsies, although not typically performed to diagnose RAO, demonstrate bronchiolar goblet cell metaplasia, bronchiolar luminal exudate, peribronchiolar lymphoplasmacytic cell infiltration, and accumulations of neutrophils within the airways.[77] The potential disadvantages of performing a lung biopsy include the risk of inducing hemorrhage (hemothorax, epistaxis) and the chance of obtaining a nonrepresentative tissue sample.

Intradermal skin testing of RAO-affected horses has been investigated by many with the aim of diagnosing RAO and identifying the offending allergens. Evans and colleagues found that in RAO-affected horses the total number of positive intradermal skin tests evaluated at 0.5, 4 to 6, and 24 hours after allergen injection exceeded that in control horses. Positive responses were detected for two pollens (English plantain, goldenrod), three molds *(Rhizopus* spp., *Monilia* spp., and *Alternaria tenuis),* and one insect extract (*Tabanus* spp.). However, this difference in skin reactivity, which involved only 3% of the possible extract reactions, did not permit discrimination between a diseased horse and a healthy horse.[96] Similarly, in a retrospective study of cases examined at a veterinary teaching hospital over a 10-year period, Jose-Cunilleras and colleagues found that the percentage of RAO-affected horses that had positive skin reactions exceeded that of the control horses at each time point examined (0.5, 4, and 24 hours).[97] In contrast, others have failed to find a significant difference between RAO-affected and control horses in either the number of positive skin responses to a variety of molds in the titers developed at the early (0.5, 4 hours) or late (24 hours) phases.[98-100] Wong and colleagues, evaluating the skin responses to intradermal histamine and *Aspergillus* antigens, found that compared with the controls the RAO-affected horses had a heightened response to histamine (evaluated at 0.5 hours post injection) and a delayed resolution of the skin wheal (after 24 hours) to the *Aspergillus* antigens.[101] Thus positive skin tests and serum precipitins to fungal and thermophilic actinomycete antigens are found in many normal as well as RAO-affected horses, reflecting a level of exposure of the horse rather than a susceptibility to disease. In general, skin testing does not allow identification of RAO-susceptible or RAO-affected horses or the specific inhaled particulate that is inciting the pulmonary inflammation.[102]

Serum allergy tests such as the radioallergosorbent test (RAST) or IgE-based enzyme-linked immunosorbent assay (ELISA), which aim to identify the allergen that is inciting the hypersensitivity, are of limited value in the diagnosis of RAO. Lorch and colleagues compared the results of three serum IgE quantitation assays (the spot test, a RAST; Allercept [Heska, Loveland, Colo.], an ELISA that uses a recombinant human FcεRIα chain as the IgE readout reagent; and equine ELISA, which uses a polyclonal antiserum to detect equine IgE) with intradermal skin test responses in RAO-affected horses. They concluded that based on the poor performance of all three tests, none should be used as a screening test for allergen hypersensitivity.[103] Similar conclusions were reached by Tahon and colleagues (2009) who compared the Allercept test and the CAST (Alpco, Salem, N.H.) test (which measures IgE-mediated release of sulfidoleukotrienes from peripheral blood basophils) with intradermal testing in RAO-affected horses and controls. None of the tests showed a significant difference in responses between diseased and control horses and thus did not support an IgE-mediated basis for RAO.[104]

Conventional pulmonary function tests, which require measurements of pleural pressure (obtained via an intrathoracic esophageal balloon catheter system) and airflow (detected by a flow meter attached to a sealed face mask worn by the horse), are typically reserved for experimental investigations and are not routinely performed on clinical patients. The characteristic alterations in the pulmonary function test results of horses with RAO are a decrease in dynamic lung compliance or lung distensibility (C_{dyn}), an increase in pulmonary resistance (R_L), an increase in maximum pleural pressure changes (ΔP_{plmax}), and an increase in peak inspiratory and expiratory flow rates.[105] In general, C_{dyn} reflects peripheral airway function, whereas R_L reflects central, larger airway function. RAO-affected horses also exhibit bronchial hyperreactivity: the dose of aerosolized histamine or methacholine required to reduce C_{dyn} to 65% of its baseline value is much less in diseased horses than in controls.[106] These alterations in lung function that develop in affected horses are repeatable on reexposure to hay dust.[107,108] During periods of clinical remission the pulmonary function test results return to normal and are not significantly different from those of healthy age-matched horses. However, an inability to detect a difference in R_L or C_{dyn} between healthy horses and RAO-susceptible horses during periods of disease remission may reflect a relative lack of sensitivity of these tests.[109] For example, some researchers have found that in RAO-susceptible horses during periods of clinical remission, some degree of bronchial hyperreactivity and airflow obstruction remains.[110,111] In some tertiary care centers, pulmonary function testing using impulse or forced oscillation methods aids in the diagnosis of RAO. (See Inflammatory Airway Disease section).

Pathophysiology The changes in respiratory mechanics and the development of clinical signs are consequences of the influx of inflammatory cells (mechanisms discussed earlier), the contraction of smooth muscle in the airways, and the production and accumulation of mucus. Bronchoconstriction probably results from the cumulative effects of (1) released inflammatory mediators (histamine, serotonin, eicosanoids, leukotrienes, endothelin) and (2) activation of muscarinic receptors on the smooth muscle by released acetylcholine.[112] In addition to their direct effects on smooth muscle tension, histamine and serotonin also augment the release of acetylcholine from parasympathetic nerves.[113] Based on in vitro muscle bath studies, there is also evidence that RAO-affected horses lack inhibitory nonadrenergic-noncholinergic innervation of the peripheral (but not central) airways, further contributing to the development of bronchospasm.[114] The expression or distribution of airway muscarinic receptor subtypes (M_1, M_2, M_3) is, however, unaltered in RAO-affected horses.[115] The magnitude of airway narrowing that occurs in response to smooth muscle contraction is a function not only of the thickness of the smooth muscle layer but also of the width of the mucosal layer between the muscle and airway lumen. Thus thickening of the airway by peribronchial infiltrates and by epithelial metaplasia amplifies the airway narrowing induced by bronchospasm.[116]

As noted earlier, excessive mucus is evident endoscopically and cytologically in RAO-affected horses. Mucus consists of a liquid sol layer, which surrounds the ciliated epithelium, and an overlying viscous gel layer, which contains water, electrolytes, lysozymes, cells, and the mucin glycoproteins. In RAO-affected horses the excessive mucus formation may be the result of an upregulation of a mucin-producing gene, responding to released elastases, reactive oxygen species, and other inflammatory mediators. However, Gerber and colleagues were unable to demonstrate an upregulation of two mucin-producing genes, MUC5AC and MUC2, in airway tissues of RAO-affected horses.[117,118] Increased viscosity of the mucus[119] may be a consequence of alterations in the side chain glycoproteins[120] and/or formation of mucin aggregates from DNA and actin released by airway neutrophils. Delayed clearance of the mucus from the lower respiratory tract contributes to the accumulation of the exudate and may reflect an impairment of the mucociliary apparatus as a result of epithelial cell destruction.[121,122]

Airways that are narrowed, obstructed, or both (as a result of inflammatory exudate, alterations in pulmonary surfactant, or both[123,124]) increase R_L and fail to participate in efficient gas exchange. Low ventilation-perfusion lung regions contribute to a widening of the alveolar-arterial oxygen-difference ($AaDO_2$) gradient and the development of arterial hypoxemia.[125,126] High ventilation-perfusion regions (dead space) also increase in affected horses, but normal arterial $PaCO_2$ levels can be maintained in some horses through increases in the total minute ventilation.[127] Changes in minute ventilation are usually due to an increase in breathing frequency, as tidal volume changes little with the disease. In general, there are no significant changes in cardiac output, heart rate, and mean systemic arterial pressure, but pulmonary artery systolic and mean pressures and pulmonary vascular resistances are significantly increased in diseased horses.[127] The combination of airway inflammation and hypoxemia, if severe enough, stimulates the respiratory controller in the ventral medulla to increase the respiratory drive and to activate inspiratory and expiratory muscles (abdominal heave). Recruitment of respiratory muscles increases the maximum pleural pressure excursion (ΔP_{plmax}), the work of breathing, and the total body oxygen consumption.[128] However, much of the increased expiratory effort (and increased intrathoracic pressures) collapses the noncartilaginous airways, further compounding gas trapping and impairing gas exchange.

Pathology The lungs obtained from RAO-prone horses that are asymptomatic at the time of death macroscopically appear normal.[125] In symptomatic horses, the lungs are pink, soft, hyperinflated, and imprinted with rib impressions. Lungs fail to collapse when the chest is opened because of gas trapping distal to occluded airways.[98] Emphysematous bullae are usually lacking, but accumulations of mucus and cellular debris occlude the small airways, forming spiral-shaped casts known as *Curschmann spirals.* Light and electron microscopic examinations of lung segments from diseased horses demonstrate that the peripheral airways are the most severely affected, although pathologic alterations do occur in the central airways.[121,122] Histologic changes include goblet cell hyperplasia, epithelial cell damage, bronchial and bronchiolar epithelial cell hyperplasia, smooth muscle hypertrophy and hyperplasia, and overinflation of the alveoli.[129-131] It is interesting to note that the extent of the bronchiolar epithelial cell hyperplasia is correlated with the increase in dead space ventilation that occurs in RAO-affected horses.[127] Peribronchiolar infiltrates consist of lymphocytes and plasma cells, along with collagen deposition[132]; eosinophils are rarely observed either within the airways or in the lung parenchyma. In the peripheral airways, the type and location of collagen I and III, examined by immunohistochemical techniques, is not increased in RAO-affected horses compared with controls.[133]

Despite these pathologic changes, the clinical signs are usually considered to be reversible. Increases in airway smooth muscle mass due to hyperplasia and hypertrophy, evident following 30 days of continuous allergen exposure in RAO-susceptible horses,[134] are reversed after long-term allergen avoidance or following inhaled corticosteroid administration.[135] In rare instances bronchiectasis may develop in RAO-affected horses. In a single case study of one such affected horse, histopathologic alterations of the affected airway demonstrated separation of the cartilaginous plates of the dilated bronchus, disorganization of the chondrocytes, reduction in the elastic fibers surrounding the perichondrium and lamina propria, and a lymphoplasmacytic infiltrate.[94]

In RAO-affected horses with cor pulmonale, reductions in the circumferential ratio of the aorta to the pulmonary artery and in the mass ratio of the left ventricle and septum to the right ventricle can be found.[85,136]

Treatment and Prognosis

ENVIRONMENTAL MANAGEMENT. Environmental management remains the single most important therapeutic and prophylactic intervention. Whenever possible, RAO-prone and RAO-affected

VetBooks.ir

horses should be kept outside at all times, blanketed during inclement weather as needed, and provided access to a well-ventilated three-sided shelter from which manure and urine are frequently removed. Horses should be provided with pasture access and supplemented with complete pelleted feed or hay cubes as needed. Some horses will tolerate hay that has been soaked in water, but this practice reduces the nutrient value of the hay and is often forsaken when the weather becomes cold. Preliminary data suggest that steamed hay may be helpful in preventing exacerbations of RAO in susceptible horses.[137] Reducing dust exposure is critical, as inhaling organic dusts for as little as 1.5 hours causes a significant increase in R_L. By 5 hours, horses exhibit significant decreases in C_{dyn} and PaO_2 and have evidence of pulmonary neutrophilia.[16,138] The ensuing inflammation from a single 5-hour dust exposure takes approximately 4 days to resolve.[139] For chronically affected horses that have been turned out to pasture, clinical remission and normalization of pulmonary function test results usually take 4 to 8 weeks depending on weather conditions.[2,140] However, owners should be warned that acute exacerbations of RAO may occur in susceptible horses turned outside during periods of hot (dusty) weather.[141]

Horses for which optimal management changes cannot be implemented should be fed pellets, hay cubes, or both and kept in well-ventilated stalls that are bedded with a material that has a low respirable dust particle count and mold concentration. Cardboard bedding has a significantly lower particulate concentration (dust, *A. fumigatus, F. rectivirgula,* and *T. vulgaris*) than do wood shavings, wheat, or flax straw, although cardboard may be difficult to obtain and store.[140,142] Horses should be removed from the barn when stalls or other areas are being cleaned. Typically, when affected horses are bedded on shavings and fed pelleted rations, significant improvements in the pulmonary function test results occur within 3 days.[143] Complete resolution of clinical signs may take 30 days, although not all horses may respond to only allergen reduction measures.[144] When RAO-susceptible horses that are in clinical remission are fed low dust–containing forages and bedded on low dust–containing materials or turned outside in a low dust environment, they can remain clinically normal for months. However, even though BALF neutrophil percentages, and indices of airway inflammation such as exhaled ethane, are normal, bronchial hyperreactivity and forced expiratory airflow in RAO-prone horses remains abnormal.[110,145-147] Therefore these horses will always be more susceptible to disease development than healthy horses when dust levels increase in the environment.

Environmental management considerations should also be implemented when horses are transported. Their heads should not be tied in close proximity to the hay net, as this practice places their breathing zone near a concentrated source of organic dusts and molds and restricts their head position so as to further decrease mucociliary clearance of respiratory secretions.[148]

BRONCHODILATORS. During acute exacerbations of RAO, bronchodilators can be very effective in improving lung mechanics and in establishing the reversibility (and thus diagnosis) of RAO. Three main classes of bronchodilators have been used in RAO-affected horses: these are the anticholinergics (muscarinic antagonists), the β_2-agonists, and the phosphodiesterase (PDE) inhibitors.

The muscarinic antagonists, of which atropine, ipratropium, and n-butyl scopolammonium bromide are examples, block the smooth muscle–constricting effects of acetylcholine. These actions have the greatest effects in the central as opposed to the peripheral airways. IV administration of 0.01 to 0.02 mg/kg of atropine sulfate decreases ΔP_{plmax} and respiratory rate and induces a clinical improvement usually within 30 minutes of administration.[149,150] Its short duration of action (2 hours) and its undesirable side effects (mydriasis, ileus, tachycardia, dry airway secretions) preclude its routine use in the treatment of RAO.[151] In contrast, ipratropium bromide is poorly absorbed from either the respiratory or gastrointestinal tract, minimizing the development of systemic effects. The powder form is nebulized (2 to 3 µg/kg) and exhibits an onset of action within 30 minutes with effects lasting from 4 to 6 hours.[152] When given to RAO-affected horses before an incremental exercise test, ipratropium reduces R_L and ΔP_{plmax} and increases C_{dyn} in resting horses but produces no significant improvement in exercise pulmonary function tests or oxygen consumption.[153] N-butyl scopolammonium bromide, when administered at 0.3 mg/kg intravenously, improves clinical scores and pulmonary function tests of RAO-affected horses within 10 minutes of its administration, with effects lasting for approximately 1 hour. No adverse effects were noted following its use in a research trial.[154]

The β_2-adrenergic agonists—clenbuterol, albuterol, fenoterol, pirbuterol, and salmeterol—produce relaxation of smooth muscle by increasing the intracellular levels of cyclic adenosine monophosphate (cAMP). The bioavailability of clenbuterol is greater than 90%, and when administered orally at a dose of 1.6 µg/kg of body weight twice per day (bid), a significant improvement in the clinical signs of horses with RAO can occur.[155] However, the effective dosage of clenbuterol may vary among horses: Traub-Dargatz and colleagues[156] found that 400 µg of oral clenbuterol hydrochloride administered twice daily failed to improve the severity of clinical signs, the BALF or tracheal cytologies, or the arterial blood gases in RAO-affected horses. During the treatment, horses were maintained outside but still fed hay. Erichsen and colleagues[155] recommended increasing the dose of clenbuterol stepwise if clinical improvement is not observed within 3 days of initiating treatment (e.g., 2.4 µg/kg for 3 days, 3.2 µg/kg for 3 days). Adverse side effects (anxiety, shivering, sweating, and tachycardia) occur at higher dosages but appear to be minimized when clenbuterol is increased in a stepwise manner. Reports of fatal overdoses of clenbuterol have been reported in horses estimated to have received 100 µg/kg orally of a compounded product.[157] In addition to its bronchodilatory effect, clenbuterol also exerts an antiinflammatory effect. When administered intravenously (0.75 µg/kg bid) to RAO-susceptible horses before hay dust exposure, there is a significant attenuation of the BALF neutrophilia and the transcription of the proinflammatory genes, TNF-α and IL-1.[158] Prolonged administration of clenbuterol (0.8 µg/kg bid for 3 weeks) may result in tachyphylaxis[159] due to downregulation of β-adrenoceptors, but this phenomenon may be reversed with concurrent corticosteroid administration.[160]

Other β_2-agonists have been administered as aerosolized drugs to RAO-affected horses. Inhalation therapy allows direct delivery of the drug to the respiratory tract, minimizes the total amount of drug needed to be delivered, and reduces the prevalence of unfavorable systemic effects. The metered dose inhaler containing the drug is attached to a delivery system such as a mask (Aeromask, Trudell Medical, Inc., London, Ontario, Canada) or other device (Equine Haler [Equine Health Care, Inc., Hørsholm, Denmark] or Aerohippus [Trudell Medical, Inc.]). The systems contain spacers to optimize the drug particle size that is inhaled (larger sized particles drop out) and deposited in the lower respiratory tract. Both the Equine Haler and Aerohippus exhibit similar efficacy in drug delivery and clinical improvement.[161] The inhaled rapidly acting β_2-agonists pirbuterol, albuterol sulfate, and fenoterol improve pulmonary function by 60% to 70% in RAO-affected horses for approximately 1 to 3 hours, necessitating frequent administration of the drugs.[162-164] They are poorly absorbed, so systemic effects are uncommon. The recommended dose of albuterol for a 450-kg horse is 600 to 720 µg q4-6h, for fenoterol it is 2 mg q4-8h, and for pirbuterol it is 16 µg/kg q4-6h. More frequent administration may be necessary in some horses. Salmeterol, a longer-acting β_2-agonist, is administered at a dose of 0.5 µg/kg q6-8h. Clinical improvement develops within 2 hours of administration, but significant decreases in pulmonary resistance last for only 6 hours.[165]

The PDE inhibitors are the third class of bronchodilators and are represented by aminophylline and pentoxifylline. These drugs inhibit the breakdown of intracellular cAMP, thus maintaining smooth muscle relaxation. PDE inhibitors also exert antiinflammatory properties.[166] The clinical efficacy of aminophylline (the soluble salt of theophylline) was evaluated by Pearson and Riebold in 18 clinical cases of RAO. Administration of 12 mg/kg IV in 1 L of 5% dextrose

VetBooks.ir

achieved blood levels of 10 µg/mL, improved clinical signs in 50% of the cases, and reduced ΔP_{plmax} in 41% of cases. Horses also became hyperesthetic and hyperexcitable and trembled.[150] Because of the narrow range between therapeutic efficacy (serum concentrations = 10 µg/mL) and toxicity (serum concentration = 15 µg/mL), aminophylline is not routinely used for the treatment of RAO. Pentoxifylline is well absorbed after oral administration (16 g bid, 32 mg/kg), improves pulmonary function test results (effects are similar to those produced with atropine), and lacks adverse side effects. It does not improve BALF neutrophilia.[167]

ANTIINFLAMMATORY DRUGS. Whereas most corticosteroids are efficacious in the treatment of RAO, NSAIDs have not proven to be beneficial.[50] Oral prednisone also does not improve the clinical signs, the BALF cytologic alterations, or the pulmonary function test results in RAO-affected horses.[143,168,169] Its therapeutic failure is attributed to its poor absorption and the lack of conversion to the active metabolite, prednisolone.[169] In contrast, both liquid and tablet forms of prednisolone are rapidly absorbed from the equine gastrointestinal tract (bioavailability is approximately 50%), achieve peak prednisolone concentrations 45 minutes post-administration, and exert pharmacologic effects (based on changes in serum cortisol levels) for 8 hours.[169] Oral prednisolone (2 mg/kg PO once per day [sid] for 7 days) improved pulmonary function test results (R_L, elastance E_L, and ΔP_{plmax}) within 3 days of its administration to RAO-affected horses stabled and continuously exposed to dusty hay[170] but was less efficacious than oral dexamethasone (0.05 mg/kg PO q24h) treatment.

The beneficial effects of dexamethasone in the treatment of RAO-affected horses have also been investigated by several different research groups.[168-173] Within 2 hours of its IV administration to RAO-affected horses (0.1 mg/kg), there is a 37% decrease in ΔP_{plmax} that is further reduced 59% by 4 hours post treatment.[169] Oral administration of the IV formulation of dexamethasone (0.164 mg/kg q24h to account for bioavailability) produces a significant improvement in lung function parameters within 6 hours of treatment, with peak effects occurring 24 hours later.[169] For horses that are maintained in dusty environments during a 10-day treatment period, IV dexamethasone (0.1 mg/kg q24h) or dexamethasone isonicotinate (0.04 mg/kg IM every 3 days for three treatments) improves pulmonary function within 3 days of initiating therapy[168] and reduces airway inflammation (BALF neutrophilia) within 10 days of treatment.[172] As might be predicted, a single dose of dexamethasone isonicotinate (0.06 mg/kg IM) administered to RAO-affected horses maintained in a dusty environment fails to provide discernible improvements in the clinical score, the pulmonary function test results, the BALF cytologic findings, or the activities of the transcription factors NF-κB or AP-1 evaluated 10 days post treatment.[173] In general, the rapid onset of action of IV dexamethasone makes this an antiinflammatory of choice in horses exhibiting respiratory distress caused by RAO.[174]

The therapeutic efficacy of triamcinolone acetonide and isoflupredone has also been evaluated in RAO-affected horses maintained in a dusty environment.[175,176] A single IM dose of triamcinolone acetonide (0.09 mg/kg) markedly improved lung mechanics evaluated 7 and 14 days post treatment, and this effect lasted for 4 weeks. Cytologic changes were also evaluated 14 days post treatment and demonstrated a reduction in airway neutrophilia (neutrophil percentages decreased from 62% to 32%), but this improvement was not statistically significant.[175] Adverse effects of triamcinolone administration were not reported. In another study, RAO-affected horses received isoflupredone acetate for 14 days (0.03 mg/kg IM q24h) while being maintained in a dusty environment. Significant increases in C_{dyn} and reductions in R_L and ΔP_{plmax} occurred within 3 days of initiation of the treatment[176]; beneficial effects continued 7 days beyond the cessation of drug therapy. The only adverse effect noted was the development of hypokalemia.

The effectiveness of a 3-week course of inhaled fluticasone on pulmonary function, BALF cytologies, and BALF cell gene expression was examined by Giguère and colleagues.[26] RAO-affected horses that received 2 mg of fluticasone propionate bid for 21 days while still being fed hay demonstrated marked (and significant) improvements in ΔP_{plmax}, C_{dyn}, and R_L by day 21 of the treatment period. Furthermore, BALF neutrophil counts became normal and IL-8 copy numbers in the BALF cell were reduced to levels equivalent to those found during remission.[26] In an experimental trial, Robinson and colleagues[174] compared the therapeutic and preventive efficacies of inhaled fluticasone (6 mg bid) and IV dexamethasone (0.1 mg/kg q24h) on pulmonary function and BALF cytologies in RAO-affected horses. They found that (1) no adverse effects, including laminitis, were associated with a 3-day course of fluticasone at 6 mg bid; (2) greater reductions in ΔP_{plmax} in RAO-affected horses were achieved with dexamethasone than with fluticasone treatment; and (3) prophylactic (3-day) and continual (4-day) administration of fluticasone (6 mg bid) to RAO-susceptible horses subjected to stabling and dusty hay exposure is more efficacious in preventing the disease than is dexamethasone. The investigators concluded that dexamethasone should be used for "rescue" therapy, whereas fluticasone is best used as a preventive agent. Fluticasone is approximately 18 times more potent than another inhaled corticosteroid, beclomethasone dipropionate. Nasal or oral administration of fluticasone has no effect on circulating glucocorticoid levels, suggesting that the bioavailability across nasal and intestinal epithelium is poor.[177] However, daily aerosolization of fluticasone (dose of 1.5, 3, or 6 mg bid) significantly reduces serum cortisol measured 72 hours after initiating therapy.[174,177] The effect of long-term fluticasone administration on innate and immune responses has also been investigated. Administration of 2 mg bid for 11 months to RAO-affected or susceptible horses had no significant effect on (1) peripheral blood leukocyte, neutrophil, or lymphocyte numbers; (2) percentages of lymphocyte phenotypes; (3) blood neutrophil chemokine (IL-8, TNF-α) and glucocorticoid receptor gene expression; (4) IgG vaccine titers induced by immunization against tetanus toxoid or an inactivated IBR vaccine; or (5) mitogen-induced lymphocyte proliferative responses.[178] These data suggest that fluticasone is a relatively safe drug for use in the treatment of RAO.

Another inhaled corticosteroid that has been widely investigated in RAO-affected horses is beclomethasone diproprionate. When administered at a dose of 1320 to 1500 µg bid for 7 to 10 days to diseased horses continuously stabled and fed dusty hay, investigators noted that by day 7 of treatment there was a significant improvement but not a complete normalization of pulmonary function test results and BALF neutrophil percentages.[81,179]

Inhaled steroids are often used in conjunction with inhaled bronchodilators for maximal therapeutic effects. When separate formulations are used, it is recommended that the bronchodilator be administered first so as to improve subsequent glucocorticoid deposition in the peripheral airways.[180] As suggested earlier, when administering glucocorticoids, adrenal gland atrophy, immunosuppression, and precipitation of laminitis remain a concern. All of the previously discussed parenteral and inhaled glucocorticoids reduce endogenous serum cortisol levels but despite prolonged treatment protocols with glucocorticoids, adrenal gland responsiveness to adrenocorticotropic hormone administration remains.[175,176,181] Finally, despite the improvement in clinical signs and in pulmonary function tests achieved with glucocorticoid therapy, BALF neutrophilia remains evident until environmental management changes are implemented.

OTHER THERAPIES. In horses that develop respiratory distress because of the bronchospasm and airway inflammation, additional therapies are required. Administering nasal oxygen at flow rates as low as 5 L/min improves arterial oxygen tension by as much as 30 mm Hg in some severely affected horses.[182] As the total nasal oxygen flow increases, so too should the mean arterial oxygen tension, although not to the same degree that occurs in healthy horses. Flow rates of 30 L/min (delivered by 2 nasal cannulae at 15 L/min) are associated with coughing and gagging in horses. Nasal oxygen supplementation does not reduce breathing frequency,

VetBooks.ir

suggesting that stimulation of vagally mediated afferents (perhaps responding to inflammatory mediators) is responsible for the tachypnea.

Furosemide (1 mg/kg IV or nebulized) provides beneficial effects to RAO-affected horses within 20 minutes of its administration, decreasing R_L and increasing C_{dyn} without affecting PaO_2.[183] The beneficial effects appear to be mediated by prostaglandin E_2, derived from either the renal or the airway epithelium, which promotes smooth muscle relaxation. Prior treatment with the cyclooxygenase inhibitor flunixin meglumine prevents the furosemide-induced bronchodilation.[184]

Additional therapeutic approaches that have *not* been found to be efficacious in the treatment of RAO-affected horses include a single acupuncture treatment,[185] the oral administration of an herbal preparation containing thyme and primula,[186] the rapid IV administration of 30 L of isotonic saline,[187] a constant rate infusion of IV lidocaine,[188] and sound-wave physiotherapy.[189]

Prognosis RAO-prone horses are likely to develop acute exacerbations of the disease when husbandry practices lapse or when weather conditions become adverse. Horses do not "outgrow" the disorder, and, in fact, some clinicians believe that the inflammation becomes more difficult to manage as the horse ages. The basis for the lack of clinical response is unknown but may be the result of lung remodeling—development of fibromuscular hyperplasia in the alveolar septa,[85] excessive smooth muscle hyperplasia,[131] bronchiectasis,[94] or potential downregulation of the glucocorticoid receptor.

If proper environmental management changes are implemented and if the appropriate therapy is initiated, then clinical remission occurs in most cases. In a follow-up survey conducted by Naylor of RAO-affected horses that had been examined and treated at a referral center 2 to 4 years previously, it was found that 20% of the original cases (3 of 15) had been euthanized, that 33% were still receiving bronchodilators on an as-needed basis, and that the athleticism had not decreased in 92% of the horses.[77] Similarly, in a follow-up survey conducted by Aviza and colleagues,[78] 13% of the horses that had been diagnosed with RAO 3 to 4 years earlier had been euthanized. However, in contrast to Naylor's findings, Aviza noted that more than 50% of the respondents in that survey stated that the athletic performance of the horse had been compromised by the disease. Perhaps this difference between the two surveys simply reflected a failure of the owners to comply with environmental management recommendations. When queried about the husbandry practices, 77% of the respondents still stabled the horse for part of the day, and 84% still fed the horse dry hay.[78]

Because the effects of repetitive episodes on the development of irreversible changes in lung structure have yet to be determined, clients should be encouraged to implement effective husbandry changes that minimize the recurrences of RAO.

Summer Pasture–Associated Obstructive Pulmonary Disease

Dorothy M. Ainsworth

Definition and Etiopathogenesis In the southeastern United States a condition clinically similar to RAO called *summer pasture–associated obstructive pulmonary disease* (SPAOPD) develops in mature horses that are kept outdoors on pasture. Clinical signs typically occur between the early summer and early autumn (June through September) when the weather is warm and humid.[1] Clinical signs partially or completely resolve during the winter or when the horse is removed from the pasture; thus the pulmonary inflammatory condition is considered reversible. The temporal pattern of clinical signs parallels increases in environmental fungal spore *(Basidiospore, Nigrospora,* and *Curvularia)* and grass pollen counts (Bermuda grass and Johnson grass).[2] Thus it is thought that these aeroallergens (and potentially others) trigger the disease. SPAOPD has also been reported to occur in horses in the United Kingdom although some of those cases may represent horses with underlying (subclinical) recurrent airway obstruction (RAO) whose condition is exacerbated by hot weather and airborne particulates.[3-5]

Investigators have sought to determine if SPAOPD reflects a T-helper type 2 (Th2) or T-helper type 1 (Th1) immune response to the airborne particulates by examining antibody and cytokine profiles in the pulmonary secretions of affected horses. In one study, neither the total nor the antigen-specific immunoglobulin E and G (IgE and IgG) titers to certain fungi (*Aspergillus* spp., *Cladosporium herbarum, Penicillium* spp.), thermophilic actinomycetes species *(Faenia rectivirgula, Saccharomonospora viridis, Thermoactinomyces thalpophilus),* or to the forage mite *Lepidoglyphus destructor* in the tracheal lavage fluid were increased in SPAOPD-affected horses relative to controls.[6] During the winter months, when the horses are free of clinical signs, *A. fumigatus*–specific (IgG) titers in the SPAOPD group exceeded those in controls, but it was not known if this increase reflected ongoing production or decreased consumption.

Cytokine profiles in bronchoalveolar lavage (BAL) cells and peripheral blood mononuclear cells (PBMCs) (or lymphocytes) isolated from SPAOPD-affected and control horses fail to provide consistent support for a Th2 response. Increased gene expression of interleukin (IL)-4 and interferon (IFN)-γ in BAL cells and PBMCs isolated from symptomatic horses relative to controls was reported in one study.[7] In another investigation by the same group,[8] the gene expression of IFN-γ and IL-13 (but not IL-4) in BAL cells and peripheral blood lymphocytes isolated from symptomatic horses exceeded that of controls. Only when horses were asymptomatic (winter) did BAL cell or peripheral lymphocyte IL-4 gene expression exceed that of controls.

Venugopal and colleagues performed differential display polymerase chain reaction on lung samples obtained from symptomatic horses and controls.[9] Of the 88 genes that were differentially expressed, 18 genes were eventually identified and assigned functional roles such as lung protection; defense; mediation of proinflammatory or antiinflammatory responses; promotion of, or protection from, oxidative stress; cell recovery and repair; and mitogenesis. Of the 18 genes, only secretoglobin was downregulated in diseased horses. This gene encodes a family of proteins that blocks the activation of phospholipase A_2 so that its decreased expression would be expected to enhance arachidonic acid metabolism and the formation of inflammatory and vasoactive leukotrienes and prostaglandins. Venugopal also reported upregulation of eight genes that encode proteins associated with cell repair and proliferation[9] involved in lung repair and airway remodeling, supporting histopathologic changes previously described in affected horses.[10] Differential expression of immune cytokines (IL-4, IFN-γ, IL-17, TGF-β) was not reported in their study.

Because of the role of endothelin-1 (ET-1) in the pathophysiology of human obstructive pulmonary disorders, investigators have evaluated ET-1 concentrations in horses with SPAOPD. This 21-amino acid peptide induces bronchoconstriction; enhances mucus secretion; promotes DNA syntheses and cell proliferation in airway smooth muscle cells; and facilitates airway inflammation by upregulating IL-1, IL-4, IL-8, TNF-α, and IFN-γ expression.[11,12] Compared with control horses, symptomatic SPAOPD horses have increased ET-1 protein concentrations in the venous blood, bronchoalveolar lavage fluid, and pulmonary epithelial lining fluid.[12] This finding, coupled with the observation that endothelin receptors A and B in the bronchial smooth muscle of affected horse are increased,[11] suggests that ET-1 is just one mediator involved in the pathophysiology of SPAOPD.

Epidemiology Based on a survey of large animal veterinarians practicing in Louisiana who had examined horses with SPAOPD,[13] the median age of affected horses was 12 years, and male and female horses were equally affected. Quarter Horses were overrepresented in the affected group. Nearly 61% of the affected horses were on pasture at all times, and 99% of the cases were kept on pasture more

VetBooks.ir

than half of each day. In an earlier retrospective study[1] Seahorn and Beadle reported the mean age of clinical cases was 13.7 years and that 79% of cases developed SPAOPD on a recurring basis over the horse's lifespan.

Clinical Signs and Differential Diagnoses The clinical signs of SPAOPD are seasonal and reversible and vary in severity depending on the duration of disease. Initial signs may be subtle and include exercise intolerance, intermittent cough, intermittent nasal discharge (serous or mucoid), and tachypnea. As the disease progresses, accentuated expiratory efforts (heave line), nostril flaring, frequent coughing, and even respiratory distress become evident.[1] Crackles, wheezes as well as silent areas, suggesting the absence of air movement, may be auscultated.[1,10] Horses are usually afebrile. Differential diagnoses include concurrent bacterial, viral, or fungal respiratory infections (ruled out by evaluation of blood work and culture/examination of tracheal aspirates) and anhidrosis (ruled out by assessing sweat production in affected animals).

Diagnosis Historical and physical examination findings, along with the temporal development of clinical signs, support the diagnosis of SPAOPD. As with RAO, endoscopy of the lower respiratory tract reveals an accumulation of mucopurulent exudate within the tracheobronchial tree and evidence of bronchial epithelial hyperemia (in some horses). During bronchoscopic examination, dynamic collapse of the airway during expiration may be evident. Cytologic analysis of tracheobronchial secretions or of bronchoalveolar lavage fluid demonstrates neutrophilia (15% neutrophils), the absence of intracellular bacteria, and excessive mucous production.[10] Microbial culture of pulmonary secretions is typically negative. Thoracic radiographic examination may reveal mild to moderate bronchointerstitial patterns with evidence of lung field hyperexpansion (flattened diaphragm). Ultrasonographic findings, although not specifically described in SPAOPD-affected horses, would be expected to be similar to those in horses with RAO. Postmortem examination of the lungs from affected horses reveals overinflation, the presence of rib impressions, and a failure to collapse. Histopathologic changes include accumulation of mucus and neutrophils in the small airways, peribronchiolar smooth muscle hypertrophy, epithelial hyperplasia, and peribronchial neutrophilic and lymphocytic infiltrates. There is usually minimal evidence of emphysema and fibrosis.[10]

Treatment The most important management change to implement is to move the horse from the offending pasture to either another pasture or to a cool, dust-free stall that is bedded with shavings. Hay should be moistened and fed to the horse from the ground to reduce inhalation of organic dusts. When stalls and barn areas are being cleaned, the horse should be removed from these areas. Medical therapies include administration of glucocorticoids and bronchodilators, as described for horses with RAO (see Treatment of RAO).

Prognosis Recurrence of the condition is likely to develop when susceptible horses are exposed to environmental triggers. Longitudinal studies have not been conducted to ascertain the risk of permanent (irreversible) lung remodeling in recurring cases. The heritability of SPAOPD has not been established.

Inflammatory Airway Disease in the Horse

Melissa Mazan

What Is Inflammatory Airway Disease? *Inflammatory airway disease (IAD), small airway inflammatory disease, small airway disease,* and *allergic airway disease* are names that are often used interchangeably, but the once-fluid definition of IAD is slowly taking form. Although low-grade inflammation of the small airways is recognized as a common cause of poor performance in young to middle-aged athletic horses, it is only recently that the clear distinction has been made between heaves, or recurrent airway obstruction (RAO), and IAD. Workers in the field continue to debate whether IAD is a discrete disease entity[1] or whether it is merely a part of the continuum of airway inflammation that, if left untreated, will progress inexorably to the better characterized syndrome of RAO.[2] Horses with IAD are generally young, although middle-aged horses may also be affected[3]; have impaired performance that may go unnoticed at rest or during light work[4-6]; have mild to moderate airway inflammation that may involve neutrophils,[6,7] mast cells,[4,8,9] eosinophils,[2] or lymphocytes[6]; have variable clinical signs, including cough, nasal discharge, and abnormal lung sounds[2,8,10]; may have endoscopic evidence of tracheobronchial mucus accumulation[2,8,11]; and may have normal lung function at rest but show evidence of airway hyperresponsiveness on exposure to nonspecific agents such as histamine[12] or evidence of low limitations on forced expiratory maneuvers.[5] These observations were confirmed by a consensus agreed on in October 2002,[13] which also stated that the clinical picture of horses with IAD includes poor performance or exercise intolerance, coughing, and excessive tracheal mucus (although not all of these need be present) and nonseptic inflammation as detected by bronchoalveolar lavage cytology. In addition, these horses may have lung dysfunction, as evidenced by airway obstruction, airway hyperresponsiveness, or abnormal blood gas exchange. This definition specifically excludes horses that appear systemically sick or that have overt evidence of respiratory dysfunction, such as flaring nostrils or excessive thoracic or obvious abdominal breathing efforts.

The prevalence of IAD is somewhat of a guessing game. One study involving 965 Standardbreds in active racing founding that 22% had evidence of mucopus at the trachea or bronchial bifurcation when examined endoscopically, although these were diagnosed as horses with chronic obstructive pulmonary disease (COPD); undoubtedly these horses properly belong in the IAD group.[14] Similarly, 27% of actively racing Thoroughbreds in one study had IAD.[15] A remarkable 55% of 2-year-old Thoroughbreds in training could be classified as having lower airway disease on the basis of finding mucus in the trachea on endoscopy and inflammation on examination of tracheal aspirate fluid,[16] and abattoir studies have shown up to 37% of horses with histopathologic evidence of airway inflammation.[17] Because a standard definition of IAD has only recently been agreed on, the prevalence of IAD has varied according to the individual researcher's case definition. Nonseptic airway inflammation, regardless of whether it causes overt signs of respiratory disease, appears to be very common in performance horses. This discussion adheres to the definitions of IAD and RAO as developed by the International Workshop on Equine Chronic Airway Disease,[13] the Havemeyer Workshop, and the recent American College of Veterinary Internal Medicine (ACVIM) consensus statement on IAD. With RAO, horses have demonstrable lower airway obstruction, characterized by peak pleural pressures of at least 15 cm H_2O, induced by an environmental challenge of moldy hay, largely reversible by use of a bronchodilator or return to nonchallenge environment, and accompanied by an increase in BALF neutrophils during challenge. In contrast, IAD refers to a nonseptic airway disease in athletic horses that does not have a clearly defined allergic cause. The data from the many studies involving horses with what was traditionally known as COPD and is now more properly referred to as RAO, or heaves, did not conform with these guidelines, and many of the horses would more properly be characterized as having IAD.

Clinical Findings Although most investigators agree that IAD is a disease of younger horses expected to do athletic work, and as such is distinct from the picture of the dyspneic horses with overt RAO, there remains a plethora of clinical signs and case definitions for IAD. One of the most common findings in IAD is exercise intolerance, with or without overt signs of respiratory disease. Of 25 horses referred either for routine physical examination or for poor performance, and without any clinical signs or history of respiratory disease, 76% had evidence of airway inflammation according to an inflammation scoring system based on endoscopy and tracheal wash findings.[18] Subclinical airway disease may result simply in mild

VetBooks.ir

abnormalities on auscultation and endoscopy, and occasionally in coughing.[19] Signs such as nostril flaring and excessive abdominal effort at rest, however mild, are usually associated with horses that have true RAO, as clinical signs that can be reliably detected using clinical scoring systems usually are accompanied by significant mechanical dysfunction of the respiratory system.[20] The prevalence of cough in horses with IAD is hard to estimate, as many studies use the presence of cough as an inclusion criterion.[5,8,21] Other studies have shown that cough may be seen less than 16% to 50% of the time.[6,21,22] On endoscopic examination, excessive airway mucus is often seen, ranging from multiple specks to streams of mucus.[23] Other clinical signs that are frequently noticed include prolonged respiratory recovery,[3] respiratory embarrassment at exercise,[11] worsening of signs during hot, humid weather, and inability to perform work during collection. Racehorses with IAD are typically described as fading during the last quarter of the race (Mazan, personal observation). It is interesting to note that horses with dorsal displacement of the soft palate (DDSP) have a higher prevalence of IAD than do control horses. This brings into play a chicken-or-egg argument, as it cannot be determined whether IAD is a risk factor for DDSP, or if DDSP is a risk factor for IAD.[24]

How does IAD affect performance? The answer depends on the use of the horse and the expectations of the owner. A practitioner with a primarily pleasure-horse practice or with show-hunter clientele might report a very low incidence of IAD in younger horses, primarily because the level of exercise in these horses is not likely to force a diagnosis through signs of exercise intolerance. A racetrack practitioner, on the other hand, would be far more likely to detect exercise intolerance resulting from lower airway disease in young horses because the level of expected athletic output is much higher and the horses have a greater likelihood of being examined endoscopically. Indeed, in a National Hunt racing population, excessive mucus was detected endoscopically in 68% of horses,[25] and IAD was one of the top two reasons cited for horses not running.[26] As might be expected, cough is more common in sport horses than in racehorses, as is an elevated respiratory rate, reflecting the generally earlier diagnosis in racehorses.[22] Indeed, racehorses with excessive tracheal mucus performed at a lower level than those with no mucus found on endoscopic examination.[14,11] Persson, looking at Standardbred trotters and saddle horses, found that low-grade nonseptic airway inflammation does have a negative impact on ventilatory capacity but that this is more pronounced in racehorses.[27] Moreover, using bronchiolar biopsy, this group also demonstrated that oxygen uptake and pulmonary ventilation correlated inversely with the morphologic grade of small airway disease and the height of the bronchiolar epithelium—the last finding suggesting that the extent of obstruction may determine the extent of exercise impairment. Racehorses with IAD have impaired gas exchange during exercise.[28,29] However, other studies have found that horses with obvious evidence of airway inflammation do not necessarily have a history of exercise intolerance.[15,30] This may reflect the difficulty of diagnosing low-grade respiratory impairment and the trainer's failure to recognize poorer performance than nature intended, however, rather than the benign nature of the underlying disease.

Diagnosis

BRONCHOALVEOLAR LAVAGE. Varying levels of specificity are used when documenting the presence of airway inflammation. The least specific is the documentation of mucus in the trachea, although it is the method that best lends itself to large studies in the field.[4,31] Visualization of mucus in the trachea gives little information, however, as to the nature and the exact origin of the inflammation. Many workers have used and continue to use tracheal aspirate cytology to describe the nature of inflammation in IAD. Although tracheal aspiration can be used to explore the presence of inflammation and has been used to document neutrophilia, mastocytosis, and eosinophilia in young performance horses,[32,15] the question of the nature and exact origin again presents itself. Studies have shown poor correlation between tracheal aspiration and bronchoalveolar lavage (BAL) cytology in horses.[33,34] Whereas tracheal aspiration harvests primarily neutrophils and epithelial cells, BAL yields primarily alveolar macrophages and lymphocytes in normal horses. Moreover, there is no evidence of correlation between tracheal wash findings and performance. Consequently, to avoid the problem of neutrophil count sensitivity to the collection method, the recent International Workshop on Equine Chronic Airway Disease recommended use of BAL to characterize horses with chronic airway disease; this recommendation was seconded by the Havemeyer Workshop on IAD.

Different pictures of inflammation emerge from various BAL studies, leading to speculation that different genetic predispositions and environmental exposures are important to the inflammatory phenotype. In comparison with healthy horses, BAL cytology in horses with IAD has shown, variably, neutrophils,[6,7] mast cells,[4,8,9] eosinophils,[2] or lymphocytes.[6] In general, horses with IAD have airway inflammation that may involve increases in nucleated cells or may also involve lymphocytosis. This is distinguished from RAO by the relatively low percentage of abnormal cells in IAD; whereas horses with RAO may exhibit almost entirely neutrophils in the BALF, horses with IAD seldom have greater than 2% to 15% neutrophils. The Havemeyer consensus has established that horses with IAD will have airway inflammation characterized by BAL cytology with any one of the following: mast cells greater than 2%, PMNs greater than 5%, or eosinophils greater than 1%.

HISTOPATHOLOGY. Histopathologic studies of IAD are sparse, but useful information can be teased from COPD studies that on inspection included horses with what would more appropriately be termed *IAD*. Bronchiolar biopsies of athletic young horses with lower airway inflammation have shown inflammatory mucosal cellular infiltrates and luminal exudates, bronchiolar hyperplasia, and goblet cell metaplasia.[2] It is interesting to note that 80% of supposedly normal horses had minimal evidence of peribronchiolitis; this raises the question of what constitutes normal. O'Callaghan, while directing his concern to exercise-induced pulmonary hemorrhage (EIPH), nevertheless found plentiful evidence of multifocal, small airway-centered disease on postmortem examination of young racehorses. These findings included thickened walls caused by increased quantities of mucosal and peribronchiolar connective tissue, mononuclear bronchiolar cuffs, and extension of nonciliated bronchiolar epithelial cells into alveolar ducts.[35] Lakritz,[36] looking at lung tissue of clinically normal, young Thoroughbred horses in training, found evidence of increased collagen, disruption of the epithelial basement membrane, and duplication of the epithelial basement membranes, suggesting previous airway inflammation and epithelial injury, which correlate with an increased interstitial pattern on radiographs. An ultrastructural study of young horses with "mild COPD" in one study found a decreased number of typical Clara cell granules and goblet cell metaplasia before the bronchioles began to show signs of inflammation typical of RAO.[37] Although the authors state that there was good correlation between histopathology and the results of a battery of pulmonary function tests, auscultation, bronchoscopy, blood gas analysis, and BAL in these horses, it is a lasting disappointment that the results of the ancillary testing remain unpublished. These data, in sum, suggest that the histopathologic lesion of IAD is not only local bronchiolar inflammation but also remodeling and thickening of the bronchioles themselves, which lends itself to at least low-grade airway obstruction.

LUNG FUNCTION TESTING. The esophageal balloon and pneumotach method for measuring lung function tends not to detect airway obstruction even in horses with RAO in remission.[38] However, use of the forced oscillatory technique[4] and forced expiratory maneuvers has shown the existence of low-grade obstruction of the small airways of some horses with IAD. The mechanical behavior of the respiratory system has been shown to differ with sampling frequencies in asthmatic humans,[39] and a pattern of decreasing respiratory system resistance (RSR) with increasing frequency has been termed *negative frequency dependence of resistance* and has been interpreted

VetBooks.ir

as evidence of underlying small airway obstruction despite baseline measurements within the expected range. Similarly, horses with IAD as a group have significantly higher values for RSR at the lower frequencies (1 to 3 Hz) and mild frequency dependence of resistance compared with controls,[40,41] although the baseline measurement of RSR may still frequently fall within the normal range. A study finding that lower oxygen uptake capacity and tidal volume correlated to a reduced diameter of the bronchiolar lumen owing to epithelial hyperplasia is strongly supportive of the existence of airway obstruction in IAD.[27] Likewise, lung resistance decreases with increasing minute ventilation in control horses but not in horses with IAD.[42] Consequently, without dynamic, frequency-dependent tests of lung function, forced maneuvers, or bronchoprovocation, it seems that researchers are simply failing to document a common feature of small airway obstruction in horse with IAD because testing devices are not sufficiently sensitive to these changes.

AIRWAY RESPONSIVENESS. Horses with clinical signs compatible with IAD also exhibit signs of airway hyperresponsiveness when they are exposed to nonspecific agents such as histamine aerosol.[12,40,43] The basis for airway hyperresponsiveness remains hotly debated among pulmonary physiologists. It is likely a multifactorial phenomenon that has been associated with airway wall thickening undetectable by conventional lung function testing,[44] airway inflammation, and autonomic nervous system dysfunction.[1] There is a paucity of information concerning the mediators of airway hyperresponsiveness in horses with IAD, although the presence of elevated levels of leukotriene C4 levels has been documented.[40,45] In our laboratory, horses with a clinical history and signs compatible with IAD have significantly greater airway reactivity than controls, although some control horses display airway hyperresponsiveness as well. This nonspecific airway hyperresponsiveness has been seen in humans and is associated with a greater risk of eventual development of asthma.[46,47] Although nonspecific airway hyperresponsiveness has been noted both in adult horses without signs of respiratory disease and in foals, the significance of this finding remains unclear.

RADIOGRAPHY. Although radiography can be useful in helping to exclude septic causes of lower respiratory tract disease, such as pneumonia, lung abscess, or pleuropneumonia, its sensitivity in IAD is too low for it to be useful for identification of this disease. Moreover, no correlation exists among thoracic radiographs, airway hyperresponsiveness, and BAL cytology.[48] However, the more frequent finding of a bronchial pattern on thoracic radiographs supports the existence of airway obstruction in these horses.

Etiology

No single cause of IAD has been identified, although there has been plentiful speculation about the role of environment, viral disease, bacterial infection, air pollution, and genetic predisposition. Although horses with IAD do not seem to experience bouts of overt airway obstruction on exposure to an allergenic environment, organic dust associated with stabling likely contributes to the initial inflammation. Sweeney noted that the racehorses in her study lived in conditions of poor ventilation, and she speculated that covert IAD may be instigated by the organic dusts, especially mold, in hay.[15] Others have noted that there is more mucopus in the tracheas of horses kept in poorly ventilated conditions, and in one study Thoroughbred racehorses in training, housed on straw, were found to be twice as likely to suffer from lower airway disease as those kept on shredded paper.[23] More recently, Holcombe and coworkers[49] showed that yearlings had a significantly higher number and percentage of neutrophils (polymorphonuclear neutrophils as high as 18%) in BALF when they were stabled versus when they were at pasture. In support of this finding, endotoxin concentrations are, as expected, higher in stables than at pasture.[50,51] Although none of these horses had any clinical signs of respiratory disease or evidence of exercise intolerance, they were not in work, and subtle signs of performance impairment could easily have gone undetected. Dust levels in the horse's breathing zone can be as high as 25 mg/m^3 (a level that would be considered unacceptable in any human workplace), which can explain the development of airway neutrophilia as a nonspecific response to high levels of particulates.[52] It is also likely that increased levels of endotoxin in hay and grain dust contribute to the development of airway neutrophilia,[53-55] which is supported by the finding that hay eating is a risk factor for increased tracheal mucus in pleasure horses.[30] In addition, the horse's position in the stable may affect development of IAD. In one study, there was a significant association between the presence of visible accumulation of mucus in the trachea and the stable, stall, and particulate concentration and numbers.[56] Moreover, even when unaffected horses are exposed to stable dust, the neutrophil chemoattractant, IL-8, increases in the BALF.[57]

Although previous viral disease is commonly invoked as a predisposing factor in the development of IAD, little evidence exists to implicate viral disease. As in humans with asthma, viral respiratory disease has been shown to cause airway hyperresponsiveness for a period of time after infection, perhaps because of denuding of the respiratory epithelium. However, no known virus was associated with poor performance and respiratory disease in 68% of cases in the United Kingdom,[23,47] although in one study various equine herpesviruses were found with greater frequency in the tracheal aspirate of poorly performing horses with signs compatible with IAD.[58]

The role of bacterial infection in IAD, particularly in young racehorses, is unclear. In several studies there was a strong relationship between inflammation of the lower respiratory tract and the presence of streptococcal species; horses with greater evidence of airway inflammation on tracheal aspiration and endoscopy had higher mean bacterial counts in tracheal aspirate,[23] and horses with bacteria found in the tracheal aspirate had a greater tendency to cough.[16] However, it is important to remember that association is not necessarily causation, and increased numbers of bacteria may reflect impaired airway clearance rather than a causative role for bacteria. The role of bacterial and viral infection in IAD remains unclear at this time.

Because horses sample the ambient air on a continual basis, it seems logical that air pollution might contribute to the development of IAD. In one study, clinically normal horses exposed to ozone had a significant increase in the glutathione redox ratio as well as total iron levels in the pulmonary epithelial lining fluid (both markers of exposure to oxidizing agents), and there was a strong correlation between airway inflammation score and the glutathione redox ratio in horses examined for poor performance but without overt airway disease.[18] In contrast, horses living in urban environments have been shown to have less airway reactivity, although greater levels of iron in the BALF, than do horses living in rural environments.[59]

There are multiple other possible contributors to the development of IAD. Cold air exposure is an important risk factor for the development of asthma in human athletes, and cold air exposure has been shown to be a risk factor for development of tracheal mucus accumulation in some horses.[30] In support of this observation, exposure of equine airways to cold air resulted in altered immunologic responses for at least 48 hours.[60] Exercise may also play a role in the development of IAD, in that neutrophils are increased in the BALF for at least 48 hours after exercise, and there is a corresponding increased late phase expression of IL-8 and TNF-α in the BALF.[61] Finally, in vitro studies showed that equine bronchial epithelial cells produce IL-8 in excess when they are exposed to blood,[62] raising the idea that EIPH may be a contributing factor in the development of IAD.

Although heaves has been shown to be at least partially allergen mediated, in which horses manifest a Th2-type cytokine response,[63] and although environmental challenge can produce a consistent exacerbation of disease,[54] there is no such convincing evidence of an allergic response in horses with IAD. However, the presence of elevated numbers of mast cells in the BALF of horses with poor performance,[64] the association of BAL mastocytosis with airway hyperresponsiveness,[65] and immunohistochemistry studies showing more IgA-containing cells and occasionally increased numbers of IgM- and IgG-containing cells are suggestive of a degree of allergic response and a heightened immune response. Anyone looking at recent studies of gene expression profiles in the BALF of horses with

VetBooks.ir

IAD should take note of whether the horses were diagnosed as having IAD on the basis of a generalized increase in inflammatory cells or if the study group was parsed more thoroughly into horses with increased mast cells or horses with increased neutrophils. One study of horses with a generalized increase in inflammatory cells revealed an upregulation of IL-1β, IL-23, and TNF-α but no evidence of a polarized cytokine response.[66] On the other hand, when horses are stratified into mast cell versus neutrophil groups, mRNA for IL-4 correlated with mast cells but not neutrophils, whereas for all groups, similarly to the previous study, TNF-α and IL-1β were increased.[67,68] It is most likely that multiple factors contribute to the development of IAD in individual horses; a critical level of risk factors or exposure is probably necessary for the disease to manifest itself.

Differential Diagnoses

The diagnosis of IAD often requires the exclusion of other diseases that may have a similar clinical picture. Whereas horses with RAO (heaves) or summer pasture–associated RAO (SPARAO) in remission may be very difficult to distinguish from horses with IAD, horses with RAO or SPARAO have a history of episodes of obvious breathing difficulty associated with exposure to either moldy hay or summer pasture. Upper airway disease, such as sinus infection or guttural pouch infection, may cause cough and nasal discharge, and both static and dynamic upper airway obstructions may cause poor performance and poor recovery from exercise. These may be largely ruled out by endoscopy. Horses with pneumonia, bronchopneumonia, or lung abscess commonly have abnormalities suggesting systemic disease, such as abnormal findings on complete blood cell count, recent history of fever, weight loss, or inappetence. In these cases tracheal wash can be very helpful in determining a septic cause of disease. Thoracic radiographs or ultrasound will also aid in the detection of these septic respiratory diseases. EIPH may be seen in conjunction with IAD, but the presence of epistaxis, blood on endoscopy of the trachea, or red cells or hemosiderophages on BAL confirm the diagnosis of EIPH. Overt viral respiratory disease is difficult to confuse with IAD, as it usually manifests with fever and malaise, but horses with viral respiratory disease may exhibit prolonged cough and airway hyperresponsiveness for weeks to months after resolution of the primary disease.

Therapy

There is remarkably little evidence-based support for any particular therapy in treating IAD. However, the mainstay of treatment has become a combination of environmental remediation, corticosteroid therapy, and bronchodilators.

ENVIRONMENTAL REMEDIATION. The barn environment is a hotbed of particulate matter, respirable endotoxin, molds, and volatile gases such as ammonia. The worst offenders appear to be hay and straw. A study looking at different management systems showed that when hay and straw bedding were replaced by pelleted feed and wood shavings, the respirable particulate levels were remarkably reduced.[51] Further improvements can be made by using cardboard bedding to reduce dust and mold levels.[69] Indoor arenas present another high dust challenge to the horse, with respirable particulate levels 20 times the level recognized to cause respiratory dysfunction in humans.[70] Other fairly commonsense strategies can be used. I make the following recommendations to owners in addition to the suggestion to change to low-dust feeds and beddings:

- Sprinkle aisles with water before sweeping.
- Avoid storing hay overhead. If unavoidable, lay a tarp under the hay to avoid dust raining down on the horses.
- Use a humectant or hygroscopic agent to reduce dust in the indoor and outdoor arenas.
- Remove horses from the barn while cleaning stalls or moving hay.
- Do not use blowers to clean aisles.
- Wet hay before feeding or use Dengie or other baked hay products.
- Remove cobwebs and other dust collectors routinely.

A recent study demonstrated that environmental control was by far the most important means of treating airway inflammation and dysfunction in horses with heaves (RAO), a more severe disease than IAD.[71] It is logical, therefore, to suppose that environmental management is equally important in the treatment of IAD.

CORTICOSTEROID THERAPY. Either parenteral or inhaled corticosteroids form the mainstay of drug therapy for IAD. Although the utility of corticosteroids for preventing or ameliorating airway remodeling in human asthma is debated,[72] corticosteroids have recently been demonstrated to prevent airway smooth muscle thickening in mice with experimental asthma.[73] The degree of efficacy in decreasing BAL neutrophilia is not completely known. Some studies show an obvious benefit of dexamethasone in improving clinical signs and lung function and reducing BAL neutrophilia,[74] whereas others show improvement primarily in lung function with little effect on BAL cytology.[71,75] Corticosteroid treatment certainly causes adrenocortical dysfunction, but this is less pronounced with inhaled therapy versus systemic.[74] Although concerns about precipitating laminitis with corticosteroid therapy are frequently expressed, the actual risk of laminitis with corticosteroid therapy is completely unknown. Prednisone has been used in the past, but studies have shown lack of effect in horses with RAO.[76] In our clinic we frequently treat with an initial course of parenteral corticosteroids, typically a 4-week decreasing course of prednisolone followed by inhaled corticosteroids. A recent study demonstrated that fluticasone propionate is detectable in blood and urine after delivery by inhalation.[77]

BRONCHODILATOR THERAPY. Bronchodilators, especially the inhaled form, appear to be efficacious in treating IAD in conjunction with corticosteroids. The most commonly used bronchodilators in IAD include aerosolized β-adrenergics, such as albuterol, and aerosolized parasympatholytics, such as ipratropium. β-Adrenergic drugs such as albuterol also increase mucociliary transport. The use of systemic β-adrenergics such as clenbuterol is not advised, as the extent of bronchoconstriction in IAD does not warrant risking the adverse effect of cardiovascular remodeling, which has been shown to occur in horses.[78] Moreover, a recent study demonstrated that when clenbuterol is given to horses with airway hyperresponsiveness, tachyphylaxis associated with increased airway reactivity develops by 21 days of treatment.[79]

MAST CELL INHIBITORS. Sodium cromoglycate can be efficacious in treating known mast cell–mediated IAD[9] but will not be of use for treating the majority of horses with neutrophil-mediated disease. The use of sodium cromoglycate requires considerable owner compliance, as the maximum response to this drug occurs at 1 to 2 weeks after beginning treatment.

AEROSOLIZED THERAPY. Aerosolized therapy using a combination of inhaled corticosteroids and bronchodilators is well established clinically in the treatment of IAD; however, there are no clinical trials establishing the efficacy of these drugs. When using inhaled drugs, we use a spacer and mask in order to improve delivery of the drug. Regardless of the type of mask and spacer device used, actual delivery of particles to the lower airways is poor in horses, as indeed it is even in humans, and the least efficacious means of delivering aerosolized drugs is by nebulization.[80-82] Unfortunately, strategies that we know improve lung deposition of aerosolized drugs in humans, such as slow deep breathing and breath holding, are not practical in horses. Devices currently on the market include the Aeromask and the Equine Haler. Individual horse and owner preference determines which device should be used. Inhaled corticosteroids commonly used in the treatment of IAD include beclomethasone and fluticasone.

Although there are no reported clinical trials using corticosteroids in horses with IAD, horses with RAO treated with 3750 μg of beclomethasone dipropionate twice daily using the Aeromask showed improvement in both clinical signs and lung function.[83] Smaller doses (500 to 1500 μg twice daily) administered with a device that is no longer on the market were shown to be efficacious in horses with

VetBooks.ir

heaves.[74] I commonly use small doses (500 to 1000 µg twice daily) using the Aeromask with good clinical effect in horses with IAD.

Fluticasone is a more potent corticosteroid than beclomethasone and has been shown to be efficacious when administered in conjunction with the Aeromask in treating horses with heaves, as well, using doses of 2000 µg twice daily. Unlike beclomethasone, in this study fluticasone did not cause adrenocortical dysfunction.[84] I use a decreasing-dose regimen, starting at 1500 to 2000 µg twice daily, working down to 1000 µg once daily or every other day. The lowest dose is reached over a 3- to 4-week period. Although we previously advised use of a short-acting bronchodilator, such as inhaled albuterol, 5 to 15 minutes before treatment with inhaled corticosteroid to increase deposition of the latter by fully opening the small airways, the accepted practice in human medicine currently is to avoid this practice. The logic behind this is that it is important to get the most useful and costly drug administered first before compliance decreases. It is important that the owner understand that even with the higher doses of inhaled corticosteroid, it may require 1 to 2 months for the best therapeutic effects to be achieved.

The most commonly used inhaled bronchodilator is albuterol, a β_2-specific adrenergic drug. The onset of effect with albuterol is quite rapid, with maximum bronchodilation being seen within 15 minutes. However, it is important to note that the maximum effect lasts in some horses for only an hour, and there are side effects (such as anxiety, nervousness, trembling, and tachycardia) with higher doses of the drug, even in the inhaled form. There is no evidence to suggest that the oral form of albuterol is even absorbed in the horse, and it is not suggested as appropriate therapy. Longer-acting β_2-adrenergic agonists, such as salmeterol and formoterol, can also be used, with bronchodilation lasting 6 to 8 hours. Parasympatholytic drugs such as ipratropium have a slower onset of action but longer duration than albuterol (at least 6 hours) and lack the severe side effects of parenteral use of drugs such as atropine. It is important to remember that these bronchodilators are symptomatic drugs only; they do not treat the underlying inflammation and therefore are unsuitable for single-drug therapy.

Mast cell inhibitors that can be administered by metered dose inhaler include Intal (cromolyn) and Tilade (nedocromil sodium). They are discussed in earlier sections.

In summary, IAD is a disease characterized by nonseptic inflammation, visible on BAL cytology as excessive neutrophils, mast cells, or eosinophils, and involving low-grade airway obstruction and airway hyperresponsiveness. Clinical signs include variable cough, nasal discharge, and poor performance. Excessive amounts of mucus may also be visualized in the trachea during endoscopic examination. The cause of IAD is unknown, but the disease is probably best avoided by achieving a low-dust and low-endotoxin environment. Treatment logically begins with environmental remediation and is supplemented by antiinflammatory drug therapy using systemic or inhaled corticosteroids and inhaled bronchodilators. IAD that involves an excess of mast cells in the airways can be further treated with inhaled mast cell inhibitors.

Tuberculosis

Peggy S. Marsh

Tuberculosis refers to any infectious disease caused by *Mycobacterium* spp. and associated with the formation of focal granulomatous lesions. In humans many forms of the disease exist, with the primary site of infection most commonly being the lungs. *M. tuberculosis* is the typical causative agent in humans, whereas *Mycobacterium avium* or *Mycobacterium bovis* is usually implicated in animal cases. Tuberculosis is extremely rare in horses, especially in the United States. Most cases in horses have reported isolation of *M. avium*[1-4]; however, there are reports of infection with *M. bovis*[5,6] and *M. tuberculosis*.[7] In equine cases it appears the organism is usually ingested, although primary respiratory infection may occur. Spread is hematogenous, and the organism frequently settles in lymph nodes and the spleen.

The most frequent presenting complaint is chronic weight loss with ensuing weakness and lethargy. Terminally ill horses with the pulmonary form are febrile and dyspneic and have a cough. Radiographic or sonographic evaluation of the thorax may be helpful in defining the pattern and distribution of lesions. Other clinical signs may be noted depending on the organ systems affected; these signs include intestinal tract abnormalities, hepatitis, and osteomyelitis of the cervical vertebrae.[1-7]

Diagnosis, usually made after the horse's death, is based on the presence of tubercles and isolation of the organism. The intradermal skin test is not reliable in the horse because a majority of clinically normal horses may have positive test results.[7,8] Cytologic or histologic evaluation of a wash or aspirate of a lesion may reveal acid-fast bacilli. Biopsy of the lesion(s) is necessary for a definitive diagnosis. When tuberculosis is suspected, culture of an appropriate sample, such as a tracheal aspirate with primary pulmonary involvement, is advisable. However, this is a very slow-growing organism, and isolation may take multiple weeks. More recently polymerase chain reaction technology has proven a useful tool.[5,7]

Treatment is not usually attempted, because of public health concerns. If treatment is undertaken, the horse should be isolated, with precautions taken to prevent spread of disease and in consultation with the public health officials and/or the horse handler's physician. Tuberculosis is a reportable disease in other species. Drugs used in other species (rifampin, isoniazid, and streptomycin) could be considered, but there are no guidelines for their use in horses with this condition. Isoniazid has been used in horses for other conditions at a dose of 5 to 15 mg/kg PO twice daily.[9] A study on rifampin pharmacokinetics in horses recommended using 10 mg/kg PO twice daily.[10] In humans, treatment periods are very prolonged, frequently a year or more. Because treatment is usually not a viable option in horses, prognosis is very poor.

Bacillus Calmette-Guérin vaccine has been used in humans with potential exposure, but the benefit of its use in horses to provide increased resistance after exposure to a tuberculosis infection is unknown.

Pneumoconiosis (Silicosis)

Peggy S. Marsh

Pneumoconiosis refers to lower respiratory tract disease associated with deposition of small particles (dust) within the lungs. In human medicine the majority of cases are related to occupation and include coalworker's lung, silicosis, and asbestosis.[1] There are two related reports of horses with silicosis.[2,3] The majority of the horses originated from the Monterey-Carmel Peninsula in California. Silicosis is a disease caused by inhalation of crystalline silica. There are several clinical forms of silicosis in humans, including simple and complicated chronic forms as well as acute silicosis (silicoproteinosis). Silicosis has been associated with mycobacterial diseases, airway obstruction, and pulmonary neoplasia.[4] Freshly fractured silica is more toxic to alveolar macrophages than aged silica. Crushing silica leads to the formation of reactive radials.[5] The small (0.5 to 5 mm) particles are deposited in small airways and alveoli and subsequently phagocytosed, initiating a cycle of granulomatous inflammation, oxidative stress, and apoptosis leading to chronic fibrotic interstitial disease.[1,4,5]

The clinical signs reported in horses are similar to those of chronic obstructive pulmonary disease and include weight loss, cough, exercise intolerance, and, sometimes, exercise-induced respiratory distress (sweating, nostril flaring, abducted elbows, reluctance to move, and shaking). Resting respiratory rates are often increased. Physical examination revealed a restrictive pattern of breathing. Auscultation revealed harsh breath sounds and some wheezing, which was exacerbated by exercise.

Diagnosis was based on the presence of birefringent crystalline inclusions within pulmonary macrophages.[3] Samples were obtained via tracheal aspiration, BAL, or lung biopsy or at necropsy. In some

VetBooks.ir

cases repeated tracheal sampling was required. Radiographs of the thorax revealed a variety of findings, including, most commonly, an interstitial pattern (miliary, reticulonodular, and linear) that was most severe in the caudodorsal lung fields. Other radiographic abnormalities noted were lymphadenopathy, pleural effusion or thickening, hyperinflation, and pulmonary consolidation.[3]

Gross pathologic analysis revealed interstitial granulomatous pneumonia and fibrosis. Histologic examination with both light and electron microscopy revealed peribronchitis, perivasculitis, and cellular infiltrates consisting of mostly macrophages and giant cells, with refractile inorganic dust particles noted both intracellularly and extracellularly.[2,3]

In general the horses reported to have silicosis had a poor prognosis. The original study discussed postmortem findings of nine horses.[2] In a related paper, a total of 19 horses were identified.[3] Short-term (2 to 12 months) follow-up evaluation was available in eight of these individuals, with a progressive loss of respiratory function noted in four of the cases, leading to euthanasia. Treatment consisted of environmental change and glucocorticoid therapy. Novel forms of therapy, including inhibition of inflammatory mediators as well as inhibition of apoptosis, may be seen in the future.[5]

Recent work has revealed a systemic osteoporosis in a group of horses associated with fibrosing pulmonary silicosis.[6] Also, there are reports of pneumoconiosis in other domestic species that was caused by environmental contamination.[7] It may be prudent to keep environmental contamination in mind when investigating chronic non-infectious forms of lower respiratory tract disease in the horse.

Mycoplasma

Peggy S. Marsh

Mycoplasma spp. are a group of bacteria that differ from other bacteria because they lack a cell wall, are much smaller than most bacteria, and need cholesterol to survive. These organisms are proven to cause respiratory disease in humans, cattle, and pigs. *M. felis* has been isolated as a pathogen causing pleuritis and pericarditis in the horse.[1-3] Experimental infection with *M. felis* in ponies induced pleuritis.[3] The relative importance of *Mycoplasma* spp. as a pathogen in acute respiratory disease of the horse has been debated. Several species of mycoplasma can be isolated from the respiratory tract of healthy and diseased animals, both adults and foals. A report from Australia did not yield growth of mycoplasmas in any of the samples from young racing horses with coughs.[4] However, a similar case control–type study from the United Kingdom showed an association between *M. felis* and inflammatory airway disease in young racehorses.[5] Also, a Canadian report demonstrated growth of *Mycoplasma equirhinis* and *M. felis,* along with other bacteria commonly thought of as respiratory pathogens, in horses with acute lung disease.[6] *M. felis* has been reported as a potential cause of an outbreak of acute respiratory disease in a stable of young racehorses, as well as of respiratory disease in foals.[7,8]

Clinical signs of pleuritis caused by mycoplasma infection, including fever, depression, and pleurodynia, mimic other bacterial pleural pneumonia cases. Auscultation of the thorax may reveal pleural friction rubs and dull lung sounds over the cranioventral thorax. Sonographic examination of the thorax reveals pleural effusion, often bilateral. Thoracocentesis should be performed for both diagnostic and, if necessary, therapeutic purposes. The fluid is most often an exudate, lacking any odor. Cytologic examination reveals large numbers of neutrophils within the pleural fluid.

Crucial to diagnosis of mycoplasma infection is the elimination of more common pathogens, such as streptococcal infections. Thus routine cultures for aerobic and anaerobic bacteria should be performed in any case of pleuritis. Culture for the presence of *Mycoplasma* bacteria is difficult to obtain. Immediate centrifugation of pleural fluid is ideal, because supernatants are the preferred culture samples.[9] These samples should then be placed in mycoplasma-specific media. Seroconversion can also be an aid in diagnosis, with seroconversion occurring in a large number of the reported cases of *M. felis* infection.[1,2,7] Experimental infection revealed that once seroconversion has occurred, the organism can no longer be isolated from culture samples.[3] Seroprevalence in the United States is not known. Diagnosis may be aided by the use of newly devolved real-time polymerase chain reaction methods for the detection of *M. felis*.[11]

Experimentally infected ponies recovered without treatment in one study, so the requirements of treatment specific for mycoplasma are unclear.[3] Although sensitivity testing should be performed on any isolate, *Mycoplasma* spp. have been found to be sensitive to gentamicin, tetracyclines, and erythromycin.[10] The role these organisms play in equine respiratory disease is still unclear, and investigation continues.

Glanders (Farcy)

Faisal Ghazi Habasha

Glanders is serious zoonotic bacterial disease that primarily affects horses, mules, and donkeys. Some animals die acutely within a few weeks. Others become chronically infected and can spread the disease for years before succumbing. Without antibiotic treatment, the case fatality rate can be as high as 95%. Glanders also occurs in other mammalian species, particularly members of the cat family, dogs, sheep, goats, camels, and humans. Swine and cattle appear to be resistant.[1,2] The term *farcy* is limited to the visible appearance of external lesions, but in the latter case, internal lesions always exist, although they may not be evident.[3]

Glanders is one of the oldest diseases of horses described. Absyrtus, a Greek veterinarian in the army of Constantine the Great (AD 300), described the disease with considerable accuracy and recognized that it was contagious.[4]

Etiology Glanders is caused by *Burkholderia mallei,* a nonmotile, nonsporulating, facultative intracellular gram-negative bacillus in the family Burkholderiaceae. The organism name comes from the Greek *melis* ("severe disease") and its Latin derivative *malleus* ("depicting a malignant disease"). The organism was first identified in Germany by Loeffler and Schutz in 1882 and confirmed as the cause of glanders in 1886.[3] The organism was formerly known as *Pseudomonas mallei* before being reclassified into the new genus *Burkholderia* in 1992. Traditionally the *Burkholderia* species are known as plant pathogens and soil bacteria, with two important exceptions, *B. mallei* and *Burkholderia pseudomallei,* the latter of which causes melioidosis. These two organisms differ in their survival in the environment. *B. mallei* is subject to inactivation in the environment, and it is not thought to persist outside equine hosts for long periods of time. Limited environmental survival, particularly in wet, humid, or dark conditions, may be possible for 3 to 5 weeks, and the organism can remain viable in 20° to 25°C (68° to 77°F) water for as long as a month.[4] It is inactivated by heat, direct sunlight, and commonly used disinfectants, including hypochlorites.[1-3]

GENOME STRUCTURE. The genome of *B. mallei* consists of two circular chromosomes. Chromosome 1 contains 3,510,148 base pairs (bp) and chromosome 2 contains 2,325,379 bp. A total of 5,535 predicted protein-encoding open reading frames are identified in the genome.[5] The genome of this organism carries a large number of insertion sequences as compared with the related *B. pseudomallei,* with a large number of simple sequence repeats that may function in antigenic variations of cell surface proteins (National Center for Biotechnology Information [NCBI] genome project).

GEOGRAPHIC DISTRIBUTION. Glanders is thought to be endemic in parts of the Middle East, Asia, Africa, Central America, and South America. Between 1998 and 2012, cases were reported from Brazil, Turkey, Russia, Eritrea, Ethiopia, Iran, Iraq,[6] United Arab Emirates, India, Pakistan, Afghanistan, and Mongolia, with suspect cases in other parts of Africa.[1] The disease was eliminated from

VetBooks.ir

horses in the United States during the 1940s, although one human case of glanders was reported in a laboratory worker in 2000.[7] This was the first human case reported in the United States since 1945.

Transmission Glanders is mainly transmitted by contact with skin exudates and respiratory secretions from infected equids. Latently infected as well as clinically ill animals can spread the disease.[1,2]

Horses, mules, and donkeys often become infected when they ingest *B. mallei*–contaminated food or water. The organism can also be spread in aerosols and entry through skin abrasions and mucous membranes. Carnivores usually become infected when they eat contaminated meat. *B. mallei* is readily spread by fomites such as harnesses, grooming tools, and food and water troughs. Humans are infected by contact with sick animals, contaminated fomites, tissue, or bacterial cultures. Rare cases of person-to-person transmission have been reported in family members who nursed sick individuals. *B. mallei* has been weaponized and was used as a biological weapon against military horses and humans during the first and second world wars. Aerosols may be the major route of infection in bioterrorist attacks.[8]

INCUBATION PERIOD. The incubation period varies with the form of disease from a few days to several weeks. Septicemia or localized disease usually becomes apparent after 1 to 5 days, while the pulmonary form typically becomes clinically apparent after 10 to 14 days.[1,2]

Clinical Signs and Differential Diagnosis In equids, glanders is traditionally categorized into nasal, pulmonary, and cutaneous forms (farcy).[1,2] In the nasal form, deep ulcers and nodules occur inside the nasal passages, resulting in a thick, purulent, yellowish discharge. This discharge may be unilateral or bilateral and can become bloody. Nasal perforation is possible. The regional (submaxillary) lymph nodes become enlarged and indurated and may suppurate and drain. Healed ulcers become star-shaped scars. In the pulmonary form, nodules and abscesses develop in the lungs. Some infections are inapparent whereas others vary from mild dyspnea to severe respiratory disease. In more severe cases, the clinical signs include coughing, dyspnea, febrile episodes, and progressive debilitation. Diarrhea and polyuria may also be seen. Discharges from pulmonary abscesses can spread the infection to the upper respiratory tract.

In the cutaneous form, the skin contains nodules that rupture and ulcerate, discharging an oily, purulent yellow exudate (Fig. 31-43). The regional lymphatics and lymph nodes become chronically enlarged and are filled with purulent exudates. There may also be swelling of the joints and painful edema of the legs. Orchitis is a common symptom in males. Clinical cases are usually a combination of these forms and can occur as acute, chronic, or latent disease. Donkeys and mules, as a general rule, manifest the acute symptoms, which progress rapidly, whereas horses usually have the chronic or latent disease.

FIG. 31-43 Typical cutaneous form of glanders (known as farcy) showing skin nodules.

Nasal and pulmonary signs are usually seen in the acute form. The symptoms include a high fever, decreased appetite, coughing, progressive dyspnea, nasal discharge, and ulcers and nodules on the nasal mucosa. Bloody crusting may be seen on the nostrils, and there may be a purulent ocular discharge. The submaxillary lymph nodes are usually swollen and painful. Central nervous system signs have been reported in experimentally infected horses, possibly as the result of secondary bacterial infection from a compromised blood-brain barrier.[9] Animals with the acute form of glanders usually die in a few days to a few weeks.

The chronic form develops insidiously and results in progressive debilitation. The symptoms may include coughing, dyspnea, intermittent fever, enlargement of the lymph nodes, a chronic nasal discharge, and ulcers, nodules, and stellate scars on the nasal mucosa. The skin and lymphatics may also be involved. The chronic form is often fatal, but affected animals may live for years before succumbing to the disease.

In the latent form, there may be few symptoms other than a nasal discharge and occasional labored breathing. Lesions may be found only in the lungs.

The differential diagnoses for glanders include strangles caused by *Streptococcus equi;* epizootic lymphangitis, which is a chronic granulomatous and suppurative fungal infection caused by *Histoplasma farciminosum;* sporotrichosis, a chronic subcutaneous lymphatic mycosis caused by a gram-positive fungus *Sporotrichum schenckii;* ulcerative lymphangitis, a bacterial disease caused by *Corynebacterium pseudotuberculosis;* and melioidosis (Whitmore disease), which is caused by *B. pseudomallei.* Melioidosis is particularly difficult to differentiate because *B. pseudomallei* and *B. mallei* cross-react in many serologic and hypersensitivity tests.[1,2]

Diagnosis A diagnosis of glanders based on clinical signs can be made when *B. mallei* is isolated from samples or an immunologic reaction to the organism is detected serologically or on the basis of hypersensitivity test results. Isolation and identification of *B. mallei* in cultures of samples from lesions or various exudates, including respiratory secretions, is regarded as a gold standard for the diagnosis of glanders. *B. mallei* can be stained with methylene blue, Wright, or Gram stain, but the staining can be weak or irregular, and bipolar staining of the gram-negative organism may be observed. They can be pleomorphic in older cultures, but in clinical samples and young cultures they typically form straight or slightly curved rods that are 0.3 to 0.8 µm in width and 2 to 5 µm in length. Some authors report that, in tissues, the organism is identified best with Giemsa stain.[10]

B. mallei can be grown on routine culture media, including nutrient, blood, and MacConkey agars; growth is slow, but colonies are usually visible within 48 hours. Optimal growth occurs at 37°C (98.6°F).

Automated bacterial identification systems do not always correctly identify this organism. All isolations must be performed in biosafety level 3 laboratories. Inoculation into laboratory animals, particularly guinea pigs (the Strauss reaction) or hamsters, was used for identification of *B. mallei* in the past, but this technique is now rarely practiced.

A cell-mediated hypersensitivity reaction test (mallein intradermal skin test) was used extensively to screen horses for glanders. This test is still used to certify horses as negative for glanders during importation to some countries. It may also be used in the diagnosis of clinical cases. The mallein test is based on hypersensitivity reaction to mallein, a commercially available, purified protein derivative of *B. mallei.* The test is performed most often by intradermal palpebral injection. Reactors are identified by marked eyelid swelling that develops within 24 to 48 hours, accompanied by fever and occasionally by purulent ocular discharge. No reaction or minimal swelling

VetBooks.ir

of the eyelid develops in unsensitized animals. False-positive reactions can occur in animals that are sensitized to other closely related *Burkholderia* spp. including *B. pseudomallei,* and cross-reactions with *Streptococcus equi* have been described.

Serologic tests are sometimes used to screen horses for importation to glanders-free countries or to identify clinically affected animals. Measurable titers of serum antibody against *B. mallei* develop approximately 1 week after infection. Complement fixation was the preferred serologic test in past eradication programs because of its ability to detect subclinically or chronically infected animals. This test was most useful when the prevalence of disease was high. Complement fixation is still used by some countries to assess imported equids for glanders. Enzyme-linked immunosorbent assay tests are also used to screen animals for international trade. Other serologic tests include indirect hemagglutination,[11] counterimmunoelectrophoresis, immunoblotting, and indirect fluorescent testing, but these tests are not approved by the World Organisation for Animal Health (OIE) for use in international trade.[1,2] Rapid DNA tests, such as polymerase chain reaction assays, are now also used.

Treatment

Treatment of glanders is often not advised because infected animals may remain subclinically infected and shed *B. mallei*.[1,2] The risk of zoonotic transmission also discourages treatment. Systemic treatment with antibiotics, including penicillin and streptomycin, is usually ineffective in controlling the disease. Some evidence has accumulated that enrofloxacin, erythromycin, ampicillin, sulfonamide, gentamicin, and tetracycline might be effective against *B. mallei.* This evidence has emerged from in vitro antibiotic sensitivity testing and from treatment studies in experimentally infected guinea pigs. Experimentally, in lab animals effective treatments also include doxycycline, ceftazidime, gentamicin, and trimethoprim sulfas.[1]

Prevention and Control

Cases of glanders in animals must be reported to the OIE.[1] The occurrence of this disease in any country can result in restrictions on international trade in horses and other affected animals. The mallein test and complement fixation test are approved assays recommended by the OIE for international trade purposes.[1]

If glanders is detected, control measures include strict quarantine of all infected and exposed animals, diagnostic testing of animals with clinical signs indicative of glanders, and assessment of apparently normal equids with the elimination of those that react positively in screening tests. Ill animals and those with positive results of mallein tests are euthanized. Horses exposed to *B. mallei* that yield negative results in mallein tests are isolated and retested 2 to 3 weeks later. Carcasses and contaminated bedding and feed should be burned or buried. Equipment or other items in contact with infected animals should be disinfected.

People who handle tissues from infected animals, bacterial cultures, or contaminated fomites should implement strict precautions to prevent infection. Protective clothing, including surgical masks, gloves, face shields, and gowns, should be worn. In clinical and research laboratories, *B. mallei* requires biosafety containment level 3 accommodation. Precautions are indicated for activities that are likely to produce aerosols, droplets, or concentrations of bacteria. Currently, there is no commercial vaccine against glanders for use in humans or any other animal species.

Exercise-Induced Pulmonary Hemorrhage

Pamela A. Wilkins[†]

EIPH is a pervasive disorder of horses that perform strenuous exercise and is best recognized in Thoroughbred and Standardbred racehorses. The disorder is associated with reduced performance of Thoroughbred racehorses, and probably in other breeds, and costs the Thoroughbred and Standardbred racing industries in the United States and Canada between $100 million and $225 million (U.S. dollars [USD]) annually.[1] The disease occurs commonly in horses; less commonly in camels and greyhound dogs; and rarely in human athletes.[2-4]

Etiology

Epistaxis and hemorrhage into airways can occur as a result of a number of diseases, including disorders of the upper airways and lungs. Hemorrhage into trachea or bronchi can be a result of EIPH, pulmonary abscess, fungal granuloma, trauma, pneumonia, pulmonary foreign body, or hemangiosarcoma or other pulmonary neoplasia. Epistaxis can be associated with all of these causes of hemorrhage into the lower airway and with diseases of the upper airway, including guttural pouch mycosis, ethmoidal hematoma, trauma, and neoplasia of the upper airways and associated structures. Thrombocytopenia can cause epistaxis.

The likely proximate cause of hemorrhage in horses with EIPH is rupture of alveolar capillary membranes, with subsequent extravasation of blood into interstitial and alveolar spaces.[5] The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested based on histologic evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH,[6] but contribution of the bronchial circulation to EIPH has not been demonstrated. Regardless of the contribution of bronchial circulation to blood in the airways, the likely initial lesion is in capillaries associated with the pulmonary circulation. Recently alteration within the pulmonary venous circulation has been postulated as a contributor to EIPH.[7] Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi, which, in rare instances, results in epistaxis.

Clinical Signs and Differential Diagnosis

HISTORY AND PRESENTING COMPLAINT. Poor athletic performance and epistaxis (Fig. 31-44) are the most common presenting complaints for horses with EIPH. Although poor performance may be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis caused by EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race or similar period of maximal exercise, particularly when the horse is returned to the paddock or winner's circle and is allowed to lower its head. It is usually bilateral and resolves within hours. Epistaxis can occur on more than one occasion in the same horse.

EXERCISE-INDUCED PULMONARY HEMORRHAGE AND PERFORMANCE. Failure of racehorses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH. Many horses with poor performance have cytologic evidence of EIPH on microscopic examination of tracheobronchial aspirates or BALF or have blood evident on endoscopic examination of the tracheobronchial tree performed 30 to 90 minutes after strenuous exercise or racing.[8,9] However, it is important to recognize that EIPH is very common in racehorses and should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of Thoroughbred racehorses.[10-13] A relationship between finishing position and incidence of EIPH, diagnosed by bronchoscopic examination, was not detected for 191 Thoroughbred racehorses that finished in first, second, or third place.[11] Furthermore, there was no relationship between the proportion of horses with EIPH and placing (first, second, or third versus other) in another 98 horses.[12] Similarly, there was no relationship between finishing position and proportion of horses with EIPH in 191 Thoroughbreds examined after racing.[13] There was no relationship between severity of EIPH, assessed on tracheobronchoscopic examination, and race performance in 258 Thoroughbreds or 296 Standardbred racehorses.[14] Together, these studies do not demonstrate a clear

[†]Previous contributions by K.W. Hinchcliff are acknowledged.

VetBooks.ir

FIG. 31-44 Horse with exercised-induced pulmonary hemorrhage and epistaxis.

relationship between the presence of EIPH, or its severity, and race performance.

In contrast to the studies just discussed, among 452 Thoroughbred horses examined after racing in Hong Kong, those finishing in the first three positions had less severe EIPH than did horses finishing in lower positions.[15] Of horses finishing in the first three places, 43.9% had evidence of EIPH on tracheobronchoscopic examination after racing, whereas 55.9% of horses finishing in fourth to fourteenth place had evidence of EIPH.

A recent study demonstrated that Thoroughbred horses with EIPH racing in Victoria, Australia, had impaired performance compared with unaffected horses. Horses were assessed as having no EIPH or grades 1 to 4 EIPH on the basis of endoscopic examination performed within 2 hours of racing. After statistical correction of other factors that could influence performance, there was a clear association between EIPH higher than grade 1 (i.e., grades 2 to 4) and impaired performance.[16] Horses with EIPH lower than grade 1 were 4 times more likely to win, 1.8 times more likely to finish in the top three positions, and 3 times as likely to be in the 90th percentile for earning as horses with EIPH higher than grade 2. Horses with EIPH finished farther behind the winner than did horses that did not have EIPH.[16]

Results of studies in Standardbred racehorses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was no relationship between the presence of EIPH and finishing position in 29 Standardbred racehorses with intermittent EIPH examined on at least two occasions[17] or in 92 Standardbred racehorses examined on one occasion.[18] However, of 965 Standardbred racehorses examined after racing, those finishing first or second were 1.4 times more likely (95%, confidence interval 0.9 to 2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in the seventh or eighth position.[19]

Physical Examination

Apart from epistaxis in a small proportion of affected horses, there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates may be increased as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different from those in horses with no evidence of EIPH. Affected horses may swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx. Coughing is common in horses recovering from strenuous exercise, and after recovery from exercise horses with EIPH are no more likely to cough than are unaffected horses.[20] Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and, when present, indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax, or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and, when present, are characterized by increased intensity of normal breath sounds during rebreathing examination.[21] Tracheal rales may be present in horses with EIPH but are also heard in unaffected horses.[22] Cardiac dysrhythmias, such as atrial fibrillation, should be ruled out as contributors to EIPH, particularly in nonracing breeds.

Horses that have experienced one episode of epistaxis, the most severe form of EIPH, are more likely to have a second episode. For this reason most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in Thoroughbred horses is approximately 13.5% despite affected horses not being permitted to race for 1 month after the initial episode of epistaxis.[23] This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

Diagnostic Approach

DIAGNOSTIC TESTS. Various techniques are available for determining the presence and severity of EIPH, including direct examination of the airways through a flexible endoscope or examination of bronchial lavage fluid or tracheal aspirates for evidence of hemorrhage. The utility of these diagnostic tests varies, and choice of examination technique depends on the time between the racing of the horse and the examination and on the desired sensitivity of the test. For instance, tracheobronchoscopic examination is most appropriate if a horse is examined within 1 to 2 hours of exercise, whereas examination of airway washings is most appropriate if the examination is days to a week after strenuous exercise. Radiography, pulmonary scintigraphic examination, and lung function tests are useful in eliminating other respiratory diseases as causes of poor performance but are minimally useful in confirming a diagnosis of EIPH or in determining the severity of hemorrhage.

TRACHEOBRONCHOSCOPY. Observation of blood in the trachea or large bronchi of horses 30 to 120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral third of the trachea (Fig. 31-45). Blood may also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60 to 90 minutes. Some horses with EIPH do not have blood in the rostral airways immediately after exercise but do so when examined 1 to 2 hours later. Blood is detectable by tracheobronchoscopic examination for 1 to 3 days in most horses, and some horses have blood detectable for up to 7 days.

Bronchoscopic examination can be used to estimate the severity of EIPH through use of a grading system.[11,24] The interobserver repeatability of tracheobronchoscopic assessment of severity of EIPH using a 0 to 4 grading scale has been demonstrated[24] (see Fig. 31-38).

VetBooks.ir

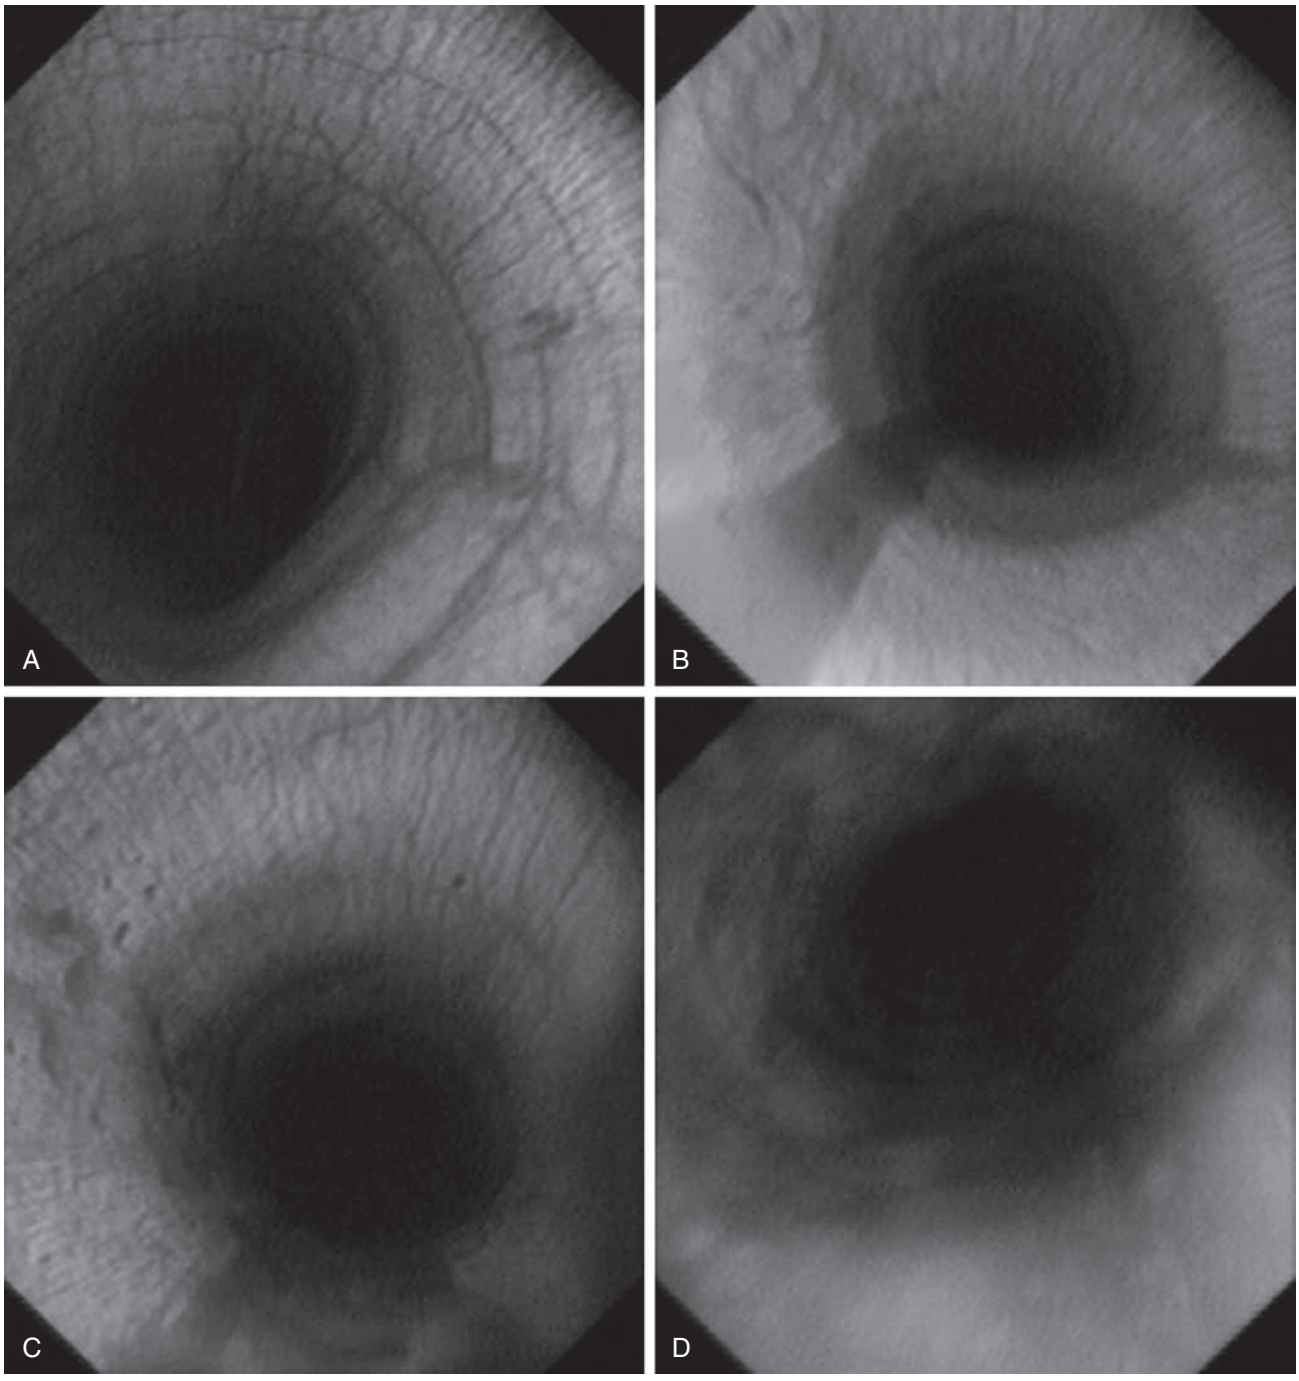

FIG. 31-45 Tracheobronchoscopic findings in horses with exercise-induced pulmonary hemorrhage. **A,** From a horse with grade 1 hemorrhage. **B,** From a horse with grade 2 hemorrhage. **C,** From a horse with grade 3 hemorrhage. **D,** From a horse with grade 4 hemorrhage.

- Grade 0: No blood detected in the pharynx, larynx, trachea, or main stem bronchi.
- Grade 1: Presence of one or more flecks of blood or <2 short (<1/4 length of the trachea) narrow (<10% of the tracheal surface area) streams of blood in the trachea or main stem bronchi visible from the tracheal bifurcation.
- Grade 2: One long stream of blood (>half the length of the trachea) or >2 short streams occupying less than 1/3 of the tracheal circumference.
- Grade 3: Multiple distinct streams of blood covering more than 1/3 of the tracheal circumference. No blood pooling at the thoracic inlet.
- Grade 4: Multiple coalescing streams of blood covering >90% of the tracheal surface with pooling of blood at the thoracic inlet.

It is assumed that a higher score represents more severe hemorrhage, but although the repeatability of this scoring system has been established, the relationship between the amount of blood in the large airways and the actual amount of hemorrhage has not been established.

TRACHEAL ASPIRATION AND BRONCHOALVEOLAR LAVAGE. The presence of red cells or macrophages containing either effete red cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal fluid or BALF provides evidence of EIPH. Detection of red cells or hemosiderophages in tracheal aspirates or BALF is believed to be both sensitive and specific in the diagnosis of EIPH.[9,25] Examination of airway fluids indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic

VetBooks.ir

examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid is likely attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. Whereas endoscopic examination may detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode.[9,25,26] Red blood cells (RBCs) and macrophages containing RBCs are present in BALF or tracheal aspirates for at least 1 week after strenuous exercise or instillation of autologous blood into airways, and hemosiderophages are present for at least 21 days and possibly longer.[9,26]

Studies have reported on the use of RBC numbers in BALF as a quantitative measure of EIPH.[27-30] However, this indicator of EIPH severity has not been validated or demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of RBC counts in BALF for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and there is a risk that this area of lung may not be representative of the lung as a whole, similar to the situation of examination of BALF of horses with pneumonia.[31] BAL of sections of both lungs, achieved using an endoscope, may obviate some of these concerns.

Tracheal aspirates may be obtained any time after exercise by either aspiration during tracheobronchoscopic examination or aspiration through a percutaneous intratracheal needle. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. BALF can be obtained through either an endoscope wedged in the distal airway or a cuffed tube inserted blindly into a distal airway. Collection of fluid through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. A commercial BAL catheter does not require use of an endoscope and can be performed readily in field situations, the disadvantage being lack of knowledge of the final location of the portion of lung that is lavaged.

RADIOGRAPHY. Thoracic radiography is of limited use in detecting EIPH in horses. Radiographs may demonstrate the presence of densities in the caudodorsal lung fields of some horses, but many affected horses have minimal to undetectable radiographic abnormalities.[32] Examination of thoracic radiographs of horses with EIPH may be useful in ruling out the presence of another disease process, such as a pulmonary abscess, that is contributing to the horse's pulmonary hemorrhage or poor athletic performance.

Pathophysiology

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen). If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures.[33] The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures that are largely attributable to capillary blood pressure and the lower intraalveolar pressure generated by the negative pleural pressures associated with inspiration.

During exercise the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure. Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses.[28,34,35] Values for mean pulmonary arterial pressure at rest of 20 to 25 mm Hg increase to greater than 90 mm Hg during intense exercise because of the large cardiac output achieved by exercising horses. The increases in pulmonary artery pressure, combined with an increase in left atrial pressure during exercise, likely result in an increase in pulmonary capillary pressure. Combined with the increase in pulmonary capillary pressure is a marked decrease (more negative) in pleural, and therefore alveolar, pressures during exercise. Pleural pressures of normal horses during inspiration decrease from approximately −0.7 kPa (−5.3 mm Hg) at rest to as low as −8.5 kPa (−64 mm Hg) during strenuous exercise.[36] Together, the increases in pulmonary capillary pressure and decrease (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillary of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.[37]

Other theories of the pathogenesis of EIPH include small airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic sheer forces associated with gait, and bronchial artery angiogenesis.[6,38] It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure, and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or lower airways has been proposed as a cause of EIPH.[39] Inspiratory airway obstruction results in more negative intrapleural, and therefore alveolar, pressures. This effect is exacerbated by exercise, with the result that alveolar transmural pressure is greater in horses with airway obstruction.[40,41] The higher transmural pressure in such horses may increase the severity of EIPH, although this has not been demonstrated. Moreover, although inspiratory airway obstruction may predispose to EIPH, the prevalence of this condition is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.

Horses with moderate to severe EIPH have histologic evidence of inflammation of the small airways,[42,43] and there is a clear association between presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid.[44] However, instillation of autologous blood into the airways induces a marked inflammatory response in normal horses,[45] and it is therefore unclear if inflammation alone induces or predisposes to EIPH or if the inflammation is a result of EIPH. Theoretically, small airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction and therefore a more negative alveolar pressure. Given that small airway disease is common in horses, there is the potential for an important effect of factors, such as viral infections, air pollution, and allergic airway disease, to contribute to the initiation or propagation of EIPH.[46]

Exercise is accompanied by marked changes in blood flow characteristics attributable to an increase in hematocrit and decrease in RBC deformability.[47,48] These changes cause an increase in microvascular shear stress and thus could conceivably contribute to capillary rupture. However, there is at present no direct evidence that indicates that this is an important feature of development of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has led to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified by the narrowing cross-sectional area of the caudal lung lobes.[38] According to the theory, the locomotory impact of the forelimbs results in transmission of forces through the scapula to the body wall; from there they pass into the lungs and caudally and dorsally. As the wave of pressure passes into the narrower caudodorsal regions of the lungs, it generates progressively greater shearing forces that disrupt tissue and cause EIPH. However, studies of intrapleural pressures have not demonstrated the presence of a systemic pressure wave passing through the lung and do not provide support for this hypothesis.[49] The observation that horses competing in hurdles or steeplechase events on hard ground have increased incidence of epistaxis lends support to the suggestion that locomotory impact, thought of as an "abdominal piston," might influence the development of EIPH.[50]

Horses with EIPH have been suspected of having defects in either hemostasis or fibrinolysis. However, although exercise induces substantial changes in blood coagulation and fibrinolysis,[51] there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[52,53]

VetBooks.ir

Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium causes inflammation of both airways and interstitium, with subsequent development of fibrosis and alteration of tissue compliance. Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways with resulting uneven inflation of the lungs.[54] The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is lifelong and continues for as long as the horse continues to perform strenuous exercise.[6]

Epidemiology EIPH occurs in horses throughout the world. It is a disorder of horses that run at high speed, such as Thoroughbred or Standardbred racehorses, Quarter Horses (racehorses and barrel racing horses), and polo ponies. The disorder is apparently uncommon in endurance horses and is very uncommon in draft breeds, such as Clydesdales, Percherons, or Belgians, after participation in weight-pulling competition.[55] As a general rule, the more intense the exercise is or the higher the speed attained, the greater the proportion will be of horses with EIPH.

The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined, as discussed later in this section. Almost all Thoroughbred racehorses in active training have hemosiderophages in BALF, indicating that all have some degree of EIPH.[9] The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

Risk Factors

BREED. EIPH is very common in Thoroughbred racehorses, with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43% to 75%.[13,15,56] The prevalence increases with the frequency of examination, with over 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races.[57] The prevalence of EIPH in Standardbred racehorses is assumed to be lower, with 26% to 34% of horses reported to have blood in the trachea after racing.[18,58] However, these studies were based on a single examination, and one study[58] reported as positive only those horses with blood covering more than one half of the tracheobronchial tree. When examined after each of three races, 87% of Standardbred racehorses showed evidence of EIPH on at least one occasion,[17] suggesting that EIPH is as common in Standardbred racehorses as it is in Thoroughbred racehorses.

EIPH occurs in approximately 62% of racing Quarter Horses and has been observed in Quarter Horses used for barrel racing.[59] The disorder occurs in racing Appaloosa horses.[60] Approximately 11% of polo ponies are affected with EIPH[61] and the disorder occurs in Chilean Criollo horses.[62]

AGE. Age is considered an important risk factor for EIPH, with the prevalence of the disorder being higher in older horses.[11,12,63,64] There is no consistent effect of sex on prevalence of EIPH.[13,15,18,56]

Among Thoroughbred racehorses the prevalence of EIPH increases with increasing speed,[13,42] being greater in Thoroughbreds after racing than after breezing (galloping). Lesions of EIPH are not detected in young Thoroughbred racehorses that have trained at speeds less than 7 m/sec.[13,42]

Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage but occurs only in a small proportion of racehorses.[23,65,66] The prevalence of epistaxis in racehorses varies between 0.1% and 9%, with the frequency depending on the breed, age, and sex of horses selected for study, the type of racing, and the timing and frequency of observation of horses after racing. Epistaxis is more common in older horses.[23,65] There are conflicting reports of a sex predisposition, although epistaxis may be more common in female Thoroughbreds.[23,65] Epistaxis is more common after races of less than 1600 m than in longer races,[23] although not all sources agree on this point.[65] However, horses in steeplechase races, which are typically longer than 2000 m, are at greater risk of epistaxis than are horses in flat races.[23,50] In addition, horses racing in hurdle or steeplechase races over hard ground in Britain are more likely to have epistaxis.[50]

The effect of genetics on the incidence of EIPH has been examined only minimally, with one study of horses with epistaxis, which is characteristically associated with severe EIPH, suggesting a hereditary predisposition among Thoroughbred racehorses in South Africa.[67] The heritability of the predisposition to epistaxis was considered low.[67]

Necropsy EIPH is a cause of sudden death of horses during racing and training[68-70] and in most studies is secondary to musculoskeletal injury as the cause of death. Necropsy examination reveals that approximately 60% of horses that die during racing or training or are euthanized because of acute injury during racing or training have evidence of EIPH.[70] Necropsy examination of affected horses is usually but not always incidental to examination for another cause of death.

Pertinent abnormalities detected on necropsy of horses with EIPH are restricted to the respiratory tract. Grossly, horses examined within hours of strenuous exercise, such as horses examined because of catastrophic musculoskeletal injuries incurred during racing, often have severe petechiation in the caudodorsal lung fields. Horses that die of EIPH also have pulmonary congestion and edema.[70] Horses with chronic disease have blue-gray or blue-brown discoloration of the visceral pleural surfaces of the caudodorsal lung fields that is often sharply demarcated, especially on the diaphragmatic surface.[70,71] The discoloration affects both lungs equally, with 30% to 50% of the lung fields being discolored in severe cases. Affected areas do not collapse to the same extent as unaffected areas and, in the deflated lung, have a spleenlike consistency. On the cut surface the discolored areas of lung are predominantly contiguous with the dorsal pleural surface and extend ventrally into the lung parenchyma. Areas of affected lung may be separated by normal lung. There is proliferation of bronchial vessels, predominantly arteries and arterioles, in affected areas.[72] In cases where upper airway obstruction might have played a role in the acute death, petechiae and ecchymotic hemorrhages are commonly present throughout the trachea and laryngeal region (Wilkins and Del Piero, unpublished data). Histologically, affected areas exhibit bronchiolitis, hemosiderophages in the alveolar lumen and interstitial spaces, and fibrosis of interlobular septa and pleura and around vessels and bronchioles.[43]

Therapy, Prevention, and Control Therapy for EIPH is usually a combination of attempts to reduce the severity of subsequent hemorrhage and efforts to minimize the effect of recent hemorrhage. Treatment of EIPH is problematic for a number of reasons. First, the pathogenesis of EIPH has not been determined, although the available evidence supports a role for stress failure of pulmonary capillaries secondary to exercise-induced pulmonary hypertension (see later). Second, there is a lack of information using large numbers of horses under field conditions that demonstrates an effect of any medication or management practice (with the exception of bedding) on EIPH. There are numerous studies of small numbers of horses (fewer than approximately 40) under experimental conditions, but these studies often lack the statistical power to detect treatment effects, and, furthermore, the relevance of studies conducted on a treadmill to horses racing competitively is questionable. Treatments for EIPH are usually intended to address a specific aspect of the pathogenesis of the disease and will be discussed in that context.

PREVENTION OF STRESS FAILURE OF THE PULMONARY CAPILLARIES. There is interest in reducing the pressure difference across the pulmonary capillary membrane in an effort to reduce

VetBooks.ir

EIPH. Theoretically, this can be achieved by reducing the pressure within the capillary or increasing (making less negative) the pressure within the intrathoracic airways and alveolus.

Furosemide apparently reduces pulmonary capillary pressure in exercising horses. Furosemide administration as prophylaxis against EIPH is permitted in a number of racing jurisdictions worldwide, most notably Canada, the United States, Mexico, and most of the South American countries.[73] Within the United States and Canada, almost all Thoroughbred, Standardbred, and Quarter Horse racing jurisdictions permit administration of furosemide before racing. The vast majority (>90%) of Thoroughbred horses racing in the United States receive furosemide before racing, at an estimated annual cost of between $6 million and $20 million (USD).[1] Although accurate numbers are not available, it appears that a smaller proportion of Standardbred and Quarter Horse racehorses receive furosemide before racing. Furosemide is administered to 22% to 32% of Standardbred racehorses and 19% of racing Quarter Horses in two racing jurisdictions.[74-76]

The efficacy of furosemide in treatment of EIPH is uncertain. Although field studies of large numbers of horses do not demonstrate an effect of furosemide on the prevalence of EIPH,[57] studies of Thoroughbred horses running on a treadmill provide evidence that furosemide reduces the severity of EIPH.[29,30,77] Under field conditions, based on tracheobronchoscopic evaluation of the severity of bleeding, furosemide has been reported to reduce, or have no influence on, the severity of bleeding.[78] This apparent inconsistency may be attributable to measurement of RBC counts in BALF of horses that have run on a treadmill not being representative of effects of furosemide under field conditions. The weight of evidence, albeit unconvincing, from field studies does not support a role for furosemide in preventing, or reducing the severity of, EIPH.

The mechanism by which furosemide may reduce the severity of EIPH is unknown, although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.[35,79,80]

Furosemide is associated with superior performance in both Thoroughbred and Standardbred racehorses.[74,81] Thoroughbred horses treated with furosemide are 1.4 times as likely to win the race, earn more money, and have a standardized 6-furlong race time 0.56 to 1.09 seconds less than that of untreated horses.[81] Similarly, furosemide reduces 1-mile race times of Standardbred pacers by 0.31 to 0.74 seconds.[74]

Enalapril inhibits angiotensin-converting enzyme activity in horses but does not affect pulmonary artery pressure of exercising horses.[82] Similarly, the efficacy of enalapril in preventing EIPH has not been demonstrated.

Nitric oxide is a potent vasodilator in many vascular beds. Administration of nitroglycerin (a nitric oxide donor) reduces pulmonary artery pressure of standing horses but does not affect pulmonary artery pressure of horses during intense exercise.[83] L-Arginine is a nitric oxide donor with no demonstrated efficacy in reducing pulmonary capillary pressure or EIPH in horses. The effect of L-NAME, an inhibitor of nitric oxide synthetase, on pulmonary artery pressure during maximal exercise is controversial, with either no effect or a decrease in pulmonary artery pressure reported.[84,85] It is interesting to note that L-NAME administration has been reported to cause an increase in severity of EIPH.[84] Sildenafil, a phosphodiesterase (PDE) inhibitor that accentuates the effect of nitric oxide and is used in the treatment of erectile dysfunction in men, has been administered to horses in an apparent attempt to reduce EIPH. However, its efficacy in preventing EIPH or reducing pulmonary capillary pressure has not been demonstrated.

An increase in pulmonary capillary pressure secondary to altered rheostotic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.[47] Furosemide increases blood viscosity, whereas pentoxifylline increases RBC deformability and may attenuate the increase in blood viscosity that occurs during exercise.[86-88] However, pentoxifylline does not affect the pulmonary capillary pressure of exercising horses and did not affect the prevalence of EIPH in a small experimental study.[89]

Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia and other abnormalities of the upper airway, whereas intrathoracic obstruction is usually a result of bronchoconstriction and IAD. Horses with partial extrathoracic inspiratory obstruction or bronchoconstriction and airway inflammation associated with recurrent airway obstructive disease (heaves) have pleural (and hence alveolar) pressures that are lower (more negative) than those in unaffected horses or in horses after effective treatment.

Partial inspiratory obstruction, such as produced by laryngeal hemiplegia, exacerbates the exercise-induced decrease in intrapleural pressures, with a consequent increase in transmural capillary pressures.[40,41,90] These changes may exacerbate the severity of EIPH, although an association between upper airway obstructive disease and EIPH has yet to be clearly demonstrated. Surgical correction of airway obstruction is expected to resolve the more negative intrapleural pressure, but its effect on EIPH is unknown.

Recently the role of the nares in contributing to upper airway resistance, and therefore lowering inspiratory intrapleural pressure, during intense exercise has attracted the attention of some investigators. Application of nasal dilator bands (FLAIR strips; http://flairstrips.com/flair-strips/) reduces nasal resistance by dilating the nasal valve[91] and reduces RBC of BALF collected from horses after intense exercise on a treadmill.[29,30] Furthermore, application of the nasal dilator strips to horses in simulated races reduces red cell count in BALF of some, but not all, horses.[92]

The role of small airway inflammation and bronchoconstriction in the pathogenesis of EIPH is unclear. However, horses with EIPH are often treated with drugs intended to decrease lower airway inflammation and relieve bronchoconstriction. β-Adrenergic bronchodilatory drugs such as clenbuterol and albuterol are effective in inducing bronchodilation in horses with bronchoconstriction, but their efficacy in preventing EIPH is either unknown or, in very small studies, is not evident. Clenbuterol neither alters the hemodynamic responses of horses to exertion nor attenuates exercise-induced arterial hypoxemia in normal horses.[93,94] Ipratropium, a parasympatholytic drug administered by inhalation, showed promise in a very small study (two horses) of preventing EIPH.[95] Corticosteroids, including dexamethasone, fluticasone, and beclomethasone administered by inhalation, parenterally, or enterally reduce airway inflammation and obstruction but have no demonstrated efficacy in preventing EIPH. Cromolyn sodium (sodium cromoglycate) has no efficacy in preventing EIPH.[96]

Water vapor treatment (inhalation of water-saturated air) has been proposed as a treatment for EIPH because of its putative effect on small airway disease. However, water vapor treatment has no effect on EIPH.[97]

The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on prevalence of the condition.[98] Although it is suggested that preventing or minimizing small airway disease may reduce the severity of EIPH, studies to demonstrate such an effect have not been reported. However, optimizing the air quality in barns and stables and preventing infectious respiratory disease appear to be sensible precautions.

INTERSTITIAL INFLAMMATION AND BRONCHIAL ANGIOGENESIS. Hemorrhage into interstitial tissues induces inflammation, with subsequent development of fibrosis and bronchial artery angiogenesis.[45,72,99] The role of these changes in perpetuating EIPH in horses is unclear but likely is of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation, and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. Although the value of rest is intuitive, there is no

VetBooks.ir

information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered by inhalation, enterally, or parenterally in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing the severity of EIPH has not been documented.

EXCESSIVE BLEEDING. Exercise induces substantial changes in blood coagulation and fibrinolysis.[51] However, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[52,53,100] Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. Although appropriate doses of aminocaproic acid inhibit fibrinolysis in stationary horses,[100] the efficacy of aminocaproic acid in preventing EIPH has not been demonstrated. Tranexamic acid is similarly administered to horses in the hope of preventing or mitigating EIPH. Estrogens are given to horses with the expectation of improving hemostasis, although the effect of estrogens on coagulation in any species is unclear. There is no evidence that estrogens prevent EIPH in horses.

Vitamin K is administered to horses with EIPH, presumably with the expectation that it will decrease coagulation times. However, because EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

Herbal preparations are marketed for treatment of EIPH. The only scientific study of these products examined the efficacy of Yunnan Paiyao or Single Immortal on RBC count in BALF of horses that had run on a treadmill. Neither product affected RBC count or coagulation variables.[101]

Aspirin inhibits platelet aggregation in horses and increases bleeding time.[102] Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH.[103] There is no evidence that aspirin exacerbates or prevents EIPH.

CAPILLARY INTEGRITY. Capillary fragility increases the risk of hemorrhage in many species. Various bioflavonoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavonoids have no efficacy in prevention of EIPH in horses.[104] Similarly, vitamin C is administered to horses with EIPH without scientific evidence of any beneficial effect.

SUMMARY OF TREATMENT OPTIONS. Selection of therapy for horses with EIPH is problematic. Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made not only as to which type of treatment to use and its timing but also which horses to treat. Moreover, the apparent progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors such as air quality and respiratory infections in inciting the disorder.

The currently favored treatment for EIPH is administration of furosemide before intense exercise. Its use is permitted in racehorses in a number of countries. Increasingly persuasive laboratory evidence of an effect of furosemide to reduce RBC count in BALF collected from horses soon after intense exercise supports the contention that furosemide is effective in reducing the severity of EIPH in racehorses. However, it should be borne in mind that neither the relationship between severity of EIPH and RBC count in BALF in racehorses in the field has been demonstrated. Only recently has there been solid evidence that furosemide reduces the prevalence of EIPH under field conditions.[105] The association between furosemide administration and superior performance in Standardbred and Thoroughbred racehorses should be borne in mind when recommending use of this drug.

Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised. The duration of rest and the optimal exercise program to return horses to racing after EIPH are unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases and minimization of noninfectious lower airway inflammation appear prudent. Horses with evidence of upper airway dysfunction, such as laryngeal hemiplegia, with concurrent evidence of EIPH may benefit from appropriate treatment.

Prognosis The prognosis for racing for horses with clinically significant EIPH is guarded because of the progressive nature of the disease. Horses that have experienced severe EIPH on one occasion are likely to do so again regardless of treatment. However, the risk of horses experiencing a repeated bout of severe hemorrhage and the effect of EIPH on career longevity and long-term health are currently unknown.

Equine Thoracic Neoplasia

Fabio Del Piero • Pamela A. Wilkins

Surveys of equine neoplasms indicate a low prevalence of thoracic neoplasia in the horse. In an abattoir survey in London of 1308 horses, only 2 horses had pulmonary tumors: one granular cell tumor and one bronchiolar adenoma.[1] Two other necropsy surveys of 155 and 687 equines reported no thoracic neoplasms.[2,3] A report on chronic pulmonary disease in the horse states that the practical importance of lung tumors in this species is negligible.[4] University of Pennsylvania researchers examined 5629 horses between 1968 and 1987. Thirty-five horses had neoplasia involving the thoracic cavity, corresponding to a prevalence of 0.62%.[5]

The prevalence of primary lung neoplasms of any type is reported to be less than 1% of all reported neoplasms in domestic animals.[6] The lungs are susceptible to tumor emboli because of the filter action of the capillary bed associated with small capillary diameter and, perhaps, specific adhesion factors. It can sometimes be difficult or even impossible to distinguish metastatic disease from primary pulmonary neoplasia; thus, an important part of the diagnosis is exclusion of possible primary sites elsewhere in the body. Primary pulmonary tumors reported in the horse include granular cell tumor, bronchial myxoma, adenoma, adenocarcinoma, anaplastic bronchogenic carcinoma, and pulmonary carcinoma (Fig. 31-46). Other primary thoracic tumors reported in the horse include pulmonary chondrosarcoma, pleural mesothelioma, thymoma, and lymphosarcoma. The majority of these neoplasms generally occurs in the mature or aged horse. The exception is lymphosarcoma, which may also be observed in young animals.

Antemortem diagnosis of thoracic neoplasia depends first on recognition of thoracic disease. Most of the reported cases of thoracic neoplasia involve metastatic disease. The horses' clinical signs are generally related to the primary site of the neoplasm; therefore the clinician often has no reason to suspect thoracic involvement. When respiratory signs such as dyspnea, tachypnea, hemoptysis, cough, cyanosis, nasal discharge, and epistaxis are present, relevant diagnostic tests are more likely to be performed. Ultrasonography and bronchoscopy increase the frequency of antemortem diagnosis of thoracic neoplasia.

Granular cell tumors are the most frequently reported primary pulmonary neoplasm of the horse. They are usually confined to the lungs and are characterized by single to multiple well-defined whitish dense nodules associated with a major bronchus, often protruding into the bronchial lumen or more distally within the parenchyma. Most granular cell tumors have been diagnosed only at postmortem examination, often as incidental findings. These homogeneous growths of granular eosinophilic cells express S-100 and occasionally neuron-specific enolase.[7] The ultrastructural morphology of this

VetBooks.ir

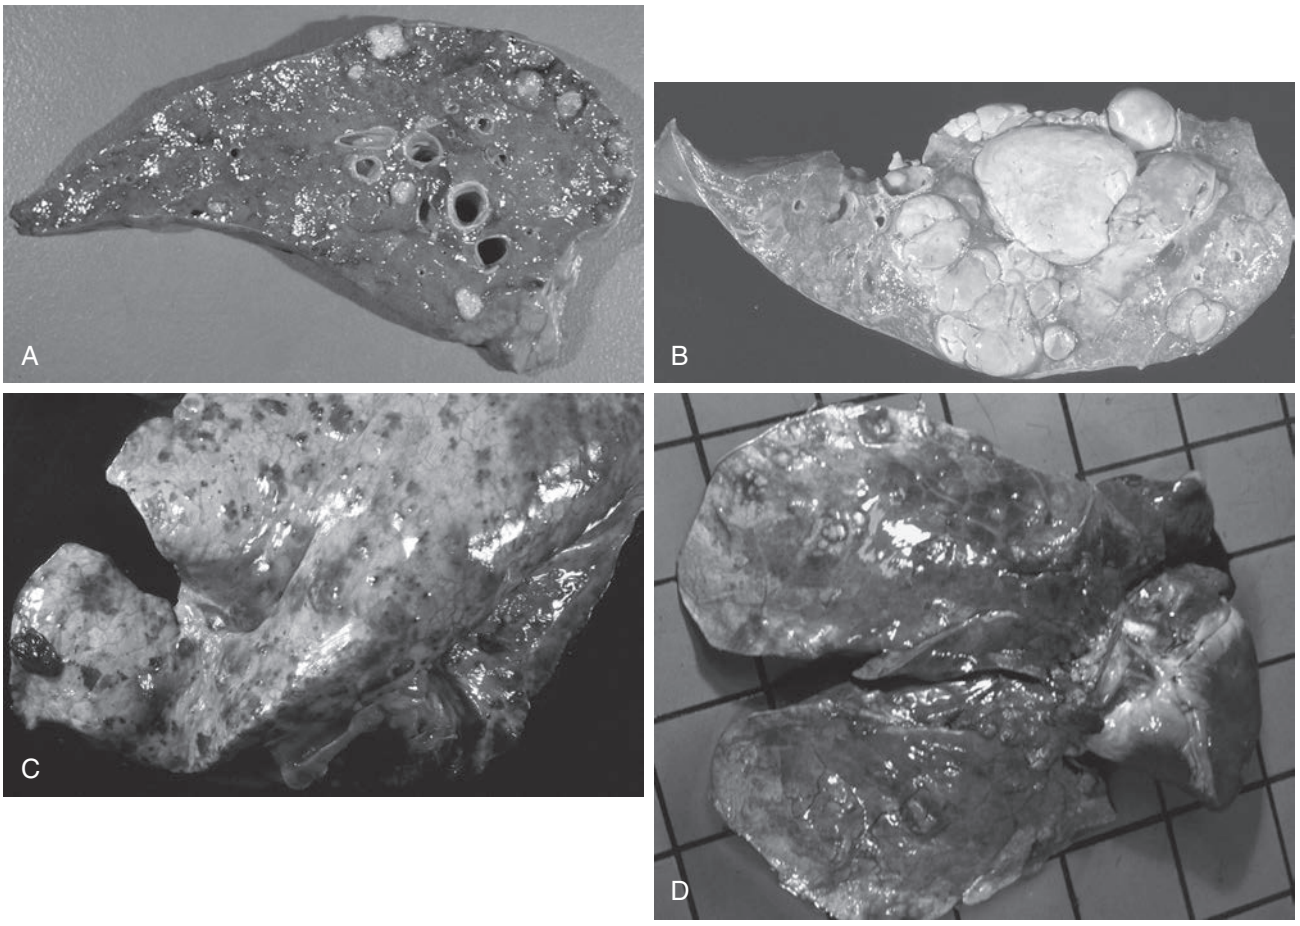

FIG. 31-46 **A,** Metastatic undifferentiated sarcoma. **B,** Granulosa cell tumor. **C,** Metastatic hemangiosarcoma. **D,** Metastatic squamous cell carcinoma.

tumor may suggest a neural origin as well. Primary pulmonary chondrosarcoma has been reported in the horse.[8] Cytologic examination of pleural fluid and antemortem needle aspirate of the pulmonary mass revealed neoplastic chondrocytes. Another report describes metastatic chondrosarcoma in the lungs of a horse with a primary tumor in a rib.[9] A primary bronchial myxoma, characterized by loose spindloid mesenchymal cells, was reported in a 25-year-old Arabian mare with a history of intermittent coughing, hyperpnea, and respiratory disease of 2 years' duration.[10]

Primary pleural tumors are also rare. The type reported in the horse is pleural mesothelioma. The tumor is frequently associated with a large volume of pleural effusion. Cytologic examination of the pleural effusion revealing numerous pleomorphic mesothelial cells may aid in the antemortem diagnosis.

Thymomas are neoplasms of thymic epithelial cells, regardless of the presence or absence of lymphocytes. They are infrequently reported in the horse.[11-13] Equine lymphosarcoma occurs in mediastinal, alimentary, multicentric, cutaneous, and generalized forms; combinations of one or more of these are not infrequent.[14,15] In a 1973 review of 54 cases of equine lymphosarcoma,[3] the lung was involved in 16.6% of the cases, whereas the thoracic lymph nodes were involved in 35.2%.[16] In the University of Pennsylvania survey, thoracic lymphosarcoma was the single most common neoplasia of the thorax and was present in 19 (54%) of the cases.[3] Pleural fluid cytologic evaluation was diagnostic in six (75%) of the eight horses. Diagnosis was made by biopsy of a peripheral lymph node in several cases. In a report from the University of Bristol, thoracic malignant lymphoma accounted for 74% of the cases of thoracic neoplasia.[16] Metastatic adenocarcinoma accounted for 20% of the cases in the University of Pennsylvania study[5] and 11% of the cases in the University of Bristol study.[16] The primary sites of the tumor were thought to be kidney, uterus, thyroid, and ovary.

Gastric squamous cell carcinomas commonly metastasize to the thoracic cavity. Cytology of pleural fluid with identification of neoplastic epithelial squamous cells has allowed for antemortem diagnosis of the carcinoma in several cases. Metastatic squamous cell carcinoma of the thorax was found in 14% and 5% of the cases in the University of Pennsylvania[5] and University of Bristol[16] surveys, respectively. Neoplastic epithelial cells may also be identified in biopsy specimens via indirect immunohistochemistry using antibodies recognizing cytokeratins of various molecular weights.

Hemangiosarcoma with pulmonary involvement was found in 9% of the horses in the University of Pennsylvania survey.[5] Hemothorax, anemia, and dyspnea were commonly seen with this type of neoplasm. Tentative antemortem diagnosis of the hemangiosarcoma can be made by transcutaneous direct thoracoscopy and observation of hemorrhages over the visceral and parietal pleural surfaces as well as tissue biopsy of these sites. Identification of neoplastic endothelial cells demarcating irregular, sometimes blood-filled cavities allows diagnosis from the biopsy specimen. Neoplastic endothelium expresses a variable amount of immunohistochemically identifiable factor VIII.

Malignant melanoma in a 20-year-old gelding had widespread infiltration of many organs, including the lungs and pleura.[16] This pattern of distribution is not uncommon in malignant, less pigmented melanomas. Amelanotic melanomas are rare in the horse, and microscopic identification of melanin simplifies the diagnosis of these tumors. Equine melanocytes express S-100 and PNL2 proteins, and their detection can be used to diagnose melanocytic neoplasms.

Other pulmonary metastatic tumors reported are mammary carcinoma,[17] seminoma,[18] and malignant pheochromocytoma.[19] Pulmonary hamartomas are occasionally observed in the newborn foal. Although they are nonneoplastic growths, they appear as tumorlike

VetBooks.ir

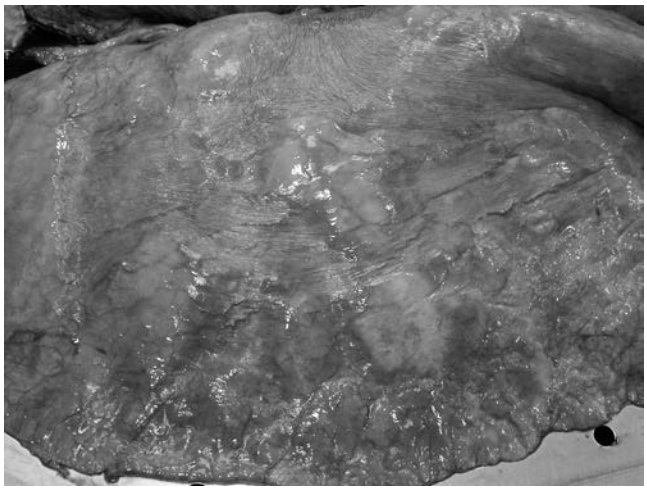

FIG. 31-47 Equine multinodular pulmonary fibrosis.

masses that can compress the surrounding parenchyma and cause systemic passive congestion and hydrops of the amnion in the fetus. Their histologic characterization is that of bronchiolar-like structures lined by cuboidal epithelium with lack of alveolar development or by normal alveoli, bronchi, and blood vessels but with an alveolus : artery ratio greater than normal. Generally they are not compatible with a long period of extrauterine life.

An unusual progressive idiopathic multifocal granulomatous pneumonia of adult horses may resemble neoplasia behaviorally and morphologically during clinical examination.[20,21] Pulmonary biopsy may allow the identification of equine multinodular pulmonary fibrosis (EMPF), which has been associated with EHV-5 infection[21] (Fig. 31-47).

Clinical signs of thoracic neoplasia are often inapparent or nonspecific—for example, depression, inappetence, weight loss, and pyrexia. More specific signs include cough, epistaxis, and dyspnea. Cytologic examination of tracheobronchial aspirate, bronchoalveolar lavage fluid, or pleural fluid and histologic examination of a thoracic mass tissue biopsy with ancillary histochemistry and indirect immunohistochemistry may allow for antemortem diagnosis of the neoplasm. Occasionally, electron microscopy may provide additional information. In equine patients with respiratory signs, all causes of infectious or allergic lung disease should be eliminated before neoplasia is considered in the differential diagnosis.

Diseases of Lymph Nodes, Vasculature, and Pharynx

Retropharyngeal Lymph Node Abscessation

John R. Pascoe

Definition and Etiology In horses, the retropharyngeal lymph nodes consist of medial and lateral lymphoid chains. The lateral chain (8 to 15 nodes) is located ventral to the atlas and along the lateral sides of the guttural pouches. These lymph nodes are covered by the parotid gland and are not clearly distinguishable from the medial retropharyngeal lymph nodes (20 to 30 nodes). The medial retropharyngeal lymph nodes are located ventral to the lateral chain on the dorsolateral aspect of the pharynx and the caudoventral aspect of the guttural pouches.[1]

Retropharyngeal lymph node abscesses in horses are generally caused by *Streptococcus equi* subsp. *equi* infection (see section on Strangles) or are secondary to trauma.[2,3] Other bacterial isolates have included *S. equi* subsp., *Streptococcus zooepidemicus, Corynebacterium pseudotuberculosis,* and *Actinobacillus* spp., including *A. denticolens*.[4,5] An unusual case of granulomatous infection of the guttural pouch caused by *M. avium* complex was believed to have originated from the retropharyngeal lymph nodes.[6] Extension of guttural pouch infections into the retropharyngeal space has been suggested as another source of infection.[7] Lymphadenopathy of the retropharyngeal nodes may also occur during viral respiratory infections, including equine herpesvirus (EHV) infection, influenza, and viral arteritis.[8] Retropharyngeal abscesses not associated with regional lymph nodes can result from perforation of the oropharynx or nasopharynx by ingested foreign bodies,[9] passage of a nasogastric tube,[10] or use of a balling gun.

In ruminants, the medial retropharyngeal lymph nodes are located on the dorsolateral aspect of the pharynx, one on each side of the midline. One to three lymph nodes may be present in cattle. The lateral retropharyngeal lymph nodes are located caudal to the medial retropharyngeal lymph nodes in the cranial neck region and are caudal to the retropharyngeal space.[11]

Abscessation of the medial retropharyngeal lymph nodes in cattle may result from pharyngeal actinobacillosis, foreign body penetration, or traumatic perforations by balling guns or dose syringes.[12-14] *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) or *Actinobacillus* spp. are frequently isolated.[8] Cattle with abscessed pharyngeal lymph nodes often have a small ulcer in the mouth, most frequently at the junction of the base and shaft of the tongue. This is more likely to occur when cattle are eating dry scabrous roughage. In addition to traumatic perforations and foreign bodies, caseous lymphadenitis (CLA) caused by *C. pseudotuberculosis* frequently results in abscessation of these lymph nodes in sheep and goats.

Clinical Signs and Differential Diagnosis Clinical signs associated with retropharyngeal lymph node infection or abscessation in horses include dysphagia, odynophagia (painful swallowing), nasal or oral regurgitation, excess salivation, difficult and often noisy breathing, painful throatlatch swelling, mucoid to mucopurulent nasal discharge, extension of the head and neck, and weight loss. In 46 horses with retropharyngeal lymph node abscessation, common clinical signs were fever and increased heart and respiratory rates (80%); unilateral or bilateral throatlatch swelling (65%); respiratory stertor or distress (35%); purulent nasal discharge (20%); inappetence and signs of depression (15%); and dysphagia (9%).[2] Other signs observed endoscopically include reduction in size or collapse of the pharyngeal lumen, asymmetry of the dorsal pharyngeal wall, and deviation of the laryngeal aperture away from the retropharyngeal mass.[2,3] Differential diagnosis for a retropharyngeal mass should include abscess, cellulitis, guttural pouch empyema or tympany, parotiditis, lymphadenopathy, neoplasia, and hematoma.

Clinical signs observed in cattle with infection or abscessation of the medial retropharyngeal lymph nodes include difficult breathing, excessive salivation, extension of the head and neck, anorexia, enlarged submandibular lymph nodes, nasal discharge, and swelling in the retropharyngeal space.[12] Other disease conditions that affect the oropharynx and surrounding lymph nodes should be considered in the differential diagnosis. These include actinobacillosis, lymphosarcoma, sialolithiasis, and necrotic laryngitis, laryngeal edema, or severe tracheitis caused by infectious bovine rhinotracheitis (IBR) virus.[8,12]

Affected sheep and goats may exhibit excessive salivation, increased respiratory rate, stertorous breathing, mucopurulent nasal discharge, regurgitation, gagging, depression, subcutaneous crepitation, weakness, and fetid breath. A false carotid aneurysm in the retropharyngeal space has been reported; on external examination it may be confused with abscessation of the medial retropharyngeal lymph nodes.[15] Enlarged retropharyngeal lymph nodes are usually easily palpated and identified in sheep and goats. CLA (see Chapter 37) is the most frequent cause of enlarged retropharyngeal lymph nodes in these species.

Clinical Pathology Collection of purulent material from abscessed lymph nodes may assist in identification of the causal

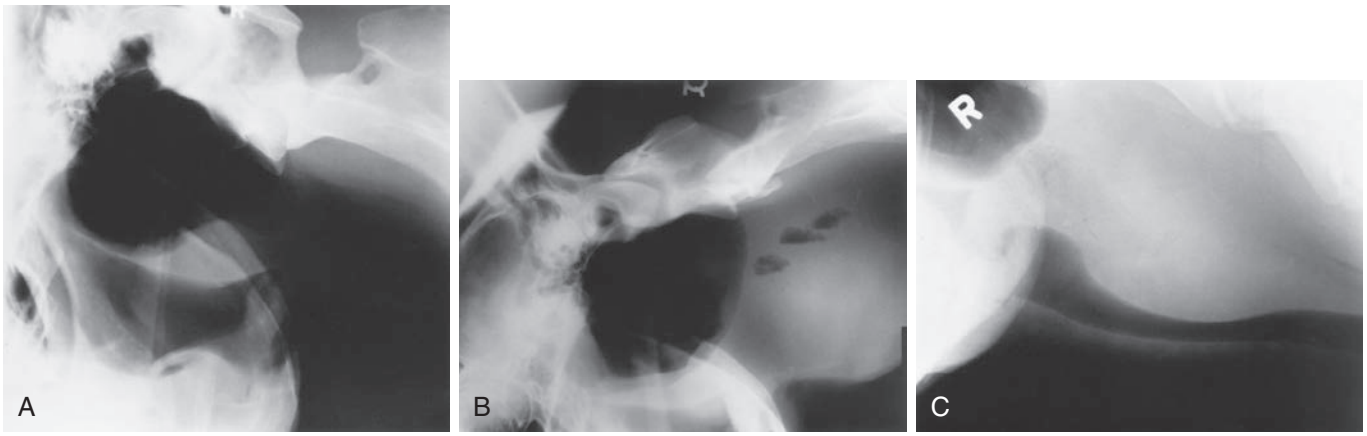

FIG. 31-48 **A,** Lateral radiograph. A soft-tissue density (retropharyngeal abscess) is distorting the floor of the guttural pouch. **B,** Lateral radiograph. There is increased soft-tissue density with gas shadows ventral to the cervical vertebrae. These changes are consistent with abscessation of the retropharyngeal lymph nodes. **C,** Lateral radiograph. There is increased soft-tissue density ventral to the cervical vertebrae, with compression of the dorsal border of the trachea. These changes were caused by cellulitis and abscessation of the retropharyngeal lymph nodes.

agent. Leukocytosis may be evident on the hemogram, with neutrophilia peaking as the lymph nodes abscess.

Laboratory Aids and Definitive Diagnostic Tests

Lateral radiographs of the pharynx, diagnostic ultrasound, and endoscopy aid in the diagnosis of retropharyngeal infections or abscesses. In horses, radiography may reveal a large soft-tissue mass impinging on the guttural pouch from a caudoventral direction (Fig. 31-48, *A*), as well as thickening of the pharyngeal roof. The soft-tissue swelling may contain gas (see Fig. 31-48, *B*). Compression of the larynx and trachea with ventral displacement may also be evident (see Fig. 31-48, *C*).[2] Observation of a gas-fluid interface on radiographs of the pharynx generally indicates abscessation, but care should be taken to distinguish a retropharyngeal abscess from guttural pouch empyema.[6] Foreign bodies associated with pharyngeal trauma are not usually radiopaque and therefore are not visible radiographically unless outlined by contrast medium. Exceptions include small wire foreign bodies likely ingested from baled hay that can perforate the tongue or oropharynx and cause cellulitis and dysphagia[9] and, in cattle, magnets that have been inadvertently placed retropharyngeally.

On endoscopy, asymmetry or collapse of the pharyngeal lumen or both signs suggests a retropharyngeal space-occupying mass. Recognition of drainage from the guttural pouch openings or examination of the guttural pouches may be necessary to differentiate between guttural pouch empyema and retropharyngeal lymphadenopathy or pharyngeal neoplasia. Occasionally the pharyngeal wall ruptures, allowing endoscopic observation of retropharyngeal drainage into the pharynx, usually near the esophageal entrance. Percutaneous needle aspiration may yield a definitive diagnosis if purulent material is obtained. Ultrasonography improves diagnostic precision by permitting more accurate identification of the abscess and highlighting its anatomic relationships as an aid to surgical drainage.[16]

Clinical examination, radiography, ultrasonography, endoscopy, and percutaneous centesis may all prove helpful in making a diagnosis of medial retropharyngeal lymph node infection or abscessation in ruminants. In cattle, localized swelling cranial to the larynx may be detected by digital palpation of the oropharynx.[12] Oropharyngeal examination must be performed carefully in animals with respiratory distress to prevent further airway compromise.

Pathophysiology

Upper respiratory tract disease, trauma, and foreign body penetration with resulting infection and drainage to local lymph nodes result in clinically apparent infection and abscessation of the retropharyngeal lymph nodes. In horses, the retropharyngeal space is occupied primarily by the guttural pouches. Because the vagus, glossopharyngeal, hypoglossal, spinal accessory, and sympathetic nerves traverse this area, their function can be affected by infectious or inflammatory processes involving the retropharyngeal space.[2] If such infections are contained within the lymph nodes or are confined within the fibrous capsule of the abscess, cranial nerve dysfunction is not usually evident.[2] Clinical evidence of dysphagia or odynophagia such as the presence of feed and saliva at the external nares may result from angina and from inflammation or injury of the glossopharyngeal nerve or pharyngeal branch of the vagus nerve, compression, or obstruction of the pharynx or esophagus. It has been suggested that retropharyngeal lymphadenitis may result in neuritis of the pharyngeal branch of the vagus nerve in young horses and contribute to the pathogenesis of dorsal displacement of the soft palate.[17]

Respiratory distress may result when enlargement of the retropharyngeal lymph nodes compresses or obstructs the nasopharyngeal, laryngeal, or tracheal lumen, and the disease caused by *S. equi* subsp. *equi* in horses is appropriately named *strangles*.

The most common cause of pharyngeal inflammation and infection in cattle is pharyngeal trauma associated with balling guns, dose syringes, paste wormer guns, esophageal feeders, or nasogastric tubes. A careful history to determine whether any of these devices were used is important in ascertaining the source of pharyngeal abscessation. Such infections usually involve mixed bacterial flora, because they are directly connected with the oropharynx.

Epidemiology

Infection with *S. equi* usually results from contact (inhalation or ingestion) with pasture, feed, or water contaminated with nasal discharge from infected horses. Asymptomatic carrier horses have also been implicated as source of infection.[18] The likely bacterial reservoir in carrier horses is the guttural pouch, particularly if chondroids are present in one or both pouches[18-20] or if swollen or discharging lymph nodes are present in the floor of the medial compartment of the guttural pouch. Infection of the pharyngeal and nasal mucosa results in an acute pharyngitis and rhinitis, and drainage to regional lymph nodes results in lymphadenopathy and possibly abscessation.[8]

CLA is spread through the discharges from ruptured lymph nodes. The causal agent *C. pseudotuberculosis* may persist in the environment for long periods, and infection results from contact of shearing, docking, or castration wounds with contaminated soil, equipment, or freshly ruptured abscesses. Sheep dips have been reported as another important source of infection.[8] Spread of infection from skin wounds often leads to involvement of local nodes and abscess formation. The mode of spread in goats is not well understood, but the disease usually spreads in a low-grade contagious manner, often involving most of the herd over a period of years.

VetBooks.ir

Necropsy Findings Fatalities are rare and most likely result from respiratory compromise or septicemia. Necropsy lesions include cellulitis with compression and ventral displacement of the larynx and cranial aspect of the cervical trachea. Abscesses are variable in size and may contain either caseous *(C. pseudotuberculosis)* or liquid material *(S. equi* subsp. *equi)*. A thick, fibrous capsule may occur in response to the infectious process and may account for the surrounding tissue compression. Occasionally, draining tracts may connect the abscess to the pharynx, guttural pouch, or skin.[10,21]

Treatment and Prognosis Treatment goals are relief of respiratory distress and control of infection. Temporary tracheotomy may be needed for relief of respiratory distress and may be prudent, especially in foals with singular, large, or multiple abscesses, before percutaneous drainage is attempted. After surgical drainage, appropriate systemic antibiotics are administered and supportive therapy to further reduce swelling may be beneficial.

Surgical approaches include percutaneous drainage, intraoral drainage, and marsupialization.[2,12] In horses, an intraoral approach is very difficult because of the long narrow oral cavity, and for this reason percutaneous drainage is commonly used. For abscesses visible through the mucosal lining of the guttural pouch, endoscopically assisted drainage into the pouch can also be considered. Surgical access to the retropharyngeal space has been described, including dorsal and ventral approaches, an approach through Viborg triangle, and a lateral approach.[3] A ventral surgical approach is recommended because of the relative lack of vital structures encountered and the excellent ventral drainage achieved. A less invasive drainage technique can be accomplished in standing sedated horses, by ultrasound-guided percutaneous needle placement into abscessed lymph nodes. Affected nodes can have a wall thickness of 1 to 2 cm and a diameter of 5 to 11 cm.[16] Aspiration of purulent matter and cavity lavage with antiseptic solutions and concurrent administration of parenteral antibiotics may be sufficient for resolution. If aspiration is not possible because the purulent material is too viscous, incision directly along the needle shaft, after careful consideration of regional anatomy, provides adequate exterior drainage and access for cavity lavage with antiseptic solutions or use of a seton or gauze packing. If the abscess is endoscopically visible beneath the guttural pouch mucosa, drainage into the guttural pouch and subsequent lavage of the purulent material can be accomplished. Before, or at the time of, abscess drainage or excision, the horse should be started on broad-spectrum antimicrobials, followed by the appropriate specific antimicrobial drug when results of the microbial culture and susceptibility testing are known.

Occasionally, medical management alone may resolve infection; however, this is less likely if abscessation has occurred. Because the most common bacterial isolate in the horse is *S. equi,* parenteral antimicrobial therapy with procaine penicillin G (22,000 IU/kg IM twice daily) or potassium penicillin (22,000 IU/kg IV four times daily) is recommended. Systemic NSAIDs are useful to reduce inflammation and swelling, and fluid and electrolyte therapy may be necessary if there is odynophagia or dysphagia. Aspiration pneumonia can occur with dysphagia or if there is oral or nasal regurgitation associated with painful swallowing.

In cattle with pharyngeal trauma, an existing wound is often draining from the retropharyngeal area into the oropharynx, making surgical drainage unnecessary, and response to parenteral broad-spectrum antimicrobial therapy is typically favorable.[22] Parenteral antimicrobial therapy alone has been ineffective in treating retropharyngeal abscesses when there is no draining tract.[12] Intraoral or percutaneous drainage has been used successfully in conjunction with broad-spectrum, parenteral antimicrobial therapy. After drainage, the abscess cavity is flushed daily with an antiseptic or antibiotic solution.[12] Surgical drainage into the oral cavity must be handled with caution. The head should be lowered so that exudate or flush solution is not aspirated; inspection of the granulating abscess cavity is necessary if feed impaction is suspected.[2,12] Aspiration pneumonia may be a serious complication when dysphagia is present.

In sheep and goats, walled-off *C. pseudotuberculosis* abscesses may often be most safely drained by suturing the skin to the thick abscess capsule (a procedure known as *marsupialization*) before opening the capsule. Marsupialization prevents contamination of other retropharyngeal structures with infected material and markedly reduces postsurgical cellulitis. Although *C. pseudotuberculosis* is susceptible in vitro to a number of antimicrobial agents, abscesses associated with the condition have not been well controlled by antimicrobial therapy. Walled-off *C. pseudotuberculosis* abscesses are difficult to eliminate solely with antimicrobial therapy, and drainage or removal of the entire lymph node gives the best results.

Prevention and Control Preventive measures to limit infection and abscessation of retropharyngeal lymph nodes include correct administration of therapeutic agents with balling guns and dose syringes, isolation of horses affected with viral or bacterial upper respiratory tract disease, vaccination against strangles, and vigorous treatment in the early stages of streptococcal infection. Reducing environmental sources of contamination and preventing contamination of shearing equipment, dipping vats, and feeders with *C. pseudotuberculosis* are important to limiting spread in sheep. Culling affected sheep and goats may also help to reduce the incidence of CLA.

Pharyngitis

John R. Pascoe

Definition and Etiology Pharyngitis is inflammation of the pharyngeal tissues. It is not generally considered to be a specific disease entity but a response to other diseases, particularly viral and bacterial respiratory disease, and to a lesser extent to local physical, chemical, or allergic causes. Acute and chronic forms are recognized.

Although physical and chemical causes of pharyngitis may be identified with certainty, the role and specificity of microbial pathogens as causative agents remain controversial. In horses, *Streptococcus* spp. and various viral respiratory diseases have been incriminated as specific causes of pharyngitis, but given the ubiquitous nature of some virus groups in horses, a direct causal association remains unsubstantiated.[1,2] In cattle, *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Actinobacillus* spp., and *Fusiformis necrophorus* are frequently isolated.[3]

Synonyms for chronic pharyngitis in horses include *pharyngeal lymphoid hyperplasia (PLH), chronic pharyngitis, chronic lymphoid follicular hyperplasia, follicular pharyngitis,* and *follikelkatarrh.*[4-6]

Clinical Signs and Differential Diagnosis In acute pharyngitis, signs are associated with pharyngeal pain (odynophagia, dysphagia), nasal discharge (serous, seromucous, mucopurulent, purulent, feed-contaminated), regional lymphadenopathy (submandibular, retropharyngeal nodes), ptyalism (especially in cattle), respiratory noise (often inspiratory), pharyngeal swelling, and cough. Mouth breathing may occur in cattle when there is increased resistance to breathing associated with excessive exudate, diphtherous membranes, and lymphadenopathy or lymph node abscess. Pharyngitis from local pharyngeal trauma or incarcerated foreign bodies may also be associated with odor of either the breath or nasal discharge. Calves with necrotic laryngitis, pharyngitis, and stomatitis have a characteristic malodorous breath. Acute laryngeal inflammation and edema of unknown cause can occur in horses and ruminants and is characterized by marked inspiratory difficulty and stertor without malodorous breath. Treatment of acute edema with dexamethasone (0.05 mg/kg IM; avoid in pregnant heifers or cows) and broad-spectrum antimicrobials or penicillin has produced rapid clinical improvement.

Signs observed on endoscopic or oropharyngeal examination in cattle include pharyngeal hyperemia and edema, lymphonodular swelling, and either a moist appearance of the pharyngeal surface

VetBooks.ir

or the presence of exudate or a diphtherous membrane adhering to the pharyngeal surface. Focal necrosis or ulceration of the mucous membrane and tonsillar tissue may occur; signs associated with rhinitis and laryngitis may be evident. Signs of chronic pharyngitis are similar. In horses, there may be endoscopic evidence of more marked hyperplasia of the lymphonodular follicles within the pharyngeal mucosa, and single or multiple lymphonodular masses may be within, or protrude from, the pharyngeal mucosa. Biopsy and cytologic evaluation are recommended to rule out neoplasia, particularly squamous cell carcinoma, lymphoma, and lymphosarcoma. Differential diagnostic possibilities include rhinitis and laryngitis, and in cattle, rabies should be strongly considered before oropharyngeal examination. If the predominant sign is dysphagia (see Chapter 7), other diagnostic ruleouts include foreign bodies in the tongue, fractures of the hyoid apparatus or jaws, and, in the horse, diseases of the guttural pouches. If exercise intolerance is the primary complaint in a horse, pharyngitis should be considered only after other possible causes of impaired performance have been eliminated (see Chapters 5 and 6).[7-11] Pharyngitis is not a risk factor for poor racing performance in racing Thoroughbreds[12] or Standardbred trotters.[10] More severe PLH grades were found in poorly performing endurance horses (primarily Arabian horses); however, more definitive causes for poor performance were identified in these horses.[11]

Upper airway inspiratory pressures recorded during strenuous exercise in horses with grade IV PLH are not different from those of normal horses under the same exercise conditions.[8] Assuming that airflow in both groups of horses was comparable, severe PLH does not appear to cause functional upper airway obstruction. It is conceivable that pharyngeal pain associated with PLH may contribute to bronchoconstriction and impaired performance; however, this effect remains unproven.

FIG. 31-49 Endoscopic view showing the nodular appearance of pharyngeal lymphoid hyperplasia.

Clinical Pathology

Changes in the hemogram and serum biochemical profiles are likely to result from concurrent respiratory disease (increases or decreases in absolute or differential leukocyte counts, hyperfibrinogenemia, anemia) or to reflect abscess formation (neutrophilia, hyperfibrinogenemia) or dehydration and fasting associated with dysphagia.

Laboratory Aids and Definitive Diagnostic Tests

Although a presumptive diagnosis can be made from clinical signs, definitive diagnosis requires observation of the pharynx (Fig. 31-49) and, more important, exclusion of other conditions that have similar signs. Radiography of the pharynx can provide information on pharyngeal anatomy, radiodense foreign bodies, soft-tissue masses, fractures, and, in horses, guttural pouch disorders. Ultrasonography of the pharyngeal region and, if indicated by the clinical examination, both radiographic and ultrasound examination of the thorax may help define the extent of concurrent pulmonary disease.

Microbial culture of pharyngeal secretions can be considered, but interpretation is difficult because (1) the pharynx normally has resident microflora with considerable individual variation, and (2) many of the microorganisms isolated are capable of opportunistic infection. In horses with grades III and IV PLH, the number of bacteria recovered per gram of pharyngeal secretion was almost 100-fold greater than in normal horses.[9] The pattern of microbial isolation was not consistent among horses, suggesting that these organisms were not the source of the pharyngitis but rather other factors had made conditions for colonization more favorable.

Biopsy and cytologic examination are indicated in refractory cases and when abnormal masses are present to rule out neoplasia.

Pathophysiology

Acute pharyngitis occurs as a sequela to inflammation of regional lymphoid tissue (see Kumar and colleagues[13] for a description of the morphologic and histochemical features of the normal equine nasopharyngeal tonsil).[14] In horses, the pharyngeal tonsil consists of discrete lymphoid follicles diffusely distributed in the dorsal and lateral walls of the pharynx. In ruminants, the pharyngeal tonsil is located caudal to the pharyngeal septum in the caudodorsal wall of the pharynx and is bounded by long ridges and grooves into which mucous glands open. In response to local or lymphogenous spread of infection, the tonsillar tissue becomes inflamed and the tonsillar crypts become filled with desquamated epithelium, leukocytes, and bacteria. Clinically this is seen as hyperemia and edema of the pharyngeal tonsil with diffuse white or yellow tips to the lymph nodules. The edematous appearance is associated with hyperplasia of the lymph nodules and sequestration of perinodular inflammatory fluid.

If extensive destruction of the lymphoid cells or subsequent invasion of the nodules or supporting soft tissue is evident, the result is focal or diffuse necrosis, which may be seen as pinpoint areas of follicular necrosis or diffuse necrosis with associated purulent or fibrinonecrotic exudate. With resolution, atrophy of some follicles and increased fibrosis are present. Follicular atrophy also occurs with aging.

Epidemiology

No specific epidemiologic data are available. When pharyngitis occurs as a sequela to respiratory tract infection, the population demographics should be similar to those known for the specific respiratory disease. For example, grade II PLH was identified in 60% of foals with distal respiratory tract infection and in only 13% of control foals.[15] Because physical and chemical injury to the pharynx occurs sporadically, no universal epidemiologic characteristics would be anticipated.

PLH is prevalent in horses less than 5 or 6 years of age, and the severity of PLH grades[5] is inversely correlated with age.[4,12,16,17] In endoscopic surveys of primarily Thoroughbreds in race training, prevalence of PLH ranges from 29% to 34%, with grade II PLH observed in 45% to 63% of 2-year-olds and less than 12% to 20% of horses older than 5 years affected.[16] Similar results are reported from Japan for racing Thoroughbreds with a history of cough or abnormal respiratory noise[18] and in a mixed population of horses in Calgary, Canada.[17] Pharyngeal mucus scores are not correlated with PLH, transtracheal wash aspirate, or bronchoalveolar lavage fluid variables, suggesting that PLH is not directly a manifestation of lower airway inflammation or disease.[17,19]

VetBooks.ir

Treatment and Prognosis Approach to treatment is largely symptomatic and directed at palliation of pharyngeal pain and maintenance of unobstructed breathing until the initiating disease process has abated. In many instances, the signs are sufficiently mild that treatment is unnecessary. When pharyngeal angina is causing inappetence or dysphagia, administration of NSAIDs should be considered. Dehydration should be corrected by either parenteral or enteral fluid administration. Enteral fluid therapy may be difficult because passage of a nasogastric tube may elicit too much pain. For inappetent animals, nutritional support may be necessary until pharyngeal pain subsides sufficiently for normal eating to resume. Soft feeds, especially green grass, should be offered when available to encourage animals with pharyngeal discomfort to eat.

Antimicrobial therapy is probably not indicated, but it is often given to limit development of secondary bacterial infection. Infections caused by foreign body injury should be treated with antibiotics that have a broad aerobic and anaerobic spectrum of activity. Daily lavage of any cavitary wounds, débridement, and removal of feed material may be necessary to prevent additional abscess formation and hasten healing.

Custom topical preparations, usually containing an antibiotic, an antiinflammatory drug, and a hygroscopic agent (glycerin) or DMSO, are often used for palliation of clinical signs, especially in horses with PLH. These preparations are usually administered two or three times daily and sprayed onto the pharyngeal surface through a transnasal catheter. Despite frequent use, the efficacy of this therapy is unknown and response may reflect natural resolution of the predisposing cause.

Treatment of PLH is empirical and generally palliative. Rest from training for 4 to 8 weeks is commonly recommended, and although some horses have recurrence when training resumes, this enforced rest is beneficial as convalescence for any concurrent subclinical respiratory disease. Horses kept in training are often initially treated empirically with sulfa compounds and topical throat preparations. With continued clinical signs, penicillin or broad-spectrum antibiotics are often administered. If PLH does not improve or resolve after therapy, pharyngeal cautery may be used. Techniques for pharyngeal cautery include topical application of trichloroacetic acid, electrocautery, freezing with liquid nitrogen or Freon, and photoablation by neodymium:yttrium aluminum garnet (Nd:YAG) laser with either a contact or a noncontact technique.[20] Although cauterization techniques have received considerable testimonial support, it is likely that cautery does not effect a cure but simply obliterates reactive tissue so that it is no longer clinically evident.

Routine immunization at frequent intervals for known viral respiratory pathogens is also recommended for treatment and prevention of PLH.[21]

Prevention and Control Methods used to control and prevent most of the common viral and bacterial respiratory diseases (see Chapter 48 for vaccines) should limit herd problems with acute pharyngitis. Non–respiratory disease-related causes such as trauma from balling guns, nasogastric tubes and dose syringes, foreign objects, and chemical burns can be minimized by improved husbandry practices.

Prevention of PLH in horses by prophylactic immunization against common equine viral respiratory agents at regular intervals has been discussed at length, but there is no evidence to support this practice. Nevertheless, racetrack veterinarians maintain that frequent immunization (60-day intervals) against influenza and rhinopneumonitis markedly reduces the severity of PLH and improves exercise tolerance.[21] Considering the mobility of racing and show horse populations, this approach should at least be beneficial for limiting outbreaks of viral respiratory disease and consequently perhaps limiting chronic PLH. Until more is understood about the clinical appearance of the pharyngeal tonsil in horses, along with normal variations that occur with aging in exercised and nonexercised horses, and these findings can be correlated with immunopathologic events and indices of performance, it will remain difficult to treat, control, and prevent pharyngitis in a systematic manner.

Guttural Pouch Diseases

John R. Pascoe

Definition and Etiology The guttural pouches are paired air-filled diverticula of the eustachian tubes that communicate between the middle ear and the pharynx. They are located ventral to the atlas, dorsocaudal to the pharynx, and rostrodorsal to the retropharyngeal lymph nodes and occupy a large part of the retropharyngeal space. Each pouch is divided into medial and lateral compartments by a stylohyoid bone that courses through the caudolateral aspect of each pouch. The medial compartments appose each other on the midline. The lateral walls of each guttural pouch contain cranial nerves VII (facial), IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal); the cranial sympathetic trunk; the internal carotid artery; and branches of the external carotid artery.[1] The intimate relationship of these vessels and nerves with the mucous membrane lining the guttural pouches explains why epistaxis and nerve dysfunction frequently accompany guttural pouch disease. Each pouch has a capacity of approximately 300 mL, with the medial compartment accounting for approximately two thirds of this volume. Communication with the pharynx occurs through a slitlike opening situated rostral and ventral to the pharyngeal recess. The pharyngeal opening of the guttural pouch is funnel shaped and wider rostrally than caudally. The plica salpingopharyngea is a fold of mucous membrane that contributes to the caudal narrowing of the pharyngeal opening and makes catheterization of the guttural pouch difficult. Redundancy of this fold of tissue may contribute to guttural pouch tympany.[1]

The guttural pouch is lined with pseudostratified ciliated epithelium containing goblet cells.[2] As an extension of the pharynx, the guttural pouches are not a sterile environment. In 30 normal horses, 59% of percutaneous guttural pouch lavage aspirates had bacterial growth, although only 7% were considered to have bacteria considered to be pathogenic; no fungi were isolated.[3] Inflammatory cell counts and distribution were correlated with recovery of bacteria. Aspirates were considered normal if they contained less than 5% neutrophils; typical cell distribution was primarily ciliated columnar epithelial cells, a few nonciliated cuboidal epithelial cells, and less than 1% monocytes, lymphocytes, and macrophages.[3] Horses exercised strenuously on a regular basis had lower total cell counts, lower neutrophil counts, and fewer bacteria isolated.[3] Preventing horses from head lowering for 12 to 24 hours increases the frequency of bacterial isolation, especially at 24 hours, including an increase in neutrophil counts, and likely indicates reduced ability to clear guttural pouch secretions.[4] Interpretation of microbial isolates from guttural pouches requires correlation with cytologic characteristics of guttural pouch fluid and clinical signs.[5]

Three disease conditions commonly affect the guttural pouches: tympanitis, empyema, and mycosis. Less common conditions include neoplasia,[6] fractures of the hyoid bone, foreign bodies,[1] and cystic structures.[7]

Guttural Pouch Tympany

Tympany of the guttural pouch occurs infrequently and is recognized in foals after birth up to 1.5 years of age[8-10]; affected foals are usually identified within the first 2 weeks of life. Fillies are more commonly affected, with the ratio of females to males ranging from 2:1 to 4:1. Familial and complex inheritance of guttural pouch tympany occurs in Arabian horses and German warmblood horses and sex-specific quantitative trait loci have been identified.[11-13]

Tympany is characterized by unilateral or bilateral distention of the guttural pouch with air. The exact cause is unknown, but congenital redundancy of the plica salpingopharyngea has been suggested. This mucosal fold acts as a one-way valve apparently permitting airflow into but not out of the pouch. Upper airway infection or inflammation has been postulated to result in neuromuscular dysfunction of the plica or enlargement contributing to air trapping.

VetBooks.ir

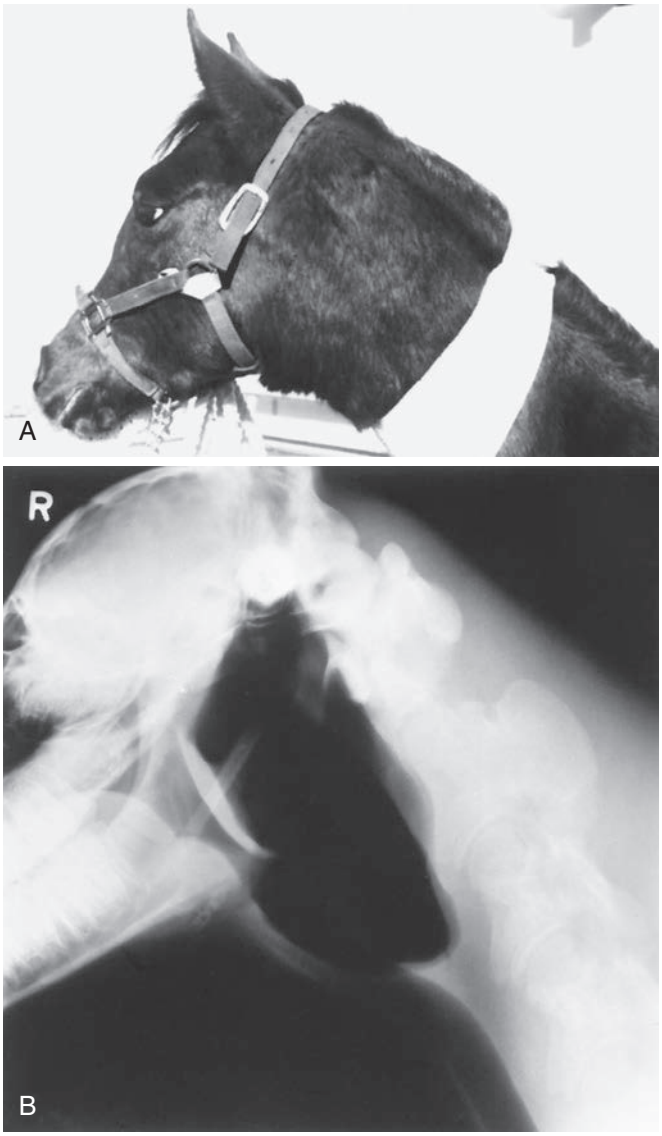

FIG. 31-50 **A,** Foal with guttural pouch tympanitis. Note the protrusion of the soft tissues over the lateral and ventral aspects of the throatlatch. **B,** Lateral radiograph of a foal with tympanitis of both guttural pouches.

Clinical Signs and Differential Diagnosis Affected foals usually have a nonpainful, soft, fluctuant swelling in the retropharyngeal space (Fig. 31-50, *A*) with variable respiratory distress, extension of the head and neck, nasal discharge, signs of dysphagia, and possible development of aspiration pneumonia.[8,9] Guttural pouch fluid accumulation and empyema can occur. Mild tympany may not result in signs other than swelling of the throatlatch (retropharyngeal) region. Respiratory distress occurs when continued distention of the pouch compresses the pharyngeal area. The differential diagnosis for throat latch regional swelling should include guttural pouch empyema and retropharyngeal abscesses or cellulitis.

Clinical Pathology Stress leukocytosis may occur if there is marked respiratory distress.

Diagnostic Aids Diagnosis of guttural pouch tympany is based on recognition of characteristic swelling in the retropharyngeal space and confirmation by physical examination. Although the distention is most often unilateral, extreme distortion of a single pouch may give the impression of bilateral involvement. Differentiation between unilateral and bilateral involvement can be difficult and may require deflation of the affected guttural pouch by catheterization or percutaneous needle aspiration combined with external compression. Other adjunctive diagnostic procedures include radiographic demonstration of gas distention of one or both pouches (see Fig. 31-50, *B*) and endoscopic observation of pouch distention and pharyngeal distortion.

Treatment and Prognosis Guttural pouch tympany and respiratory distress can be alleviated temporarily by aspiration of air from the affected pouch by means of either percutaneous decompression at the point of greatest distention through Viborg triangle or introduction of a catheter through the pharyngeal opening of the guttural pouch. These measures are palliative, and the pouch rapidly refills when decompression is discontinued. Treatment methods of choice include surgical excision of the plica salpingopharyngea and part of the medial lamina of the eustachian tube, partial resection of the plica, or photoablation of the plica; fenestration of the median septum between the two pouches by excision, electrosurgery, or photoablation; and creation of a salpingopharyngeal fistula by photoablation and temporary stenting of the fistula.[8-10,14-17] The latter technique is similar to an older, successful approach that involved incising the floor of the guttural pouch into the pharynx.[18] If the condition is bilateral, fenestration of the median septum alone does not successfully resolve the condition, and excision of one or both plica salpingopharyngea, in combination with septal fenestration or septal fenestration and salpingopharyngeal fistula formation, must be performed. After surgery the prognosis for resolution of guttural pouch tympany is generally considered favorable[10] unless complicating factors such as aspiration pneumonia exist.[9] Early recurrence after surgery can range from 15% to 30%, but further resection of the plica salpingopharyngea or refenestration of the mesial septum or enlargement of the fenestration typically results in resolution of signs.[9,10]

Guttural Pouch Empyema

Guttural pouch infections are introduced either directly through the pharyngeal opening or by lymphatic spread. Accumulation of purulent material (empyema) is considered to be a secondary, chronic, localized manifestation of a more generalized ascending respiratory infection. Empyema is usually unilateral and is often a sequela to an infectious respiratory disease, especially infection by *S. equi* subsp. *equi*.[19-21] Typically a horse with guttural pouch empyema displays continued nasal discharge after recovery from streptococcal infection.[21] In a case control study of foals with lower respiratory tract infection, 21% had concurrent mucopurulent drainage from the pharyngeal openings of the guttural pouches.[22] *S. equi* subsp. *zooepidemicus* was isolated from respiratory secretions of most infected foals and from exudate collected from guttural pouches.[23] Rupture of retropharyngeal abscesses into the guttural pouch has also been associated with empyema, suggesting that strangles or other upper respiratory tract infections may have an important role in the development of guttural pouch infection in horses.[19]

Clinical Signs and Differential Diagnosis Clinical signs include intermittent nasal discharge that may worsen when the head is lowered, retropharyngeal swelling, cough, fever, parotid swelling and pain, dysphagia, difficult breathing, dysphagia, and pneumonia.[24] Nasal discharge can be unilateral or bilateral, even if only one pouch is affected, because the pharyngeal openings of the guttural pouches are located caudal to the nasal septum. Nasal discharge is generally nonodorous, white, and opaque. Signs of dysphagia may be observed secondary to pharyngeal compression or paresis. Labored breathing may result from gradual collapse of the pharynx as the guttural pouch distends. Inspissation of the purulent material results in chondroids (hard concretions of inspissated pus). Differential diagnosis of guttural pouch empyema should include diseases with chronic mucopurulent nasal discharge such as pneumonia, sinusitis, upper respiratory tract infections, and guttural pouch tympany.

VetBooks.ir

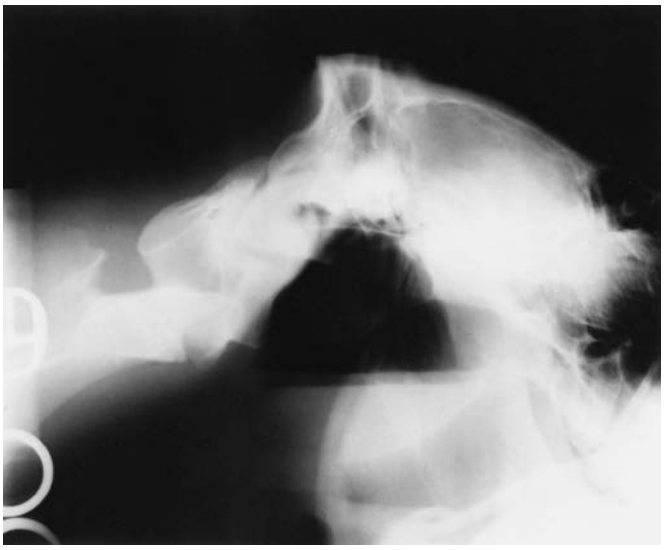

FIG. 31-51 Lateral radiograph demonstrating distinct fluid lines in both guttural pouches.

Clinical Pathology Leukocytosis is often present. Plasma fibrinogen levels are often increased,[24] and these changes generally parallel development of leukocytosis, pyrexia, and clinical signs of strangles or primary guttural pouch empyema. Analysis of fluid obtained by catheterization of the guttural pouch often yields a β-hemolytic *Streptococcus* spp.,[19] although other bacterial species have been isolated.[24]

Diagnostic Aids Guttural pouch empyema should be considered when there is a chronic, nonresponsive nasal discharge. Diagnostic aids include radiography, endoscopy, percutaneous centesis, and aspiration of material from the pouch through the pharyngeal opening. Recognition of fluid (Fig. 31-51) or radiodense masses (chondroids) within the pouch on standing lateral radiographs supports a diagnosis of empyema. Physical and endoscopic examination or oblique radiographic projections may be needed to identify which pouch is involved. Endoscopic examination permits identification of the affected pouch and evaluation of the character of the fluid. Endoscopic examination of the lateral compartment is important to avoid missing sequestered fluid or chondroids.[25] Absence of fluid at the pharyngeal ostium does not preclude the possibility of guttural pouch empyema, if the fluid is inspissated or the ostium is sealed.[26] Fluid identified on radiographs should be characterized by endoscopic examination of the pouches or aspiration of the fluid with cytologic and microbial analysis. Fluid samples can be aspirated through the pharyngeal ostium using a sterile artificial insemination pipette, a Chambers catheter, or tubing advanced through the biopsy channel of an endoscope. Alternately, fluid can be aspirated percutaneously, but this may lead to cellulitis along the needle tract if pathogenic bacteria are tracked through tissues on needle withdrawal.

Pathophysiology Strangles is a common upper respiratory tract disease affecting young horses. Primary clinical signs of strangles usually develop after a short incubation period of 2 to 6 days and include depression, pyrexia, coughing, and ocular and nasal discharges that become mucopurulent as the disease progresses. Lymph nodes of the head and neck become enlarged and painful and often form abscesses. Guttural pouch empyema may result from extension of the upper respiratory tract infection with *S. equi* (strangles) to the guttural pouches or from rupture of retropharyngeal lymph node abscesses into the guttural pouch.[19] Commonly isolated bacteria from guttural pouch empyema include *S. equi, S. zooepidemicus, E. coli,* and *Klebsiella* spp.[24] Not all horses with empyema have a history of strangles or previous respiratory infection, and empyema seemingly can occur by many of the same mechanisms as middle ear infection: that is, fluid accumulates in the area, and uncontrolled growth of bacteria normally present results in inflammation and exudation. Most streptococcal isolates are resistant to potentiated sulfonamides and sulfadimethoxine.[24]

Treatment and Prognosis Treatment of guttural pouch empyema is complicated by poor drainage from the affected pouch. The pharyngeal opening of the guttural pouch is located rostrodorsal to the floor of the guttural pouch, and drainage can be achieved only by lowering the horse's head. In horses with empyema, lowering the head may not achieve adequate drainage if there is ventral distortion of the pouch. Inflammation of the lining mucosa may result in swelling of the tissue surrounding the pharyngeal opening, further compromising normal drainage.

Choice of medical or surgical treatment depends on the duration and nature of the empyema and the presence of chondroids. Parenteral antimicrobial therapy may reduce the quantity of the nasal discharge, but relapse often occurs after cessation of treatment.[24] The early stages of empyema may respond to daily lavage of the affected guttural pouch. Because of the thin nature of the mucosal lining and the proximity of cranial nerves VII and IX-XII and the cranial sympathetic trunk, it is important to use physiologic solutions, saline antibiotic solutions, or nonirritating solutions to avoid neural inflammation or neuritis. Large volumes have caused guttural pouch rupture. Typically, 500 mL should be flushed into the pouch under moderate pressure to create contact with as much of the interior of the guttural pouch as possible. During lavage the head should be lowered to prevent aspiration of fluid. Purulent fluid from the affected guttural pouch should be aspirated on initial catheterization and submitted for bacterial culture and antimicrobial susceptibility testing. This can be accomplished with most flexible uterine culturettes under direct endoscopic observation. Parenteral antimicrobial drugs should be administered on the basis of susceptibility testing results; although medication may be of benefit in treating empyema, adequate drainage and local therapy are of primary therapeutic importance.

Indwelling catheters in normal guttural pouches have caused increasing purulent discharge with time; nasal discharge diminished after catheter removal and was absent after 3 days. Although indwelling catheters are convenient, daily catheterization and irrigation with an artificial insemination pipette or Chambers catheter should be considered to diminish the inflammatory response associated with indwelling catheters in an already inflamed guttural pouch. However, consideration of daily catheterization must be weighed against stress, possible tissue trauma, and time requirements for intermittent catheterization.

Treatment with parenteral antimicrobials and local lavage is successful and requires a patent opening for adequate drainage, but the course of treatment may be protracted. Povidone iodine (1% available iodine) diluted to a 10% solution (0.1% available iodine) for lavage of the guttural pouch caused considerable reaction, including inflammatory infiltrates, hemorrhage, necrosis, and lymphoid reaction.[27] Likewise, antimicrobial concentrations of chlorhexidine gluconate are not recommended.[28] Although acetylcysteine, a mucolytic, was used successfully to resolve inspissated empyema,[29] subsequent reports have shown lack of efficacy and concern for added mucosal inflammation.[30] If response to lavage is poor or if secretions reaccumulate and empyema returns, surgical drainage of the guttural pouch should be considered.

Surgery is generally indicated when purulent material becomes inspissated or chondroids have formed,[31] although resolution has been reported in one horse after prolonged lavage (14 days) through an indwelling catheter.[32] Surgical approaches include percutaneous drainage through standard approaches to the guttural pouches in anesthetized recumbent or standing sedated horses and creation of a nasopharyngeal fistula by use of an Nd:YAG laser.[33] Other approaches when chondroids are present include removal by retrieval snares passed endoscopically, standing removal through a modified Whitehouse approach,[34] and removal from the contralateral pouch after

VetBooks.ir

fenestration of the mesial septum when the ipsilateral ostium is closed.[26]

The prognosis for guttural pouch empyema is generally favorable if it is recognized promptly and treated appropriately.[24] Likewise, removal of chondroids typically carries a good prognosis.[24]

Guttural Pouch Mycosis

Guttural pouch mycosis is a fungal disease of the guttural pouch that typically affects the dorsocaudal region of the medial compartment, although lesions affecting larger areas, including the lateral compartment, occur.[35-37] Fungal invasion of neurovascular structures coursing through the walls of the guttural pouches results in clinically apparent disease. The exact cause is unknown, although a number of fungi, especially *Aspergillus (Emericella) nidulans* and *Aspergillus fumigatus,* have been isolated from lesions.[37-41]

Clinical Signs and Differential Diagnosis Lesions are usually unilateral but can occur bilaterally. The wide spectrum of clinical signs that can occur with guttural pouch mycosis reflects the degree of fungal invasion and subsequent inflammation of vascular structures or nerves beneath the lining mucous membrane of the guttural pouch; however, the size of the lesion apparently is not correlated with the severity of clinical signs. Intermittent spontaneous epistaxis and dysphagia are the common clinical signs that stimulate owners to seek veterinary care; however, the earliest clinical sign in most affected horses is nasal discharge (serous to mucopurulent).[42] Epistaxis generally results from fungal erosion of the wall of the internal carotid artery in the roof of the medial compartment and, less commonly, from erosion of the external carotid artery (or its branches, e.g., caudal auricular artery) and maxillary artery in the lateral compartment. Epistaxis is usually unilateral from the ipsilateral nostril, but it can be bilateral because the pharyngeal openings of the guttural pouches are located caudal to the caudal border of the nasal septum.[36] Episodes of epistaxis typically occur at rest and vary from mild to severe, with several premonitory bleeds that generally culminate in a fatal episode of epistaxis.[36,37] Occasionally a horse dies of a single episode of epistaxis without previous clinical signs. Epistaxis may recur at intervals varying from 24 hours to 3 weeks.[36]

Dysphagia, the second most common clinical sign, likely results from damage to the pharyngeal branches of the vagus and glossopharyngeal nerves and generally occurs later than epistaxis in the course of the disease.[36] Horses with dysphagia cough during attempts to eat solid food, and, in addition to food material in the nasal discharge, a considerable quantity of food is coughed out the mouth. Recovery from dysphagia may occur,[36] but in general the prognosis for full recovery is poor.

Other clinical signs include parotid pain, abnormal head posture, unilateral or bilateral nasal discharge, head shyness, abnormal respiratory noise from pharyngeal paralysis or laryngeal hemiplegia, sweating and shivering, Horner syndrome, visual disturbances, colic, and facial paralysis.[36,37] These signs are the result of angina and dysfunction of cranial nerves and the sympathetic nervous system.

The differential diagnosis for a horse with epistaxis should include EIPH, ethmoid hematoma, guttural pouch or pharyngeal neoplasia, tracheobronchial foreign bodies, and guttural pouch mycosis.[36] Differentiation of these diseases is aided by a thorough history and endoscopic examination. Differential diagnosis for dysphagia should include fractures of the hyoid apparatus; pharyngeal and guttural pouch fistula; cleft palate; esophagitis; pharyngeal paralysis; foreign body entrapment in the mouth or esophagus; pharyngeal neoplasia; lead poisoning; bacterial, viral, and mycotic central nervous system infections; and guttural pouch mycosis.[36]

Clinical Pathology If epistaxis is the presenting complaint, moderate to severe anemia with accompanying hypoproteinemia may also be present. Differential white cell distributions may be normal or may indicate a stress response. If dysphagia becomes a dominant clinical sign, other hematologic changes indicative of infection secondary to aspiration pneumonia may be evident.

Diagnostic Aids Clinical signs of epistaxis or cranial nerve dysfunction are suggestive of a diagnosis of guttural pouch mycosis. A thorough physical examination may reveal abnormal sensitivity on digital palpation of the parotid area on the affected side.[35] A definitive diagnosis of guttural pouch mycosis requires endoscopic observation of the characteristic diphtheritic lesion in the dorsocaudal aspect of the medial compartment, typically covering over the temporohyoid joint and internal carotid artery, or elsewhere within the guttural pouch.[36] Aneurysm of the internal carotid artery is rarely present. A healed lesion may be identified by presence of scar tissue within the mucous membrane.[36] Lesions vary in color (brown, yellow, black, or white) and size (from discrete nodules to diffuse irregular patches covering the roof of both the medial and lateral compartments)[37]; erosion with fistula formation can occur into the opposite guttural pouch or pharynx. Occasionally the characteristic lesion is obscured by clotted blood, so that the diagnosis is based on the clinical signs of epistaxis correlated with blood present in the guttural pouch. Because hemorrhage may originate from the internal carotid, external carotid, or maxillary arteries, it is important to identify the source of bleeding before therapy, particularly if surgical intervention is being considered. Care should be taken not to dislodge a thrombus and produce further hemorrhage. If dysphagia is apparent, food and saliva may be identified during endoscopy of the pharynx and nasal passages.

In guttural pouch mycotic infections, radiographs are of limited value because only minimum suppuration is associated with mycotic infections; however, a lateral projection may allow assessment of the degree of fibrous reaction and loss of normal air space. Radiography may also aid in diagnosing some of the long-term sequelae, such as fibrous deposits in the pouch and associated bony changes.

Serum titers to *A. fumigatus* are not diagnostic; however, reactivity to 22-kd and 26-kd serum antigens measured by immunoblot analysis may be diagnostic for guttural pouch mycosis.[39]

Pathophysiology The pathogenesis and predisposing factors leading to guttural pouch mycosis and arterial erosion are unknown, but it is believed that the disease is initiated by some stress (inflammation, trauma, vascular insult) to the soft tissues where the mycotic plaques are generally found.[37] Aneurysm formation is not well correlated with the severity of the plaque formation. Although the nature of the initiating lesion remains unclear, it is generally agreed that the later stages are associated with deep fungal infections.[37] *A. nidulans* and other *Aspergillus* spp. have been isolated and may be the causative agents[37-41]; *A. nidulans* is rarely pathogenic but may grow as an opportunist in the warm humid environment of the guttural pouch.[37] The mycotic lesions show no predilection for either the right or the left guttural pouch.[36] Fungal infection of the pouch, erosion of major blood vessels, and involvement of nerves (IX, X, XI, XII, cranial cervical ganglion, and postganglionic sympathetic fibers) that traverse the area explain the epistaxis, local pain, and neurologic signs associated with guttural pouch mycosis.[36,37]

Epidemiology No apparent age, sex, breed, or geographic predispositions have been observed. Guttural pouch mycosis is a sporadic disease that tends to arise during the warmer months of the year and rarely affects more than one horse in a particular stable.[36] Affected horses are afebrile; infection is diagnosed when clinical signs such as epistaxis and dysphagia occur, although nasal discharge is often the earliest reported sign.[36]

Necropsy Findings Lesions are confined to the pharyngeal muscles, guttural pouch, and bones of the skull.[35] Gross findings may include large blood clots in the nasal passages and at the pharyngeal opening of the guttural pouch. Unilateral denervation atrophy of the ipsilateral pharyngeal or laryngeal muscles may occur if there is involvement of the pharyngeal and recurrent laryngeal branches of

VetBooks.ir

the vagus nerve.[35] Examination of the guttural pouch generally reveals clotted blood and a diphtheritic plaque in the dorsocaudal aspect of the medial compartment that is firmly adherent to the underlying tissue and is clearly demarcated from surrounding tissue.[37] The lesion may be localized or may affect the entire roof of the pouch. If hemorrhage has occurred, the lesion may be obscured by clotted blood, pus, or mucus.[37] An intense inflammatory reaction may be evident in response to acute fungal infection, whereas the inflammation may subside with chronic healing lesions so that scar tissue is evident.[37] Active inflammation may also predispose to osseous lesions of the petrous temporal and stylohyoid bones.[35,37] Some cases of guttural pouch mycosis may not have associated clinical signs and may only be diagnosed on necropsy.[36]

Treatment and Prognosis Without treatment a poor prognosis is warranted, because affected horses are at risk for a fatal episode of epistaxis. Both medical and surgical treatments have been recommended, with variable results; however, surgical treatment by an intraarterial occlusion technique is generally considered to yield the best prognosis.[43-45] Spontaneous regression of guttural pouch mycosis can occur and must be considered when the various medical or surgical treatments are being evaluated.[36]

Medical treatment is topical therapy of the mycotic lesion through the pharyngeal opening of the guttural pouch by means of a catheter. Bathing the lesion may be facilitated by anesthetizing the horse and positioning it in dorsal recumbency. Instilling fungicidal and fungistatic drugs, topical enzymes, and organic iodine compounds into the guttural pouch has been attempted with variable success.[46,47] The necessity and efficacy of these treatments are unknown, and systematic treatment is hampered by a lack of knowledge of the pathogenesis of guttural pouch mycosis.[48] Parenteral administration of antibiotics, corticosteroids, thiabendazole, ketoconazole, and iodine compounds also has questionable efficacy.[48] The response of guttural pouch mycosis to local and parenteral treatment is protracted; thus the risk of fatal hemorrhage exists long after initiating treatment.[49,50]

Surgical treatment of guttural pouch mycosis appears to offer the best prognosis for eventual cure. The internal carotid artery is not an end artery, and blood can enter this vessel from the bifurcation of the common carotid or return from the cerebral arterial circle. Various surgical techniques have been described,[1] and use of a balloon-tipped catheter inserted into the distal internal carotid artery combined with proximal ligation of the internal carotid artery,[49-51] transarterial coil embolization,[44,52,53] or transarterial nitinol vascular plugs[54] induces thrombus formation and prevents hemorrhage from normal and retrograde blood flow. Thrombosis sufficient to prevent hemorrhage may develop in the distal internal carotid artery within 10 days of catheter placement.[51] Mucosal healing and complete regression of the fungal plaque have been reported to occur as early as 5 weeks after arterial catheterization[49] and as early as 15 days after coil embolization.[44] Insertion of a balloon-tipped catheter successfully prevented fatal epistaxis in 13 horses.[49] Topical or systemic treatment of the mycotic plaque is considered unnecessary after arterial catheterization.[49] Intraarterial insertion of latex balloons, embolization coils, or nitinol vascular plugs also results in lesion resolution,[54-57] although progression of a mycotic plaque after coil embolization and subsequent development of neurologic signs have been reported.[58] Complications associated with each of these arterial occlusion techniques have been reported.[59]

Diseases of the Paranasal Sinuses

Sinusitis

John R. Pascoe

Definition and Etiology *Sinusitis,* inflammation of the paranasal sinuses, results from primary microbial infection or from secondary bacterial infection associated with dental or other sinus disease. Lined by respiratory mucosa, the paranasal sinuses are at risk for developing diseases affecting the respiratory tract. Sinus empyema, accumulation of pus within a sinus cavity, may result from bacterial or viral infection.

Incidence of sinusitis is relatively low, likely less than 0.5% of disease in equine practice.[1] In two longitudinal retrospective studies, covering 25 years, of 477 horses referred with sinonasal disease, the distribution of causes was primary sinusitis (subacute or chronic; 33%), dental-associated sinusitis (21%), sinus cysts (13%), sinonasal neoplasia (7%), ethmoid hematoma (6%), sinonasal trauma (6%), mycotic lesions (4%), dental-related oromaxillary fistula (3%), and miscellaneous causes (6%).[2,3] The caudal maxillary, rostral maxillary, ventral conchal, and conchofrontal sinuses are more commonly involved, and the sphenopalatine sinus is affected less often.[4] The median age of horses affected with sinonasal disease is 7 to 11 years.[2]

Acute or chronic upper respiratory tract infections of viral or bacterial origin can result in primary sinusitis; *Streptococcus* spp. infection is the most common. Maxillary sinusitis caused by disease of the third (caudal roots) through sixth cheek teeth (modified Triadian numbers 109 to 111, 209 to 211) often results from alveolar periostitis, patent infundibula, fractured or split teeth, or deep diastemata between caudal maxillary teeth. Dental defects can permit access of food material or bacteria to the tooth root and sinus cavity, with extension to the frontal sinus likely through the frontomaxillary opening. Reported neoplasms include osteoma, osteosarcoma, adenocarcinoma, lymphosarcoma, squamous cell carcinoma, neuroendocrine tumors/neuroblastoma, fibroma, and chondrosarcoma.[5-7]

Clinical Signs and Differential Diagnosis Signs vary depending on cause, location, and extent of sinus involvement, with unilateral nasal discharge (serous, mucoid, mucopurulent, purulent) being the most frequent sign.[2,3] Physical examination of a horse with sinusitis should include observation for epiphora, facial asymmetry, altered nasal airflow, abnormal breath odor, mandibular lymphadenopathy, and sinocutaneous fistula.

Nasal discharge is typically unilateral because the nasomaxillary opening is located rostral to the caudal edge of the nasal septum. Intermittent or continuous nasal discharge need not be related to a previous upper respiratory tract infection. Although malodorous discharge is commonly associated with dental sinusitis and sinonasal mycosis, it has been reported to occur in 14% to 27% of primary sinusitis cases.[2,3] Mucopurulent discharge is more commonly associated with sinus cysts.[2] Sanguineous discharge is common with ethmoid hematoma and sinonasal trauma; however, guttural pouch mycosis, pulmonary hemorrhage, nasal turbinate necrosis, and neoplastic or granulomatous lesions should also be considered. Other differential diagnoses of nasal discharge should include guttural pouch empyema or mycosis, acute pharyngitis (strangles, rhinopneumonitis, influenza, trauma), neoplasia or necrosis of the turbinates, ethmoid hematoma, and pulmonary disease.

After nasal discharge, submandibular lymphadenopathy is the most common sign, particularly when microbial infection is a component of sinusitis.[3] Facial swelling occurs with frequency similar to that of lymphadenopathy, typically when sinus drainage is obstructed, there is an expansile mass within the sinus, or as an acute sign after facial trauma. Occasionally exophthalmos can occur with marked sinus distortion.

Patency of the nasomaxillary opening generally precludes facial distortion. Loss of patency occurs when inspissated exudate accumulates or mucosal lining tissue reaction obstructs the opening. Expansion of the sinus may result in reduced ipsilateral nasal airflow caused by distortion of the architecture of the nasal passages. In these cases abnormal respiratory noise rather than nasal discharge may be the primary presenting sign.

Epiphora occurs if there is nasolacrimal duct involvement from trauma, compression, or destruction of the duct from underlying sinus disease. Approximately 20% to 50% of horses with dental sinusitis, sinus cyst, or sinonasal trauma have epiphora as a presenting sign.[2,3]

VetBooks.ir

Percussion of the affected sinus may reveal dullness or pain, although normal resonance does not preclude the possibility of sinusitis. If there is bone thinning over gas above a fluid line (as can occur with some maxillary sinus cysts), percussion may elicit increased resonance.

Careful examination of the oral cavity for signs of dental or periodontal disease should be performed when any of these signs are present. Particular attention should be paid to examination of the occlusal surface of the teeth with a very fine dental pick (e.g., 22-gauge needle); however, it should be recognized that periapical abscess formation can occur without defects in the occlusal surface. Accuracy of diagnosis of dental disease is substantially enhanced by use of intraoral endoscopy and computed tomography.

Clinical Pathology The hemogram generally remains within the normal range, although acute sinusitis of infectious origin may be associated with neutrophilia. With chronic sinusitis there may be concurrent hyperfibrinogenemia. Sinus fluid obtained by percutaneous centesis should be examined cytologically (including a Gram stain) and submitted for microbial culture and susceptibility testing to differentiate among bacterial, fungal, and neoplastic disease. Flecks of feed material indicate sinusitis secondary to dental abnormalities.

Laboratory Aids and Definitive Diagnostic Tests A presumptive diagnosis of sinusitis can be made from the physical examination and associated clinical signs.[2,3,8] Procedures most helpful in establishing a diagnosis are sinonasal endoscopy, oral cavity examination, imaging (radiography, computed tomography [CT], scintigraphy, magnetic resonance imaging [MRI]), sinus centesis, and sinoscopy.[4,8]

Nasal cavity endoscopy may permit identification of exudate draining from the nasomaxillary opening or, in advanced cases, may reveal distortion of the nasal cavity secondary to sinus enlargement. Middle meatus examination is an important component of endoscopic examination. Diagnosis beyond recognition of the potential source of the nasal discharge is limited unless an obvious mass or abnormal tissue is observed. Sinoscopy can be accomplished by using an arthroscope[9] or flexible endoscope[10] inserted through small trephine holes in either the maxillary or the frontal sinus. Examination of the rostral compartment of the maxillary sinus requires a separate portal unless the bony septum between the rostral and caudal compartments has been destroyed. Observation may be limited by fluid or tissue, especially in the rostral compartment of the maxillary sinus, but can potentially be enhanced after sinus lavage and aspiration. Alternately, fenestration of the ventral conchal bulla can be used to facilitate endoscopy of the rostral compartment of the maxillary sinus.[4]

Standard radiographic projections include standing lateral, dorsoventral, and right and left oblique views.[11,12] Radiographic findings include fluid lines within the sinus, space-occupying soft-tissue densities, areas of decreased bone density, fractures, or dental abnormalities. Dental root disease is identified radiographically by a loss of continuity of the lamina dura and lysis of the tooth root or surrounding bone, combined with new bone formation and cement deposition.[11] Anatomy of normal equine skulls as demonstrated by CT and MRI has been described.[13-15] Diagnostic accuracy, especially determination of the extent of involvement of structures within the skull, can be enhanced by CT.[16,17] MRI may be useful in some sinonasal disorders.[18]

Findings associated with dental caries include hypoattenuation of cementum, destruction of enamel, and filling of the infundibular cavity with gas, whereas with dental decay there is gas accumulation in the root area or fragmentation of the root, and sinus mucosal thickening. Additional changes with sinusitis typically involve the maxilla with endosteal sclerosis, thickening, periosteal reaction, and deformation, especially involving the facial crest.[17] Scintigraphic examination may improve specificity in identification of dental involvement in sinusitis.[19]

Percutaneous sinus centesis may provide a definitive diagnosis and allow an avenue for subsequent therapy. Cytologic evaluation, with concurrent microbial culture and antibiotic susceptibility testing, may elucidate the cause of the sinusitis. Isolation of a single organism such as *Streptococcus* spp. generally indicates a primary sinusitis, whereas polymicrobial infection is more compatible with sinusitis of dental origin. Visual examination of the oral cavity, especially intraoral endoscopy, and careful probing of the occlusal surfaces with a dental pick may help practitioners identify dental abnormalities.

Necropsy Findings Affected sinuses contain fluid or tissue of variable color and consistency. Fluid character ranges from clear and odorless with cystic sinus disease to white, yellow, or green purulent fluid with a variable, but often putrid, odor in sinusitis resulting from other causes. Sinusitis of dental origin has a characteristically pungent and unpleasant odor. Granulomatous lesions often appear as large lobular gelatinous masses filling the sinus cavity. The gross appearance of neoplastic lesions within the sinus cavity depends on the type of neoplasm. Neoplasia may cause surrounding soft-tissue and bony destruction, whereas large, benign space-occupying lesions may result in distortion of the nasal turbinates and nasal septum, as well as external facial bone distortion.

Treatment and Prognosis Not infrequently, horses with a chronic mucopurulent nasal discharge from sinusitis have a history of response to antimicrobial therapy, followed by recurrence of the discharge after antibiotic therapy ceases. Definitive diagnosis of sinusitis can be accomplished using the techniques described earlier. Sinoscopy permits examination of the paranasal sinuses and, in some instances, facilitates treatment.[20-22]

Suggested treatment for primary sinusitis or empyema involves daily lavage of the sinus through a percutaneous centesis site with 1 L of saline, to which a broad-spectrum antibiotic or antiseptic has been added. Once the results of culture and susceptibility testing are available, the appropriate antibiotic should be administered locally in the flush solution, as well as systemically, for 14 days. Resolution or reduction in the volume of nasal discharge is an indication of successful therapy. Sinus lavage often fails to remove inspissated material, which is often the nidus for continuing sinusitis and must be removed for resolution.[8] If little progress is made after 10 to 14 days of lavage or if drainage recurs, sinusotomy (trephination or bone flap technique, standing or recumbent anesthetized) is recommended to remove inspissated material[22] or identify other causes. The prognosis is generally favorable if primary sinusitis is not chronic and if the mucous membrane is not markedly thickened.[21,22] Chronic sinus disease (longer than 6 months) carries a poor prognosis, and, for resolution to occur, surgical removal of the thickened, infected mucous membrane is required; creation of sinonasal drainage by sinus fenestration is also recommended.

Sinusitis that results from secondary factors is generally not responsive to medical management. Such conditions include diseased teeth, granulomas, or neoplasia; surgical removal of the inciting cause is required, and adjunctive treatment may be required. The prognosis for sinusitis associated with dental abnormalities is usually favorable once the diseased tooth has been removed.[21,22] Complications are lower with oral extraction rather than repulsion of diseased teeth.[22] Generally, failure of oral extraction and subsequent tooth or tooth fragment repulsion results in lower morbidity than initial repulsion.[22] If the periodontal ligament is intact, endodontic therapy can be used to save the tooth. This is accomplished by surgical apicoectomy and retrograde occlusion of the root canal after débridement of the pulp. In geriatric horses with dental-associated sinusitis, when economic constraints limit surgical options, sinusotomy and periodic sinus lavage and antibiotic therapy have been used successfully to manage nasal discharge.

The prognosis for resolution of granulomatous lesions is generally guarded and depends on surgical access and extent of the lesion. Neoplastic lesions are often well established and have metastasized,

VetBooks.ir

either locally or regionally, by the time they become clinically apparent; the prognosis for resolution is generally guarded to poor.[4]

Prevention and Control Prevention of sinusitis in horses is difficult because of the variety of causes. Isolation of horses from those with upper respiratory bacterial or viral diseases may be of benefit in preventing primary sinusitis. Regular dental care and a proper diet may help circumvent sinusitis caused by dental abnormalities, although many cases most likely result from a variety of causes not yet defined or over which the owner or veterinarian has no control.

Ethmoid Hematoma

John R. Pascoe

Definition and Etiology Ethmoid hematomas (*progressive ethmoidal hematoma*[1]; *hemorrhagic nasal polyps*[2]) are slowly expanding angiomatous masses (median dimensions: 3.8 × 9 × 13 cm)[3] originating principally from the mucosal lining of the ethmoid conchae. Smaller hemangiomas arising from the mucosal lining of the frontal, maxillary, and sphenopalatine sinuses have been recognized, but the relationship between these benign endothelial tumors and ethmoid hematoma remains uncertain. Ethmoid hematoma is a relatively uncommon condition of unknown cause. Distinctly different histologic features characterize ethmoid hematoma and paranasal sinus cysts,[4] which makes it unlikely that these lesions are variants of each other with a common cause.[5] Although ethmoid hematomas have been reported in a 4-week-old foal and in 3-year-old horses, most affected horses are older than 8 years and are generally Thoroughbred, Arabian, or warmblood horses[6,7]; males (geldings) seem to be more commonly affected.[3]

Clinical Signs A blood-tinged nasal discharge with intermittent epistaxis from one or both nostrils is the most common clinical sign. Unilateral or bilateral, epistaxis varies from blood-tinged mucoid or mucopurulent discharge to blood spots or a trickle of blood; fulminant or fatal epistaxis is uncommon. If the hematoma occupies the choana(e) or nasal cavity, a mucopurulent, occasionally malodorous nasal discharge with some blood discoloration is more commonly seen. Typically there is a history of abnormal respiratory noise, both inspiratory and expiratory, especially during exercise. With nasal cavity involvement, airflow may be reduced or absent on the affected side. Facial distortion or asymmetry is uncommon and more likely to occur with involvement of the frontal and maxillary sinuses. Secondary mycotic infections and empyema may be associated with intraparanasal sinus ethmoid hematoma.[8] Less commonly there may be an associated history of coughing, choking, ptyalism, increased respiratory effort during resting breathing, and either head shyness or headshaking.[1] If the hematoma has expanded into the paranasal sinuses, percussion yields a dull sound.

Laboratory Aids and Definitive Diagnostic Tests Confirmation requires endoscopy of the ethmoid conchae and diagnostic imaging (Figs. 31-52 and 31-53). Although survey radiography is useful to identify the mass, its origin and extent are delineated more accurately with CT, which is also more reliable than a combination of clinical examination, endoscopy, and conventional radiography.[3] Limited information is available to assess the value of magnetic resonance imaging for diagnosis of ethmoid hematoma.[9] In the absence of CT, sinoscopy may be of diagnostic value when the ethmoid hematoma involves the paranasal sinuses without nasal cavity protrusion. Rarely, ethmoid hematoma infiltrates the nasal conchae; these lesions, identifiable by CT, may be missed on sinoscopy. Definitive localization of ethmoid hematoma involving the sphenopalatine sinus is not likely to be achieved through use of radiography or sinoscopy.[3]

Ethmoid hematomas are bilateral in 30% to 50% of affected horses, so it is prudent to examine both ethmoidal conchae. The

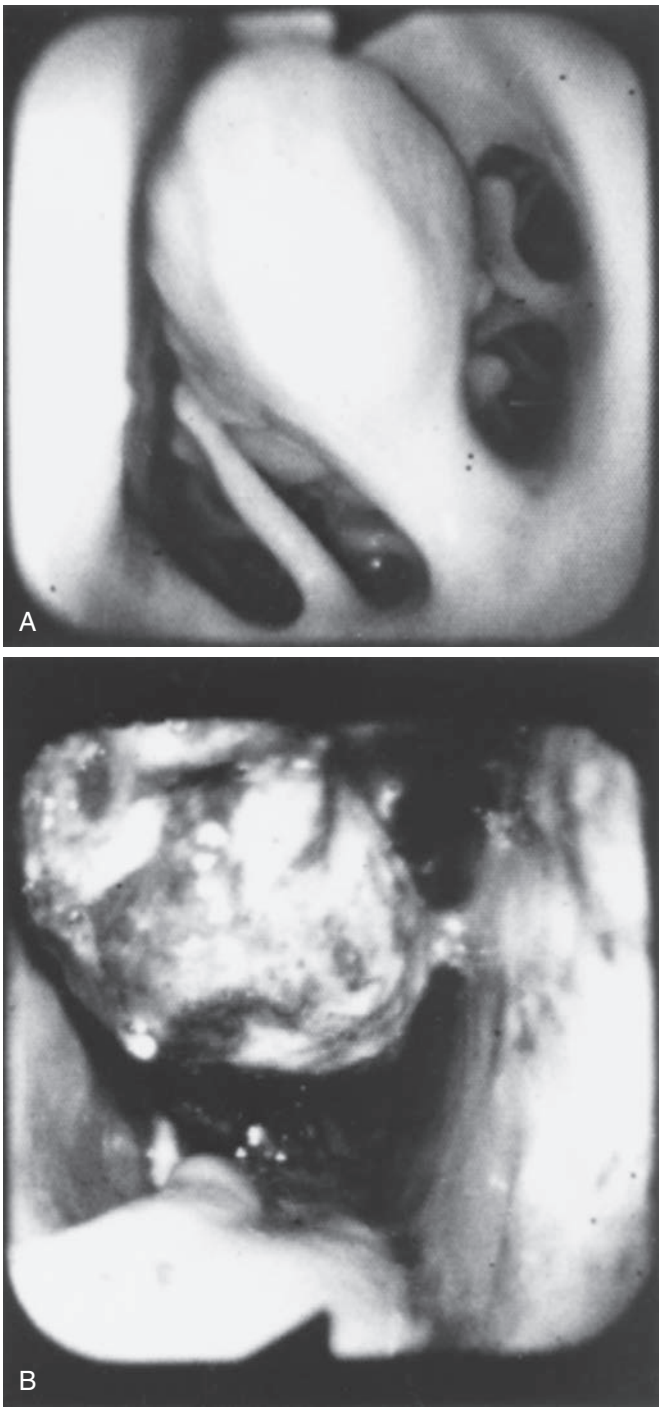

FIG. 31-52 Endoscopic view of left ethmoturbinate. **A,** Normal appearance. **B,** Ethmoturbinate obscured by an ethmoid hematoma.

FIG. 31-53 Lateral radiograph demonstrating an ethmoid hematoma.

VetBooks.ir

ethmoidal labyrinth is visible approximately 25 cm from the nares, with the endoscope positioned in the ventral nasal meatus and the viewing tip deflected dorsally. The rostral surface of the ethmoidal concha does not protrude beyond the caudal aspect of the nasal cavity; it has a bulbous shape and a moist pink to pale red mucosal covering. Distal to the rostral surface are numerous pillars that form the ethmoidal conchae and separate the ethmoidal spaces (cellulae ethmoidales). Ethmoid hematomas that project into the ventral meatus or through the choana into the nasopharynx often obscure the ethmoidal concha. Unilateral ethmoid hematomas that expand into the nasopharynx may extend into the contralateral ventral meatus and obscure that ethmoidal labyrinth.

The origin of hematomas that expand dorsally into the frontal sinus may not be visible on endoscopy, but hemorrhage that originates deep to the visible portion of the ethmoidal conchae may be evident or noticed from the region of the nasomaxillary opening in the middle meatus. Visible ethmoid hematomas vary in color from deep red to red-purple or may have a yellow-brown or yellow-green-brown to bronze color. The surface is irregularly rounded, with small punctate hemorrhages or erosions, and may be partially covered in yellow-white mucopurulent material that may be admixed with blood. Often the floor of the ventral meatus and regions of contact with the nasal cavity have pooled exudate (blood and mucopurulent matter). Manipulation of the hematoma surface with the endoscope may cause bleeding or oozing.

Radiographic recognition of a discrete, often smooth-surfaced homogeneous radiodensity originating from the ethmoidal conchae and extending into the frontal, maxillary, or sphenopalatine sinuses, or into the pharynx or nasal cavity, is suggestive of ethmoid hematoma. Precise definition of the hematoma origin is difficult to determine from radiographic projections, and small hematomas contained within the ethmoid labyrinth may not be visible.

CT examination allows more accurate assessment of the origin of the ethmoid hematoma,[3] allows determination of the extent of involvement of the paranasal sinuses (especially the sphenopalatine sinus) and conchae, and facilitates surgical planning. On CT scans, masses are often associated with bone destruction, especially of the ethmoturbinates and infraorbital canal, and typically abut the cribriform plate in 50% of cases. Masses commonly have mild to moderate signal heterogeneity and a hyperdense swirling appearance consistent with recent hemorrhage or mineralization, which are also common morphologic features.[3]

Necropsy Findings Morphologic features have been described from surgical specimens, but few skulls with intact ethmoid hematomas have been examined.[2,3] Except in regions with necrosis or secondary infection associated with contact with the sinus or nasal cavity walls, the hematoma is a smooth-surfaced saclike structure containing blood in various stages of organization. The sac lining is generally healthy respiratory mucosa originating from a pedunculated region of the mucosal covering of the ethmoturbinate or sinus wall. On section, contents are amorphous red-black to chocolate brown, and in larger masses some evidence of irregular compartmentalization by fibrous tissue exists, especially on the inner surface of the sac.

Morphologic features include an outer covering of respiratory epithelium (flattened columnar or cuboidal ciliated epithelium containing glands, and occasionally stratified squamous epithelium[4]) overlying an irregular zone of submucosal fibrous tissue, containing hemosiderophages, occasional plasma cells, and lymphocytes, less commonly neutrophils, that forms a pseudocapsule around hemorrhage in varying states of organization. There is variable organization of the fibrous tissue components. Endothelial cells do not show evidence of neoplasia. Thin endothelium-lined sinuses are often present within the myxomatous stroma. The respiratory epithelium is sometimes focally ulcerated and infiltrated with neutrophils, and occasionally there are squamous metaplastic changes. Ethmoid adenocarcinoma with a similar gross appearance to that of ethmoid hematoma has been reported.[3,10]

Treatment and Prognosis Ethmoid hematomas slowly and progressively increase in size and can cause skull distortion if there is paranasal sinus involvement, so removal is recommended. Treatment method depends on location and size. Surgical ablation has been the preferred method; however, destruction of the hematoma by intralesional injection of formaldehyde solution is associated with less morbidity, although recurrence rates are similar to those achieved through other methods.[6-8,11,12] Surgical access is achieved by sinusotomy and then hematoma ablation by curettage, cryosurgery, or use of an Nd:YAG laser[12]; photoablation can be achieved through the biopsy channel of an endoscope. After sinusotomy, the pedunculated origin of the hematoma is identified by digital palpation and then dissected, frozen, or photoablated, and the hematoma removed. If the hematoma is friable, intact removal may not be possible, and hemorrhage may make observation of the origin of the mass difficult. After removal, the paranasal sinuses and nasal cavity are packed with gauze to control postoperative hemorrhage.

Surgical curettage can be associated with marked intraoperative blood loss typically from the turbinates or sinus mucosa rather than the hematoma. Temporary occlusion of both carotid arteries[13] can reduce blood loss until the sinus cavity is packed with gauze. Blood loss is minimized with cryosurgical extirpation and photoablation techniques, but these approaches are not always practical with large hematomas. Although blood loss is minimal with transnasal photoablation, this technique requires multiple procedures to destroy large masses but can be performed in the standing sedated horse. Photoablation (Nd:YAG laser, 100 W in noncontact technique) is effective in controlling remnants after surgical extirpation or subsequent regrowth.[14]

Destruction of ethmoid hematomas by endoscopically guided intralesional injection of formalin in standing sedated horses may reduce the need for surgical ablation.[11,15] A catheter passed through the endoscope biopsy channel is advanced through the rostral surface of the mass toward its origin, then 10% formalin (4% formaldehyde solution) is injected intralesionally. Commercially available catheters with a beveled needle tip are available, but relatively stiff plastic tubing that slides through the biopsy channel will penetrate the hematoma capsule. Sufficient volume (10 to 100 mL) is injected until fluid leaks back alongside the catheter or from the mass. For visibly pedunculated masses, formalin should be injected at the origin or neck of the mass. Tissue necrosis and slough occur within 5 to 10 days and may be associated with nasal discharge. Repeat injections, typically at no longer than 10- to 14-day intervals, may be needed to destroy the mass. Removal of necrotic tissue can be facilitated by use of long grasping forceps and hydropulsion. Mycotic plaques may cover the treated site during healing but typically resolve without treatment; endoscopically delivered topical natamycin has been used if mycotic plaque is extensive and associated with malodorous, purulent discharge.[16] If the hematoma has a paranasal sinus extension, necrosis of that tissue within the sinus, after destruction of the ethmoturbinate origin of the hematoma, may result in sinus empyema, mycotic infection, or both,[9] requiring ancillary treatment.

Occasionally progression of the ethmoid hematoma may result in weakening or loss of the cribriform plate or roof of the sphenopalatine sinus.[16] During mass removal, loss of this protective bony covering may result in intraoperative or postoperative neurologic complications. Recognition of loss of the integrity of these bony plates may not occur until sinus lavage. In a rare complication, death occurred following intralesional formalin injection in a horse where the cribriform plate had been eroded by the ethmoid hematoma.[17] Erosion of calvarial bone is rare, but careful computed tomographic evaluation of these regions in horses with extensive hematoma formation involving the frontal or sphenopalatine sinuses is warranted.[3]

Irrespective of treatment method, recurrence of the hematoma occurs in 17% to 50% of cases from several months to years after the initial surgery.[2,3,6-8,11,12,16] Increased use of CT to guide surgical planning and for postoperative evaluation is likely to contribute to a reduction in recurrence rates.

Disorders of the Equine Soft Palate

Safia Z. Barakzai • Padraic Martin Dixon

VetBooks.ir

Anatomy and Physiology of the Soft Palate The equine soft palate extends caudally from the hard palate and completely divides the pharynx into nasal and oral compartments. Because the horse is an obligate nasal breather, the caudal border of the soft palate normally fits snugly around the base of the epiglottis and the palate remains in this subepiglottic position at all times except during deglutition. The soft palate consists of the oral mucous membrane, palatine glands, palatine aponeurosis, palatal muscles, and nasopharyngeal mucosa. The soft palate is relatively thick (>2 cm) rostrally and tapers caudally as the amount of glandular tissue within it reduces considerably.[1] The paired muscles that control palatal position include the palatinus muscles (running rostrocaudally on either side of midline); the palatopharyngeus muscles (running from the palatine aponeurosis and lateral aspect of the palatinus, sweeping laterally up the walls of the nasopharynx); the tensor veli palatini muscles, which tense the rostral aspect of the soft palate; and the levator veli palatini muscles, which elevate the soft palate during deglutition.

Endoscopically, the dorsal aspect of the soft palate forms the floor of the nasopharynx and has longitudinal ridges that become more apparent when the palate is flaccid. Horses that resent endoscopic examination of the respiratory tract often tense their soft palate, giving its rostral aspect a dorsally "domed" appearance.

Dysfunction of the soft palate presenting as dorsal displacement of the soft palate or palatal instability at fast exercise is by far the most frequent palatal abnormality that clinicians are presented with in equine practice. Other palatal disorders are relatively uncommon.

Dorsal Displacement of the Soft Palate and Palatal Instability

Palatal dysfunction, which includes the two syndromes of dorsal displacement of the soft palate (DDSP) and palatal instability (PI), is the most commonly diagnosed cause of upper airway obstruction in racehorses (reported prevalence around 10% to 20%[2,3]). It also occasionally affects other types of horses, particularly those that are exercised with their head and neck in a flexed position, such as dressage horses, showjumpers, and Saddlebreds.[4,5] Intermittent DDSP is a disorder that characteristically occurs in horses toward the end of fast work, when the caudal border of the soft palate becomes displaced dorsal to the epiglottis (Fig. 31-54). A definitive diagnosis of intermittent DDSP or palatal instability can be made only with the use of exercising endoscopy. Palatal instability is seen as wavelike dorsal billowing of the rostral and caudal soft palate but without actual displacement of the caudal border of the soft palate dorsal to the epiglottis. Palatal instability commonly precedes DDSP.[6-9] Swallowing may temporarily halt PI, but instability usually recurs within a few seconds in affected horses and may progress to true DDSP. As the soft palate billows dorsally, it may lift the epiglottis, changing the epiglottic conformation and cause the aryepiglottic folds to deviate axially.[9,10] It is unclear what degree of soft palate instability is "normal" and what percentage of horses diagnosed with PI would experience DDSP under different conditions, such as racing. When PI is observed in isolation, it has been described as equivalent to a "presumptive" diagnosis of DDSP[11] and has also been suggested as a "prodromal" sign of impending DDSP.[9,12]

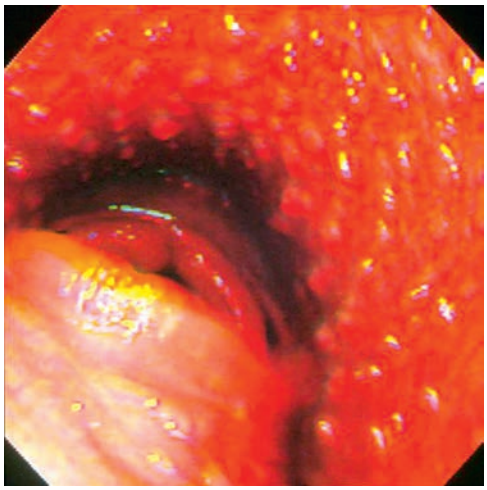

FIG. 31-54 Dorsal displacement of the soft palate seen in a horse undergoing exercising endoscopy, with marked airflow obstruction.

Rostral palatal instability is another form of palatal instability that has been reported in horses and ponies and is associated with neck flexion during exercise.[13,14] As the name suggests, the condition is characterized by dorsoventral billowing confined to the rostral soft palate. Rostral palatal instability causes inspiratory nasopharyngeal obstruction and respiratory noise. This condition has been produced experimentally by bilateral tensor veli palatini tenectomy.[15]

Pathophysiology Horses that have other abnormalities of the palate or larynx, such as epiglottal entrapment, pharyngeal paralysis, or palatal cysts, are predisposed to DDSP. The cause of the disorder in horses without such abnormalities is currently unknown. Research efforts have focused on determining the pathophysiology of DDSP in an attempt to improve understanding of the condition, with the ultimate goal of developing more effective treatments.[15-20] Current theories include neuromuscular dysfunction of the intrinsic soft palate muscles,[20-22] variations in positioning of the laryngohyoid apparatus,[19,23] and the role of the distal hypoglossal nerve in maintaining nasopharyngeal stability.[24] Epiglottic hypoplasia or flaccidity was previously thought to be associated with intermittent DDSP. However, clinical and experimental data show that the epiglottis is not required to maintain the palate in a normal position and that the majority of horses that experience DDSP during treadmill endoscopy have an epiglottic length that is within normal limits.

Clinical Signs Most horses with DDSP make a "gurgling" noise during exercise and may either pull up abruptly or slow down significantly after the palate has displaced. DDSP results in a flow-limiting expiratory obstruction leading to decreased airflow, increased tracheal expiratory pressure and impedance, reduced minute ventilation and subsequent hypoxia, hypercapnia, and impaired athletic performance.[17,25,26] Conversely, once the palate has displaced, minimal obstruction is observed during inspiration, as the upper airway inspiratory pressure maintains the soft palate in close apposition to the dorsal aspect of the epiglottis. During expiration, because a proportion of the exhaled air is directed ventral to the displaced palate and into the oral cavity, some horses are reported to exhibit "fluttering" of the cheeks during exhalation. Palatal instability has also been shown to have a negative effect on ventilatory parameters if moderate to severe.[27] Low frequency fluttering of the caudal border of the palate is believed to be the source of the loud expiratory and inspiratory gurgle or "snore" reported in 70% to 80% of affected horses[28]; however, up to 30% of horses can experience DDSP yet make no audible abnormal respiratory noise (these cases are referred to as "silent displacers").[29-31]

Diagnosis An accurate history, including details of reduced exercise performance, abnormal noise production, type of noise made, and stage of exercise when the noise occurred, can be very helpful. A thorough resting endoscopic examination of the nasopharynx should be performed to rule out other causes of palatal dysfunction, such as pharyngeal or palatal cysts, epiglottic entrapment, or pharyngeal paralysis. DDSP and PI are dynamic conditions, and findings of resting endoscopy have been shown to correlate poorly with

VetBooks.ir

dynamic endoscopic findings.[12,30,31] Horses that displace their soft palates at rest are often normal during exercising endoscopy, and conversely, many horses that are normal during resting endoscopic examination can develop DDSP at exercise.[30] One study reported that use of a characteristic history and findings at resting endoscopy alone resulted in a 35% misdiagnosis rate of palatal dysfunction as compared with findings of treadmill endoscopy.[31]

High-speed treadmill videoendoscopy has been the gold standard for diagnosis of DDSP and PI for the past 20 years.[6-8,12,31] The recent development of portable telemetric endoscopic systems used in horses undergoing ridden exercise provides an alternative method of visualizing the upper respiratory tract during exercise.[3,32,33] Clinically normal horses may transiently displace their soft palates during exercise, particularly when pulling up. However, a normal horse typically swallows and replaces the palate to its normal subepiglottic position within a few breaths, whereas DDSP is typically diagnosed if the palate remains dorsal to the epiglottis for a longer period of time, or if DDSP occurs repeatedly.

Sound analysis has been used as a research tool for diagnosis of DDSP[29]; however, given that up to 30% of horses are known to be silent displacers, the level of false-negative diagnoses made using sound analysis may be reasonably high. A significant relationship has recently been reported between the depth of the basihyoid bone measured using percutaneous ultrasonography at the caudal aspect of the lingual process at rest and the occurrence of DDSP at exercise.[34] A more ventrally located basihyoid at rest was associated with an increased probability of DDSP occurring during treadmill endoscopy. This test had a high negative predictive value (89%) but a low positive predictive value (36%), meaning that DDSP could be ruled out with reasonable certainty using laryngeal ultrasound, but care should be taken when making a positive diagnosis of DDSP using this method.

Treatment Many treatments are available for horses with DDSP, and this probably reflects both the unknown cause(s) of the disorder and the fact that most treatments have a similar success rate. Concurrent respiratory disorders, including upper or lower airway inflammation or infections, should be addressed fully before resorting to surgical remedies. The use of systemic corticosteroids, nonsteroidal antiinflammatory drugs, and topical antiinflammatory nasopharyngeal ("throat") sprays have been advocated to try to reduce upper airway inflammation.[2,30] Tack changes, including use of a tongue tie,[35] dropped or crossed noseband,[35-37] and "W" or Serena Song bits, have also been reported to be of benefit in affected racehorses. The laryngohyoid support device (Cornell collar) has been advocated as a nonsurgical "tie-forward" procedure for horses with DDSP and was effective in 100% (7 of 7) of horses with experimentally induced DDSP.[38] Results of the Cornell collar in horses with naturally occurring DDSP are not available.

Surgical treatments for DDSP are numerous and include insertion of a thyrohyoid prosthesis (the tie-forward or laryngohyoid reduction procedure), staphylectomy, myectomy of the sternothyrohyoideus muscles, epiglottic augmentation with Teflon, tension palatoplasty, thermocautery of the oral surface of the palate, laser cautery of the nasopharyngeal surface of the palate, in addition to multiple combinations of these procedures. A systematic review of treatments for palatal dysfunction in the horse concluded that there currently is no clearly superior treatment for DDSP.[39] The use of combinations of surgeries usually represents a "belt and braces" approach, but it may be argued that this provides a multimodal approach to a disorder with a multifactorial etiology. The use of multiple treatments in scientific studies means that researchers are often left unsure as to which of the reported treatments, if any, may have had a beneficial effect.[39]

Persistent Dorsal Displacement of the Soft Palate

Persistent DDSP, where the soft palate is permanently positioned dorsal to the epiglottic cartilage is rare, compared with intermittent DDSP. It is observed in the resting horse and is usually secondary to underlying structural abnormalities such as subepiglottic cysts, epiglottitis, epiglottic entrapment, intrapalatal cysts, pharyngeal paralysis, pharyngeal neoplasia, or pharyngeal foreign bodies,[13,40] but it can also be idiopathic. Persistent DDSP may also be observed following epiglottic or laryngeal surgery, particularly after surgery to release epiglottal entrapment[41,42] if a large fold of the subepiglottic mucosa is resected. Horses affected with persistent DDSP make a loud gurgling noise at exercise, have poor exercise tolerance, and are often mildly dysphagic.

Diagnosis Diagnosis is easily made by endoscopic examination of the nasopharynx in the resting horse where the epiglottis is not visible because the soft palate lies dorsal to it. Ulceration of the caudal border of the soft palate can sometimes be observed. Observation of persistent DDSP with the scope passed *per nasum* (through the nose) is an indication to perform endoscopy of the oropharynx (with a full dental speculum in place) to examine the epiglottis and associated structures for abnormalities.

Treatment In most cases, persistent DDSP is secondary to some other disorder, and treatment should therefore be directed at the initiating cause. If no primary disorder is found, the tie-forward procedure (laryngohyoid prosthesis) can be done, as it has been reported to be effective in alleviating idiopathic persistent DDSP in 7 of 15 horses in a recent case series.[40] In the same case series, 8 of 15 horses required laser staphylectomy after the tie-forward procedure to resolve persistent DDSP.[40]

Congenital Palatal Defects

Congenital defects of the palate (cleft palate of palatal hypoplasia) are rare in horses, having a reported prevalence of 0.01% to 0.02%.[13] These defects arise from incomplete embryologic closure of the palatal folds and may involve only the caudal aspect of the soft palate (Fig. 31-55), or both the hard and soft palates. Affected foals should be examined carefully for other congenital defects such as cardiac, gastrointestinal, or nasal septum abnormalities.

Clinical Signs and Differential Diagnosis Clinical signs of cleft palate include nasal regurgitation of milk (in foals) or other feed material in older horses, coughing, poor growth, and signs indicative of aspiration pneumonia. If the defect is small, abnormal respiratory noise due to palatal instability or DDSP may be the only presenting sign. Endoscopic examination of the nasopharynx (using a small-diameter endoscope) reveals an abnormal outline to the caudal border of the soft palate and food material within the nasopharynx, larynx, and trachea. Differential diagnoses for dysphagia with aspiration of food material in foals includes subepiglottic cysts,

FIG. 31-55 Congenital midline defect ("cleft") of the soft palate.

VetBooks.ir

pharyngeal paralysis or dysfunction (which can be transient in neonatal foals[43]), and in older horses, esophageal obstruction (choke), guttural pouch mycosis, severe arytenoid chondritis, complications of laryngeal surgery (e.g., laryngoplasty or arytenoidectomy), and large pharyngeal cysts or pharyngeal/laryngeal foreign bodies or neoplasms.

Treatment Surgical repair is possible for foals with less than 30% of the palatal tissue missing, but this is generally a salvage procedure only, and they may be unable to perform athletically when older, even if surgery is successful.[2] Surgical repair of soft palate defects is challenging and has a high prevalence of complications and failure; therefore, if signs of severe aspiration pneumonia are present, euthanasia of affected foals should be considered as an alternative. Surgical approaches to the soft palate include transoral, pharyngotomy, and mandibular syphysiotomy.[44,45] If signs of the palatal defect are confined to occasional coughing after eating, nasal discharge, or both (i.e., there are minimal or no systemic signs), some affected foals can survive to adulthood and may be capable of ridden work if left untreated or treated symptomatically.[46]

Palatal Cysts

These rare lesions usually occur in young horses and may be a cause of abnormal respiratory noise and airway obstruction if they become large or if they disrupt the normal palatoepiglottic relationship. Palatal cysts probably form as the result of the obstruction of mucus-secreting glands within the soft palate, or they may have a traumatic etiology.[13,47] The presence of palatal cysts predisposes horses to DDSP.

Clinical Signs and Diagnosis Clinical signs include respiratory noise (at rest or during exercise), coughing, exercise intolerance, nasal discharge, dysphagia, and signs of aspiration pneumonia. Diagnosis is made by endoscopic examination of the nasopharynx where a raised intrapalatal mass can be seen. Obtaining an open-mouthed straight lateral radiograph (with the incisors held apart with a gag) will cause the soft palate to move dorsally away from the tongue and allows focal thickening of the palate to be visualized more easily than on a closed-mouth lateral view. Differential diagnoses include palatal neoplasia and intrapalatal abscesses, the latter being usually associated with intrapalatal foreign bodies or strangles infection. Transendoscopically guided aspiration of the cyst should yield clear viscous fluid.

Treatment Treatment involves surgical excision or laser ablation of the cystic structure, if it is large enough to cause abnormal respiratory noise or airway obstruction. If the cyst is simply drained and some of the lining is left in situ, it is likely to recur.

Neoplasia

Neoplasms of the soft palate are rare. Lymphosarcoma and squamous cell carcinoma (Fig. 31-56) occur most frequently, and lesions may vary markedly in appearance. Surgical excision of pharyngeal neoplasms is rarely successful, because total excision with wide margins is almost impossible to achieve. Radiotherapy may provide an alternative for treatment of pharyngeal neoplasms, but it is not widely available for horses.

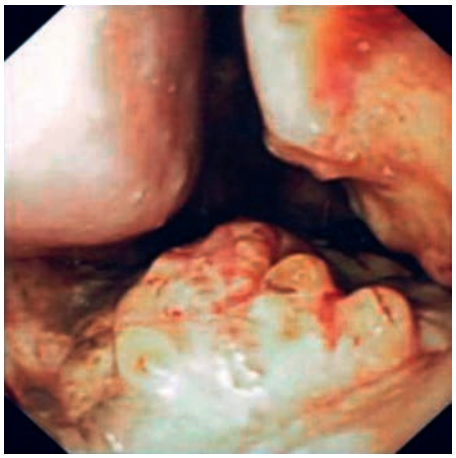

FIG. 31-56 Squamous cell carcinoma of the soft palate viewed at the caudal edge of the nasal cavity, where the hard palate meets the soft palate.

Disorders of the Trachea

Anatomy of the Trachea

The equine trachea extends from the caudal larynx to the carina, where it divides into the two main stem bronchi at the level of the fifth and sixth intercostal spaces. It is about 75 to 80 cm long in a 500-kg horse.[48] The trachea occupies a midline position in the neck and also in the rostral thorax, where it lies in a fold of mediastinum, but at its termination, it becomes slightly displaced to the right by the adjacent aortic arch.[49] It is composed of 48 to 60 individual tracheal rings of hyaline cartilage, which are incomplete dorsally.[48] In the cervical trachea, the free ends of the tracheal rings usually overlap, but in the thoracic trachea, they rarely meet.[49] Each individual tracheal ring is 10 to 12 mm wide, being 2 to 3 mm thick dorsally and 5 to 7 mm thick ventrally. The dorsal tracheal ligament completes the dorsal aspect of the tracheal lumen, attaching to the inner surface of the tracheal rings. The cartilage rings vary a little in shape in the normal horse: the first few rings are slightly dorsoventrally flattened, but as the trachea is traced distally, the rings become more circular in shape. Finally, at the level of the aortic arch, the rings can become slightly laterally flattened, particularly on the left side.[48] The tracheal ligament contains the transversely oriented trachealis muscle; this elastic structure allows the trachea to expand slightly during times of increased respiratory effort.

Each tracheal ring is covered by and connected to adjacent rings by an intimately attached fibroelastic ligament, termed the *annular ligament.* This arrangement of semi-rigid cartilaginous rings and elastic annular ligaments, along with the loose attachment of the tracheal adventitia to other tissues, allows much flexibility of the trachea during head and neck movement while retaining its cross-sectional shape. The cricotracheal ligament, which attaches the first tracheal ring to the cricoid cartilage, is of similar structure to the annular ligaments but is wider (craniocaudally) and under less tension.

Running bilaterally along the dorsolateral aspects of the trachea are many vital structures, including the carotid artery, vagus and recurrent laryngeal nerves, sympathetic truck, tracheal lymph ducts, and cervical lymph nodes. The trachea is lined by a pale mucosa, containing numerous mucus and serous glands and possibly fine longitudinal folds. Ciliated epithelial cells are the predominant cell type,[50] with each cell containing about 200 cilia that beat 15 to 20 times per second. These cilia transport mucus from the lungs proximally to the nasopharynx. In the equine trachea, mucus is transported at a velocity of 13 to 20 mm/min.[51,52] The "sump-like" depression in the rostral thoracic trachea is a common place for respiratory secretions to accumulate in horses.[53]

Primary tracheal disorders are relatively uncommon in horses, but abnormal pooling of respiratory secretions in the "sump" of the trachea is often seen as a consequence of lower airway inflammation or exercise-induced pulmonary hemorrhage. Primary lung disorders are not discussed further in this section.

Cricotracheal Ligament Prolapse

A limited number of clinical reports describe this disorder in Thoroughbred racehorses during fast exercise.[53-55] The cricotracheal membrane is normally longer (rostrocaudally) and under less tension than

VetBooks.ir

the tracheal annular ligaments. It is suggested that a congenitally abnormally long and/or slack cricotracheal ligament may prolapse dorsally, ventrally, or circumferentially into the airway lumen as a result of the very negative inspiratory airway pressures that are generated during fast exercise. Concurrent upper and lower airway disorders may increase the severity of cricotracheal ligament prolapse by further increasing the negative pressure generated within the upper respiratory tract.

Clinical Signs and Diagnoses Clinical signs are reported to be abnormal respiratory noise during exercise and reduced exercise performance[53-55] due to the dorsally displaced ligament causing turbulent airflow and obstructing the airway. Differential diagnoses must include all forms of dynamic upper airway collapse, in particular those that are associated with inspiratory noise, including recurrent laryngeal neuropathy, axial deviation of the aryepiglottic folds, vocal fold collapse, collapse of the apex of the corniculate cartilages, epiglottic retroversion, and nasopharyngeal collapse. Diagnosis requires exercising endoscopy, either over ground or on a high-speed treadmill, with a specific effort made to examine the caudal laryngeal area. In the most recent report concerning two horses,[55] both horses had concurrent dynamic upper airway abnormalities. Presumably, cricotracheal collapse is exacerbated with head and neck flexion as this position will reduce tension on the cricotracheal ligament; however, this has not been discussed in any of the case reports to date. Ultrasonography of the ventral aspect of the cricotracheal ligament with the horse's head extended may be useful to measure the length and thickness of the ligament, but the range of these ultrasonographic measurements in normal horses has not yet been reported.

Treatment The reported treatment of cricotracheal membrane prolapse is to imbricate the ventral aspect of this ligament; one surgeon has suggested that the residual cricotracheal membrane should be left approximately 1.5 cm wide rostrocaudally.[54] However, the use of videoendoscopy during exercise has shown other aspects of the cricotracheal membrane can also collapse and these areas would also need treatment. In conclusion, there is little factual evidence regarding either the significance of cricotracheal membrane collapse in exercising horses or the response of affected horses to treatment.

Tracheal Collapse

Tracheal collapse is commonly recorded in many breeds of toy dogs[56-58] and can also occur in goats[59] and sheep and cattle (Dixon, personal observations). In equidae, this developmental disorder is often reported in small ponies and miniature horses[60-65] but also occurs in larger breeds of ponies[66] and donkeys.[63,67] In many small ponies, the disorder remains undiagnosed because of their low workload. There is a high prevalence of tracheal deformities in donkeys; in one postmortem study, 68.8% of tracheal rings did not have an oval or circular shape. Affected donkeys are usually asymptomatic, unless severe tracheal deformity or intercurrent pulmonary disorders, such as advanced pulmonary fibrosis, are present.[67]

Pathophysiology Tracheal collapse is usually caused by a cartilage ring deformity, including where the normal rounded or oval tracheal ring is replaced classically by a flatter tracheal ring with a greatly reduced dorsoventral diameter (Fig. 31-57). In some cases, a slack and elongated dorsal tracheal ligament can exacerbate the dynamic collapse.[60,61,66] A more recent study also showed most cases of tracheal collapse in donkeys were caused by structural cartilage abnormalities other than those previously mentioned[67]; thus perhaps a term other than *tracheal collapse* should now be used.

Many ponies and donkeys with tracheal collapse will have some dorsoventrally flattened tracheal rings (especially in their lower cervical trachea) but will also have other types of ring deformities (Fig. 31-58) at more caudal sites.[63,67] In other affected cases with relatively normal-shaped tracheal rings, there appears to be separation of the dorsal ligament from the dorsal aspect of the tracheal rings (Fig. 31-59). This defect usually involves the mid and distal cervical, as well as the intrathoracic trachea, and may occasionally involve the main stem bronchi. Some affected equids may also have some degree of tracheal rotation, with the dorsal aspect of the trachea facing dorsolaterally (authors' personal observations).

Most ponies and miniature horses develop clinical signs of tracheal collapse in middle age,[65,68] thus indicating that some degenerative process of the tracheal cartilage or connective tissue may play a role in the pathogenesis of this disorder. In one case series of 13

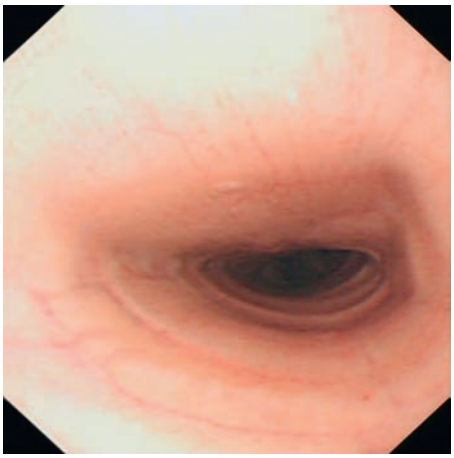

FIG. 31-57 Endoscopic view of dorsoventrally collapsed trachea

FIG. 31-58 Severe structural abnormality of an equid trachea.

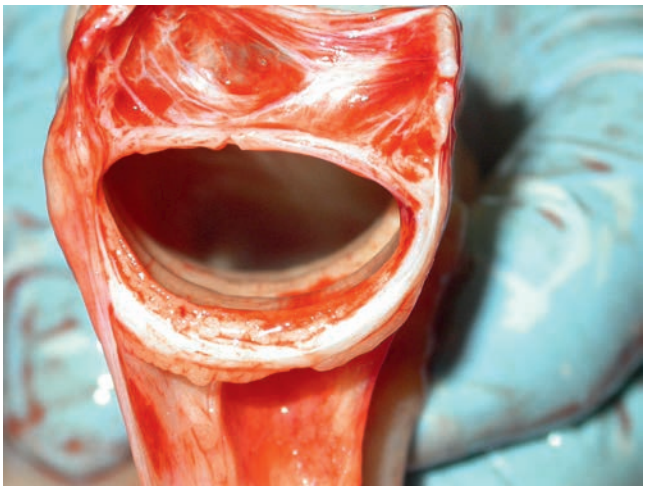

FIG. 31-59 This tracheal ring is a normal C shape, but the dorsal tracheal ligament has separated from the dorsomedial aspect of the tracheal rings.

VetBooks.ir

American Miniature Horses, all four horses, which had histopathology performed, had tracheal chondromalacia that varied from mild multifocal hyalinization of the extracellular matrix to marked multifocal coalescing areas of chondromalacia characterized by complete degradation of the cartilaginous matrix and loss of chondrocytes.[65] The presence of chronic respiratory disease that may cause tracheal mucosal thickening and also increase intrapleural pressure swings and neuromuscular problems causing loss of tone of the trachealis muscle have also been implicated in the pathogenesis of this disorder in donkeys.[67]

Temporary Tracheal Collapse

Horses with severe expiratory dyspnea caused by pulmonary disease have increased positive intrathoracic pressure during expiration, which can cause a temporary collapse of the intrathoracic trachea, particularly of its dorsal ligament. Such temporary and often near total tracheal collapse can also be seen transiently in all horses if they cough during bronchoscopy.

Clinical Signs and Diagnosis The typical clinical signs in affected equids are dyspnea and stridor, which commonly occur in hot or humid weather and may regress in autumn. Aleman and colleagues[65] report that clinical signs were initially intermittent and often associated with stressful events, exercise, dusty environment, and eating but that all owners reported increasing severity of clinical signs with age. Stridor may be very loud, with Delahanty and Georgi[60] reporting a pony that made sounds like a truck horn that could be heard over 800 meters away! The stridor is loudest when auscultated directly over areas of tracheal obstruction. Severe dyspnea may occur even at rest, because hyperventilation will exacerbate the partial tracheal obstruction in a self-perpetuating cycle. Affected horses can also exhibit tachycardia (60 to 130 bpm) and hyperthermia (38.2 to 40° C).[65]

Exercise-induced pulmonary hemorrhage may occur in severe cases, presumably because of increasingly subatmospheric intrathoracic pressures. Coughing may also occur and it is unclear if this is due to tracheal inflammation caused by abnormal contact of dorsal and ventral tracheal mucosa, or due to underlying pulmonary disease that may have precipitated the clinical problem.

Diagnosis Palpation of a collapsed cervical trachea may reveal lateral protrusion of cartilage rings. However, palpation of the lateral edges of the flattened trachea can be difficult, as the deeper, distal cervical trachea is most commonly affected. Additionally, some small ponies such as Shetlands have very thick skin and much subcutaneous fat, which makes tracheal palpation difficult.[48]

Endoscopy of affected cases will show the normal circular or oval appearance of the tracheal lumen to be replaced by a wider, flatter, or otherwise restricted lumen. Additionally, excessive dynamic movement of the dorsal tracheal wall and even airway occlusion may be observed during deep breathing, with inspiratory narrowing of the cervical tracheal lumen and expiratory narrowing of the intrathoracic tracheal lumen. The mucosa may be red and inflamed.

Lateral radiographs of the distal cervical and thoracic trachea may be diagnostic, demonstrating the flattened appearance of the trachea,[61,65] but radiographs must be taken during inspiration for the cervical trachea and during inspiration for the intrathoracic trachea. Radiography can be misleading in cases where tracheal rotation is present along with collapse, where the trachea may actually appear wider than normal on lateral radiographs.

Treatment and Prognosis Treatment of such cases should initially be conservative, by restricting exercise, keeping affected cases indoors in cool boxes in hot weather, and treating any concurrent pulmonary disease. Acutely affected horses will benefit from intranasal oxygen therapy that reduces hyperventilation and thus decreases the degree of tracheal collapse. Tracheostomy usually does not provide relief because it does not bypass the affected region (usually distal cervical and intrathoracic trachea). Therefore insertion of an endotracheal tube via the tracheotomy to keep the collapsed trachea patent is usually necessary to provide a functional airway in severely affected animals. Hyperthermia, if present, increases the metabolic rate and thus increases the respiratory demand further, causing a vicious cycle of events. Cooling down such ponies with a cold-water hose can be beneficial. Parenteral corticosteroids are also indicated in severely affected cases to reduce the secondary tracheal mucosal inflammation/edema that is likely to be present. The long-term prognosis for severely affected miniature horses with such conservative therapy appears to be poor, with 10 of 13 horses in the largest case series to date either dying or requiring euthanasia.[65]

Surgical correction of affected cartilaginous cervical tracheal rings (as is commonly performed in miniature dogs)—such as placing external stents over deformed tracheal rings[62,69] or inserting stainless steel sutures into every third tracheal ring along with imbrication of the slack dorsal membrane[60]—has been performed in ponies with limited success. The use of a metallic intraluminal stent has also been reported to have been successful in one miniature horse; however, intratracheal granulation tissue formation and lower airway infection was associated with the stented area.[64] In some ponies, altering the shape of the tracheal rings may not be successful, because separation of the dorsal ligaments from the cartilage rings is the primary problem. Additionally, careful evaluation will usually reveal involvement of the intrathoracic trachea and, because only three or four intrathoracic rings can be exteriorized rostrally to the distal cervical area for surgical correction, this may be of limited benefit to the horse. Although intrathoracic surgery to correct more caudal tracheal deformities is technically feasible, it is not practical.

Other Congenital Defects of the Trachea

Congenital defects of the trachea, other than tracheal collapse, are rare in horses. Only a few other types of deformities have been recorded, including a few reports of accessory or ectopic pulmonary tissue, such as that by Davis and colleagues,[70] who recorded an accessory cervical tracheal bronchus in a 3-day-old foal. The foal presented with a large, air-filled sac in its cervical region caused by a rudimentary accessory lung that contained cartilaginous tissue and ciliated epithelium. Peek and colleagues[71] reported a combined tracheal and esophageal duplication cyst in a 4-month-old Arabian foal with a slowly developing cervical swelling that was successfully resected.

EXTERNAL TRACHEAL TRAUMA. Tracheal trauma is usually caused by blunt trauma, such as kicks to the neck region that can cause severe tracheal damage, particularly if the trachea is compressed between a hoof and the overlying cervical vertebral body. Tracheal trauma can cause tearing of the mucosa (Fig. 31-60), tearing of the overlying annular ligaments, and fracture of tracheal rings. Penetrating tracheal injuries occur less commonly.

FIG. 31-60 Tracheal trauma: oval-shaped tear in the tracheal mucosa showing separation of the underlying tissues.

VetBooks.ir

Clinical Signs and Diagnosis A common presenting sign in horses with tracheal rupture is extensive subcutaneous emphysema and swelling over the cranioventral aspect of the neck.[72-74] External skin wounds are not always present. The emphysema may later spread to involve the head, trunk, mediastinum, and even limbs. Horses will later become stiff, and possibly febrile from secondary infection, and epistaxis and coughing may occur.[73] In addition to possibly having a ruptured trachea, horses with emphysematous cervical swellings should always be suspected of suffering from a ruptured esophagus[75] (authors' personal observations). Because the esophagus may lie ventrolateral, or even ventral to the trachea at around the level of the sixth cervical vertebra in some horses, it is prone to trauma at this site.[48]

Cervical radiography of horses with tracheal or esophageal rupture will show extensive gas infiltration along the fascial planes of the neck, in addition to variable soft-tissue or fluid-filled swellings of the cranial and ventral neck regions. Thoracic radiography may also reveal pneumomediastinum and possibly pneumothorax. Endoscopy (tracheoscopy) will confirm if tracheal trauma has occurred, by evidence of mucosal tears, prolapse of submucosal tissue into tracheal lumen, distortion or partial occlusion of the lumen caused by cartilage ring fractures, and/or local inflammation.[73,74] Esophageal endoscopy to examine the integrity of the esophagus should also be performed with the greatest of care in horses with neck swelling and emphysema.

Treatment and Prognosis If the esophagus is ruptured, the prognosis is poor, as compared with tracheal rupture, where the prognosis is usually good. Small tears of the tracheal mucosa will usually heal spontaneously. In addition to tetanus prophylaxis, NSAIDs should be administered to such cases to decrease the traumatic inflammation, along with broad-spectrum antibiotics to reduce the potential spread of pathogenic bacteria with entrapped air along the fascial planes of the neck and into the mediastinum. The emphysema present in such cases will usually resolve in 1 to 2 weeks but may remain for up to a month in some horses.[73] Large rents in the tracheal mucosa with extensive herniation of soft tissue into the tracheal lumen can be sutured, as described by Fubini and colleagues.[74]

Fractures of the cartilaginous tracheal rings with gross distortion of the trachea may also occur, and it may be difficult to evaluate the degree of the cartilage ring damage in the presence of severe local inflammation and emphysema. If available, computer tomography or magnetic resonance imaging of such lesions are the optimal methods of assessing cartilage damage. If life-threatening tracheal obstruction occurs, a temporary tracheostomy may be performed with insertion of an uncuffed endotracheal tube through the tracheostomy to open up the collapsed section of trachea if the obstruction is distal to the mid-cervical region.

Intraluminal granulation tissue and subsequent development of fibrotic bands of tissue can be long-term sequelae of tracheal trauma. Occasionally such rings of tissue may eventually (months later) reduce the tracheal lumen to a significant extent, leading to respiratory obstruction with stridor. Transendoscopic laser resection of the protruding stricture can be attempted, but the site should be monitored postoperatively for recurrence of the lesion. The use of topical corticosteroid after laser surgery may help to prevent a recurrence of strictures. Complete resection of the affected cervical tracheal ring(s) (up to 4 rings maximum) with end-to-end tracheal anastomosis can also be attempted, but such procedures can be very challenging. If the stricture is in the cranial cervical trachea, then a permanent tracheostomy can be placed at a more distal site.

Focal Intraluminal Tracheal Lesions Including Neoplasia

Apart from granuloma formation post tracheostomy (Fig. 31-61) or after tracheal trauma, focal intraluminal tracheal lesions are rare in horses (although many horses and especially ponies have multiple small cartilaginous nodules that are of no clinical significance). Charlton and Tulleners[76] reported infected/necrotic mid-cervical tracheal proliferative lesions in two adult horses, following intratracheal antibiotic administration in one and following a transtracheal aspiration in the other. The masses were resected using a transendoscopic laser in one horse and combination of transendoscopic laser and conventional surgery in the other.

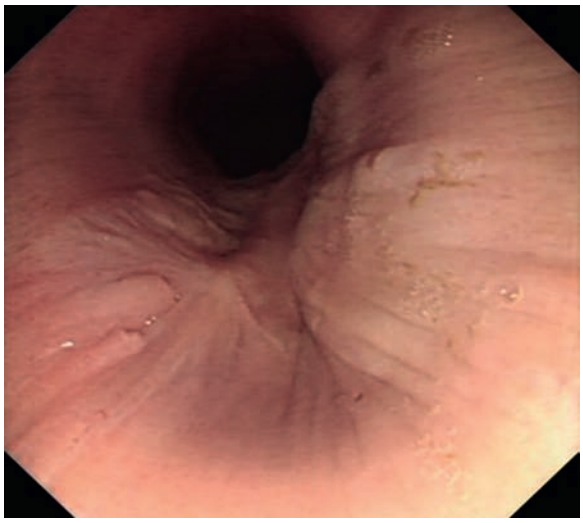

FIG. 31-61 Intraluminal scar tissue formation and cartilage deformity after tracheostomy tube removal.

Malignant tracheal tumors are rare in horses, but squamous cell carcinomas have been reported in the trachea of aged horses.[77] Benign lesions, including papillomas, fibromas, eosinophilic polyps, chondromas, and adenomas, are more common.[78,79] Benign lesions can often be successfully resected using a distal cervical tracheostomy and/or a transendoscopic laser (although transnasal retrieval of excised masses can be difficult if the lesion is at a distal site).

Extramural Tracheal Compression

Occasionally, enlarged lymph nodes compress the trachea, causing stridor. Severe lymphadenopathy is usually associated with *Streptococcus equi* subsp. *equi* (strangles) infection[80] and may involve the upper cervical chain, compressing the proximal cervical trachea. The distal cervical chain that compresses the trachea at the thoracic inlet may also be involved.[48,80-82] Diagnosis can usually be made from the history and clinical signs indicative of strangles, and confirmation can be made by needle aspiration and/or ultrasonography of cervical swellings. The abscessed lymph nodes should be drained and then lavaged with dilute povidone iodine solution.[81]

Mediastinal tumors (mainly lymphosarcomas), other cranial thoracic tumors (including primary lung tumors), or grossly abscessed mediastinal lymph nodes can cause compression of the intrathoracic trachea (Fig. 31-62) or of one or both main stem bronchi, leading to stridor and dyspnea. Such an endoscopic finding should lead to a careful thoracic examination, including radiography and ultrasonography. Thoracic tumors are usually untreatable in the horse.

Tracheobronchial Foreign Bodies

Inhaled foreign bodies are common in humans and dogs but less common in horses because of their height. O'Connor[83] described a range of laryngeal and tracheal foreign bodies in horses and stated that a fatal bronchopneumonia could develop if the foreign body is not expelled by coughing. Inhaled foreign bodies seldom bypass the larynx, but if they do, they will usually become entrapped at the carina or in the main stem bronchi,[84-87] predominantly the right main stem bronchus.[68]

A history of sudden onset of persistent coughing is a very prominent finding in these cases, and malodorous breath will often be present. Other signs of pulmonary disease, such as increased

VetBooks.ir

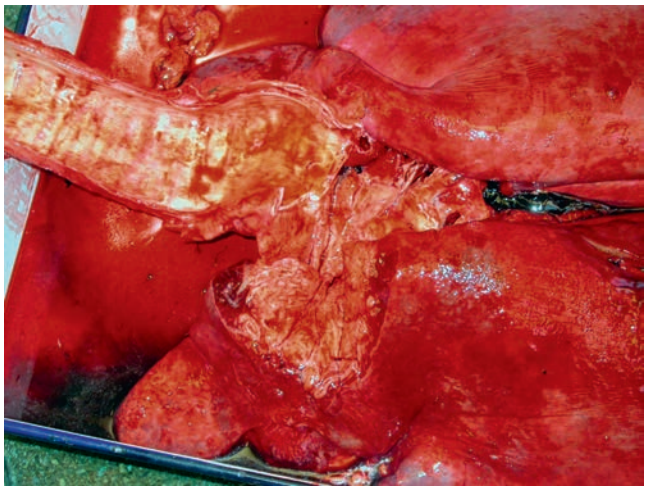

FIG. 31-62 Intrathoracic tracheal deviation and lateral collapse caused by extramural pressure from a mediastinal tumor.

respiratory rate or the presence of abnormal lung sounds, are usually absent, at least initially, unless secondary lung infection occurs. If significant pulmonary infection develops, abnormal lung sounds and possibly purulent or blood-tinged nasal discharge may occur. No response or only a temporary response (decreased nasal discharge) may occur following antibiotic therapy. Radiography may show a localized interstitial pattern caudal to the vena cava.[86]

Endoscopically, local airway inflammation and purulent respiratory secretions may obscure a foreign body. Even small foreign bodies may significantly obstruct airflow if they become lodged in the bronchii, and the induced local bronchial inflammation may also obstruct normal drainage of respiratory secretions from the affected bronchus, inducing severe, focal pulmonary infection. Transendoscopic lavage of the area may help determine if a bronchial foreign body or tumor is present. When identified, bronchial foreign bodies may be removed using transendoscopic grasping or basket forceps. Cranially facing branches and thorns will make the recovery of such vegetation difficult, but with persistence, most bronchial foreign bodies will eventually become loose and retrievable. If this is unsuccessful, a distal cervical tracheostomy can be performed and long, rigid grasping instrumentation (such as a bronchoesophageal grasping forceps) can be used under endoscopic guidance to retrieve the foreign body.[85,86]

Epiglottic Entrapment

Santiago D. Gutierrez-Nibeyro

Definition and Etiology Epiglottic entrapment, persistent or intermittent, refers to the dorsal displacement of the aryepiglottic folds and subepiglottic mucosa over the epiglottis. The aryepiglottic folds attach to the free margins of the epiglottis and blend with both the dorsal epiglottic and subepiglottic mucosa. Normally, the subepiglottic mucosa is loosely attached to the epiglottis to allow movement of the cartilage during swallowing. The cause of the disease is unknown, but inflammation of the subepiglottic mucosa and submucosa, redundant subepiglottic mucosa, and epiglottic hypoplasia or flaccidity have been reported as predisposing factors.[1-4] Epiglottic entrapment is typically a disease of Thoroughbred and Standardbred racehorses,[4] although it has been reported in nonracing Thoroughbreds and other breeds.[5] Epiglottic entrapment is often an incidental finding in weanlings and yearlings.[6]

Clinical Signs and Differential Diagnoses Clinical signs are variable and depend on the severity of the entrapment and the presence of other diseases of the upper respiratory tract. Some Thoroughbred and Standardbred racehorses can be asymptomatic

FIG. 31-63 Endoscopic image of the nasopharynx of a 3-year-old Standardbred racehorse with a history of increased respiratory noise and chronic epiglottic entrapment. The entrapping membrane was thick, wide, and mildly ulcerated, and the epiglottis had moderate hypoplasia once the entrapment was corrected surgically. As in this case, most epiglottic entrapments are persistent and thick, and approximately half are ulcerated.

and compete successfully with an entrapped epiglottis.[7] However, affected horses most commonly have a variable degree of abnormal respiratory noise, exercise intolerance, or both, because of partial airflow obstruction.[1,2,8] Severe inflammation and ulceration of the entrapping tissue can exacerbate airway obstruction and noise production; in rare cases, it may also cause cough and dysphagia.[1,8] Potential endoscopic differential diagnoses include subepiglottic cysts, epiglottitis, epiglottic granulomas, and dorsal displacement of the soft palate.[5,9,10]

Definitive Diagnostic Tests Endoscopic examination of the nasopharynx with the horse at rest is frequently diagnostic. Typically, the scalloped edge of the epiglottis and the vessels on its surface are not evident on endoscopy because they are obscured by the entrapping aryepiglottic fold (Fig. 31-63). Most epiglottic entrapments are persistent and thick, and approximately half are ulcerated.[2,8] If the epiglottis is not entrapped during the initial endoscopic evaluation but intermittent entrapment is suspected, endoscopy during a high-speed treadmill stress test may be necessary for diagnosis.

Although radiography is not used to diagnose the disease, an epiglottic entrapment can be detected with this diagnostic technique.[4] Epiglottic hypoplasia can be determined with both subjective endoscopic evaluation and radiographic measurement of the epiglottic length (determined by thyroepiglottic length).[4,11]

Treatment and Prognosis Intermittent epiglottic entrapment may be treated conservatively with topical and systemic antiinflammatory therapy and exercise restriction. Persistent epiglottic entrapment is typically treated surgically.[2,8] There are several surgical techniques to correct epiglottic entrapment: transendoscopic axial division using a Nd:YAG or diode laser,[2] transnasal or transoral axial division using a curved bistoury,[1,8,12-14] transnasal axial division using a shielded curved bistoury,[15] transendoscopic axial division using monopolar electrocautery,[16] and surgical excision via a laryngotomy.[3] Currently axial division of the entrapping aryepiglottic folds and subepiglottic mucosa is the preferred technique because the tissues are simply transected, avoiding "debulking" of the epiglottis and excessive scarring postoperatively, which can cause dorsal

VetBooks.ir

displacement of the soft palate.[17] Resection of the entrapping tissues through a ventral laryngotomy is typically reserved for excessively thickened, ulcerated, or fibrotic-appearing entrapping membrane.[3] Postoperative care consists of topical and systemic antiinflammatory therapy and exercise restriction.

The prognosis is typically good; however, postoperative complications include recurrence of the entrapment, intermittent or persistent dorsal displacement of the soft palate, and epiglottis deformity.[2,8,13,18] The recurrence rate after surgical correction of an entrapped epiglottis using laser axial division is 5%[2]; it is up to 15% using a curved bistoury,[8,12,14,15] and it is as high as 40% using electrosurgical division.[16]

Pharyngeal Cysts in Horses

Santiago D. Gutierrez-Nibeyro

Definition and Etiology Pharyngeal cysts are uncommon in the horse[1-3]; however, they are occasionally diagnosed in young Thoroughbreds, Standardbreds, and Quarter Horses.[4-8] Pharyngeal cysts occur most commonly in the subepiglottic region (Fig. 31-64) and occasionally in the soft palate or dorsal wall of the nasopharynx (Fig. 31-65).[4,6,8] Some authors believe subepiglottic cysts are embryonic remnants of the thyroglossal duct (precursor of the thyroid gland), but others believe these cysts are secondary to inflammation and obstruction of the mucus-secreting glands that line the pharynx.[5] Cysts formed within the dorsal nasopharyngeal wall are thought to be embryonic remnants of the craniopharyngeal duct (precursor of the adenohypophysis).[4] The origin of soft palate cysts has not been elucidated; however, histopathologic examination of these cysts is consistent with a mucocele.[6]

Clinical Signs In foals subepiglottic cysts are frequently asymptomatic,[3] but many cause increased respiratory noise, cough, nasal discharge, persistent dorsal displacement of the soft palate, dysphagia, and aspiration pneumonia.[5,6] The most common presentation in the adult performance horse is partial obstruction of the upper respiratory tract, abnormal respiratory noise, exercise intolerance, coughing, dysphagia, and, in rare cases, complete obstruction of the upper respiratory tract.[4,7-9]

Clinical Pathology Complete blood cell count and biochemistry profiles are typically within normal limits unless concurrent inflammatory airway disease, pneumonia, or acute upper respiratory tract obstruction exists.

Definitive Diagnostic Tests Endoscopic examination of the nasopharynx confirms the diagnosis and may also detect concomitant pathology such as epiglottic entrapment.[4,5,8] Occasionally, a lateral radiographic view of the pharynx or transoral endoscopic examination of the oropharynx with the patient anesthetized is needed if the cyst is within the soft palate or beneath the epiglottis protruding into the oropharynx. Although contrast pharyngography has been described to help delineate cysts in the oropharynx,[6] in the authors' opinion the use of contrast is unnecessary if digital radiography is available. The use of ultrasound has been described to delineate the cyst from the adjacent structures before surgery, if necessary.[10]

Treatment and Prognosis Pharyngeal cysts can be surgically removed, ensuring complete removal of the secretory lining without excessive excision of surrounding pharyngeal mucosa in the case of a subepiglottic cyst, which may lead to cicatrization and epiglottic dysfunction.[8] Subepiglottic cysts can be removed via a ventral laryngotomy,[4] via an oral or transnasal approach using an endoscopically guided laser, electrocautery snare, or a cyst snare constructed with obstetrical wire loop threaded through a Chambers catheter.[8,9] More recently, intralesional administration of 10% formalin has been reported, which provides an economically suitable alternative to surgical treatment[11]; however, multiple treatments may be required for complete resolution of the cyst.[11] Postoperative care consists of topical and systemic antiinflammatory therapy and exercise restriction. The prognosis following removal of subepiglottic cysts is good, and most horses return to full athletic function.[4,8] Less information is available regarding the prognosis after removal of other pharyngeal cysts.

Nasopharyngeal Cicatrix Syndrome

Ben Buchanan

The nasopharyngeal cicatrix syndrome is an inflammatory condition that was first described in 1987 in horses from south Texas[1] and

FIG. 31-64 Endoscopic image of the nasopharynx of a 2-year-old Standardbred horse with a small smooth and rounded subepiglottic cyst. The horse had a history of abnormal respiratory noise during training.

FIG. 31-65 Endoscopic image of the nasopharynx from a 1-week-old foal with a large cyst attached to the dorsal wall of the pharynx and a nasogastric tube in place. The cyst was resected with a cyst snare under endoscopic control.

VetBooks.ir

continues to be a common finding of horses grazing pastures in certain areas of Texas. It is also sporadically reported in other Gulf Coast (U.S.) states. The syndrome is a combination of inflammation and scarring of the nasal passage, pharynx, larynx, arytenoid cartilages, and proximal trachea. Severity ranges from incidental findings during endoscopy to airway obstruction that requires permanent tracheostomy.[2,3]

Clinical Signs Clinical signs include abnormal respiratory noise, nasal discharge, exercise intolerance, coughing, respiratory distress, and abnormal vocalization.[4] The character of the nasal discharge is frequently clear and mild. When compared with a case-controlled population in a retrospective study, affected horses made up 118 of 1236 horses examined endoscopically for any reason.[4] Of these affected horses, 97% had some degree of pharyngeal inflammation or scarring, of which 50% had a circumferential scar. In addition, 91% of affected horses had some inflammation or scarring of the larynx, and 39% had an airway obstruction with the majority being at the level of the larynx. In this same study, horses with endoscopic evidence of acute nasopharyngeal cicatrix syndrome were more likely to have nasal discharge and respiratory distress, whereas horses with endoscopic evidence of chronic nasopharyngeal cicatrix syndrome were more likely to make respiratory noise or suffer from respiratory distress.

Endoscopic Signs A scoring system used by the author is presented in Fig. 31-66 and builds on a system previously proposed by Rakestraw.[5] This system was developed to provide practitioners with a concise, simple, and complete system to document any abnormality of the upper respiratory tract seen on standing endoscopy.

NASAL PASSAGE. Both nasal passages should be examined. Lesions in the nasal passage appear as ulcerations and occur in less than 10% of cases.[4]

PHARYNGEAL SCAR. Schumacher and Hanselka first proposed a scoring system for this syndrome that focused on the pharyngeal scar.[1] This system has been adapted into a 7-point scale with 0 indicating no visible scarring. A score of 1 indicates a scar just forming on the ventral floor. A score of 2 indicates a consistent ventral scar. A score of 3 indicates a prominent ventral ridge with scarring just evident on the lateral walls of the pharynx. A score of 4 indicates a ventral scar with evidence of a dorsal scar just forming. A score of 5 indicates a complete ring with less than 25% reduction in the size of the airway. A score of 7 indicates a severe case with a complete ring that has reduced the airway over 75% (Fig. 31-67).

GUTTURAL POUCH PLICA. Occasionally scarring of the external guttural pouch plica is observed as a deformity to the guttural pouch openings.

PHARYNGEAL INFLAMMATION. The overall appearance of the pharyngeal walls should be graded with attention to degree of redness, edema, and chronic scarring. Acute/active is indicated by erythematous edematous tissue with or without discharge and no areas of scarring noted (Fig. 31-68). The level of inflammation should be graded as mild, moderate, or severe. Chronic/active is similar, with areas of active inflammation mixed with areas of previous scarring (Fig. 31-69). The degree of inflammation should be graded as mild, moderate, and acute. A chronic description is indicated when there are areas of scarring with no active inflammation (Fig. 31-70). Any level of pharyngeal lymphoid hyperplasia should be noted.

DORSAL PHARYNGEAL RECESS. The dorsal pharyngeal recess should be examined for inflammation and areas of previous scarring. Occasionally this area is the only area of inflammation noted in the pharynx. The recess should be graded as mild, moderate, severe, and chronic.

EPIGLOTTIS. The epiglottis should be examined for swelling, scarring, displacement, occlusion of the airway, and cysts. Mild changes of the epiglottis include diffuse swelling with some curling of the margins. Moderate changes, although more severe, do not occlude the airway. Severe changes are noted as scarring of the epiglottis with occlusion of the airway. Any displacement of the soft palate or epiglottic cysts should be recorded.

ARYEPIGLOTTIC FOLD. The aryepiglottic fold should be examined for edema and entrapment of the epiglottis. The abnormalities should be described as mild, moderate, or severe. Mild abnormalities are noted as minimal edema just making the fold visible. Severe changes are noted as significant edema causing the fold to overlap the arytenoid cartilages.

ARYTENOIDS. The left and right arytenoid cartilages should be evaluated for swelling, reddening, scarring, and abnormalities of abduction. Each cartilage is graded separately as having mild, moderate, or severe changes. Mild changes are noted as minimal edema/inflammation with or without reddening of the cartilage, with complete abduction. Moderate changes are noted as significant edema/inflammation with or without scarring, causing altered abduction of the cartilages. Severe changes are noted as obvious scarring of the cartilage that cannot be abducted from midline. Any laryngeal hemiplegia should be recorded.

VOCAL FOLDS. The vocal folds should be evaluated for edema and scarring. Changes in this area are common and should be recorded as present or absent.

PALATOPHARYNGEAL ARCH. The palatopharyngeal arch should be examined for edema and rostral displacement. The abnormalities should be described as mild, moderate, and severe. Mild abnormalities are noted as minimal edema causing minimal displacement. Moderate changes are noted as significant edema causing a prominent rostral displacement. Severe changes are noted as significant edema causing overlap of the palatopharyngeal arch over the apex of the arytenoids. Rostral displacement of the palatopharyngeal arch was noted in 36% of cases.[4]

TRACHEA. The proximal trachea should be evaluated for areas of edema, inflammation, and scarring, as lesions in the proximal 6 to 10 rings of the trachea are common. Changes in this area should be graded as mild, moderate, and severe. A mild change is focal to multifocal areas of inflammation not reducing the size of the airway. A moderate change is areas of inflammation causing a reduction in the airway less than 25%. A severe change causes airway reduction greater than 25%. Abnormalities in the trachea have been reported in 75% of cases.[4]

Progression This syndrome is rarely seen in horses under 4 years of age, and the length of time for an acute case to develop respiratory distress is unknown. In the author's experience the most severe cases occur in older horses.

Pathogenesis To date no specific etiology has been identified, although some risk factor analysis has been completed. A retrospective case-control study of 121 horses[2] with the nasopharyngeal cicatrix syndrome found a high association with housing on pasture or part time on pasture and with increased age. Cases of nasopharyngeal cicatrix syndrome were more likely to be presented in the summer months with acute cases also being seen in the spring and fall. No breed or sex risk factor was noted. Cases seem to be more prevalent in years with higher rainfalls, although a few new cases may be seen during times of drought.

Inhalation of larger sized particulate matter (>5 microns) is suspected to be the inciting cause as these particulates are deposited in the nasal mucosa, pharynx, larynx, and proximal trachea. This corresponds to the anatomic areas where the inflammation and

VetBooks.ir

Pharyngeal/Laryngeal Evaluation

PICTURES ON FILE
REPEAT EXAM

Name: Date:

Nasal Passage – Are lesions present?
Left nasal passage ☐ YES ☐ NO **Right** nasal passage ☐ YES ☐ NO

Pharyngeal Scar – Describe pharyngeal scar / cicatrix according to the scale below.
0. No scarring visible
1. Scarring just visible on floor of pharynx
2. Scarring on floor of pharynx w/ prominent ventral ridge
3. Prominent ventral ridge with scarring evident on lateral walls of pharynx
4. Prominent ventral ridge with scarring evident on walls and forming dorsally
5. Complete circular scar with prominent ventral ridge and just starting to constrict <25% of airway
6. Complete circular scar constricting 25-50% of airway
7. Complete circular scar constricting >50% of airway

Guttural Pouch Plica – Are alterations to plica of guttural pouch opening present?
Left plica ☐ YES ☐ NO **Right** plica ☐ YES ☐ NO

Pharyngeal Inflammation – Describe the overall inflammation of the pharynx.
None
Acute/Active – Tissue inflamed with no areas of chronic scarring noted. Score changes as mild, moderate, or severe.
Mild – Diffuse reddening with or without some yellow discharge and minimal edema
Moderate – Edema present in mucosal tissue with diffuse reddening and/or yellow discharge and plaques
Severe – Significant edema present in mucosal tissue
Chronic/Active – Areas of previous scarring visible with new areas of acute inflammation. Score changes as mild, moderate, or severe.
Mild – Diffuse reddening with or without some yellow discharge and minimal edema
Moderate – Edema present in mucosal tissue with diffuse reddening and/or yellow discharge and plaques
Severe – Significant edema present in mucosal tissue
Chronic – No edema, reddening, or yellow discharge present. Areas of scarring may be visible.
Is there lymphoid hyperplasia? ☐ YES ☐ NO

Dorsal Pharyngeal Recess – Describe the inflammation / scarring of the dorsal pharyngeal recess.
Normal
Mild – Minimal edema of tissue
Moderate – Significant edema of tissue
Severe – Severe edema of tissue obliterating the recess
C **Chronic Scarring** – No inflammation but obvious scarring present

Epiglottis – Describe changes to epiglottis. Score changes as mild, moderate, or severe.
Normal
Mild – Inflamed w/ diffuse swelling +/– curling of margins
Moderate – Scarring of epiglottis not occluding airway
Severe – Scarring of epiglottis occluding airway
Is there dorsal displacement of soft palate (DDSP)? ☐ YES ☐ NO Is there an epiglottic cyst? ☐ YES ☐ NO

Aryepiglottic Fold – Describe changes to aryepiglottic fold. Score changes as mild, moderate, or severe.
Normal
Mild – Minimal edema of fold just making it visible
Moderate – Significant edema of fold making it prominent
Severe – Severe edema of fold causing overlapping of the arytenoid cartilages
Is there an epiglottic entrapment? ☐ YES ☐ NO

Arytenoid – Describe changes to left and right arytenoid cartilages. Score changes as mild, moderate, or severe.

Left	**Right**
Normal	**Normal**
Mild – Minimal edema/inflammation with or without reddening. Maintains complete abduction	**Mild** – Minimal edema/inflammation with or without reddening. Maintains complete abduction
Moderate – Significant edema/inflammation with or without scarring. Altered but not complete abduction	**Moderate** – Significant edema/inflammation with or without scarring. Altered but not complete abduction
Severe – Obvious scarring of cartilage that cannot be abducted from midline	**Severe** – Obvious scarring of cartilage that cannot be abducted from midline
Is there laryngeal hemiplegia? ☐ YES ☐ NO *I, II, III, IV, V*	*Is there laryngeal hemiplegia?* ☐ YES ☐ NO *I, II, III, IV, V*

Vocal Folds – Are alterations to vocal folds present?
Left ☐ YES ☐ NO **Right** ☐ YES ☐ NO

Palatopharyngeal Arch – Describe changes to the palatopharyngeal arch. Score changes as mild, moderate, or severe.
Normal
Mild – Mild rostral displacement of palatopharyngeal arch
Moderate – Prominent displacement and inflammation of palatopharyngeal arch
Severe – Prominent displacement and inflammation of palatopharyngeal arch overlapping arytenoid cartilages

Trachea – Describe changes to the proximal trachea. Score changes as mild, moderate, or severe.
Normal
Mild – Focal to multi-focal areas of edema/inflammation
Moderate – Multi-focal coalescing areas of inflammation constricting airway <25%
Severe – Areas of inflammation/cicatrix constricting airway >25%

FIG. 31-66 Pharyngeal/laryngeal scoring system.

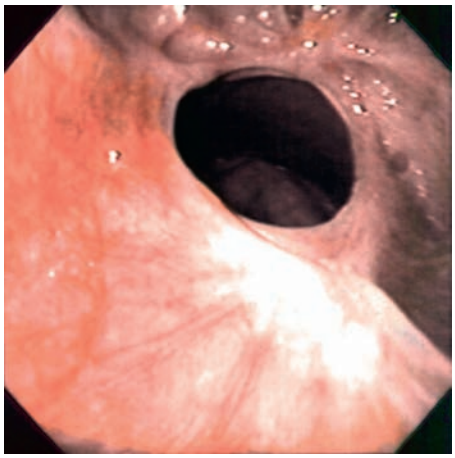

FIG. 31-67 Endoscopic image of nasopharyngeal cicatrix. This is an example of a grade 7 cicatrix.

FIG. 31-68 Endoscopic image of acute pharyngeal inflammation and swelling consistent with nasopharyngeal cicatrix syndrome.

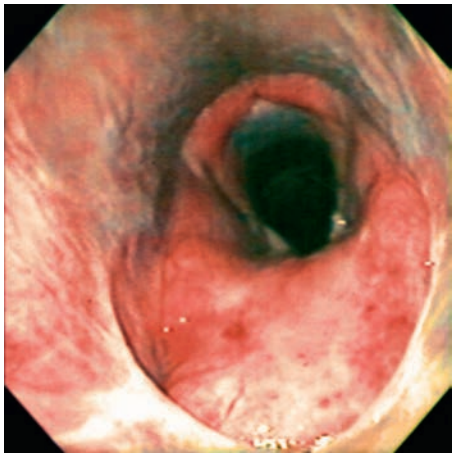

FIG. 31-69 Endoscopic image of chronic/active nasopharyngeal syndrome. There is both inflammation and swelling with a grade 3 cicatrix.

subsequent scarring are noted. Whether these particulates include bacteria, fungus, allergen, or some other irritant is not known. There is some discussion of pythium insidiosum as a possible cause, although in the author's experience this is not likely a primary pathogen in these cases.

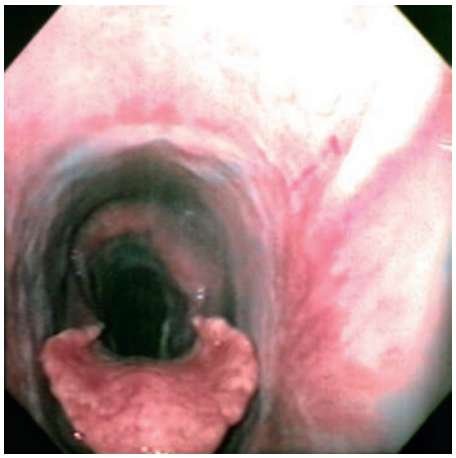

FIG. 31-70 Endoscopic image of chronic nasopharyngeal syndrome. There is scarring of the epiglottis and left arytenoid cartilage and a grade 3 cicatrix.

Treatment Because the agent or combination of agents causing this syndrome has not been identified, a single effective therapy has not been found. In addition, identification of effective treatments is complicated by the chronicity of the syndrome when it is typically first identified, the cyclical/seasonal nature of the clinical signs, and the response to changes in environmental factors. Current therapy consists of reducing exposure to pasture and reducing inflammation. No treatment has been effective if the horse remains on pasture. Surgical resection of affected areas frequently leads to excessive granulation tissue, especially after arytenoidectomy. If the airway is compromised, a permanent tracheostomy is the therapy of choice. If surgical reduction of the affected tissue is elected and the horse is not moved to a new environment, the lesions will recur.

Outcome In acute cases, simply removing the horse from pasture and feeding in a dry lot or stall resolves most of the condition. It is believed that repeat or continual exposure of acute cases lead to the chronic scarring. Once the chronic scarring has developed, it will not resolve.

Equine Influenza in Australia

James R. Gilkerson • Charles Mark El-Hage • Brett Tennent-Brown • Andrew W. Van Eps

Until 2007, Australia was one of a small number of countries that had never experienced an outbreak of equine influenza (EI). Equine influenza has never been reported in New Zealand. In August 2007 a consignment of horses was admitted into the quarantine station in Sydney, all of which had been vaccinated in accordance with Australian quarantine requirements. At least one of these horses was subclinically infected with EI. The virus spread among horses within the quarantine station and, following a breakdown of quarantine procedures, escaped into the general horse population. Because the Australian general horse population was highly susceptible to EI, the virus spread rapidly, affecting more than 76,000 horses on 10,600 premises in New South Wales and Queensland. Control of the outbreak and eradication of the virus from Australia had an estimated cost of approximately US$1 billion.

As soon as EI had been confirmed in the general population, a control and eradication program based on movement restrictions and, subsequently, vaccination was initiated. Although only two states were affected, a complete national ban on all horse movements was put in place immediately. All race meetings and other horse events were cancelled. Horses already at events were not permitted to leave until cleared by government veterinarians. Whereas movement restrictions proved highly effective in preventing the spread of virus beyond those areas affected in the first week of the outbreak,

VetBooks.ir

these restrictions were financially extremely damaging to horse-related businesses. To alleviate some of the economic concerns, especially those of the breeding industry, some movement restrictions were eased to allow the breeding season to proceed.

At the time of the outbreak in August 2007 there were no EI vaccines registered for use in the Australian general horse population. When additional measures were required to contain the outbreak, an emergency use permit was issued in September 2007 for a canarypox-vectored recombinant EI vaccine (ProteqFlu, ProteqFlu-TE [Merial, Lyon, France]). This vaccine was selected for several reasons, including rapid onset of immunity[1]; the ability to differentiate vaccinated horses from those naturally infected; and reports of efficacy in the South African 2003/2004 outbreak.[2] Vaccination was initially employed to create buffer zones around infected areas to contain spread of the epidemic. Horses inside the infected areas on unaffected properties were subsequently also vaccinated. Most horses received a primary course booster at 4 weeks (the recommended interval); however, some horses received an accelerated primary course schedule with the interdose interval reduced to 14 days.[3,4]

Approximately 4 months after the outbreak commenced, the last reported infected premise was reported. Provisional freedom from disease was declared in March 2008, and EI-free status was confirmed by the OIE (World Organisation for Animal Health) the following year.

The EI virus isolated from horses in the quarantine station and horses in the general population was named A/equine/Sydney/2888-8/2007 (H3N8).[5] Following molecular characterization, the virus was classified as an American lineage, Florida sublineage, Clade 1 type[6] and is phylogenetically similar to the EI viruses that were circulating in Japan and the United States at the time.[7]

Clinical disease caused by the EI virus in adult horses was considered mild in the vast majority of cases; however, secondary bacterial bronchopneumonia was described as a complication and occasional cause of death in predominantly mature horses.[8] Infection of late gestation mares was associated with increased severity of clinical signs and neonatal morbidity.[8,9] A fatal bronchointerstitial pneumonia associated with EIV infection was reported in several foals from infected properties.[10]

Hendra Virus

Andrew W. Van Eps • Brett Tennent-Brown • Charles Mark El-Hage

Hendra virus (HeV) was first identified in September 1994 following the deaths of 14 Thoroughbred horses and 1 human during an outbreak of respiratory disease at racing stables located in Hendra, Queensland, Australia.[1] Severe, acute respiratory disease due to HeV occurred sporadically over the subsequent 14 years; however, neurologic signs have predominated in cases since 2008. In 2011 there was a marked increase in HeV incidence (18 separate incidents in total) occurring over a wider geographic area than previously reported. At the time of writing, infection has been confirmed in a total of 56 horses, 7 humans (with 4 human fatalities), and 1 dog (seroconversion without clinical signs) in the states of Queensland and New South Wales.

Epidemiology

Hendra and the closely related Nipah viruses together form the genus *Henipavirus* in the family Paramyxoviridae. The natural hosts for HeV are fruit bats (flying foxes or *Pteropodidae* spp.), which are widely distributed throughout northern and eastern Australia.[2] Hendra virus infection of fruit bats is asymptomatic and apparently widespread. Serologic surveys indicate a high prevalence of HeV antibodies in fruit bats, including those in areas where equine or human disease has not been documented. In infected bats, HeV can be detected in urine, uterine fluids, placental tissues, and aborted pups.[3]

The majority of equine cases have occurred between June and December, although the reason for this apparent seasonality is unclear. On many occasions, the index case has been a horse that is kept outdoors in an area attractive to fruit bats. The mechanism of virus transmission to horses is not completely understood but likely follows ingestion of contaminated feed or water.[3] Horse-to-horse (and horse-to-human) transmission requires close contact with body fluids (particularly respiratory secretions) and appears to occur infrequently in horses kept at pasture but more efficiently in stabled horses.[4] HeV uses the cell surface receptors ephrin-B2 and ephrin-B3 that are widespread on vascular endothelium.[5] As a consequence, HeV infection of horses results in a vasculitis that affects, in particular, the respiratory and central nervous systems.

Hendra virus poses a serious zoonotic risk to animal caretakers and attending veterinarians. Although the risk of viral transmission increases as the disease progresses, virus is shed at low levels prior to the appearance of clinical signs in experimental infections. Horse-to-human transmission is thought to require direct physical contact with nasopharyngeal secretions; however, the virus can survive for several hours in the environment, and transmission by fomites might be possible. The risk of transmission to humans is particularly high in the terminal stages of disease and postmortem. Postmortem examinations should be postponed in suspect cases until HeV infection has been ruled out by appropriate testing.

Clinical Signs

In experimental infections, the incubation period ranges between 5 and 16 days in horses and 5 and 21 days in humans.[4,6,7] Prior to 2008, signs of acute severe respiratory disease predominated in HeV infections. However, since 2008, neurologic signs have been described more commonly and might be the result of a minor genetic change to the virus. Approximately 75% of cases are fatal, and these typically progress rapidly. Sudden death of one or more horses without obvious signs of illness should raise suspicion of HeV infection. Clinical signs in animals that survive beyond the peracute stages include pyrexia, depression, and signs of respiratory and/or neurologic disease. Signs related to respiratory tract involvement include tachypnea, respiratory distress, and a frothy nasal discharge. Commonly described neurologic signs include weakness, collapse, and an inability to rise; ataxia; altered mentation; central blindness; head tilt and circling; and urinary incontinence. Additional clinical signs might include tachycardia, frequent weight shifting or restlessness, muscle fasciculation, colic, and facial swelling or edema.

Pathology

Gross changes at postmortem include edematous (submandibular and bronchial) lymph nodes, dilated pulmonary lymphatics, subpleural hemorrhages, and pulmonary consolidation and edema. Edema of other tissues might also be apparent. Histologically, HeV infection is characterized by a systemic vasculitis, particularly of the respiratory tract, brain, and meninges. In addition to edema, syncytial cells, viral inclusion bodies, and alveolitis can be seen in pulmonary tissues. Perivascular lymphocyte cuffing, neuronal necrosis, and focal gliosis have been observed in the brain.

Diagnosis

In regions where the virus is known to occur, HeV infection should be considered in any horse exhibiting a high fever and signs of acute lower respiratory tract or neurologic disease. Hendra virus infection should also be considered in cases of sudden death. Differential diagnoses for HeV infection include plant (e.g., Crofton weed, avocado) or ionophore toxicity; bacterial pneumonia; and viral encephalitis/meningoencephalitis (e.g., equine herpesvirus 1 [EHV-1], flavivirus infection).

Laboratory testing is essential for confirmation or exclusion of HeV infection and includes virus isolation, detection of viral nucleic acid in body fluids or tissues, and demonstration of specific serum antibodies. Blood, nasal swabs, oral swabs, or rectal mucosal swabs are suitable for quantitative real-time reverse transcriptase polymerase chain reaction (qRT-PCR) testing of both living and dead horses. However, samples collected very early in the disease incubation period can produce a negative result by qRT-PCR testing. Detailed guidelines for sample collection, handling, and submission

VetBooks.ir

are available from local Australian government sources (e.g., the Department of Primary Industries). Appropriate personal protective equipment (protective eyewear, particulate mask, impervious gloves, and gown) must be worn when collecting samples from suspect horses. Postmortem examinations pose the highest transmission risk for humans, and necropsies of suspect cases should be postponed until HeV infection has been ruled out.

Treatment and Prevention In regions where HeV occurs, owners are advised to reduce contact between fruit bats and horses. Recommendations include the following: avoid placing feed or water beneath trees in which fruit bats might roost, limit horse access to flowering or fruiting trees that might attract fruit bats, and stable horses at dusk and overnight when fruit bats are most active.

In November 2012, a subunit, adjuvanted vaccine containing soluble HeV G-proteins was released under a "minor permit" requiring strict conditions for its use.[8] All vaccinated horses must be identified by microchip prior to vaccination and the two doses of vaccine must be administered exactly 21 days apart. Effective antibody levels were present 21 days after administration of the second dose and prevented infection in limited experimental trials. The duration of protection is currently unknown. At present, treatment of confirmed cases is not permitted and all horses infected with HeV must be euthanized.

Crofton Weed Poisoning (Numinbah Horse Sickness, Tallebudgera Horse Disease)

Andrew W. Van Eps • Brett Tennent-Brown

The plant *Eupatorium (Aregatina) adenophora* is native to Central America but now appears as an intractable weed in many countries, including Australia and New Zealand.[1] Ingestion of large quantities of *E. adenophora* causes a pneumotoxicosis characterized by increased respiratory effort and rate. Outbreaks of respiratory disease caused by *E. adenophora* were reported in Southern Queensland and New South Wales in the 1940s and have occurred periodically since then.[1] Respiratory disease caused by *E. adenophora* has also been reported in New Zealand. The related species *Eupatorium riparium* is a perennial weed in Queensland and New South Wales and causes a similar syndrome in feeding trials. However, field cases of disease caused by *E. riparium* have not been reported.[2]

Epidemiology Respiratory disease caused by *E. adenophora* has been described in horses aged between 18 months and 12 years with no gender predilection. Horses appear to be the only large animal species affected. Flowering stages are more toxic than non-flowering stages and most cases occur during the summer following ingestion of the plant in spring.[1,3] There is typically a minimum of 2 months between plant ingestion and the appearance of clinical signs.[2]

Clinical Signs The earliest clinical sign noted in affected animals is coughing that is exacerbated by exercise.[1,3] Respiratory rate and effort are markedly increased and, in some cases, a double expiratory effort is apparent. Affected horses have reduced exercise tolerance and adventitial sounds may be appreciated on thoracic auscultation. Severely affected horses experience weight loss and may be cyanotic. Cardiac arrhythmias that can result in sudden death develop in some horses.[1,3]

Pathology The toxic principle of *E. adenophora* is unknown.[2] Pyrrolizidine alkaloids are suspected because of the condition's similarity to *Crotalaria*-associated lung disease ("jaagsiekte") seen in South African horses. The toxin (or toxins) appears to be absorbed from the gastrointestinal tract, and inhalation of plant material (e.g., pollen) is not required for disease.

At necropsy, the lungs are firm and do not collapse on opening the thorax. Pulmonary fibrosis is widespread, and there may be cavities containing necrotic material within the parenchyma. The visceral pleura are often thickened and white in appearance with focal adhesions to the parietal pleura. Hydrothorax, pulmonary edema and emphysema, hydropericardium, and cardiac dilation may be found in horses dying suddenly.[1,3]

Sheets of epithelial-like cells lining the alveoli are apparent on histologic examination. Accumulations of inspissated protein are present within the alveoli of most chronic cases, and eosinophils and neutrophils commonly fill the bronchioles and surrounding alveoli.

Treatment No effective treatment is known; once diagnosed, the condition is irreversible although antimicrobials and corticosteroids have improved clinical signs in some cases.

Ruminant Respiratory System

Amelia R. Woolums, *Consulting Editor*

Upper Respiratory Tract Diseases

Amelia R. Woolums[‡]

Diseases of the Nasal Cavity

Amelia R. Woolums

Mycotic or Bacterial Nasal Granuloma

Infectious granulomas in the nasal cavity of ruminants are not common. Documented causes include the fungal organisms *Rhinosporidium seeberi* and other *Rhinosporidium* spp. (which cause rhinosporidiosis), *Helminthosporium* spp. (which cause maduromycosis), *Drechslera rostrata, Aspergillus* spp., *Phycomycetes* spp., *Stachybotrys* spp., and *Bipolaris* spp. Nasal granuloma caused by *Nocardia* spp. bacteria has also been reported.[2] There is no apparent age, breed, or seasonal predilection, and cases are sporadic. The major clinical signs are upper respiratory noise (stridor), dyspnea, and mucopurulent nasal discharge, sometimes with epistaxis. Affected animals may rub the nose, suggesting pruritus or irritation. Nasal airflow may be reduced, and open-mouth breathing may occur in advanced cases. Hot or dusty weather may accentuate the signs, giving the appearance of seasonal exacerbation, but the lesions are progressive. The granulomas may be single or multiple, unilateral or bilateral, and located anywhere in the nasal cavity. They consist of 0.5- to 5-cm yellow to yellow-green or red nodules or polyps, which may be sessile or pedunculated. Rhinosporidiosis tends to be a single unilateral polyp in the posterior nasal cavity, and maduromycosis tends to occur in

[‡]Previous contributions by John C. Baker and John A. Smith are acknowledged.

VetBooks.ir

the anterior cavity, but these distinctions are not consistent. Red and black spots (spores) may occur on the masses, and some may become secondarily infected with bacteria and ulcerate. Differential diagnoses include allergic rhinitis, foreign bodies, tumors, nasal actinobacillosis, nasal actinomycosis, and *Oestrus ovis* infection in small ruminants.

Endoscopy, biopsy, and culture of the lesions aid in the diagnosis. Histopathologic analysis reveals granulation tissue containing eosinophils, mononuclear cells, round sporangia, and sometimes hyphae or filamentous bacteria.[1,2] The pathogenesis of the disease involves inoculation of eroded nasal mucosa with fungal spores or filamentous bacteria from the environment. The infectious agent causes a chronic delayed (type IV) hypersensitivity reaction, which eventually leads to the formation of a granuloma. Fungal granulomas can be more common in warm, wet climates. The granulomas can be difficult to treat and, although rarely fatal, the disease is chronically debilitating, with salvage often being the most practical solution.

Recommended treatments include surgical removal of the granulomas when possible and long-term sodium iodide (NaI) therapy. NaI can be administered at a dose of 66 mg/kg IV as a 20% solution, repeated at 10- to 14-day intervals until remission or iodism occurs. Iodism is characterized by lacrimation, cough, and scaling of the skin. The use of antifungal drugs to treat this condition in ruminants has not been reported.

Allergic Rhinitis and Enzootic Nasal Granuloma

Allergic rhinitis occurs in cattle and in its chronic stages may lead to the formation of granulomas. A similar condition may occur in sheep.[3] The inciting antigen is frequently a plant pollen or more likely a fungal spore.[4] Once homocytotropic antibody (immunoglobulin E or possibly other classes in cattle) to the allergen has developed, subsequent exposure results in a localized, ongoing, immediate (type I) hypersensitivity reaction.[4-6] If recurrent exposure to the allergen occurs, repeated tissue damage by mast cell factors results in chronic epithelial, duct, and goblet cell hyperplasia and metaplasia, as well as mucous hypersecretion and granulomatous inflammation, suggesting that a type IV hypersensitivity reaction contributes to the chronic lesion.[4,5,7]

Any breed may be affected, but Channel Island breeds and Friesians seem most susceptible.[4] The disease occurs sporadically in the United States. A familial predisposition has been reported.[8] Most affected animals are between 6 months and 2 years of age. The signs are initially seasonal, usually occurring in warm, moist conditions; they include rhinorrhea, sneezing, nasal pruritus, a sudden onset of dyspnea, and stertorous inspiration.[8,9] There is a profuse bilateral nasal discharge. Intense pruritus is characteristic and associated with sneezing, headshaking, and nose rubbing.[9] In severe cases facial swelling, tachypnea, hyperpnea, and ulceration of the nasal mucosa may occur.[5,9] Nasal foreign objects may result from the animal's attempts to scratch the nasal mucosa. Lacrimation, chemosis, and blepharitis may also be present. In the chronic stages (the "enzootic nasal granuloma"), the signs are more constant, with seasonal exacerbations.[5,7,9] The granulomas tend to be multiple, firm, white, raised nodules 1 to 2 mm in diameter with an intact mucosa or pale pink flat plaques scattered throughout the nasal cavity. Differential diagnoses include fungal granulomas, foreign bodies, respiratory viruses, nasal actinomycosis or actinobacillosis, tumors, *O. ovis* infection (small ruminants), and irritation caused by inhalation of hot or irritant gases.

Endoscopy, biopsies, cultures, antigen detection tests for viruses, bacteria, or fungi, and serologic analysis can be used to rule out these differential diagnoses. Eosinophil counts in nasal secretions correlate with the susceptibility of the animal and activity of the disease, but no absolute level is diagnostic.[4] Intradermal allergen testing has been suggested to aid in diagnosis, but interpretation of results needs to be done in conjunction with historical and clinical findings.[6] This condition should be differentiated from fungal or bacterial granuloma because the therapy is different.

Treatment and control entail removal of the allergen, or removal of the animal from the allergen, and therapy to block the hypersensitivity reaction. Recommended drugs include various antihistamines, meclofenamic acid, and corticosteroids at standard antiinflammatory doses (0.05 to 0.2 mg of dexamethasone per kilogram IM or IV or 1 to 2.2 mg of prednisolone per kilogram IM or IV daily). Topical corticosteroid therapy can be considered in severe, acute occurrences of the disease. The adverse effects of corticosteroids on milk production and their potential to induce abortion or parturition should be considered before their use. Antihistamine therapy has had equivocal results.[6]

Nasal Foreign Bodies

Cattle are more prone than small ruminants to the acquisition of nasal foreign bodies. Foreign objects may be acquired as a result of attempts to scratch the nose in cases of allergic rhinitis or because of the cow's aggressive eating habits. Depending on the size and duration of residence of the object, signs may include headshaking, stridor, sneezing, snorting, frequent nose licking, unilateral decreases in airflow, foul odors, and serous, mucopurulent, or hemorrhagic discharges. Differential diagnoses include fungal granulomas, allergic rhinitis, tumors, nasal actinomycosis or actinobacillosis, and *O. ovis* (small ruminants). Many objects can be visualized on careful examination of the nasal cavity with an adequate light source, whereas some may require endoscopy for diagnosis and removal.

Nasal Trauma and Fractures

Trauma to the facial bones, sinuses, and turbinates may result from fighting, accidents caused by improper restraint, farm machinery accidents, human maliciousness, and passage of excessively large nasogastric tubes. Severe fractures can lead to facial swelling, subcutaneous emphysema, obstruction of airflow, stertor, and epistaxis. Secondary infection causes foul odors and mucopurulent nasal discharge. Differential diagnoses for the acute external swelling of the head with stertor include snakebite, actinobacillosis, actinomycosis, and phlegmon (*Fusobacterium, Clostridium* spp.). Unless the development of severe depression fractures, formation of sequestra, or severe obstruction of airflow occurs, surgery is usually not indicated. Radiographs confirm the diagnosis and help determine the need for surgical removal of potential sequestra or elevation and fixation of large displaced segments. Prophylactic antibiotics (typically penicillin G procaine, 22,000 IU/kg IM q12-24h) are recommended to prevent fracture infection and sinusitis, and nonsteroidal antiinflammatory drugs (aspirin, 100 mg/kg PO q12h; flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help relieve pain, swelling, and stridor. The prognosis is usually good.

Nasal Tumors and Polyps

Tumors and polyps of the nasal cavity and sinuses are rare in ruminants. Nasal tumors reported in cattle include osteomas and osteosarcomas of the sinuses, squamous cell carcinomas,[10] neuroblastomas, and adenocarcinomas of the ethmoid mucosa. Ethmoid adenocarcinomas are speculated to be caused by viruses on the basis of an endemic pattern in some cases.[11] They tend to occur in cattle 6 to 9 years of age and are frequently unilateral. Metastasis occurs to the lymph nodes and lungs. There is a report of a hemangiosarcoma involving the external naris of a cow.[12] Signs common to all nasal tumors include mixed or inspiratory dyspnea, stridor, nasal discharge, epistaxis, foul breath odors, unilateral decreases in airflow, open-mouth breathing, and distortion of the facial bones. Differential diagnoses include fungal granulomas, atopic granulomas, foreign bodies, sinusitis, fractures, and nasal actinobacillosis and actinomycosis. Treatment has not been investigated.

The majority of nasal neoplasms in sheep and goats are adenopapillomas, adenomas, or adenocarcinomas.[13] Squamous cell carcinoma[14] has also been reported. An enzootic form of nasal adenocarcinoma occurs in both sheep and goats and is associated with ovine nasal adenocarcinoma virus (ONAV)[15,16] or caprine nasal adenocarcinoma virus (CNAV),[17] respectively. These agents are

VetBooks.ir

β retroviruses that are closely related to, but distinct from, jaagsiekte sheep retrovirus (JSRV), the cause of ovine pulmonary adenocarcinoma (OPA).[17,18] Although nasal adenocarcinoma has been difficult to consistently reproduce experimentally, inoculation of kids with concentrated cell-free and bacteria-free filtrate containing virus from naturally infected goats has resulted in disease.[19] Neoplastic transformation is limited to secretory epithelial cells of the nasal turbinates, but CNAV appears to have a wider tissue tropism than ONAV; in one study viral provirus incorporated into host DNA was found in many tissues of infected goats but was largely confined to tumor tissue of infected sheep.[17] There is no breed or sex predisposition for enzootic nasal adenocarcinoma; affected animals are most commonly young adults, but the tumor has been identified as early as 4 months of age.[15] Signs include progressive inspiratory dyspnea; stridor; exercise intolerance; mouth breathing; serous, mucoid, or mucopurulent nasal discharge, which is typically profuse; tachypnea; decreased airflow; headshaking; sneezing; exophthalmos; and facial asymmetry. The lesions may be unilateral or bilateral, originating in the olfactory region of the ethmoid turbinates. The neoplasia arises either from Bowman glands or serous glands of the nasal mucosa. The tumor begins as a small nodule that can grossly resemble the mucoid polyps that occur in animals with chronic rhinitis. Over time the adenocarcinoma grows into a soft, gray to grayish pink, mucoid, nodular, cystic mass. The tumor is benign but locally expansive, often entering the sinuses and eroding overlying bone. Histologically the tumor is typically classified as a low-grade adenocarcinoma, but it may also be identified as an adenopapilloma or adenoma. In the initial stage, affected animals eat and drink normally and maintain body condition, but as the tumor expands the animal begins to lose condition, and death eventually occurs as a result of inanition, asphyxia, or aspiration pneumonia. Necrosis or secondary bacterial infection of the tumor can occur and may lead to the production of foul-smelling, purulent discharge and systemic signs related to bacterial infection, such as fever, depression, and hyperemic mucous membranes.

Differential diagnoses for nasal neoplasia in small ruminants include nasal fungal or bacterial granuloma, actinobacillosis, actinomycosis, *O. ovis* infection, and sinusitis. Endoscopy and radiology are helpful in establishing an initial diagnosis of a nasal mass. Preoperative or antemortem punch biopsies and exfoliative cytologic analysis frequently are nondiagnostic, and findings may be misleading.[13,14] Identification of tumors in multiple animals in a herd or flock supports a diagnosis of enzootic nasal adenocarcinoma. Definitive identification of infection with ONAV or CNAV can be difficult. Serologic tests are not reliable because animals do not consistently produce antibody to the viruses,[20] possibly because of the presence of endogenous retroviruses[21] that share epitopes with ONAV and CNAV and induce the development of immunologic tolerance. Polymerase chain reaction has been used to specifically identify and differentiate ONAV, CNAV, and JSRV in tissues of affected animals.[22] Surgical management of nasal adenocarcinoma in sheep has been described.[23]

Oestrus ovis Infestation

Amelia R. Woolums

Definition and Etiology *O. ovis* is parasite of the nasal passages and sinuses of sheep and, less commonly, goats. Goats are relatively resistant to infection and, even when housed with sheep, tend to have a lower prevalence of infection.[1] Occasionally humans and other animals are accidentally infected, with conjunctival infection the most common form of disease in humans.[2,3] The pathogenic stage of the parasite is the larval stage. The first instar larvae are deposited near the nostrils of sheep by the adult female fly and migrate into the nasal and ethmoid turbinates; in the ethmoids the larvae molt to second instars, which migrate to the sinuses before molting again and becoming third instar larvae. Third instar larvae, which are yellow-white in color and have a dark dorsal stripe with rows of spines on the ventrum of each segment, return to the nasal passages and are sneezed out onto the ground, where they pupate and eventually develop into adult flies.[4,5] The adult is active during warm months, and the parasite may overwinter either as a first instar larva in the host or as a pupa in the ground. Larvae can persist in the upper airways for weeks to months and appear to be able to arrest development for a period of time if necessary to avoid climate extremes.[6] Adult flies have a rudimentary mouthpiece and are not able to feed; thus the larvae must ingest adequate nutrients while in the host to support the life of the adult fly.[7]

Clinical Signs The larvae cause irritation of the nasal passages and sinuses, leading to mucoid to mucopurulent and sometimes blood-tinged nasal discharge, sneezing, nose rubbing, and inspiratory stridor. Adult flies cause annoyance by flying around the heads of animals; thus both stages can lead to decreased productivity by decreasing the time spent grazing by affected animals. Occasionally the larvae may cause sinusitis or pneumonia owing to secondary bacterial infection associated with irritation caused by the larval infestation. Differential diagnoses to consider include nasal foreign bodies, allergic rhinitis, nasal adenocarcinoma, fungal rhinitis, trauma, sinusitis, actinobacillosis, or actinomycosis.

Pathogenesis The larvae cause direct irritation to the nasal passages and sinuses, and this irritation may predispose animals to the development of secondary bacterial rhinitis, sinusitis, and/or pneumonia. Interstitial pneumonia has also been seen on occasion in affected sheep, presumably induced by inhalation of parasite antigens and inflammatory mediators from the upper respiratory tract.[8]

Epidemiology Infection is more common in warm climates. European surveys have identified *O. ovis* in 35% to 91% of sheep surveyed,[9,10] with seroprevalences of 46% to 69%.[1,10,11] A majority of flocks surveyed had at least one infected animal.[1,9] No North American reports describing the prevalence of *O. ovis* infestation have been published in recent decades.

Diagnosis Diagnosis is usually presumptive, based on typical clinical signs. The larvae can also be identified via radiographs of the head or by endoscopy, but these tests may not be practical for field use. Serologic diagnosis has been used for research studies of the epidemiology of *O. ovis* infection, but these tests are unlikely to be available at most diagnostic laboratories.

Treatment and Prevention The larvae are susceptible to ivermectin at 200 µg/kg PO.[12] Moxidectin at 0.2 mg/kg as a 0.1% oral drench was not effective against *O. ovis*[13]; these investigators found that the same dose given as a 1% injectable solution was effective, but this route is not approved in the United States. Pour-on eprinomectin at 0.5 mg/kg (applied immediately after shearing)[14] and injectable doramectin at 200 µg/kg IM[15] have also been shown to be effective in sheep, but these treatments are also not approved for use in sheep or goats in the United States. Because the adult fly should be killed by freezing weather, in areas with a season of freezing weather it is logical to treat after the first hard freeze, when sheep will no longer be susceptible to infection until warm weather returns. Prevention is aimed at regular strategic treatment with effective anthelmintics to prevent long-term infection with the larvae.

Congenital Cystic Nasal Turbinates in Cattle

An apparently developmental anomaly that results in signs of nasal obstruction has been reported in cattle.[1] The nasal conchae lack the normal communication with the nasal cavity and become filled with a thick white fluid, which may account for the enlargement. Signs are evident at or near birth and include progressive stridor, tachypnea, decreased airflow, exercise intolerance, mouth breathing, and short, convex nasal bones. Digital, radiographic, and endoscopic examinations of the nasal cavity reveal large, smooth, bilateral cystic ventral nasal conchae, often bilobate. Differential diagnoses include foreign

bodies, trauma, and tumors. Surgical removal of the conchae with bilateral dorsolateral nasal bone flaps relieves the obstruction. Transnasal removal using obstetric wire has been described.[2]

Diseases of the Sinuses

John R. Pascoe

Sinusitis

Definition and Etiology Inflammation of the paranasal sinuses is most common in cattle and occurs infrequently in sheep and goats. Typically the frontal or maxillary sinuses are involved, and a variety of bacteria may be isolated. The proximate cause for infection is usually dehorning (frontal sinusitis) or infected teeth (maxillary sinusitis). Other causes include extension of actinomycosis or nasal neoplasia into the sinus, injuries to the horn, facial fractures, respiratory viruses (including malignant catarrhal fever, infectious bovine rhinotracheitis [IBR], and parainfluenza viruses), sinus cysts,[1] lymphosarcoma,[2] and *O. ovis* (in sheep).

Clinical Signs and Differential Diagnosis Sinusitis associated with dehorning may be acute or may occur weeks to months later; typically only one sinus is affected. Nonspecific clinical signs include anorexia, lethargy, reluctance to move, and fever. When sinusitis occurs acutely after dehorning, the portal of entry is frequently open and discharging pus, and the animal is often febrile (39.5° C to 40.5° C). In chronic sinusitis, signs may include unilateral or bilateral nasal discharge, mild stridor, changes in airflow, and foul breath odors that are frequently unilateral; fever is not common. The animal may hold its head at an odd angle (extended up or down, tilted) and may squint the eyelids as if in pain.[3,4] With chronicity, frontal bone distortion, exophthalmos, and neurologic signs may occur.[4,6] In one report of 12 cattle with frontal sinusitis, 4 cattle had abnormal posture, with an extended head and neck, partially closed eyes, and a tendency to head-press or to rest the head on a stationary object; the other 8 cattle were apprehensive and intolerant of head manipulation.[4] Extension of infection may involve the central nervous system.

Occasionally sinusitis irritates the animal sufficiently that it may rub its head on the ground, driving more debris into the sinus. Maxillary sinus cysts have been observed in cattle.[1] Typical signs included unilateral facial swelling over the affected sinus; mucopurulent, nonfetid nasal discharge; and radiographic evidence of septal deviation. One cow had stertorous respiration with diminished airflow. Differential diagnoses for sinusitis include facial fractures, nasal tumors, actinomycosis, actinobacillosis, retrobulbar abscess, and lymphosarcoma.

Diagnosis Diagnosis can usually be made based on clinical signs. Diagnostic aids may be useful in selected cases, particularly when there is no recent history of dehorning, or in cases of maxillary sinusitis. The hemogram is quite variable and is of little assistance in diagnosis. Percussion of the sinus may reveal a dull, full sound and may elicit pain. If the bone has been greatly thinned and has gas underlying it, percussion may produce a hyperresonant sound. Fractures, soft-tissue masses, dental disease, fluid in the frontal sinus, or lysis of bony septa may be evident on radiographs.[4] Sinus centesis may yield purulent material, which should be cultured and examined cytologically. A small area over the affected sinus is clipped and surgically prepared, and local anesthetic is infiltrated subcutaneously. Then a small stab incision is made through the skin and periosteum, and a Steinmann pin is used to drill a small hole. Polyethylene tubing is inserted, and attempts are made to aspirate material. A small amount of sterile isotonic fluid can be injected and aspirated to obtain a washing. The stab incision is closed unless sinusitis is confirmed.

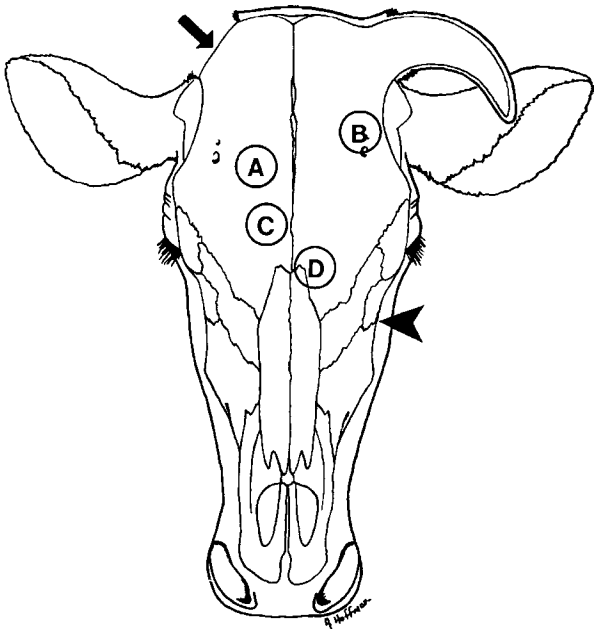

FIG. 31-71 Trephine sites for sinusotomy. **A,** Dorsal frontal sinus. **B,** Postorbital diverticulum. **C,** Rostral frontal sinus. **D,** Turbinate portion of frontal sinus. The maxillary sinus is trephined ventral to a line from the infraorbital foramen to the medial canthus *(arrowhead)*. If draining tracts are present at the poll, an additional sinusotomy can be made in the cornual portion of the frontal sinus *(arrowhead)*.

Treatment and Prognosis Trephine sites for sinusotomy (Fig. 31-71) are as follows:

1. Dorsal frontal sinus
2. Postorbital diverticulum
3. Rostral frontal sinus
4. Turbinate portion of the frontal sinus
5. Maxillary sinus

Cattle that have frontal sinusitis after dehorning should be treated by sinusotomy and drainage of the sinus.[7] Sinusotomy sites should be based on anatomic landmarks[4] and modified as needed to accommodate any frontal bone distortion or wounds related to dehorning.[4] Sinusotomy should be performed 3 to 4 cm from midline, intersecting a line drawn between the caudal aspect of the orbits. If draining tracts are present at the poll, an additional sinusotomy can be made in the cornual portion of the frontal sinus.[4] Sinusotomy is performed after sedation and local anesthetic infiltration of the centesis site(s). A 2-cm-diameter circular piece of skin is excised, and a 19-mm (¾-inch) trephine used to create an opening into the sinus, through which purulent fluid should be evacuated and the sinus lavaged.

Additional trephine sites that permit access to other regions of the frontal sinus include the postorbital diverticulum, which is trephined approximately 4 cm caudal to the dorsal rim of the orbit, just above the temporal crest of the frontal bone; the rostral frontal sinus, which is trephined just caudal to a line between the centers of the orbits and to either side of the midline; and the turbinate portion of the frontal sinus, which is trephined just rostral to the line described and to either side of the midline.

Access to the maxillary sinus is achieved by trephining ventral to a line from the infraorbital foramen to the medial canthus. If an infected tooth is the cause of maxillary sinusitis, a sinusotomy is created with a trephine over the affected tooth to repel it; otherwise, the hole is usually made just dorsal and caudal to the facial tuberosity. The trephine site should be higher in the sinus of younger animals because the tooth roots are longer.

If the frontomaxillary and nasomaxillary openings are still patent, one trephine site may be sufficient, with the natural opening providing ventral drainage. In more chronic cases, two trephine sites (for

VetBooks.ir

VetBooks.ir

ingress and egress) are needed. Another alternative in chronic sinusitis is the use of a curved steel sinus probe (1 cm diameter × 55 cm long), which is forcefully driven through the septal plates of the frontal sinus into the nasal meatus for ventral drainage.[8] The frontal sinus is very compartmentalized in mature sheep and goats, and effective drainage is difficult. Therapy should therefore be aggressive in these species, even in early cases, and double trephination or bone flaps for exposure and curettage should be considered.

If a tooth has been repelled, a roll of gauze or dental impression material should be used to occlude the alveolar socket to prevent feed material from entering the sinus. A strip of umbilical tape tied around the gauze roll or a wire in the dental material is passed through socket, sinus, and trephine hole and secured to the face by tying around another roll of gauze as a stent. These gauze packs are replaced each time the sinus is flushed. The sinus is lavaged daily with dilute antiseptic solutions such as 0.1% povidone iodine or chlorhexidine in saline. Lavage is continued until infection is resolved. Enzymes (papain or 200,000 U of streptokinase and 50,000 U of streptodornase in at least 10 mL of normal saline solution) may help remove thick exudate.

Parenteral antibiotics and NSAIDs (aspirin, 100 mg/kg PO q12h or flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) are indicated if systemic signs are present. In the absence of microbial culture and susceptibility results, penicillin G procaine (22,000 U/kg IM q12h) is recommended as the antibiotic of choice because *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) is the most common organism isolated from cattle with chronic frontal sinusitis resulting from dehorning. *Pasteurella multocida* is the most common organism isolated from infections of the frontal sinus not associated with dehorning.[4] Penicillin may be effective against some isolates of *P. multocida;* alternatively, oxytetracycline can be administered if *P. multocida* is suspected (11 mg/kg IV or SC q24h, or 20 mg of long-acting oxytetracycline per kilogram SC q72h). If bacterial culture and susceptibility results are available, antimicrobial therapy should be modified accordingly. Early cases often resolve in 10 to 14 days, with a good prognosis. Long-term therapy (weeks) is frequently needed in chronic cases; the prognosis is more guarded, and salvage is often the best option.

Prevention and Control Dehorning ruminants as neonates, particularly if a "closed" method such as a dehorning iron is used, is the most effective way to prevent frontal sinusitis. In larger cattle, surgical dehorning with primary skin closure achieved under aseptic conditions minimizes the likelihood of sinusitis.[9] When this is not practical, dehorning should be avoided in rainy, windy, or dusty conditions, and fly control must be used. The dehorning of mature sheep or goats leaves massive wounds that typically take 4 to 6 weeks to close by second intention and so are susceptible to infection; special care, such as bandaging for the initial 7 to 10 days, must be taken.[10] Sinusitis did not occur in goats aged 2 to 24 months dehorned with a technique in which primary skin closure was achieved.[11]

Diseases of the Pharynx, Larynx, and Trachea

Amelia R. Woolums[§]

Pharyngeal Trauma, Abscesses, Cellulitis, and Granulomas

Definition and Etiology Pharyngeal trauma may result in hematomas, foreign body granulomas, cellulitis, or abscesses. Trauma usually results from careless use of balling guns, dose syringes, paste-type anthelmintics or calcium preparations, specula, and stomach tubes. Rough, stemmy feeds (especially when chopped), grass awns, briars, and foreign objects (e.g., nails, baling wire) may also cause punctures. Migrating foreign objects or medications (e.g., mineral oil, anthelmintics) may cause pharyngeal granulomas. Hematomas and puncture wounds often result in abscess formation. Diffuse cellulitis may also result. Common bacteria involved include *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Actinobacillus* spp., *Pasteurella* spp., *Bordetella* spp., *Fusobacterium necrophorum,* and *Streptococcus* spp. In cases of particularly virulent bacterial invasion, the condition can become rapidly fatal. *C. pseudotuberculosis* (caseous lymphadenitis) may localize in the pharyngeal nodes of sheep and especially goats. Caseous lymphadenitis is discussed later in this chapter and also in relation to the hemolymphatic system in Chapter 37.

Clinical Signs and Differential Diagnosis Signs of pharyngeal trauma vary with the severity of the resulting reaction (e.g., peracute cellulitis vs. chronic abscess or granuloma). Prominent signs include inspiratory dyspnea with stertorous inspiratory sounds and a prolonged inspiratory phase; extended head and neck; ptyalism, which is often profuse; quidding; evident pain on swallowing or reluctance to swallow solid feed but willingness to drink liquids; prolonged chewing of boluses; regurgitation of food or saliva through the nostrils caused by pharyngeal paresis; mucopurulent to bloody nasal discharge and fetid odors, usually bilateral; cough; bloat; and visible or palpable swelling in the pharyngeal area.[1,2] Megaesophagus has been reported subsequent to pharyngeal trauma.[3] Palpation of the pharynx may increase the stertor and cause pain. In severe cases, systemic signs of fever, anorexia, depression, dehydration, and forestomach stasis may be present. Aspiration pneumonia may be a secondary complication.

Differential diagnoses include pharyngeal tumors; lymphosarcoma; sialoliths; rabies; botulism; actinobacillosis; necrotic laryngitis; laryngeal abscesses, trauma, edema, or paralysis; and laryngeal tumors.

Diagnosis A thorough manual examination of the oropharynx or a visual examination with an adequate speculum and light source usually confirms the diagnosis of a pharyngeal swelling and often reveals a puncture that is discharging pus. Cases in which the infection is diffuse can be more difficult to recognize, and endoscopy or radiography can be particularly helpful.[1] Restraining the jaws with a McAllum speculum allows a guarded needle attached to a length of tubing and a syringe to be inserted into the swelling for aspiration of any swelling identified. This helps to differentiate localized abscesses from granulomas, hematomas, cellulitis, and tumors; allows culture and sensitivity determinations on abscesses; and may aid in cytologic diagnosis of granulomas or tumors. Radiographs may reveal foreign bodies (Fig. 31-72) or air densities (Fig. 31-73) in the pharyngeal tissues. The complete blood cell count (CBC) usually reflects an inflammatory process, with a neutrophilic leukocytosis and a left shift, or a neutrophil-lymphocyte reversal. Dehydration is frequently evident. If the animal is unable to swallow, large amounts of bicarbonate may be lost through the saliva, which may lead to evidence of metabolic acidosis on blood gas analysis or serum biochemical profile.

Treatment and Prognosis Discrete pharyngeal abscesses are usually best drained into the pharynx. Whenever possible, the procedure should be done on the standing animal without sedation to preserve the cough reflex and prevent aspiration. A good oral speculum and excellent restraint are needed. The head should be kept lowered. A guarded blade such as a hook blade from a fetotomy set is introduced into the pharynx, and the abscess is lanced. The cavity is flushed with a mild antiseptic such as 0.2% povidone iodine in saline solution, again taking care to prevent aspiration. Other options include drainage to the exterior, drainage and flushing with a large-gauge needle and tubing, and extirpation.[2] Removal of a

[§]Previous contributions by John C. Baker and John A. Smith are acknowledged.

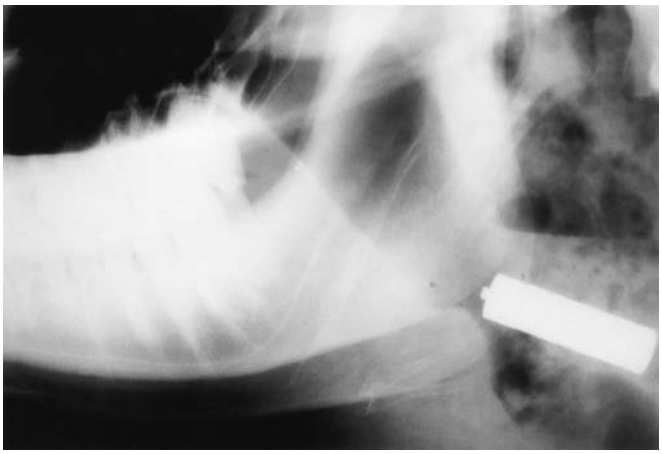

FIG. 31-72 Radiograph of the pharyngeal area of a cow. Note magnet located in the retropharyngeal tissue.

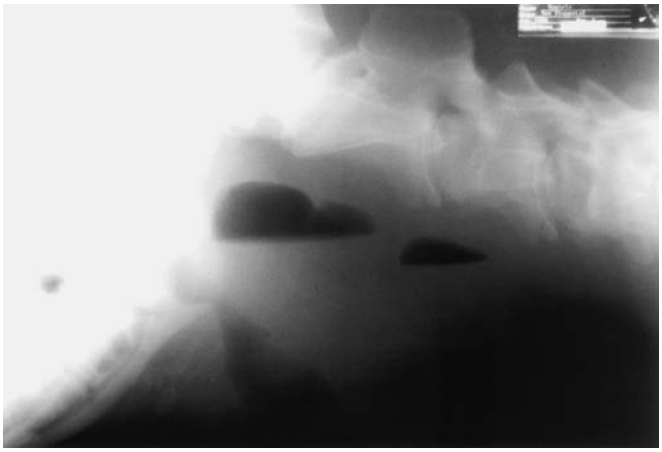

FIG. 31-73 Radiograph of the pharyngeal area of a cow. Note air densities in the tissue, suggestive of abscess formation.

bacterial granuloma from the pharynx of a cow via electrocautery has been described.[4] Systemic antibiotics are administered in accordance with culture and sensitivity results, or, in their absence, procaine penicillin G (22,000 U/kg IM q12-24h), tetracyclines (11 mg/kg IV or SC daily, or 20 mg/kg of long-acting oxytetracycline SC q72h), or sulfadimethoxine (55 mg/kg IV loading dose followed by 27.5 mg/kg IV q24h) are used. Nonsteroidal antiinflammatory drugs (NSAIDs) such as aspirin (100 mg/kg PO q12h) or flunixin (1.1 to 2.2 mg/kg IV daily or divided twice daily) help relieve pain, swelling, and stertor. In animals with severe persistent dyspnea, tracheostomy may be necessary. Granulomas and diffuse cellulitis are likewise treated medically with appropriate antimicrobials and antiinflammatory drugs. Supportive therapy such as IV fluids or feeding through a rumenostomy site may be necessary if the animal refuses to eat or drink. The prognosis for most pharyngeal abscesses, hematomas, cellulitis, and granulomas is usually good with appropriate therapy.

Dorsal Displacement of the Soft Palate

Although rare, dorsal displacement of the soft palate has been reported in cattle.[5] Respiratory noise is apparent on inspiration and expiration but is loudest on inspiration. Diagnosis can be made by endoscopic examination. Treatment is similar to that used in horses and can include conservative therapy, which consists of antiinflammatory drug therapy and rest, or the condition can be surgically corrected.

Subepiglottic Cyst

Although rare, a subepiglottic pharyngeal cyst causing upper airway obstruction has been reported in cattle. Surgical removal by a peroral approach has been described.[6]

Necrotic Laryngitis (Calf Diphtheria, Laryngeal Necrobacillosis)

Definition, Etiology, and Epidemiology Acute to chronic infection of the laryngeal mucosa and cartilage of young cattle is very common, particularly in feedlots. Laryngeal contact ulcers[7] probably provide a damaged mucosal surface, which then allows invasion of the cartilage by *F. necrophorum,* which is the proximate cause of the lesions. It has also been suggested that *Histophilus somni* is the primary agent inducing a perilaryngeal vasculitis and that *F. necrophorum* represents a secondary bacterial invader.

The disease is most common where cattle are housed in dirty or crowded conditions and in feedlots. Most feedlot cases occur in animals on feed for longer than 30 days. The incidence is sporadic. Cases occur year round, but there appears to be a higher incidence in fall and winter. The disease has a worldwide distribution.

Clinical Signs and Differential Diagnosis The problem occurs most commonly in calves from 3 to 18 months of age, up to about 24 months. It is characterized by an acute onset of a moist, painful cough, which the animal may attempt to suppress because of pain. Frequently a severe inspiratory dyspnea with a loud guttural stertor and open-mouth breathing with the head and neck extended are observed. The animal may salivate, make frequent painful swallowing movements, and stand and sip water continually. Signs of systemic disease include anorexia, depression, and fever (as high as 106° F [41.1° C]), and hyperemic mucous membranes are present. There is often a bilateral nasal discharge and a fetid odor to the breath. The larynx may be visibly or palpably swollen, and palpation may elicit a cough, cause pain, and markedly increase the dyspnea and stertor. If untreated, many calves will die in 2 to 7 days as a result of systemic effects of bacterial toxins and upper airway obstruction. Recovered cases may have a chronic roaring respiration and a harsh, dry cough because of the misshapen larynx. Aspiration pneumonia and chronic "poor doers" are common sequelae. Differential diagnoses include pharyngeal trauma (abscess, cellulitis), severe viral laryngitis (e.g., infectious bovine rhinotracheitis [IBR]), actinobacillosis, and laryngeal edema, abscesses, trauma, paralysis, and tumors.

Diagnosis The diagnosis is usually made presumptively based on clinical signs alone. A laryngoscopic or endoscopic examination can help confirm the diagnosis, but care must be taken to prevent further stress and respiratory embarrassment. Acute cases show changes in the CBC consistent with any acute septic condition: leukopenia caused by neutropenia with a left shift. In chronic or ongoing cases, leukocytosis with neutrophilia, monocytosis, and hyperfibrinogenemia may be present.

Pathophysiology *F. necrophorum* normally does not penetrate intact mucous membranes. Laryngeal contact ulcers are thought to provide the portal of entry for *F. necrophorum,* which is ubiquitous. Laryngeal contact ulcers are also very common in slaughter cattle and are speculated to be caused by the following combination of factors: (1) an acute mucositis from mixed upper respiratory tract infections (such as IBR virus, bovine respiratory syncytial virus [BRSV], parainfluenza virus type 3 [PIV-3], mycoplasma, and bacteria, including *Mannheimia, Pasteurella,* and *Histophilus* spp.); (2) reflex coughing and swallowing, which accelerate the rate of laryngeal closure; and (3) resulting erosion of the swollen membranes over the vocal processes and medial angles of the arytenoid cartilages.[8] It has also been proposed that necrotic laryngitis results from

VetBooks.ir

a perilaryngeal vasculitis initiated by *H. somni* with secondary invasion by *F. necrophorum*.[9] Necrotic laryngitis can alter pulmonary function such that the growth rate is impeded, and it also predisposes to secondary bacterial pneumonia.[10]

Necropsy Lesions The lesions are typically located over the vocal processes and medial angles of the arytenoid cartilages. Acute lesions consist of marked edema, hyperemia, and swelling of the mucous membrane around a necrotic ulcer, with accumulated exudate. The lesions spread along the vocal processes and vocal folds and may extend into the cricoarytenoideus dorsalis muscles. In chronic cases the lesions consist of a focus of necrotic cartilage surrounded by purulent exudate, with a tract extending to the mucosal surface. The tract opening is surrounded by granulation tissue and may drain pus. The arytenoid cartilage may be rotated into the lumen or may contain mucosal cavities lined with thin, hyperemic epithelium.[8]

Treatment, Prognosis, Prevention, and Control Oxytetracycline (11 mg/kg IV or SC q24h, or 20 mg/kg of long-acting oxytetracycline SC q72h) or procaine penicillin G (22,000 U/kg IM q12-24h) is appropriate; sulfonamides are also usually effective. NSAIDs (aspirin, 100 mg/kg PO q12h, or flunixin, 1.1 to 2.2 mg/kg IV once daily or divided twice daily) reduce swelling, inflammation, and fever. Cases with severe respiratory distress may benefit from one or two doses of steroids (dexamethasone 0.05 to 0.2 mg/kg IV or IM once or twice), but repeated doses of steroids are not recommended. A tracheostomy may be necessary in severe cases to relieve dyspnea and rest the larynx. Good nursing and supportive care are also important, including shelter, adequate ventilation, easy access to feed and water, and oral or intravenous fluids if needed. The prognosis is good when the condition is detected very early and treated vigorously; when extensive cartilage necrosis occurs, a fatal outcome or chronic ill-thrift with stertorous breathing is expected. There are no specific control measures. The proposed pathogenesis would suggest that measures to control other respiratory diseases may reduce the incidence of necrotic laryngitis.

Laryngeal Granulomas

Laryngeal granulomas have been described in cattle.[11] They may originate from laryngeal contact ulcers that have been described in feedlot cattle at slaughter (see the previous section on necrotic laryngitis for more information).

Laryngeal Papillomatosis

Papillomas of the larynx are common in feedlot cattle. They are caused by a papovavirus, which is thought to enter laryngeal contact ulcers (see the previous section on necrotic laryngitis). Characteristic signs of laryngeal papillomatosis are stertorous respiration and cough. Differential diagnoses include necrotic laryngitis; pharyngeal trauma, abscess, or granuloma; actinobacillosis; and laryngeal abscesses, trauma, edema, paralysis, and tumors. The lesions are sessile to pedunculated, yellow, frondlike, 1- to 10-mm growths over the vocal processes of the arytenoid cartilages.[8] Treatment usually is not indicated but involves surgical removal. Measures to decrease other respiratory infections and thereby decrease contact ulcers may lower the incidence of papillomas.

Laryngeal Abscesses

Abscessation of the arytenoid cartilages caused by *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) has been reported in calves[12] and sheep.[13] Clinical signs include tachypnea, extension of the head and neck, cyanosis, and a severe progressive dyspnea with marked stertor that can be localized to the larynx. Many affected animals remain alert and afebrile and continue to eat until the terminal stages of severe dyspnea. Endoscopy reveals generalized edema and hyperemia of the laryngeal mucosa and obstruction of the rima glottidis by swelling of one or both arytenoids. Radiographs may demonstrate soft-tissue swelling of the larynx. The condition has been speculated to be initiated by grass awns, trauma, hereditary predisposition, or congenital cavitations in the cartilages. In sheep, rams appear to be more commonly affected than ewes, and two reports found a breed predisposition in Texels and Southdowns, although other reports have indicated that various breeds are affected.[13] The necropsy lesions consist of encapsulated abscesses containing pus and necrotic debris in the arytenoid cartilage, usually in the vicinity of the vocal cord. A tract from the abscess typically opens in an area of granulation tissue in the laryngeal mucosa. Treatment consists of tracheostomy, antibiotics (usually penicillin G procaine at 22,000 U/kg IM q12-24h), and NSAIDs (aspirin, 100 mg/kg PO q12h, or flunixin, 1.1 to 2.2 mg/kg IV daily or divided twice daily). The prognosis for recovery is considered guarded unless the condition is detected in the earliest stages and treated vigorously; however, one affected heifer lived for at least 1 year and was bred successfully after permanent surgical tracheostomy for chronic arytenoid abscessation.[14]

Other Laryngeal Obstructions (Laryngeal Trauma, Edema, Paralysis, and Foreign Objects)

Other laryngeal obstructions are all sporadic and may manifest with similar signs. Trauma to the larynx may result from roping or injury in restraint devices. Inappropriate placement of an endotracheal tube can potentially damage the larynx. The respiratory system is the main target organ for anaphylaxis in ruminants, and laryngeal edema can be a prominent component of this syndrome. Inhalation of smoke or other noxious gases also may cause laryngeal edema. Paralysis of the larynx was reported in a sheep with a false carotid aneurysm[15]; presumably other lesions of the neck or anterior mediastinum could cause laryngeal paralysis through involvement of the recurrent laryngeal nerves. Laryngeal hemiplegia has been reported in association with *Sarcocystis* spp. infection of the muscles of the larynx and pharynx in a ram.[16] Foreign objects more commonly lodge in the pharynx, but sharp objects and food materials may be aspirated and lodge in the larynx. Signs common to these laryngeal obstructions include inspiratory dyspnea, prolongation of the inspiratory phase, mouth breathing, stertor, cyanosis, salivation, and extension of the head and neck. Palpation of the larynx may reveal swelling and may exaggerate the dyspnea and stertor. Differential diagnoses include necrotic laryngitis, laryngeal abscesses, severe viral laryngitis, actinobacillosis, and tumors. Endoscopy and radiology are required in most cases to differentiate these conditions. Hematologic analysis may give some indication of the presence of bacterial infection; a stress leukogram may also be seen. Tracheostomy is indicated in all severe cases. Surgical correction of laryngeal obstruction by tracheolaryngotomy has been described in cattle.[17]

Laryngeal trauma and paralysis may resolve spontaneously or may require reconstructive surgery. Foreign objects should be removed surgically or endoscopically. NSAIDs (aspirin, 100 mg/kg PO q12h, or flunixin, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help reduce swelling, edema, and respiratory embarrassment in all forms of obstruction. If anaphylaxis is suspected, corticosteroids may be useful.

Tracheal Collapse and Stenosis

Definition and Etiology Tracheal collapse or stenosis is infrequently reported in cattle and goats.[18-21] The cause is usually unknown, but the problem may result from cranial thoracic trauma, roping, tracheostomies, or possibly congenital defects. In cattle the majority of reports have described tracheal collapse in calves in which signs were usually first evident at several weeks of age.[18,19] The

VetBooks.ir

FIG. 31-74 Radiograph demonstrating collapse of the thoracic trachea in a calf.

majority of these cases also involved the thoracic trachea (Fig. 31-74), suggesting a congenital lesion. However, in most calves with tracheal collapse the condition has been a result of dystocia at birth, especially breech presentations, which suggests a traumatic cause.[22] In contrast to reports in cattle, tracheal collapse has been reported in a mature goat that showed no previous signs of respiratory abnormality.[21]

Tracheal collapse has also been reported in Texel-cross lambs with inherited chondrodysplasia[23]; affected lambs were normal at birth but developed exercise intolerance as early as 1 week of age. Severely affected lambs developed fatal respiratory compromise when exercised. Tracheal stenosis can also occur in lambs born to ewes that ingest *Veratrum californicum* root and rhizome material at days 31 through 33 of gestation.[24]

Clinical Signs and Differential Diagnosis

Clinical signs of tracheal collapse may include fever, tachycardia, tachypnea, cyanosis, and mucosal hyperemia with vessel engorgement, but affected animals may have normal vital signs and are otherwise alert and in good condition. Dyspnea is usually induced or exacerbated by excitement or exercise or may be severe at rest. Stertorous respiration is usually evident, is frequently worse on inspiration, and can often be localized to the trachea on auscultation. The inspiratory phase is prolonged, and a "honking" cough is characteristic, especially with intrathoracic collapse. Palpation may reveal or induce the collapse when the cervical trachea is involved. Tracheal palpation or elevation of the head may increase the stertor or induce the honking cough. In some cases there may be other evidence of trauma (fractured ribs, sternebrae), and in some animals pneumonia may be present. There is no response to antibiotics, steroids, or tracheostomy.

Texel-cross lambs with tracheal collapse resulting from inherited chondrodysplasia also exhibited retarded growth, forelimb varus, and reluctance to walk. Severity of signs varied among affected individuals; some died or were euthanized within weeks because of respiratory compromise, whereas others survived to breeding age.[23] Animals that survived for several months often developed arthritis characterized by severe erosive lesions of the articular cartilage of major joints, including the shoulder, hip, and stifle. Lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* died within 5 minutes of birth after signs of severe respiratory distress.

Other possible disorders with signs similar to those seen in animals with tracheal collapse or stenosis are tracheal foreign bodies, tracheal actinobacillosis, neoplasms, bronchopneumonia, necrotic laryngitis, and extratracheal compressive lesions (e.g., abscesses, tuberculosis, hematomas).

Diagnosis

Any deviation of the hemogram from normal is probably a reflection of associated pneumonia or stress. Endoscopy and radiography are the most helpful ancillary aids. Care must be taken when restraining, sedating, and passing the endoscope in these animals; oxygen should be available. In cattle with idiopathic tracheal collapse, radiography (see Fig. 31-74) and endoscopy usually reveal a dorsoventral flattening, most typically in the caudal cervical and cranial thoracic trachea, although lateral collapse and collapse in other locations (cranial cervical, intrathoracic) are occasionally encountered.

Pathophysiology

Proposed causes of tracheal collapse in other species include congenital malformations, genetic or nutritionally induced weakness of cartilage, deficient innervation of the trachealis muscles, trauma, ischemic lesions from endotracheal tube cuffs, and primary pulmonary disease. No histologic differences were noted in tracheal rings from collapsed and normal segments when this has been assessed.[18]

As previously mentioned, most calves with tracheal collapse have a history of dystocia at birth. During delivery, compression of the chest wall with fracture of the first pair of ribs may cause injury at the thoracic inlet.[25] Signs of tracheal collapse are not immediately evident at birth but rather develop over time.

Lambs with tracheal collapse associated with inherited chondrodysplasia had clinical signs most similar to a condition in humans that results from a mutation in the diastrophic dysplasia sulfate transporter gene,[26] but the causative mutation in sheep has not yet been reported. Preliminary data indicated that the chondrodysplasia was inherited via a recessive mode of inheritance.[23] Tracheal stenosis in lambs born to ewes fed *V. californicum* was presumed to be caused by cyclopamine, a steroidal alkaloid that is the toxic principle in highest concentration in *V. californicum*. It was notable that lambs developed tracheal stenosis when ewes were fed *V. californicum* at 31 to 33 days of gestation, whereas craniofacial defects typically recognized in lambs born to exposed dams are seen when the ewe ingests the toxic plant by day 14 of gestation.[24]

Necropsy Lesions

At necropsy, affected animals may have either a laterally or a dorsally compressed trachea; typically several centimeters of the trachea are affected. Necropsy of sheep with inherited chondrodysplasia reveals a trachea that is flaccid, flattened, and sometimes irregularly kinked. Tracheal rings are markedly thickened, and the lumen is narrow, possibly extremely so. Diffuse pulmonary congestion and edema, with epicardial ecchymoses, may occur as a result of terminal anoxia and respiratory distress. Other lesions include exaggerated convex curvature of the ribs, angular limb deformities, and erosive arthritis with exposure of the subchondral bone in one or more joints. Histologically, hyaline cartilage in affected organs is hypercellular and disorganized, with foci of apparent chondrolysis. Chondrocytes are larger than normal, although shrunken, apparently necrotic chondrocytes are also seen. Necropsy of lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* reveals pronounced lateral flattening of the trachea. Tracheal rings are reduced in number, with abnormal size and shape and irregular spacing. Histologically the cartilage rings in affected lambs were flattened and thin and had a thinner zone of proliferating chondrocytes on their outer surface compared with normal age–matched controls.[24]

Treatment and Prognosis

Mild cases may respond to confinement sufficiently to be fed out for slaughter. A number of surgical treatments have been proposed in other species, including anastomosis, bisection of tracheal rings, internal and external prostheses, and plication of the dorsal membrane.[18] External prostheses have been used successfully in calves,[18,22,25] adult cattle,[27] and a goat.[21] A favorable prognosis for surgical correction is estimated at approximately 30%.[22] A detailed description of surgical repair in calves by external prostheses has been published.[23] Successful management of lambs with congenital tracheal collapse or stenosis has not been reported, although mildly affected lambs with congenital chondrodysplasia survived into adulthood. Because of the apparent genetic basis for the disease, breeding of affected animals should not be recommended.

VetBooks.ir

Tracheal Foreign Bodies and Masses

Ruminants may occasionally inhale foreign objects that lodge in the trachea. There are also two reports of tracheal actinomycosis that resulted in signs of tracheal obstruction.[29] Signs include a chronic cough, inspiratory dyspnea, audible stridor that can be localized to the trachea, extension of the head and neck, open-mouth breathing, and salivation. Differential diagnoses should include pharyngeal trauma; necrotic laryngitis; laryngeal abscesses, trauma, edema, or paralysis; tracheal collapse; and extratracheal compressive lesions. Endoscopy and radiology are important aids to diagnosis. Care must be exercised in restraint and in passage of the endoscope. Some small objects may be retrieved by a snare passed through an endoscope; others may require tracheostomy. When possible, the tracheostomy should be performed below the object. The actinomycotic masses are soft, pedunculated lesions with a granular surface containing small yellow foci. Of the two reported cases of tracheal actinomycosis, one died of asphyxiation and the other responded initially to partial surgical removal of the masses, tracheostomy, and therapy with sodium iodide, penicillin, and streptomycin but relapsed some months later.

Tracheal Edema Syndrome of Feedlot Cattle

Tracheal edema syndrome has also been referred to as *tracheal stenosis* in feedlot cattle. In this condition extensive edema and hemorrhage in the dorsal wall of the trachea result in coughing, dyspnea, and stertor, which has given rise to the term "honker cattle."[30] Tracheal edema syndrome occurs in two forms, characterized by either acute dyspnea or a chronic cough. It is not known whether the two forms are related. Although the syndrome has been recognized for years, no controlled research has been undertaken to determine the cause or risk factors of this syndrome, and the cause is unknown. Theories regarding possible causes include infections with upper respiratory viruses or bacteria such as *P. multocida* or *H. somni,* trauma to the trachea from feedbunks, passive congestion and edema from excessive fat accumulation in the thoracic inlet, hypersensitivity reactions, and mycotoxins.[31]

The acute dyspnea syndrome occurs mainly in heavy feedlot cattle in the latter two thirds of the feeding period and is most common in southern plains feedlots. It is sporadic and more common in summer, possibly because of exacerbation by hot weather. At one extreme, sudden deaths without the onset of noticeable clinical signs have been reported, and at the other extreme subclinical disease was evidenced by lesions in animals at slaughter that did not have clinical signs. Other factors that increase respirations also may cause signs to appear. Signs include an acute onset of dyspnea and loud guttural inspiratory sounds that can be localized to the lower trachea. Open-mouth breathing, extension of the head and neck, and cyanosis, leading to recumbency and death by asphyxiation, are present. Differential diagnoses for this form include pharyngeal trauma or abscess; necrotic laryngitis; IBR; laryngeal abscess, tumor, foreign object, edema, or paralysis; tracheal foreign object, mass, or collapse; and acute interstitial pneumonia.

The chronic form occurs in lighter cattle (135 to 400 kg [300 to 900 lb]) and is more common in western plains feedlots. It is also sporadic but less seasonal. Affected animals may have a history of IBR or pneumonia. The main sign is a continuous, frequent, deep, hacking, nonproductive cough. The animal may be unthrifty but is otherwise normal in appearance. The main differential diagnoses are necrotic laryngitis or mild, chronic suppurative pneumonia. Endoscopy and visualization of the lesions subsequently described aid in the diagnosis. Necropsy of the acute form reveals an edematous thickening of the submucosa and mucosa of the dorsal trachea (Color Plate 31-1) as much as 5 cm thick and extending 20 to 30 cm from the midcervical area to the thoracic inlet or tracheal bifurcation. There is also extensive mucosal, submucosal, and peritracheal edema and/or hemorrhage, possibly related at least in part to agonal breathing. There may be no other lesions of the airway or lungs, and abnormalities (e.g., pulmonary edema, bronchitis, interlobular edema and emphysema, alveolar hemorrhage) may not be seen. Lesions in the chronic form consist of hyperemia of the mucosa of the caudal third of the trachea, with a thin layer of mucopurulent exudate. The mucosa may have a cobblestone appearance or even large, fiber-like projections and polyps. No effective treatment exists for the chronic form. Corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV; prednisolone, 1 to 2.2 mg/kg IM or IV daily) are recommended for the acute form, as well as such practices as preventing stress, providing shade, and cooling with water sprays and fans. Broad-spectrum antibiotics have been recommended by some,[30,31] whereas others have not found them to be necessary.[32] However, because animals with tracheal edema syndrome may be difficult to distinguish clinically from animals with conditions that could respond to antimicrobials (such as necrotic laryngitis), antimicrobials are often administered. Because withdrawal times associated with antimicrobial administration could delay shipment of affected animals to slaughter, drugs with a short withdrawal time should be used if salvage is an option. Tracheostomy may not be helpful if placed proximal to the obstruction, and relief of dyspnea via tracheostomy may require insertion of an endotracheal tube to the tracheal bifurcation. Oxygen administration could be beneficial if available. Recovered patients tend to relapse and should be salvaged.

Lower Respiratory Tract Diseases

Amelia R. Woolums[‖]

Clinical Classification of Pneumonia

Amelia R. Woolums

In an effort to simplify the differential diagnosis of the array of lower respiratory tract diseases of cattle, a classification system based on pathophysiology and clinical signs has been suggested.[1] Three classifications were proposed:

1. Bronchial pneumonia (bronchopneumonia) is characterized pathophysiologically by invasion of pathogenic organisms that gain access to the lung through the pulmonary tree. It is characterized clinically by depression, fever, and other signs of sepsis (such as hyperemic mucous membranes or scleral injection), and an anterior-ventral distribution of abnormal lung sounds and lesions. Bronchopneumonia is the final outcome of the respiratory disease complex of ruminants, and because viruses play an important role in this disease complex, viral causes of respiratory tract disease in ruminants are placed in this category.
2. The interstitial pneumonias are a very diverse group of (usually) noninfectious diseases. Although it is difficult to make generalizations, these diseases are characterized pathophysiologically by an interstitial reaction that usually results from ingestion or inhalation of toxins or allergens. Clinically affected animals tend not to be as depressed and septic, the abnormal lung sounds and lesions are diffusely distributed, and there is little or no response to antibiotic therapy.
3. Metastatic pneumonia is characterized pathophysiologically by septic embolization of the lungs from other foci in the body, classically liver abscesses and postcaval thrombi. Clinically, cases of metastatic pneumonia exhibit signs of sepsis, as with bronchopneumonia, but with widespread pulmonary lesions and abnormal lung sounds and the eventual development of hemoptysis (see descriptions of vena caval thrombosis and metastatic pneumonia in this chapter).

The Bronchopneumonias (Respiratory Disease Complex of Cattle, Sheep, and Goats)

Amelia R. Woolums

The respiratory disease complex of ruminants consists of the single clinical entity of bronchopneumonia or pleuropneumonia but is caused by numerous combinations of infectious agents, compromised host defenses, and environmental conditions. Bronchopneumonia causes greater economic losses than any other disease of feedlot cattle or lambs and is one of the most common causes of dairy calf mortality.

In dairy calves, bronchopneumonia, sometimes called *enzootic pneumonia,* is most common in housed calves. It is called *shipping fever* in beef calves because the greatest incidence of bronchopneumonia occurs after shipment to stocker operations or feedlots; the term *bovine respiratory disease* (BRD) is also used to describe bronchopneumonia in cattle. Bronchopneumonia also occurs in nursing beef calves and in mature beef or dairy cows, sometimes in outbreaks that can have significant morbidity or mortality. Less is known about which factors are specifically the most important for putting these populations at risk for bronchopneumonia, but they are likely similar to risk factors described for housed dairy calves or feedlot cattle. The infectious agents and risk factors of bronchopneumonia of sheep and goats are similar to those of calves.

Bronchopneumonia of ruminants is a disease of multifactorial causation that occurs when a certain combination of host, environment, and infectious agent characteristics (risk factors) is active. The numerous infectious agents (Boxes 31-3 and 31-4) that are associated with bronchopneumonia are ubiquitous in ruminant populations, and the bacteria most often associated with pneumonic lesions are part of the normal resident flora of the ruminant nasopharynx. In addition to recognition of the microbial agents that contribute to the development of bronchopneumonia in ruminants, understanding of the management practices that also play a role is necessary for developing successful programs of prevention. Management practices and other risk factors for bronchopneumonia are discussed in the section Host and Environmental Risk Factors for Undifferentiated Ruminant Respiratory Disease (see p. 611).

Infectious Agents Associated with the Respiratory Complex of Cattle, Sheep, and Goats

Etiology Numerous infectious agents have been isolated from cases of bronchopneumonia in ruminants (see Boxes 31-3 and 31-4). Although infectious bronchopneumonia of ruminants is usually caused by two or more infectious agents acting together, some agents can also cause significant disease alone. Therefore the clinical and epidemiologic characteristics, means of diagnosis, and treatment and prevention of the infectious agents will be first considered individually. A description of epidemiology, diagnosis, and treatment of "undifferentiated" bronchopneumonia (bronchopneumonia with no specific causative diagnosis attempted) will then follow. The clinical signs, gross pathologic lesions, and recommended methods of diagnosis for the major infectious causes of ruminant respiratory disease are listed in Table 31-11.

Viral Agents

Bovine Herpesvirus Type 1 (Infectious Bovine Rhinotracheitis Virus)

Definition and Etiology Bovine herpesvirus type 1 (BHV-1) is an enveloped DNA virus that is classified in the family Herpesviridae, subfamily Alphaherpesvirinae, genus *Varicellovirus*. It is associated with multiple, distinct disease syndromes of cattle that include

BOX 31-3

Viral Agents Associated with Respiratory Tract Diseases in Ruminants

Bovine

Viruses of Major Importance (Commonly Isolated or Generally Accepted to Be Important Contributors to Ruminant Respiratory Disease)

Bovine herpesvirus type 1 (BHV-1, aka infectious bovine rhinotracheitis virus [IBRV])
Bovine respiratory syncytial virus (BRSV)
Bovine viral diarrhea virus (BVDV)
Bovine parainfluenza virus type 3 (PIV-3)
Bovine respiratory coronavirus
Alcelaphine herpesvirus types 1 and 2/ovine herpesvirus type 2 (malignant catarrhal fever)

Viruses of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Bovine herpesvirus type 4 (BHV-4)
Bovine adenovirus
Bovine rhinitis virus
Bovine reovirus
Calicivirus
Influenza virus

Ovine and Caprine

Bovine respiratory syncytial virus (BRSV)
Parainfluenza virus type 3 (PIV-3)
Adenovirus
Bluetongue virus
Ovine progressive pneumonia (maedi-visna) virus of sheep*
Pulmonary carcinoma of sheep*

*Cause of chronic progressive respiratory disease.

BOX 31-4

Bacteria, *Mycoplasma, Ureaplasma,* and *Chlamydophila* Species Associated with Bronchopneumonia of Cattle, Sheep, and Goats

Bacteria of Major Importance (Commonly Isolated or Generally Accepted to Be Important Contributors to Ruminant Respiratory Disease)

Mannheimia haemolytica
Pasteurella multocida
Histophilus somni
Mycoplasma bovis
Bibersteinia trehalosi
Mycoplasma dispar
Ureaplasma spp.
Mycoplasma ovipneumoniae (sheep and goats only)
Mycoplasma mycoides subsp. *mycoides,* large colony variant (goats)
Trueperella pyogenes (formerly *Arcanobacterium pyogenes*) (secondary opportunistic pathogen)

Bacteria of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Pseudomonas aeruginosa
Escherichia coli
Streptococcus spp.
Staphylococcus spp.
Moraxella spp.
Salmonella spp.
Bacteroides spp. (anaerobe)
Peptococcus indolicus (anaerobe)
Fusobacterium spp. (anaerobe)
Chlamydophila spp.

TABLE 31-11

Clinical and Gross Pathologic Characteristics of Common Infectious Agents That Cause Respiratory Disease in Ruminants

Agent	Species	Clinical Signs*	Gross Pathology*	Diagnosis
Viruses				
BHV-1 (IBR)	Cattle	Fever, depression, anorexia, serous to mucopurulent nasal discharge, muzzle hyperemia, nasal plaques, coughing, inspiratory stridor (conjunctivitis ± keratitis, abortion)	Congestion; fibrinopurulent exudate of nasal passages, larynx, trachea; in young calves, pneumonia and involvement with other organs	VI or IFA nasal swabs, conjunctival scrapings PS VI, IFA, or IHC of tissue from upper airways or lungs collected at necropsy
BRSV†	Cattle, sheep, goats	Fever, depression, anorexia, tachypnea, nasal discharge (±), coughing, expiratory dyspnea, harsh bronchovesicular sounds over cranioventral lung, crackles and wheezes rarely, quiet lung sounds caused by pneumothorax, subcutaneous emphysema	Lobules in cranioventral lung collapsed, firm, dark red; caudodorsal lung fails to collapse, rubbery texture (suggestive of acute interstitial pneumonia); dorsocaudal emphysema	IFA or RT-PCR of nasal swabs (VI unreliable) PS IFA or IHC of lung at necropsy (most reliable in acute stage of disease)
PIV-3	Cattle, sheep, goats	Like BRSV but milder, commonly asymptomatic; contributes with other agents to enzootic calf pneumonia or shipping fever	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI or IFA of nasal swabs PS VI, IFA, or IHC of lung at necropsy
BVDV	Cattle	Fever, depression, anorexia, nasal discharge, tachypnea, coughing (±); contributes with other agents to enzootic calf pneumonia or shipping fever (diarrhea, abortion, congenital defects, PI calves, hemorrhagic syndrome)	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI, ELISA, or PCR of peripheral blood buffy coat PS VI, IFA, or IHC of lung at necropsy
Respiratory coronavirus†	Cattle	Contributes with other agents to enzootic calf pneumonia or shipping fever	Not yet well characterized, probably as for PIV-3	VI (need special cells) or RT-PCR of nasal swabs PS VI or IFA of lung at necropsy
Bacteria				
Mannheimia haemolytica	Cattle, sheep, goats	Fever, depression, anorexia, signs of endotoxemia, tachypnea, evidence of pleural pain, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles (coughing not prominent)	Cranioventral lung lobes firm, dark red to gray-brown; fibrin on pleura; yellow pleural fluid that may be gelatinous; infarct-like (wedge-shaped) lesions sometimes seen	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Pasteurella multocida	Cattle, sheep, goats	Fever, tachypnea, cough, depression, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles	Cranioventral lobules (sometimes lobes) firm, dark red to purple; purulent exudate in airways; fibrin on pleura not expected	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Histophilus somni†	Cattle, (uncommon in sheep, goats)	As for *P. multocida*; possibly also evidence of pleural pain (joint effusion, infertility or abortion, otitis, conjunctivitis, neurologic signs)	As for *M. haemolytica*, although fibrinous pleuritis not as consistent; fibrinopurulent arthritis, myocarditis often seen in respiratory cases	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Mycoplasma bovis‡	Cattle	Fever, anorexia, tachypnea, cough, nasal discharge; chronic or ongoing pneumonia that fails to respond as expected to therapy (joint or tendon sheath effusion, otitis, conjunctivitis)	Cranioventral lobules collapsed, firm, dark red; multiple grossly visible raised nodules filled with caseous material (abscesses or caseous necrosis); (fibrinopurulent arthritis, tenosynovitis, or otitis common in respiratory cases; myocarditis or pericarditis)	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret; more meaningful if several in group have positive culture from characteristic lesions at necropsy)

*Clinical signs not related to the respiratory system but possibly also prevalent are listed in parentheses. Note that respiratory disease is often caused by two or more agents, so clinical signs and gross pathology in an individual or herd may be any combination of those listed for individual agents.

†Agent does not survive transport well or can be difficult to isolate; requires special handling or culture techniques to maximize likelihood of isolation.

‡Usually need to specifically request tests to isolate mycoplasmas and to specifically identify the species *M. bovis*.

BVDV, Bovine viral diarrhea virus; *BHV-1,* bovine herpesvirus type 1; *ELISA,* enzyme-linked immunosorbent assay; *IBR,* infectious bovine rhinotracheitis; *IFA,* immunofluorescent assay; *IHC,* immunohistochemistry, most commonly used on formalin fixed lung tissue collected at necropsy; *PCR,* polymerase chain reaction; *PIV-3,* parainfluenza virus type 3; *PS,* paired serology; *RT-PCR,* reverse transcriptase–PCR; *TTA,* transtracheal aspirate; *VI,* virus isolation.

VetBooks.ir

infectious bovine rhinotracheitis (IBR), conjunctivitis (see Chapter 39), infectious pustular vulvovaginitis, balanoposthitis, abortion (see Chapter 43), encephalomyelitis (see Chapter 35), and mastitis. Although only a single serotype of BHV-1 is currently recognized, two subtypes have been identified on the basis of restriction endonuclease cleavage patterns. These subtypes are referred to as BHV-1.1 and BHV-1.2; BHV-1.2 can be divided further into 1.2a and 1.2b. Either subtype can cause respiratory or genital disease; only the respiratory manifestations of infection with BHV-1 are discussed here. The respiratory form is characterized by rhinitis, tracheitis, and pyrexia and is referred to as IBR. BHV-1 can also cause pneumonia as part of a severe generalized infection in newborn calves.[1] The virus is also of great importance in the BRD complex because of its role in enhancing secondary bacterial bronchopneumonia by causing respiratory injury and immunosuppression,[2] as discussed later.

Clinical Signs Clinical signs vary and range from mild to severe. Genetic factors also appear to be an important determinant of the severity of BHV-1 infection, specifically the type-I interferon genotype.[3] Clinical signs include pyrexia, anorexia, a dramatic drop in milk production in dairy cattle, increased respiratory rate, a slight degree of hyperexcitability, ptyalism, coughing, and nasal discharge that progresses from serous to mucopurulent. Dyspnea characterized by open-mouth breathing may appear if the larynx or trachea becomes partially blocked with mucopurulent material. Auscultation of the lungs may reveal harsh bronchovesicular sounds and referred tracheal sounds. Clinical signs of lower respiratory tract infection may be exacerbated by secondary bacterial pneumonia, which is a common sequel to BHV-1 infection. Severe hyperemia and reddening of the muzzle can occur, which is the reason for the common name of "red nose" to describe BHV-1 infection. Pustules may develop on the nasal mucosa and later form diphtheritic plaques. Conjunctivitis with excessive ocular discharge may be present. Conjunctivitis with corneal opacity can also occur as the principal manifestation of BHV-1 infection and may be misdiagnosed as infectious bovine keratoconjunctivitis (pinkeye). Abortions may occur concurrently with respiratory disease, but they can also occur as late as 100 days after infection.[4] Abortions may also occur in cattle that escape serious respiratory disease.

On rare occasions, neonatal calves may suffer from both an acute respiratory and a systemic form of BHV-1 infection. The infection is characterized by rhinitis, marked lacrimation, inflammation and necrosis of the soft palate, laryngotracheitis, and ulceration of the gastrointestinal tract.[1] Vaccination of calves within 3 days of age with modified live viral vaccines has also been associated with severe fatal systemic BHV-1 infection.[5] The severity of disease in vaccinated calves was suspected to be caused by lack of maternal antibody and resultant widespread multiplication of the vaccine virus.

Pathogenesis The route of infection is by direct contact with infected cattle or aerosol; apparent transmission by aerosol has been recognized among calves separated by as little as 4 m.[6] At least three of the surface glycoproteins of BHV-1, gC, gD, and gB, mediate host cell attachment and entry through interaction with heparan sulfate proteoglycans and other host cell proteins.[7,8] Epithelial cells of the respiratory tract are the initial target of infection after respiratory exposure, and after initial infection the virus can spread intracellularly to neighboring epithelial cells via intracellular bridges. Lymphocytes and monocytes are also susceptible to infection; although infection with these cells produces little virus, they appear to be a means by which the virus reaches extrarespiratory sites after respiratory infection. In severe field cases of BHV-1 infection, the virus can be found in multiple organs, including the esophagus, spleen, and liver.[9,10]

Respiratory disease caused by BHV-1 is mediated by two major mechanisms: (1) direct injury and destruction of infected epithelial cells in the upper respiratory tract and bronchi, with resultant inflammation and increased susceptibility to infection with secondary opportunistic pathogens, and (2) immunosuppression resulting from dysfunction of neutrophils, lymphocytes, and macrophages. Immunosuppressive actions of BHV-1 include decreased neutrophil chemotaxis and mitogen-induced blastogenesis of lymphocytes,[11] decreased expression of MHC class I molecules,[12] and induction of apoptotic death of lymphocytes and monocytes.[13] BHV-1 infection modifies expression and activity of cell surface receptors in ways that can be harmful; binding of the adhesion molecule ICAM-1 (CD18/CD11a) on bovine leukocytes to *Mannheimia haemolytica* leukotoxin was increased after BHV-1 infection of cattle, leading to enhanced leukocyte death.[14]

Another important mechanism of pathogenesis of BHV-1 is the ability to establish latent infection in neural tissue.[8] After acute infection, BHV-1 can be found in a latent state in the trigeminal ganglia; the virus may also persist latently in the tonsil.[15] During latent BHV-1 infection, virus is not actively produced in infected cells; thus latently infected cattle do not shed virus. However, an RNA molecule termed the *latency related transcript* (LRT) is abundantly produced in latently infected cells. Research indicates that the LRT prevents apoptosis in cells receiving signals that should trigger apoptosis, suggesting that the LRT functions, at least in part, to promote survival of infected cells.[8] One or more proteins encoded by the LRT appear to be required for the virus to reactivate from latency.[16] Stress or administration of glucocorticoids causes reactivation of the latent virus, leading to shedding of virus and the possibility of infection of in-contact susceptible animals. Latency appears to occur in effectively all cattle that are infected with BHV-1, thus ensuring that the virus can be spread during times of stress by animals that have been free of clinical disease from BHV-1 infection for months to years. Modified live BHV-1 vaccines are also capable of causing latent infections.[17] Calves that are exposed to BHV-1 when they have moderate levels of circulating maternal antibody can develop latent infection while never showing signs of clinical disease.[18] Latency of BHV-1 is thus an important mechanism by which the virus can persist and spread in a group of cattle.

Epidemiology Studies of antibody prevalence to BHV-1 indicate that infection is widely distributed in the cattle population.[4] Adult cattle are thought to be the principal reservoirs of infection.[4] Infections of the respiratory tract by BHV-1 are prevalent when large concentrations of beef or dairy cattle are assembled, although BHV-1 does not appear to have an important role in enzootic pneumonia of calves.[19,20] Feedlot cattle appear to have higher attack rates, more severe disease, and higher case fatality rates than do range or dairy cattle. This is likely because of the stressful conditions experienced by feeder calves at the time of entry into feedlots. Entry into feedlots may also coincide with decline of passive immunity. The case fatality rate is generally low unless complicated with secondary bacterial pneumonia. Historically, disease caused by BHV-1 infection was most commonly recognized within the first few weeks after feedlot entry. However, since the 1990s, disease resulting from BHV-1 has sporadically been recognized in cattle that have been in feedlots for several months; these "late breaks" of disease are noteworthy in that they often occur in cattle that have been previously vaccinated against BHV-1.[21,22] Although BHV-1 is a relatively genetically stable virus, there is evidence that mutations are occurring in BHV-1 isolates currently circulating in cattle populations, which may help the virus escape host immunity.[22] Studies have shown that, although commercially available vaccines can still prevent disease resulting from experimental challenge with modern BHV-1 isolates, viral shedding is increased relative to cattle challenged with older BHV-1 isolates that are more similar to the strains of virus included in vaccines.[22,23] Repeat vaccination later in the feeding period has been recommended to decrease risk of late BHV-1 breaks,[21] although the efficacy of this practice has not been confirmed in clinical trials.

Necropsy Findings IBR is rarely fatal in mature cattle unless it occurs during periods of severe stress or is complicated by secondary bacterial infection of the lung. Lesions caused by BHV-1 infection

include rhinitis, laryngitis, and tracheobronchitis. The mucosa of the nasal passages and trachea can be congested or hemorrhagic. Pustular lesions (sometimes referred to as "plaques") may be observed, and these lesions may coalesce to form adherent necrotic material on respiratory (Color Plate 31-2), ocular, and reproductive mucosa. Usually the inflammatory lesions induced by BHV-1 do not extend into airways contained within the lung, but secondary bacterial bronchopneumonia with the expected pathology is common. Conjunctivitis and, less commonly, keratitis may be present. Esophageal erosions have been identified in severe natural outbreaks.[9] Perinatal infection of calves can lead to fatal systemic disease, with necrotic foci found in the liver, adrenal glands, kidneys, and other organs.[5] Although intranuclear inclusion bodies are a feature of herpesvirus infections, they are not a common histologic feature of BHV-1.

Diagnosis BHV-1 can be diagnosed by virus isolation, immunofluorescent antibody (IFA) testing, or polymerase chain reaction (PCR) to identify virus or viral nucleic acid in nasal swabs or conjunctival scrapings antemortem or from samples collected postmortem. Infection can also be diagnosed by paired serology, with tests for serum neutralizing antibody most commonly done.

Treatment and Prevention Cattle infected with BHV-1 should receive supportive care. Good-quality feed and water should be made easily available, and additional stressors such as transport, castration or dehorning, or introducing new cattle to the group should be avoided or postponed. NSAIDs such as aspirin or flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) may help severely affected individuals maintain water and feed consumption. Administration of antimicrobials appropriate to prevent infection with bacteria likely to cause secondary bronchopneumonia (Table 31-12) may be appropriate. Steroids should not be administered. Because protective immunity develops rapidly after either intranasal or intramuscular vaccination,[24-28] BHV-1 vaccination in the face of an outbreak may help limit disease, although the efficacy of this practice has not been tested in a controlled study.

Efforts to prevent BHV-1 infection should include practices that optimize host immunity and avoid management practices that put cattle at risk, such as mixing newly introduced cattle with established populations. Many brands of inactivated and attenuated BHV-1 vaccines for subcutaneous or intramuscular administration are commercially available; products are available that contain BHV-1 alone or in combination with other pathogens. Modified live vaccines are also available for intranasal administration; intranasal vaccines also include parainfluenza virus type 3 (PIV-3) with or without bovine respiratory syncytial virus. Numerous reports confirm that either parenteral or intranasal BHV-1 vaccines can protect cattle from disease after experimental challenge with virulent BHV-1[24-28] or BHV-1 followed by *M. haemolytica*[29]; only a few are referenced here. Unfortunately, there are few studies of BHV-1 vaccine efficacy in field trials, which better reflect the impact of vaccination in the "real-life" setting. In one older trial, vaccinated feedlot cattle were more likely to develop respiratory disease than unvaccinated cattle[30]; in a more recent trial there was no difference in respiratory disease between vaccinated and unvaccinated cattle, but vaccinated cattle had improved feed efficiency over the first 28 days after entering the feedlot.[31] The lack of field trials confirming vaccine efficacy may result in part from reluctance on the part of veterinarians or producers who perceive the vaccines to be useful to allow the inclusion of control groups of animals that are not vaccinated; researchers have admitted to being thwarted by this obstacle when organizing a field trial of BHV-1 vaccine efficacy.[32] In spite of the lack of published field trials supporting efficacy of BHV-1 vaccines to prevent respiratory disease, they are widely used; over 90% of feedlot cattle are reported to receive BHV-1 vaccines.[33] Historically it was thought that vaccination with modified live BHV-1 leads to protective immunity for years, or perhaps even the life of the animal, but recent evidence of infection and disease in feedlot animals within months of vaccination[21,22] indicates that this is not the case.

Although both modified live and inactivated BHV-1 vaccines are available, modified live vaccines are preferable when it is safe to use them because they are more likely to stimulate a cell-mediated immune response similar to that induced by infection. Few studies to date have compared modified live to inactivated vaccines in the same trial. When this comparison has been made, it has been to compare protection against experimental BHV-1 infection, with modified live vaccines providing superior protection in some[34] but not other[35] studies. Improved efficacy of inactivated vaccines in more recent studies[35] may be a result of inclusion of more advanced adjuvants, which can greatly improve the immune response to inactivated vaccines. Modified live BHV-1 vaccines are capable of causing latent infections, which could theoretically lead to shedding and spread of the vaccine strain of virus to in-contact naive animals.[17] Because modified live BHV-1 vaccines can induce abortion, the manufacturer's label recommendations regarding administration to pregnant cattle should be closely followed. Modified live vaccines may also lead to severe disease if administered to calves within a few days of birth[5]; intranasal modified live BHV-1 vaccines may be safer than parenterally administered modified live virus vaccines in very young calves.[36]

If a modified live vaccine is to be used, the veterinarian must then decide whether to use a product for intranasal or for parenteral administration. Both have been shown to provide protection rapidly; in one study, intranasal vaccination protected calves challenged within 48 hours of vaccination,[24] whereas other studies have shown that intramuscularly or subcutaneously administered modified live vaccine can protect cattle challenged 72 hours after vaccination.[25,28] Both types of vaccines can induce protection in cattle before serum neutralizing antibodies are evident,[27,28] indicating that cell-mediated rather than humoral immunity is responsible for protection soon after vaccination. In one trial that compared the protection afforded by intranasal versus parenteral BHV-1 vaccine, feedlot cattle that received intranasal vaccine had improved feed efficiency over cattle that received parenteral vaccine, but there was no difference in morbidity or mortality attributable to respiratory disease between the two groups.[31] Intranasally administered BHV-1/PIV-3 vaccines are theoretically preferable to parenteral vaccines because they induce a better mucosal immune response; they may also have an advantage when calves are vaccinated in the presence of passive immunity.[26,37] It appears that intranasal modified live vaccines are more likely to be spread to in-contact animals than are parenteral modified live vaccines; two studies confirmed BHV-1 shedding by nonvaccinated cattle in contact with cattle vaccinated intranasally with modified live BHV-1,[38,39] although two different studies could not identify evidence that modified live virus vaccine given intramuscularly spread to nonvaccinated cattle.[40,41]

Vaccines that have gene deletions have been developed and used in Europe.[42] These vaccines allow serologic differentiation of vaccinated from naturally infected animals and have application for BHV-1 control or eradication programs.

Herpesviruses in Sheep and Goats

Herpesviruses have been isolated from sheep and goats. The importance of herpesviruses in respiratory disease of small ruminants in North America has not been well defined.

Respiratory Syncytial Virus of Cattle, Sheep, and Goats

Definition and Etiology Bovine respiratory syncytial virus (BRSV) is an enveloped RNA virus that is classified in the family Paramyxoviridae, subfamily Pneumovirinae, genus *Pneumovirus*. This virus is named for the characteristic cytopathic effect it produces in vitro and in vivo, which is the formation of syncytial cells. BRSV shares many similarities in its biology and epidemiology with the human respiratory syncytial virus (HRSV), a common respiratory pathogen of humans with particular importance in disease of young children and the elderly. Although BRSV and HRSV are closely related, they are distinct viruses.[1] Respiratory syncytial virus (RSV) has also been isolated from sheep and goats with respiratory disease.

TABLE 31-12

Antimicrobials Approved by the FDA for Treatment of Bronchopneumonia of Beef Cattle

Antimicrobial	Label Dose	Route of Administration	Treatment Interval (Hours)	Slaughter/Milk Withdrawal	Approved for BRD Control (Metaphylaxis)?	Approved for Sheep and Goats?
Standard Preparations						
Amoxicillin	11 mg/kg	IM, SC	24	25 days/96 hours	No	No
Ampicillin	2-5 mg/kg (22 mg/kg)*	IM	24	6 days/48 hours	No	No
Ceftiofur (sodium)	1.1-2.2 mg/kg	IM, SC (cattle) IM (sheep and goats)	24	4 days/0 days	No	Sheep and goats
Ceftiofur (HCl)	1.1 mg/kg	IM, SC	24	3 days/0 days	No	No
Enrofloxacin†	2.5-5.5 mg/kg multiday therapy	SC	24 or once	28 days/not approved	No	No
Erythromycin	8.9 mg/kg	IM	24	14 days/72 hours	No	Sheep
Oxytetracycline	11 mg/kg	IV,‡ IM,‡ SC‡	24	15-22 days‡/not approved	No	Not for injection§
Procaine penicillin G	6600 U/kg (22,000 U/kg)*	IM	24	10 days (cattle), 9 days (sheep)/ 48 hours	No	Sheep
Spectinomycin	10-15 mg/kg	SC	24	11 days/not approved	No	No
Sulfadimethoxine	55 mg/kg, initial treatment 27.5 mg/kg thereafter	IV, PO	24	7 days/60 hours	No	No
Tylosin	17 mg/kg	IM	24	21 days/not approved	No	No
Long-Acting Preparations						
Ceftiofur crystalline free acid	6.6 mg ceftiofur equivalent per kg (1.5 mL/45 kg)	SC in the ear	Once	13 days/0 days	Yes	No
Danofloxacin†	6 mg/kg	SC	48 for 2 treatments total	4 days/not approved	No	No
	8 mg/kg	SC	Once	4 days/not approved	No	
Enrofloxacin†	7.5-12.5 mg/kg	SC	Once	28 days/not approved	Yes	No
Florfenicol	20 mg/kg	IM	48	28 days/not approved	No	No
	40 mg/kg	SC	Once	38 days/not approved	Yes	No
Gamithromycin	6 mg/kg	SC	Once	35 days/not approved	Yes	No
Oxytetracycline (product formulated at 200 mg/mL)	20 mg/kg	IM, IV, SC	48-72	28 days/96 hours	No	No
Oxytetracycline (product formulated at 300 mg/mL)	30 mg/kg	IM, SC	Once	28 days/not approved	No	No
Sulfadimethoxine (sustained-release bolus)	138 mg/kg	PO	7 days	21 days/not approved	No	No
Tilmicosin	10 mg/kg	SC	72	28 days/not approved	Yes	Sheep Toxic to goats
Tildipirosin	4 mg/kg	SC	Once	21 days/not approved	Yes	No
Tulathromycin	2.5 mg/kg	SC	Once	18 days/not approved	Yes	No

*Dose that has been shown to be more effective than label-approved dose. Higher dose can be given by the same route of administration and with the same treatment interval, but use of extralabel dosages must comply with the Animal Medicinal Drug Use Clarification Act (AMDUCA), and withdrawal times must be extended.

†Extralabel use in food animals prohibited by law.

‡Varies with preparation.

§Oxytetracycline is labeled for administration to sheep in feed; not a recommended route for treatment of respiratory disease.

BRD, Bovine respiratory disease; *FDA,* Food and Drug Administration; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

Note: Many of the drugs listed in this table are not approved for use in veal calves; some are not approved for use in lactating dairy cattle.

Research suggests that ovine RSV may be distinct from HRSV and BRSV, whereas caprine RSV may be more closely related to BRSV.[2,3] The possibility of interspecies transmission has not been well defined. However, a European serologic survey undertaken to determine whether nonbovine species were likely to harbor BRSV infection found that only goats, in addition to cattle, were commonly seropositive.[4] These results indicate either that goats are commonly infected with BRSV or that antigenic similarities between caprine RSV and BRSV led to production of cross-reactive antibodies in many goats. Although two major antigenic subtypes, A and B, of HRSV have been clearly defined, research has shown that BRSV is less variable than HRSV at the genetic level.[5] However, in spite of minimal to moderate differences among BRSV isolates at the genetic level, isolates can differ notably in their reactivity with monoclonal antibodies directed against individual BRSV proteins[6,7]; this indicates that apparently minor genetic differences could lead to changes that allow the virus to evade host immunity. Differences in molecular weights of viral proteins also divide isolates into two major groups.[8] A study of genetic variability in BRSV isolates collected over several decades showed that genetic change occurred over time[9,10] and that BRSV isolates commonly included in commercial vaccines differed a relatively large amount from some isolates collected from recent natural outbreaks.[9] Studies have also shown that genetic differences in BRSV isolates can be grouped by geographic origin, with some European isolates differing to a notable degree from isolates from the United States or Japan.[9,10] It is important to note that European research identified genetic changes in a region of the BRSV G glycoprotein (the viral attachment protein) that was previously thought to be highly conserved and difficult or impossible for the virus to change.[9] These changes appear to be driven by vaccination, indicating that antigenic pressure induced in cattle by vaccination can lead BRSV to change in unexpected ways. These data indicate that commercial vaccines may need to be reformulated periodically to include isolates of the virus that are similar to isolates currently circulating in natural populations.

Clinical Signs

Clinical signs of BRSV infection can vary from inapparent to severe in an infected group of cattle.[11-13] Signs of disease are limited to the respiratory system. Infected animals may display elevated rectal temperature of 40°C to 42.2°C (104°F to 108°F), depression, decreased feed intake, elevated respiratory rates, ptyalism, cough, and nasal and lacrimal discharges. Signs of disease may progress rapidly, and early signs may be missed. Thoracic auscultation may reveal increased bronchial and bronchovesicular sounds; fine crackles or wheezes may be heard, particularly in the middle or dorsocaudal lung fields. Absence of bronchovesicular sounds may be noticed in the dorsal or dorsocaudal lung fields if an emphysematous bulla is present, or if a bulla has ruptured, leading to pneumothorax. In later stages of the disease, dyspnea can become pronounced and is characterized by increased expiratory effort and mouth breathing. Subcutaneous emphysema and intermandibular edema are sometimes noted. Dramatic reduction in milk production has been reported in dairy cattle. Duration of disease is variable (1 to 2 weeks). A biphasic clinical course has been described but does not appear to be a consistent finding. Experimental infections of lambs with ovine RSV caused a mild primary pneumonia and was also capable of causing lower respiratory tract lesions in calves and deer.[14]

Pathogenesis

The means of transmission appears to be contact with infected cattle and aerosols. Fomites such as bottles and buckets are also a likely means of transmission, as fomites are an important source of HRSV transmission to children. The incubation period is 3 to 5 days. Infection with BRSV can cause bronchitis, bronchiolitis, alveolitis, and interstitial pneumonia.[11-13] After experimental infection, BRSV is found in cells of the nasal, tracheal, and bronchial epithelium by 2 days post infection and in bronchiolar and alveolar epithelial cells by day 4 post infection.[15] The virus causes epithelial cells to fuse, resulting in the characteristic multinucleated cells, or syncytia, which are seen in airways and alveoli. Epithelial cells, which may undergo apoptosis after BRSV infection,[15] slough into the lumen of airways and are phagocytized by neutrophils or alveolar macrophages.[15] Infection of alveolar macrophages and circulating peripheral blood mononuclear cells occasionally occurs,[16,17] and BRSV infection of macrophages decreases important functions of these cells, including Fc receptor expression, phagocytosis, phagosome-lysosome fusion, and production of factors that induce neutrophil chemotaxis.[18,19] Infection leads to bronchitis, bronchiolitis, alveolitis, and sometimes acute interstitial pneumonia (AIP); these changes lead to clinical signs referable to small airway and alveolar disease, including expiratory dyspnea, auscultable wheezing, and hypoxemia.[20]

The severity of disease after BRSV infection is related to host immunity. Both humoral and cell-mediated immunity contribute to protection. Clinical signs of infection are less severe in animals with moderate to high levels of serum antibody against BRSV,[21,22] and more extensive pathology is seen in calves depleted of $CD8^+$ T cells before infection.[23] Protection after intranasal vaccination is related to rapid onset of BRSV-specific immunoglobulin (Ig) A production in nasal secretions,[24] indicating that mucosal immunity is likely also important in protection against naturally occurring disease. Host immunity after exposure to BRSV can minimize disease, and clinical signs are usually the most noticeable in calves under 6 months of age.[12,25] However, very young calves are not necessarily most likely to have the most severe disease; clinical signs after experimental infection were less severe in 1-day-old calves than 6-week-old calves, apparently because of a less robust inflammatory response in younger calves.[26] Ruminants appear to be susceptible to reinfection with BRSV throughout their lives, and adult cattle can develop severe disease after BRSV infection.[12,13] Because genetic variability among BRSV isolates is not great, reinfection does not seem to be largely due to viral strain variation. Although data investigating the duration of BRSV immunity after natural infection are limited, it appears that natural infection does not confer lifelong immunity, and some cattle may be reinfected annually,[27] although clinical signs are not always apparent.

Although host immunity can protect ruminants from severe disease after BRSV infection, the host immune response can also contribute to disease. Evidence for BRSV immunopathogenesis comes from both natural outbreaks and experimental challenge studies. Cattle with severe disease after natural infection have a higher proportion of degranulated mast cells in their lungs than less severely affected cattle,[28,29] indicating that mast cell mediators contribute to physiologic and pathologic changes seen in severe cases. In experimentally challenged cattle, BRSV-specific IgE has sometimes been associated with disease severity.[30,31] Exposure to the fungus *Saccharopolyspora rectivirgula* (formerly *M. faeni*), the spores of which induce pulmonary hypersensitivity in cattle and other species, enhanced BRSV-specific IgE production in calves, indicating that environmental allergens can also affect the nature of the immune response to BRSV infection.[31] Calves infected with BRSV before infection with *Histophilus somni* developed higher levels of *H. somni*–specific serum IgE than did calves infected with *H. somni* alone.[32] Thus BRSV infection can lead to production of virus-specific IgE, which may be enhanced by coexposure to allergens; and BRSV infection may also increase IgE production in response to infection with other agents. In these cases, cross-linking of IgE bound to mast cells by binding of BRSV or other specific antigen is expected to lead to mast cell degranulation and subsequent bronchoconstriction, pulmonary edema, and other sequelae of mast cell mediator release and immediate hypersensitivity.

Other evidence that BRSV can trigger immunopathogenesis is the fact that certain BRSV vaccines have, on rare occasion, been shown to cause enhanced disease when vaccinated animals are subsequently infected with BRSV. Vaccine-enhanced disease has been seen after both natural[33,34] and experimental[35,36] infection. Vaccine-enhanced disease has also occurred in human infants vaccinated with a formalin-inactivated RSV vaccine,[37] and formalin-inactivated BRSV vaccines have caused enhanced disease in cattle in some[35,36] but not

VetBooks.ir

all[20] studies. Inactivated BRSV vaccines have also been shown to prevent disease after infection[38,39]; therefore not all inactivated BRSV vaccines enhance disease. It appears that the dose of BRSV protein, the adjuvant included in the vaccine, and probably additional factors related to the formulation of the vaccine and the genetics of vaccinated cattle determine whether enhanced disease is likely after infection of cattle given a particular BRSV vaccine.[40] Apparent vaccine-enhanced disease has also been reported in cattle that received a modified live vaccine in the early stage of a natural BRSV outbreak, which suggests that BRSV vaccination in the face of a BRSV outbreak could be harmful.[33] It is important to note that BRSV vaccines are commonly used and that vaccine-enhanced disease is rarely reported; thus vaccination is still recommended as part of any plan to control disease caused by BRSV. Many gaps exist in our understanding of what aspects of the immune response contribute to disease severity after BRSV infection or vaccination. Most research completed to date has focused on enhanced disease in calves that received formalin-inactivated BRSV. The data suggest that when enhanced disease occurs in calves vaccinated with formalin-inactivated BRSV, it is related to a relatively strong response by T-helper type 2 (Th2) cells, as evidenced by decreased production of the Th1 prototype cytokine interferon gamma,[41] increased production of BRSV-specific IgE,[42] and pulmonary eosinophil infiltration.[35] The association of BRSV-specific IgE production with disease severity in some experimental studies indicates that at least some individual ruminants will produce IgE after BRSV vaccination or infection, which may contribute to severe disease in these individuals.

The presence of co-infection with other pathogens such as *M. haemolytica*[43] or bovine virus diarrhea virus (BVDV)[44] can also increase the severity of disease after BRSV infection. Although genetic variation among BRSV isolates is not extensive, experimental challenge with certain isolates of BRSV can lead to serious disease,[20,45] whereas challenge with other isolates leads to only minimal disease.[46,47] This indicates that, in spite of limited differences among viral isolates at the genetic level, variation among BRSV isolates may still contribute to variations in disease severity.

Epidemiology

Prevalence of antibodies to BRSV in the cattle population of the United States ranges from approximately 60% to 80%.[48] The virus has been recognized in association with respiratory tract disease in nursing beef calves, dairy calves, adult dairy cows, and cattle entering into feedlots. BRSV was demonstrated to be involved in 14% to 71% of respiratory disease outbreaks in North American and European studies of calf pneumonia outbreaks involving several farms.[49] Seroconversion to BRSV has been significantly associated with treatment for respiratory disease in feedlot cattle,[50,51] and cattle with low antibody titers to BRSV at feedlot entry have increased risk of developing disease.[50] Although feedlot cattle are commonly infected with BRSV after arrival, a survey of necropsy findings at 72 Canadian feedlots found BRSV at postmortem of only 11% of the cattle that died or were euthanized because of pneumonia.[52] The low rate of isolation at necropsy suggests that if the virus contributes to the development of pneumonia in feedlot cattle, it is often no longer present by the time the animal dies or is euthanized.

BRSV therefore represents an important virus in the BRD complex on the basis of its frequency of occurrence and predilection for causing infection of the lower respiratory tract. In general, morbidity rate tends to be high in outbreaks of BRSV, whereas case fatality rate is variable, ranging from no fatalities to as high as 20%.[49]

Cattle are most likely the principal reservoirs of infection, although a European serologic survey of different species found that goats were also often seropositive,[4] indicating that goats may be a source of BRSV infection for cattle, and vice versa. The mechanism by which BRSV persists in the cattle population is not known. Possibly a similar epidemiologic pattern to that described for HRSV also exists for BRSV. HRSV is capable of reinfecting the host throughout his or her life, with the most severe disease occurring in the very young or elderly. Subsequent exposure results in mild upper respiratory tract disease. Similarly, adult cattle may periodically undergo subclinical to mild infections and serve as a source of infection for susceptible young stock. However, one study concluded that transmission among seropositive cattle was not a plausible mechanism of BRSV persistence in a dairy herd.[53] These authors suggested that persistent BRSV infection in individuals is a more plausible explanation of population persistence of BRSV. BRSV has been identified in B lymphocytes in tracheobronchial and mediastinal lymph nodes of calves 71 days after experimental infection,[54] so it may be that individual cattle harbor the virus long term and periodically begin shedding it, allowing it to periodically reappear in herds even if they are closed to new introductions. However, more research is needed before persistent infection is clearly proven to be a means by which BRSV remains established in herds.

Necropsy Findings

Grossly, BRSV infection can cause signs of AIP; therefore differential diagnoses for the typical gross lesions include other causes of AIP. Signs of AIP are most evident in the dorsocaudal lung; the affected lung is heavy, with a rubbery texture, and fails to collapse when the thorax is opened. Individual lobules may appear dark, and interstitial or bullous emphysema is often present in the dorsocaudal lung in severe cases (Color Plate 31-3). Pathologic emphysema must be differentiated from that sometimes caused by agonal breathing of cattle. Cranioventral lobes or lobules are often dark red and collapsed (Color Plate 31-4). Histologic lesions depend on the stage of infection. Neutrophilic and later mononuclear bronchitis, bronchiolitis, and alveolitis are present in infected animals. Syncytial cells may be seen in the airways or alveoli; intracytoplasmic inclusion bodies are rarely present.[12,22,45] Signs of AIP, including alveolar epithelial hyperplasia, hyaline membrane formation, and interstitial inflammatory cell infiltrate, hemorrhage, and edema, are seen in severe cases. Later, evidence of chronic bronchitis and bronchiolitis obliterans can be found.[12]

Diagnosis

Infection is diagnosed by identification of the virus in nasal secretions, tracheal aspirates, or lung lavage fluid from live calves or in lung tissue collected postmortem. BRSV is difficult to isolate, as it does not survive transport well; thus methods of identification that do not require the virus to be alive (such as immunofluorescence, immunohistochemistry [IHC], and real-time PCR [RT-PCR]) are preferable to virus isolation for the identification of BRSV. IHC of formalin-fixed tissue is convenient because the virus can be identified in tissue processed for histopathologic evaluation. If virus isolation is to be attempted from samples collected in the field, it is recommended that the veterinarian contact his or her diagnostic laboratory before collecting samples to confirm the method of sample handling to optimize the likelihood of success. Although virus is readily identifiable in lung tissue of cattle early in the course of disease (within approximately 7 days of infection), it is less likely to be found in lung tissue by 10 to 15 days post infection, even when IHC is used.[15,35]

Seroconversion as evidenced by paired serology also supports a diagnosis; virus-neutralizing or enzyme-linked immunosorbent assays (ELISAs) are most commonly used to identify BRSV-specific antibody. Identification of BRSV-specific IgM in a single acute sample is also diagnostic, but testing for BRSV-specific IgM may not be available at most diagnostic laboratories.

Treatment and Prevention

Treatment of BRSV is supportive and aimed at limiting the inflammatory response in bronchioles and alveoli and preventing secondary bacterial infection. Antiinflammatory therapy with NSAIDs (such as flunixin meglumine at 1.1 to 2.2 mg/kg IV daily or divided twice daily) is considered appropriate, but controlled studies of these drugs in animals with disease caused by BRSV are limited. Administration of one or two doses of steroid therapy (dexamethasone 0.05 to 0.2 mg/kg IV or IM once or twice) is appropriate in selected individuals with severe respiratory distress or evidence of AIP. Antimicrobials appropriate for preventing

VetBooks.ir

secondary bacterial infection are listed in Table 31-12. Insufflation with intranasal oxygen, if available, and diuretic therapy with furosemide (0.5 to 1 mg/kg IM or IV once or twice daily) may be helpful for animals suspected of having AIP. Although the prognosis for animals with uncomplicated BRSV infection is good, the prognosis for animals with AIP is guarded. Animals with severe respiratory distress should be handled with care, as even careful manipulation to administer treatment can lead to rapid respiratory decompensation and death.

Both modified live and inactivated BRSV vaccines for IM or SC administration are commercially available, and a modified live vaccine for intranasal (IN) administration which contains BRSV with BHV-1 and PIV-3 was recently released in the United States and Canada. Reports have confirmed that commercially available vaccines for IM or SC administration can protect calves against virulent experimental challenge.[38,39,55] Intranasal (IN) vaccination can also protect calves from disease following experimental BRSV challenge.[56,57] Results of some well-designed field trials testing the efficacy of parenteral (IM or SC) BRSV vaccines have been published.[58-61] In some of these trials the effect of BRSV vaccination on all clinical respiratory disease (i.e., not only disease caused specifically by BRSV) was evaluated, whereas in other trials, protection against disease caused by BRSV was specifically evaluated. Vaccination decreased all respiratory morbidity in some but not other groups of cattle evaluated. Vaccination decreased disease specifically caused by BRSV in large groups of calves if all calves in the group were vaccinated but not if half of the calves in the group were vaccinated.[59] A large clinical trial evaluating the effect of vaccination of feedlot cattle with a modified live vaccine containing BHV-1, PIV-3, and BVDV, with or without BRSV, found that pens of cattle that received the vaccine including BRSV had lower overall morbidity and mortality and lower numbers of respiratory deaths than pens of cattle that received the vaccine that did not include BRSV.[61] In summary, there is some evidence from well-designed field research that BRSV vaccines can improve resistance of cattle to respiratory disease, although this is not invariably the case. More research comparing IM/SC to IN BRSV vaccination is needed; currently data are lacking to clarify whether one route is superior to the other, particularly in field trials.

There is no RSV vaccine licensed for use in small ruminants, although these vaccines are sometimes administered to sheep or goats in an extralabel manner. However, controlled studies of the effects of extralabel administration of BRSV vaccines licensed for cattle on respiratory disease in sheep or goats have not been published.

Bovine Viral Diarrhea Virus

BVDV is an enveloped RNA virus of the genus *Pestivirus* in the family Flaviviridae. A wide spectrum of disease has been associated with BVDV infection, including subclinical infection, bovine virus diarrhea and mucosal disease (see Chapter 32), immunosuppression, repeat breeding problems, abortion, fetal mummification (see Chapter 43), congenital defects, immunotolerance, and persistent infections. Only the contribution of this virus to respiratory disease is discussed here.

Historically the role of BVDV in the BRD complex was controversial,[1-3] but more recent research provides good evidence that the virus contributes to BRD and related decreased productivity of cattle in the field in at least some cases.[4,5] Experimental challenge of cattle with BVDV alone leads to mild pneumonia,[6,7] and occasionally herd outbreaks of BVDV are first identified by the presence solely of signs that are likely to be interpreted as evidence of respiratory disease, such as fever, tachypnea, and loud bronchovesicular sounds.[8] Experimental infection studies have also shown that respiratory disease caused by *M. haemolytica*,[6] BHV-1,[9] or BRSV[10] is significantly more serious when cattle are co-infected with BVDV. This synergistic effect of BVDV with other respiratory pathogens is believed to be a result of immunosuppression caused by BVDV. The ability of BVDV to cause respiratory disease appears to depend in part on the strain of infecting virus.[7,11]

Although the results of experimental challenge studies show that BVDV can cause mild respiratory disease alone and can contribute to the development of more serious disease in combination with other pathogens, data from field cases of respiratory disease are generally considered to be of greatest relevance. Studies of naturally occurring BRD have shown that in some situations BVDV can be isolated from a majority of cattle affected with shipping fever pneumonia, particularly in association with *M. haemolytica*,[12,13] or in association with *Mycoplasma bovis* in animals with chronic pneumonia.[14,15] Seroepidemiologic studies have indicated an association of BVDV with respiratory disease in some but not all cases. The most convincing data linking BVDV to respiratory disease has come from studies of calves purchased and assembled at sale barns for shipment to feedyards across several states.[5] In 2 consecutive years BVDV was significantly more likely to be isolated from calves that were treated for respiratory disease than calves in the same group that were not treated; calves treated for respiratory disease were also significantly more likely to seroconvert to BVDV than penmates who were not treated for respiratory disease.

In addition to contributing directly to BRD by infecting the respiratory tract and enhancing the pathogenicity of co-infecting bacteria or viruses, BVDV may also contribute to respiratory disease by impairing the ability of cattle to respond properly to vaccination against other respiratory pathogens. Calves infected with BVDV before BHV-1 vaccination shed BHV-1 longer after subsequent BHV-1 infection than calves that were not co-infected with BVDV.[16] In another study, calves persistently infected with BVDV failed to develop a serologic response to a *M. haemolytica* vaccine, in contrast to control animals not infected with BVDV.[17]

In summary, although the importance of BVDV in the BRD complex has previously been debated, recent research indicates that BVDV is significantly associated with the development of BRD in at least some cases. Whereas experimental challenge studies indicate that BVDV can cause at least mild respiratory disease when acting alone, the virus appears to contribute most importantly by impairing the host's ability to resist infection and limit disease caused by other pathogens that infect the animal at the same time or soon after BVDV infection occurs.

Bovine Parainfluenza Virus 3 of Cattle, Sheep, and Goats

Definition and Etiology

Bovine PIV-3 is an enveloped RNA virus classified in the family Paramyxoviridae, subfamily Paramyxovirinae, genus *Respirovirus*. The virus has been associated with respiratory tract disease in cattle, sheep, and goats. It hemagglutinates and hemadsorbs red blood cells of certain species, which means that serum antibodies can be identified by hemagglutination inhibition assays. Variation in virulence among strains of PIV-3 has been reported.[1] Significant similarities between bovine PIV-3 and human PIV-3 have led to efforts to use bovine PIV-3 as a modified live intranasal vaccine for humans; bovine PIV-3 was found to be safe and immunogenic in a clinical trial in human infants.[2]

Clinical Signs

Uncomplicated PIV-3 infections result in subclinical to mild signs. Clinical signs, if present, may include fever, cough, nasal and ocular discharge, increased respiratory rate, increased bronchovesicular sounds, and wheezes.[3-5] The most important role of PIV-3 is in predisposing the respiratory tract to subsequent infection by other viruses and bacteria such as *Mannheimia (Pasteurella) haemolytica*. Severity of signs increases with the development of secondary bacterial pneumonia, and if death occurs it is usually the result of secondary bacterial infection. Infection with PIV-3 is widespread in sheep and goats.[6,7] Only one serotype of ovine PIV-3 has been identified, and it is related to, but distinct from, the bovine strain. Most infections are inapparent to mild.

Pathogenesis

Infection with PIV-3 can lead to signs referable to both upper and lower respiratory tract infection. After experimental infection of calves, clinical signs are evident by 2 days

VetBooks.ir

post infection, and signs peak 4 days post infection. Virus is found in the nasal passages, trachea, and bronchiolar and alveolar epithelial cells. The virus damages the pulmonary mucociliary apparatus[8] and depresses several important functions of alveolar macrophages such as Fc receptor expression, phagocytosis, and microbicidal activity,[9] which are important in predisposing infected animals to secondary bacterial pneumonia.

Epidemiology The widespread prevalence of antibodies to this virus indicates that it commonly circulates in ruminant populations.[7,10,11] This finding suggests the possibility of repeat infections or at least the persistence of antibodies after infection. Inapparent or subclinical infections with PIV-3 are common; in one report, 28 groups of calves seroconverted to PIV-3 over 8 months, but respiratory disease was seen in association with PIV-3 infection in only four of these groups.[12] Although infection can often be inapparent, if environmental and managerial practices are suboptimal, PIV-3 may become an important initiator of respiratory tract disease. Infection appears to spread rapidly in susceptible cattle housed at high population densities and in close contact. In seroepidemiologic surveys evaluating groups of calves in herds experiencing outbreaks of respiratory disease, seroconversion to PIV-3 has been associated with 14% to 38% of outbreaks evaluated.[13,14] In some surveys PIV-3 is the virus most commonly isolated from the lungs of calves that die or are euthanized because of pneumonia.[15] Feedlot cattle commonly seroconvert to PIV-3 soon after feedlot arrival, and seroconversion has been associated with treatment for respiratory disease in some[16] but not all[17] cases. In spite of the fact that feedlot cattle frequently become infected with PIV-3 after feedlot entry, a recent survey of necropsy findings at 72 Canadian feedlots found PIV-3 at postmortem examination of only 4% of the cases with pneumonia.[18] The low rate of isolation at necropsy suggests that if the virus contributes to the development of pneumonia, it may no longer be present by the time the animal dies or is euthanized.

Necropsy Findings Lesions of PIV-3 infection alone are rarely seen during postmortem examination. Experimental PIV-3 infection results in congestion of the respiratory mucosa, swelling of lymph nodes associated with the respiratory tract, and lobular consolidation concentrated in the cranioventral lung.[5] Bronchiolitis and alveolitis are seen histologically with both proliferative and degenerative changes in the epithelial cells of the bronchioles and alveoli. Syncytia and intranuclear and intracytoplasmic inclusion bodies may be seen.[5] In many respects, pathologic features of PIV-3 infection are similar to those caused by BRSV, although the lesions produced by the latter are generally more extensive and pronounced.

Diagnosis PIV-3 can be identified by virus isolation or RT-PCR of nasal swabs from infected animals. Unlike BRSV, which is also a paramyxovirus, PIV-3 is not particularly difficult to isolate. Diagnosis can also be confirmed with paired serology, with virus neutralizing or hemagglutination inhibition assays most commonly used.

Treatment and Prevention There is no specific treatment for infection with PIV-3; as for other respiratory viruses of ruminants, administration of appropriate antibiotics to prevent secondary infection with likely bacteria may be appropriate. As for any viral respiratory tract infection, supportive care is indicated, such as providing readily available good-quality feed and water and avoiding or postponing additional stressors such as movement or mixing of animals. Both inactivated and modified live PIV-3 vaccines are available for parenteral administration, and modified live PIV-3 vaccines are available in combination with BHV-1 with or without BRSV for intranasal administration; these vaccines are labeled for use in cattle but not in sheep or goats. Experimental challenge studies have shown that both parenteral and intranasal vaccines can decrease viral shedding and clinical signs after challenge.[3-5] No field trials have specifically evaluated the effect of PIV-3 vaccines to decrease respiratory disease. One study reported that a modified live BHV-1/PIV-3 vaccine licensed for use in cattle decreased clinical signs and viral shedding when administered before experimental challenge of sheep, but the vaccinated sheep also appeared to become latently infected with BHV-1.[19] The investigators noted that induction of latent BHV-1 infection could be an important negative side effect of vaccination, as sheep could theoretically spread BHV-1 to other in-contact ruminants, such as cattle. Although the practice appears to occur commonly, administration of BHV-1/PIV-3 vaccines to sheep or goats constitutes an extralabel use of these products.

Bovine Coronavirus

Coronaviruses are enveloped, single-stranded positive sense RNA viruses of the family Coronaviridae. Bovine coronavirus is a major cause of calf diarrhea and has also been implicated as a cause of winter dysentery in cattle. Although it has been known for some time that bovine coronavirus can infect the respiratory tract of calves,[1] the practical relevance of this agent as a respiratory pathogen has been debated. However, evidence is accumulating that bovine coronavirus may be an important contributor to outbreaks of respiratory disease in some cases.

One reason for the lack of awareness regarding a role for coronavirus in respiratory disease may be the fact that standard cell lines used for isolation of other respiratory viruses are often not permissive to bovine respiratory coronavirus infection. Thus, coronavirus may not be isolated if only standard cell lines are used to attempt to isolate viruses from cattle experiencing respiratory disease. Bovine respiratory coronavirus can readily be recovered by using human rectal tumor-18G cell lines.[2] An antigen-capture ELISA and a sensitive RT-PCR assay have also been developed for identification of the virus.[3] It is not yet clear whether the coronaviruses that have been associated with respiratory disease in cattle are different in important ways from the coronaviruses that cause enteric disease; studies comparing biological and antigenic properties of enteric and respiratory isolates have yielded mixed results.[4,5]

An association of coronavirus with two naturally occurring outbreaks of shipping fever was described in a well-detailed report.[6] In these outbreaks, which were characterized by high morbidity and mortality, coronavirus was isolated from the nasal passages of over 80% of the cattle in the early stages of the outbreaks. No other respiratory viruses were identified in most of the cattle, but *M. haemolytica* was also isolated from a majority of cattle as the two epizootics progressed. However, a clear causative role for coronavirus was difficult to identify because so few cattle remained healthy that it was apparently not possible to find a difference in viral shedding or seroconversion in animals that had respiratory disease versus those that did not. In a separate report the researchers used Evans's criteria of causation, which have been suggested as more appropriate than Koch's postulates for evaluation of causative factors in complex diseases such as the BRD complex, to support a causative role for coronavirus in the outbreaks they studied.[7] A more recent study found that calves with low antibody titers to bovine coronavirus at feedlot entry were more likely to be subsequently treated for respiratory disease than calves entering the feedlot with higher titers.[8] Other researchers attempting to confirm or refute an important causative role for coronavirus in BRD have nearly always found the virus when calves are sampled soon after feedlot entry.[3,8,9,10] Moreover, it is very common for a majority of cattle to have antibody titers to the virus at feedlot arrival or to seroconvert soon after feedlot entry; therefore it is clear that cattle are often infected with the virus at times when respiratory disease is likely to occur.[3,9,11] However, the importance of the virus in causing respiratory disease has still been debated[11] because seroconversion has not always been significantly associated with treatment for respiratory disease or with decreased weight gain during the feeding period.[11-13]

Although vaccines labeled for the prevention or control of respiratory disease due to bovine coronavirus are not currently marketed in

VetBooks.ir

the United States or Canada, a research trial tested the value of a modified live bovine coronavirus and rotavirus vaccine commercially marketed to decrease diarrhea caused by these viruses (i.e., an extra-label use of the vaccine). In this study, vaccination significantly decreased the subsequent rate of treatment for respiratory disease in cattle that had relatively low serum antibody titers against coronavirus at feedlot arrival.[10]

In summary, some of the currently available data support an important role for coronavirus in contributing to the BRD complex, but other data do not. In this regard coronavirus is similar to other infectious agents, which can be identified as important players in some outbreaks studied but not identified at all in others.

Malignant Catarrhal Fever Virus

The African (wildebeest-associated) form of malignant catarrhal fever virus (MCFV) is caused by alcelaphine herpesvirus types 1 and 2. A causative agent for the American (sheep-associated) form is believed to be ovine herpesvirus type 2. The occurrence of MCFV in the cattle population is sporadic. There is multisystemic involvement, including involvement of the respiratory tract. MCFV is discussed in Chapter 32.

Bovine Herpesvirus Type 4

Bovine herpesvirus type 4 (BHV-4) is in the subfamily Gammaherpesvirinae, genus *Rhadinovirus;* therefore it is serologically distinct from BHV-1. Although the seroprevalence of BHV-4 is high in the cattle population of the United States, it has been implicated in several disease conditions of cattle, including reproductive disorders (abortions and metritis), mammillitis, and enteric disease. Several of these viruses (DN-599, Movar 33/36, FTC-2) have been isolated from cattle with respiratory tract disease, and experimental inoculation of calves with some strains can cause respiratory disease.[1] However, BHV-4 can also be isolated from apparently healthy cattle. The role of BHV-4 in BRD has not been well defined.

Adenoviruses of Cattle, Sheep, and Goats

Adenoviruses are nonenveloped double-stranded DNA viruses of the family Adenoviridae. At least 10 serotypes of bovine adenovirus (BAV) have been identified. BAV infection is widespread and frequently subclinical[1,2]; adenoviruses are also often isolated in association with other viruses and bacteria,[1] making it difficult to assign causation in naturally occurring disease outbreaks. Adenoviruses have been associated with pneumonia, enteritis, conjunctivitis, keratoconjunctivitis, and "weak calf syndrome."[3] When calves develop pneumonia and enteritis at the same time, adenoviral infection in particular should be considered as a possible cause.

At least six antigenic types of ovine adenovirus and two types of caprine adenovirus have been identified. Little information concerning the incidence and distribution of adenovirus infection in the sheep and goat population is available; however, it appears likely that this virus causes widespread infection.[4] A study in Iowa reported that adenovirus infections were widespread in the sheep population and that the prevalence of active infection based on seroconversion rates was approximately 45%.[4] The majority of isolations of this virus have been from young lambs, and it has been isolated in association with respiratory and enteric disease. Experimental infections result in mild disease with anorexia, pyrexia, increased respiratory rates, coughing, and diarrhea. Gross lesions observed include atelectasis, edema, and consolidation of the lungs.[5] Ovine adenovirus serotype 6 has been shown under experimental conditions to act synergistically with *Mannheimia (Pasteurella) haemolytica* in the production of pneumonia in lambs.[6]

Bovine Rhinitis Virus

Bovine rhinitis virus is a nonenveloped single-stranded RNA virus in the family Picornaviridae. There are two serotypes of bovine rhinitis virus, bovine rhinitis virus A and bovine rhinitis virus B. Little information is available that characterizes the relative importance of rhinitis virus in the BRD complex.

Bovine Reovirus

Bovine reovirus is a nonenveloped, double-stranded segmented RNA virus in the family Reoviridae. Reoviruses have been isolated from the respiratory and digestive tracts of apparently healthy cattle. Infections appear to be common in cattle, and bovine isolates are antigenically identical to human serotypes. The importance of reovirus infections in bovine respiratory tract disease is unclear. Subclinical infections appear to predominate under field conditions.

Calicivirus

A calicivirus has been isolated from dairy calves from a herd with a persistent respiratory disease problem.[1] This virus caused only minimal disease in experimentally infected calves, but a persistent infection was produced.

Influenza Virus

Influenza virus has not historically been considered to cause naturally occurring respiratory disease in ruminants in North America. However, it is possible to experimentally infect cattle with influenza,[1] and a report from England described several cattle that seroconverted to human influenza A virus during outbreaks of clinical respiratory disease and decreased milk production in dairy cattle.[2] Antibodies from the cattle reacted most strongly with a human H1N1 virus (A/England/33/80) and a human H3N2 virus (A/England/427/88). Retrospective analysis of banked serum samples also identified measurable antibody titers to human influenza in 49% to 59% of samples tested, with several sets of paired sera taken from animals during respiratory disease outbreaks showing evidence of seroconversion, with relatively high virus neutralizing antibody titers.[2,3] Attempts were made to isolate influenza virus from cattle with signs of respiratory disease but were not successful.[3] It was not possible to rule out other more recognized causes of BRD in the outbreaks in which cattle seroconverted to influenza, so it has not been proven conclusively that influenza is a significant contributor to naturally occurring BRD. However, the relatively high rate of seropositivity seen in cattle in England suggests that the virus may commonly circulate among cattle in at least a subclinical form, and thus cattle may be a significant reservoir of virus that could infect other species. More research is necessary to determine the significance of influenza infection in cattle and other ruminants.

Bacterial and Chlamydial Agents

Mannheimia haemolytica

Definition and Etiology *M. haemolytica* (formerly *Pasteurella haemolytica*) is a gram-negative aerobic bacterium of the family Pasteurellaceae. There are at least 12 serotypes of *M. haemolytica,* and some ruminant isolates are untypable with currently available laboratory tools. Some serotypes of *M. haemolytica* are pathogenic, whereas others are nonpathogenic commensals of the ruminant nasopharynx, and the serotypes that are pathogenic for cattle are not the same as those that are pathogenic for sheep or goats. Serotype A1 is the most common isolate from pneumonic lungs of cattle, and serotype A6 is the next most common[1,2]; serotype A2 is the most common isolate from the nasopharynx of normal cattle.[3] Serotype is also relevant to pathogenicity of isolates from sheep and goats; serotype A2 is the most common isolate from sheep and goats with pneumonia, and serotypes A7, A9, and several others have also been associated with disease.[4-6]

Clinical Signs Cattle, sheep, or goats infected with *M. haemolytica* display a dull or depressed attitude and lose interest in eating. Fever, tachypnea, and depression are often the only abnormal signs early in the course of infection[7-9]; coughing is not a prominent sign in the acute stage of disease[8,9] unless co-infection with another agent such as BHV-1 or BRSV is present. Animals may display evidence of thoracic pain, such as standing with elbows abducted or catching the

VetBooks.ir

breath before expiration; these signs are a result of the painful fibrinous pleuritis caused by *M. haemolytica*. Because *M. haemolytica* is a gram-negative organism, endotoxin (lipopolysaccharide) is produced by the agent, and thus cattle with mannheimiosis may show signs of endotoxemia, including fever, tachycardia, tachypnea, salivation, respiratory distress, pale or dark mucous membranes with prolonged capillary refill time, and cool extremities. Thoracic auscultation may reveal harsh or loud bronchovesicular sounds consistent with pulmonary consolidation,[8] particularly over the cranioventral lung. Disease after *M. haemolytica* infection can be fatal, particularly if it is not treated; it can also lead to chronic pneumonia associated with secondary invasion with agents such as *P. multocida, Mycoplasma bovis,* or *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*).

It is important to remember that naturally occurring disease caused by *M. haemolytica* is commonly preceded by infection with a viral agent such as BHV-1, BRSV, or BVD; therefore the clinical signs described previously for these and other respiratory viruses may also be present in animals infected with *M. haemolytica*.

Pathogenesis *M. haemolytica* is a normal inhabitant of the nasal and pharyngeal mucosa,[10] but not the lung, and is considered an opportunistic pathogen. Calves and lambs become infected at an early age and carry *Mannheimia* as a minor part of the upper respiratory tract flora. Only a small percentage of nasal swabs yields positive results for *M. haemolytica* serotype A1 in healthy, unstressed calves,[11] but if several areas of the nasal mucosa are cultured at necropsy, it is often possible to isolate *M. haemolytica* from animals that previously had negative findings on nasal swabs.[12] The stress of transportation or viral infection causes a breakdown of the defense mechanisms that limit normal bacteria flora, resulting in a rapid proliferation of virulent *M. haemolytica* serotype A1. A greater number of calves will yield positive nasal swab *M. haemolytica* culture during and after transport, and there is a large increase in the numbers of *M. haemolytica* in positive samples.[11,12] BHV-1 and PIV-3 have been shown to have the same effect as transportation on *Mannheimia* populations of the nasal mucosa. *M. haemolytica* has been demonstrated in the tracheal air of stressed, healthy calves harboring the organism on their nasal mucosa. Some of these inhaled organisms are deposited deep within the lung and normally are cleared within hours. But under conditions of impaired pulmonary defenses caused by insults to the upper respiratory tract, nutritional deficiencies, or preexisting viral infection, *M. haemolytica* is able to proliferate rapidly within the lung and, with the aid of its virulence factors and toxins, to produce a severe lobar necrotizing fibrinous pleuropneumonia. Calves infected with respiratory viruses, including BHV-1, PIV-3, BVDV, and BRSV, or *Mycoplasma* spp. have increased susceptibility to severe bronchopneumonia when exposed to *M. haemolytica*. Similarly, infection of lambs with PIV-3 or adenovirus followed in several days by *M. haemolytica* causes severe pneumonia.[13]

Once *M. haemolytica* becomes established in the lungs, interactions between the bacteria and the host defenses result in tissue damage and elimination of the invader.[14] A major virulence factor of *M. haemolytica* is an exotoxin that is lethal to ruminant leukocytes, the leukotoxin. Leukotoxin, which is produced by *M. haemolytica* during the logarithmic phase of growth, causes cytolysis of ruminant platelets, lymphocytes, macrophages, and neutrophils.[15] There is diversity in the gene encoding the leukotoxin molecule among *M. haemolytica* serotypes, and genetic diversity is related to differences in toxicity. For example, the leukotoxin encoded by some pathogenic bovine serotype A1 strains differs from the leukotoxin encoded by ovine A1 strains by only one amino acid but is substantially more toxic for bovine leukocytes than for ovine leukocytes.[16] Leukotoxin binds to cells via CD18, the beta subunit of the β_2 integrins CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and CD11c/CD18 (CR-4),[17,18] and although leukotoxin can bind to cells from nonruminant species, only ruminant cells are killed by the toxin.[15] Contact with leukotoxin increases expression of LFA-1 on ruminant leukocytes, making the cells even more sensitive to injury by leukotoxin.[19] At low concentrations, leukotoxin induces leukocyte death by apoptosis, whereas at higher concentrations the toxin causes cell lysis.[20] *M. haemolytica* expressing a mutant nontoxic leukotoxin induced less lung pathology in calves as compared with *M. haemolytica* producing functional toxin, but clinical signs were not different between the two groups of calves, indicating that leukotoxin is not the only virulence factor of importance in causing disease.[21]

Another virulence factor that contributes to disease resulting from *M. haemolytica* is lipopolysaccharide, or endotoxin. As in other species, exposure of ruminants to endotoxin from gram-negative bacteria induces a multitude of responses leading to inflammation, including initiation of the complement and coagulation cascades, activation of endothelial cells and recruitment of neutrophils, and activation of neutrophils and alveolar macrophages, leading to their production of proinflammatory cytokines, which further amplify the inflammatory response. The proinflammatory cytokines TNF-α, IL-1β, and IL-8 are expressed in the lungs of cattle within 48 hours of *M. haemolytica* infection.[22] Calves exposed to a preparation containing *M. haemolytica* endotoxin develop leukopenia, fever, tachypnea, diarrhea, and dyspnea as early as 2 hours after exposure.[23] Endotoxin potentiates the effects of leukotoxin by inducing increased expression of β_2-integrins on leukocytes, which contain CD18, the receptor for leukotoxin.[19,24] Bovine alveolar macrophages first exposed to endotoxin were susceptible to death induced by concentrations of leukotoxin too low to cause cell death alone, and macrophages exposed to both endotoxin and leukotoxin produced more of the proinflammatory cytokines IL-8 and TNF-α than did macrophages exposed only to leukotoxin.[24] These data indicate that leukotoxin and endotoxin work in synergy to cause disease in ruminants. The production of IL-8 is of particular importance, because IL-8 is a major inducer of neutrophil chemotaxis.[25] The massive influx of neutrophils induced by IL-8 and other inflammatory mediators is a key factor in lung tissue destruction caused by *M. haemolytica*. Calves experimentally depleted of neutrophils are completely protected from gross and microscopic lesions of the severe fibrinonecrotic bronchopneumonia that is induced by intratracheal inoculation of *M. haemolytica* in calves with normal neutrophil levels.[26] Lysis of neutrophils results in the release of lysosomal products, including elastase, collagenase, and reactive oxygen intermediates. These chemicals are bactericidal but also capable of destroying the neutrophils themselves and surrounding tissues. Neutrophil-mediated damage to the endothelial cells results in exudation and thrombosis, which produce the classic lesions of necrosis and fibrinous exudation.[27]

In addition to leukotoxin and endotoxin, *M. haemolytica* possesses other factors that contribute to its virulence. The bacteria have a polysaccharide capsule that aids in attachment and prevents phagocytosis by neutrophils,[28] and iron-regulated outer membrane proteins (IROMPs) that bind transferrin and alter the function of neutrophils.[29,30] The bacteria produce adhesions that mediate attachment to host cells,[31] and neuraminidase produced by the bacteria may aid in host colonization by decreasing the viscosity of respiratory mucus[32] and decreasing the repellant negative charge on host cells by cleaving sialic acid residues.[33]

Epidemiology In many studies over several decades, *M. haemolytica* has been found to be the most common bacterial isolate from feedlot cattle with fatal fibrinous bronchopneumonia.[34-37] *M. haemolytica* was isolated postmortem from 25% to 30% of cattle that died or were euthanized because of pneumonia in two studies evaluating causes of mortality in feedlot cattle.[34,37] Seroconversion to *M. haemolytica* or *M. haemolytica* leukotoxin has been significantly associated with treatment for respiratory disease or "undifferentiated fever" in feedlot cattle in some[38,39] although not all[40] studies. Booker and colleagues found that the odds of developing undifferentiated fever (case definition similar to that usually used for undifferentiated respiratory disease) was 2.8 times greater for cattle that developed a fourfold rise in antibody titer to *M. haemolytica* leukotoxin, as compared with cattle that did not seroconvert to leukotoxin.[39] And whereas O'Connor and coworkers found no association between seroconversion to *M. haemolytica* and treatment for undifferentiated

VetBooks.ir

respiratory disease, they did find that vaccination against *M. haemolytica* was significantly associated with protection against the development of undifferentiated respiratory disease in feedlot cattle in their study, which indirectly indicated a role for *M. haemolytica* in the development of respiratory disease.[40] Although *M. haemolytica* is recognized as the bacteria most commonly contributing to fibrinous pneumonia in feedlot cattle, one study that used bronchoalveolar lavage (BAL) to identify bacteria present in the lungs of feedlot cattle before antimicrobial treatment for acute pneumonia found that *M. haemolytica* was not identified more frequently in the lungs of cattle with pneumonia than normal controls, whereas *P. multocida* was significantly associated with bronchopneumonia.[41] In this study, none of the calves died or were euthanized because of the naturally occurring disease, indicating that disease was not severe. Because *M. haemolytica* is relatively more likely to cause acute fatal pneumonia than other bacterial pathogens of the ruminant lung, it may be overrepresented in necropsy surveys in which only fatal cases of disease are sampled.

In contrast to the situation in feedlot cattle, *M. haemolytica* is not commonly associated with outbreaks of pneumonia in dairy calves. At postmortem examination of 43 calves from 34 outbreaks of respiratory disease, *M. haemolytica* was isolated from only two calves[42]; in another study, *M. haemolytica* was isolated from calves in 4 of 14 outbreaks of respiratory disease.[43] Although *M. haemolytica* is not as commonly isolated from calves as are other bacterial pathogens, it can be a cause of fatal disease; in one study, only *M. haemolytica* was significantly more often isolated from calves with fatal pneumonia as compared with calves with subclinical pneumonia.[44]

Necropsy Findings Infection with *M. haemolytica* causes fibrinopurulent bronchopneumonia or pleuropneumonia (Color Plate 31-5). The infection is aerogenous, so disease occurs primarily in the cranioventral lung, but in severe cases, a majority of the lung may be affected. Affected areas of lung are dark red to purple or gray-brown (Color Plate 31-6), firm, and heavy; discolored areas may be wedge-shaped owing to thrombosis of a vessel supplying the affected region during the severe inflammatory response. The interlobular septa are expanded by clear to yellow gelatinous material that represents proteinaceous fluid that has leaked from blood vessels in the lung. The inflamed areas of lung are covered with yellow fibrin that may adhere to the pleura of the thoracic wall, and the pleural cavity usually contains straw-colored fluid, which may be voluminous.[7-9] In cases that have been ongoing for a few days, firm, gritty lumps that are dry and crumbly on sectioning may be identified; these represent areas of necrotic tissue.[9] Bronchial lymph nodes may be swollen, wet, and dark red. Histologically, alveoli are filled with edema and fibrin, and there is massive infiltration of neutrophils and macrophages. "Oat cells" can be seen, which are necrotic leukocytes with streaming of the chromatin.[34] Foci of coagulative necrosis are often found rimmed by a basophilic border of leukocytes; coagulative necrosis may expand to fill entire lobules. Hemorrhage is often present both within and between alveoli, and an occasional vessel may be found to contain a thrombus. Interlobular septa and lymphatics can be found dilated with edema and fibrin. Bronchioles are filled with leukocytes and may have foci of epithelial necrosis.[8,9,34] *M. haemolytica* may also produce pneumonia characterized by firm, dark red pulmonary consolidation without fibrinous pleuritis; this is especially common in dairy calves or sheep and goats. Animals that survive the acute stage of pneumonia caused by *M. haemolytica* may have multiple abscesses and pleural adhesions; in these cases other bacteria such as *P. multocida, Mycoplasma bovis,* or *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) may be contributing to pathology.

Diagnosis Diagnosis of pneumonia caused by *M. haemolytica* is most reliably made by culture of lungs with typical gross pathology at postmortem evaluation of animals that die or are euthanized as representative cases in outbreaks. Antemortem diagnosis in individual animals can be made by collecting fluid by transtracheal aspiration (TTA) or BAL and submitting the fluid for aerobic bacterial culture. These methods are not practical for widespread use in the field, but they may be warranted for valuable individual animals or to identify the cause of an outbreak of respiratory disease in several animals. Cytologic evaluation of TTA or BAL samples would be expected to reveal septic purulent inflammation characterized by large numbers of neutrophils that may be degenerate, exhibiting toxic change, and possibly containing intracellular bacteria. Deep nasopharyngeal swabs may accurately indicate involvement of *M. haemolytica* in a respiratory disease outbreak in a group of cattle, but the results of deep nasopharyngeal swabs collected from individual cattle are hard to interpret because *M. haemolytica* can be found in the normal bovine nasopharynx. Thoracocentesis can be a useful diagnostic procedure for identifying fluid accumulation in the thorax; fluid collected shows a high percentage of neutrophils with a high (>3 g/dL) total protein content if bacterial pleuropneumonia is the cause of fluid accumulation. Pleural fluid collected by thoracocentesis can also be submitted for aerobic bacterial culture to confirm infection with *M. haemolytica*. In a hospital with the necessary equipment, transthoracic ultrasound evaluation can be used to confirm the presence of consolidated lung tissue and pleural effusion with fibrin.[45] Thoracic radiography, if possible, is expected to show evidence of consolidation of the cranial lung and possibly pleural fluid accumulation.[46] Evidence of pneumonia identified by either radiography or transthoracic ultrasound evaluation has been shown to correlate strongly with findings on postmortem examination of calves with bacterial bronchopneumonia.[45,46]

Serologic tests can be used to identify serum antibodies to *M. haemolytica,* and seroconversion identified by paired serologic testing could be used to confirm infection with *M. haemolytica* in one or more ruminants. However, these tests are most commonly used for research applications, and they may not be available at all diagnostic laboratories.

Treatment and Prevention Treatment of *M. haemolytica* requires administration of an antimicrobial effective against the organism. Many antimicrobials are currently labeled for the treatment of *M. haemolytica* (see Table 31-12). The decision to choose any one of the many approved products is based on multiple factors, including regional susceptibility of *M. haemolytica* isolates, the number of times it is possible to treat animals, withdrawal times, and cost.

In addition to appropriate antimicrobial therapy, treatment to prevent the adverse effects of endotoxin should be considered for ruminants suspected or confirmed to have pneumonia caused by *M. haemolytica.* The NSAID flunixin meglumine can ameliorate the inflammatory response to endotoxin, and treatment with flunixin meglumine has been shown to improve outcome in individual animals infected with *M. haemolytica.* However, administration of NSAID drugs such as flunixin meglumine has not been shown to be reliably cost-effective in the treatment of large numbers of feedlot cattle with respiratory disease. Thus a consideration of the value of the animals treated may be necessary before NSAID therapy can be justified in an entire group of calves.

Prevention of infection and disease caused by *M. haemolytica* is approached by three avenues: administering antimicrobials prophylactically to animals at high risk of disease; increasing host immunity by ensuring adequate passive transfer and administering vaccines against *M. haemolytica;* and minimizing factors such as viral respiratory tract infection, mixing of animals from various sources, and long-distance shipment, which increase the susceptibility of animals to disease caused by pathogenic serotypes of *M. haemolytica.*

Prophylactic or metaphylactic administration of antimicrobials effective against *M. haemolytica* is a reliable means of decreasing morbidity and mortality associated with respiratory disease in calves at high risk for disease because of recent weaning, uncertain immune status, mixing with cattle from a variety of sources, and long-distance shipment. In one study, administration of tilmicosin to groups of such high-risk calves either before shipment or on arrival at feedlots

VetBooks.ir

decreased the proliferation of *M. haemolytica* serotype A1 in the nasopharynx of calves and was associated with decreased treatment for respiratory disease as compared with calves not treated with tilmicoson.[47] In a later study, administration of florfenicol at arrival decreased colonization of the nasopharynx with *M. haemolytica* A1 and delayed treatment for respiratory disease.[11] Further discussion of the role of metaphylactic administration of antimicrobials to control BRD can be found elsewhere in this chapter.

Mixing recently weaned calves from multiple sources and shipping them long distances is a well-known precursor to outbreaks of fibrinous pneumonia[48]; and because *M. haemolytica* is the species of bacteria most commonly associated with fatal fibrinous pneumonia, it follows that efforts to minimize stresses and improve immunity for calves moving through the marketing chain should lessen disease caused by *M. haemolytica.* Recent studies have indicated that preconditioning, wherein vaccination and stressful procedures such as weaning and castration are carried out well in advance of mixing and shipment, can decrease costs associated with fibrinous pneumonia in feedlot cattle.[49] However, preconditioning should not be considered a guarantee against all respiratory disease; disease that is sometimes severe can occur in preconditioned calves. Further discussion of the role of preconditioning to prevent BRD is continued elsewhere in this chapter.

Vaccination can be used as part of a plan to decrease disease caused by *M. haemolytica.* Many experimental and commercially marketed vaccines have been tested for efficacy in preventing either disease resulting from experimental infection with *M. haemolytica* or naturally occurring respiratory disease, and the published literature is too extensive to describe in detail here. In summary, some research indicates that vaccination can lessen disease, other research shows that vaccination has no effect, and a few older reports show that *M. haemolytica* vaccination can enhance disease after infection.[50] Although commercially marketed vaccines are tested for safety, and no published reports exist that describe enhanced disease caused by currently available products, the fact that *M. haemolytica* bacterins historically caused enhanced disease is a reason to avoid the use of autogenous products that are not thoroughly tested for safety before administration. To induce protective immunity, a vaccine against *M. haemolytica* must contain leukotoxin; additional benefit may be gained by including other antigens associated with the bacterial cell wall.

Experimental challenge studies have shown that currently available commercial vaccines can lessen disease caused by infection with *M. haemolytica.*[51-53] However, data from well-designed field trials, which are a more relevant measure of the value of vaccination in the field, have reported mixed results. Recently a meta-analysis of 18 clinical trials testing the efficacy of *M. haemolytica* vaccines to prevent respiratory disease in feedlot cattle was published.[54] The 18 trials included were selected from a larger number of published trials based on the quality of their design and the fact that they evaluated the effect of vaccination on naturally occurring disease in feedlot cattle. The summary relative risk for respiratory morbidity in vaccinated cattle was 0.93 (95%, confidence interval 0.89 to 0.98), indicating that *M. haemolytica* vaccination was associated with a statistically significant decrease in morbidity when considering all the trials included in the meta-analysis. However, the summary relative risk for mortality was not significantly different for vaccinated cattle. Thus this assessment of the current research indicated that respiratory morbidity in feedlot cattle is decreased by *M. haemolytica* vaccination, but total mortality is not. Because *M. haemolytica* vaccines can be relatively expensive, they may be most cost-effective in cattle at high risk for respiratory disease.

Vaccination of sheep or goats using commercially available vaccines labeled for use in cattle is not likely to provide reliable protection against disease, as serotypes of *M. haemolytica* that most commonly cause disease in sheep and goats are not included in vaccines for cattle. Moreover, although vaccination with sheep-associated serotypes can provide protection against infection, cross protection among different serotypes is not reliable,[5] indicating that an effective vaccine will likely need to contain antigens from multiple serotypes.

Pasteurella multocida

Definition and Etiology *P. multocida* is a gram-negative aerobic bacterium of the family Pasteurellaceae. Like *M. haemolytica, P. multocida* can be found in the nasopharynx of healthy ruminants. Although *P. multocida* is regularly isolated from the lungs of ruminants with bronchopneumonia, there has been debate over the years as to whether this species is a primary pathogen—that is, capable of causing disease alone—or whether some other primary stressor or insult is required to occur before this agent can participate in disease. As with *M. haemolytica,* experimental challenge of calves with *P. multocida* alone does cause clinical signs and pathologic change in the lung similar to that seen in natural outbreaks of disease,[1-3] but large numbers of the bacteria must be administered in a way that bypasses the upper respiratory tract (most commonly by intratracheal instillation). Alternatively, prior administration of a viral respiratory pathogen makes ruminants more susceptible to disease caused by experimental *P. multocida* infection. These findings indicate that some insult that weakens the ability of the respiratory tract to resist advancement of these bacteria into the lower airways is necessary for most if not all cases of naturally occurring disease to occur. However, because *P. multocida* can cause lung lesions that can be severe,[2] and because the bacteria can exacerbate disease caused by primary viral infection, it is logical to consider this agent when planning strategies to treat and control ruminant respiratory disease.

P. multocida is a diverse species of bacteria that is classified into five serogroups (A, B, D, E, and F) based on antigenic differences in the bacterial capsule. Serogroups B and E cause hemorrhagic septicemia, a disease predominantly seen in Asia and Africa; these serogroups are rarely isolated in the United States. Serogroup A is by far the predominant serogroup associated with ruminant respiratory disease,[4,5] although serogroups D and F may be common in some regions, particularly in sheep.[6] In addition to the alphabetic serogroup designation, isolates may also receive a numeric designation based on cell wall antigen types (e.g., *P. multocida* A3 has been commonly isolated from cases of bovine pneumonia). A report characterizing 153 *P. multocida* isolates from cases of pneumonia and mastitis in cattle in England and Wales indicated that relatively few strains of *P. multocida* cause the majority of disease in cattle. Moreover, although a few strains isolated from cattle had also been associated with disease in swine and poultry, the majority of strains were uniquely associated with their host species of origin.[5] Other research indicated that certain strains of *P. multocida* had a predilection for the respiratory tract of sheep, whereas other strains were associated with the reproductive tract.[6] Taken together, these data suggest that differences among strains of *P. multocida* are related to the type of disease caused and the host likely to be affected. Therefore merely isolating *P. multocida* without further characterizing the isolate could make it difficult to know with confidence whether the type of bacteria isolated was actually contributing to disease. It has been suggested that strain variation is related to differences in severity of respiratory disease occurring in ruminants infected with *P. multocida.*[2]

Clinical Signs Calves infected with *P. multocida* alone display clinical signs of fever, increased respiratory rate, and sometimes depression, coughing, and mucoid to mucopurulent nasal discharge.[1-3] Loud or harsh bronchovesicular sounds may be heard over the cranioventral lung fields owing to pulmonary consolidation, and coarse crackles may be heard as a result of air moving through exudate in large airways. Because *P. multocida* is a gram-negative organism that produces endotoxin, signs of endotoxemia (tachypnea, tachycardia, fever) may also contribute to signs that accompany infection with the organism. Compared with calves infected with *M. haemolytica,* calves infected with *P. multocida* tend to have less severe signs, and signs of disease last for a shorter time.[1-2] *P. multocida* is more commonly isolated from young calves with pneumonia[7,8] than with other

VetBooks.ir

bacterial respiratory pathogens such as *M. haemolytica,* but it is less commonly isolated from feedlot cattle with acute bronchopneumonia.[9] Thus *P. multocida* is considered to be of relatively greatest importance in contributing to calf pneumonia. *P. multocida* has been found to overgrow *M. haemolytica* in the lungs of calves experimentally challenged only with *M. haemolytica*[1]; therefore *P. multocida* may also be an important contributor to cases of subacute to chronic pneumonia in feedlot cattle initiated by other organisms.

Pathogenesis Little is known about the pathogenesis of *P. multocida* in ruminant respiratory disease. In addition to lipopolysaccharide (LPS), the organism also has a capsule that allows it to resist phagocytosis. Outer membrane proteins, particularly iron-regulated outer membrane proteins, are likely to contribute to the ability of the bacteria to establish and proliferate within the host.[10,11] The prominent role of *P. multocida* in dairy calf pneumonia and the rather minor role in acute bronchopneumonia of feedlot cattle suggests that prolonged impairment of the respiratory defense mechanisms is necessary for this organism to establish in the lungs in sufficient numbers to create bronchopneumonia. It is likely that the organism is chronically inhaled in small numbers into the lungs of calves with persistent damage to the respiratory defenses from infectious agents such as viruses or mycoplasmas and environmental insult from inadequate housing and ventilation, allowing it to colonize and produce an expanding lesion. This proposed pathogenesis agrees with the insidious onset that is commonly observed with enzootic calf pneumonia (ECP) and would also fit the association of *P. multocida* with chronic or ongoing pneumonia in feedlot cattle. It is important to remember that culture of *P. multocida* from pneumonic lung does not exclude the possibility of other bacteria such as *M. haemolytica* being the primary pathogen, because *P. multocida* has been shown to overgrow *M. haemolytica* in challenge studies using large doses of pure cultures of *M. haemolytica.*[1]

Epidemiology *P. multocida* is commonly isolated from the lungs of calves that die or are euthanized because of bronchopneumonia, with mycoplasmas being the only bacteria isolated more often in surveys involving multiple farms experiencing outbreaks of calf pneumonia.[7,8] In contrast, *M. haemolytica* is more frequently isolated postmortem from feedlot cattle with fibrinous pneumonia than is *P. multocida.*[9,12] However, one study of bacterial isolates from BAL of feedlot cattle found that *P. multocida* was the only species isolated more frequently from cattle with clinical signs attributed to acute pneumonia as compared with normal cattle.[13] A notable aspect of this study was that animals were sampled before treatment with antimicrobials; in surveys of bacteria identified postmortem, animals have usually received antimicrobial treatment before death, which may bias the microbiological findings.

Necropsy Findings *P. multocida* produces a purulent bronchopneumonia with plum-colored cranioventral consolidation and purulent exudate on cut section within the airways; when calves are experimentally infected with *P. multocida* alone, the lesion is usually not extensive and is typically confined to the cranioventral lung lobes.[1-3] Histologically, bronchopneumonia characterized by infiltration of neutrophils and macrophages into alveoli and airways is seen. Microscopic evidence of abscesses may be present. Fibrin deposition with expansion of lymphatics and interlobular septa with edema, and focal areas of coagulative necrosis, has been reported in calves infected with *P. multocida,*[2,3] but this lesion is more typical of infection with *M. haemolytica.*[1]

Diagnosis Bronchopneumonia caused by *P. multocida* is diagnosed as described for *M. haemolytica.* The species is most commonly identified by culture of lung lesions identified at postmortem examination of affected animals. Because of the association of *P. multocida* with chronic or ongoing pneumonia, identification of this agent may indicate that the animal has been affected with bronchopneumonia for several days to weeks.

Treatment and Prevention Treatment of *P. multocida* is as described for *M. haemolytica.* Several antimicrobials are labeled specifically for the treatment of *P. multocida,* and products labeled for the treatment of *M. haemolytica* are also likely to be effective against this organism (see Table 31-12). Because *P. multocida* seems to be associated with chronic or ongoing pneumonia, effective treatment of infection with this species may require longer therapy than the 3 to 5 days historically recommended for ruminants with bronchopneumonia, but this recommendation has not been tested in controlled studies and would be an extralabel use of some antimicrobials.

Because prior insult to respiratory defense mechanisms appears necessary for infection with *P. multocida* to cause disease, prevention of disease is likely to be aided by undertaking efforts to prevent other primary respiratory injury. This would include efforts to prevent infection with viral respiratory pathogens and to establish management practices that help minimize respiratory tract disease (see more discussion of management-related risk factors for respiratory disease at the end of this section).

As compared with *M. haemolytica,* relatively little is known about protective immunity to *P. multocida.* Modified live vaccines can protect calves from disease caused by experimental challenge.[14,15] Antibody responses to several outer membrane proteins were associated with protection in one study, and these were induced by live but not killed vaccine.[15] Several commercial vaccines are marketed that contain *P. multocida* in combination with *M. haemolytica*. There are currently no vaccines marketed that contain only *P. multocida.* A recent meta-analysis evaluated clinical trials testing the efficacy of *M. haemolytica, P. multocida,* and *H. somni* vaccines to decrease morbidity and mortality due to BRD.[16] This meta-analysis included three trials testing vaccines including both *M. haemolytica* and *P. multocida;* no clinical trials were found to be suitable for inclusion that tested only the effect of *P. multocida* vaccines. Of the three trials testing vaccines containing *P. multocida,* one trial found a statistically significant decrease in respiratory morbidity in vaccinated cattle. More data from properly designed clinical trials are needed to clarify the value of *P. multocida* vaccination to prevent or limit respiratory disease in different cattle populations.

Histophilus somni

Definition and Etiology *H. somni* is a gram-negative aerobic bacterium of the family Pasteurellaceae. *H. somni* can be found on the genital and upper respiratory mucosa of normal ruminants,[1-4] but it can also cause a variety of diseases, including septicemia, thrombotic meningoencephalitis (TEME), endometritis, abortion and infertility, pneumonia, pleuritis, laryngitis, otitis, conjunctivitis, myocarditis, mastitis, and polyarthritis.[5] Only pneumonia and pleuritis resulting from this organism are considered here. Two bacteria very similar to *H. somni, Haemophilus agni* and *Haemophilus ovis,* have been isolated from sheep with septicemia, meningitis, mastitis, and reproductive abnormalities; DNA hybridization studies have indicated that these three organisms should all be classified as *H. somni.* Although specific serotypes of *H. somni* have not been associated with disease as is the case for *M. haemolytica* and *P. multocida,* differences in virulence among different strains have been demonstrated in experimental challenge studies.[6] Moreover, differences in expression of molecules considered to be virulence factors have been demonstrated when strains from healthy animals are compared with strains from diseased animals.[7] Thus it appears that some isolates of *H. somni* are more likely to cause disease than others, but more research is needed to confirm the characteristics that define a pathogenic isolate.

Clinical Signs As mentioned earlier, *H. somni* can cause disease in a variety of organ systems, and the clinical signs of infection will depend on the organ system affected. The possibility of concurrent infection of multiple systems should be considered in patients suspected to have disease caused by *H. somni.* In a Canadian retrospective study from the early 1990s, the majority of animals

VetBooks.ir

presented to a regional diagnostic laboratory for necropsy as a result of haemophilosis had disease in more than one organ system.[8] Signs of respiratory tract infection can range from mild to severe and can include fever, tachypnea, cough, nasal discharge, and depression. Severe cases of the disease can be fatal.[6,9] Harsh or loud bronchovesicular sounds may be heard on thoracic auscultation because of pulmonary consolidation, particularly over the cranioventral lung fields. Affected animals may have signs of pain owing to fibrinous pleuritis,[9] including reluctance to move, standing with elbows abducted, and catching the breath before expiration. The cell wall of *H. somni* contains lipooligosaccharide (LOS), which induces inflammatory responses identical to those induced by LPS from *E. coli*[10]; therefore animals with pleuritis or pneumonia caused by *H. somni* could also have clinical signs referable to endotoxemia, including tachypnea, tachycardia, dark or pale mucous membranes with prolonged capillary refill time, salivation, or dyspnea.

Pathogenesis *H. somni* can live on respiratory or genital mucous membranes without causing disease, and it is not entirely clear what factors related to the pathogen or host must change for disease to occur. The physical and immunologic barriers presented by the upper respiratory tract are apparently of major significance; calves exposed to *H. somni* by aerosol did not develop disease,[11] whereas instillation of the bacteria directly into the trachea or bronchi led to disease that could be severe.[6,9] As has been shown for *M. haemolytica* and *P. multocida,* primary infection by a viral respiratory pathogen is likely a predisposing factor that allows *H. somni* to advance and establish in the lower respiratory tract in many cases. Calves infected with BRSV before infection with *H. somni* had disease of greater severity than that seen in calves infected with either BRSV or *H. somni* alone.[9,12]

H. somni has many features that help the bacteria escape the immune response.[13] The bacteria have outer membrane proteins that bind to the Fc region of antibody, allowing them to escape opsonization.[7] When the bacteria are ingested by neutrophils or macrophages, they are able to resist being killed.[14] The bacterial LOS induces inflammatory responses similar to the LPS of other gram-negative bacteria,[10] and *H. somni* is able to periodically change the structure and antigenicity of its LOS, which is likely to be important in evading the host immune response.[15]

An important aspect of the pathology caused by *H. somni* is the formation of vasculitis and vascular thrombi; this was first recognized in the context of the neurologic lesion caused by the bacteria, which is known as *thrombotic meningoencephalomyelitis* (TME), but vascular thrombi are also identified histologically in the lungs of animals with pneumonia caused by *H. somni*.[9] For some time the exact cause of the vascular thrombosis typical of *H. somni* infection was not known, but research now indicates that the bacteria cause the death of vascular endothelial cells by inducing apoptosis (programmed cell death).[16] Apoptotic death of endothelial cells is mediated in part through the bacterial LOS, which interacts with the P2X7 purinergic receptor on endothelial cells, inducing activation of certain caspases, enzymes that activate the apoptotic pathway and initiate a cell suicide program.[2] Although the entire pathway leading to vasculitis and thrombosis has not been completely elucidated, thrombosis is no doubt mediated in part by exposure of the vascular basement membrane on endothelial cell death, which leads to exposure of the basement membrane, activation of platelets and the coagulation cascade, and thrombosis.

Another important aspect of *H. somni* is the propensity of infection to induce IgE production by the host.[12,17] Infection with BRSV before infection with *H. somni* led to production of high levels of *H. somni*–specific IgE, which was associated with disease of increased severity as compared with control calves.[12] Cattle vaccinated with four different *H. somni* bacterins were all found to develop serum levels of *H. somni*–specific IgE that were significantly higher than levels seen in control unvaccinated cattle.[17] Because IgE mediates type I (immediate) hypersensitivity, animals that produce IgE against *H. somni* after vaccination or primary infection could have signs of an allergic or anaphylactic response on subsequent revaccination or reinfection. Such IgE-mediated hypersensitivity reactions have been proposed to contribute to the adverse reactions sometimes seen in cattle after vaccination for *H. somni*.[17] In addition to inducing IgE production, *H. somni* directly produces histamine,[18] which could further contribute to the development of hypersensitivity-like signs during *H. somni* infection. Among other actions, histamine increases permeability of the bronchial epithelium; this may aid the bacteria in moving out of the airway and into the lung parenchyma.

Epidemiology Exposure to *H. somni* is common, with 25% to 100% of cattle in various populations having serum antibodies.[19] A retrospective study of bovine carcasses submitted to a regional diagnostic laboratory in western Canada from 1970 to 1990 indicated that cases affected with the neurologic form of haemophilosis were decreasing, whereas cases with respiratory and/or myocardial disease caused by *H. somni* were increasing.[8] The reason for the apparent shift in type of disease caused in cattle could not be determined from the study, and a similar study has not been repeated to see if the trend is continuing.

It is common for feedlot cattle to have measurable antibody titers to *H. somni* at feedlot entry,[20,21] indicating that cattle are commonly exposed on the farm of origin or in transit to the feedlot. Seroconversion is also common in the first few weeks after feedlot entry,[21,22] indicating that cattle also continue to be exposed to *H. somni* in the feedlot. Several Canadian reports have indicated that *H. somni* can be a significant contributor to the development of respiratory disease or undifferentiated fever in feedlot cattle,[23-25] although studies of feedlot respiratory disease do not always find the bacteria involved. A causative association is typically inferred either by the association of seroconversion with respiratory morbidity and mortality during the period of study or by the association of *H. somni* vaccination with decreased respiratory morbidity and mortality. By these measures it appears that most disease resulting from *H. somni* occurs within the first 2 months of the feeding period[25] and perhaps even within the first 2 weeks.[22] In some cases the association of seroconversion or vaccination with all morbidity and mortality is also evaluated, but one study found that when causes of mortality were separated into those in which it was biologically plausible for *H. somni* to be involved and those in which it was not (e.g., cattle with musculoskeletal injuries), vaccination was associated with decreased mortality attributable to *H. somni* but not with a decrease in all causes of mortality.[25] A causative association for *H. somni* (or any respiratory pathogen) is sometimes assumed when animals with high antibody titers to the organism at feedlot entry ultimately have lower respiratory morbidity and mortality,[21] although the case has been made that this is not a reliable marker of causation.[22] A decreasing antibody titer to *H. somni* was associated with decreased likelihood of disease in one study[21] and increased likelihood of disease in another[20]; this demonstrates that it is not always easy to develop a unified theory regarding the role of infectious agents and the immune response from the available data. It is also noteworthy that high-quality field research on the role of *H. somni* in feedlot respiratory disease in recent years has come almost entirely from Canada; it is not clear whether this indicates that *H. somni* is a less significant contributor to disease in the United States or whether the research has just not been done.

H. somni is uncommonly isolated in surveys of the causes of pneumonia in young calves,[26,27] but it can cause bronchopneumonia that is significant; one necropsy survey found pneumonia in 12 of 15 calves under 8 weeks of age submitted because of disease resulting from *H. somni,* and in 8 of the 15 calves, pneumonia was the only lesion found.[8]

Necropsy Findings *H. somni* produces lesions similar to those of *P. multocida,* and it may rarely produce lesions that resemble those of *M. haemolytica,* creating a fibrinous pleuropneumonia.[5,6,9] Grossly, plum or red to brown consolidated lobules are seen in the cranioventral lung, sometimes with abscesses containing brown-red fluid material. Interlobular septa can be distended with edema and

VetBooks.ir

fibrin (Color Plate 31-7), and hemorrhage may be grossly visible.[6] Purulent material is seen within airways on the cut surface of lung. The surface of the pleura may be flecked with fibrin, or in some cases fibrin deposition may be extensive, with varying amounts of straw-colored fluid in the pleural cavity. Bronchial lymph nodes may be enlarged, with ecchymotic hemorrhages on the cut surface.

Histologically, inflammatory cells predominantly made up of neutrophils infiltrate the alveoli and airways. Edema, hemorrhage, and fibrin can be seen in alveoli and interstitial spaces, and areas of coagulation necrosis surrounded by inflammatory cells may be found. Interlobular septa are expanded with fibrin, and thrombi are seen in blood vessels.[6,9]

A massive fibrinous pleuritis with pleural effusion sometimes results from septicemic spread of *H. somni.* This condition can be differentiated from the fibrinous necrotizing lobar pleuropneumonia of shipping fever caused by *M. haemolytica* because the *H. somni* lesion involves only the pleural surface, not the lung.

Diagnosis Bronchopneumonia or pleuropneumonia caused by *H. somni* is diagnosed as described for *M. haemolytica.* The bacteria can be difficult to isolate, so samples collected for culture should be transported to the diagnostic laboratory without delay, and the diagnostic bacteriology laboratory should be specifically requested to attempt to isolate *H. somni* if involvement of the agent is suspected. Samples are ideally taken from animals before antimicrobial treatment, as *H. somni* is susceptible to a wide variety of antimicrobials and treatment makes it difficult to isolate the bacteria.[5] Serologic tests have been used to identify antibodies to *H. somni* for studies of the epidemiology of *H. somni* infection,[21,22] and seroconversion as measured via paired serology could be used to confirm infection in a group of cattle, but these assays may not be available at all diagnostic laboratories. IHC has been used to identify *H. somni* in association with lesions in formalin-fixed tissues,[28] and this may be an additional test available at some diagnostic laboratories.

Treatment and Prevention *H. somni* is susceptible to a variety of antimicrobials, including tetracycline, penicillin, sulfonamides, and erythromycin, as well as more recently developed antimicrobials, many of which are labeled for use in the treatment of *H. somni* (see Table 31-12). In a feedlot with unusually high morbidity and mortality because of haemophilosis, prophylactic treatment with oxytetracycline was administered at different time points within the first 2 weeks of the feeding period in an effort to decrease haemophilosis morbidity or mortality, to no avail (although morbidity from all causes of respiratory disease was decreased).[29]

Several *H. somni* vaccines are commercially available; all are killed whole bacteria preparations (bacterins). Vaccination can prevent disease caused by experimental challenge; in one study, vaccination of 10-week-old calves with a commercial bacterin significantly decreased clinical signs and pulmonary pathology resulting from *H. somni* challenge.[6] Clinical trials of *H. somni* bacterins in the 1980s gave mixed results, with evidence that vaccination decreased respiratory morbidity and/or mortality in some trials but not in others,[25,30,31] and very little research has provided more information since then. In a cow-calf herd with a high incidence of calf pneumonia, vaccination of calves at 3 and 5 weeks of age with an *M. haemolytica* and *H. somni* bacterin in combination with a modified live BRSV vaccine led to a trend toward statistically significantly decreased treatment rates as compared with calves not vaccinated or calves vaccinated with either the bacterin or the BRSV vaccine alone.[32] Because of the trial design, the effect of *H. somni* vaccination could not be separated from the effect of *M. haemolytica* vaccination. A recent meta-analysis evaluated clinical trials testing the efficacy of *M. haemolytica, P. multocida,* and *H. somni* vaccines to decrease morbidity and mortality due to BRD.[33] Three trials testing the efficacy of *H. somni* vaccines to decrease respiratory morbidity were included in this meta-analysis—a summary relative risk of 0.97 (95%, confidence interval 0.61 to 1.54), indicating that vaccination has a statistically significant impact on respiratory morbidity. However, the authors noted that the small number of published trials testing *H. somni* vaccines gave their meta-analysis low power to detect an effect of vaccination.

The fact that *H. somni* vaccines induce cattle to produce IgE against the bacteria[17] indicates that vaccinated cattle may be at increased risk for a hypersensitivity reaction after a booster vaccine or infection. Although some older clinical trials showed a benefit associated with vaccination in terms of decreased respiratory morbidity and/or mortality, *H. somni* vaccination may also put cattle at risk for adverse reactions. Therefore it may be most prudent to recommend vaccination only for groups of cattle on operations in which significant morbidity or mortality caused by infection with *H. somni* has been confirmed.

As described for *M. haemolytica* and *P. multocida,* preventing primary injury to the respiratory tract by viral infection and limiting other causes of stress that suppress the host immune response are expected to help animals resist disease caused by *H. somni.*

Mycoplasma bovis

Definition and Etiology *Mycoplasma bovis* is a member of the genus *Mycoplasma* of the class Mollicutes, and as such it is among the smallest free-living organisms. The first known mycoplasma, identified in 1898, was the causative agent of contagious bovine pleuropneumonia, *Mycoplasma mycoides* subsp. *mycoides,* small colony variant. Mycoplasmas have since been recognized to cause disease in humans and a wide variety of animal and plant hosts. Mycoplasmas are small (approximately 200 nm) and pleomorphic, with a genome of only approximately 500 to 1000 kD. They are bounded by a single membrane, and because they lack a cell wall they are naturally resistant to antimicrobials such as penicillins and cephalosporins that work by impairing cell wall synthesis. *M. bovis* was first identified in 1961 in the United States, where it was isolated from a case of mastitis.[1] It has since spread worldwide. The bacterium was originally considered a subspecies of *Mycoplasma agalactiae,* and the two agents can be difficult to distinguish. However, *M. agalactiae* is a pathogen of sheep and goats and is rarely isolated in the United States, whereas *M. bovis* is regularly isolated in cases of pneumonia, respiratory disease, arthritis, tenosynovitis, and other disorders of cattle. *M. bovis* can cause disease in sheep, goats, and other species, but this is a rare occurrence. An overview of the clinical syndromes associated with *M. bovis* and the approach to their treatment and prevention was recently published.[2]

Clinical Signs Respiratory infection with *M. bovis* causes fever, tachypnea, inappetence, and sometimes respiratory distress.[3] Coughing and nasal discharge are reported in some outbreaks.[4,5] Respiratory disease caused by *M. bovis* can occur in outbreaks; in young calves, a subset of calves affected often develops otitis, characterized by unilateral or bilateral drooping of ears with purulent aural discharge, possibly with facial paralysis caused by cranial nerve VII involvement, and vestibular signs such as head tilt, nystagmus, and ataxia.[4-6] In weaned beef calves and cattle entering feedlots, a subset of affected animals may develop arthritis and tenosynovitis[7-9]; this syndrome is sometimes referred to as *chronic pneumonia and polyarthritis syndrome* (CPPS).[9,10] Young calves can also develop arthritis or tenosynovitis.[5] A typical complaint by the producer experiencing a respiratory disease outbreak involving *M. bovis* is that cattle do not respond to therapy as expected, and a significant proportion of affected animals remain chronically ill and unthrifty for weeks after the onset of disease.[7,8] In addition to respiratory disease, *M. bovis* can also cause mastitis, arthritis and tenosynovitis, conjunctivitis, otitis, sinusitis, and myocarditis and/or pericarditis. The bacteria can also be isolated from aborted fetuses and from semen, linking the agent to reproductive failure. North American bison *(Bison bison)* can develop severe and sometimes fatal disease following *M. bovis* infection, with mature adults often being predominantly affected.[11]

The ability of *M. bovis* to act as a primary respiratory pathogen has been debated. Classically the agent has been understood to be an opportunist, establishing itself after primary infection with viral pathogens or other bacteria. However, experimental challenge of

VetBooks.ir

gnotobiotic calves with *M. bovis* alone induced respiratory disease with clinical signs of fever, tachypnea, and inappetence in four of seven calves and grossly evident lung lesions in all seven.[3] These findings indicate that *M. bovis* can cause disease while acting alone, but, as for other bacterial respiratory pathogens described earlier, it is likely that natural disease often follows other primary insult. A survey of causes of death in cattle in Ontario feedlots identified caseonecrotic pneumonia caused by *M. bovis* as a cause of more fatalities within the first 60 days of the feeding period than acute fibrinosuppurative pneumonia typical of disease caused by *M. haemolytica* or *H. somni*.[12] This study indicates that *M. bovis* is an important contributor to mortality in some feedlots, but more research is needed to determine whether the factors that predispose cattle to fatal disease resulting from *M. bovis* are different from the factors known to predispose cattle to fibrinous bronchopneumonia caused by *M. haemolytica.*

Pathogenesis Although *M. bovis* has been recognized to cause respiratory disease in cattle for some time, little is known about the mechanisms by which the agent causes disease. In disease caused by other mycoplasmas, attachment has been shown to be a key factor in pathogenesis. In vitro studies of *M. bovis* suggest that pathogenicity is likewise associated with the ability to attach, as isolates from cases of clinical disease were better able to attach to embryonic bovine lung cells than were isolates from asymptomatic animals or high passage laboratory isolates.[13] Antibodies against several of the variable surface proteins (Vsps) expressed by *M. bovis* were able to partially but not completely block attachment, indicating that the Vsps play a role in attachment.[13] Invasiveness is another pathogenic mechanism of *M. bovis; M. bovis* was found to be capable of migration between ciliated respiratory epithelial cells, whereas *Mycoplasma dispar,* another mycoplasma commonly isolated from cases of bovine pneumonia, remained on the surface of ciliated epithelial cells.[14] The ability of *M. bovis* to invade allows the organism to cause disease in organs outside the respiratory tract, such as joints and tendon sheaths.

Available data indicate that *M. bovis* may cause disease in part through evading or impairing host immune function. Although not yet well characterized, a feature of *M. bovis* that is likely important in enabling the bacteria to escape the host immune response is the expression of Vsps. The ability to vary surface protein expression has been shown to be an important pathogenic mechanism in certain mycoplasmas.[15] *M. bovis* expresses at least three Vsps (VspA, VspB, and VspC), and isolates have been found that express some or all of these proteins.[16] A study of 50 *M. bovis* isolates, including many field isolates, showed extensive variability in Vsps at both the genetic and the antigenic level.

Evidence indicates that *M. bovis* can directly impair the activity of neutrophils. In one study *M. bovis* was found to adhere to bovine neutrophils, but adherence did not elicit an expected activation response by the neutrophils. Moreover, adherent *M. bovis* inhibited normal neutrophil microbicidal activity.[17] The bacterium is also able to kill lymphocytes by inducing them to undergo apoptosis (programmed cell death).[18] Induction of proinflammatory cytokine production by the host may also contribute to disease caused by *M. bovis.*[19]

Other research suggests that *M. bovis* may induce an immune response that is not optimally protective. Vanden Bush and Rosenbusch showed that in calves experimentally infected with *M. bovis,* serum titers of *M. bovis*–specific IgG1 increased significantly after infection, whereas titers of *M. bovis*–specific IgG2 did not increase as markedly.[20] Because IgG2 is considered superior in opsonizing ability as compared with IgG1, the authors speculated that preferential induction of IgG1 by *M. bovis* infection may be related to the apparent inability of the immune response to rapidly clear the organism.

Epidemiology *M. bovis* can be isolated from the respiratory tracts of normal cattle[21,22] and from cattle with respiratory disease.[23-25] Surveys of nasopharyngeal swabs taken from dairy calves with no clinical signs of respiratory disease found *M. bovis* in up to 34% of the animals sampled.[25,26] A survey of multiple source weaned beef calves sampled soon after arrival at nine different backgrounding or stocker operations identified nasal shedding of *M. bovis* in up to 6% of animals at each operation.[27] *M. bovis* can also be found in bovine lungs without evidence of disease at postmortem examination.[12] The fact that *M. bovis* can be isolated from animals with no clinical or pathologic signs of pneumonia has led some to question whether the agent is a true respiratory pathogen. However, a consistent association of *M. bovis* with a clinical syndrome of chronic nonresponsive pneumonia with or without otitis, arthritis, or tenosynovitis and a pathologic syndrome of bronchopneumonia with multifocal caseous necrosis visible histologically and/or grossly has led to general acceptance that *M. bovis* can contribute to significant morbidity and mortality in some situations.

Currently available data support the concept that *M. bovis* can spread from a few animals carrying the bacteria to others until a large proportion of a group is infected; transmission in these cases is most likely via respiratory infection by direct contact or short-distance aerosol.[7,8,21] Feeding milk infected with *M. bovis* appears to be another important source of infection for dairy calves.[5-7] The fact that *M. bovis* infection can be widespread in some populations was illustrated by a case-control study of cattle in the first 4 weeks after feedlot entry. *M. bovis* was found in bronchoalveolar lavage fluid of 52% of controls that were not treated for respiratory disease in the first 28 days on feed, versus 61% of cases that were treated for respiratory disease within 28 days.[28] Two weeks later *M. bovis* was found in BAL fluid from over 80% of the controls and in 100% of animals who ultimately were treated for respiratory diseases by 28 days, indicating that colonization of the respiratory tract of all cattle sampled was widespread within a short period after feedlot entry.[21] More recent work has confirmed that a large proportion of cattle can be infected with *M. bovis* over the first weeks after feedlot entry[29,30] and that infection is associated with decreased weight gain.[29] *M. bovis* infection of the respiratory tract appears to persist for weeks in feedlot cattle, but data are mixed in terms of whether cattle clear one infection only to be infected with a new isolate[30] or whether a single isolate persists for several weeks.[31] More than one genetic lineage of *M. bovis* can be involved with outbreaks; in one report, a single genetic lineage was associated with disease in a closed herd, whereas multiple genetic lineages were associated with disease in a calf ranch where animals were frequently brought on-site from multiple sources.[32]

M. bovis has been isolated from both dairy calves and feedlot cattle with respiratory disease in multiple studies, with particularly high prevalence occurring in animals with chronic pneumonia nonresponsive to antimicrobial therapy. In a survey of cattle subjected to necropsy within 60 days of arrival at 72 feedlots, lung lesions were categorized as either fibrinosuppurative (typical lesion caused by *M. haemolytica* or *H. somni*) or caseonecrotic, which were characterized grossly by the presence of multiple foci of dry caseous material and histologically by areas of eosinophilic necrotic cellular debris (caseous necrosis) surrounded by inflammatory cells and fibrous tissue. *M. bovis* was isolated in 53 of 54 cases (98%) with caseonecrotic lesions and in 52 of 58 of cases (89%) with fibrinosuppurative lesions; it was also isolated from 6 of 13 animals (46%) with normal lungs in this study.[12] In 49 chronically sick cattle from a single feedlot, *M. bovis* was identified in the lungs of 82% of the cases and in the joints of 45% of the cases.[33] BVDV was also present in 39% of the cases from which *M. bovis* was isolated. A later retrospective study by the same authors found BVDV in the lungs of 44% of cattle subjected to necropsy with a final diagnosis of pneumonia caused by *M. bovis;* these data led the authors to suggest that immunosuppression resulting from BVDV may predispose a subset of animals to chronic pneumonia and/or arthritis caused by *M. bovis*. In contrast, others found that BVDV infection was not more common in feedlot cattle with caseonecrotic lesions typical of *M. bovis* infection.[24]

Necropsy Findings Grossly, lungs of cattle with pneumonia caused by *M. bovis* have dark red, firm consolidated lobules of the

VetBooks.ir

cranioventral lung. In some cases, raised white to yellow, firm nodules that range from 0.5 to several centimeters in diameter, or that may coalesce, are seen clustering in the cranioventral lung (Color Plates 31-8 and 31-9).[3,10,34] These nodules may appear to be abscesses, but in most cases they are actually foci of coagulation necrosis.[3,24] Differential diagnoses for gross lesions of abscessing pneumonia in cattle include infection with *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *F. necrophorum,* or *Mycobacterium bovis* (tuberculosis). Other gross lesions include enlargement of interlobular septa by edema and fibrin; fibrinous or fibrous pleural adhesions are unusual but could be present if the animal is or has been co-infected with *M. haemolytica* or *H. somni*. Animals with pneumonia typical of *Mycoplasma bovis* may also have arthritis in one or more joints, characterized by abundant yellow fluid with fibrin and sometimes purulent material, and tenosynovitis, characterized by extensive caseous exudate and pyogranuloma formation in the tendon sheaths.[8,10] Fibrin, purulent material, and caseous material may be present in the tympanic bullae.

Histologically there is purulent pneumonia and bronchiolitis, with extensive infiltration of neutrophils in airways, and peribronchiolar cuffing with lymphocytes and mononuclear cells. Foci of eosinophilic coagulation necrosis are surrounded by a rim of dark pyknotic inflammatory cells and, farther out, a region of primarily macrophages and some plasma cells.[3,10] Immunohistochemical staining for the organism often shows large numbers surrounding the periphery of areas of coagulation necrosis, as well as in association with bronchiolar and alveolar epithelial cells.[10,35] Histologic evaluation of joints, tendon sheaths, and the tympanic bullae and petrous temporal bone will reveal changes consistent with the gross lesions. Close inspection may also reveal foci of mononuclear cell accumulation with positive staining for *M. bovis* by IHC in the liver and kidney[35] or in the pericardium.[36]

Diagnosis Confirmation of respiratory disease caused by *M. bovis* is best made by identification of the agent by culture or IHC in conjunction with typical gross and histopathologic lesions. Thus, in order to reliably confirm a role for *M. bovis* in an outbreak of BRD, postmortem of representative affected cases is necessary. Identification of the bacteria in nasal swabs is less reliable; the agreement between the results of nasal swab culture and the presence of lung disease caused by *M. bovis* was good in one study[23] and only moderate to poor in two other studies.[28,37] Deep nasopharyngeal swabs may accurately indicate involvement of *M. bovis* in a respiratory disease outbreak in a group of cattle if swabs from multiple animals are positive. Therefore, if diagnosis is to be attempted via nasopharyngeal swabs, multiple animals should be sampled. The results of deep nasopharyngeal swabs collected from only one or two cattle are hard to interpret because *M. bovis* can be found in the normal bovine nasopharynx. It is important to request that the diagnostic laboratory specifically identify *M. bovis;* in many cases diagnostic laboratories characterize mycoplasmas only to the level of the genus. Because other mycoplasma such as *Mycoplasma bovirhinis, Mycoplasma dispar,* and *Mycoplasma alkalescens* can also be isolated from the respiratory tract of cattle with pneumonia, a report of "*Mycoplasma* sp." is not equivalent to a diagnosis of disease caused by *M. bovis*. Species-specific identification of *M. bovis* can be made by antibody-based tests such as IHC or immunofluorescence (available at the Iowa State University Veterinary Diagnostic Laboratory, and possibly others) or PCR (available at many laboratories, including the University of Georgia Athens Veterinary Diagnostic Laboratory).

Although available data suggest that *M. bovis* is less commonly isolated from healthy cattle than are other mycoplasmas, because the organism can be found in nasal swabs and lung tissue of apparently normal animals, an isolation of the bacteria in the absence of evidence of disease is of uncertain significance. Serologic assays have been used to characterize seroconversion in epidemiologic studies, but the tests are not widely available, and their results have not been shown to reliably indicate active infection.[38] If serology is attempted, paired serology with evidence of rising titers in association with outbreaks of respiratory and/or joint disease is likely to be more useful than measurement of titers on a single occasion.

Treatment and Prevention Multiple authors report that cattle with pneumonia or arthritis caused by *M. bovis* respond poorly to antimicrobial therapy.[8,9,38] Early studies indicated that tilmicosin had good effect against experimentally induced[38] disease caused by *M. bovis* in cattle; however, recent studies of in vitro susceptibility profiles of panels of *M. bovis* isolates reveal evidence of widespread resistance to tilmicosin, as well as to erythromycin, ampicillin, and ceftiofur.[39,40] Susceptibility to oxytetracycline and chlortetracycline has been variable; most isolates have been susceptible to fluoroquinolones such as enrofloxacin or danofloxacin.[40-42] Several antimicrobials are currently labeled in the United States for treatment of disease caused by *M. bovis,* including tulathromycin (Draxxin, Zoetis, Florham Park, N.J.); florfenicol (Nuflor Gold, Merck Animal Health, Summit, N.J.); enrofloxacin (Baytril 100, Bayer Healthcare LLC, Animal Health Division, Monheim, Germany); and gamithromycin (Zactran, Merial, Duluth, Ga.).

Although clinical trials and data from well-controlled experimental studies under conditions typical of U.S. and Canadian cattle operations are lacking, reports suggest that in vitro minimum inhibitory concentration (MIC) data may not always predict antimicrobial efficacy in the field.[38,43] If in vitro susceptibility tests fail to predict clinical efficacy, the reason for this failure is not certain. Because *M. bovis* can be seen in association with foci of coagulation necrosis in lungs of affected cattle,[10,24] it may be that antimicrobials are not maximally effective in this environment, or it may be that insufficient duration of treatment is carried out in at least some cases. Controlled trials indicating the duration of antimicrobial therapy needed for effective treatment of pneumonia caused by *M. bovis* are lacking, but anecdotal reports suggest that early treatment is critical for success[5,44] and that treatment should be continued for at least 7 to 10 days. Failure of antimicrobials that are predicted to be efficacious against *M. bovis* may also be related to inability of the immune response to effectively clear the organism, due to immunosuppressive mechanisms described previously. Some veterinarians report that outbreaks of *M. bovis* cannot be stopped with any treatment but that outbreaks are eventually terminated when chronically affected animals die or are shipped to slaughter.

Research indicates that vaccination can afford some protection against experimental challenge with *M. bovis.*[45,46] Autogenous vaccines have been used for years, but no reports with large numbers of animals and appropriate controls are available to provide information about efficacy. Vaccines for control of disease caused by *M. bovis* are licensed for sale in the United States; for vaccines to be fully licensed, evidence of safety and efficacy in experimental challenge studies must be presented. However, properly designed field trials provide better evidence of usefulness of vaccines in the field, and reports of field trials to test the efficacy of currently licensed *M. bovis* vaccines are sparse. Results from two trials testing the effect of *M. bovis* vaccines on respiratory disease in dairy or veal calves were recently reported.[47,48] In one trial, there was no difference in respiratory morbidity or mortality in the first 90 days of life for vaccinated calves, as compared with unvaccinated controls.[47] In the second trial, which evaluated the effect of two different commercially available *M. bovis* vaccines on lung lesions at harvest of veal calves at approximately 145 days of age, lung lesions were decreased in one vaccine group but not the other group, as compared with unvaccinated controls.[48] More properly designed field trials are needed to determine the value of *M. bovis* vaccination as used in the field in different types of cattle populations.

It is not yet clear why some cattle develop chronic disease typical of *M. bovis* and others do not when it can be found in the respiratory tracts of animals in both populations. Certainly the primary insults known to put cattle at increased risk for infection with other bacterial respiratory pathogens—insults such as primary viral infection, mixing of animals from multiple sources, inadequate host immunity, and environmental stressors—may all play a role, but the relative

VetBooks.ir

importance of these and other factors in predisposing animals to disease caused by *M. bovis* are not yet known. One group presented data suggesting that disease resulting from *M. bovis* has increased in severity since the early 1980s,[24] so it may be that factors such as increasing virulence of currently circulating isolates or changes in certain management practices are involved. Because of the chronic nature of disease often associated with *M. bovis,* the syndromes described warrant control from both a financial and an animal welfare perspective. Anecdotal reports indicate that some producers with at-risk cattle have more problems with chronic nonresponsive disease caused by *M. bovis* than other producers with similarly at-risk cattle.[9] More research is needed to clarify the factors that put animals at specific risk for chronic disease associated with *M. bovis* infection.

Mycoplasma mycoides Subsp. *mycoides*, Large Colony Type

Definition and Etiology Caprine pneumonias that are not contagious among adults can be caused by several species of *Mycoplasma*. However, *M. mycoides* subsp. *mycoides* Large Colony type (MmmLC) can be a very serious cause of mortality among goat kids and does in North America.[1,2] It has been proposed that MmmLC be reclassified as a serotype of *Mycoplasma mycoides* subsp. *capri* (Mmc), as the two organisms can only be distinguished serologically.[3] *Mycoplasma mycoides* subsp. *mycoides* Small Colony type (MmmSC), which is more distantly related to MmmLC and Mmc, is the causative agent of contagious bovine pleuropneumonia, a serious cause of sickness and death in cattle in Africa. MmmSC has been eradicated from North America.

Clinical Signs In herds with MmmLC infections, goat kids usually appear clinically normal until 2 to 8 weeks of age, when any of the following three clinical syndromes occur[1,2]:

1. A peracute illness characterized by high fevers (41.1°C to 42.2°C [105.8°F to 107.9°F]) and death within 12 to 24 hours
2. A central nervous system syndrome with opisthotonos and death within 24 to 72 hours
3. An acute to subacute syndrome with high fevers, multiple hot swollen joints, and pneumonia

The most common manifestations are swollen joints, lameness, and recumbency. About one half of affected kids have increased lung sounds on expiration and elevated respiratory rates. During an outbreak, 80% to 90% of kids die or are euthanized because of permanent recumbency. MmmLC infection in adult does is also life-threatening. Forty-six does died in 1 week on a 600-goat dairy during an acute outbreak of arthritis and polyarthritis, mastitis, and interstitial pneumonia caused by MmmLC infection.[4]

Necropsy Findings The most common necropsy finding in goat kids that die of MmmLC infections is a fibrinopurulent polyarthritis.[1,2] Approximately one half of field cases have pneumonia. One or more lung lobes have areas of patchy to diffuse red consolidation that is sometimes covered with a fibrinous exudate. Clear, golden yellow to serosanguineous fluid is found in the thorax in half of the cases. In some patients there are fibrinous adhesions between the lungs and thoracic wall. Affected lungs have microscopic evidence of bronchopneumonia or interstitial pneumonia. Other common lesions include pericarditis, peritonitis, and enlargement of the kidneys, liver, and spleen.

Diagnosis The definitive diagnosis of MmmLC infection in individuals requires isolation of the agent from milk, joint fluid, blood, urine, or tissue. Infected goat herds can be readily identified by culturing bulk tank milk because infected does shed up to 10^{10} MmmLC organisms per milliliter of milk.[1] Inapparent carriers can be identified by milk culturing, but false-negative results are a risk because organisms are shed intermittently. Goats can carry MmmLC in their external ear canal, and PCR of auricular swabs has been shown to be a sensitive means of diagnosis of chronic carriers.[5]

Treatment and Prevention Conventional antibiotic therapy for goats with MmmLC infections is almost always unsuccessful.[1,2] Tylosin or tetracyclines have been used; newer generation antibiotics effective against *Mycoplasma bovis* could also be tried, although this would be an extralabel use of these drugs. A low percentage of kids make a clinical recovery from the septicemic illness but often have arthritis by the time they freshen. Does that recover from mastitis become chronic carriers.

Prevention is based on maintaining herds free of MmmLC infection. Purchased does should originate only from herds that have no history of mortality in kids from arthritis and pneumonia and that have negative bulk tank cultures for MmmLC. Purchased individuals should be held separate from the milking herd until they have an MmmLC-negative milk culture result; treatment for ear mites may also be prudent. A vaccine is not commercially available.

Control of MmmLC outbreaks is centered on prevention of the systemic infection in kids and mastitis in milking does. Rapid prevention of new cases in kids can be expected from a program of feeding heat-treated goat colostrum (56°C [132.4°F] for 1 hour) or cow colostrum at birth, pasteurized milk up to 1 month of age, and pasteurized milk or a high-quality milk replacer from 1 month to weaning.[1] All kids with swollen joints should be culled. Milking hygiene should be improved to prevent transmission of infection during milking. Udders should be dried with individual cloths or paper towels, teats should be dipped with an organic iodine base preparation, and teat cups should be backflushed. Milk samples from all does in the milking herd should be cultured to identify carrier does. Infected does should be kept in a separate string and milked last or culled, depending on production. Colostrum of dry does should be cultured as they freshen, and the does should be hand-milked separately until their milk is found to be free of Mmm. Monthly cultures of the bulk tank milk from the noninfected string should be performed to ensure that it is free of Mmm infection. The goal of control procedures is eradication of Mmm from the herd.

Other Mycoplasmas

Mycoplasmas are isolated, usually in combination with other pathogens, from 50% to 90% of beef and dairy cattle pneumonias.[6-9] Mycoplasmas have been associated with peribronchial and peribronchiolar lymphoid hyperplasia, which is sometimes referred to as a "cuffing pneumonia," a common lesion in calves that die or are euthanized because of pneumonia.[10,11] Mycoplasmas have also been recovered from lesions of acute and chronic bronchopneumonia in which a cuffing pneumonia was not apparent.

Other than *Mycoplasma bovis,* the species of mycoplasmas (see Box 31-4) prevalent in North America are generally considered to be mild respiratory pathogens, mainly causing subclinical infections unless coupled with environmental stresses or infections by other pathogens. Tracheobronchial aspiration performed on dairy calves at random found that calves with both *Mycoplasma* spp. and *Pasteurella* spp. present in the aspirate were at significantly greater risk of developing pneumonia than calves with only one organism or no organisms. A study of feedlot cattle found seroconversion to *M. alkalescens* to be significantly associated with undifferentiated fever, a clinical definition similar to undifferentiated respiratory disease.[12] Effects such as immunosuppression and inhibition of the mucociliary transport mechanism, which can be mediated by mycoplasmas, suggest that they may play an important contributory role in the pathogenesis of bovine pneumonia. *Mycoplasma ovipneumoniae* is often isolated from pneumonic lungs of sheep and goats, usually accompanied by *M. haemolytica.* On its own, *M. ovipneumoniae* is capable of causing mild, subacute to chronic bronchiolitis or bronchopneumonia that probably predisposes to *M. haemolytica* infections.

Bibersteinia trehalosi

Bibersteinia trehalosi (formerly *Pasteurella trehalosi* and before that *Pasteurella haemolytica* biotype T) causes pneumonia or systemic disease with multiorgan infection in sheep. Recently *B. trehalosi* was isolated from the lungs of cattle or recently weaned calves with severe

VetBooks.ir

peracute to acute bronchopneumonia.[1] Affected cattle described in this report often died before they were noticed to be ill, and antimicrobial therapy did not seem to be very effective in spite of the fact that *B. trehalosi* isolated from lungs of affected cattle were susceptible to many antimicrobials in vitro. Vaccines against *Mannheimia haemolytica* may help limit disease caused by *B. trehalosi,*[1] but the efficacy of this has not been confirmed in field trials.

Trueperella pyogenes (formerly *Arcanobacterium pyogenes*)

Trueperella pyogenes[1] (formerly *Arcanobacterium pyogenes,* before that *Actinomyces pyogenes,* and before that *Corynebacterium pyogenes*) is a gram-positive rod-shaped species of bacteria that is a common cause of internal or subcutaneous abscesses in ruminants. *T. pyogenes* is occasionally isolated from the lungs of ruminants with pneumonia, typically from animals that have chronic pneumonia, especially with grossly visible abscesses. This species is viewed as an opportunist that contributes to respiratory disease as a secondary or possibly "tertiary" invader after viral pathogens and other bacterial respiratory pathogens have become established. *T. pyogenes* has a variety of virulence factors including a cytolytic toxin termed *pyolysin,* as well as several molecules that aid in adherence to host cells.[2] Diagnosis of this pathogen is usually made as an incidental finding at necropsy of an animal with significant respiratory disease from other primary causes. Finding *T. pyogenes* during a respiratory necropsy should not induce efforts to directly treat or prevent this pathogen, but rather should induce efforts to prevent other primary or secondary causes of pneumonia and to treat animals in a timely manner with appropriate therapy for an adequate duration in order to prevent chronic pneumonia.

Chlamydial Agents (*Chlamydophila* Species)

Chlamydial agents, most commonly *Chlamydophila abortus, Chlamydophila psittaci,* or *Chlamydophila pecorum,* have been associated with a variety of disease syndromes in cattle and small ruminants, including abortion and infertility, conjunctivitis, polyarthritis, encephalomyelitis, and enteritis. These agents are also occasionally identified in pneumonic ruminant lungs. Because chlamydial agents can also be identified in ruminants with no signs of disease, and because seroprevalence is high, the importance of chlamydial agents in ruminant respiratory disease has been debated.[1] Whereas experimental infection of calves with high numbers of *C. psittaci* via a route that bypasses the upper respiratory tract can lead to clinically evident respiratory disease that may be severe,[2] in the natural setting, these agents are most likely to participate as one of multiple factors necessary to induce important ruminant respiratory disease. Research indicates that calves are infected with chlamydial agents relatively early in life and that crowding enhances the likelihood of a high proportion of animals being infected.[3]

Approach to Diagnosis and Treatment of Respiratory Disease of Undetermined Cause (Undifferentiated Ruminant Respiratory Disease)

Amelia R. Woolums[¶]

Information regarding diagnosis and treatment of individual infectious agents that can cause ruminant respiratory disease was described earlier. However, it is common for multiple agents to be involved when a group of cattle, sheep, or goats has an outbreak of respiratory disease. Moreover, when a veterinarian is called to make an initial evaluation of a group of ruminants with respiratory disease, the infectious agents involved are not yet known. The term *undifferentiated respiratory disease* has been applied to respiratory disease of undetermined cause. Thinking of an outbreak as "undifferentiated respiratory disease" before one or more specific etiologic agents are identified is helpful to ensure that the veterinarian considers all possible infectious agents and management factors that may be contributing to disease in the animals in question, rather than immediately focusing on one agent or factor that is guessed to be of importance. A plan to diagnose and treat the current problem and prevent future respiratory disease can then be made by administering treatments and instituting management changes appropriate for any of the agents likely to affect the class of animals involved.

History Successful management of one or more ruminants with respiratory disease will require identification and alteration of the risk factors associated with occurrence of the disease; this is particularly true when multiple animals are affected in an outbreak or when endemic disease occurs at an unacceptable rate. Evaluation of the problem begins with collection of a thorough history and is followed by examination of affected animals and the environment. The history questions are directed at management practices that predispose to respiratory disease. It is important to observe personally as many management practices as possible to ensure that what is described is actually implemented. Examination of the environment includes evaluation of animal housing to determine whether poor ventilation, crowded or dirty housing, or temperature extremes are likely increasing the disease susceptibility of animals. The nutrition program should be assessed to determine whether nutritional deficiencies are likely contributing to disease susceptibility.

Clinical Signs Once a thorough history is collected, several animals involved in the outbreak should be examined. The degree of fever and severity of abnormal lung sounds were correlated with risk for retreatment for respiratory disease in feedlot cattle[1]; thus clinical examination may be important not only for accurate identification of sick cattle but also for improving estimates of outcome for cattle with respiratory disease. A scoring system has been developed to aid in the assessment of clinically evident respiratory disease in individual dairy calves and in groups of dairy calves.[2]

Ruminants affected by bronchopneumonia exhibit signs of respiratory tract inflammation and, sometimes, systemic inflammatory response. In early stages, animals stand off by themselves and do not readily approach feed. They hold their heads and ears low, appear depressed, and move slowly. Respirations become rapid and shallow, there may be frequent licking of the muzzle, and a moist cough is often present. Animals may have a fever of 40° C to 41° C (104° F to 105.8° F), and as the disease progresses they appear gaunt, have deep labored respirations, and may hold the head extended. Dyspnea may be both inspiratory and expiratory. Ocular and nasal discharges progress from serous to mucopurulent. The heavy chest wall of larger cattle may make it difficult to hear normal airway sounds. Auscultable lung changes may include increased harshness or loudness of inspiratory sounds ("large airway sounds" or "bronchial tones"). Auscultation of the anterior ventral lung fields may reveal crackles and wheezes. When ventral consolidation occurs, harsh breathing is still audible ventrally, but percussion reveals ventral dullness. Percussion is best accomplished on young calves and goats of any age. Recently shorn sheep can be readily percussed, but heavy wool makes percussion difficult. Animals in which a fibrinous pleuritis develops are reluctant to move (because of pain), have shallow respirations, and sometimes have pleural friction rubs detectable on auscultation.

Nasal discharge, dyspnea, abnormal lung sounds, cough, and high fevers are cardinal signs of bronchopneumonia. Other respiratory tract conditions that must be considered as differential diagnoses include acute bovine pulmonary edema and emphysema (ABPEE), interstitial pneumonia, pulmonary edema, pleuritis, laryngitis, tracheitis, and lungworms. Rare conditions include thoracic neoplasia and diaphragmatic hernia. Nonrespiratory diseases that may result in abnormal respiratory signs include septicemia, heart failure, acid-base imbalances, and poisonings such as nitrate toxicity. In sheep

[¶]Previous contributions by John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

and goats, ovine progressive pneumonia (OPP), caprine arthritis-encephalitis (CAE), and lung or mediastinal abscesses caused by *Corynebacterium pseudotuberculosis* or other bacteria are additional differential diagnoses.

Because ruminants are often housed in groups and are often not acclimated to individual handling, signs of respiratory disease in one or more individuals are often first noticed from a distance rather than from "hands-on" examination. Early signs of bronchopneumonia include mildly depressed attitude and appetite; thus caretakers may first identify animals with bronchopneumonia when they are offered feed, at which time affected animals fail to come forward to consume feed with normal enthusiasm. Groups at particularly high risk for respiratory disease, such as animals that have been recently weaned and/or transported by truck or trailer, should be evaluated two or three times per day for at least the first week or two after weaning or transport. Frequent evaluation of animals at high risk is important because the early signs of respiratory disease are nonspecific and subtle, and severe bronchopneumonia can advance rapidly, sometimes leading to death that is sudden and unexpected in as little as a few hours. For this reason, it is preferable to feed groups of ruminants at high risk for bronchopneumonia relatively small amounts of feed frequently, providing only what they will consume in 12 to 24 hours, rather than providing enough feed for several days in a self-feeder or via large round bales of hay. It is important to remember that once obvious signs of bronchopneumonia (such as coughing, profuse mucopurulent nasal discharge, and dyspnea) are evident from a distance, disease is often advanced and animals are less likely to respond well to therapy.

Diagnostic Evaluation of Undifferentiated Ruminant Respiratory Disease If clinical examination of a group of cattle, sheep, or goats indicates that respiratory disease is present, it is not always necessary to immediately submit samples for diagnostic testing. Occasional outbreaks of respiratory disease occur in groups of ruminants, and such occasional outbreaks can often be managed successfully with administrative symptomatic therapy alone. However, if recurrent outbreaks occur, or if animals do not respond appropriately to symptomatic therapy, then diagnostic tests are warranted so that more information is available to better characterize the nature of the problem. In such situations a careful evaluation of management practices and facility design is also warranted to ensure that all practices possible are in place to maximize the ability of animals to resist respiratory infection. Management practices that may help decrease respiratory disease are described in the section Prevention and Control of Undifferentiated Ruminant Respiratory Disease (see p. 613).

Clinical Pathology and Assessment of Immune Status Complete blood cell counts or serum biochemical analyses are rarely of much value in diagnosis of respiratory disease in ruminants. Some viruses, such as BVDV, may cause leukopenia, but when bacterial pneumonia is superimposed the white blood cell (WBC) count is most often in the high-normal range to mildly elevated with a left shift. Animals with bacterial pneumonia may have an inflammatory leukogram characterized by a leukocytosis with a mature neutrophilia, possibly with a left shift; hyperfibrinogenemia is likely to occur. Animals with chronic pneumonia may have a normal WBC count even when there is significant pulmonary pathology.

Failure of passive transfer is an important risk factor for disease in calves, so investigation of respiratory disease outbreaks in calves should include an evaluation of passive transfer status by measurement of immunoglobulins or total solids in the serum of a subset of calves 1 to 7 days of age. The zinc sulfate turbidity test, sodium sulfite test, and measurement of total serum protein with a refractometer are alternative procedures for estimation of serum immunoglobulin concentrations in groups of calves.

Necropsy Findings The value of necropsy findings to confirm the cause of death, particularly in animals that die unexpectedly, cannot be overemphasized. If producers can be convinced to allow animals that die to be subjected to necropsy, much valuable information may be gained before a disease outbreak causes excessive mortality. On a herd level, establishing a practice of subjecting all animals that die to at least gross necropsy can aid greatly in maintaining management practices that limit animal disease and death; this is because the actual cause of death identified at necropsy can sometimes be unexpected. For example, if an animal is assumed to have died of pneumonia, but it actually died of acute enterocolitis, then inappropriate control measures may be undertaken.

The cost of having animals sent to the local diagnostic laboratory for full necropsy may dissuade some owners from allowing necropsies. However, much useful information can be gained simply by gross necropsy evaluation performed on the farm by the local veterinarian. With some practice, veterinarians can develop confidence in identifying the major differentiating gross features of common diseases, and they can thus ensure that management is aimed at control of disease of the correct organ system. Moreover, there are some identifiable characteristics typical of the major infectious causes of bronchopneumonia. Gross necropsy can help the veterinarian make a more accurate list of differential diagnoses for outbreaks of bronchopneumonia, allowing the development of a more appropriate plan for treatment and prevention. Gross pathologic features of disease caused by infectious respiratory agents are described elsewhere in this chapter and are summarized briefly below. Recent reviews of the pathology of common pulmonary diseases of cattle are available for additional information.[3,4]

A respiratory necropsy should include assessment of the upper airways and trachea. Fibrinopurulent material in the larynx is evident in cattle with necrotic laryngitis. Infection with BHV-1 (IBR virus) causes generalized reddening (congestion) and small, raised, red or pale plaques on the mucosa of the nasal passages and trachea; more severe cases have dark red, hemorrhagic changes, possibly with yellow-brown exudate adherent to the mucosa (fibrinopurulent tracheitis) (see Color Plate 31-2).

Bronchopneumonia in recently transported cattle (shipping fever pneumonia) is most commonly a fibrinopurulent bronchopneumonia or pleuropneumonia. The infection is aerogenous; it begins in the bronchioles and extends into the surrounding parenchyma. The cranioventral areas of affected lungs are swollen, dark red to gray-brown in color, firm, and heavy. Bronchial lymph nodes are swollen, wet, and dark red. The inflamed lung and parietal pleura are sometimes covered with variable amounts of white or yellow fibrin, and the pleural cavity may contain straw-colored or red-tinged fluid (see Color Plate 31-5). Fibrinous pleuritis usually indicates the presence of *M. haemolytica* or *H. somni,* or possibly *Bibersteinia trehalosi*. These species can also cause necrosis of the lung, which will be firm and brown to gray (see Color Plate 31-6) and which may contain dark red wedge-shaped lesions (infarcts) that are caused by thrombosis of an artery supplying the region. The dorsal regions of the caudal lobes often are mottled by interspersed patches of inflammation and normal parenchyma. In some bronchopneumonia cases, forced respirations result in vesicular to bullous pockets of emphysema in the dorsal areas of the caudal lobe (see Color Plate 31-3). These changes can also be seen with primary BRSV infections or with AIP. Focal or multifocal areas of firm white to yellow material that look like abscesses may actually be caseous necrosis caused by *Mycoplasma bovis* (see Color Plate 31-9); the chronic phase of pneumonia resulting from *M. haemolytica* may also cause similar lesions. Abscesses containing caseous or liquid purulent material may also be caused by *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) or anaerobic bacteria. Sheep or goats that die of bronchopneumonia caused by *M. haemolytica* may have swollen lungs with reddish purple cranioventral consolidation. An extensive fibrinous pleuritis with large amounts of straw-colored exudate is often present. Chronic cases have multiple abscesses and pleural adhesions. As much as 60% to 80% of the lung tissue is often involved in fatal cases of severe bacterial pneumonia.

VetBooks.ir

Bronchopneumonia in housed dairy calves is less often fibrinous; rather it is characterized by the presence of firm, collapsed, dark red lobules in the cranioventral and possibly the caudoventral lung (Color Plate 31-10); in severe cases whole lobes of the lung may be affected. Firm dark red lobules without fibrin on the pleura are common in pneumonia caused by *P. multocida, M. bovis,* or other mycoplasmas. Infection with BRSV and PIV-3 can also cause lobular consolidation of the ventral lung. Less commonly *M. haemolytica* or *H. somni* organisms are isolated from such lesions in the absence of fibrinous pleuritis.

Animals that die after chronic persistent coughing, dyspnea, and weight loss often exhibit lesions of chronic suppurative pneumonia. Bronchi and bronchioles are filled with purulent exudate, there are multiple mature lung abscesses, and greatly dilated bronchioles contain malodorous exudate. When bronchiectasis is severe, the lung lobes have a nodular appearance.

Although gross necropsy alone can be very helpful in generating an accurate list of differential diagnoses, histopathologic and microbiological findings may add valuable information. Gross necropsy findings alone are not always definitive; for example, in one study of AIP in feedlot cattle, only 67% of the cases that were diagnosed with AIP based on clinical and gross pathologic findings were confirmed by histopathology.[5] Therefore, in outbreaks with relatively high mortality or in cases in which long-term and possibly expensive therapy is not yielding expected results, the cost of full necropsy of two or three typical cases is likely to be well worth the expense.

If full necropsy at a local diagnostic laboratory is to be undertaken, two or more animals showing signs that are typical of the early stages of the disease outbreak should be sent for euthanasia and necropsy. Although the producer may be reluctant to euthanize animals that may recover, and would rather send animals with chronic, nonresponsive disease, the chronic cases are unlikely to yield information relevant to the primary problem.

Microbiological Tests

Samples for identification of viral and bacterial pathogens associated with cases of respiratory disease can be collected antemortem from live animals or at necropsy of animals that have died or been euthanized. Appropriate samples to collect from live animals include nasal swabs, deep nasopharyngeal swabs, TTA, or BAL. Each of these samples has benefits and drawbacks. Nasal swabs are usually collected with a 6-inch (13.5-cm) swab that is not guarded (protected) from contamination. After sampling, the swab is put into transport medium that may come with the swab or may be obtained from a veterinary diagnostic laboratory. Deep nasopharyngeal swabs are usually collected using a longer swab guarded by an outer sheath, such as is used for mare or cow uterine culture. Although these swabs are unwieldy for use in sampling young calves, they allow the swab to be protected from contamination by commensal bacteria in the outer nasal passage, providing a theoretically more representative sample of viruses and bacteria in the nasopharynx that are more likely contributing to respiratory disease. Identification of common respiratory viruses such as BHV-1, BRSV, or BVDV from either a nasal or nasopharyngeal swab is significant. Although these viruses can be shed by cattle without signs of respiratory disease, if these viruses are identified in animals with respiratory disease, they should be considered contributing factors. Identification of bacterial respiratory pathogens such as *M. haemolytica, P. multocida,* or *H. somni* from nasal or deep nasopharyngeal swabs is of less certain significance. These bacteria can all be found in the upper respiratory tract of normal cattle and are thus considered part of the normal flora. However, these bacteria can cause disease if they become established in the lung. Therefore identification of these bacteria in samples collected from the respiratory tract distal to the nasopharynx (e.g., TTA or BAL) is more likely to signify lower respiratory tract infection. However, TTA or BAL samples are more time-consuming to collect than are nasal or deep nasopharyngeal swabs, particularly if multiple animals are to be sampled in an outbreak investigation. The results of bacterial culture of deep nasopharyngeal swabs and TTA or BAL have been compared.[6-8] Taken together, these studies indicate that, for individual animals, the results of a deep nasopharyngeal swab do not predict the bacteria identified in the lower respiratory tract with a high level of accuracy. However, the results of deep nasopharyngeal swabs taken from multiple animals do appear to accurately represent the status of the group. Therefore the use of deep nasopharyngeal swabs to identify bacterial pathogens likely causing a respiratory outbreak appears to be reliable if multiple animals are sampled and the same bacteria are found in a majority of the animals sampled. Because deep nasopharyngeal swabs are not reliable for identifying bacterial pathogens causing lower respiratory tract infection in an individual animal, TTA or BAL should be used to obtain a representative sample for identification of bacterial pathogens in the lung if only one or two animals are to be sampled.

Proper handling and transport of the specimens collected from live animals or at necropsy is critical to maximizing the chance of an accurate diagnosis. The veterinarian is encouraged to contact the diagnostic laboratory if he or she is uncertain about the proper methods of sample collection and transport; most laboratories now post this information on their websites. Recent reviews of diagnostic sample collection and submission in the diagnosis of respiratory disease of cattle are available for additional information.[4,9] See Table 31-11 for guidelines for identification of common infectious respiratory pathogens.

Viruses

A specific viral diagnosis requires laboratory confirmation. Most laboratories direct their diagnostic efforts toward the viruses for which vaccines are available. Diagnosis of other respiratory viruses may require the assistance of specialized laboratories.

VIRUS ISOLATION. Virus isolation is time-consuming and expensive, but it can be a sensitive method for identifying some viruses. Virus isolation is performed in cell culture. A variety of specimens can be tested, including nasal, nasopharyngeal, conjunctival, and tracheal swabs, TTA, BAL, and a variety of respiratory tract tissues that can be obtained at postmortem examination. Fluids, tissues, and swabs may be frozen; however, freezing may kill some of the virus in the sample. Alternatively, swabs and tissue specimens may be placed in a viral transport medium and kept refrigerated or on ice packs until arrival at the diagnostic laboratory, preferably within 24 hours. In general, better success at virus isolation is obtained when specimens are collected in the acute phase of disease. Chances of successful isolation may be improved by sampling asymptomatic animals that are in close contact with affected animals. These animals may be in an incubation phase of infection. Some viruses appear to be more difficult to isolate than others. For example, BRSV can be difficult to isolate by routine procedures, and other diagnostic procedures should be performed in conjunction with attempts at virus isolation to confirm BRSV infection.

DETECTION OF VIRAL ANTIGENS. IFA staining is a rapid method for identification of specific respiratory viruses. Antemortem identification can be made in cells in material obtained from nasal, nasopharyngeal, or conjunctival swabs or from cells obtained by TTA or BAL. Postmortem identification can be made from frozen tissue sections prepared from a variety of respiratory tract tissues.

Another technique that is used to detect viral antigen in tissues is immunohistochemical (IHC) testing, which is most often carried out on formalin-fixed tissue. This is a very useful procedure that allows histologic examination of tissues in conjunction with specific identification of the causative agent.

Antigen capture enzyme immunoassay (EIA) provides a rapid means for detection of respiratory viruses. These tests can be performed on fluids or homogenates of tissues obtained from the respiratory tract. Commercially available antigen capture EIAs are available for diagnosis of HRSV infections in infants and young

VetBooks.ir

children that are also capable of detecting BRSV,[10] and these are in use in some veterinary diagnostic laboratories. The same technique has been developed for the detection of BVDV and is in use for screening serum samples to detect cattle persistently infected with BVDV.

DETECTION OF VIRAL NUCLEIC ACIDS. Testing of material from swabs, fluids, or tissues for viral nucleic acid by PCR (for DNA viruses) or reverse transcriptase (RT)-PCR (for RNA viruses) is widely available at veterinary diagnostic laboratories. One benefit of using nucleic acid detection to identify pathogens is that the pathogen does not have to be viable to be identified; this can be a particular benefit for relatively labile viruses such as BRSV.

SEROLOGIC DIAGNOSIS. Retrospective diagnosis of viral infections can be made by determination of antibody titers in paired sera from individual animals. The first sample is collected in the acute phase of the disease (the "acute" sample), and the second is collected 2 to 4 weeks later (the "convalescent" sample). In a respiratory disease outbreak, multiple animals should be tested to achieve a serologic diagnosis; it is typical for seroconversion to be identified in only a subset of animals tested in any outbreak. Serologic diagnosis is made by demonstrating a fourfold increase in antibody titer in the convalescent sample as compared with the acute sample; a fourfold fall in titer from the acute to the convalescent sample also indicates recent infection. Because day-to-day variation in results of tests used for serologic diagnosis is typical, the acute and convalescent samples should be run by the laboratory on the same day. Thus the acute serum samples should be processed and stored in the freezer by the local veterinarian and later shipped together with the convalescent samples.

Because infections in young ruminants can occur in the presence of passively derived antibodies, seroconversion might not always occur during outbreaks of bronchopneumonia involving young animals.[11] This problem may be overcome by inclusion of older individuals in contact with the younger animals in the population sampled, which are likely to have lost passively derived antibodies to these viruses and will be more likely to seroconvert. A wide variety of serologic procedures is available for antibody determinations, but most laboratories use a serum neutralization (SN) test (also known as a virus neutralization [VN] test) for identification of antibodies to viruses. It is important to remember that SN tests take several days to run. Some laboratories use more rapid procedures such as ELISA or IFA for determination of virus-specific serum antibody titers. A hemagglutination-inhibition test can also be used for PIV-3 and respiratory coronavirus.

Bacteria

A wide variety of bacteria have been isolated from the respiratory tract of ruminants in association with respiratory disease. However, the most frequent and most important isolates are *M. haemolytica, P. multocida, H. somni,* and *M. bovis*. The isolation of *T. pyogenes,* coliforms, or anaerobic bacteria often is indicative of chronic pneumonia or aspiration pneumonia and may be associated with lung abscessation.

Before bacterial culture is attempted, the status of any recent antibacterial therapy should be determined, and, if possible, specimens from untreated cattle should be collected. It is important to remember that *M. haemolytica, P. multocida, H. somni,* and mycoplasmas are normal inhabitants of the nasal passages of cattle and may be cultured from respiratory tissue in the absence of respiratory disease. Not all laboratories will identify the species of mycoplasmas cultured; thus an isolate may be identified only as "*Mycoplasma* sp." If involvement with *Mycoplasma bovis* is to be confirmed, the veterinarian will likely need to specifically request species identification for any mycoplasmas isolated. Specific identification of *M. bovis* is most often done by IFA, IHC, or PCR. Some mycoplasmas are hardier or easier to grow than others; for example, it is not unusual for *M. bovis* to overgrow *M. dispar* when both are present in the same sample. Culture of mycoplasmas typically takes at least 1 week, and laboratories often call a sample negative only after the sample has been subcultured at least once, which usually requires at least an additional week.

As discussed earlier, although isolates obtained from nasal or deep nasopharyngeal swabs may reflect the bacteria causing pneumonia on a group level, accuracy may be improved by obtaining specimens from the lower respiratory tract.[8] When sampling lung tissue for bacterial infection at necropsy, contamination of the sample with environmental agents can best be prevented by first searing the lung surface with a heated spatula or knife, then making an incision with a sterile scalpel, followed by sampling with a swab through the incision. However, it may not be practical to sear the surface of the lung in the field setting. Alternatively, sections of lung and other tissue samples can be sent in sterile sealed containers on ice to the diagnostic laboratory for appropriate sampling for bacteria there.

DETECTION OF BACTERIAL ANTIGENS OR NUCLEIC ACIDS. It is common for diagnostic laboratories to use IHC for identification of bacteria in formalin-fixed tissues. This technique offers many advantages, including correlation of the pathogenic organism with the lesion and detection of pathogens not found on bacterial culture because of overgrowth of other organisms such as *T. pyogenes* or *P. multocida*. The use of PCR for identification of bacterial agents in a variety of samples is also increasingly available. The veterinarian is encouraged to contact the diagnostic bacteriologist at the local diagnostic laboratory or check the laboratory website for information regarding which tests are available.

SEROLOGIC TESTING FOR BACTERIAL PATHOGENS. Diagnosis of infection with bacterial pathogens can be attempted retrospectively through use of serologic testing as described earlier for viral pathogens. However, the use of serologic tests for identification of infection by bacterial respiratory pathogens has mostly been limited to use in research. Thus these tests are not likely to be widely available in veterinary diagnostic laboratories.

Treatment of Undifferentiated Ruminant Respiratory Disease

Amelia R. Woolums[#]

ANTIMICROBIAL THERAPY. The basic principles of antimicrobial therapy for bacterial bronchopneumonia are to treat early enough, treat long enough, and treat with the appropriate antimicrobial agent. Because there are currently many effective antimicrobials marketed for the treatment of important bacterial respiratory pathogens in cattle (see Table 31-12), failure to treat early enough is more likely an important cause of treatment failure than failure to choose the correct antibiotic. If lung lesions becomes too advanced before treatment is initiated, it may not be possible to reverse lung pathology with a practicable course of any antimicrobial.

Treating early enough requires timely identification of animals with clinical signs of respiratory disease. Because individual ruminants in production agriculture settings often receive their first treatment for undifferentiated respiratory disease from a layperson caretaker and not from a veterinarian, it is appropriate for caretakers to be taught by the supervising veterinarian to recognize signs of respiratory disease. Caretakers should be trained to watch for these signs whenever they are in contact with ruminants in their care. A clinical scoring system for use in evaluating individual and groups of dairy calves has been developed[1]; this system may help improve timely identification of calves with clinical signs of respiratory disease. Similarly, in cattle feedlots clinical signs are assessed by lay caretakers, including the pen riders who evaluate cattle in the feedlot pens and the "hospital crew" who examine individual cattle "pulled"

[#]Previous contributions by John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

or removed from feedlot pens by the pen riders and sent to a treatment area for individual assessment and treatment by the hospital crew. It is imperative that lay caretakers evaluating animals for clinical signs of disease receive training from the supervising veterinarian and that training be reviewed regularly so disease identification and treatment is as accurate and timely as possible. Additionally, treatment of affected animals by lay caretakers should be based on written protocols established by the supervising veterinarian and maintained for easy review on the farm or feedlot.

It is often the case that ruminants with undifferentiated bronchopneumonia are identified and treated presumptively based on clinical signs, without diagnostic testing to identify specific viral or bacterial causative agents. However, if animals fail to respond as expected to nonspecific therapy, diagnostic tests are warranted, as they may reveal an unexpected pathogen, a bacterial pathogen with unexpected antimicrobial resistance pattern, or another underlying disease that must be addressed. (See page 606 for a discussion of appropriate sample collection for bacterial culture and susceptibility testing.)

Because bacteria often contribute to bronchopneumonia in ruminants, appropriate presumptive treatment includes an antimicrobial effective against the most common causes of bacterial bronchopneumonia. Selection of the appropriate antimicrobial tends to be what most veterinarians focus on when treating respiratory disease because this is the aspect of therapy over which they have the greatest control. Factors such as cost, route of administration, treatment interval, drug label restrictions, necessity of extralabel doses, and withholding times may exclude a number of antimicrobials, leaving a short list of suitable alternatives for use as a first-line antimicrobial agent. Antimicrobials that are associated with severe injection site reactions, such as erythromycin, or those associated with complications of administration, such as balling gun injuries with oral boluses, are often avoided. Only antimicrobials that are licensed and effective at label doses should be considered for routine use in food animals. Table 31-12 lists antimicrobials currently approved in the United States for the treatment of respiratory disease in cattle, sheep, and goats. If data regarding the MIC of bacteria isolated from untreated animals are available, the dose or duration of therapy can be rationally modified, but it is imperative that proper withdrawal times be observed when antimicrobials are used in an extralabel fashion. At the time of this writing, the Food Animal Residue Avoidance Databank (FARAD; www.farad.org or 1-888-USFARAD) is an invaluable resource for veterinarians who need to identify withdrawal times for drugs administered to food animals in an extralabel manner. The use of MIC data requires some understanding of the pharmacokinetics and pharmacodynamics of the drugs to be considered; published information is available regarding interpretation of MIC data, or veterinarians can contact FARAD, the diagnostic bacteriologist at their local diagnostic laboratory, or a veterinary clinical pharmacologist for assistance.

A decision regarding which antimicrobial to use to treat bronchopneumonia may be based on the results of antimicrobial susceptibility testing or MIC data for bacteria isolated antemortem or postmortem from animals in the group. However, such results must be interpreted carefully. The most relevant information is gained from bacterial culture and susceptibility testing of samples collected from diseased lung at postmortem from animals that have not yet received any antimicrobial therapy. However, because animals are often treated presumptively before they die or are euthanized, it may be difficult to obtain diseased lung from postmortem of animals that have not already been treated. Once an animal has been treated, bacteria later cultured from the animal may be resistant to antimicrobials given in the past. Many bacteria, including *M. haemolytica,* can develop plasmid-mediated multiple antimicrobial resistance by bacterial conjugation so that they can become, with acquisition of a single plasmid, resistant to multiple antimicrobials.[2] Anecdotal reports indicate that bacteria recovered from the respiratory tract of cattle that have been treated with multiple antimicrobials (e.g., cattle with chronic, poorly responsive bronchopneumonia) can be resistant to multiple antimicrobials. However, bacteria isolated from the lungs of cattle that have been treated with antimicrobials are not always resistant to these drugs.[3] If bacteria resistant to certain antimicrobials are isolated from cattle that have been treated with multiple antimicrobials, it is not clear how such results should be interpreted. It may not be true that the bacteria with the same resistance profile are present in cattle in the group that have not yet been treated. Therefore treatment decisions based on bacterial culture and susceptibility results from animals that have been treated multiple times may be incorrect if applied to animals that have not yet been treated.

In situations where animals have failed to respond to therapy and a new antimicrobial choice is being considered for first-line treatment, it would seem appropriate to collect samples for culture and susceptibility testing from new cases before they are treated. However, researchers in one study that evaluated the response of cattle to treatment with tilmicosin when *M. haemolytica* or *P. multocida* resistant to tilmicosin were isolated from nasopharyngeal swabs before treatment found no difference in subsequent response to treatment by cattle with resistant pathogens isolated from the nasopharynx and cattle with no resistant pathogens isolated.[4] More research is needed to provide evidence-based guidance for interpretation of antimicrobial susceptibility data in the treatment of cattle in groups with BRD.

The choice of which antimicrobial to use can also be based on records of efficacy for animals treated in the past. Producers who keep accurate records of drugs used, with results of treatment responses, relapses, and proportion of treated animals that become chronic cases, may select first-line antimicrobials based on historical performance of a drug. This may be the best approach to antimicrobial selection. Guidelines for response to antimicrobial therapy for feedlot cattle with BRD have been suggested: 70% to 80% of animals should respond to the first treatment they are given, the case fatality rate should be between 4% and 7%, and the ratio of chronic cases to cases that die should be 0.5 to 1.0.[5]

A final method of choosing a first-line antimicrobial drug is reliance on published treatment trials. Published trials give comparisons among responses for various antibiotics in cattle with naturally occurring bacterial bronchopneumonia. The outcomes for these trials are often expressed as both health and production values. When evaluating published treatment trials that use cases of naturally occurring bacterial bronchopneumonia, it is important to realize that the results may not be applicable to the cattle and pathogens outside the operation where the trial was carried out.

Mass medication of an entire group of cattle during an outbreak can curtail the daily number of new cases and improve outcomes. In the acute stages of an outbreak, whatever drug is chosen should be given by injection; therapeutic levels are not likely to be reliably maintained by administering drugs in feed or water because of suppressed feed intake by sick cattle. It is important to base a decision to mass-medicate on measurable criteria. Some feedlot veterinarians implement mass medication when the pull rate of sick animals is 10% on each of 3 consecutive days, or 25% on a single day.[6]

Although little research has been undertaken to determine optimal duration of therapy for undifferentiated respiratory disease of ruminants, a general recommendation is that therapy should be continued for at least 48 hours after clinical signs of fever, dyspnea, and systemic inflammatory response have abated. Many of the antimicrobial drugs labeled for use in the treatment of pneumonia in cattle provide multiple days of therapeutic drug concentrations in lung tissue after only a single injection. These products decrease the time and stress associated with daily treatment; in feedlots, they also make it easier for caretakers to return animals to home pens rather than keeping them in hospital pens, which may be associated with poorer responses by treated animals. Although a 3-day course of antimicrobial therapy for undifferentiated bronchopneumonia was considered adequate in the past, the view is increasingly held that treatment for a longer duration may be more appropriate. This is particularly true for pneumonia caused by *M. bovis* in dairy calves or feedlot cattle, which may respond better to treatment for at least 7 to 10 days.[7,8] Although treatment for 7 to 10 days would be

VetBooks.ir

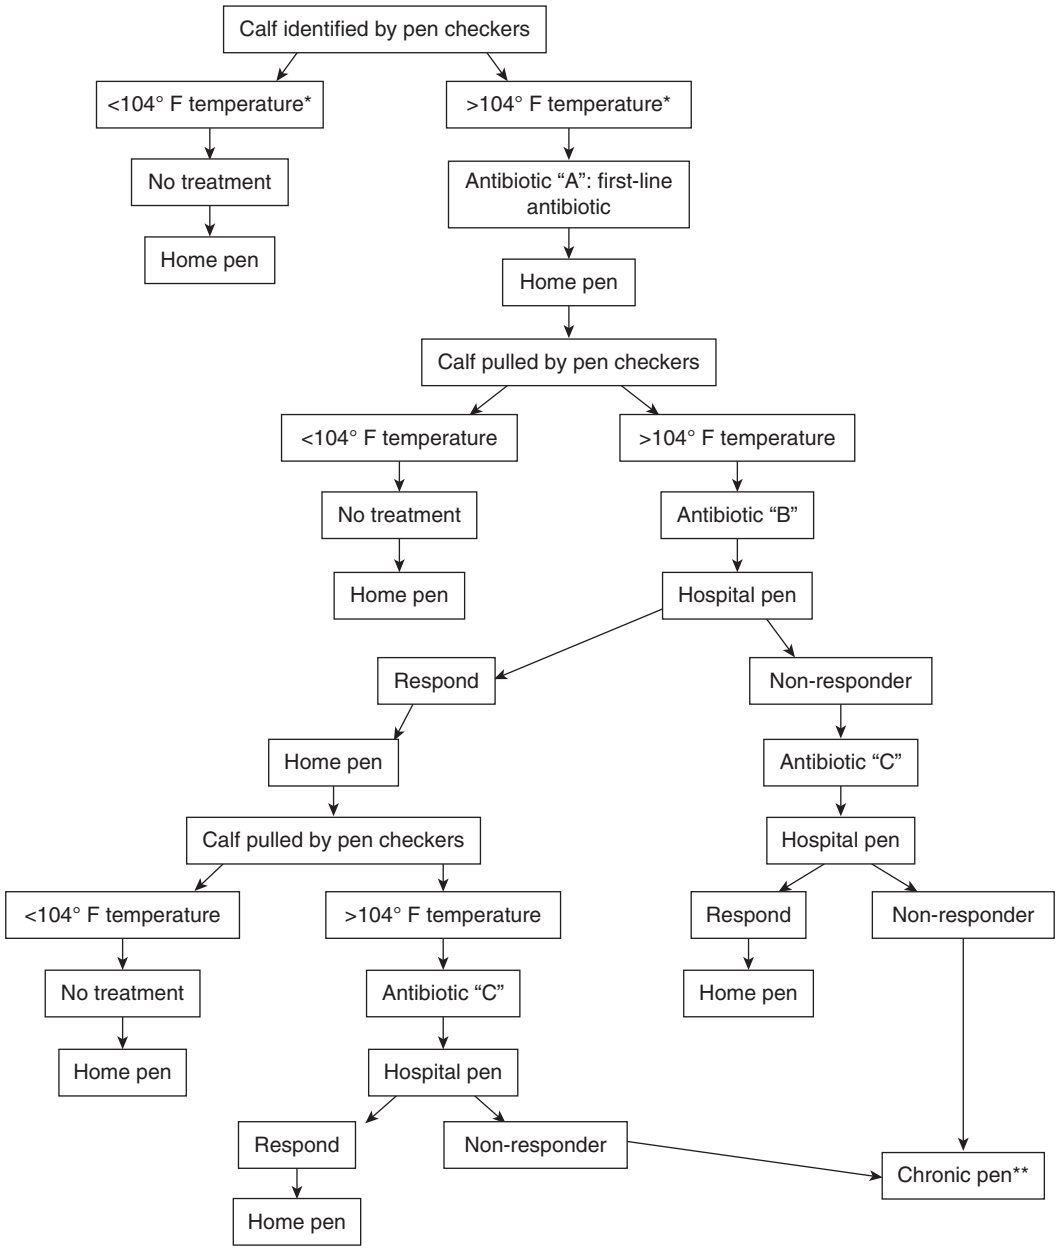
extralabel for some antibiotics, multiple drugs currently marketed have been shown to provide therapeutic drug levels for at least 7 days when used at dosages recommended on the label.

In some cases clinical signs of bronchopneumonia do not resolve following treatment with the first-line antimicrobial. In such cases, veterinarians must decide when to give a new drug and which drug to choose for second-line therapy. In the past, a standard recommendation was to administer a second antimicrobial if the animal was still febrile 72 hours after treatment with the first-line antimicrobial. However, recent research has suggested that, for cattle given a long-acting antibiotic as a first line of treatment, it may be acceptable to wait longer than 72 hours before administering a second antibiotic. For example, it has been recommended that cattle not responding to treatment with long-acting (200 mg/mL) oxytetracycline should be treated with a second drug after 2 to 3 days, whereas cattle treated with ceftiofur crystalline free acid (Excede, Zoetis) should be treated with a second drug if not responding after 5 to 7 days, and cattle treated with tulathromycin (Draxxin, Zoetis) should be treated with a second drug if not responding after 7 to 14 days.[9] It can be difficult for a veterinarian to withhold treatment with a second or even third drug if cattle are not improving quickly, but administering a different long-acting product every 3 days may not improve outcomes, although the practice will increase cost of treatment and may also increase opportunities for the development of bacteria resistant to the antimicrobials. More research is needed to provide evidence-based guidelines regarding when a second or third drug should be given to nonresponding cattle. At this time, veterinarians often make recommendations based on past experience. A typical decision tree for treating feedlot cattle with antibiotics is shown in Fig. 31-75, but protocols such as these may be modified as more information about the use of long-acting antimicrobials is obtained from field research.

The same principles of therapy described previously apply to the treatment of sheep and goats. Unfortunately, fewer drugs are labeled for the treatment of sheep and goats as compared with products used for cattle. Drugs labeled for use in sheep and goats are listed in Table 31-12. Note that whereas tilmicosin (Micotil 300, Elanco Animal Health, Indianapolis, Ind.) is labeled for use in sheep, fatal reactions to tilmicosin have occurred in goats treated with this drug. Goats should not be treated with tilmicosin. It is imperative to ensure that producers are given an appropriate meat and milk withdrawal time when antimicrobials are administered to sheep and goats at extralabel dosages; this is a particular concern in feedlot lambs or goats and in lactating dairy sheep or goats, from which products may enter the food chain in a relatively short time after treatment.

ANTIINFLAMMATORY THERAPY. Viral or bacterial infection that leads to bronchopneumonia can cause significant tissue injury and inflammation. Moreover, many of the bacteria that cause bronchopneumonia are gram-negative bacteria that produce endotoxin, which can cause a systemic inflammatory response that can be harmful and even fatal. Treatment with NSAIDs could mitigate these effects; treatment should also decrease fever and discomfort, which should lead to improved feed intake and improved growth or milk production. For these reasons, it is rational to consider treatment of ruminants with bronchopneumonia with NSAIDs. A recent review critically evaluated the published evidence for the use of NSAIDs in treatment of BRD.[10] Whereas NSAIDs often decrease fever and improve clinical appearance in cattle with BRD in the first few days after administration, a positive impact of NSAID treatment on other outcomes has not been as consistent. For example, average daily gain was improved for cattle with BRD given an NSAID as well as an antimicrobial in one study[11] but not in another.[12] Mortality was not decreased by NSAID treatment,[12,13] but lung consolidation at slaughter or necropsy was decreased in cattle receiving certain NSAIDs.[11,13] The number of properly designed studies attempting to quantify the impact of NSAID therapy on BRD is quite small; thus more research is needed to provide strong support for their use. Therapy with NSAIDs might be justified on the grounds that they should improve animal comfort and therefore animal welfare, but the degree to which they actually improve comfort and welfare has not been quantified. It has also not been well established that NSAIDs are cost-effective; this will likely vary in different settings depending on the number of animals to be treated and the cost of the drug administered. If NSAIDs are to be used for BRD treatment, in the United States and Canada flunixin meglumine (Banamine, Merck Animal Health, Summit, N.J.) is approved for control of pyrexia associated with BRD (1.1 to 2.2 mg/kg IV either as a single dose or divided into two doses at 12-hour intervals for up to 3 days). It is important to remember that flunixin meglumine is labeled only for IV use; administration via the IM or SC route can result in violative residues in tissues if longer withdrawal times are not observed. Phenylbutazone, which has been used in the past for antiinflammatory effect in ruminants, is now illegal to use in lactating dairy cattle in the United States, and because of prolonged tissue levels found in treated cattle, its use is discouraged in all food animals. Aspirin (100 mg/kg PO q12h) is sometimes used for antiinflammatory effect in cattle; however, in the United States it is not specifically approved for treatment of BRD and thus use of aspirin for BRD therapy would be extralabel. Recently meloxicam has received significant attention in North America for the control of pain and inflammation in cattle (1 mg/kg PO[14] or 0.5 mg/kg IM[15]). Like aspirin, at the time of this writing meloxicam is not specifically approved for the treatment of BRD in the United States or Canada; it is approved in Canada for treatment of calves with diarrhea or for pain control associated with disbudding. At the time of this writing no NSAID is labeled in the United States or Canada for the treatment of respiratory disease in sheep or goats.

Because NSAIDs can be nephrotoxic and because nephrotoxicity is exacerbated by dehydration, dehydrated animals should be rehydrated before administration of these drugs. Care should also be taken not to overdose NSAIDs or use them for prolonged periods, because they may also result in abomasal ulceration.



Although corticosteroids have a potent antiinflammatory effect and are sometimes used for treatment of severe inflammation associated with an infectious disease, they should not be used indiscriminately in the treatment of respiratory disease because of the potential for immunosuppression. Corticosteroids may have a place in treatment of respiratory diseases such as necrotic laryngitis or tracheal edema syndrome of feedlot cattle because edema of the larynx or trachea can cause life-threatening airway narrowing. The dose for dexamethasone in cattle is 0.05 to 0.2 mg/kg IM or IV, and the dose for isoflupredone acetate is 10 to 20 mg IM for an adult bovine animal. Treatment with corticosteroids may cause recrudescence of BHV-1 infections.

There has been little or no properly designed research to support the use of antihistamines, expectorants, or other adjunct therapies for ruminant respiratory disease.

ANTIVIRAL AND IMMUNOMODULATING THERAPY. Although antiviral drugs, in theory, could be beneficial treatment for ruminants with undifferentiated bronchopneumonia, they are not routinely used. Levamisole and isoprinosine have been used in attempts to stimulate the bovine immune system with equivocal success.[16] It is important to recognize that the immunostimulatory benefits of levamisole occur at doses in the 2- to 3-mg/kg range, compared with the anthelmintic dose of 6 mg/kg. A decreased immune response has been observed after an 8-mg/kg dose of levamisole. Vitamin C (1 g/45 kg; 1 g/100 lb) has been shown to enhance the activity of bovine neutrophils and reverse dexamethasone-induced suppression of neutrophil activity.[17] However, a recent critical review of published research testing ancillary therapies such as immunostimulants for BRD treatment[10] did not find quality evidence to support their use at this time.

SUPPORTIVE THERAPY. Supportive treatment may foster recovery of patients with respiratory disease. Sick animals should be provided shelter that protects them from rain, cold, wind, and hot sun. They should not be crowded, and good-quality feed and clean water should be easily accessible. Mineral and vitamin deficiencies

VetBooks.ir

*Temperature at which cattle are treated can vary from 103.5° F to 104.5° F; cutoff is selected at discretion of supervising veterinarian.
**Calves in chronic pen should be monitored for weight gain, suffering, and withholding times, so that appropriate action can be taken (i.e., euthanize, sell, continue feeding).

should be corrected with the use of injections or oral preparations if necessary.

Epidemiology of Undifferentiated Ruminant Respiratory Disease

Amelia R. Woolums**

RESPIRATORY DISEASE IN DAIRY CALVES. Respiratory disease in dairy calves has been described to occur both in epizootics (outbreaks), and also in an endemic (enzootic) pattern ("enzootic calf pneumonia"). At the farm level, the occurrence of producer-identified calf respiratory disease is skewed, with few or no calves being identified with respiratory disease on many farms, and many calves being identified with respiratory disease on a few farms.[1-3] The median farm-level incidence of producer-identified respiratory disease is 3% to 17% (range: up to 91%).[3-5] Reported case fatality rates for respiratory disease in dairy calves are 2.2% to 9.4%.[2,5,6] Respiratory disease accounts for a significant proportion of the total mortality (proportionate mortality) in dairy calves, with proportionate mortality rates of 30% to 52% reported.[2,7] Respiratory disease in dairy calves can be identified as early as the first week of life.[2,5] The median age at which calves are first identified by producers to have respiratory disease is between 25 and 37 days of life,[6,8] and the age at which the highest proportion of calves are treated ranges from 35 to 70 days (5 to 10 weeks) of life.[2,5,9] In a study following a large number of calves until they were 18 months old, the highest proportion of calves were treated for respiratory disease at 4 months of life.[10]

**Previous contributions by John C. Baker and Trevor R. Ames are acknowledged.

VetBooks.ir

The agreement between producers and veterinarians in identification of dairy calf respiratory disease was evaluated in two studies. Van Donkersgoed and colleagues[4] found that the risk of respiratory disease in Saskatchewan dairy calves was 39% as diagnosed by the farmer and 29% when the disease was veterinarian diagnosed. Virtala and colleagues[5] found that the risk of respiratory disease was 11% in New York dairy calves when diagnosed by producers and 26% when diagnosed by a veterinarian. In both studies the agreement between veterinarian and producer diagnosis was poor at the level of the individual calf but moderate at the level of the herd. Agreement of diagnosis in these studies was likely influenced at least in part by the fact that producers see their calves daily, while veterinarians examined calves every 1 or 2 weeks in these studies. Sivula and colleagues[2] evaluated the accuracy of producer diagnosis by subjecting 52 of the 64 calves that died to necropsy. For calves subjected to necropsy, and using necropsy as the gold standard, the antemortem diagnosis of respiratory disease by producers was determined to have a sensitivity of 56% and a specificity of 100%. Therefore producers commonly failed to identify calves with respiratory disease, but no producer incorrectly identified a calf as having respiratory disease when it did not. Although the number of cases evaluated was small, this study supports the value of necropsy for calves that die in order to ensure the correct identification of causes of death that might otherwise be missed.

Respiratory disease in dairy calves can have a negative impact on their subsequent growth and productivity. Calves treated for respiratory disease in the first 90 days of life were 2.5 times more likely to die before weaning than calves that were not treated.[11] Multiple investigators have shown that calfhood respiratory disease decreases calf growth.[12-14] Dairy heifers treated for respiratory disease weighed 10.6 kg less at 6 months of age than untreated calves.[14] Calves without signs of respiratory disease in the first 3 months of life were twice as likely to calve in the herd and calved 6 months earlier as compared to calves with signs of respiratory disease.[13]

RESPIRATORY DISEASE IN PREWEANING BEEF CALVES. As in dairy calves, respiratory disease can occur in preweaning (nursing) beef calves. Respiratory disease was reported to be the leading cause of preweaning death for beef calves 3 weeks of age or older on U.S. cow-calf operations.[15] Sixteen percent of deaths in calves born alive are attributed to BRD.[16] However, as compared with dairy calves, much less research has characterized the epidemiology of preweaning beef calf respiratory disease. Two reports described the pattern of respiratory disease occurring over several years in nursing calves in a single large herd.[17,18] In 110,412 calves over 20 years, the annual incidence of preweaning calf BRD in the herd varied from 3% to 24%, with an average annual incidence of 11%. Annual mortality among calves with preweaning respiratory disease varied from 7% to 17%, with an annual average of 13%. In some years the incidence of preweaning BRD was higher than the incidence of respiratory disease after calves were weaned and transferred to the feedlot. Calves identified with preweaning respiratory disease weighed 7.7 kg less at weaning than calves not identified with preweaning respiratory disease. A mail survey of cow-calf producers in Québec found that 16% of respondents with fewer than 40 cows recognized calves with BRD, as compared with 36% of respondents with 40 cows or more.[19] In a mail survey of producers in six U.S. states, 21% of operations reported observing one or more calves with preweaning respiratory disease. Of these, 89% treated one or more calves and 46% reported one or more calf deaths attributed to preweaning respiratory disease.[20]

RESPIRATORY DISEASE IN FEEDLOT AND STOCKER CATTLE. In the U.S. and Canadian cattle production systems, weaned beef calves are typically transported from the farm where they are born (cow-calf operation) to feedlots where they are fed and managed until they have reached the appropriate weight for slaughter. Calves may enter feedlots directly from their cow-calf operation of origin, although they often are sold by the farmer (cow-calf operator) to the feedlot "order buyer" at local or regional auction markets. Alternatively, after they are sold by the cow-calf operator, calves may not enter a feedlot directly but instead they may be sent for temporary management to a "backgrounding" (aka "conditioning") operation, where they may receive vaccinations or other treatments such as anthelmintics and growth implants, with dehorning and/or castration if necessary. At this time they may be sorted based on their size, breed type, and/or gender into new groups before being sent on to feedlots. Similarly, after sale, weaned calves are sometimes transported to "stocker" operations, where they are housed or "stocked" on pasture for weeks to months with supplemental feed given as needed, along with vaccinations and other treatments, before being transported to a feedlot at a later date. Undifferentiated BRD is the most common cause of morbidity and mortality in feedlot and stocker cattle. The disease is also known as "shipping fever" because it commonly occurs after cattle have been transported. The pattern of BRD in North American feedlot cattle has been well characterized. Jensen and colleagues described the diseases identified in feedlot cattle that died in a population of 407,000 yearling cattle in 1974.[21] Approximately 5.1% of the total population became sick, and 1% died. Of the cattle that died, approximately half were subjected to necropsy, which revealed that respiratory disease was the cause of death in 64% of the cases. Bronchopneumonia or pleuropneumonia was the type of respiratory disease present in 75% of the cases of BRD, and 72% of the bronchopneumonia/pleuropneumonia cases that ultimately died occurred within the first 45 days of the feeding period.

Another detailed report described health outcomes and necropsy findings in cattle from over 60 feedlots in Bruce County, Ontario, over a 3-year period.[22] The Bruce County study was noteworthy because it was the first large-scale study to prospectively evaluate management practices to determine which were associated with feedlot BRD. Mortality was approximately 1% over the course of the study, and the majority of cattle that died were subjected to necropsy. The most common cause of death was BRD, which caused 50% of the deaths in the first year of the study.

Two studies occurring approximately 10 years later also evaluated the epidemiology and risk factors associated with BRD.[23,24] In the study by Alexander and colleagues,[23] data from 17,696 cattle in a single feedlot were evaluated, and factors related to respiratory disease morbidity were evaluated (rather than BRD mortality, as in the Jensen[21] and Martin[22] studies). Respiratory disease was the cause of treatment for 50% of the cattle treated, with 58% of BRD cases developing in the first 40 days on feed. In the study by Ribble and colleagues,[24] data were collected on all 58,885 spring-born calves entering a single western Canadian feedlot over a 4-year period. Across the 4 years of the study, total (crude) mortality was fairly consistent, ranging from 2.4% to 4.8%, whereas the mortality caused specifically by BRD varied more than tenfold (0.25% to 2.73%). Across years proportionate mortality caused by BRD ranged from 10% to 57%. Epidemic curves constructed for each of the 4 years showed that peak mortality occurred approximately 16 days after arrival at the feedlot and that at least 50% of BRD mortalities occurred within 3 weeks of arrival. Similar results were found in the Alexander study,[23] where 58% of BRD cases were found to develop in the first 40 days on feed. The consistent onset of fatal disease in cattle within days of their arrival at the feedlot indicates that the disease process is often well under way in affected animals before feedlot entry. Ribble and colleagues[24] demonstrated that when the incidence of fatal BRD was high (greater than 2%), the disease clustered within truckload groups of calves and also, in 1 year, within pens.

A recent epidemiologic study evaluated patterns of BRD in the first 100 days after feedlot entry in lots (cohorts) of cattle entering 10 U.S. feedlots over 8 years.[25] For 1.2 million cattle in 7553 lots, the cumulative within-lot BRD morbidity ranged from 0.3% to 84.3%, with a median of 4.2% and a mean of 8.8%. This study demonstrated that the pattern of BRD occurrence in the first 100 days on feed can vary greatly among lots of cattle. For some lots, 80% of BRD cases occurred within the first 10 days on feed, whereas in other lots, 80% of BRD cases had not occurred until the cattle had been on feed for more than 90 days. For some lots the proportion of cattle treated for

VetBooks.ir

BRD increased rapidly over relatively few days, and for others, the proportion treated increased slowly over several weeks. For some lots a rapid increase in the proportion of cattle treated for BRD occurred relatively late, between 60 and 100 days on feed. The reasons for the different patterns of BRD occurrence that were observed in different lots of cattle were not determined, but they are likely related to a combination of factors related to the cattle and their environment.

Feedlot BRD has a significant negative impact on productivity of cattle. Numerous reports have demonstrated that BRD can decrease average daily gain, final weight at slaughter, and carcass quality, with these impacts decreasing producer profit.[26-30] Feedlot BRD has been shown to decrease average daily gain during the entire feeding period by 0.06 to 0.08 kg.[29,30] In one study, cattle treated once, twice, or three times for BRD yielded $41, $58, or $292 less, respectively, than cattle not treated for BRD.[26] Although the negative impacts of BRD are well established, affected cattle sometimes exhibit compensatory growth in the later phase of feeding period, so that cattle with BRD do not always perform more poorly than unaffected cattle when the entire feeding period is considered.[28] Therefore the exact impact of BRD on the performance and profit returned by a group of feedlot cattle will vary substantially depending on numerous variables, including the specific risk factors the cattle have encountered; the management of health and nutrition in the feedlot; the cost of feed, medications, and labor; and the value of the cattle at the time they are purchased and marketed.

Although little is published that specifically describes the epidemiology of BRD in stocker and backgrounding operations, an informative summary has been presented by Smith and Gill.[31] These authors estimate that respiratory disease accounts for 88% of the disease in stocker and backgrounding operations.

RESPIRATORY DISEASE IN ADULT DAIRY OR BEEF CATTLE. Although anecdotal reports indicate that adult beef or dairy cows can experience outbreaks of respiratory disease with high morbidity and an important impact on milk production in dairy herds, the epidemiology of respiratory disease in adult cows has not been well characterized. Surveys of U.S. producers indicated that respiratory disease is the cause of 3.4% of the deaths that occur in adult beef cattle[15] and 11.3% of deaths that occur in adult dairy cattle.[32] The lack of data regarding respiratory disease in adult cows is likely due to the fact that other diseases that affect reproductive performance and milk yield are of greater economic significance in this class of cattle. However, the few published descriptions of respiratory disease outbreaks confirm that the problem can be of major importance to individual herds.[33,34]

RESPIRATORY DISEASE IN SHEEP AND GOATS. Little information is available regarding the epidemiology of respiratory disease in sheep and goats in North America. A survey of U.S. producers indicated that 7% of death in adult sheep is due to respiratory disease, whereas 12% of lamb deaths are due to respiratory disease.[35] Feedlots reported that shipping fever pneumonia accounted for 13% of feedlot lamb deaths, and other respiratory disorders accounted for 29% of lamb deaths.[35]

Host and Environmental Risk Factors for Undifferentiated Ruminant Respiratory Disease

Amelia R. Woolums[††]

In general, risk factors for respiratory disease in all ruminants are related to (1) factors that impair the host physiologic and immunologic responses that defend against respiratory infection, and (2) characteristics of the environment that overwhelm the ability of these physiologic and immunologic responses to prevent respiratory infection. More specifically, host risk factors are related to (1) mechanical respiratory defense by the anatomic features of the upper respiratory tract and the mucociliary elevator; (2) innate immune defense provided by soluble factors, such as lysozyme and defensins, and cells, such as granulocytes, macrophages, and natural killer cells; and (3) acquired immune defense provided by antibodies on mucosal surfaces and in serum, and cells such as T-helper lymphocytes and T-cytotoxic lymphocytes. Characteristics of the host that can impair these mechanisms include other concurrent disease, nutritional deficiency, pronounced or chronic stress related to events such as mixing animals from various sources, crowding, and/or long-distance transport. In young animals, failure of passive transfer is a cause of transient immunodeficiency that may contribute to respiratory disease.

Environmental factors can also contribute to the development of respiratory disease in ruminants. High concentrations of airborne particulates, infectious agents, or noxious gases impair the function of host respiratory defense mechanisms or enhance the transmission of infectious respiratory pathogens. Inadequate housing can lead to cold or heat stress, which may increase nutritional requirements beyond what is available and lead to increased disease susceptibility. Crowding or mixing animals of different age groups can increase opportunities for transmission of infectious respiratory pathogens. Long-distance transport is well known to predispose animals to respiratory disease; this is due to close contact with other animals, which enhances transmission of infectious agents, as well as inhalation of particulates and noxious gases in truck exhaust. Mixing animals from multiple sources, such as occurs when animals are sold through livestock auctions, increases risk for respiratory disease by increasing opportunities for exposure to respiratory and other types of pathogens; psychological stress associated with establishment of new hierarchies may also contribute to immune suppression and increased rates of disease.

When respiratory disease occurs in any group of ruminants, a systematic evaluation of host and environmental factors that may increase risk of respiratory disease should be undertaken. The purpose of this evaluation is to identify modifications in management and husbandry that should help to limit ongoing respiratory disease and that should decrease the risk of future respiratory disease. Although this approach is logical, there is unfortunately little research that confirms that management modifications decrease respiratory disease in ruminants; it is hoped that future work will address this knowledge gap. Specific risk factors relevant to various classes of ruminants are discussed below.

DAIRY CALVES. In young calves, adequate passive transfer of antibody (and possibly also cells from colostrum) is very important to improve the defense against respiratory and other infections. Nutritional deficiency, stress associated with weaning, mixing of calves from different sources, castration and/or dehorning, concurrent disease, and temperature extremes may all impact host defense mechanisms. Environmental risk factors are related to (1) air quality, including humidity and the concentration of bacteria, other particulates, and noxious gases in air; (2) ambient temperature extremes; and (3) opportunities for exposure of calves to respiratory pathogens through new introductions or through contact with older animals in the same herd. When dairy calves are affected by either epizootic respiratory disease (outbreaks) or enzootic calf pneumonia, careful evaluation of management practices that influence both host and environmental risk factors may help prevent future disease.

Specific risk factors for respiratory morbidity and mortality in dairy calves have been evaluated in many research studies.[1-10] It is noteworthy that factors significantly associated with respiratory morbidity and/or mortality in some studies are not always associated with disease in other studies; this is likely because of differences in the populations studied or in methods of collection or analysis of data. Factors identified as significant in more than one study may be relatively more important. Knowledge of factors associated with dairy calf respiratory disease can help veterinarians focus efforts to modify management to limit or prevent respiratory disease in herds where calf respiratory disease is a problem. Calf-level and farm-level factors

TABLE 31-13

Factors Associated with Respiratory Disease in Dairy Calves

Risk Factors Associated with Increased Respiratory Disease Morbidity in Dairy Calves

Calf-Level Factors

Having diarrhea[2]
Serum total IgG ≤ 1200 mg/dL[27]
Being fed mastitic colostrum[27]
Certain sires[1]
Calfhood in fall or winter[1,6,27]

Farm-Level Factors

Shared housing with cows[9,27]
Larger herd size[3,5,9]
More than 8-week age range among calves in same pen[9]
Leaving calves with dams for more than 24 hours after birth[9]
Housing calves in group pens with 6 to 30 calves and automatic feeders (vs. hutches or group pens with 3 to 8 calves individually fed)[6,28]
Diarrhea occurring in calves[2,9]

Risk Factors Associated with Decreased Respiratory Disease Morbidity in Dairy Calves

Calf-Level Factors

Being housed individually in outdoor hutch (vs. any other housing)[2]
Having supervised calving[7]
Serum total IgG > 800 mg/dL[5]
Receiving antibiotic preventively[2]

Farm-Level Factors

Decreased total bacterial counts in calf pen air[29]
Solid barriers between individual calf pens[29]
Bedding deep enough for calves to nest[29]
Antibiotics in feed or milk replacer[2]

that have been found to be significantly associated with dairy calf respiratory disease (morbidity) are presented in Table 31-13.

PREWEANING BEEF CALVES. As compared with dairy calf respiratory disease, less is known regarding factors that increase risk for respiratory disease in preweaning beef calves. Calf-level factors associated with preweaning respiratory disease over several years in a large U.S. herd included the year of the calf's birth, the location of the calf's group on the operation, whether or not the calf experienced dystocia requiring major assistance, the calf's sex (with male calves being at greater risk), and the age of the calf's dam (with calves born to heifers being at greater risk).[11]

A survey of Canadian cow-calf producers in the province of Québec[12] found that farms with fewer than 40 cows were less likely to report a problem with preweaning calf pneumonia than farms with 40 or more cows (16% vs. 36% of producers recognizing nursing calf pneumonia). There were regional differences in the rate of recognition of preweaning calf pneumonia, with producers in the northern regions of the province reporting treatment of a larger proportion of their calves for preweaning pneumonia. The rate of preweaning calf pneumonia was associated with calving season length, with a longer calving season being associated with more cases of calf pneumonia. Another study in Québec found that the incidence of preweaning calf respiratory disease in the first month of life was decreased if the producer vaccinated cows for respiratory viruses, with a 13% incidence in herds with nonvaccinated cows versus a 6% incidence in herds with vaccinated cows.[13]

More recent research has evaluated herd-level risk factors for preweaning calf respiratory disease in U.S. cow-calf herds. An analysis of USDA NAHMS data collected by producer survey found that introduction of steers from outside sources, herd breed makeup, number of visits to the herd by outsiders, administration of antibiotics in feed to prevent calf respiratory disease, and the herd being the primary source of income for the producer were factors associated with preweaning calf respiratory disease treatment rate.[14] A mail survey of cow-calf producers in three eastern U.S. states and three Plains states found that occurrence of preweaning calf respiratory disease was significantly associated with larger herd size, respiratory disease in cows, and diarrhea in calves.[15] Calving season length was associated with calf respiratory disease in Plains but not eastern U.S. herds. Cumulative treatment incidence was negatively associated with larger herd size and checking cows for pregnancy, and positively associated with winter calving, bringing calves into the herd from outside sources, giving calves supplemental feed, and using a heat synchronization program. Common features of risk factors identified to date may be that they increase opportunities for introduction of respiratory pathogens new to the herd, and they increase opportunities for close contact between calves and among cows, older calves, and younger calves. This increased contact may lead to more opportunity transmission of infectious doses of respiratory pathogens to calves when passive or active immunity is inadequate to resist disease.

FEEDLOT AND STOCKER CATTLE. Risk factors for respiratory disease in feedlot and stocker cattle are active in three areas: at the farm of origin, during transit, and in the stocker operation or feedlot.[16-18]

On the farm (cow-calf operation) of origin, management practices can have an impact on subsequent occurrence of respiratory disease in stocker operations or feedlots. Weaning, creep feeding, and performance of routine surgeries at least 3 weeks before shipment ("preconditioning") have been shown to reduce morbidity rates by 20% to 25%.[18] Vaccination on the farm against respiratory pathogens would be expected to reduce the incidence of stocker and feedlot cattle pneumonia, but the practice is not always beneficial. For example, Step and colleagues[19] found that calves kept on the farm for 45 days after weaning and prior to shipment had significantly decreased respiratory morbidity in the first 42 days after feedlot entry, as compared with calves shipped immediately at weaning. However, administration of a multivalent modified live viral respiratory vaccine and an *M. haemolytica* vaccine to the calves that had been weaned for 45 days prior to shipment did not significantly improve resistance to respiratory disease at the feedlot. Thus, this study suggested that, to limit feedlot respiratory disease, weaning 45 days in advance of shipment was more important than vaccination prior to shipment. Nevertheless, preconditioning programs that include vaccination have been associated with improved resistance to feedlot respiratory disease when morbidity and mortality rates and total profit for calves managed in such programs are evaluated over several years.[18] (Preconditioning is discussed in more detail on page 614.)

Risk factors that are active during transport from the farm to the feedlot include sale through auctions, feeding of low-energy diets before shipping, and prolonged time in market channels (sales barns, transport vehicles). Excessive dehydration or "shrink" from transport has been shown to account for significant morbidity and mortality in the feedlot. Movement through multiple auctions greatly increases the risk of respiratory disease.

Risk factors that influence morbidity and mortality rates at the stocker operation or feedlot include processing procedures, numbers of calves and number of different origins of calves per pen, diet, on-arrival surgeries (e.g., dehorning), and environmental conditions. In a Canadian study of risk factors for feedlot respiratory disease from the 1980s,[20] the administration of respiratory vaccines at arrival, feeding of corn silage in the first weeks after arrival, and mixing cattle from various sources were consistently associated with higher mortality in groups of cattle. The negative effect of vaccination at arrival was decreased if vaccination was delayed for 2 weeks. The results of this study led many to question the value of vaccination on arrival for control of feedlot respiratory disease. A relevant finding was that infectious bovine rhinotracheitis virus (IBRV) was more often

VetBooks.ir

associated with respiratory disease in cattle that were not vaccinated for IBRV, indicating that IBRV vaccination was protective against disease specifically caused by IBRV.

More recent studies have confirmed that mixing cattle from multiple sources prior to or at feedlot entry is an important risk factor for feedlot respiratory disease.[19,21,22] Shipment for longer distances prior to feedlot entry has been associated with increased rates of respiratory disease in some studies[22,23] but not others.[24] Changes in weather have been associated with respiratory disease; Alexander and colleagues[21] found that a wide range between the high and low environmental temperatures in the first 2 weeks after feedlot entry was associated with increased respiratory disease. Cernicchiaro and colleagues[25] found that several weather-related variables such as maximum wind speed, mean wind chill, and temperature range were significantly associated with increased daily BRD incidence in the next 7 days, although the effect of weather was dependent on various characteristics of the cattle, such as their average weight, risk category, month of arrival, and the number of cattle in the group. Heavier weight at entry has been shown to decrease feedlot BRD risk.[22] Metaphylactic antibiotic administration at arrival has been shown in multiple studies to decrease risk for subsequent respiratory disease (see more discussion of metaphylaxis later in this chapter).

Although vaccination of cattle to prevent respiratory disease when they are first received by feedlot or stocker operations is a common practice, published research evaluating risk factors for feedlot respiratory disease have not found the practice to be consistently associated with decreased risk.[20,22] Failure of vaccination at arrival to protect cattle against later respiratory disease may be because cattle are already infected at the time of vaccination or because they are not capable of mounting an adequately protective immune response because they are immunologically naive or they are immunosuppressed by a variety of possible factors. Because of this, cattle sometimes are given a second dose of respiratory vaccine 7 to 21 days after the initial dose at feedlot entry, although few data from properly designed trials are available to support the practice of revaccination. Many large feedlots carry out private research trials to determine whether practices such as vaccination at arrival are beneficial; because the practice is still quite prevalent, it may be that some feedlots have confirmed vaccination on arrival to be beneficial but have not published the data supporting it. It should be noted that clinical trials evaluating vaccines for specific agents, such as BRSV or *M. haemolytica,* have found vaccination at arrival to be associated with decreased rates of respiratory disease in feedlot cattle in some cases. (For more information, see earlier sections on specific infectious agents.)

Calves that arrive in the feedlot with moderate concentrations of serum antibodies against respiratory viruses have sometimes been shown to have a decreased incidence of BRD, indicating that natural exposure or vaccination prior to arrival can be protective. Starting calves on diets containing 75% concentrate or greater or feeding corn silage as a major dietary component during the first month is associated with higher mortality and morbidity rates, possibly because of inhibition of certain immune functions by systemic acidosis. Feeding of nonprotein nitrogen, such as urea, is associated with increased rates of respiratory disease. The addition of antibiotics to the drinking water of newly arrived feedlot cattle has been shown to be detrimental to their health, possibly because of decreased water consumption.

Smith and Gill[26] have presented a helpful summary of risk classification of cattle in stocker and backgrounding operations. Stocker and backgrounding cattle can be grouped into one of three categories: (1) high risk, exposed: cattle with little or no history of vaccination, adaptation to hay or concentrate diet, or other preventive health management, and with a history of mixing with cattle from multiple sources; (2) high risk, not exposed: as for high risk, exposed, but with no history of mixing with cattle from multiple sources; and (3) low risk: cattle that have been vaccinated, weaned, and turned out for a period of time before shipment. By nature most backgrounding/stocker cattle are in categories 1 or 2 and thus are at risk for respiratory disease because of various factors, including inadequate immunity, stress of recent weaning, and suboptimal nutritional history. Cattle may require dehorning, castration, or both, when entering the facility, which will further impact their health and productivity. Respiratory disease in high-risk, exposed calves is likely incubating when these calves reach the backgrounding or stocker facility, because they may have been accumulated from several different locations over several days before arrival. The impact of commingling cattle from multiple sources to increase respiratory disease has been shown clearly in a recent study that identified 42% respiratory morbidity in auction market–derived cattle entering a feedlot versus 11% respiratory morbidity in calves entering the same feedlot directly from their ranch of origin without mixing with other cattle.[19] If such calves are not sick on arrival, then BRD can be expected to peak within the first week after arrival. Respiratory disease in high-risk, not exposed calves often peaks at 2 weeks post entry, because these calves are not mixed with calves from other sources before they reach the backgrounding or stocker operation.

ADULT DAIRY AND BEEF CATTLE. Studies confirming risk factors for respiratory disease of adult dairy and beef cattle in modern North American production systems are lacking, but it is assumed that factors are similar to those described previously for calves and for cattle entering stocker operations and feedlots.

SHEEP AND GOATS. Many of the risk factors that have been found to predispose sheep and goats to undifferentiated respiratory disease are similar to those affecting cattle. Respiratory disease is more common in younger animals, after shipping or storms, and under crowded conditions. In addition, cold stress is an important risk factor for respiratory disease in young lambs and recently shorn adult sheep and goats. In contrast, heat stress may predispose to respiratory disease in unshorn sheep that do not have access to shade. Respiratory disease is also associated with semiconfinement or total confinement of sheep in poorly ventilated barns.

Prevention and Control of Undifferentiated Ruminant Respiratory Disease

Amelia R. Woolums[‡‡]

MANAGEMENT PRACTICES TO MINIMIZE DAIRY CALF RESPIRATORY DISEASE. Efforts to minimize respiratory disease in calves should begin with assessment of factors that may be impairing host defense mechanisms, which were outlined earlier. Ensuring adequate transfer of maternal antibodies to newborn calves by appropriate colostrum handling and administration is one of the practices most important to ensuring calf health. On farms with high rates of calf respiratory disease, particularly in calves in the first month or two of life, efforts to address respiratory disease should include assessment of passive antibody transfer in calves within the first week of life. If rates of failure of passive transfer are unacceptably high, management practices should be corrected to address the problem.

Although passive antibody transfer is important to ensuring calf health, groups of dairy calves with adequate passive antibody transfer can still have high rates of respiratory disease. Thus, other risk factors must also be assessed on dairies with unacceptable rates of calf respiratory disease. The method of calf housing has an important impact on risk for respiratory disease. Commonly used dairy calf housing includes individual calf hutches outdoors, super-hutches for small groups of calves outdoors, individual calf pens inside a building, and group calf pens inside a building. Respiratory disease is less common in calves housed in individual hutches outdoors, as compared with calves housed in individual pens indoors or in group pens indoors.[1,2] In spite of this, many producers house calves in individual pens or group pens indoors because of the negative impact of weather

[‡‡]Previous contributions by John C. Baker, Trevor R. Ames, and Steven E. Wikse are acknowledged.

VetBooks.ir

extremes for calves housed outdoors in hutches and for their caretakers. Group pen housing also facilitates use of automatic self-feeders to allow calves to nurse milk more frequently, and group pen housing allows calves to interact socially with other calves. These benefits of group pen housing must be weighed against the likelihood of increased rates of respiratory disease for group housed calves. If calves are housed in group pens, respiratory disease is less common when the pens contain smaller numbers of calves (9 or fewer per pen)[3,4]; however, on large dairies it may not be practical or cost-effective to house calves in such small groups.

Standards for ventilation of calf housing have been reported.[6-8] A study evaluating respiratory disease prevalence in calves housed in individual pens in naturally ventilated barns[5] found that respiratory disease prevalence was decreased on farms where pens had lower total airborne bacterial counts, solid barriers between calves, and bedding that was deep enough for calves to nestle into (so that their legs could not be seen when they were lying down). Airborne bacterial counts in the alleys between the calf pens were not related to calf respiratory disease in that study. Because having four or more solid partitions around a calf increased total bacterial counts in pen air, solid partitions should be placed between calves but on no more than three sides; on the front, back, and top of calf pens, mesh barriers should be used.

Calf housing with overcrowding of calves or excessive stocking densities results in increased transmission of pathogens, especially if there is mixing of calves of wide age range. Overcrowding also puts additional stress on the building ventilation through buildup of noxious gases and pathogens. Cleaning of calf crates with high-pressure water sprayers is associated with new cases of pneumonia several days later. Sivula and colleagues[7] found that 80% of calf barns provided housing that failed to meet adequate standards of ventilation and housing regardless of whether calves were housed individually or in groups. In addition, calf housing in which calves shared the same air space as adults never met the adequate standards of ventilation and housing. A much higher percentage of calf housing that used calf hutches met these adequate standards of ventilation and housing, and virtually 100% would have been adequate housing if the hutches had been positioned correctly. Calves raised in inadequate housing have significantly poorer growth rates than do calves raised in housing that is considered adequate, which emphasizes the importance of adequate housing. A review of factors relevant to adequate ventilation of calf housing was recently published.[8]

After weaning, calves need to move to housing that allows small groups to be segregated from older age groups. Sharing air space or having direct contact with older calves or adult cattle is an important risk factor for calf respiratory disease. Super-hutches or pens in pole sheds separated by barrier walls can effectively provide this post-weaning housing. Calves should be fed proper nutrition for protein, energy, minerals, and vitamins and should be vaccinated appropriately. Vaccination programs are often used in dairy calves beginning at 1 to 2 months of age in situations where housing or mixing of postweaning calves results in a high incidence of respiratory disease. More information regarding the use of vaccines for preventing infectious respiratory disease is presented in the following sections. Historically it has been recommended that vaccination be delayed until maternal immunity has waned, but recent research indicates that calves can often be primed for a protective immune response by vaccination in the face of maternal antibodies (see further discussion in Chapter 48).

Nutritional problems that predispose to calf pneumonia include deficiencies of energy, protein, vitamins, or the minerals necessary for the immune response. Deficiencies of copper, selenium, zinc, manganese, iron, and vitamins A and E are of special concern. Dairy managers sometimes create energy and protein deficiencies by feeding calves a low volume of milk during the first few weeks of life to minimize the incidence of neonatal diarrhea. Therefore it is important to evaluate feeding practices to determine whether nutritional deficiencies are likely when attempting to limit dairy calf respiratory disease.

Ambient temperature is an important factor affecting dairy calf health. Cold weather is especially detrimental to young calves, which have little body insulation. Increased humidity or precipitation in the calf's environment exacerbates the impact of cold weather on the calf's ability to maintain thermoneutrality. Warm weather can also be undesirable, because young calves are capable of greater perspiration per pound of body weight than are adults, and warm weather may predispose young calves to dehydration.

Veal calves are at great risk for respiratory disease because they are often reared in rooms that are filled to high stocking density with calves from multiple dairies that may put minimal effort into ensuring that the calves are fed adequate amounts of high-quality colostrum. Similar problems occur on "calf ranches" or dairy heifer rearing operations where hundreds to thousands of very young dairy calves are raised to the point at which they are old enough to be returned to dairies or sent on to feedlots. A high proportion of calves that enter calf-rearing operations may have failure of passive antibody transfer unless the managers uphold standards for passive antibody transfer status for dairies that are the source of their calves. Also, the accumulation of a large number of calves with a variety of histories and from a variety of sources causes problems similar to those encountered with older animals in feedlots.

MANAGEMENT PRACTICES TO MINIMIZE PREWEANING BEEF CALF RESPIRATORY DISEASE. Relative to dairy calves, less is known regarding management practices that should prevent preweaning respiratory disease in beef calves. Risk factors identified include a longer calving season, concurrent neonatal calf diarrhea, and practices that increase opportunities for introduction of respiratory pathogens to the herd, or that increase opportunities for close contact among calves and between cows, older calves, and younger calves. Thus, in herds where preweaning calf respiratory disease is a problem, it may be helpful to shorten or prevent situations where preweaning calves and/or cows are brought together in close proximity. Improving immunity of preweaning calves by addressing factors that can lead to failure of passive antibody transfer from colostrum (such as dystocia and hypothermia) may help mitigate preweaning calf respiratory disease, particularly in herds with a high incidence of respiratory disease in calves in the first month or two of life. Because occurrence of calf diarrhea has been associated with preweaning calf respiratory disease, efforts to control calf diarrhea, which usually precedes respiratory disease, should be undertaken in herds with both problems. Administration of vaccines for viral and bacterial respiratory pathogens to preweaning calves may help decrease disease; if vaccination is attempted, two doses of vaccine should be administered, with the second dose timed to occur at least 2 weeks before the expected onset of respiratory disease. More information about vaccination of calves in the face of maternal antibodies follows. Once an outbreak is under way, anecdotal reports suggest that vaccination with intranasal or injectable modified live vaccines containing IBRV, PIV-3, and/or BRSV may be helpful to shorten the outbreak, but this is not yet supported by controlled research. Moreover, BRSV vaccination in the face of a BRSV outbreak has been associated with apparent disease enhancement[9]; thus there is a possibility that administration of BRSV vaccine could make an outbreak of undifferentiated calf respiratory disease worse if BRSV is the cause of the outbreak.

MANAGEMENT PRACTICES TO MINIMIZE FEEDLOT AND STOCKER RESPIRATORY DISEASE

Preconditioning. Preconditioning of calves is an attempt to eliminate certain risk factors that influence the occurrence of BRD in feedlot cattle. Preconditioned calves are weaned well in advance of shipment to feedlots. They are trained to eat some grain from feed bunks and drink water from tanks (this is especially important for calves raised on rangeland where feed bunks or water tank may not be seen). Calves are castrated and dehorned, treated for internal and external parasites, and vaccinated against respiratory pathogens, with one dose of vaccine administered before weaning and the second

VetBooks.ir

dose administered at or after weaning. The exact details of a preconditioning program can be tailored to the needs and characteristics of the individual herd of cattle. A variety of preconditioning protocols have been described, and most of the major companies that sell vaccines have recommended standardized preconditioning programs. Also, in many areas of the United States and Canada, state, provincial, or regional groups may offer a standardized preconditioning program for local cattle producers. Some sort of validation that calves have received preconditioning typically is available through these organizations. Some of these groups also help the participating producers market the preconditioned calves in large, relatively uniform groups, which may help the calves bring better prices. In some cases, producers can retain ownership of their cattle after they enter the feedlot and receive data regarding health and performance of their animals throughout the feeding period and at slaughter. Information about local preconditioning programs can usually be obtained from agricultural extension agents or from faculty members who specialize in beef cattle management and health at colleges of animal science or veterinary medicine.

The value of preconditioning has been debated over the decades. A summary of eight studies comparing the health of preconditioned calves with that of control calves indicated that, on average, preconditioning reduced morbidity rates by 23% and mortality rates by 50% in the feedlot.[10] However, preconditioned cattle do not always escape disease once they enter feedlots, and they sometimes experience outbreaks of high morbidity and mortality not unlike those seen in high-risk calves that are not preconditioned. Moreover, even when preconditioned calves experience less disease, their performance in the feedlot is not always better than that of nonpreconditioned calves,[11] or they may not always perform well enough that a profit is returned that is greater than the cost of preconditioning.[12] An evaluation of data collected over 8 years by the Texas A&M Ranch to Rail program showed that preconditioned cattle returned, on average, $90 more per head than nonpreconditioned cattle. However, in some years the return was better for preconditioned cattle than in other years. These data emphasize that preconditioning is likely to be cost-effective in the long run, but it may not always be cost-effective for an individual group of cattle in a single year. Also, while cattle that develop BRD in the feedlot often have decreased weight gain and/or feed efficiency and reduced carcass quality at slaughter,[13-15] they sometimes exhibit compensatory gain after they recover from BRD, which allows them to "catch up" to cattle that do not develop BRD.[16] For this reason, some feedlot operators elect not to specifically purchase preconditioned cattle, which can cost more to purchase and which may not consistently yield higher profits. Because of year-to-year uncertainty in the economic advantage of preconditioned cattle, producers who sell preconditioned calves may not always be able to sell calves at a price that provides a profit over the cost of preconditioning. If an individual producer or producer organization develops a good reputation for generating reliably healthy preconditioned calves, marketing these calves directly to cattle buyers may be the best way for the producer to realize a profit from preconditioned calves. Retaining ownership of calves sent to feedlots may also allow the producer to realize better profits, but this requires a relationship with a feedlot that will manage the calves in ways that will continue to optimize health once the calves enter the feedlot. It has also been shown that preconditioning can help the producer net greater returns simply because preconditioned calves weigh more when they are sold.[17]

Backgrounding. Another practice similar to preconditioning is the practice of backgrounding. In backgrounding, weaned beef calves from a variety of sources (often purchased from multiple sale barns) are accumulated and processed in a manner similar to that carried out for high-risk calves at feedlot entry (Box 31-5). Calves are then sorted by size and type and sold to feedlots, usually within a few days of arriving at the backgrounding operations. Backgrounding operations are sometimes referred to as "conditioning" operations. A variation of the backgrounding operation is the stocker operation; in stocker operations calves are processed and then "stocked" onto pastures, often with supplemental concentrate feeding, to graze and grow for a few weeks to months before shipment to feedlots. The difference between preconditioning and backgrounding is that preconditioning occurs on the farm where the calf is born, or at least before the calf is mixed with other calves from different sources, with some aspects of treatment such as the first dose of vaccines ideally being administered before weaning. Calves that enter backgrounding or stocker operations often have uncertain health histories, they have often been weaned immediately before purchase, and when they arrive they have been mixed with calves with similar uncertain backgrounds from a variety of sources. Because of these factors, disease outbreaks of high morbidity and mortality are not uncommon on backgrounding and stocker operations, and respiratory disease is the leading cause of morbidity and mortality.[18] The backgrounder or stocker operator is thus taking on some of the risk of high-risk calves and is theoretically providing the feedlot with animals more likely to grow well with minimal disease than if the cattle entered the feedlot straight from the auction market.

BOX 31-5

Examples of Processing Protocols for High- and Low-Risk Cattle Entering Feedlots

Processing Protocol for High-Risk, Fall-Weaned, Auction Market Calves

1. Modified live BHV-1 (IBRV), BVDV-1, BVDV-2, BRSV, and PIV-3 vaccines
2. Eight-way clostridial bacterin
3. Antiparasitic
4. *Mannheimia haemolytica* ± *Pasteurella multocida* vaccine
5. *Histophilus somni* vaccine (if significant problem in past)
6. Growth implant
7. Ear tag identification
8. Bulls castrated (if needed)
9. Tip dehorning (if needed)
10. Metaphylactic antimicrobial treatment

Processing Protocol for Healthy Yearlings Previously Fed in Backgrounding Operations

1. Modified live BHV-1 (IBRV), BVDV-1, BVDV-2, BRSV, and PIV-3 vaccines
2. Eight-way clostridial vaccine
3. Antiparasitic
4. Growth implant
5. Ear tag identification

Management at Feedlot Entry. It is not surprising that preconditioning does not always influence the occurrence of respiratory disease in cattle after they enter the feedlot, because it has no effect on many risk factors active during transit and in the feedlot. Therefore optimal control of feedlot respiratory disease should begin with preconditioning and continue with avoidance of auction yards, minimization of transport time to the feedlot, limited mixing of calves from different sources, limited number of calves per pen, control of dust, and careful diet management in the feedlot. Correction of vitamin and/or mineral deficiencies (if known or detected) with vitamin injections in entering calves may be helpful to decrease disease associated with immunodeficiencies of nutritional origin.

Processing procedures on arrival at the feedlot affect the incidence of pneumonia. General recommendations for handling incoming cattle can be made that are appropriate for any category of animals.[18-20] In a receiving program, rest, rehydration, and ruminal restoration need to be addressed because cattle are physically and psychologically stressed by the marketing and transportation processes. It is recommended that these cattle be rested for 12 to 24 hours and that in the summer they should be processed before the hottest part of the day. Prolonged holding before processing is associated with increased illness, and holding times over 48 hours should be avoided. Holding pens should be clean and dry or have dry bedding, because this

VetBooks.ir

allows all cattle to lie down and rest. Shelter from wind, sun, rain, and dust should also be present in the receiving pen.

It is important that incoming cattle have access to clean, fresh water. Raised spigots have been suggested as a way to teach incoming cattle to drink out of automatic watering devices because cattle will be attracted to the sound of splashing water. Incoming cattle should also be offered good-quality, long grass hay on arrival. Hay is the best foodstuff for restoring or refilling the rumen. Hay can be put in the feed bunks as well as in feeders in the pen as a way of teaching cattle to eat out of bunks. Hay feeders may also be put along the pen perimeter to decrease walking the fence line and encourage eating. The starter ration is an important source of energy and should be highly palatable. The proportion of the starter ration dry matter that is forage is not usually less than 50%; this will prevent problems of acidosis. Starter rations often contain a coccidiostat, because coccidiosis can occur in calves after commingling.

Processing protocols may be tailored to the category of the incoming cattle. Pharmaceutical processing options include vaccination (respiratory and nonrespiratory), vitamin injections, growth hormone implanting, deworming for internal parasites and acaricides for external parasites (may be the same product for both), long-acting antibiotic therapy, drugs for aborting pregnant heifers, and probiotic administration. Management procedures for processing include ear tagging, branding, tail trimming, castration, and tip dehorning. Some management procedures such as castration and dehorning could be left for a later time—for example, at reimplanting at 70 to 90 days on feed (if cattle are expected to be on feed for more than 150 days). Taking the rectal temperature of cattle at initial processing can be very useful, because even cattle that look bright can have very high temperatures and thus can be identified as "sick" by this procedure. Examples of processing protocols for high- and low-risk cattle are shown in Box 31-5.

Metaphylactic Antimicrobial Therapy. The term *metaphylaxis* refers to the administration of an antimicrobial to a group of animals that may be in the early stages of bacterial pneumonia or that are at significant risk of developing bacterial pneumonia. Thus the antimicrobial drug administered may have either a therapeutic or a prophylactic effect, depending on the state of each animal treated. Metaphylactic administration of antibiotics to feedlot cattle on arrival, in order to prevent bacterial bronchopneumonia, has been shown in many studies to decrease morbidity and mortality in groups of high-risk cattle.[21,22] Long-acting antibiotics have been reported to significantly alter the number of calves from which *M. haemolytica* can be cultured.[23,24] An additional rationale for metaphylaxis on arrival is based on the epidemic curve of fatal disease onset for bacterial bronchopneumonia, which shows that feedlot calves dying from fatal fibrinous pneumonia are already sick on arrival or become ill within days of arrival. Although metaphylaxis through feed and water was used in the past, it is currently recommended that metaphylaxis be administered by use of injectable antimicrobial agents. The ability of these drugs to reach therapeutic levels quickly in all animals gives them a clear advantage given the previously discussed rationale for bacterial bronchopneumonia metaphylaxis.

A number of trials have been published that examine various antimicrobial agents and their effectiveness for bacterial bronchopneumonia metaphylaxis. Most of these studies have examined both health and production values, and a variety of products have been shown to be efficacious in decreasing respiratory morbidity and mortality and sometimes in improving production parameters. At the time of this writing, several antimicrobials are approved for administration to control BRD (metaphylaxis; see Table 31-12).

Similar use of long-acting antimicrobials in dairy calves may also be of value. The disease process does not have the same narrow windows of therapeutic intervention that occur in calves entering the feedlot. Dairy calves properly managed in maternity facilities and raised in hutches are typically relatively protected against respiratory disease until they are moved to postweaning group housing. Injectable mass medication is often used at the time calves are moved as a means of controlling postweaning BRD.[25]

MANAGEMENT PRACTICES FOR PREVENTING RESPIRATORY DISEASE IN SHEEP AND GOATS. Prevention of pneumonia in sheep and goats is also based on altering the risk factors that predispose to pneumonia. Minimizing cold and heat stress, providing properly ventilated housing, avoiding overcrowding, and avoiding long transports in adverse weather aid in prevention. Mass medication can be used to control outbreaks of pneumonia in flocks. Injectable long-acting oxytetracycline is often used; tilmicosin can also be used for mass medication therapy for sheep, but tilmicosin should never be administered to goats, as it can result in fatal reactions. Feedlot lambs are sometimes administered metaphylactic therapy (long-acting oxytetracycline) on arrival. See Table 31-12 for a list of antimicrobials approved for administration to sheep and goats.

Vaccination to Prevent Undifferentiated Ruminant Respiratory Disease

Amelia R. Woolums

Impact of Maternal Antibody on the Response to Vaccination

Historically veterinarians were taught that young animals cannot be effectively vaccinated when they have circulating maternal antibodies obtained through passive transfer after birth. This was based on numerous research studies that showed that vaccination of young animals with maternal antibodies did not lead to the expected increase in serum antibodies to the agent in the vaccine. However, an important finding is that some vaccines appear to prime calves for an improved response to subsequent challenge, even when vaccination occurs in the presence of maternal antibodies. In such cases vaccination may not induce an increase in serum antibody titer within 2 weeks of vaccination, but when calves are vaccinated or challenged at a later date, they respond with what appears to be an anamnestic response as measured by increased serum antibodies, or protection against disease resulting from experimental or natural challenge, as compared with unvaccinated calves.[1-4] In general and based on research to date, a response is most reliably induced when modified live vaccines are administered and when the calves receive at least two doses of vaccine at an appropriate (at least 2- to 4-week) interval. Similarly, calves exposed to live pathogens in the face of maternal antibody can develop a protective immune response, even though they do not seroconvert after exposure.[5,6] It has been shown that a cell-mediated immune response can be measured even when there is no evidence of humoral response in calves infected in the face of maternal antibodies.[6] Although multiple studies show that calves can be primed for an anamnestic immune response in the face of maternal antibodies, if very high titers of maternal antibody are present, priming by the vaccine can be blocked, as traditionally understood.[4] Intranasal (IN) vaccination may be more effective than intramuscular or subcutaneous vaccination when calves have moderate concentrations of circulating maternal antibody to antigens in the vaccines.[7] In a recent study, 10- to 13-week-old calves with maternal antibodies that were vaccinated IN with modified live multivalent vaccine containing BRSV had significantly higher serum neutralizing titers to BRSV after they were boosted subcutaneously 3 months later, as compared with calves that did not receive the IN vaccine.[8] This indicated that IN vaccination in the face of maternal antibodies primed the calves for an anamnestic serum antibody response when they were later boosted. However, another recent study indicated that IN vaccination of 3- to 8-day-old calves did not lead to protection at challenge 4.5 months later,[9] indicating that IN vaccination is not invariably effective in calves with maternal antibodies.

This information suggests that, at least in some cases, a protective immune response can be initiated in calves when the first dose of vaccine is given in the face of maternal antibodies; a cell-mediated response may occur even if calves do not have an increase in serum antibody titer after vaccination. This is particularly useful in the

VetBooks.ir

context of pneumonia in nursing dairy or beef calves, as it supports the concept that vaccination can improve the immune response to challenge even if calves have some level of maternal antibodies at the time of vaccination. More research is needed to confirm which vaccines have this effect and to determine how this information should be used to guide vaccination recommendations for calves. It is also not known if this information can be extrapolated to sheep and goats.

Efficacy of Vaccines for Preventing Ruminant Respiratory Disease

Information regarding the use of vaccines for individual agents that cause ruminant respiratory disease was presented earlier, in the section describing the individual infectious agents. There has been considerable debate over the years regarding whether vaccines have any impact on ruminant respiratory disease. The literature on the subject is extensive, and interpretation of the data is complicated by the fact that there is much variation among research studies in the type and number of animals studied, the nature of animal management, and the outcomes measured as evidence of efficacy. There are three major types of research studies by which vaccine efficacy can be measured: (1) studies that measure production of antibodies or in vitro cell-mediated immune responses in vaccinated animals; (2) studies that measure the resistance of vaccinated animals to experimental challenge with viral or bacterial pathogens; and (3) studies that measure the impact of vaccination on health and productivity of animals in a conventional field setting (field trials). Of the three methods, field trials are the most meaningful, but they are also the most expensive and difficult to undertake. When they are undertaken, it is often in small numbers of animals under management practices that may not be representative of practices in other regions. Moreover, they rely on the natural occurrence of the disease in question in the animals under study. A well-designed field trial can be very expensive and time-consuming, and the results can be useless if no animals in the study contract the disease naturally.

In spite of these limitations the results of some field trials testing the efficacy of respiratory disease vaccines have been published. For some important pathogens (e.g., BVDV), there are still no large-scale field trials published that show evidence of efficacy in preventing respiratory disease. One trial showed an economic advantage to administering a modified live vaccine containing BHV-1, BVDV, PIV-3, and BRSV over the use of a modified live vaccine containing only BHV-1 in feedlot cattle,[10] but it was not possible to determine which component of the multivalent vaccine was responsible for efficacy. Multiple field trials have been published that tested currently available vaccines against *M. haemolytica* and BRSV; these are discussed further in earlier sections on these specific pathogens. In general, some of these studies found that vaccination could prevent disease and sometimes improve productivity, and some of these studies could not find a beneficial effect of vaccination. It is important to remember that in nearly all of these field trials, the effect of vaccination to decrease *all* respiratory disease was measured. That is, in most cases, no effort was made to determine whether disease specifically caused by the agent included in the vaccine was affected by vaccination. Therefore the apparent lack of efficacy of vaccines in some studies may have been because animals developed disease caused by other respiratory pathogens.

Occasionally, in addition to evaluating the impact of vaccination on morbidity, mortality, and measures of productivity, investigators calculate the economic advantage or disadvantage of vaccination. When such calculations are made, it is important that the reader assess the assumptions made and determine whether they are appropriate. It has been noted that when the economic advantage of using a given vaccine is calculated, various scenarios should be considered that might prove the vaccine to be economically advantageous in some situations and disadvantageous in others.[11]

The mixed results of clinical trials published to date indicate that vaccines decrease respiratory disease, improve animal productivity, and save money for the producer in some cases, and in some cases they do not. This should not be a surprise when the multitude of factors that can converge to cause an outbreak of respiratory disease is considered. Vaccination should be seen as one component of a multifactorial approach to minimize animal disease; it should not be seen as a guarantee against all disease, all the time. Thus the value of vaccination will depend on the risk of disease in the population in question, and the risk of disease will depend on the likelihood of pathogen exposure and the likelihood that other host and management factors can be modified to maximize the ability of the host to respond to vaccination and resist disease.

No single, simple recommendation for vaccination of ruminants for the control of respiratory disease can be made. The veterinarian must individualize each vaccination program to the situation at hand. Many factors need to be considered in formulating recommendations for vaccination, including type of production unit, age of animals, system of management, housing facilities, amount of stress imposed on animals, open or closed herd, type of ration, and level of sanitation. In addition, some infectious agents such as BHV-1, BVDV, and *H. somni* can cause other disease problems not associated with the respiratory tract. Thus the complete spectrum of disease caused by these agents must be considered in formulation of a vaccination program. Examples of respiratory vaccination protocols that could be used in a cow-calf operation and in a dairy are presented in Boxes 31-6 and 31-7.

BOX 31-6

One Example of a Respiratory Vaccination Protocol for Use in a Cow-Calf Herd

Replacement Heifers

Modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 with boost 4 weeks later, before breeding

Cows

Modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 before breeding
Boost with killed or approved modified live* BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 at pregnancy check
Consider *M. haemolytica/P. multocida* vaccine at pregnancy check with boost 4 to 8 weeks before calving in herds with history of problems with pneumonia in nursing (preweaning) calves.

Calves

Consider killed or approved modified live* BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 and *M. haemolytica/P. multocida* vaccine at 1 to 4 months of age with boost 4 to 8 weeks later. If herd has a history of nursing calf pneumonia, time boost to occur approximately 4 weeks before expected onset of calf pneumonia.

To Minimize Pneumonia in Calves Postweaning

Killed or approved modified live* (preferable) BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 4 weeks before weaning with boost at weaning
Consider *M. haemolytica/P. multocida* vaccine preweaning with boost at weaning in herds with a history of postweaning pneumonia, or if required for participants in defined preconditioning programs.

*Certain modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 vaccines are approved for use in pregnant cattle and in calves nursing pregnant cattle when administered in accordance with label directions.

The Interstitial Pneumonias

Amelia R. Woolums[§§]

Understanding of the interstitial pneumonias of ruminants has undergone considerable evolution over several decades. Unfortunately, lack of clarity still exists, particularly with regard to

[§§]Previous contributions by Daniel L. Grooms and John A. Smith are acknowledged.

VetBooks.ir

BOX 31-7

One Example of a Respiratory Vaccination Protocol for Use in a Dairy

Replacement Heifers

Modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 with boost 4 weeks later, before breeding

Cows

Modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 before breeding, OR killed or approved modified live* BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 at dry off

Consider *M. haemolytica/P. multocida* vaccine at 8 weeks before calving, with boost 4 weeks later, in herds with history of problems with pneumonia in calves under 6 months of age.

Calves

In herds with significant calf pneumonia, consider modified live† BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 and *M. haemolytica/P. multocida* vaccine at 1 to 4 months of age with boost 4 weeks later, timed so the boost occurs approximately 4 weeks before expected onset of calf pneumonia.

To Minimize Pneumonia in Calves Postweaning

Modified live† BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 4 weeks before weaning with boost at weaning

Consider *M. haemolytica/P. multocida* vaccine 4 weeks before weaning with boost at weaning in herds with a history of postweaning pneumonia.

*Certain modified live BHV-1/PIV-3/BRSV/BVDV-1/BVDV-2 vaccines are approved for use in pregnant cattle when administered in accordance with label directions.

†Injectable modified live BHV-1 and BVDV vaccines can occasionally induce disease in very young (<1 month of age) or very debilitated calves. In such calves, intranasal modified live vaccines or inactivated vaccines may be safer.

terminology. Terms such as *acute bovine pulmonary emphysema, atypical interstitial pneumonia* (AIP), *fog fever, pulmonary adenomatosis, farmer's lung,* and *acute respiratory distress syndrome* (ARDS) have been used interchangeably for all of the conditions that follow. This text uses a classification presented by Breeze,[1] which places the interstitial pneumonias into four groups: (1) ARDS, (2) hypersensitivity diseases, (3) chronic conditions that may be sequelae of ARDS or hypersensitivity diseases, and (4) parasitic diseases. Bovine respiratory syncytial virus (BRSV) infection can also cause AIP; this disease was discussed earlier in this chapter in relation to the respiratory disease complex of cattle, sheep, and goats.

Acute Respiratory Distress Syndromes

ARDS is any respiratory condition characterized clinically by a sudden onset of (usually severe) dyspnea (Fig. 31-76) with gross and histopathologic findings consistent with AIP. The characteristic gross findings of AIP are lungs that fail to collapse when the thorax is opened (Color Plate 31-11) and that are heavy and have a firm, rubbery texture on palpation. Interlobular or bullous emphysema is usually present (see Color Plate 31-3), and sometimes the cut surface of the lung has a shiny or wet appearance because of edema. In some cases affected lobules, which are dark red to purple, or sometimes grayish, are interspersed with normal-looking lobules, giving the lung a "patchwork" appearance. Although the gross findings are suggestive and often characteristic, other lung diseases can cause similar changes, so a diagnosis of AIP can be confirmed only by histopathologic evaluation. The histopathologic changes that confirm a diagnosis of AIP include alveolar hyaline membrane formation and fibrin deposition, alveolar and interstitial edema, and type II pneumocyte proliferation. Hemorrhage, emphysema, and interstitial inflammatory cell infiltrate can also be seen.

FIG. 31-76 Heifer exhibiting respiratory distress typical of acute respiratory distress syndrome (ARDS). Note extended head, frothing at mouth, and wide-set front legs.

The term *atypical interstitial pneumonia* has often been applied to describe the changes characteristic of AIP, but it has been pointed out that the clinical and pathologic changes in affected cattle are not "atypical" but are rather "typical" of acute lung injury.[1,2] Use of the term *acute interstitial pneumonia* to describe the characteristic pathologic changes and the term *acute respiratory distress syndrome* to describe the clinical picture in an animal with AIP of as-yet-undetermined cause is both accurate and all-encompassing. A diagnosis of AIP should be understood as a pathologic diagnosis rather than a causal diagnosis, because a variety of insults can lead to AIP.

Acute Bovine Pulmonary Edema and Emphysema

Definition and Etiology Acute bovine pulmonary edema and emphysema (ABPEE), classically known as *fog fever,* is an ARDS of adult (over 2 years old) cattle that occurs when they are changed from dry, sparse forages to lush green pastures. It is caused by the conversion of L-tryptophan ingested in the lush forages to a pneumotoxic compound (3-methylindole [3-MI]), which leads to the development of pulmonary edema, alveolar epithelial hyperplasia, hyaline membranes, and emphysema.

Clinical Signs Adult brood cows are most commonly affected because this is the type of animal most likely to be subjected to the abrupt pasture change required to produce the condition. No breed is resistant. The type of pasture appears to be unimportant, as long as it is lush; ABPEE has been reported on a wide variety of grasses, alfalfa, rape, kale, and turnip tops.[3] Signs usually occur within 2 weeks of the pasture change. In severe cases there is an acute onset of very severe dyspnea with a loud expiratory grunt, frothing at the mouth, mouth breathing, and tachypnea. The animals are obviously distressed (as opposed to exhibiting the typical depression that occurs with infectious respiratory diseases) and stand with the head and neck extended and elevated and the nostrils dilated. Temperature and heart rate may be elevated secondary to the severe dyspnea and hypoxia. On auscultation the breath sounds are usually surprisingly soft in view of the gross dyspnea and tachypnea; a few crackles may be heard. Even mild exercise increases the dyspnea and may precipitate collapse and death. As many as 30% of severely affected patients may die, usually within 2 days. Those that survive typically show a dramatic improvement after 3 days. Recovering patients and those that are less severely affected exhibit tachypnea, harsh breath sounds, and crackles and wheezes, particularly in the caudal lung fields. Subcutaneous emphysema may develop. The demeanor of the entire group tends to become more tranquil. In cattle that have repeated episodes of nonfatal ABPEE, a chronic respiratory condition characterized by diffuse pulmonary fibrosis and alveolitis may develop.[4] For

VetBooks.ir

purposes of differential diagnosis, it is important to note that coughing is not prominent in the individual or the group. The main differential diagnoses are those diseases that cause ARDS in pastured adult cattle, usually in outbreak form. The association of ABPEE with typical management conditions (e.g., changes of pasture) and the absence of coughing, signs of sepsis, and adventitious lung sounds in early cases are also very important features. Primary considerations should include the other plant toxicities (moldy sweet potatoes, perilla mint, and possibly others) that can be differentiated only by identifying the source. An outbreak of BRSV infection or parasitic bronchitis could cause similar clinical signs and pathology, but these are characterized by more coughing, signs of depression, and more prominent adventitious sounds; fever is common in animals with acute BRSV infection.

Pathophysiology L-Tryptophan in lush forages is converted by ruminal microorganisms to indole acetic acid and eventually to 3-MI, which is rapidly absorbed from the rumen into the blood. Metabolism of 3-MI by the cytochrome P-450 mixed function oxidase system in the nonciliated bronchiolar epithelial (Clara) cells and type I pneumocytes results in one or more highly reactive intermediates that bind to intracellular proteins or other macromolecules and thus lead to damage or death of the cells. These intermediates are detoxified by conjugation with glutathione.[5] Cellular damage results in degeneration, necrosis, exfoliation of type I pneumocytes and Clara cells, and edema. These lesions in turn cause hyaline membrane formation, proliferation of type II pneumocytes, and, to a lesser extent, proliferation of Clara cells.[6] The proliferation of type II cells is also known as *adenomatosis*.

Epidemiology As indicated, ABPEE is consistently related to management practices in which hungry adult cattle are suddenly moved from sparse, dry grazing to lush green pastures. The British name *fog fever* arose from the association of the disease with "fog" pastures, which are the lush green regrowth pastures after hay or silage has been cut. The problem usually occurs in the fall. In the typical pattern in the western United States, cattle are moved from dry summer range onto irrigated or fertilized aftermath pastures. The disease usually appears as a herd outbreak, but individuals may be affected to widely varying degrees[7]; the morbidity rate commonly approaches 50%, with a case fatality rate as high as 30%.[8] Nursing calves are typically not affected.

Necropsy Findings In animals that die of ABPEE, ecchymotic to petechial hemorrhages occur in the larynx, trachea, and bronchi, and frothy fluid is present in the airways. The gross and histopathologic lung lesions are consistent with AIP. Congestion, edema, and hyaline membranes cause deep red to purple coloration of the cranial lung lobes and a smooth, glistening appearance to the cut surface. Interstitial emphysema with large bullae and gelatinous yellow interlobular edema is common. Histologically, eosinophilic hyaline membranes line alveoli and alveolar ducts, and there edema and proliferation of type II alveolar epithelial cells are present. In animals that are killed after 3 to 4 days, emphysema and edema are less obvious, and the lungs tend to be light brown, firm, heavy, and rubbery. There is severe diffuse alveolar epithelial hyperplasia (adenomatosis), and large mononuclear cells, multinucleated giant cells, and hyaline membranes are present in alveolar spaces. Edema, eosinophils, and inflammatory cells occupy the septa.

Diagnosis Diagnosis is usually presumptive based on the history of recent exposure to lush green forage, typical clinical signs, and gross and histopathology in fatal cases. Measurement of metabolites of 3-MI in blood or urine can be diagnostic, but this test is typically reserved for research applications.[9] Thoracic radiographs could be used to identify changes consistent with interstitial pneumonia in valuable individual animals. The results of TTA or BAL cytology have not been reported for cattle with ABPEE, but a nonseptic mixed inflammatory cell response would be expected. There are no unique hematologic or biochemical changes. A stress leukogram may be seen.

Treatment and Prevention The stress of handling cattle can precipitate further deaths; because there is no specific treatment for ABPEE, moving cattle to attempt treatment may cause more deaths than it prevents. Some authors maintain that most cases in an outbreak occur within 4 days, that removing the herd from the pasture does not prevent additional cases, and that leaving the herd on the pasture does not result in additional cases; consequently the recommendation has been to handle severely affected cattle only if necessary to remove them to shade or to slaughter. Others recommend careful removal from the offending pasture. Antihistamines, corticosteroids, epinephrine, atropine, diethylcarbamazine, and diuretics are alleged to be of palliative value, but none of these has been confirmed to be effective in a properly designed trial. Recovery often occurs without therapy in the less severe cases. In view of the dangers of handling affected cattle, the questionable efficacy of medical treatment, the probable irreversible nature of severe lesions, and the probability of spontaneous recovery in less severe cases, the best treatment may be no treatment. If treatment must be attempted, affected cattle should be handled very cautiously, and furosemide (0.5 to 1 mg/kg IM or IV once or twice daily) and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or steroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV once daily) may be given. Most fatalities occur in the first 2 days. Severely affected animals that survive may develop chronic emphysema or heart failure secondary to cor pulmonale. Moderate to mild cases often show marked improvement after day 3, with recovery over about 10 days; relapses do not typically occur.

Prevention is based on modification of management and prophylactic drugs. Management strategies that have been recommended to prevent the exposure of susceptible cattle to potentially toxic pastures include the following[5-8,10]:

1. Place the cattle in a dry lot, feed the cattle palatable hay for several days, and turn them onto the lush pasture for 2 hours the first day. Gradually decrease the amount of hay fed and increase the time on pasture over a period of 10 to 12 days.
2. Delay use of lush pastures until after a hard frost.
3. Mow and windrow the pasture before turning cattle out.
4. Use the pasture for young stock (less than 15 months old) or sheep or other livestock; turn adult cattle out only after the pasture has been thoroughly grazed over.
5. Use the pasture before it becomes particularly lush.
6. Use continuous strip-grazing.

Because such management changes are frequently not feasible, prophylactic medication is a useful alternative. Monensin or lasalocid at 200 mg/head/day PO reduces the conversion of tryptophan to 3-MI.[3] Treatment with monensin should be started at least 1 day before pasture change and should be continued an additional 10 days, whereas lasalocid requires a longer pretreatment period of 6 days.[11] Monensin or lasalocid is not expected to be beneficial after the onset of signs. Future possibilities include blockers of the mixed function oxidase system and enhancers of intracellular glutathione levels.

Feedlot Acute Interstitial Pneumonia

Definition and Etiology In feedlot cattle an ARDS occurs that is commonly referred to as *feedlot AIP*. The exact cause of this syndrome is unknown; it is probably multifactorial. Feedlot management practices typically do not include exposure of cattle to lush forages similar to those that cause ABPEE, and the feeding of moldy sweet potatoes has not been associated with feedlot AIP.[12] A variety of causes have been proposed[13,14]; unfortunately, the amount of research to confirm or refute the various hypotheses ranges from small to nonexistent. The most commonly suggested possible causes or predisposing factors are (1) feed-associated pneumotoxins such as 3-MI[9,15,16] or dietary factors related to protein metabolism,[17] (2) chronic bacterial pneumonia,[18,19] (3) gender[9,15] and hormonal influences,[20,21] (4) chronic small airway injury,[18,19,22] (5) BRSV

VetBooks.ir

infection,[19,23] (6) heat or dust exposure,[22,24] and (7) hypersensitivity reactions.[22,25,26] These possible causes could also work together in various combinations to cause feedlot AIP.

Support for 3-MI as a cause of feedlot AIP comes from research that showed that levels of a stable metabolite of 3-MI, 3-methyleneindolenine (3-MEIN), were significantly higher in the blood of cattle with AIP than in control cattle.[9,15] Increased levels of 3-MEIN may be a result of decreased clearance of the toxin.[15] Loneragan and colleagues also found that 3-MEIN levels were higher in lung tissue of AIP cases as compared with animals without lung disease, but they were not higher than 3-MEIN levels in the lung tissue of cattle with bronchopneumonia; this suggested that 3-MI may contribute to the pathogenesis of both AIP and bronchopneumonia.[15] The mechanism by which 3-MI is generated and leads to lung damage was discussed earlier, in the section describing ABPEE. If 3-MI does contribute to the pathogenesis of feedlot AIP, it is not clear what about the feedlot diet predisposes cattle to produce high levels of 3-MI. Normal cattle produce some 3-MI through metabolism of dietary proteins. It may be that the protein composition (e.g., the tryptophan concentration) of feedstuffs sometimes added to feedlot rations can lead to spikes in 3-MI production. Cattle with feedlot AIP have been found to have higher ruminal pH values than expected for cattle adapted to a high concentrated diet. Ruminal pH in AIP cases ranged from 5.6 to 7.2 in one study[19] and from 4.9 to 7.4 in another,[27] whereas the ruminal pH of cattle adapted to a high concentrate diet is typically about 5.5 to 5.6.[28] Many proteins are relatively basic; therefore the high ruminal pH could be related to abnormal protein metabolism. However, the relatively high ruminal pH could also be caused by anorexia. The concept that abnormal ruminal protein metabolism could contribute to feedlot AIP was also supported by a small study that found increased ammonia levels in the ruminal gas cap of cattle with AIP.[29] An interaction between digestive health and AIP was also suggested by the finding that in feedlot pens in which at least one animal had died from digestive disease, the incidence of AIP was approximately 70% greater than in pens in which digestive disease deaths did not occur.[17]

The hypothesis that bacterial bronchopneumonia contributes to feedlot AIP is supported by the finding by multiple authors that cattle with AIP frequently have superimposed gross and histopathologic lesions consistent with bacterial bronchopneumonia.[18,19,30] In a study evaluating the bacteria isolated from the lungs of cattle with feedlot AIP that had not received antimicrobial therapy, *Pasteurella multocida* and *Mycoplasma* spp. were significantly more likely to be isolated from the lungs of cattle with AIP than from the lungs of normal penmates.[19] An earlier study found that bacterial respiratory pathogens were not more likely to be isolated from cases of AIP as compared with controls, but the samples in this study were collected at necropsy of animals that received antimicrobial treatment before death in at least some cases.[31] No study has yet been able to confirm whether, in cases with both lesions, the bacterial bronchopneumonia was present before AIP occurred or the bacterial bronchopneumonia developed after the animals had AIP. If bacterial bronchopneumonia leads to the development of AIP, it is not clear how this happens. In humans with ARDS, bacterial infection is often a predisposing factor that appears to lead to ARDS through the induction of high local or systemic levels of proinflammatory cytokines.[32] The role of proinflammatory cytokines in cattle with feedlot AIP has not been investigated.

A role for gender and/or hormonal influences in the pathogenesis of feedlot AIP is related to the frequent (although not inevitable)[18] finding that the majority of affected animals are heifers.[15,17,19] Feeding of melengestrol acetate (MGA), which is fed to heifers to control estrus, has been suggested to contribute to AIP by some authors,[20] but others have not found evidence of any association between MGA and AIP.[33] Although one research study indicated that MGA could exacerbate experimentally induced AIP in sheep,[20] a well-controlled experimental study to determine the effect of MGA on AIP in cattle in the field is needed to clarify the involvement of MGA with AIP. It has also been suggested that growth hormone implants may contribute to development of feedlot AIP, although a survey of feedlot managers did not find data to support this.[33]

Infection with BRSV was linked to feedlot AIP in an early study.[23] Because BRSV infection can sometimes cause AIP, the possibility that a ruminant with lesions of AIP is simply a case of BRSV infection must always be considered. However, cattle with feedlot AIP do not always have a fever,[19] which is expected in animals with acute BRSV infection. Moreover, feedlot AIP can occur in outbreaks, but cases often occur sporadically, which would be less consistent with BRSV infection. Neither Sorden and colleagues nor Loneragan and colleagues found BRSV significantly more often in animals with feedlot AIP than in controls.[18,31] In another study the difference in frequency of identification of BRSV in feedlot AIP cases as compared with normal penmates approached significance ($P = .07$).[19] Although AIP is by definition "acute," it is interesting that several authors have reported histopathologic evidence of chronic airway injury (particularly, bronchiolitis fibrosa obliterans) in the lungs of animals with AIP.[18,19,22] In one study, the presence of bronchiolitis fibrosa obliterans was identified significantly more often in cattle with AIP than in penmates with no history of treatment for respiratory disease; this was in spite of the fact that AIP cases in the study also had no history of previous treatment for respiratory disease.[19] It is not known how past airway injury is related to the development of AIP, although chronic airway injury could be linked to the occurrence of chronic bacterial pneumonia, which has also been associated with feedlot AIP, as described previously. It may be that the chronic airway injury is related to dust exposure, although it is not clear why animals with AIP would be more likely to have airway injury caused by dust exposure than other penmates. Dust exposure has been anecdotally related to AIP,[22,24] and feedlot managers often report that efforts to control dust, such as spraying water lightly onto the surface of pens, decreases AIP occurrence when the disease is a problem. However, repeated exposure to feedlot dust or to fungal organisms from feedlot dust did not induce AIP in sheep or goats in experimental studies.[34,35] One study of the effect of dust on feedlot respiratory disease found only a weak association between airborne dust particles and respiratory disease.[36]

High ambient temperatures are thought to contribute to feedlot AIP because several investigators have found that the majority of cases occur in the summer,[17,22] but no mechanism by which hot weather might exacerbate AIP has been researched. Hypersensitivity reactions are often suggested to cause AIP. It is true that anaphylaxis can cause pulmonary edema, hemorrhage, and emphysema, with microscopic evidence of hyaline membrane formation.[37] However, animals that survive longer than a few hours after an episode of anaphylaxis do not have lung changes consistent with AIP, such as type II pneumocytic proliferation and interstitial inflammatory cell infiltrate.[38] Therefore an anaphylactic reaction may cause an occasional case of sudden death with lung changes typical of AIP, but anaphylaxis does not explain the majority of feedlot AIP cases. Other types of hypersensitivity-mediated lung diseases have pathology that is unlike that seen in feedlot AIP, also making other types of hypersensitivities unlikely causes of the majority of feedlot AIP cases.[1]

In summary, the cause of feedlot AIP is unknown, but the strongest support currently exists for some role for (1) factors related to feed, or ruminal metabolism, including 3-MI; (2) infectious respiratory disease, especially chronic bacterial pneumonia, and possibly BRSV; (3) gender and/or other hormonal influences; and (4) chronic airway injury, which may be related to infectious respiratory disease. It seems likely that multiple factors can contribute to the development of feedlot AIP, and the factors may act in some as-yet unidentified combination in at least some cases. It is also possible that some causes predominate in some feedlots or individual cases, whereas other causes predominate in other feedlots or individual cases. A study evaluating the occurrence of bacterial respiratory pathogens in cattle with feedlot AIP found bacterial respiratory pathogens in the lungs of the majority of cases in one feedlot, and in almost none of the cases in a second feedlot,[19] suggesting that bacterial infection

VetBooks.ir

played a role in the development of AIP cases in the first feedlot but not the second.

Clinical Signs Feedlot cattle with AIP may be found dead in the pen. Clinical presentation includes rapid onset of expiratory dyspnea and tachypnea, although if the respiratory effort is great, the actual respiratory rate may not be greatly elevated. Cattle typically exhibit open-mouth breathing and stand with their heads extended and front legs spread apart (see Fig. 31-76). Frothing from the mouth may also be observed. Rectal temperatures are variable, ranging from normal to elevated.[19] Physical examination may reveal cyanosis, tachycardia, and subcutaneous emphysema that extends from the cervical to dorsal thoracic area. Auscultation of lungs reveals dull areas throughout the lungs, along with some crackles. Differential diagnoses of bronchopneumonia, tracheal edema, tracheal obstruction, and hypersensitivity pneumonitis should be considered.

Pathogenesis Because the cause of feedlot AIP is unknown, the pathogenesis is also uncertain. If feed-related pneumotoxins cause at least a subset of cases with AIP, the pathogenesis will be similar to that described for ABPEE, 4-ipomeanol toxicity, and perilla ketone toxicity. If bacterial infection is a cause of some cases of feedlot AIP, as is true for some human cases of ARDS, then proinflammatory cytokine production and the resultant inflammatory cascades they initiate are likely involved. More research is necessary to determine the cause and the pathogenesis of feedlot AIP.

Epidemiology In the 1999 NAHMS survey of feedlots, AIP was identified as the second leading cause of feedlot mortality, behind bronchopneumonia (shipping fever).[39] Mortality rates resulting from AIP of 0.03% to 0.15% have been reported.[17,22,30,33] An important feature of AIP is the tendency of the disease to occur most often in cattle on feed more than 60 days,[15,19,22,31] as opposed to shipping fever, in which mortality peaks by 45 days after feedlot entry. This means that losses due to AIP deaths are amplified by the fact that relatively more resources in feed and labor have been invested in cattle that die of AIP, as compared with cattle that die of shipping fever. Most cases of feedlot AIP occur in the summer,[17,33] but the disease can occur in any season of the year; and most studies report that heifers are disproportionately affected.[15,17,19] One survey found the odds of an animal with AIP being a heifer were 3.1 times greater than the odds of the animal being a steer.[17] In feedlot pens in which an animal died from a digestive disorder, the relative risk of AIP occurring was about 1.7, indicating that pens with a digestive disorder death were about 70% more likely to also have an AIP death, as compared with pens with no digestive disorder deaths.

Necropsy Findings The gross pathology of feedlot AIP is essentially the same as that described for ABPEE. If there is concurrent bacterial bronchopneumonia, there may be cranioventral consolidation, with fibrin deposition on the pleura, but in cases with no concurrent bacterial pneumonia, the pleura is free of fibrin. Grossly it is common to see a "patchwork" appearance of dark and light colored lobules interspersed, and the lobules are freely movable (see Color Plate 31-11). Histologically, the most acute cases will have only hyaline membrane formation and alveolar edema, possibly with hemorrhage in the alveoli or interstitium; cases that have been going on longer will have proliferation of type II alveolar epithelial cells and inflammatory cell infiltrate into the interstitial space (septa). It is not unusual to find evidence of chronic airway injury, such as peribronchiolar lymphoid cuffing, peribronchiolar vascular fibrosis, and bronchiolitis fibrosa obliterans.[18,19] Whether the chronic airway injury is related to the pathogenesis of AIP or whether it is an incidental finding is unknown.

Diagnosis Diagnosis of feedlot AIP can be confirmed only by histopathologic evaluation of lung from animals that die or are euthanized because of the disease. Clinical signs and even gross pathology are not definitive; only 65% to 80% of cases identified based on clinical signs were confirmed by histopathologic evaluation to have AIP in two studies.[6,15]

Treatment and Prevention Treatments recommended are similar to those recommended for ABPEE. However, feeding monensin does not preclude development of feedlot AIP, as cattle that die of AIP are often consuming feed including monensin when they contract AIP.[15] Treatment is supportive and typically includes administration of antiinflammatory drugs such as steroids (dexamethasone at 0.05 to 0.2 mg/kg once or twice) or flunixin meglumine (1.1 to 2.2 mg/kg IV q24h), and diuretics such as furosemide (1 mg/kg IM or IV q12-24h). Antimicrobial drugs are appropriate given the fact that cases often have superimposed bacterial pneumonia (see Table 31-12). There are no studies evaluating the response of cattle with AIP to any treatment, and such studies would be difficult because there is no perfect method of making an antemortem diagnosis of the disease. However, anecdotal reports indicate that the prognosis is guarded even with treatment. It is important to note that simply moving cattle out of the pen could lead to death from severe respiratory compromise. Because of the risks and uncertainties of treatment and the expected high case fatality rate, immediate salvage slaughter may be the most economic course to take; if salvage slaughter is attempted, remember to observe proper drug withdrawal times.

Because the cause of feedlot AIP is unknown, it is difficult to recommend control measures. Administration of aspirin and of vitamin E have been suggested as rational preventive strategies to counteract inflammatory pathways suspected to be involved in feedlot AIP; however, two trials showed no clear effect of these therapies on levels of 3-MI in treated cattle.[40,41] No cattle in these trials developed AIP, so an effect on disease could not be identified. The risk factors identified suggest that management strategies to minimize abrupt dietary changes and to control infectious respiratory disease may be helpful; anecdotal reports also suggest that efforts to control feedlot dust may be helpful.

4-Ipomeanol (Moldy Sweet Potato) Toxicity

Definition and Etiology Moldy sweet potato toxicity is caused by the ingestion of a furanoterpenoid toxin produced by sweet potatoes *(Ipomoea batatas)* in response to infestation with the fungus *Fusarium solani (javanicum).* It should be emphasized that this disease is an intoxication and not an allergic response to the fungus.

Clinical Signs There is an acute onset of tachypnea, tachycardia, hyperpnea, and dyspnea, with loud expiratory grunting, frothing at the mouth, extension of the head and neck, flaring of the nostrils, and frequent deep coughing. Crackles and harsh bronchial sounds are heard on auscultation. Signs usually occur within 1 day of exposure, and deaths may occur 2 to 5 days later. Differential diagnoses are as for ABPEE (see earlier discussion), which this condition closely resembles, except for the history of exposure and the more prominent cough and adventitious lung sounds.

Pathogenesis When *F. solani* (or closely related species) grows on sweet potatoes, the potato produces several 3-substituted furans, including 4-hydroxymyoporone, which is hepatotoxic. This is converted by the fungus to a series of pneumotoxins, the most abundant of which is 4-ipomeanol. When ingested by cattle in sufficient amounts, this toxin is absorbed, carried to the lungs in the blood, and converted to a highly reactive metabolite by a cytochrome P-450–dependent mixed function oxidase system. From this point the pathogenesis is similar to that of ABPEE—that is, the toxin binds to intracellular macromolecules in the cell, causing cellular damage, particularly in Clara cells, type I pneumocytes, and endothelium; edema, hemorrhage, cellular necrosis, hyaline membrane formation, and proliferation of cuboidal epithelium result, with secondary emphysema.

Epidemiology The disease usually occurs in outbreak form when groups of cattle are fed damaged sweet potatoes. Morbidity

VetBooks.ir

and case fatality rates are high. Calves nursing affected cows are unaffected.[42]

Necropsy Findings The lungs are wet, firm, and large and fail to collapse. Hemorrhages, yellow gelatinous edema fluid, and emphysema with bullae occur throughout. Lobules are dark red and firm. Microscopic lesions include edema, emphysema, hyaline membranes, hemorrhage, mixed interstitial infiltrates, alveolar epithelial hyperplasia, peribronchiolar fibrosis, and bronchiolitis obliterans.

Diagnosis Diagnosis is made based on history of feeding sweet potatoes and identification of clinical signs and pathology consistent with AIP. Other diagnostic tests as described for ABPEE could also be attempted in valuable individual animals.

Treatment and Prevention Treatment has not been investigated. Because the pathophysiologic mechanisms are similar to those of ABPEE, similar recommendations are suggested: handle affected animals with extreme care; if treatment is attempted, furosemide (0.5 to 1 mg/kg IM or IV q12-24h) and flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) or dexamethasone (0.05 to 0.2 mg/kg IV or IM q24h) may be given. The prognosis for moderate to severe cases is grave, regardless of management. Because toxicity is difficult to predict and is usually severe and irreversible when it occurs, the feeding of mold-damaged sweet potatoes should be strictly prevented.

Perilla Ketone *(Perilla frutescens)* Toxicity

Definition and Etiology Perilla ketone toxicity is an ARDS caused by ingestion of a pneumotoxin found in the leaves and seeds of *Perilla frutescens,* a common weed in the southeastern United States. This plant is also known as purple mint, perilla mint, wild coleus, and beefsteak plant.[43] It is an erect herbaceous annual about 2 m high, with characteristic square stems, an aromatic odor, and opposite, coarsely serrated ovate leaves 5 to 10 cm long and 4 to 8 cm wide, with a purplish tint at maturity. The seed and flower stage, which occurs in August to October, appears to be most toxic. The flowers are small, white to purple blooms on a long raceme. The plant prefers semishade, such as damp, open wooded areas.

Clinical Signs Animals are often found dead.[43] Signs observed include a sudden onset of moderate to severe dyspnea, wheezing, frothing at the mouth, and an expiratory heave or grunt. In less severe cases the cow may pant. Exertion worsens the signs and may precipitate death. Mature cows are most often affected, but deaths have been reported in yearlings and calves.[43] Death occurs in 3 to 7 days in experimental toxicity.[43] Differential diagnoses are as for ABPEE, which this condition closely resembles and from which it can be differentiated only by history of exposure.

Pathogenesis The volatile oils of *P. frutescens* contain a number of 3-substituted furans that are chemically similar to 4-ipomeanol, the moldy sweet potato toxin. One of these, perilla ketone, predominates in the later growing season (when most toxicities occur) and has been shown to be pneumotoxic when given parenterally to mice, hamsters, goats, calves, and sheep.[43] The toxin is absorbed from the rumen, carried to the lungs through the blood, and probably metabolized to the toxic form by the mixed function oxidase system, as for 4-ipomeanol and 3-MI. The pathogenesis from this point parallels that of ABPEE or moldy sweet potato toxicity.

Epidemiology *P. frutescens* seems to thrive in late summer, when pastures in the southeastern United States are frequently dry and dormant. This also corresponds with the more toxic stage of the plant. Cattle normally avoid the plant when other pasture is available but may be forced to consume it during this critical period. However, under experimental conditions calves were noted to prefer the mint.[43] The preseed stage appears to be of relatively low toxicity; the green seed–stage plant is most toxic, especially the seed parts; dried hay from seed-stage plants is less toxic than green plants but is still potentially lethal; and frosted plants appear to have relatively low toxicity.[43] The exact toxic dose is unknown, but 2.3 kg of green seed–stage plant and 11.2 kg of hay were lethal for cattle in one trial.[43]

Necropsy Findings The lungs are distended (often bearing the impressions of the ribs), fail to collapse, and are moist, heavy, edematous, and emphysematous. There are often bullae, pleural effusions, and froth in the airways. Histologic characteristics are edema, extensive alveolar epithelial hyperplasia, emphysema, and congestion.

Diagnosis Diagnosis is based on history of exposure to perilla mint and characteristic clinical signs and lung pathology.

Treatment and Control Treatment has not been investigated. On the basis of the similar pathophysiologic mechanisms, the recommendations for ABPEE should be followed. The prognosis for severe cases is grave, regardless of management. Cattle should be provided sufficient forage that they do not seek out perilla mint; once they have begun to eat it, they should be fenced away from stands of the plant, and other forage should be provided.

Other Toxic Plants

As mentioned in relation to ABPEE, *Brassica* spp. (rape, kale, turnip tops) are one of the types of pastures that can precipitate the 3-MI–associated disease. The possibility that other specific toxins may be identified in these species has not been excluded. Morbidity and mortality rates appear to be much higher on *Brassica* spp. pastures than on other lush forages.[1] The hepatotoxic effects of pyrrolizidine alkaloids, which are found in certain toxic plants, are well known; pyrrolizidine alkaloids also cause lung lesions. Lung lesions develop only in animals with chronic liver lesions, and the minimum dose necessary to produce lung lesions is never less than that which is hepatotoxic; therefore signs of liver disease usually predominate. *Crotalaria* and *Trichoderma* spp. are the most common offenders; to a lesser extent, *Senecio* spp. are a cause. Horses, sheep, cattle, and pigs have been affected. Pulmonary lesions include edema, congestion, hemorrhage, proliferation of bronchiolar and alveolar epithelial cells with megalocytosis, and interstitial fibrosis and cellular infiltration. As with 3-MI, 4-ipomeanol, and perilla ketone, the toxicity of the pyrrolizidine alkaloids depends on activation by the mixed function oxidase system.

Toxic Gases

Ruminants may be exposed to a variety of toxic gases in the environment. The most important are ammonia, hydrogen sulfide, carbon dioxide, and methane from excreta and respiration; these can be especially important when excreta is collected in pits or tanks. Other gases include nitrogen dioxide from silos; carbon monoxide from machinery exhausts and heaters; zinc oxide from welding of galvanized metal in barns; and chlorine, formaldehyde, insecticides, and other fumes from agricultural chemicals and cleaners. Smoke from fires can also cause pulmonary damage. In most cases concentrations usually remain below overtly toxic levels, and effects are very subtle. Such chronic low-level exposure may result in decreased disease resistance and depression of growth rates. Slightly higher levels of chronic exposure may cause clinically vague syndromes of lethargy, mild dyspnea, anorexia, depressed growth, excessive lacrimation and salivation, low incidence of sudden deaths over weeks or months, and stillbirths. Acute, severe outbreaks usually occur in tightly enclosed facilities and are related to accidents, power outages, agitation or pumping of manure pits, or other combinations of unusual circumstances. Such outbreaks are characterized by an ARDS of variable morbidity and frequently a high case fatality rate.

NITROGEN DIOXIDE. Nitrogen dioxide (NO_2) is a yellow-orange to brown gas with an acrid odor that is produced by anaerobic fermentation of green plant material. It is a major component of "silo

VetBooks.ir

gas." Acute exposure of farm workers to high concentrations of NO_2 causes a respiratory condition known as "silo-filler's disease," characterized by severe acute edema and congestion and followed by bronchiolitis obliterans and progressive interstitial pulmonary fibrosis. A similar condition has been induced experimentally in cattle,[44] and apparent spontaneous field cases have been reported.[45,46] Clinical signs in experimental and apparent field cases include cough, tachycardia, tachypnea, respiratory grunting, depression, anorexia, hypogalactia, extension of the head, open-mouth breathing, fever, salivation, lacrimation, and subcutaneous emphysema. Auscultation reveals decreased breath sounds and crackles. The primary differential diagnoses should include other ARDSs of housed cattle that occur in outbreak form, especially exposure to other toxic gases (manure pit gases, zinc oxide, chlorine, carbon monoxide), and hypersensitivity pneumonitis from moldy hay. Nitrate toxicity should also be considered. Clinical pathologic evaluation is of limited benefit. Leukocyte counts remained normal in experimental cases; methemoglobin levels increased to a peak at 30 minutes after exposure and returned to normal in 12 to 24 hours.[44] The pathophysiologic mechanism probably involves the dissolution of the NO_2 in the water of the respiratory tract to form nitric acid. Nitrates and nitrites are also formed; these are irritating, and the nitrites cause methemoglobinemia. NO_2 is also an oxidant itself and may contribute directly to the injury. The disease occurs as an outbreak, usually in housed cattle in proximity to a silo chute in a tight or poorly ventilated barn.[45,46] NO_2 is heavier than air and layers on the top of silage or spills out around the bottom of the silo. Corn silage produces more gas than hay, and a high nitrate content increases the danger. The levels are highest in the first 48 hours after filling the silo but may remain dangerous for 2 to 3 weeks.

Necropsy findings in experimental disease include hyperemia of the upper airways; hemorrhages, fibrinous membranes, and froth in the trachea; distended, noncollapsing lungs with rib imprints; a patchwork appearance caused by consolidated lobules alternating with emphysematous lobules; and bullae. Microscopic lesions include alveolar epithelial hyperplasia, large foamy alveolar macrophages, hyaline membranes, hyperemia, hemorrhage, and edema.

Treatment involves the establishment of adequate ventilation; cows should be completely removed from closed buildings if necessary. Corticosteroids have apparently been beneficial in field cases,[45,46] but no controlled studies have been performed to confirm efficacy. Because of the obvious differences in pathophysiologic characteristics, it would be unwise to extrapolate treatment regimens from those of ABPEE. Suggested empirical therapy might include corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice daily), and appropriate antibiotics to prevent secondary bacterial infections.

ZINC OXIDE. Zinc oxide (ZnO) fumes have been associated with ARDS in cattle.[47] Oxyacetylene cutting or arc welding of galvanized pipe results in production of white fumes of ZnO containing colloidal particles 0.3 to 0.4 mm in diameter, which can reach the terminal alveoli when inhaled. Construction activities in closed barns containing animals may result in toxicity in animals in close proximity or in the path of ventilation. All ages may be affected.

Clinical signs in severe cases include acute onset of anorexia, frothing at the mouth, anxiety, extension of the head and neck, mouth breathing, expiratory grunting, tachypnea, tachycardia, mild fever, subcutaneous emphysema, and crackles on auscultation of the lungs. Death may occur within 12 hours. Less severely affected animals exhibit depression, mild fever, and tachypnea. Differential diagnoses include other ARDS of housed cattle that occur in outbreak form, such as exposure to other toxic gases (nitrogen dioxide, manure pit gases) or hypersensitivity pneumonitis. The pathophysiologic process presumably involves direct damage to cells by the ZnO and its products dissolved in the fluid lining the respiratory tract. Necropsy findings include purulent conjunctivitis; subcutaneous emphysema; congestion of the airways; tracheal hemorrhages; stiff, noncollapsing lungs; and pulmonary congestion, edema, and emphysema with bullae. Histologic lesions include pulmonary congestion, emphysema, edema, and mixed cellular infiltrates with a prominent eosinophil component. Treatment of severe cases with epinephrine, antihistamine, atropine, and corticosteroids had no effect in one outbreak, whereas mild cases recover spontaneously. Suggested empirical therapy could include ventilation of the area, dexamethasone (0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily or twice), and appropriate antibiotics to control secondary bacterial invaders.

CHLORINE. Chlorine is a greenish yellow gas widely used in manufacturing. Animal exposure is usually the result of industrial accidents. Exposed animals may be found dead. Signs include depression, profuse nasal discharge, lacrimation, and dyspnea; crackles may be heard on auscultation.[48] The toxic effects are the result of the formation of hydrochloric and hypochlorous acids; the latter breaks down to hydrochloric acid and oxygen, both of which are toxic to tissues. Necropsy findings include congestion of the nasal mucosa, tracheitis, and pulmonary edema, hemorrhage, and emphysema. Histologic lung lesions include edema, emphysema, hemorrhage, atelectasis, hyaline membrane formation, and lymphocytic bronchitis. Treatment is empirical; suggestions include corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IM or IV daily), furosemide (0.5 to 1.1 mg/kg IM or IV daily to twice daily), and appropriate antibiotics to prevent secondary bacterial infection.

MANURE GASES. Manure gases include mixtures of hydrogen sulfide, ammonia, carbon dioxide, methane, and carbon monoxide.[1] Accumulation of these gases can result in asphyxiation of animals in enclosed barns over manure pits.

Hypersensitivity Pneumonitis

Definition and Etiology Hypersensitivity pneumonitis, also known as *extrinsic allergic alveolitis* (EAA) or "bovine farmer's lung," is an allergic respiratory disease caused by inhalation of organic dusts. Several such conditions are recognized in humans, differing only in the nature of the antigen and the circumstances under which exposure occurs. The classic example, of which the bovine disease is probably the counterpart, is "farmer's lung." EAA is caused by exposure to the dust from moldy hay, grain, or other plant matter containing spores and products of thermophilic actinomycetes such as *Saccharopolyspora rectivirgula* (formerly *Micropolyspora faeni*) and *Thermoactinomyces vulgaris*.[1,2] Other unidentified forms of hypersensitivity pneumonitis probably occur in cattle.

Clinical Signs EAA is a disease of confined adult cattle; consequently it is more common in dairy than in beef breeds. Typically a succession of acute cases occurs during the winter housing period, so the clinician is presented with a group problem in which animals are in varying stages of the disease. The acute form is indicative of recent exposure and is characterized by a sudden onset of dullness, decreased appetite, hypogalactia, coughing, expiratory tachypnea, dyspnea, and cranioventral crackles on auscultation of the lungs.[1-3] There is a moderate transient fever, which is frequently missed. The chronic form is insidious at onset and may not be detected until there is considerable fibrosis. Animals with the chronic disease may have acute exacerbations as a result of heavy antigen exposure; some may not be detected until turned out in the spring, when increased exercise causes an acute crisis. There is a history of weight loss and coughing for several winters, with remission in the grazing season. Chronic signs include hypogalactia, weight loss, productive coughing, tachypnea, obvious hyperpnea, and widespread crackles and wheezes on auscultation of the lungs, especially in the rostroventral areas. Differential diagnoses should include respiratory diseases affecting groups of housed adult cattle in winter. Infectious diseases (viral and bacterial pneumonias) can usually be differentiated from farmer's lung by careful evaluation of factors such as

VetBooks.ir

clinical signs of fever and pulmonary consolidation. Therefore the main differential diagnoses are the toxic gases. It should be emphasized that hypersensitivity pneumonitis is not considered an ARDS and that no evidence exists for the involvement of hypersensitivity in the pathogenesis of the ARDS described previously. However, severe cases of EAA with prominent dyspnea and moderate, nonfatal cases of gas intoxication may appear clinically similar. If the group outbreak aspect of EAA is ignored, the clinician who examines one individual may be unable to distinguish this condition from fibrosing alveolitis.

Pathogenesis The spores of the thermophilic actinomycetes are 0.7 to 1.3 mm in diameter and can easily reach the alveoli, where they induce both humoral (precipitating) and cellular immune responses. It is thought that repeated exposure results in the activation of a number of immunologically specific and nonspecific cellular and humoral effector mechanisms at the alveolar level, which results in tissue damage.[1,2]

Epidemiology EAA is a problem in areas with wet summers and severe winters, a situation characterized by the combination of moldy hay and housing of cattle in winter. In North America, EAA occurs primarily in the Great Lakes region of the United States and the eastern provinces of Canada.[3] Baling and stacking of hay with a high moisture content (over 30%) results in overheating of the stacks. Thermophilic molds become dominant and produce billions of spores, which are released when the hay is distributed for feeding. A similar situation can occur in stored grains. Affected hay is usually dry, friable, discolored, and dusty; however, it is not necessary for hay to be grossly dusty and poor in quality to release large numbers of spores.[2]

Necropsy Findings In acute cases the lungs are superficially grossly normal. Closer inspection reveals small gray spots in many lobules, which represent interstitial and peribronchiolar accumulations of lymphocytes. Other lobules exhibit dark red centers of atelectasis surrounded by pale pink, raised edges of trapped air that are caused by narrowing of airways with lymphocytic infiltrates. Histologic evaluation confirms the presence of these lymphocytic infiltrates and aggregations, as well as epithelial granulomas, bronchiolitis, and bronchiolitis obliterans. The gross appearance in chronic cases is similar, with the addition of focal areas of interalveolar fibrosis and epithelial hyperplasia; epithelioid granulomas are absent unless a recent acute exposure has occurred.[1,2]

Diagnosis Precipitating antibodies to *S. rectivirgula* are found in the serum in most cases.[1,2] However, two precautions are necessary. First, the presence of precipitating antibodies only indicates exposure to the antigen; many normal animals also have antibodies. Second, it is possible that other as yet unidentified antigens may cause allergic respiratory disease in cattle. The presence or absence of titers is therefore not necessarily diagnostic of the clinical status of the animal, and the magnitude of the titer does not reflect the extent of disease.

Treatment and Prevention Treatment and control center on removal of the offending antigen, which is frequently difficult from an economic and management standpoint. Corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IV or IM daily) may be beneficial in acute cases. Suggestions to decrease the molding of hay or degree of exposure include making silage instead of hay, ensuring proper drying before baling, and feeding hay outside. If the condition can be arrested before significant fibrosis occurs, the prognosis is good.

Anaphylaxis

In ruminants the lung is the major target organ in immediate (type I) hypersensitivity reactions. Precipitating antigens include vaccines, drugs, blood, *Hypoderma bovis* or *Hypoderma lineatum* larvae, insect bites, and bee stings. Signs of anaphylaxis usually develop in 10 to 20 minutes and include severe acute dyspnea, with flaring of the nostrils, extension of the head and neck, open-mouth breathing, frothing of the mouth, hyperpnea, and abduction of the elbows. Pharyngeal and laryngeal edema cause stertor and inspiratory dyspnea. Urticaria may occur in some cases, such as milk allergy in Jersey cows. Shivering, salivation, lacrimation, pruritus, diarrhea, fever, edema (eyes, muzzle, anus, and vulva), collapse, nystagmus, cyanosis, and discharge of froth from the nostrils also may occur. On auscultation there are harsh breath sounds, large airway sounds, and crackles. The primary differential diagnosis is peracute interstitial pneumonia. The pathogenesis involves an initial exposure to the antigen, which results in a genetically determined production of immunoglobulin E (IgE); IgG may also be involved. This antibody attaches to receptors on mast cells and basophils. On subsequent exposure to the antigen, bridging of the Fab parts of the antibody on these cells results in degranulation, with release of a variety of mediators such as histamine, bradykinin, 5-hydroxytryptamine, serotonin, slow-reacting substance-anaphylaxis (SRS-A), eosinophil chemotactic factor A, platelet-activating factor, kinins, and prostaglandins. These mediators result in a cascade of vascular events, notably increased vascular permeability, which in turn results in acute severe edema. Pulmonary venous constriction, pulmonary artery hypertension, splanchnic pooling, increased mucus secretion, and bronchospasm also occur. Ruminants that die of anaphylaxis have severe pulmonary congestion and edema, laryngeal edema, and froth in the airways. Lung lesions of ARDS may be present.

The treatment of choice is epinephrine, 4 to 8 mg (4 to 8 mL of 1:1000 solution) IV or SC or 1 to 5 mg IV for an average 500-kg cow and 1 to 3 mg IV or SC for an average adult sheep or goat. Epinephrine has a short half-life, and animals should be observed closely for relapse. Ancillary therapy includes corticosteroids (dexamethasone, 0.1 mg/kg IM or IV; prednisolone, 2.2 mg/kg IM or IV daily). Other supportive therapies include shock doses of IV fluids (40 mL/kg/h), aminophylline, diuretics such as furosemide, oxygen therapy, and tracheostomy if necessary.

Miscellaneous Chronic Pneumonias

At least two chronic interstitial pneumonias of uncertain cause have been identified in cattle: fibrosing alveolitis and bronchiolitis obliterans. These are typically chronic diseases of individual animals.

Fibrosing Alveolitis

Fibrosing alveolitis is, by definition, a chronic disease of unknown and possibly multiple causes, characterized by diffuse inflammation of the lung beyond the terminal bronchiole. Approximately 50% of cases produce positive results for precipitating antibody to *M. faeni,* and it is possible that these cases represent chronic farmer's lung, whereas others (that have negative *M. faeni* results) may be the chronic stage of hypersensitivity to other unidentified antigens.[1] Field investigations have failed to substantiate any connection between fibrosing alveolitis and repeated episodes of ARDS such as ABPEE. Furthermore, recovery from a single dose of 3-MI does not result in lesions typical of fibrosing alveolitis. However, repeated doses of 3-MI at weekly intervals experimentally cause fibrosing alveolitis–like lesions. Fibrosing alveolitis occurs in individual adult cattle (usually over 6 years of age) in both housing and pasture conditions. The history is usually that of a chronic progressive respiratory disease several weeks to 2 years in duration. Affected cattle remain bright and alert and continue to eat until the terminal stages of cor pulmonale and heart failure intervene. Signs include marked weight loss; consistent coughing; tachypnea; very marked hyperpnea, even at rest; and dyspnea after mild exertion. Auscultation may reveal crackles in the rostroventral lung field and widespread wheezes. Fever is not apparent. The primary differential diagnoses to consider are other chronic respiratory conditions of individual adult cattle. Chronic suppurative pneumonia and metastatic pneumonia can usually be differentiated from fibrosing alveolitis by careful physical examination and detection of depression, anorexia, shallow respiration,

VetBooks.ir

thoracic pain, and hemoptysis. ARDS caused by feed-associated pneumotoxins and lungworms are typically group problems, with at least some severe cases in the group. Differentiation from EAA may be impossible if the group outbreak nature of farmer's lung is not apparent; in fact, at least some cases of fibrosing alveolitis may represent chronic farmer's lung. At necropsy the lungs are very pale, firm, and heavy throughout. Scattered lobules are gray-red, slightly collapsed, and edematous. Thick mucus may be found in the airways, and there is frequently right ventricular hypertrophy as a result of cor pulmonale. Histologic changes are diffuse and include interalveolar fibrosis and infiltration with plasma cells, lymphocytes, mast cells, and interstitial cells; obliteration of alveolar spaces; mononuclear exudates in alveoli; alveolar epithelial hyperplasia; bronchitis; and bronchiolitis. The epithelioid granulomas characteristic of acute farmer's lung are absent. No treatment exists, and the lesions are irreversible.

Bronchiolitis Obliterans

Bronchiolitis obliterans is a chronic respiratory condition of yearling or young adult cattle characterized by a deep infrequent cough, tachypnea, hyperpnea, and an exaggerated expiratory effort. There is no fever. The cause is unknown; the condition is speculated to be a sequela to viruses (respiratory syncytial virus [RSV], parainfluenza virus type 3 [PIV-3], infectious bovine rhinotracheitis [IBR]), parasites such as *Dictyocaulus viviparus,* or hypersensitivity pneumonitis. The lungs appear grossly normal at necropsy, except that they do not collapse. Histologic examination reveals extensive bronchiolitis and bronchiolitis obliterans, with epithelium-covered polyps with a connective tissue core projecting into and obstructing the lumen.[1]

Parasitic Bronchitis and Pneumonia

Dwight D. Bowman • Anne M. Zajac

There is only a single lungworm, *Dictyocaulus viviparus,* which matures to the adult stage within the lungs of cattle. In sheep, the three main lungworms that may occur are *Dictyocaulus filaria, Muellerius capillaris,* and *Protostrongylus rufescens;* some other species mature in the lungs of sheep and goats around the world, but they are fairly rare compared with these other species. *Toxocara vitulorum* of cattle larvae undergo a liver to lung migration on their way to the intestine after infective eggs are ingested, and they can induce a transient pneumonitis during lung passage. In cattle, *Ascaris suum* of pigs can also cause signs similar to larval toxocariasis if cattle ingest large numbers of eggs; these infections do not develop to patency. In sheep and goats, *Toxocara canis* (and perhaps other species from carnivores) can cause transient pneumonitis as the larvae migrate through the liver and lungs on their way to arrest as larvae in other tissues such as muscle and nervous tissues.

Lungworms of Cattle: *Dictyocaulus viviparus*

Definition and Etiology *Dictyocaulus viviparus* is a trichostrongylid nematode that is found in the bovine trachea and bronchi. These are robust white worms that can reach lengths of 8 cm; the slightly smaller males have very dark brown stubby spicules that can often be visualized within the body of the worm just anterior to the copulatory bursa. The life cycle of *D. viviparus* is direct. The female produces larvated eggs that hatch in the lungs, and the larvae make their way up the respiratory tract, are coughed up, and swallowed to be passed in the feces. The larvae on pasture ultimately develop to an infective third stage without feeding and can develop in the laboratory in aerated water into double-sheathed infective stages. The larvae take 5 days or longer, depending on environmental conditions, to develop to the infective stage on pasture. The larvae then migrate onto grass where they are ingested by the feeding cattle. After ingestion, the larvae migrate through the intestinal wall and make their way into the mesenteric lymph nodes where they molt to the fourth stage. It is the fourth-stage larvae that make their way to the lungs via the blood and lymph systems and initially are found in the terminal capillaries of the ventral parts of the caudal lobes. About 7 days after ingestion, the fourth-stage larvae enter the alveoli and then molt to the immature adult stage. The adults develop and mate. Eggs will first appear in the bronchi, and subsequently larvae in the feces, some 3 to 4 weeks after the animal was initially infected. Clinically evident infection with *D. viviparus* typically occurs in young, nonimmune stock (less than 12 months old) or in previously unexposed yearling or adult cattle. A reinfection syndrome can also occur when previously infected (and therefore immune) adults are subjected to massive challenge with infective larvae.[1,2]

Clinical Signs and Differential Diagnosis Primary infection with *D. viviparus* can be broken down clinically into a prepatent phase, a patent phase, and a postpatent phase.[3] No signs are associated with the initial penetration of larvae until they reach the alveoli, where they provoke an eosinophilic exudate that blocks small airways. During the prepatent phase (approximately 7 to 25 days after ingestion), there is a gradual onset of coughing and tachypnea (35 to 60 breaths/min), which becomes increasingly apparent from day 14 to day 25. The severity of signs in this stage is proportional to the number of larvae ingested, the rate of ingestion, and the proportion reaching the lungs. Severe illness and death can occur in cases of heavy infection. In the patent phase (approximately 25 to 55 days after ingestion), a parasitic pneumonia with consolidation develops in the ventral areas of the caudal lung lobes as a result of aspiration of eggs and larvae into these areas. Tracheitis and bronchitis associated with the adult worms also develop. Clinical signs vary in severity and range from intermittent to marked coughing, tachypnea (respiratory rate may increase to more than 70 breaths/min), dyspnea, anorexia, and weight loss. Fever may develop with secondary bacterial infection. Auscultation reveals harsh breath sounds and widespread crackles and wheezes. In severe cases animals may exhibit open-mouth breathing, extended head and neck, protrusion of the tongue, and an expiratory grunt. Death is common in untreated, heavily infected animals.[2,3]

Recovery begins in the late patent phase, and the signs gradually resolve, sometimes over several months. During the postpatent phase (about days 55 to 90), adult parasites are expelled by a self-cure phenomenon. In approximately 25% of severe cases the postpatent phase is characterized by a sudden exacerbation of dyspnea at days 45 to 60 that is often fatal, after secondary bacterial infection or alveolar epithelialization.[1,3] The reinfection syndrome occurs 14 to 16 days after adult cattle are placed on heavily contaminated pastures. Signs include acute hypogalactia; severe, frequent coughing; marked tachypnea; and depression. Auscultation reveals only harsh breath sounds with no crackles or wheezes.[1,3]

Relative to *D. viviparus,* an ancillary finding occurred as part of a 3-year study in Sweden that examined the effects of different parasite control strategies administered to cattle during their first grazing season on their weight gain during the three second grazing seasons when they were all handled equivalently.[4] Basically, during the second season of grazing, deficits acquired within each management group the first year were maintained during the second year, but the first season of treatment had no effect on weight gain the second season. During the second and third second-season grazing period, *D. viviparus* entered the groups when additional contaminated pastureland was added to the grazing area in the last 2 years. The work then clearly showed that the presence of *D. viviparus* had a detrimental effect on all animals both seasons, and during the second such season, signs of dictyocauliasis appeared in August and the cattle underwent dramatic weight loss (the trial precluded treatment without more serious signs of induced disease). Thus, it was fairly clear that the larvae had overwintered on pasture, increased in number within the herd, and was there in sufficient numbers to cause significant effects the second year.

Differential diagnosis should be straightforward if both the clinical signs and epidemiologic characteristics of the disease are taken into account, especially in endemic areas. This is a disease of groups of cattle at pasture, typically in late summer or fall in northern

VetBooks.ir

temperate climates; the situation thus resembles ABPEE, which differs in clinical signs (i.e., less coughing and fewer adventitious lung sounds). The signs associated with lungworm infection are reminiscent of those of farmer's lung, which occurs in quite different circumstances. In typically nonendemic areas, outbreaks associated with climatic changes are frequently mistaken for acute bacterial bronchopneumonia.[1]

Diagnosis Classically, diagnosis has been through the detection of the characteristic larva passed in the feces. In cattle, this is the only nematode parasite routinely producing larvae found in the feces, and thus, if the fecal sample is fresh, the finding of larvae is fairly diagnostic. Rectal fecal samples are preferred for parasite examination because samples picked up off the ground may contain free-living nematodes that can be difficult to differentiate from lungworm larvae. Recovery of larvae from fecal samples is substantially diminished if the sample is stored at room temperature for more than a few hours. The larvae are best detected by the Baermann test[5] and may be seen on a transtracheal wash. The larvae themselves are large (390 to 450 μm × 25 μm), have a somewhat pointed tail (compared with *Dictyocaulus filaria* of the sheep), and an intestine is filled with dark granules. The esophagus appears clear compared with the intestine under the microscope and is about one fourth of the total length of the larva. If the Baermann test cannot be set up soon after fecal collection, the sample can be safely refrigerated for 24 to 48 hours without serious larval loss.[6] No larvae are detected in the reinfection syndrome. In some European countries, enzyme-linked immunosorbent assay (ELISA) tests are used within various diagnostic laboratories to detect antibodies in cattle that have been exposed to infection.[7] An increase in eosinophils in the peripheral blood may also occur approximately 2 weeks after infection, peaking at 4 to 7 weeks after infection.[8]

In Europe, ELISA technology has now been developed to detect antibody in the milk and serum of cattle that is based on an antigen that is a recombinant product representing a major sperm protein of the adult male.[9,10] Examination in experimentally infected dairy cows revealed that the ELISA detected antibodies in the serum and milk some 30 to 32 days after infection and remained elevated for 112 to 138 days postexposure even though the cows had been treated for their infections with eprinomectin 49 days after infection and had ceased larval shedding.[9] However, if the cattle were treated during the prepatent period, larvae were never shed in the feces, and the animals remained antibody negative. This technique has now been adapted to determine the presence of antibodies in bulk milk and has been used for the collection of epidemiologic data. Of 810 dairy farms in Germany that were tested in January, September, and November, some 18% were positive on one occasion, and most positive samples were detected in January.[11] It was not known what percentage of zero-grazing herds were included in the bulk-milk samples.

Pathophysiology Once the fourth-stage larvae enter the alveoli, they incite an eosinophilic exudate that blocks small bronchi and bronchioles, resulting in atelectasis and causing the cough and tachypnea of the prepatent phase. As these larvae mature and migrate up the airways, these lesions may resolve. However, the adult worms produce an inflammatory response in the larger airways, and aspirated eggs and larvae cause a marked macrophage and giant cell response, with consolidation of the ventral caudal lobes; these lesions are the cause of the signs in the patent phase. At any point in the pathogenesis (prepatent, patent, or postpatent stage), complications may occur that account for acute exacerbation and death. These complications are as follows:

- Development of pulmonary edema caused either by heart failure or by extensive alveolar epithelial damage and hyaline membrane formation
- Severe interstitial emphysema from the severe dyspnea
- Alveolar epithelial hyperplasia
- Secondary bacterial infection (relatively uncommon)

In the reinfection syndrome the immune response cannot completely overcome a massive challenge, and a small number of larvae reach the lungs. The signs are caused by the immune reaction to the migrating larvae. Lymphoid nodules develop around dead larvae in the bronchioles.[1-3]

Epidemiology Parasitic bronchitis and pneumonia in cattle occur most often in temperate areas with high rainfall or intense irrigation. In the United States, lungworm infection is widely distributed, but disease outbreaks are uncommon, probably because periods of dry summer weather limit larval survival and accumulation on pasture.[2] In the southern United States, lungworm transmission is probably greatest in the cool winter months,[12] whereas autumn is probably the season of most intense transmission in the northern United States.[13,14]

Dictyocaulus infections have been studied extensively in Europe, where the parasite is an important pathogen. Disease outbreaks occur most frequently in first-season grazing animals. If large numbers of larvae are present on pasture at spring turnout of calves, disease may develop at that time. Often, however, levels of pasture larvae are too low to cause disease but lead to low-level primary infections in calves that result in the accumulation of additional larvae on pasture. This second wave of infection may lead to clinical lungworm disease when the primary infection did not produce adequate levels of immunity. If infection levels remain low, disease may not be observed until a third generation of parasites occurs. Immunity develops beginning about 10 days after heavy infection, and patent infections usually persist for only a few months. In the absence of continued exposure to parasites, immunity to reinfection will begin to decline after several months.[2,15]

Older animals without immunity also develop lungworm disease when exposed to high levels of pasture contamination with larvae. This can occur when animals from a nonendemic area are moved to an endemic area. In recent years outbreaks of primary parasitic bronchitis have become an important cause of respiratory disease in adult dairy cows in Europe. The increased prevalence of disease in this older age group is likely the result of decreased levels of immunity after the widespread use of powerful suppressive anthelmintic regimens in first- and second-season grazing animals. Other management factors, such as isolation of calves from adult carrier animals and increased movement of livestock, may also contribute to a decline in levels of immunity.[7,16] Beef animals are less often affected than dairy cattle because management practices are more extensive and levels of infective larvae on pastures are generally lower.[2] The reinfection syndrome occurs in immune adult animals when, for example, immune cows are placed on a pasture previously contaminated very heavily by calves with patent disease.[1,2]

In northern temperate climates, the infection is carried from year to year by overwintering of larvae on pasture in some areas, by spreading of manure from infected housed calves in the spring, and by carrier cattle. Lungworm larvae also may be inhibited in the lungs of calves in winter (as with *Ostertagia* spp. in the abomasum) and mature in the spring.[1,3]

Necropsy Findings In the prepatent phase the lungs are largely normal, with a few atelectatic lobules in the ventral caudal lobes; adult worms are not present until late in this phase, but larvae may be detectable by microscopic examination of smears of bronchial exudate. In the patent phase there is usually bilaterally symmetric red consolidation of the ventral caudal lobes. Adult worms can be recognized on necropsy by their relatively large size and location in the trachea and bronchi. The lesions of the postpatent phase are similar, but no adult worms or larvae are present. In those animals that die of an acute exacerbation, there is extensive pulmonary edema and emphysema, with hyaline membranes and alveolar epithelial hyperplasia.

In the reinfection syndrome the pulmonary lymphoid nodules may be 3 to 4 mm in diameter and thus grossly visible as raised, gray-red to greenish yellow nodules under the pleura. Initially these

TABLE 31-14

Anthelmintics Approved for Treatment of *Dictyocaulus viviparus* in the United States

Anthelmintic	Formulation	Efficacy of a Single Treatment	Approved for Dairy Cattle of Breeding Age
Levamisole	Drench, bolus, injection		
Fenbendazole	Paste, suspension, medicated feed, mineral		+
Oxfendazole	Suspension		
Albendazole	Paste, suspension		
Ivermectin	Injection, pour-on	28 days	
Eprinomectin	Pour-on	28 days	+
Doramectin	Injection, pour-on	Injection: 28 days Pour-on: 21 days	
Moxidectin	Pour-on, injection	42 days	+ Pour-on only

are composed of a core of eosinophilic parasitic debris surrounded by macrophages, multinucleated giant cells, hyperplastic bronchiolar epithelium, eosinophils, and plasma cells. The lesions eventually mature to lymphoreticular nodules with a germinal center. There is also greenish mucus in the airways and a greenish discoloration to the tissues, both caused by eosinophil infiltration. There is no edema or emphysema, and the rare lungworms that may be found are small and stunted.[1]

Treatment, Prognosis, Prevention, and Control *D. viviparus* infection can be treated with a number of bovine anthelmintics available in the United States and other countries (Table 31-14). Macrocyclic lactone products also have residual efficacy against *D. viviparus*.[17] Animals with only cough and tachypnea respond well, whereas those with dyspnea, fever, anorexia, and depression have a more guarded prognosis; some of these can be expected to die or remain chronically unthrifty.[1] Control (see also Chapter 49) involves appropriate pasture management and the strategic use of anthelmintics to prevent buildup of infection in the herd and on pastures. Several strategic deworming programs have been developed in Europe, which effectively suppress lungworm infection throughout the grazing season. These programs include use of ivermectin at 3, 8, and 13 weeks after turnout and use of doramectin or eprinomectin at 0 and 8 weeks. Use of an oxfendazole pulse release bolus (not available in the United States) also provides strategic treatments. Alternatively, use of a continuous-release ivermectin or fenbendazole bolus (not available in the United States) will prevent development of lungworm infection during its period of efficacy.[16] A long-acting moxidectin injection product that provides protection from lungworm infection for 120 days is also now available in some countries.[18] Anthelmintic treatment with moxidectin or fenbendazole followed by movement of calves to safe pasture 9 weeks after turnout was also effective in controlling lungworm.[19] None of these control programs has been extensively tested under the variety of grazing conditions found in the United States.

Despite concern that suppressive programs may limit exposure to larvae and interfere with the development of immunity to lungworm, several studies conducted in Europe have shown that stimulation of the immune response still occurs, although relative levels of immunity may vary with different management systems and with annual variation in the intensity of lungworm challenge.[7,20-22] In Europe, methods of control also include an effective irradiated larval vaccine.

Delay of spring turnout is an adjunct to control but should not be relied on as the sole means of control.[21] A targeted selective deworming program was successful in controlling lungworm infection in a dairy herd in Sweden. Only cattle testing positive for lungworm by the commercial ELISA test were treated at each sampling date.[23] In an attempt to eradicate *D. viviparus* from two farms in the Netherlands that had had lungworm-associated disease outbreaks, both herds were mass treated with eprinomectin at turnout.[24] From August to November of the first year after treatment, all first-year heifers remained lungworm negative as determined both by fecal examination and by monitoring for *D. viviparus*–specific antibodies. However, in the second year following treatment, one of the herds developed signs of parasitic bronchitis that was confirmed serologically. The other herd remained negative until at least the fourth year after treatment, but at that time signs of parasitic bronchitis were observed and the cattle were treated. The authors believe that in both cases, either the *D. viviparus* was reintroduced into the herd from an outside source or the reuse of pastures that may have lain fallow for an extended period provided the source of the new infections.

TOXOCARA VITULORUM. This parasite seems to be reemerging in prevalence within the developed world; there have been recent reports from a bison herd in western Canada, suckling beef calves in the Netherlands, suckling Simmental cattle in the United Kingdom, and in a closed cow-calf beef operation in north central Florida, 17.6% of 105 calves under 3 months of age were found infected.[25-28] Infections in neonatal calves are acquired by fairly large larvae (0.75 to 1.5 mm in length) that are passed from cow to calf in the milk. In cows that ingest eggs, the larvae undergo a liver-lung migration before they make their way to the various tissues of the cow where they are known to persist for at least 5 months.[29] There typically do not appear to be any signs associated with the lung migration of the larvae, but repeated passage of the larvae through the lungs on contaminated pasture could perhaps produce respiratory signs in older calves or adult animals.

ASCARIS SUUM. Cattle exposed to large numbers of *Ascaris suum* eggs in areas contaminated by swine may have an interstitial pneumonia. Animals are typically affected approximately 10 days after exposure. Signs include depression, anorexia, fever, tachycardia, tachypnea, dyspnea with an expiratory grunt, variable coughing, ruminal stasis, and bloat. Auscultation of the lungs reveals increased breath sounds without adventitious sounds. Some deaths may occur. Differential diagnosis is difficult. Differentiation from the other interstitial pneumonias depends more on history of exposure to the causative agents (e.g., lush pastures, moldy sweet potatoes, *P. frutescens,* toxic gases, moldy hay). Differentiation from viral pneumonia (such as that caused by RSV) and *D. viviparus* reinfection syndrome requires necropsy and demonstration of larvae. Ascarid larvae have characteristic lateral alae in histologic sections. Patent *D. viviparus* infection can be differentiated by Baermann examination of the feces. In fatal cases the lung lobes are firm and mottled blue, red, and gray. The cut surface oozes thin yellow exudate. There is emphysema in the dorsal diaphragmatic lobes and subpleural hemorrhage with neutrophil infiltration and necrosis of bronchiolar and alveolar epithelium. In chronic cases the cellular infiltrate is lymphocytic, bronchiolar epithelium proliferates, and peribronchial fibrosis is present. Recommended treatments include corticosteroids (dexamethasone, 0.04 mg/kg IM or IV, or prednisolone 1 mg/kg IM or IV daily) and antibiotics to control secondary bacterial infection.[30] Clinical signs

VetBooks.ir

resolved after treatment with oxfendazole in one outbreak of suspected *A. suum* migration.[31] Cattle should not be exposed to areas heavily contaminated by swine.

Lungworms of Sheep and Goats

Three species of lungworms are of primary importance in sheep and goats: *D. filaria* and the two metastrongylid nematodes, *M. capillaris* and *P. rufescens*. Other genera of metastrongylid lungworms of minor pathogenic importance in sheep and goats include *Cystocaulus, Spiculocaulus,* and *Neostrongylus*. These parasites are rare or absent in North America.[32]

DICTYOCAULUS FILARIA. *D. filaria* has a life cycle essentially identical to that of *D. viviparus;* the time from ingestion to the appearance of larvae in the feces is about 4 weeks. Mainly young animals are affected, but disease can also occur in adults. Dyspnea, tachypnea and coughing, and loss of condition occur in clinical cases.[32,33] Differential diagnosis includes the progressive viral pneumonias. Diagnosis is made by finding larvae in fresh feces by the Baermann test.[5] Samples should be tested soon after collection because larval recovery is significantly reduced in stored samples.[6] Larvae of *D. filaria* are similar in size and appearance to those of *D. viviparus* but also have a distinctive knob on the anterior end. The pathogenesis is similar to that of *D. viviparus* (see earlier discussion). The adults are found largely in the dorsal-caudal regions of the diaphragmatic lobes. Bronchitis and peribronchitis, along with cone-shaped areas of pneumonia and atelectasis, and emphysema are present. Secondary bacterial infections may also occur.[32,33] Levamisole (8 mg/kg), fenbendazole (5 to 10 mg/kg), ivermectin (0.2 mg/kg PO),[33] and moxidectin (0.2 mg/kg, PO or SC)[32-36] can be used for treatment. When outbreaks occur, all animals should be treated and moved to fresh pasture when possible. Clinical *D. filaria* infections seem to occur most frequently in areas with warm climates. In temperate areas the parasite overwinters either as arrested larvae in ewes or as larvae on pasture.[32]

MUELLERIUS CAPILLARIS. *M. capillaris* is probably the most common of the lungworms of sheep and goats. Infection is more pathogenic in goats than in sheep. Surveys in Maryland and Georgia detected the parasite in 64% and 68% of goats, respectively.[37,38] The life cycle is indirect. First-stage larvae are coughed up, swallowed, and passed in the feces. These larvae are relatively resistant and may survive for several months in the environment. After penetration of an appropriate molluscan intermediate host, the infective third stage develops in a minimum of about 12 days, is ingested with the snail, and passes to the mesenteric lymph nodes. The fourth-stage larva proceeds to the lungs, where adults develop in the alveoli. The prepatent period of *M. capillaris* infection is about 6 weeks.[39] Although many infections are subclinical, clinical disease may develop. Goats appear to be more likely than sheep to develop unthriftiness, coughing, and dyspnea. Infection may also predispose to secondary bacterial infection.[33,40] The difference in clinical signs between sheep and goats probably results from a difference in the pathogenesis of infection. The adult worms live in the pulmonary parenchyma, particularly the subpleural tissue. In sheep they produce grayish nodules typically 2 to 3 mm in diameter. On palpation at necropsy, these nodules have been described as feeling like "lead shot."[39] Each nodule contains a worm and necrotic leukocytes and pulmonary tissue surrounded by a connective tissue wall and giant cells.[32] They may calcify or become secondarily infected with bacteria. Reports of lesions in goats indicate that *M. capillaris* causes an interstitial pneumonia. The lungs are resilient and firm, fail to collapse, and have tan, yellow, or gray patches located especially in the dorsal diaphragmatic lobes. The histologic lesion in goats is a diffuse thickening of alveolar septa, with a mononuclear cell infiltrate and alveolar epithelial hyperplasia that extends far beyond the area immediately around the parasite. The local reaction around the worm is quite variable and does not appear to produce the nodules seen in sheep.[40] Diagnosis is made by Baermann examination of the feces. The larvae are smaller than those of *D. filaria* and have a kink at the end of the tail with a characteristic subterminal accessory spine.[5]

Several anthelmintics have been used in the treatment of *M. capillaris* infections. Moxidectin (0.2 mg/kg in oral or injectable formulation) is effective in treating sheep infected with M. capillaris and other small lungworms *(Cystocaulus ocreatus, Neostrongylus linearis,* and *P. rufescens)* and may be equally effective in goats.[41] Although larvae may initially disappear in the feces after treatment, they often reappear in fecal samples again after 1 to 2 months, either because anthelmintics are ineffective against immature worms and/or because of resumption of development by inhibited larvae. Treatments that appear to eliminate adult parasites in goats include fenbendazole (15 to 30 mg/kg),[39,40,42-44] albendazole (10 mg/kg),[44] oxfendazole (7.5 to 10 mg/kg),[45] and ivermectin (0.3 mg/kg).[42,46] *M. capillaris* is largely resistant to levamisole.[33] Better control of immature or inhibited larvae with fenbendazole was achieved by administering the drug (1.25 to 5 mg/kg) for 7 to 14 days, although a regimen of 1 week on/1 week off/1 week on appeared to provide the most effective treatment. Albendazole (1 mg/kg PO daily) for 7 to 14 days was also effective.[44] Possible teratogenic effects of extended benzimidazole treatment in goats have not been thoroughly investigated, and albendazole should be used cautiously in the first 35 days of pregnancy.[42] Administration of ivermectin (0.3 mg/kg) or fenbendazole (15 mg/kg) two or three times at 35-day intervals has also been suggested for treatment.[33] Control methods include avoiding wet pastures and treating animals before the start of the grazing season to reduce infection levels in the intermediate host.[33]

PROTOSTRONGYLUS RUFESCENS. *P. rufescens* also uses molluscan intermediate hosts, and adults develop in the small bronchioles of sheep and goats.[39] Most infections are probably subclinical or produce only mild signs of chronic bronchitis or bronchopneumonia with nasal discharge and cough. Occasionally *P. rufescens* may produce severe or even fatal disease.[47] The diagnosis of *Protostrongylus* spp. infection is made by finding larvae in the feces via the Baermann technique. The larvae are similar to those of *Muellerius* except *Protostrongylus* larvae lack the subterminal accessory spine on the tail.[5] Fenbendazole, levamisole,[47] and moxidectin[41] can be used for treatment at the dosages used for *Dictyocaulus*. Other macrocyclic lactone products may also be effective but have not been tested. Control strategies are identical to those for *M. capillaris*. Few cases of infection have been reported in the United States, but nonspecific clinical signs, presence of subclinical carriers, and need for a special diagnostic technique may produce an underestimation of the prevalence of *P. rufescens* infection in sheep and goats.[47]

LARVAL TOXOCARIASIS. The dog ascaridoid, *Toxocara canis,* will infect and persist in the tissues of sheep and goats following the ingestion of infective eggs from pasture.[48-50] Although migration of the larvae through the lungs results in diffuse pulmonary inflammation, there do not seem to be any clinical pulmonary signs that have been noted accompanying the experimental infections.[51,52] Serologic examination of sheep through use of antibody detection tests shows the prevalence of infection increases with age, with overall prevalences being 50% or more in the older animals that were sampled in Wales and Brazil.[53,54]

Progressive Viral Pneumonias of Sheep and Goats

Jeanne Lofstedt

Chronic progressive pneumonias are diagnosed with some frequency in mature small ruminants. In sheep, ovine progressive pneumonia (OPP) and *Corynebacterium pseudotuberculosis*–induced mediastinal lymph node and lung abscesses are the chief causes of chronic progressive pneumonia. Chronic progressive pneumonia in goats has

VetBooks.ir

been associated with the pneumonic form of caseous lymphadenitis (CLA) and occasionally with caprine arthritis-encephalitis virus (CAEV)–induced lung lesions. Additional differential diagnoses that should be entertained in small ruminants exhibiting signs of chronic pneumonia include ovine pulmonary adenomatosis (OPA) in the case of sheep and chronic bacterial pneumonia, verminous pneumonia, mycotic pneumonia, tuberculosis, and pulmonary neoplasia in sheep and goats.

Ovine Progressive Pneumonia (Maedi-Visna)

Definition and Etiology

OPP and *maedi-visna* (MV) are North American and European names, respectively, for multisystemic diseases of adult sheep characterized by chronic, progressive, debilitating pneumonia; wasting; indurative mastitis; arthritis; and, occasionally, neurologic signs.[1-6] Synonyms are *Marsh progressive pneumonia, Montana sheep disease, zwoegerziekte, la bouhite,* and *Graaff-Reinet disease*.[2,4] The OPP virus (OPPV) and MV virus (MVV) are nononcogenic exogenous retroviruses that belong to the genus *Lentivirus,* which includes the human, simian, feline, and bovine immunodeficiency viruses, equine infectious anemia (EIA) virus, and CAEV.[4-6] These enveloped, single-stranded RNA viruses contain the enzyme RNA-dependent DNA polymerase or reverse transcriptase (RT). With this enzyme the viruses use cellular machinery to transcribe a segment of DNA from a template of single-stranded viral RNA; the DNA strand or provirus is then incorporated into the host genome. Close similarity of causal viruses, clinical signs, and lesions produced in tissues permits discussion of OPP and MV as a single disease entity.[3] Extensive mutation of the gene encoding for envelope glycoproteins occurs in all lentiviral infections; this allows the mutated virus to escape elimination by the host immune response. Antigenic variation in the MVV has been documented.[4] The ovine lentiviruses (OvLVs) are closely related to the CAEV of goats and cross-species transmission is possible through feeding of infected milk and colostrum.[5,8] These two viruses are now often referred to as *small ruminant lentiviruses* (SRLVs).[4,5]

Clinical Signs and Differential Diagnosis

The incubation period of OvLV infections is prolonged and most infections are subclinical.[4,5] Approximately 25% to 30% of infected sheep eventually exhibit clinical symptoms.[1] Clinical disease is usually not evident until at least 50% of a flock is seropositive.[1] Conditions in sheep attributed to infection with OvLV include progressive emaciation ("thin ewe syndrome"), progressive respiratory failure, indurative lymphocytic mastitis ("hard bag"), posterior paresis, and chronic nonsuppurative arthritis.[1,4,5]

In North America, progressive pneumonia and aseptic indurative mastitis are the most common clinical manifestations of OvLV infections.[3] Clinical signs of disease are usually first observed in 2- to 3-year-old sheep, but most affected animals are 4 or 5 years old before they exhibit signs.[3,7,8] Emaciation, despite a good appetite, is one of the earliest symptoms. Tachypnea and respiratory distress develop gradually and initially are evident only on exertion.[4-6] Flared nostrils, neck extension, and open-mouth breathing are seen in advanced cases. Thoracic auscultation may reveal increased breath sounds, but crackles and wheezes are typically absent.[6] Pyrexia and purulent nasal discharge are uncommon and, if present, usually indicate concurrent secondary bacterial pneumonia.[5] Wool loss may be seen in advanced cases.[4] Affected ewes may give birth to small, weak lambs.[5] Death from anoxia or secondary bacterial infection ensues within 6 to 12 months of first appearance of clinical signs. In some flocks the disease appears to persist virtually unrecognized, whereas in flocks kept under harsh environmental conditions, mortality rates are quite high.[4]

The neurologic form of OPP is accompanied by weight loss and neurologic signs such as hindlimb ataxia, stumbling, and proprioceptive deficits, which progress over a period of months to paralysis or occasionally quadriplegia[5,6] (see Chapter 35). This form of the disease is encountered sporadically in heavily infected flocks and may occur separately or concurrently in sheep with respiratory distress.[4,5] Indurative mastitis is often encountered in heavily infected flocks. The somatic cell count (SCC) in affected ewes is increased but the milk is grossly normal; a firm udder may be detected with careful palpation.[4] The main consequence is poor weight gains in lambs suckling affected ewes, particularly if there are twins or triplets.[4] Arthritis, primarily affecting the carpal joints, is a rare manifestation of OvLV infection.[4,5]

Chronic pneumonias of sheep that have to be differentiated from OPP include chronic bronchopneumonia caused by *Mannheimia (Pasteurella) haemolytica,* OPA, verminous pneumonia, and pulmonary and thoracic lymph node abscesses caused by *C. pseudotuberculosis.*[1,2] Thoracic radiographs, culture of tracheal wash material, and fecal examination by the Baermann technique are useful for antemortem differentiation. Gross and histopathologic evaluations of pulmonary tissues obtained at necropsy are helpful for diagnosing a flock problem.

Clinical Pathology and Diagnosis

Hematologic changes in sheep with OPP are nonspecific and may include lymphocytosis early in the course of disease and mild hypochromic anemia and hypergammaglobulinemia in advanced cases.[6,8] A presumptive diagnosis of OPP can be made on the basis of clinical signs of progressive weight loss and chronic pneumonia or, in rare cases, neurologic disease in adult sheep,[4,5] but the diagnosis is often overlooked if mildly affected sheep are culled for other reasons.[4] The majority of sheep infected with OvLV do not show obvious clinical signs and are essentially asymptomatic virus carriers serving as a reservoir of virus for other sheep in the flock.[4,5] For disease control purposes it is important to identify such animals as soon as possible after infection. Several tests, based on detection of antibodies or virus, have been used to identify subclinically infected sheep.

Serologic tests include the agar gel immunodiffusion (AGID) test, several ELISAs, and the Western blot assay.[4,6] The time period from infection to seroconversion typically ranges from 3 weeks to several months but can take up to a year.[4] Some infected sheep never seroconvert, whereas others with advanced disease become transiently seronegative.[5] The AGID test has been the preferred serologic test for many years. It has good specificity but has gradually been replaced by a variety of ELISAs.[4,5] ELISAs are more sensitive than the AGID test and are useful when large numbers of samples need to be screened.[4-6] The use of ELISAs to detect antibodies in milk offers the option of low-cost screening in milking sheep flocks.[4] The Western blot test is used on occasion to confirm ELISA results.[5]

Tests for virus include virus isolation in cell culture or viral genome detection by polymerase chain reaction (PCR).[5,9,10] These tests are usually reserved for select cases—for example, when infection is suspected in a seronegative animal or in young lambs that have received colostrum from seropositive ewes.[5] Milk or lung lavage samples are useful substrates for this purpose. Virus isolation, which is time-consuming and expensive, is accomplished by coculture of infected fresh or frozen tissue with indicator cell lines. In culture, retroviruses form characteristic multinucleated syncytia.[8] Viral antigens can be detected in these syncytia by use of immunofluorescent staining.[8] PCR testing is more cost-effective than virus isolation.[4,6]

Pathophysiology

OvLVs gain access to the body via ingestion of milk or colostrum or through inhalation of aerosolized infectious particles. Infection is then established in the monocyte or macrophage cell line and spreads via these infected cells to the lungs, lymph nodes, choroid plexus, spleen, bone marrow, mammary glands, and kidneys.[8] The virus is able to persist in the face of humoral and cellular immunity through (1) latent infection of host cells by DNA provirus, (2) long-term nonproductive infection of blood monocytes (virus replicates only on differentiation of monocytes into macrophages), and (3) virus mutation with emergence of new antigenic variants that are not neutralized by preexisting antibody.[8] Because of the interaction of the virus with the macrophage

VetBooks.ir

monocyte series, a progressive multisystem chronic inflammatory process is initiated, primarily, but not exclusively, in the lungs and mammary gland.[4] Variations in genetic susceptibility, virus genotype, and the immune response of individual sheep influence target organ involvement and disease progression.[4]

Epidemiology OPP and MV are present in many sheep-rearing countries but has not been diagnosed in Australia or New Zealand.[5] The seroprevalence of OPP in cull ewes in the United States has ranged widely and increases with advancing age.[2] With the exception of West Texas, with an infection rate of 0.5%, serologic surveys in cull ewes in other states have revealed infection rates of 30% to 67%. The low seroprevalence in Texas has been attributed to the hot dry climate and extensive grazing practices.[8] Limited studies in large mixed-breed flocks have provided evidence that some sheep breeds may be more resistant to infection than other breeds.[2] Additional research is required before a particular breed or line of sheep can be viewed as resistant to OvLV infection. The lung and mammary gland are believed to be the main sources of excreted virus.[2] Studies conducted in Europe and Iceland have shown that transmission from the ewe to her lambs commonly occurs through the ingestion of infected colostrum and milk.[2] In other studies, close confinement of diseased or seropositive sheep with healthy or seronegative sheep resulted in disease or seroconversion in the previously healthy or seronegative animals; these infections were presumed to have occurred via the respiratory route.[2] Concurrent OPA is believed to have a synergistic effect on disease transmission via the respiratory route.[4] OvLV transmission has been shown to occur through fecal contamination of drinking water.[2] Blood contaminated placentas, contaminated milking equipment, and poor biosecurity practices have also been implicated as playing a role in the spread of infection.[2,4] Transmission through the uterine wall, or via germ cells, can occur but is of minor importance compared with other routes.[2,4]

Necropsy Findings Lesions may develop in any or all of the following tissues of OPPV-infected sheep: lungs and regional lymph nodes, brain, joints, mammary glands, and blood vessels.[4] Changes are most obvious in the lungs, which do not collapse on opening of the thorax.[4,5,8] Vertical rib impressions may be seen on the exterior lung surface. Affected lungs are heavy and, after removal of any visible trachea, weigh more than 1 kg (normal lung weight is up to 500 g) and have a mottled to uniform pink-brown to gray-blue discoloration.[5] Secondary bacterial pneumonia may cause anterior-ventral pulmonary consolidation. Tracheobronchial and mediastinal lymph nodes are markedly enlarged (up to 10 times normal size), bulge on cut surfaces, and are homogeneous, gray-white throughout.[4,5] Histologic examination reveals a diffuse lymphoproliferative pneumonia characterized by prominent lymphoid follicle formation adjacent to bronchioles and small vessels; discrete nodules of lymphocytes, unrelated to vessels or airways, are also found in the lung parenchyma.[8] Lymphocytes, plasma cells, and macrophages infiltrate into interalveolar septa, and hyperplasia of alveolar epithelium and terminal bronchial smooth muscle may be seen.[4] In some flocks uncomplicated OPP is the norm. In other flocks it may occur as a mixed infection with lungworm, bacterial bronchopneumonia, or pulmonary adenomatosis, which may result in the OPP lesions being overlooked on routine necropsy.[4]

Treatment and Prevention OPP is not treatable. Antimicrobials can be used to control secondary bacterial pneumonia, but most sheep die within a year of first exhibiting clinical signs.[2,7] No effective vaccines are presently available for control of the disease.

OPPV is difficult to eradicate from a flock once infection has been established. Uninfected flocks should maintain strict biosecurity measures to avoid introduction of the disease. This may include not sharing rams, not mixing sheep with other flocks, and maintaining segregation at shows.[4] Breeding stock should be purchased from known OPP-free herds and quarantined and tested to ensure that they are seronegative before being introduced into the flock. Control methods that may be economically feasible for purebred flocks with a low seroprevalence rate include (1) a "test-and-cull" practice and (2) isolation of infected adults and artificial rearing of their offspring.[3] With the first method, all sheep are tested annually for antibody, and seropositive animals and their progeny younger than 1 year of age are culled or isolated from the negative flock; culling is preferred because of the risk of cross-contamination. New additions should be seronegative and originate from seronegative flocks. Annual testing should be performed until two consecutive negative test results are obtained to be reasonably confident that the flock is virus free. With the second approach, progeny are removed from their dams before they nurse and are fed cow's colostrum or colostrum from seronegative ewes and raised in isolation. The clean herd should be kept isolated from infected sheep and goats and from humans and equipment in contact with infected sheep. Herd additions and annual testing should be handled as described for method 1. In flocks with well-established infections and a high seroprevalence rate, control options are limited.[4] The test-and-cull procedure and removal of lambs are impractical under commercial conditions. Increasing the flock replacement rate by strict culling of suspect cases and not keeping ewes beyond 4 to 5 years of age will assist in keeping the flock seroprevalence down and in reducing the incidence of clinical disease.[4]

Ovine Pulmonary Adenocarcinoma

Definition and Etiology OPA, also known as jaagsiekte (South Africa), sheep pulmonary adenomatosis (United Kingdom), or pulmonary carcinoma (United States),[11] is a naturally occurring retrovirus-induced bronchioloalveolar carcinoma of sheep and, in rare cases, goats that has been associated etiologically with a betaretrovirus named jaagsiekte retrovirus (JSRV).[12,13] OvLVs and herpesviruses have been isolated from OPA tumors; however, they are not consistently present and do not induce OPA when inoculated experimentally.[14] One theory is that these viruses may act as cofactors in tumor induction. Defining the role of JSRV in OPA has been complicated by the presence of 15 to 20 endogenous jaagsiekte retroviruses (enJSRVs) that are stably integrated into the genomes of sheep and goats.[15,16] Recent research has indicated that exogenous JSRV is likely not of endogenous origin. There has been speculation that the endogenous viruses may modify the genome of exogenous JSRV, either by inducing the expression of an oncogene or by inactivating a tumor suppressor gene.[13] Sequence analyses of exogenous JSRV and enJSRV suggest that endogenous viruses do not directly contribute to the pathogenesis of OPA through large-scale recombination events, but small-scale recombination or complementation of gene function has not been definitively excluded.[15] There has been speculation that expression of enJSRV in the fetal or neonatal period may influence expression of OPA through induction of immunologic tolerance.[12,15]

Clinical Signs and Differential Diagnosis Symptoms normally appear in mature sheep between 2 and 4 years of age, although lambs as young as 3 months of age and sheep as old as 11 years have occasionally been diagnosed with OPA.[11] Signs include exercise intolerance, weight loss despite a good appetite, tachypnea, dyspnea, occasional cough, and high-pitched crackles on thoracic auscultation. A characteristic feature of OPA is the accumulation of abundant fluid in the respiratory tract that is frothy, clear, milky, or at times pink-tinged and may flow from the nostrils of affected sheep when the rear limbs are raised and the head is lowered ("wheelbarrow test").[11-13] Up to 400 mL of nasal secretions may be collected in a day, although 10 to 40 mL/day is more usual. Rectal temperature is usually normal unless secondary bacterial infection is present. Sheep with OPA typically succumb within a few weeks to months after first exhibiting clinical signs.

Chronic pneumonias of sheep that have to be differentiated from OPA include chronic bronchopneumonia caused by *M. haemolytica*, OPP, verminous pneumonia, and pulmonary and thoracic lymph node abscesses caused by *C. pseudotuberculosis*.[1,2] Thoracic radio-

VetBooks.ir

graphs, culture of tracheal wash material, and fecal examination by the Baermann technique are useful for antemortem differentiation. Gross and histopathologic evaluations of pulmonary tissues obtained at necropsy are helpful for diagnosing a flock problem.

Clinical Pathology and Diagnosis The only reported clinical pathologic abnormality in sheep with OPA is hypergammaglobulinemia. Advanced clinical cases in mature sheep can be presumptively diagnosed based on clinical signs of weight loss and respiratory distress accompanied by copious nasal secretions, but in many cases the disease is subclinical.[11,12] To date, sensitive and specific tests for identifying apparently healthy animals that may be infectious are lacking. The absence of JSRV-specific antibodies in infected sheep have precluded the use of serologic tests for diagnosing infection.[12,13] PCR tests, capable of demonstrating viral nucleic acids of endogenous JSRV tissues in OPA-infected animals, have been developed but have a high false-negative rate and are not useful for identifying individual animals for eradication purposes.[12] The most successful approach for early diagnosis of OPA is PCR testing of bronchoalveolar fluid collected from live animals, but this is impractical for widespread testing and saliva and nasal secretions of infected sheep often test negative for JRSV.[12]

Epidemiology OPA has been reported in sheep-rearing countries throughout the world but not in Australia, New Zealand, or the Falkland Islands.[12,13] Iceland is currently free of OPA as a consequence of implementing an aggressive slaughter policy in endemic areas in the 1950s.[12] The prevalence of OPA varies among countries in which the infection occurs; it is endemic in Scotland, Peru, and South Africa, where annual losses range from 2% to 10%. In contrast, OPA is infrequently diagnosed in the United States and Canada, where totals of 11 and 43 cases, respectively, have been reported.[13]

OPA has been reproduced experimentally by intratracheal inoculation of lung homogenates or pulmonary lavage fluids obtained from infected animals.[17] Lambs between birth and 5 weeks of age have been shown to be more susceptible to experimental infection than 10-week-old lambs.[17] This age-related susceptibility to OPA suggests that natural virus transmission occurs in the neonatal period.[12] Aerosol transmission and contamination of feed and water by respiratory secretions are likely methods of disease spread, particularly in confined sheep.

Necropsy Findings OPA lesions in the lungs are categorized as classical OPA or atypical OPA based on their appearance.[11,12] In classical OPA the lungs are heavy (two to three times normal weight) and exude clear fluid from the cut surface.[11-13] The trachea and bronchi often contain clear, foamy fluid. Large, firm, gray masses are commonly encountered in the cranioventral regions of one or both lungs. Smaller (1- to 2-cm) nodules are occasionally visualized in the caudodorsal lung regions. In atypical OPA the tumors consist of solitary or aggregated hard white nodules that are clearly demarcated from normal lung tissue and have a dry cut surface.[11,12]

Metastasis to regional lymph nodes occurs in approximately 10% of cases, resulting in pulmonary lymph node enlargement.[11,12,18] Metastases to cardiac and skeletal muscles are infrequently reported.[11,12,18] Secondary bacterial pneumonia caused by *M. haemolytica* may mask the lesions of OPA.[12]

OPA is classified by the World Health Organization (WHO) as a bronchioloalveolar carcinoma arising from alveolar type II pneumocytes or nonciliated bronchiolar cells.[18] Histologic lesions in the lungs consist of columnar or cuboidal cells arranged in an acinar or papillary pattern and are similar for classical or atypical OPA but with an exaggerated inflammatory response and fibrosis in the atypical form of the disease.[11]

Treatment, Prevention, and Prognosis There are no known treatments for this disease. Antibiotics may prolong the life of OPA-affected sheep through control of secondary bacterial pneumonia.[13]

There are no vaccines for OPA at this time.[12] Prompt culling of ewes suspected to be infected, as well as their offspring, has been employed to decrease disease prevalence in endemic flocks.[11,12] OPA was eradicated from Iceland by slaughtering all sheep in endemic areas.[11-13] Contaminated areas where infected sheep were held should be left vacant for 2 months.[12] OPA has reportedly been eliminated from two flocks by removing the lambs at birth, depriving them of maternal colostrum, and raising them in isolation or by using embryo transfer.[11,12] This approach is impractical for commercial flocks. Until reliable diagnostic tests for subclinically affected sheep are developed, control will remain problematic.

Caprine Arthritis-Encephalitis

CAE is a persistent lentiviral infection of goats with four possible clinical presentations: leukoencephalomyelitis in kids 2 to 6 months of age and chronic, hyperplastic polysynovitis, indurative mastitis, and interstitial pneumonia in mature goats.[19-21] Mild interstitial pneumonia, which is silent clinically, is a common postmortem finding in goat kids infected with CAEV.[22] Occasional kids with the leukoencephalomyelitis may have diffuse involvement of one or more lung lobes.[21] In one study, 60% of adult goats serologically positive for CAEV had lesions of severe chronic interstitial pneumonia at slaughter.[22] In addition, chronic interstitial pneumonia, accompanied by exercise intolerance and dyspnea, was described in dairy goats originating from herds that had clinical cases of arthritis and leukoencephalomyelitis.[23] The lung lesions in these goats resembled those of OPP and MV and were positive for CAEV.[23,24] However, CAEV has been recovered from the lungs of goats with advanced arthritis but without interstitial pneumonia. In addition, goats inoculated intratracheally with purified CAEV did not develop pulmonary lesions.[23] This may indicate that there is no causal relationship between CAEV and interstitial pneumonia in goats, or that an additional agent such as a helper virus is required for the lesions to develop.[21] The first signs of chronic progressive pneumonia associated with CAEV infection appear at times of stress such as kidding and include exercise intolerance, dyspnea, weight loss, and occasionally a cough.[21] Enlarged carpi may be present in some of the affected goats.[21] Radiographs in advanced cases demonstrate large areas of lung consolidation and sometimes bullous emphysema in the cranioventral or caudal lung lobes.[23] Histopathologic examination of lung biopsy samples may assist with an antemortem diagnosis.[21] Serologic testing is of no diagnostic value other than identifying the presence of CAE in the herd of origin. Lesions in the lungs at postmortem are as for sheep with the pneumonic form of OPP.[21] CAE is discussed in detail in Chapter 38.

Caseous Lymphadenitis

CLA, caused by *C. pseudotuberculosis* (previously known as *C. ovis*), is a chronic disease of sheep and goats characterized by the development of pyogranulomatous abscesses in lymph nodes and internal organs.[25-30] The disease affects small ruminants worldwide.[30] CLA most commonly presents as an external form characterized by abscesses in superficial lymph nodes.[28,30] The internal, or visceral, form of CLA manifests as internal abscesses in the mediastinal and mesenteric lymph nodes as well as internal organs, primarily the lungs, but also the liver, kidneys, and central nervous system.[30] Small ruminants with the visceral form of the disease rarely have concurrent abscessation of external lymph nodes.[29] Goats are more commonly afflicted with external abscesses, whereas the visceral form of CLA appears to be more common in sheep.[25] Visceral CLA may be asymptomatic but is typically associated with progressive weight loss.[25,29,30] Specific clinical signs that may implicate visceral CLA of the lungs and associated lymph nodes include exercise intolerance, tachypnea, dyspnea, and chronic cough. Because of the encapsulated nature of pulmonary abscesses and the lack of exudate in airways, pulmonary crackles are rarely auscultated.[29,30] Nonspecific laboratory findings in sheep and goats with CLA include leukocytosis,

VetBooks.ir

hyperfibrinogenemia, hyperproteinemia, and hypergammaglobulinemia; however, laboratory findings are frequently normal in animals with chronic abscesses.[27,28] A definitive diagnosis of visceral CLA with pulmonary involvement may be achieved by thoracic radiographic and ultrasonographic findings of abscesses in the lungs and mediastinal lymph nodes or by isolating *C. pseudotuberculosis* from a transtracheal aspirate (TTA).[25,29] Failure to isolate the organism from tracheal wash fluid, however, does not rule out CLA as the cause of pulmonary disease. Characteristic postmortem findings of the respiratory form of CLA are one or more thick-walled, laminated, encapsulated, caseopurulent abscesses in the bronchial lymph nodes, mediastinal lymph nodes, and/or lung parenchyma.[27] Serologic tests have been developed for the detection of asymptomatically affected animals or those with internal abscess. They include the synergistic hemolysis inhibition (SHI) test and several ELISAs.[27,28] Most serologic tests are not specific enough to justify their use in culling programs. However, an ELISA test developed in the Netherlands for disease eradication purposes has recently been improved to increase sensitivity (94%) and specificity (98%).[31] CLA is discussed in more detail in relation to the hemolymphatic system (see Chapter 37).

Other Pneumonias

Amelia R. Woolums[III]

Aspiration Pneumonia

Aspiration pneumonia is caused by inhalation of large amounts of foreign material, often liquids. The most common cause is careless drenching or passage of stomach tubes during administration of milk or liquid medication. It also occurs occasionally in pail-fed calves, animals with pharyngeal paresis, animals with necrotic laryngitis, lambs with nutritional myodegeneration, anesthetized animals, sheep that are dipped, cattle that have parturient paresis, and cattle that ingest crude oils or fuel oils. Meconium aspiration secondary to fetal distress has been recognized as a possible risk factor of neonatal calf mortality.[1]

If large quantities of fluid are aspirated, death may be almost instantaneous, but generally a gangrenous bronchopneumonia develops as a result of infection and the irritating properties of the inhaled material. Affected animals exhibit depression, tachypnea, dyspnea, coughing, and fever and may have putrid breath. Crackles, wheezes, and occasionally pleural friction rubs can be heard on auscultation.

A presumptive diagnosis is based on the history and clinical evidence of bronchopneumonia; definitive diagnosis can be confirmed by gross or histopathologic identification of feed, milk, or other aspirated material in airways. Differential diagnoses include acute bacterial bronchopneumonia and septicemia. Necropsy reveals consolidation of the anterior ventral areas of the lungs. Affected areas are severely hemorrhagic in acute cases and contain suppuration and liquefactive necrosis in subacute cases.

The prognosis is guarded in all cases of aspiration pneumonia, but some animals can be successfully treated. Antibiotics combined with antiinflammatory agents should be promptly administered, and long-term antimicrobial therapy (weeks) is required. Prevention of aspiration pneumonia centers on careful administration of medication and avoidance of other risk factors that may promote inhalation of foreign materials.

Mycotic Pneumonias

Fungal pneumonia is a rare occurrence in ruminants. The clinical presentation is typically one of poor response to antimicrobial therapy. Cases of fungal pneumonia with metritis or placentitis have been reported.[2,3] Diagnosis is confirmed by identification of fungal organisms with an inflammatory reaction in tracheal aspirate or bronchoalveolar lavage, or at postmortem, with fungal culture to confirm the identity of the agent. Little information is available regarding successful treatment of ruminants with fungal pneumonia. In other species such as horses, treatment requires weeks to months of therapy with antifungal agents such as ketoconazole or itraconazole; these drugs may be cost-prohibitive for many ruminant cases, and their disposition in the rumen has not been described. Therapy with oral potassium iodide is an inexpensive alternative that might be attempted for some cases, but the efficacy of this therapy has not been confirmed. Prognosis for fungal pneumonia in all species is guarded to poor, depending on the severity of disease and the feasibility of treatment. Given these restrictions, treatment of fungal pneumonia in ruminants is likely reserved for valuable individuals. More guidelines regarding treatment for fungal pneumonia are presented in the section on equine respiratory diseases.

Vena Caval Thrombosis and Metastatic Pneumonia

Definition and Etiology Metastatic or embolic pneumonia in cattle, also called *caudal vena caval thrombosis, pulmonary thromboembolism,* or *embolic pulmonary aneurysm,* is a distinct syndrome associated with multifocal abscessation of the lungs caused by septic thromboembolism of the pulmonary arterial system. The septic emboli arise from septic thrombi of the caudal vena cava (Fig. 31-77) or, less commonly, the cranial vena cava. Vena caval thrombi are, in turn, a sequela to various septic conditions such as jugular phlebitis, mastitis, metritis, foot rot, or, most often, liver abscesses secondary to rumenitis.[1] A variety of bacteria may be involved; those most frequently encountered include *Fusobacterium necrophorum, Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), staphylococci, streptococci, and *Escherichia coli.*

Clinical Signs Because of its association with rumenitis, this condition is most commonly seen in feedlot cattle, but any age, breed, sex, or class of cattle may be affected. The problem is unusual in cattle less than 1 year of age. Cattle with metastatic pneumonia usually exhibit respiratory disturbance or weight loss or, occasionally, thoracic pain. The clinical signs in affected cattle have been described.[2,3] The classic presentation includes tachycardia, tachypnea, dyspnea, coughing, heart murmurs and pale mucous membranes (caused by anemia), widespread wheezes, epistaxis, and hemoptysis. The duration of signs is quite variable, ranging from acute respiratory distress

VetBooks.ir

to a chronic history of weight loss and coughing for weeks to months. Other signs, which are more variable, include fever, thoracic pain on deep palpation of the sternum and intercostal spaces, hepatomegaly (indicated by the ability to palpate the caudal edge of the liver in the right paralumbar fossa), subcutaneous emphysema, froth at the muzzle, and melena caused by coughing up and swallowing blood. Nonspecific accompanying signs include depression, anorexia, ruminal stasis, scant feces, and decreased milk production. In chronic cases, cor pulmonale may lead to signs of right ventricular failure, such as jugular distention and brisket edema. The combination of respiratory signs with anemia, widespread wheezes, and especially hemoptysis is generally regarded as pathognomonic for this syndrome. Animals usually deteriorate rapidly once hemoptysis becomes evident, and death despite treatment is typical. Many patients die suddenly with an acute episode of severe intrapulmonary hemorrhage or hemoptysis after a variable course of respiratory disease. Some of these cases in which the respiratory signs were overlooked may account for the reports of sudden death attributed to vena caval thrombosis. Caudal vena caval thrombosis can also lead to hepatomegaly and extensive ascites, but most of these animals also have respiratory signs.[3] Sudden erosion of a large hepatic abscess into the caudal vena cava may also result in a massive embolic shower, with acute respiratory distress and death.

In patients with the pathognomonic signs (the majority of cases), other differential diagnoses are unlikely. However, many patients are examined before the onset of hemoptysis, and a few may die without exhibiting these signs.[3] Differential considerations in such cases, which usually manifest as acute dyspnea, should include anaphylaxis, various causes of ARDS, hypersensitivity pneumonitis, lungworms, and acute bronchopneumonia. Patients with right ventricular failure should be differentiated from those with pericarditis, lymphosarcoma, cardiomyopathy, and endocarditis.

Pathogenesis The pathogenesis of this disease begins with the development of rumenitis secondary to lactic acidosis caused by highly fermentable diets such as those used in feedlots, some dairies, and some growing rations. Bacteria such as *F. necrophorum* and *T. pyogenes* are then able to penetrate the damaged ruminal epithelium and are transported to the liver in the portal drainage system, where they are filtered out and result in abscesses. If an abscess is located next to the caudal vena cava (where the vessel is closely applied to the left border of the liver), a septic thrombus may form in the vena cava as a result of infiltration of its wall by the abscess (see Fig. 31-77). Septic emboli detach from the thrombus and reach the lungs through the pulmonary arterial system. Alternatives to this classic pathway are rare; they include the following: thrombosis of the cranial vena cava from primary lesions such as jugular phlebitis; thrombosis of the caudal vena cava from other subdiaphragmatic abscesses; right-sided endocarditis; and emboli arising from other septic foci, such as mastitis, metritis, and foot rot. Large emboli may block lobar or larger arteries, causing an acute crisis and death. More typically, smaller emboli lodge in arterioles, where they cause arterial thromboembolism, arteritis, endarteritis, and pulmonary abscesses (Color Plate 31-12). The widespread arterial embolism also results in pulmonary arterial hypertension. Arteritis and endarteritis weaken the vessel walls and, in combination with pulmonary hypertension, lead to the formation of aneurysms. In some cases, a perivascular abscess not only erodes an arterial wall to produce an aneurysm but simultaneously erodes a bronchial wall; when the aneurysm ruptures, the abscess cavity channels the blood into the bronchus, resulting in massive hemoptysis. In other cases, rupture of aneurysms results in large interstitial hematomas. Both processes result in anemia; when coughed-up blood is swallowed, melena may result. Coughing and wheezes are probably caused by blood clots in airways, peribronchial aneurysms and abscesses, and suppurative pneumonia. Pain results from dissecting aneurysms and hematomas.[2]

Epidemiology Metastatic pneumonia accounted for 1.3% of necropsy diagnoses in one large feedlot survey, with a rate varying between 1.6 and 7.3 cases per 100,000 head on feed. Cases occurred year round and during all stages of fattening, although 68% of cases occurred during the first 90 days on feed.[4] The case fatality rate is usually 100%.

Necropsy Almost all patients with significant hemoptysis have a thrombus in the posterior vena cava between the liver and the right atrium. There is usually an adjacent hepatic abscess, varying degrees of venous congestion of the liver, and hepatomegaly. The lungs are large, uncollapsed, and firm. Aneurysms may occur in either lung or both. Hematomas associated with ruptured aneurysms are frequently 3 to 10 cm in diameter.[4] Large blood clots may be found in the airways, aspirated blood in the alveoli, and swallowed clots in the rumen. Areas of suppurative pneumonia and multiple abscesses are present (see Color Plate 31-12).

Diagnosis The complete blood cell count (CBC) may reveal anemia and a neutrophilic leukocytosis with a regenerative left shift. Hyperglobulinemia is frequently present. Serum chemical analysis may reflect chronic passive congestion of the liver, with elevation of liver enzymes. Radiographs often reveal only an irregular increase in lung density. Small discrete densities (areas of embolic infarction and collapse); large, discrete, spherical opacities (hematomas); cavitating nodules, sometimes with gas-fluid interfaces (abscesses); bullae; and areas of consolidation may be observed in some cases.[2,3]

Treatment and Prevention The prognosis is grave, so treatment is rarely indicated, and salvage is the most feasible recommendation. In valuable individuals, antibiotics and supportive therapy may be attempted. Penicillin, oxytetracycline, or florfenicol may be effective; treatment should be administered for extended periods (weeks to months). Supportive therapy for cases with acute severe dyspnea includes furosemide (0.5 to 1 mg/kg IV or IM once or twice daily) and flunixin meglumine (1.1 to 2.2 mg/kg once or divided twice daily). One or two doses of corticosteroids (dexamethasone at 0.05 to 0.2 mg/kg IV or IM q24h) may be helpful in cases with severe respiratory distress.

On the basis of the assumption that rumenitis and liver abscesses are the first steps in the pathogenesis of most cases, measures to reduce the incidence of these problems are appropriate. Recommendations include slow adaptation of animals to high-energy rations and feeding of antibiotics to reduce the incidence of liver abscesses.

Bovine Tuberculosis

W. Ray Waters

Definition, Etiology, and Epidemiology Tuberculosis (TB) in animals and humans may result from exposure to bacilli within the *Mycobacterium tuberculosis* complex (i.e., *M. tuberculosis, M. bovis, M. africanum, M. pinnipedii, M. microti, M. caprae,* or *M. canetti*).[1] *M. bovis* is the species most often isolated from tuberculous cattle, and it is infectious to humans (zoonotic). Within the United States, bovine tuberculosis is nearly eradicated in cattle; however, sporadic cases are detected primarily because of ongoing importation of tuberculous cattle from Mexico, spillover from a wildlife reservoir host (i.e., white-tailed deer, *Odocoileus virginianus*) in the northeast region of the lower peninsula of Michigan, and transmission from captive cervids infected with *M. bovis.* From 1998 to 2011, there were 114 TB-affected herds within the United States (62% beef, 27.5% dairy, 1.5% mixed, and 9% captive cervids). In Great Britain, the prevalence of bovine TB has been steadily rising despite continuous compulsory testing, with 10% of cattle herds in England (22.7% in the South West region) under movement restriction and nearly 25,000 cattle slaughtered at a cost of £91 million.[2] This dramatic and steady rise in TB prevalence in Great Britain is most likely due to the failure of the tuberculin skin test and slaughter strategy and the presence of a wildlife reservoir (Eurasian badgers, *Meles meles*[2]). Wildlife

VetBooks.ir

reservoirs also hinder eradication efforts in New Zealand and Spain with continual spillover from brushtail possums *(Trichosurus vulpecula)* and wild boar *(Sus scrofa)*/red deer *(Cervus elaphus),* respectively. In Latin American and Caribbean countries, bovine TB is relatively common, with estimates of 70% of cattle being held in regions with *M. bovis* prevalence rates higher than 1%.[3] In underdeveloped regions of Africa and Asia, bovine TB is endemic and is causing significant economic losses for producers and public health concerns as a result of the close contact of humans and animals and the frequent consumption of raw milk. Bovine TB in African free-ranging species (e.g., African buffaloes *[Syncerus caffer]* and lions *[Panthera leo]*) threatens wildlife conservation efforts and ecotourism, thereby impacting the balance of entire ecosystems.[4] Tuberculosis in goats and sheep, primarily caused by *M. bovis* or *M. caprae,* is uncommon in the United States but may occur in other regions of the world (e.g., Spain, Italy, New Zealand, Ireland, United Kingdom, and Sudan and other African countries).[5,6]

In most countries with active control programs, affected cattle herds contain few infected animals; this suggests low rates of cattle-to-cattle transmission and a slowly progressive course of disease.[7] Transmission is generally by direct contact with TB-infected animals, as the organism may occur in exhaled droplets, saliva, feces, milk, urine, vaginal discharges, semen, or exudate from tuberculous lesions (e.g., lymph nodes with draining tracts that communicate to the exterior). Infection of the upper respiratory tract, pharyngeal area, and gastrointestinal tract may also result from ingestion of infected feeds.[8] Housing (e.g., milking parlors and cattle sheds) and crowding increase contact between naive animals and infected animals and enhance the spread of this disease. *M. bovis* is also transmitted by indirect contact through contaminated feed and water, feeding and watering equipment, cleaning equipment, or movements of personnel—anything that mechanically transfers the organism between locations. Movement of infected animals resulting from transfer of ownership, sharing of breeding animals, and fence-line contact with other herds is a common means of transferring the disease between herds and regions. Additionally, global trade agreements are increasingly being implemented to promote international trade of livestock, thereby significantly increasing risks for interregional spread and distribution of TB over great distances.

Primary control strategies for bovine TB include diagnosis via tuberculin skin test and/or interferon-gamma (IFN-γ) release assays, isolation of affected herds, subisolation of infected animals within affected herds (i.e., Bang method), slaughter of infected animals, slaughter surveillance, and movement/border testing policies.[9] In addition to these traditional methods, antibody-based tests have recently emerged for use in the detection of *M. tuberculosis*–infected elephants[10,11] and *M. bovis*–infected captive cervids.[12] In addition, molecular-based tools such as mycobacterial interspersed repetitive-unit-variable number tandem repeat (MIRU-VNTR), spoligotyping, and restriction fragment length polymorphism (RFLP) analysis of mycobacterial DNA are used to characterize mycobacterial isolates for epidemiologic investigations to determine potential links between new cases and prior outbreaks as well as the likely origin of infection. Most recently, high throughput whole genome sequencing and rapid sequence analysis tools have been developed for a more thorough comparison of relatedness between *M. tuberculosis* complex isolates obtained from livestock, wildlife, humans, and zoo species.

Clinical Signs and Diagnosis

In most animals, the disease is slowly progressive; however, bovine TB occasionally follows a more rapid, fulminating course with early dissemination. Most animals do not show clinical signs of *M. bovis* infection until late in the course of the disease. Clinical signs, when present, are often nonspecific (e.g., weight loss, inappetence, and a low-grade fluctuating fever) and vary according to organs involved. Respiratory signs are generally mild and may include a soft, moist cough more noticeable during cold weather and after exercise. In advanced stages, animals may exhibit obvious dyspnea, emaciation, and respiratory distress. Enlarged lymph nodes may rupture and drain. Enlarged mediastinal lymph nodes may cause bloat. Enlarged retropharyngeal lymph nodes, a frequent sequela in cervids, may cause dysphagia, stridor, and salivation. Enlarged mesenteric lymph nodes may cause intestinal obstructions. Lesions occur less frequently in peripheral lymph nodes, the reproductive tract (causing infertility, abortion, metritis, and vaginitis), and the mammary gland. Particularly with chronic cases, tuberculous mastitis may occur with the potential for transfer of *M. bovis* to humans, calves, cats, or other animals through ingestion of nonpasteurized milk or processed dairy products.

The tuberculin skin test remains the primary tool for the diagnosis of bovine TB. Specific applications of the tuberculin skin test, however, vary according to regional and country directives.[9] Primary screening tests may use a single injection of *M. bovis* purified protein derivative (PPD) applied either to the skin fold at the base of the tail (e.g., caudal fold test used in New Zealand, United States, Canada, and Mexico) or skin of the mid-cervical region (e.g., many European Union member states). Alternatively, a dual injection of *M. avium* and *M. bovis* PPD may be applied to separate mid-cervical sites as the primary screening test (Great Britain, Ireland, and Portugal) or as a confirmatory test (United States, Canada). An IFN-γ release assay (i.e., Bovigam, Prionics, Schlieren, Switzerland) is also used as a confirmatory test in many countries.[9,13] Test specificity varies regionally, most likely because of application techniques (including differences in PPD usage), environmental factors, and co-infection (e.g., parasite burden[14]). In particular, it is widely recognized that exposure of cattle to various nontuberculous *Mycobacterium* spp. may confound interpretation of PPD-based tests. The use of dual injection of *M. avium* and *M. bovis* PPDs at separate sites was developed to address this issue, and comparative tests improve test specificity with only a slight loss in test sensitivity when compared with single injection tests (e.g., caudal fold test). Recently, *M. tuberculosis* complex–specific antigens such as ESAT-6, CFP10, and Rv-3615c have been developed for use with IFN-γ release assays and skin test.[15] These antigens are generally not produced by nontuberculous *Mycobacterium* spp., including *M. avium* subsp. *paratuberculosis;*[16] thus, they afford greater specificity with only minimal loss in test sensitivity.

Potential pathogens for differential diagnosis consideration are nontuberculous *Mycobacterium* spp., *Nocardia* spp., *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*), *Corynebacterium pseudotuberculosis* (caseous lymphadenitis in goats/sheep), and mycotic infections. In particular, nontuberculous mycobacteria (e.g., *M. avium* subsp. *paratuberculosis, M. avium* subsp. *avium, M. kansasii,* and many others) are common isolates within tissues obtained from domestic livestock and wildlife. Johne's disease, caused by *M. avium* subsp. *paratuberculosis,* is common in domestic livestock and causes a mild to severe granulomatous enteritis. Other nontuberculous mycobacteria occasionally cause clinical disease that results in granulomatous lesions in lymph nodes, lungs, and visceral organs.

Pathophysiology and Necropsy Findings

Although often viewed as a pulmonary disease in humans, TB is primarily a disease of the lymphatic system. With ruminants, tuberculous lesions are most commonly detected within the pulmonary and cranial lymph nodes as well as the lungs. A survey of naturally infected cattle revealed that 67% of tuberculous lesions are detected within the lungs and pulmonary lymph nodes, 39% in cranial lymph nodes, and 8% in mesenteric lymph nodes.[17] Lesions are most commonly detected in the medial retropharyngeal lymph nodes of infected white-tailed deer[18]; lungs, pulmonary lymph nodes, and pleura are other common sites of lesions in deer. In pigs (i.e., Eurasian wild boar and free-ranging domestic black pigs), tuberculous lesions are most commonly detected in the cranial lymph nodes, and dissemination is common.[19,20] Infectious doses affect disease severity and progression: animals exposed to high doses develop an earlier onset of lesions with greater severity than animals exposed to lower doses. The infectious dose of *M. bovis* for ruminants is quite low. Experimentally, intratracheal administration of one colony-forming unit may cause disease.[21]

VetBooks.ir

Mycobacterium tuberculosis complex bacilli (including *M. bovis*) infect cells primarily of monocyte/macrophage lineage and may also be associated with type II alveolar epithelial cells, dendritic cells, neutrophils, and a few others. The pathognomonic lesion of *M. bovis* infection is the granuloma. Tuberculous granulomas form in response to pathogen virulence factors and chronic antigen stimulation (caused by persistent infection). Granulomatous inflammation is thought to limit the spread of tuberculous bacilli within the host by walling off the infection. The combination of the initial site of infection and the regional (i.e., draining this site) lymph node constitutes the primary complex commonly referred to as the *Ghon complex* with pulmonary *M. tuberculosis* infection of humans. Dissemination from the primary complex occurs via both lymphatic and hematogenous spread. Particularly in cases of prolonged or severe disseminated disease, determination of the primary complex may be impossible, confusing speculation on the initial route of infection. When infection occurs across mucous membranes, such as the oropharynx or intestine, the initial lesion in the mucous membrane may not be visible, whereas lymph node lesions are generally obvious.[22] From the initial site of entry, the organism invades local lymph nodes, where it causes necrosis surrounded by granulomatous inflammation consisting of primarily mononuclear cells. Localized lesions stimulate development of a fibrous capsule that varies in severity depending on the rate of development and chronicity of infection. Postprimary dissemination may occur, leading to spread of the organism and resulting in discrete nodular lesions in various lymph nodes and organs. Diffuse miliary tuberculosis may occur in severe cases. Latency, although a common sequela with *M. tuberculosis* infection of humans, is typically not considered a common stage of disease with *M. bovis* infection of cattle; however, *M. bovis* may be isolated from tissues without visible gross lesions, indicating a potential for "latent" infection.

Postmortem diagnosis is based on (1) gross and microscopic evaluation for tuberculous lesions, (2) detection of the organism by mycobacterial culture of tissues with follow-up confirmation/characterization using molecular techniques, and (3) detection of *M. tuberculosis* complex–specific DNA by PCR on histologic sections. Often, multiple lesions are detectable on examination, but it is possible that infected cattle will display no grossly visible lesions or only a single visible lesion. Macroscopic lesions appear as firm encapsulated nodules and vary in size from barely visible to more than 100 mm in diameter. Lesions may contain thick, white to yellow/orange, creamy to caseous purulent material. Lesions may be calcified. Lymph nodes, organs, and pleural/peritoneal serosa may be riddled with small miliary tubercles, and in the lungs these lesions may coalesce into a suppurative bronchopneumonia. Granulomas, along the pleural serosa (i.e., pearl disease), often appear glossy. Chronic lesions are characterized by a discreet, thickened fibrous to calcified capsule, often containing thick caseous material. Lesion cavitation caused by *M. bovis* infection in cattle is rare. Microscopically, lesions in lymph nodes or organs are granulomatous, generally consisting of caseous necrosis surrounded by infiltrates of epithelioid macrophages, Langhans-type multinucleated giant cells, and lymphocytes. Lesions with necrotic cores may contain dystrophic calcification. Detection of acid-fast bacilli within granulomatous lesions in tissue sections provides a preliminary diagnosis of mycobacterial infection that must be confirmed by mycobacterial culture and PCR. Acid-fast bacilli are often few in number and most commonly detected within the caseum of the necrotic core. Resolving lesions are rare. Lesion development can be divided into four different stages primarily based on the level of necrosis, fibrous encapsulation, and mineralization: stage 1 (no necrosis), stage 2 (minimal central necrosis, thin connective tissue capsule), stage 3 (central caseous necrosis with complete fibrous encapsulation), and stage 4 (extensive multicentric caseous necrosis with mineralization).[23] Differentiation between the thickness of the fibrous capsule and the histopathologic stage of development may assist in determining the chronicity of the infection.

Mycobacterial culture is the gold standard for TB diagnosis. *M. bovis* grows slowly, and cultures are incubated for 8 weeks; growth usually becomes visible within 3 to 6 weeks. The identity of the organism in cultures is confirmed with biochemical tests, colony morphology, and *M. tuberculosis* complex–specific PCR.

Treatment, Prevention, and Control Bovine TB is rarely, if ever, treated in domestic livestock. Particularly in developed countries, affected animals are slaughtered to limit potential transmission to other animals and to limit the duration and/or severity of regulatory restrictions. Antimycobacterial therapy may be indicated for rare or endangered animals or for those considered valuable as zoologic exhibits.[10] Antituberculous first-line chemotherapies include isoniazid, rifampin, pyrazinamide, ethambutol, and streptomycin. These are agents with the greatest activity and the least undesirable side effects. Second-line agents include capreomycin, ethionamide, cycloserine, and thiacetazone. The fluoroquinolones (moxifloxacin, ciprofloxacin, levofloxacin, and enrofloxacin), although not considered as first-line agents, have significant bactericidal activity against *M. tuberculosis* complex species. Outside of these rare cases, treatment for TB in animals is generally not considered practical on a cost basis.

Many countries have official bovine TB eradication and/or control programs including uniform methods and rules for application. Prevention and control efforts are designed to identify affected herds and remove infected animals or depopulate the entire herd (stamping out). These efforts are generally achieved via routine slaughter surveillance to identify affected herds, targeted testing schemes to remove TB test–positive animals (reactors), movement restriction of affected herds, thorough epidemiologic investigations of reported cases to determine risks for other impacted herds, and depopulation of affected herds. Additionally, movement testing with certification of a negative TB test(s) may be required prior to entry of animals into certain countries or regions, particularly with animals entering from bovine TB–affected regions. In certain instances, entry of animals from known TB-affected regions may not be allowed. Specific regulations and rules concerning bovine TB control are provided within specific country and regional directives.[2,24,25] Because of limitations in the sensitivity of antemortem diagnostic tests for tuberculosis, depopulation of infected herds is thought to be the most effective means to ensure eradication of the disease from the target population. Surveillance and control of *M. bovis* infection in wildlife reservoirs, as well as mitigation efforts to limit spread from wildlife to livestock, is also critical for bovine TB control.

In instances where herds are depopulated and the owner intends to repopulate in the future, it is important to remove or thoroughly clean and disinfect facilities and equipment potentially exposed to the organism. The ability of *M. bovis* to survive for an extended period in the environment, and the ineffectiveness of disinfection of organic materials, necessitates that pastures and fields to be used in repopulation schemes be left vacant for a period of time prior to use. Instances of infection that are thought to originate from wildlife sources may precipitate changes in facilities, management and feeding practices, or wildlife control to prevent reinfection. Current experience with endemic *M. bovis* infections in wildlife in numerous countries has demonstrated that eradication of TB in free-ranging wildlife is difficult and is a long-term proposition. Vaccines are rarely used for the control of bovine TB in regions with official control programs, primarily because of the potential for interference with traditional antemortem testing strategies using PPD as antigen (i.e., tuberculin skin test and IFN-γ release assays).[26] Bacillus Calmette-Guérin (BCG) is an attenuated *M. bovis* developed by Albert Calmette and Camille Guérin circa 1911 at the Pasteur Institute in Lille, France. Field efficacy trials performed in the early twentieth century demonstrated the partial effectiveness of BCG for the control of bovine TB.[26] Recent experimental trials with cattle have demonstrated that (1) subunit vaccines may boost immunity elicited by BCG in cattle, (2) BCG is particularly protective when administered to neonates, and (3) differentiation of infected from vaccinated animals is feasible in cattle through use of in vitro or in vivo methods.[15,26] With regard to wildlife reservoirs, the efficacy of BCG delivered orally has been

VetBooks.ir

demonstrated for brushtail possums (in field trials) as well as Eurasian badgers, wild boar, and white-tailed deer (each in experimental challenge studies). The most practical route of vaccine delivery to wildlife reservoirs of *M. bovis* is via oral-delivered baits, although a parenteral route is being deployed for badgers in England. Additional research is needed in the areas of diagnostic testing, environmental sampling, vaccine development, and management practices that may decrease the risk of disease spillover from wildlife reservoirs to cattle.

Diseases of the Thoracic Wall and Cavity

Amelia R. Woolums[¶]

Pleuritis and Pleural Effusions

Definition and Etiology Acute, primary pleuritis is rare in ruminants. It is almost always a secondary condition. The most common primary cause is most likely bronchopneumonia caused by *Mannheimia haemolytica* or *Histophilus somni*. Other possible causes of pleuritis and pleural effusions include traumatic reticulopericarditis, extension from other causes of peritonitis, tuberculosis, liver abscesses, tumors (especially lymphosarcoma), external trauma, fractured ribs, gunshot, perforating injuries, various septicemic conditions, acorn toxicity and other causes of uremia, uroperitoneum, right ventricular failure, hypoproteinemia, ruptured thoracic duct, and hemothorax from trauma or hemangiosarcoma.

Clinical Signs The signs depend on, and may be overshadowed by, the primary disease process. Pleuritis is a painful, septic process, whereas the signs associated with nonseptic effusions depend largely on the cause. Signs referable to pleuritis itself include anorexia, depression, fever, weight loss, decreased milk production, progressive dyspnea, and a characteristic stance and respiratory pattern, with the head and neck extended, elbows abducted, restricted excursion of the thorax, abdominal breathing, tachypnea, and a grunting or groaning with respiration. The animal may be reluctant to move. If a cough is present, it is often soft and suppressed because of pain. Jugular distention and pulsation may result from interference with venous return. Auscultation may reveal creaking or rubbing noises in dry pleuritis or a cranioventral masking of sounds caused by effusion. Percussion may reveal dullness ventral to the fluid line and may elicit pain. Differential diagnoses for dyspnea with abnormally quiet lung fields may include acute interstitial pneumonia, pneumothorax, and space-occupying lesions such as large abscesses, tumors, and diaphragmatic hernia. Once pleuritis or pleural effusion has been identified, the main differential diagnostic consideration is the determination of the underlying cause, as listed previously.

Diagnosis A CBC helps to separate infectious from noninfectious causes and distinguish relatively acute conditions (with significant left shifts) from those of a more chronic nature (with mature neutrophilia, hyperglobulinemia, and nonregenerative anemia of chronic disease). Serum chemical determinations and urinalysis identify hypoproteinemia and azotemia. A thoracocentesis should be performed and submitted to cytologic and cultural examination for bacteria, mycoplasma, and chlamydia. Nonseptic transudates indicate conditions such as neoplasia, heart failure, hypoproteinemia, and uremia. Septic exudates high in both cells and protein occur with pleuropneumonia, hardware, peritonitis, abscesses, penetrating trauma, and septicemias. A transtracheal wash is usually indicated because of the common association with pneumonia. Pericardiocentesis, abdominocentesis, and radiographs may indicate the primary source of an infection. Tuberculosis tests, leukemia virus titers, electrocardiography, echocardiographic examinations, ultrasonographic examination of the liver, and exploratory laparotomy may also help to detect other primary processes.

Treatment The primary problem should be treated. Effusions should be drained, either periodically or continuously through a Heimlich valve or a suction device fashioned from a syringe with the plunger transfixed with a pin. Effective drainage can be difficult in ruminants because of their propensity for fibrin formation and loculation of the fluid. Intermittent drainage is as effective as continuous drainage and simpler to maintain. Attempts at lavage have rarely been successful because of adhesions. Appropriate antibiotics are indicated in the presence of sepsis. NSAIDs (aspirin, 100 mg/kg PO twice daily; flunixin meglumine, 1.1 to 2.2 mg/kg IV or divided twice daily) are useful to relieve pain, ease respiration, and improve appetite. Rest and good nursing care are essential. The prognosis obviously depends on the extent and duration of the disease.

Pneumothorax

Pneumothorax is not common in ruminants. Most cases result from the rupture of an emphysematous bulla associated with pneumonia, straining, or coughing or from puncture of the lung by a fractured rib. The bullae that occur in pneumonia induced by bovine respiratory syncytial virus (BRSV) are a common source. Trauma to the pharynx or larynx can also lead to pneumothorax, presumably caused by air traveling from the cranial cervical regions through soft tissues and into the thoracic cavity. Penetration from the exterior is possible but less common. A case has been described in a postparturient cow with no other underlying cause found.[1] A retrospective study of 30 cattle with pneumothorax presented to a referral hospital found that 18 of the cases (60%) were associated with bronchopneumonia, 7 cases were associated with interstitial pneumonia, 3 cases were associated with laryngeal or pharyngeal trauma, and 2 cases were associated with neonatal respiratory distress.[2] Of interest was the finding that 13 of the 18 cases with bronchopneumonia were chronic, based on history and diagnostic findings; an association between pneumothorax and chronic bronchopneumonia had not been previously reported. The rate of survival for cattle with pneumonia and pneumothorax was lower than for cattle with pneumonia but no pneumothorax, with an overall survival rate of 60% for cattle with pneumothorax.

Clinical signs of pneumothorax include inspiratory dyspnea, sometimes severe, with open-mouth breathing sometimes present.[1] One side of the thorax may be relatively collapsed and immobile, with a compensatory increase in the size and excursion of the other side; however, this latter finding is often subtle and difficult to appreciate. Ruminants have a complete mediastinum; thus, when pneumothorax occurs it is usually unilateral, and the animal is able to ventilate adequately using the opposite lung. Unless an infectious disease is responsible, affected animals are often alert and anxious. They may attempt to stand with the forefeet elevated. There is a pronounced abdominal component to the respirations. Cyanosis may occur, and airflow may be markedly reduced in severe cases. On auscultation there is an obvious disparity between the two sides; bronchovesicular sounds will be diminished dorsally on the affected side or may be entirely absent. Those lung sounds that are audible have a harsh, high-pitched, large airway character similar to those of a consolidated lung, especially over the carina; these sounds seem to be distant, as if the animal were breathing in a barrel. The point of maximum intensity of the heart may be displaced, and tachycardia is often present. Percussion may reveal an abnormal resonance when compared with that of the normal side, and simultaneous auscultation and percussion may produce a "ping" over the thorax. Subcutaneous emphysema is a fairly common feature, and pleuritis is often a sequela. Differential diagnoses of the inciting cause should include the various causes of ARDS, bronchopneumonia, viral pneumonias (especially BRSV), pleural effusions, diaphragmatic hernia, other space-occupying lesions (large abscesses, tumors), and clostridial

[¶]Previous contributions by John A. Smith are acknowledged.

VetBooks.ir

infections. Pneumothorax can be diagnosed with radiographs, transthoracic ultrasound, or thoracocentesis; radiographs and ultrasound will also be useful to characterize the extent of any underlying lung disease. Other diagnostic tests to characterize underlying lung disease as described for infectious bronchopneumonia or interstitial pneumonia are appropriate.

If the affected animal shows signs of significant distress, the air in the pleural space should be evacuated. Evacuation can be accomplished by aseptically placing a teat cannula into the thoracic cavity at the dorsal aspect of the thorax at the tenth intercostal space and withdrawing air by use of an extension set, three-way stopcock, and syringe. In some cases this method can be successfully used to intermittently remove air; in other cases, continuous removal with a pleural evacuation device (Pleur-evac A-8000, Teleflex, Research Triangle Park, N.C.) has been more effective.[3] If continuous evacuation is attempted, the animal must be adequately restrained; this is likely to be possible only with hospitalized animals. Other treatment includes therapy appropriate for underlying acute or chronic pneumonia, as described previously for infectious bronchopneumonia or interstitial pneumonia. External wounds allowing air to enter the thorax should be closed.

Diaphragmatic Hernia

Definition and Etiology Diaphragmatic hernias are uncommon in ruminants. Hernias may be congenital, but most appear to be acquired, including those occurring in neonates. A congenital weakness in the diaphragm may predispose to some cases. Causes include difficult parturition, external trauma, and, by far the most common cause, traumatic reticuloperitonitis (TRP).

Clinical Signs and Differential Diagnosis Affected animals can be asymptomatic for a prolonged period.[4] Most affected cattle are in late gestation or have calved recently. The history may include decreased milk production, weight loss, capricious appetite, difficulty in swallowing or regurgitation, previous signs of abdominal pain (possibly associated with acute TRP), vomiting, and abnormal posturing of the head and neck on swallowing or regurgitation. Respiratory signs are actually fairly uncommon, with the exception of large congenital hernias, in which there is obvious severe dyspnea and abdominal respiration from birth. Occasional cough and dyspnea have been reported, and auscultation may reveal asymmetric sounds, with lack of lung or heart sounds in the affected area, or splashing sounds similar to those heard with pericarditis. Gastrointestinal signs are actually more common and include bloat, signs consistent with TRP, difficulty or pain on passage of a stomach tube, diarrhea, constipation, and ruminal hypomotility. Some cows may retch or vomit on regurgitation. Pain is evidenced by odontoprisis or grunting on regurgitation. The primary differential diagnoses are TRP, pericarditis, esophageal stricture, esophageal foreign body (choke), neoplasia, and abscessation.

Diagnosis Radiographs can be used to confirm the diagnosis. The normal outline of the diaphragm and heart may be obscured, and the honeycombs or foreign objects in the reticulum may be seen in the thorax[4] because this organ is most commonly involved. Oral barium may also aid in the radiographic interpretation, particularly in early small hernias that will be missed on plain films. Pleuritis and other masses such as tumors and abscesses can also mimic hernias on plain films.[4] If TRP is involved, the CBC, pleural effusions, and abdominocentesis may reflect the septic process. In cases not associated with TRP, the pleural effusion may be hemorrhagic in acute cases and normal in chronic cases.

Necropsy The hernial ring is usually located at the junction of the musculotendinous portion of the diaphragm, about 12 cm ventral to the vena cava and slightly lateral to the midline. The ring is usually round to oval, with a diameter of 7 to 20 cm. The reticulum is usually herniated, most frequently to the right side of the chest. The liver, spleen, rumen, omasum, abomasum, intestine, and omentum may also be involved. Extensive adhesions usually develop between the herniated organs and the thoracic organs, and evidence of hardware can often be found.

Treatment and Prognosis Treatment is surgical. A two-stage approach is usually used. First, a standing left flank laparotomy and rumenotomy are performed; the defect is identified, foreign bodies are removed, and the ruminoreticulum is emptied. Because of the complete mediastinum, ventilatory assistance is rarely needed during this stage. Next, the animal is placed under general anesthesia with positive pressure ventilation. Various approaches have been used for this portion, including ventral midline, paramedian, semilunar postxiphoid, paracostal, and transthoracic with rib resection. The hernia is reduced, and the rent is repaired with sutures or mesh grafts. Mesh grafts are contraindicated if infection is present.

Pleural Mesothelioma

Mesotheliomas have been reported in cattle and goats,[5] including a congenital form in calves.[6] Most are peritoneal, but pleural mesotheliomas also occur.[7] Mesotheliomas result in the accumulation of large amounts of fluid in the involved body cavity; signs of pleural mesothelioma are therefore related to pleural effusion. They include dyspnea, tachypnea, decreased lung and heart sounds (sometimes unilateral, with a concomitant increase in sounds on the normal side), dullness on percussion, exercise intolerance, cyanosis, tachycardia, anorexia, weight loss, decreased production, cough, and weak pulses. If peritoneal lesions are also present, as is common but not universal, ascites is also present. Radiographs confirm the pleural effusion, and thoracocentesis yields a serous, sometimes blood-tinged or gelatinous fluid. Cytologic examination may reveal reactive mesothelial cells. At necropsy the pleura is thickened and contains multiple nodules of gray to yellowish white tissue measuring several millimeters to several centimeters in diameter. Metastasis is uncommon. The tumor can be difficult to diagnose histologically and may resemble inflammation, pleural tuberculosis ("pearl disease"), or metastasis of another tumor.[6] There is no treatment.

Miscellaneous Conditions

Amelia R. Woolums[##]

Lung Tumors

Lung tumors are uncommon in ruminants. Those reported include pulmonary alveolar carcinomas, pulmonary adenomas, pulmonary adenocarcinomas, bronchogenic carcinoma, and pulmonary blastoma.[8,9] Malignant forms metastasize to regional lymph nodes and occasionally to other organs. Lymphosarcoma is the most frequent neoplasm to become metastatic to the lung, and uterine and ovarian adenocarcinoma may undergo metastasis to the lung. Because many lung neoplasms in cattle are incidental findings at slaughter or necropsy, clinical signs are therefore not well documented. The lesions are typically discrete, round, yellow to gray masses distributed throughout the lung tissue. Tumors are most likely to be detected antemortem by radiographic examination. Differential diagnoses in such cases include pulmonary abscesses, mycotic pneumonias, and tuberculosis.

Diseases of the Alimentary Tract

SAMUEL L. JONES and BRADFORD P. SMITH, *Consulting Editors*

Diseases of the Equine Alimentary Tract

Samuel L. Jones, *Consulting Editor*

Diagnostic Procedures in the Examination of the Equine Alimentary System

Samuel L. Jones

A thorough physical examination is compulsory, and tests that provide a minimum database (complete blood count [CBC], serum chemistries, and urinalysis) are often indicated in horses with suspected alimentary tract disease. Once a list of differential diagnoses is compiled, a number of ancillary diagnostic tests are available to narrow the possibilities. Each diagnostic test or procedure is limited in the type and extent of information that can be obtained, and therefore the clinician should select the complement of procedures that is most likely to provide the information required to make a proper diagnosis and determine the appropriate therapy.

Rectal Examination

A systematic approach to examining the abdominal and retroperitoneal viscera should be established and applied during each examination to ensure that all pertinent regions and structures are examined. When feasible and if required, the patient should be sedated to allow a more thorough examination. In some cases, epidural anesthesia is required to obtain adequate access to structures during rectal examination. The principal goal of a rectal examination is to identify changes in size, texture, shape, or location of visceral organs, peritoneum, mesentery, vasculature, or objects that are normally not present. Rectal examination is often performed with ultrasonographic examination, and information derived from each must be considered in order to draw conclusions. Ultrasonographic examination will be described in a later section.

In the pelvic region of the normal horse, the urethra and accessory sex glands (male) or the vaginal vault and cervix (female) can be palpated. The urethra is usually not discernible in the female, but abnormalities such as uroliths may be felt. In the caudal abdominal cavity, the bladder, the uterus in females, and the pelvic flexure and small colon typically should be felt. The pelvic flexure and left ventral and left dorsal colons are normally located ventrally, on midline, or toward the left side of the abdomen. The small colon, with formed fecal balls palpable, courses throughout the caudal abdomen, mostly on the left side. In females the left ovary can be felt in the left dorsal, caudal region of the abdomen. Both ovaries should be palpated in conjunction with palpation of the uterus. The peritoneal surface should be felt along the surface of the abdominal wall and the surfaces of the viscera. It should feel smooth, with no crepitus or irregularities. Advancing along the left side of the abdomen, the spleen can be felt as a smooth structure, with the caudal border having a well-delineated, tapered border. The size and location of the spleen are variable, because it can extend from the left body wall to the right ventral region of the abdomen. Advancing cranially and dorsally, the left kidney can be palpated. The kidney should feel smooth with the renal pelvic fissure discernible, although in the overweight horse extensive perirenal fat may obscure this detail.

From the left kidney, moving toward midline and extending from the abdominal aorta, the cranial mesenteric and ileocecocolic arteries may be felt. Palpation of fremitus in these arteries may be associated with arteritis and thrombus formation secondary to *Strongylus vulgaris* larval migration, although this association has been very inconsistent. Fremitus is frequently absent when severe arteritis exists, or the arteries may be entirely normal and fremitus felt. Fremitus can often be elicited by compressing the wall of the normal artery, thus accelerating flow through the compressed lumen. The mesenteric root of the colon can be felt ventral to the cranial mesenteric artery. This should palpate as a mildly taut band of tissue extending from the dorsal midline ventrally. Excessive tension, displacement, thickening, or masses within the mesentery should be considered abnormalities. It may be possible to palpate an enterolith, fecalith, or gravel impaction in the transverse colon, although this may be beyond the reach of the examiner because the transverse colon is located cranial and medial to the left kidney.

Sweeping to the right side of the abdomen, the base and cupola of the cecum can be felt. The body of the cecum can be followed partially by sweeping along the medial aspect of the cecum, cranially toward midline. The cecum has a prominent ventral band and sacculations. Gas, together with ingesta that is soft and mainly of a fluid consistency, can be felt within the cecum. Firm or excessive ingesta suggest an abnormality.

Findings that are different from normal often must be differentiated as being variations of normal or truly abnormal. Some common abnormal findings include abnormalities of the peritoneal surface. Crepitus, or a "plastic wrap" texture, is indicative of gas secondary to trauma or infection. An irregular or rough surface may be indicative of fibrin on a visceral surface or neoplasia, or with a perforated intestine there may be ingesta adhered to a visceral surface. There are many abnormal presentations of the large colon, most of which are associated with signs of colic. Thickening of the wall of the colon may

VetBooks.ir

be appreciated on rectal palpation and is indicative of edema or cellular infiltration of the colon. Palpation of abnormal masses in the wall of the colon or associated with the colonic mesentery is indicative of infection, infarction, granulomatous colitis, or neoplasia.

Normally the small intestine is not discerned by palpation. Occasionally, though, peristaltic contractions may be felt in the small intestine as it courses across midline toward the base of the cecum. In some cases this will cause the small bowel to palpate as a firm, tubular structure. Relaxation of the peristaltic contraction should be discerned in such cases. Distention of the small intestine is abnormal. In some cases the bowel may feel thickened, which can occur with ileal muscular hypertrophy, edema, or inflammatory disorders of the small bowel.

Other abnormal findings that may accompany disorders of the abdominal alimentary system include masses, adhesions, enlarged and thickened mesenteric arteries, and caudal displacement of the spleen (secondary to gastric distention or neoplasia).

Paracentesis

Abdominal paracentesis is performed routinely in patients with suspected disorders of the abdominal viscera. Cytologic examination of peritoneal fluid; white blood cell (WBC) and red blood cell (RBC) counts; protein, fibrinogen, lactate, phosphate, and glucose concentrations; lactate dehydrogenase (LDH), creatine kinase (CK), and alkaline phosphatase (ALP) activity; and pH can be quantitated. The results of peritoneal fluid analysis may help establish a specific diagnosis but, more important, may reflect inflammatory, vascular, or ischemic injury to the intestine, requiring surgical intervention.

Endoscopy

There are two basic types of endoscopic equipment available: equipment based entirely on a fiberoptic system and equipment based on a video chip system. A wide array of affordable endoscopes is now available, and endoscopic examination of the proximal alimentary tract is now common. A typical endoscope found in many private practices is a fiberoptic endoscope that has an insertion tube that is 100 to 110 cm in length and 10 to 14.5 mm in outer diameter. The larger-diameter tube can be inserted only through the nasal passages of older yearlings and adults and is not suitable for alimentary endoscopy, whereas a diameter of 10 mm allows passage through the turbinates of young foals. An insertion tube of 100 cm is sufficient for esophagoscopy in foals up to approximately 3 months of age. For older animals, an insertion tube length of 150 to 180 cm is required for esophagoscopy.

An insertion tube length of 110 cm is sufficient to reach the stomach of foals up to 30 to 40 days of age. A length of 150 to 180 cm is required for weanlings, and 200 cm is usually required for yearlings and adults. An insertion tube length of 200 cm is sufficient to reach the stomach of all adults of warm-blooded breeds, although 280 to 300 cm is required to examine the pylorus in adult horses. A 280- to 300-cm-long insertion tube permits duodenoscopy in adult horses.

Before a gastroscopic examination, suckling foals up to 20 days of age are not routinely kept from nursing for more than 1 hour. Older foals and mature horses should not have solid feed for 6 to 10 hours so that ingesta from the stomach may be adequately emptied. Longer duration of feed deprivation (12 to 18 hours) is desirable to view the antrum and pylorus of horses. Many foals less than 30 days old do not require sedation for gastroscopy, although sedation with 0.5 mg of xylazine per kilogram may facilitate the procedure. Sedation is required if the foal is to be placed in a recumbent position so that the entire glandular portion of the stomach can be examined. Sedation of older foals and horses is required. Xylazine (0.5 mg/kg given intravenously [IV]) usually provides adequate sedation. For greater sedation, detomidine (0.005 to 0.05 mg/kg IV) or a combination of xylazine and butorphanol (0.01 mg/kg) is effective.

After insertion of the endoscope, the stomach is distended with air until the nonglandular and glandular regions of the gastric surface can be observed. Distention with air is tolerated by foals and horses and has been associated only rarely with adverse effects. Occasionally, sick neonates with poor intestinal motility developed small intestinal distention and experienced discomfort after gastroscopy.

More complete descriptions of techniques of gastroduodenal endoscopy can be found elsewhere.[1,2]

Endoscopy of the rectum and distal small colon can be performed with most flexible endoscopes in use in equine practice and should be preceded, as much as possible, by evacuation and saline lavage of the rectum and distal small colon. The mucosal surface should appear pink to pale red and should have a smooth, "velvety" appearance. Mucosal edema or thickening, hyperemia, irregularities, defects, tears, and intraluminal masses are abnormal findings. Because of the concern for trauma to the rectum and small colon, the horse should be adequately sedated and restrained before preparation and examination of the distal alimentary tract.

Laparoscopy

Laparoscopy can offer valuable diagnostic information regarding the abdominal cavity and is only minimally invasive.[3,4] It should always be preceded by a thorough physical examination, including abdominal palpation per rectum, and abdominal ultrasonographic examination, paying particular attention to the sites for trocar insertion to ascertain that there are no adherent masses or viscera in the area. If abdominocentesis is to be part of the diagnostic workup, it should be performed before laparoscopy because of the effect of laparoscopy on abdominal fluid values. In experimental animals undergoing diagnostic laparoscopy with carbon dioxide insufflation, both the abdominal WBC count and the abdominal total protein increased.[5]

The indications for laparoscopy include palpable abdominal masses, enlarged viscera, adhesions, acute or chronic colic, weight loss, or the need to obtain visceral biopsy specimens. Contraindications include adherent viscera or masses at the site of laparoscopic trocar insertion, diaphragmatic hernias, or extreme bloating. Horses with acute colic can be safely examined laparoscopically if one is careful when inserting the trocars and telescopes.

The basic instruments for laparoscopic examinations include a laparoscopic telescope, laparoscopic cannula and trocar assembly, fiberoptic light source and cable, insufflator, and biopsy and manipulation instruments. The 30-degree laparoscope allows better visualization of the less accessible areas compared with the 0-degree telescopes. Video cameras make visualization easier with less eyestrain but require more powerful light sources. The cost of laparoscopic instrumentation has decreased recently as a result of the explosion of popularity of laparoscopy in humans, increasing the supply and availability of used instruments.

Horses should be fasted for 18 to 24 hours before most laparoscopic procedures; water is allowed on an ad libitum basis. Fasting increases intraabdominal visualization and decreases the possibility of penetrating a gas-distended viscus. The animal is restrained in standing stocks if the procedure is to be done while it is standing. Preoperative antibiotics, antiinflammatory drugs, tetanus prophylaxis, and a sedative analgesic combination are administered. It is important to administer the analgesics before abdominal insufflation. The flank areas are prepared for aseptic surgery. Local anesthetic agents are infiltrated subcutaneously (SC) and intramuscularly (IM) in the middle of the paralumbar fossa slightly above the crus of the internal abdominal oblique muscle for the insertion of the laparoscopic telescope. If additional instruments are to be used, their insertion sites are similarly anesthetized.

It is preferable to begin the laparoscopic procedure on the left side of the abdomen to minimize the chance of penetrating the cecal base. The horse is then draped and a stab incision is made. The laparoscopic cannula and trocar assembly are inserted through the musculature and into the abdominal cavity. It is useful to orient the trocar toward the opposite coxofemoral joint when inserting it. The trocar is exchanged for the telescope, and confirmation of entry into the abdominal cavity is made before insufflation is commenced. If the

VetBooks.ir

abdominal cavity has not been penetrated, a quick thrust with the telescope will usually penetrate the peritoneum. Insufflation of the abdomen with CO_2 to 8 to 10 mm Hg will usually be sufficient for most examinations.

Systematic examination of the abdominal cavity is then carried out. On the left side of the abdomen, the spleen, left kidney, nephrosplenic ligament (Fig. 32-1), stomach, left side of liver, diaphragm, and ventral colon may be visualized cranially. Looking caudally, the examiner will see the root of the mesentery, the isolated small intestinal and small and large colon sections, the urogenital tract, the bladder, and the terminal rectum. The procedure is repeated on the right side of the abdomen. Looking cranially, the examiner will see the liver, epiploic foramen, right kidney, descending duodenum, cecal base, and large colon. Caudally, the urogenital tract, root of mesentery, and isolated pieces of intestine are visible. Liver biopsies and right kidney biopsies are taken from the right side. Left kidney and spleen biopsies are taken from the left side of the abdomen. Mesenteric lymph node biopsies are usually obtained via the left flank. Other masses are biopsied from the more accessible side. At the end of the procedure the abdomen is deflated, and the skin is closed with skin sutures only. Closure of the skin incision should wait until examination of both sides is completed in order to minimize subcutaneous emphysema.

In some horses with ventral or cranial abdominal masses as determined with ultrasound, it is useful to anesthetize the animal in dorsal recumbency for better characterization of the mass. Biopsies may be readily obtained. In horses with acute colic but without obvious signs indicating the necessity for surgery, laparoscopy can help in making the decision to continue medical therapy or proceed to surgery. Strangulated sections of small intestine can be seen, proximal enteritis can be diagnosed, and edema and vascular compromise to the large colon can be seen. No abnormalities may be detected in some animals with very localized lesions, or lesions may be inaccessible, depending on location.

Laparoscopic complications are similar to those of any other abdominal exploratory procedure. Inadvertent penetration of a viscus may occur. The left kidney may be perforated if the laparoscope is inserted too far dorsally. The spleen may be penetrated if the laparoscope is inserted too far ventrally or is not aimed toward the opposite coxofemoral joint. The cecum may be perforated when entering from the right side. Fasting the horses and carefully inserting the laparoscopic trocars will minimize the occurrence of these problems. Subcutaneous emphysema occurs commonly but has not caused any clinical problems. The peripheral WBC count increased but stayed within normal limits in experimental animals undergoing laparoscopy.[5]

Transcutaneous Ultrasonography of the Mature Equine Alimentary Tract

Michelle Henry Barton

Technique

One of the most innovative, practical, affordable, and portable diagnostic tools introduced into the field of equine internal medicine in the past two decades is transcutaneous ultrasonography. Although several different types of ultrasound transducers exist, adult equine abdomens are most completely imaged using a 2- to 5-MHz curvilinear array transducer, although a high-frequency (6- to 8.5-MHz) linear array transducer can be used to optimize resolution of superficial intraabdominal structures. Ideally, before getting started, the patient's hair should be clipped, the skin cleaned, and coupling gel applied. If clipping the hair is not an option, removing debris with grooming aids and soaking the hair with isopropyl alcohol will often suffice. Most horses tolerate transabdominal ultrasonography without sedation. In patients sedated with α_2-adrenergic agonists, small intestinal and cecal motility can be transiently reduced, especially in fasted horses, and the luminal diameter of the small intestine may appear more dilated than in unsedated patients.[6,7] Detailed review of the physics of ultrasonography is beyond the scope of this section; however, there are several general principles that should be kept in mind when transabdominal ultrasonography is performed. First, to ensure that all structures are properly assessed, it is essential to have a consistent and systemic approach for covering the entire area to be evaluated—for example, scanning one side at a time, dorsal to ventral, cranial to caudal. Using seven discrete locations in horses being evaluated for acute abdominal pain, the FLASH (fast localized abdominal sonography) method can be completed in less than 15 minutes and is highly effective in correctly assisting diagnosis.[8] The seven locations evaluated in the FLASH method are ventral, gastric, splenorenal, left middle third of the abdomen, duodenal, right middle third, and thoracic.

Next, being mindful of the position of the transducer and its orientation marker on the patient relative to the "default" method for display of the image on the monitor greatly facilitates correct orientation to the anatomy being imaged (Fig. 32-2). Because abdominal

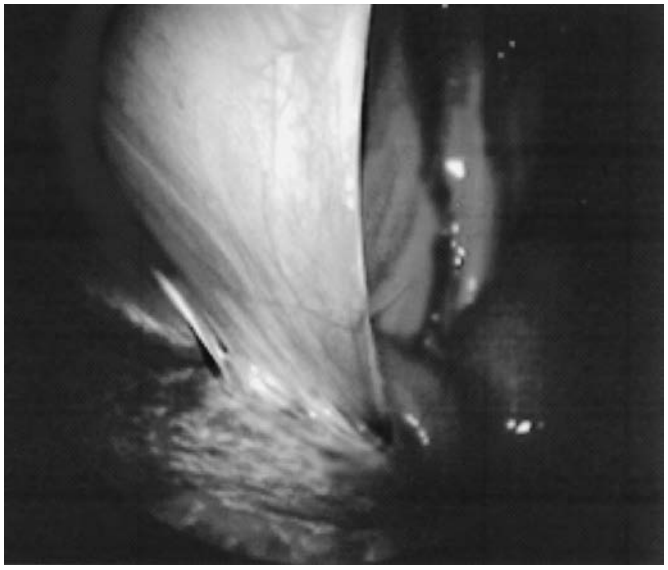

FIG. 32-1 Laparoscopic view of nephrosplenic ligament in a horse.

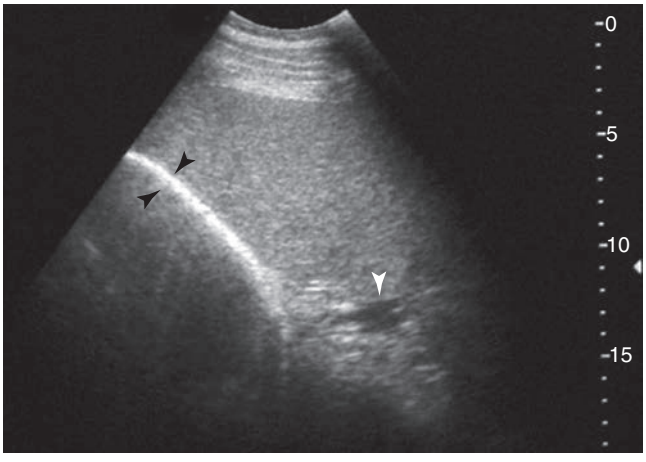

FIG. 32-2 This image is from the gastric window at the left eleventh intercostal space at the level of the shoulder. The left side of the image is dorsal. The black arrowheads mark the serosal layer to mucosal-luminal interface of the stomach wall, which appears as a curved hyperechoic line. The spleen is located in the near field between the stomach wall and the body wall. The white arrow is the splenic vein. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 19 cm.

VetBooks.ir

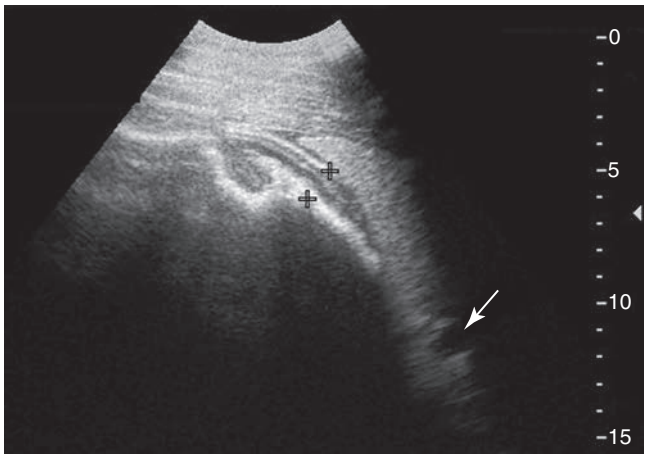

FIG. 32-3 Layers of the stomach wall. This image is from the gastric window with the left side of the image dorsal. The white arrow marks the splenic vein. The electronic calipers (+) are placed at the serosal layer and mucosal-luminal interface and mark the stomach wall. The five ultrasonographic layers of the wall are visible, and it is abnormally thickened at 1.34 cm. On follow-up gastroscopy, this horse had severe gastric ulceration.

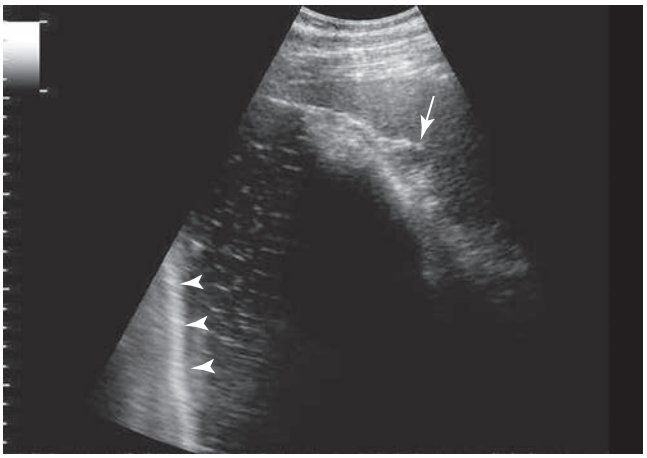

FIG. 32-4 This image is from the gastric window with the left side of the image dorsal. The white arrow marks the splenic vein. The white arrowheads mark the interface between hyperechoic fluid in the dependent portion of the stomach *(right)* and gas dorsally. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 23 cm.

ultrasonography is often performed with the footprint of the transducer in an intercostal space, most imaging of the abdomen is performed with the transducer oriented in a slightly oblique transverse plane (i.e., slicing across the long axis of the body). Careful attention should be paid to the spatial relationship of the viscera because this may be the only key feature distinguishing normal from abnormal.[9] Furthermore, the walls of some sections of the gastrointestinal tract appear strikingly similar and cannot be distinguishable unless information is provided about the probe's exact location on the patient.[10]

Third, in any ultrasonographic examination, it is important to be aware of the depth of the field of view. Selecting the appropriate frequency for the transducer is the key to producing high-quality images that are suitable for the depth of display. High-frequency probes provide sharp images, but the resolution is compromised as the depth of the viewing field increases.

A final general and helpful principle of ultrasonography is that more sound waves reflect to the transducer if two adjacent interfaces have markedly different acoustic impedances. The more sound that reflects to the transducer, the "whiter" the interface appears on the monitor; these tissue interfaces are called *echogenic* or *hyperechoic*. In contrast, less dense tissues reflect less sound, appear darker, and are referred to as *anechoic* or *hypoechoic* structures. The soft tissue of the walls of the gastrointestinal tract have an acoustic impedance that is several thousand-fold greater than that of the free gas inside the adjacent lumen.[11] Consequently, the image at this soft tissue–to-gas interface appears as a fuzzy hyperechoic border (see Fig. 32-2). Because most of the sound waves at this interface are reflected and the free gas in the lumen has extremely low impedance, the rest of the lumen is obscure as sound is neither penetrating nor reflecting from the lumen. Gas within a large luminal viscus is one of the greatest limitations to gastrointestinal ultrasonography in the horse, as it impedes visualization of deeper structures. While imaging a patient, the ultrasonographer should remember that gas rises to the nondependent portion of the abdomen and fluid and heavier structures fall to the dependent locations. When using a 3.5- to 5-MHz curvilinear transducer, identification of the anatomic layers of the intestinal wall in healthy horses is less distinct, with the wall typically appearing as a single hyperechoic line. Depending on the surrounding tissue and the contents of the lumen, three to five layers of the gastrointestinal wall may be visible when a high-frequency transducer is used; these five layers are the hyperechoic serosa, hypoechoic muscularis, hyperechoic submucosa, hypoechoic mucosa, and the hyperechoic mucosal interface with the lumen (Fig. 32-3).[12]

Ultrasonography of the Left Side of the Abdomen

In the following sections, transabdominal ultrasonography of the gastrointestinal tract will be reviewed with a systematic approach of scanning the left side of the abdominal cavity, cranial to caudal, followed by scanning the right side of the abdominal cavity. For the gastrointestinal tract, the ultrasonographer should be careful to document the following key elements: motility, presence of luminal distention, wall thickness and morphology, luminal contents, and viscera position.

STOMACH. When imaging is started on the left rostral side of the abdomen, the stomach should be located deep to the spleen between the ninth and thirteenth intercostal spaces at approximately the level of the shoulder. In this location, the only part of the stomach that can usually be seen is the wall of the greater curvature, which can be reliably identified as a smooth curved hyperechoic line adjacent to the spleen and the splenic vein (see Fig. 32-2).[13] The motility of the stomach is sluggish and the ultrasonographer may get the impression that the greater curvature of the stomach remains stationary.[7] The stomach has the thickest wall in the gastrointestinal tract, measuring approximately 7 mm thick from the serosal layer to the mucosal-luminal interface.[14] When the stomach is empty, the wall measures up to 1 cm thick, ill-defined loops of small intestine may appear between the stomach and the spleen, gastric rugal folds may be visible, and the gastric wall may be found only below the costochondral junction.[7,14]

Gastric Impaction and Ulceration. Because only the dorsal portion of the greater curvature can be seen and the lumen generally contains gas at this location, transcutaneous ultrasonography of the stomach is not a sensitive diagnostic tool for gastric ulceration, intramural gastric masses, or gastric impaction. However, if the wall of the greater curvature of the stomach extends beyond the fourteenth intercostal space in a horse that has not recently drunk or eaten, gastric distention should be suspected.[15] Furthermore, if excessive gastric fluid is present ventrally, a distinct hyperechoic gas–fluid interface may be apparent in the lumen (Fig. 32-4). If the stomach wall appears irregular or thickened, follow-up gastroscopy is indicated for a more definitive diagnosis (see Fig. 32-3).

SPLEEN AND LEFT KIDNEY. Although the focus of this section is gastrointestinal ultrasonography, the proximity of the spleen and left kidney to the gastrointestinal tract warrants brief review. Caudad from the stomach, the spleen should be identifiable immediately adjacent to the body wall, from the left ventral eighth intercostal

VetBooks.ir

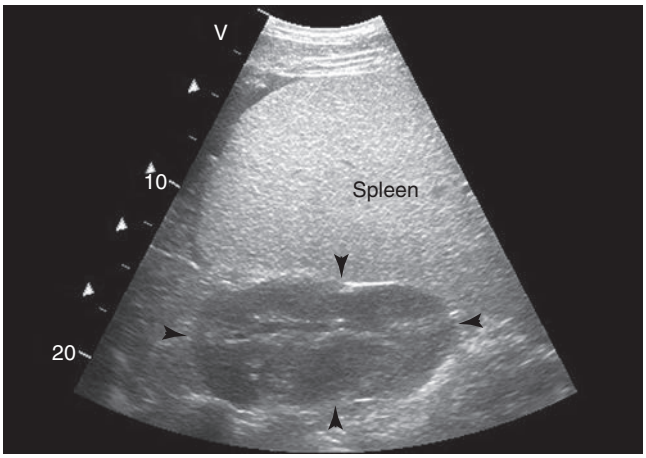

FIG. 32-5 This image was obtained at the left dorsal fifteenth intercostal space and shows the normal adjacent orientation of the spleen to the left kidney *(black arrows).* This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm. Left is dorsal.

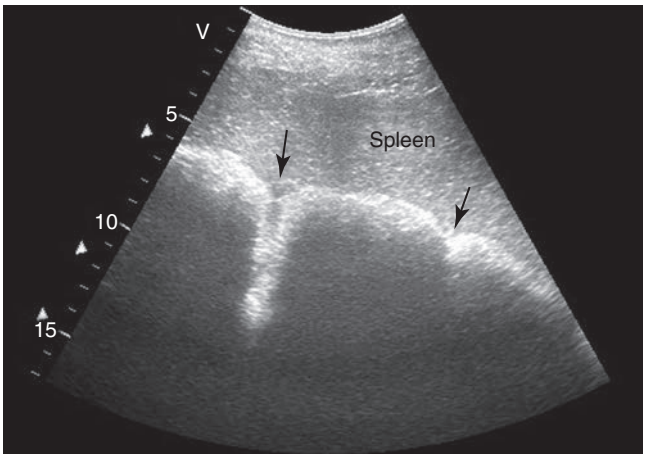

FIG. 32-6 This image was obtained from the left flank and shows the spleen adjacent to left ventral colon, identifiable by its location and the presence of sacculations *(black arrows).*

space to the paralumbar fossa. The size and location of the spleen vary greatly: the spleen can be left of the midline or extend slightly right of the ventral midline. In the rostral ventral left abdomen of some horses, the most rostral aspect of the spleen can be seen either lateral or medial to the liver.[9] The spleen's ultrasonographic architecture is usually homogeneous, with vessels that are rarely visible. The echogenicity of the spleen is greater than that of the liver or kidneys.

The left kidney can be found between the fifteenth and seventeenth intercostal spaces and the first to third lumbar vertebrae, medial or deep to the spleen (Fig. 32-5), between the level of the tuber coxae and the tuber ischii.[16,17] Rarely, the left kidney can directly appose the left body wall.[9] Gas in the small colon, left colon, or lung can normally preclude transabdominal viewing of the left kidney, though colonic gas obscuring visualization of the left kidney may be adjunct evidence of dorsal displacement of the left colon.[18] The ultrasonographic dimensions of the left kidney vary according to the location from which the measurements are obtained. The longitudinal axis for craniocaudal length (i.e., the dorsal plane parallel to the spine) is difficult to measure because of interference by the ribs.[17] In Thoroughbred horses, the length of the left kidney varies from 9.6 to 15.6 cm.[16] The dorsoventral height in the slightly oblique transverse plane varies from 3.1 to 8.1 cm and the lateromedial thickness varies from 6.6 to 9.1 cm.[16] The corticomedullary junction should be distinct, with the cortex being more echogenic. The adrenal glands are not usually identifiable via transabdominal ultrasonography.[9]

LEFT COLONS. Many disorders of the large colon can be palpable by rectal examination, and thus transabdominal ultrasonography is an ancillary tool. Ventromedial to the spleen, the left ventral colon can be identified by its sacculated wall (Fig. 32-6) and sluggish but visible motility, normally contracting two to six times per minute.[7,10,12] Precise measurement of the colonic wall can be difficult because of the indistinct mucosal-luminal interface; in general, however, the wall of the colon should measure less than 4 mm.[10,12,14] The left dorsal colon is not sacculated and can be located dorsal, lateral, medial, or even ventral to the left ventral colon. Gas in the left ventral colon often precludes distinct identification of the left dorsal colon when the latter lies medial or dorsal to the left ventral colon. Gas in the colon typically generates a hyperechoic wall with an indistinct luminal border and intraluminal acoustic shadowing that precludes identification of the contents and the medial walls.

Colitis. When visualized through ultrasonographic exam of the left colon, wall thickness and morphology, orientation of the colon, and its contents, are useful diagnostic characteristics. For example, thickening of colon wall can be caused by inflammation, infiltration by neoplastic cells, hemorrhage, or edema. Inflammation of the colon wall (i.e., colitis) can result in mural widening, but the mucosal

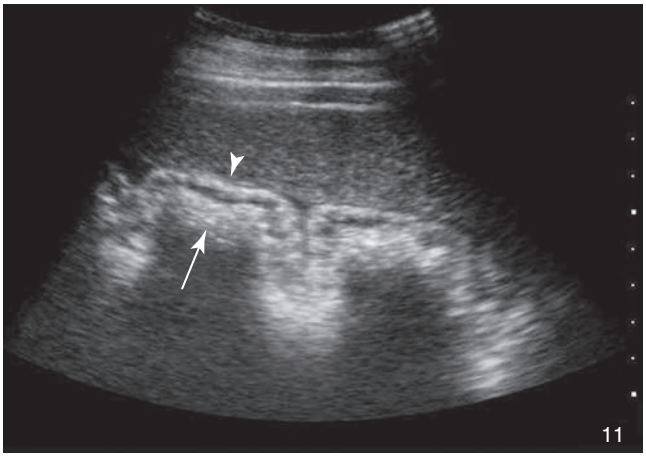

FIG. 32-7 This image was obtained from the same location as Fig. 32-6 from a patient with colitis. The left ventral colon is identifiable by its location medial to the spleen and by its sacculations. The wall of the colon was thickened to approximately 1 cm with three distinct layers: hyperechoic serosa *(white arrowhead),* hypoechoic muscularis, and submucosal, hyperechoic mucosal-luminal interface *(white arrow).* This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 11 cm. Left is dorsal.

border often appears shredded, undulating, or wavy (Fig. 32-7). These later findings may be particularly helpful in identifying horses in the prodromal phase of colitis, prior to the onset of diarrhea. The contents of the colon can change from characteristic acoustic shadowing to that of swirling mixed echogenic fluid that may enable visualization of the distal colonic wall. With colitis, colon motility can be increased, decreased, or remain unaffected.

Colon Volvulus. Colonic edema resulting from a volvulus of the colon will also result in uniform hypoechoic mural thickening that is best identified with imaging along the ventral midline behind the xyphoid. In one study that evaluated colon wall edema by transcutaneous ultrasonography using a ventral abdominal window, a colon wall thicker than 9 mm had a sensitivity of 67% and specificity of 100% for colon volvulus.[19] In addition, in some cases of colonic volvulus, nonsacculated colon replaces sacculated colon in the left ventral abdomen.[20] Furthermore, the blood supply to the ascending colon is located in the mesentery along its medial aspect, and thus there are normally no major blood vessels visible ultrasonographically on the lateral surface (adjacent to the body wall) of the ascending colon. The ultrasonographic finding of distended vessels with reduced blood flow in colonic mesentery adjacent to the body wall implies that the colon is rotated along its long axis and would be

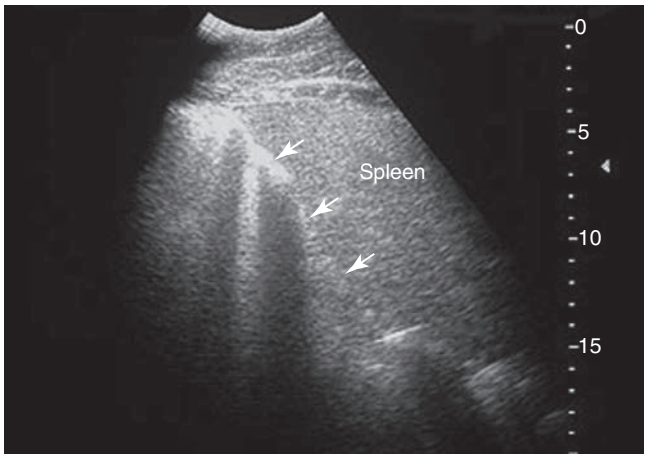

FIG. 32-8 This image was obtained from the same location as Fig. 32-5 using a 3.5-MHz curvilinear probe set to a depth of 20 cm. This horse had a left dorsal displacement of the colon into the renosplenic space. The gas-distended colon *(arrows)* obscures visualization of the left kidney. *(Courtesy Science In 3D, Inc. and © 2002—University of Georgia Research Foundation, Inc.)*

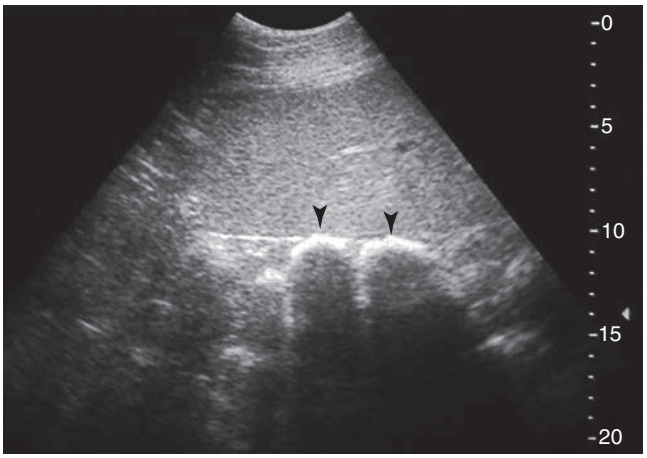

FIG. 32-10 This image was obtained from the left dorsal paralumbar fossa. The spleen is in the near field. The serosal surface *(black arrowheads)* of two adjacent loops of small colon are visible. Note the anechoic shadowing that precludes visualization of the distal small colon wall. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm. Left is dorsal.

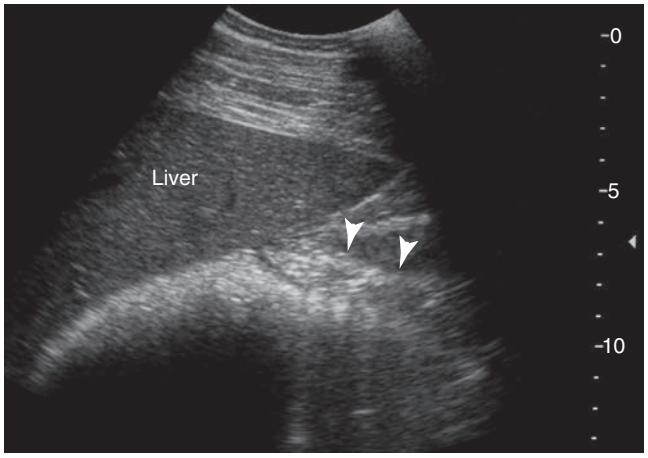

FIG. 32-9 This image was obtained from the same location as Fig. 32-23 using a 3.5-MHz curvilinear probe set to a depth of 13 cm. The left side of the image is dorsal. Sand and gravel in the dependent portion of the right dorsal colon (*white arrowheads* on serosal surface) create reverberation artifacts in the lumen. The colon wall is thickened. *(Courtesy Science In 3D, Inc. and © 2002—University of Georgia Research Foundation, Inc.)*

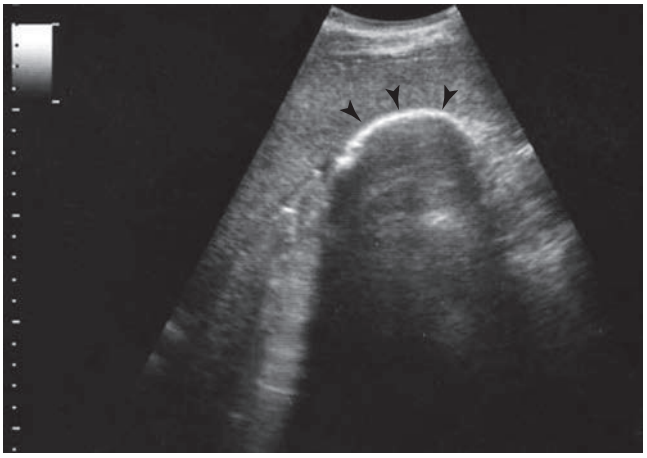

FIG. 32-11 This image was obtained from the left dorsal paralumbar fossa. The spleen is in the near field. The serosal surface *(black arrowheads)* of the small colon is visible and is bulging. Note the dramatic anechoic shadowing that was created by an intraluminal enterolith. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm. Left is dorsal. *(Courtesy Science In 3D, Inc. and © 2002—University of Georgia Research Foundation, Inc.)*

consistent with a diagnosis of displaced colon or a colon volvulus.[21] Colonic motility would be reduced with a volvulus.

Left Colon Displacement. On the left side of the abdomen, dorsal displacement of the left colon over the nephrosplenic ligament may obscure ultrasonographic visualization of the dorsal aspect of the spleen or left kidney, or the colon may appear lateral to the spleen (Fig. 32-8).[18] However, if gas is not present in the entrapped colon, the ultrasonographic diagnosis can be missed. Likewise, gas within the left colon can obscure the left kidney without the colon being entrapped. When ultrasonographic and other clinical findings support the diagnosis of left dorsal displacement of the colon, serial ultrasonography of the area can be a useful noninvasive method to determine if the colon has relocated to its ventral position upon successful ultrasonographic visualization of the left kidney.

Colon Impaction. Gas within the colon often precludes accurate ultrasonographic diagnosis of colonic impaction. An impaction should be suspected in the ventral colon by the presence of a hyperechoic border at the mucosal surface that casts a strong acoustic shadow and flattened sacculations. Sand impactions are best seen in the ventral abdomen and often compress the mucosal surface, create excessive acoustic shadowing or reverberation artifacts (Fig. 32-9), and significantly reduce visible motility of sacculations.[22]

SMALL COLON. The small colon is located in the left paralumbar fossa medial or ventral to the spleen. Because of its small diameter, sacculations, and packed serpentine loops that suspend from the dorsal mesocolon, often only small sections of the surfaces are visible ultrasonographically as short, sharply curving, hyperechoic lines (Fig. 32-10). As with the large colon, the motility of the small colon is slow (no more than 3 contractions per minute) and luminal surface gas typically prevents visualization of the contents and the distal walls.[12] Likewise, the dense content of fecal balls in the small colon often generate anechoic shadows from the near wall that precludes visualization of the distal wall (see Fig. 32-10).

Small Colon Impaction. Impactions or enteroliths obstructing the lumen of the small colon can usually be readily diagnosed by transrectal examination; however, transabdominal ultrasonography may reveal loss of, or enlargement of, sacculations and intense anechoic shadowing (Fig. 32-11).

SMALL INTESTINE. In fed healthy horses, the jejunum can only be identified in approximately 10% of horses.[7] One must carefully watch for peristaltic activity that creates transient expansion of the lumen from movement of ingesta. The medial location of the ileum precludes distinct identification by transcutaneous ultrasonography.

VetBooks.ir

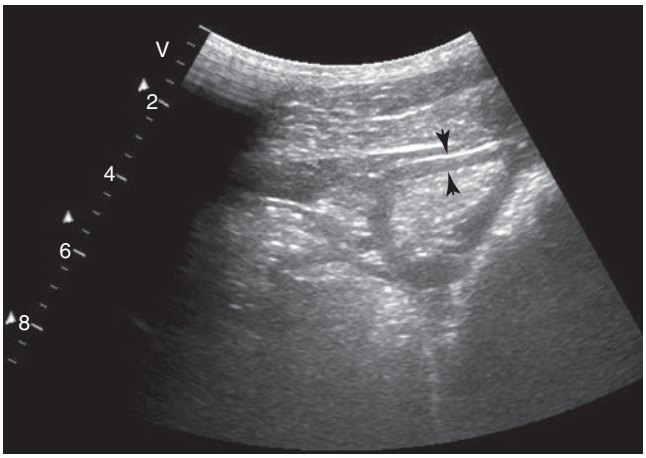

FIG. 32-12 This image was obtained from a healthy unsedated horse in the left flank using a 3.5-MHz curvilinear probe set to a depth of 8 cm. A single loop of small intestine is present between the body wall and the left ventral colon. The serosal to mucosal surfaces are most distinct in the near wall and are marked by the black arrowheads.

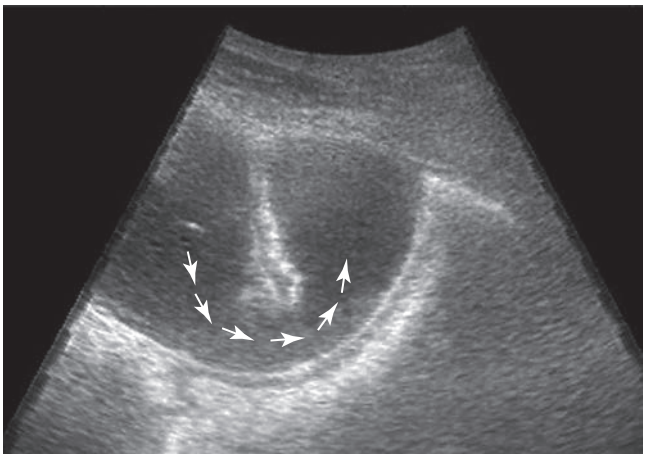

FIG. 32-13 This image was obtained from the left flank and depicts a segment of distended small intestine that is folding back on itself, creating the appearance of a "U turn" *(arrows).* This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 10 cm.

The jejunum is most consistently found in the left inguinal area, medial to the spleen and the left ventral colon (Fig. 32-12). The small intestine has the most visible motility of any part of the gastrointestinal tract, with peristaltic waves producing frequent rhythmic contractions. Fluid luminal contents typically enable accurate measurement of the wall (<3 mm) and visualization of the far wall along its long or short axis.[14] In healthy horses, jejunal luminal diameters rarely exceed 3 cm.[14] Following complete contraction with peristalsis, a distinct lumen becomes difficult to discern. Fasting and/or sedation with an α_2-adrenergic agonist decreases motility of the small intestine, thereby significantly increasing the likelihood of visualization.[6,7]

Distended Loops of the Small Intestine. Distended loops of small intestine often look the same on ultrasound, despite the underlying cause. Recalling that normal duodenum and jejunum are difficult to visualize in healthy fed horses, if the small intestine is found easily by ultrasonographic exam, the luminal diameter of small intestine exceeds 3 cm, or peristaltic contractions are notably reduced, it should be considered abnormal. Small intestinal distention can result from paralytic causes, in which there is reduced motility without physical luminal blockage or from mechanical reasons, in which there is a distal luminal or extraluminal obstruction impeding peristalsis. With either paralytic or mechanical ileus, small intestinal distention can progress to the point where the dilated segments of small intestine must fold back on themselves, creating the appearance of turns or curves within the lumen when caught in long axis (Fig. 32-13). As ileus progresses, denser ingesta will settle to the dependent portion of the affected segments (Fig. 32-14). In general, if small intestinal distention progressively increases and motility decreases over serial examination, mechanical causes of obstruction that require surgical intervention should be considered.[23,24] Scrutiny of the patient's clinical signs, ancillary diagnostic findings, and some distinguishing ultrasonographic features can be helpful in discriminating paralytic versus mechanical causes of small intestinal distention. In particular, the ultrasonographer should pay close attention to the small intestinal wall thicknesses and morphology, progression of distention, degree of motility, and appearance of the intestinal contents.

Acute Enteritis. The wall of the small intestine can be thicker than normal (i.e., >3 mm) from inflammation, edema, hypertrophy, or neoplasia. Some causes of inflammation and edema are acute in nature, such as proximal or anterior enteritis, and some causes are chronic or insidious in nature, such as the inflammatory bowel syndromes or idiopathic intestinal hypertrophy. In addition to the clinical signs and other diagnostic features of proximal enteritis (low-grade fever, gastric reflux, inflammatory leukogram, pain followed by

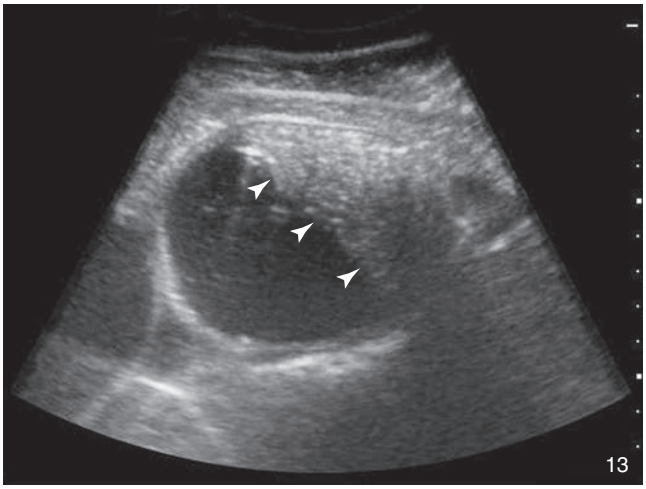

FIG. 32-14 This image was obtained from the left flank and depicts a segment of distended small intestine with hyperechoic ingesta settled dependently *(arrowheads).* The left side of the image is dorsal. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 13 cm.

depression after gastric decompression), on ultrasonographic exam, the mucosal wall of the small intestine may appear shredded, [14] corrugated, or wavy, resembling the edge of a lasagna noodle (Fig. 32-15). The proximal portions of the small intestine, especially the duodenum (see duodenum section below; Fig. 32-16), and the stomach may be distended with fluid. The motility of these loops can vary from low to apparently no movement to hypermotile. For horses with enteritis, the expected response to medical therapy varies, but lessening degrees of luminal distention with progressive improvement in motility are expected. If hyperechoic gas sounds are seen within the wall of the small intestine, it is indicative of either necrosis or anaerobic bacterial infection.

Inflammatory Bowel Disease and Ileal Hypertrophy. If the signs of abdominal pain are more insidious, if there is weight loss despite a good appetite, or if panhypoproteinemia is present, symmetrically and diffusely or regionally thickened small intestine may be a sign of infiltrative or hypertrophic disease, such as inflammatory bowel disease, neoplasia (especially lymphosarcoma), or idiopathic ileal hypertrophy.[25] In these circumstances, the wall can be either uniformly or irregularly thickened, often with a narrow or obscure lumen (Fig. 32-17). Motility is usually preserved, unless mural thickening results in secondary mechanical obstruction. Definitive

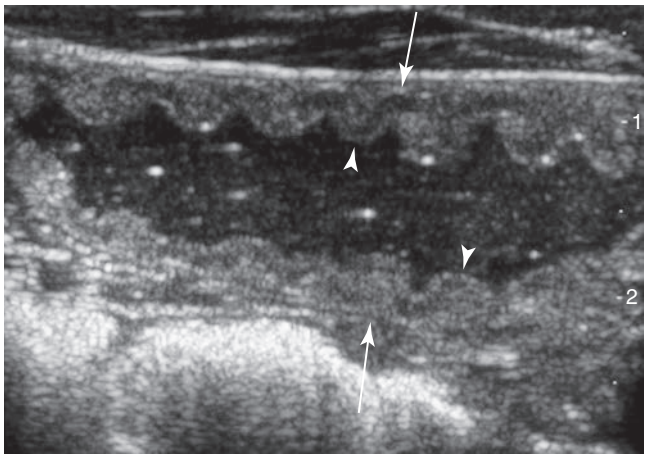

FIG. 32-15 A linear probe set to a depth of 3 cm was used to capture this image of enteritis, obtained from the ventral left flank. The small intestinal wall is thickened (up to 6 mm in some areas) and the mucosa has a "wavy" or corrugated appearance. The white arrows mark the serosa and the arrowheads mark the mucosal-luminal interface.

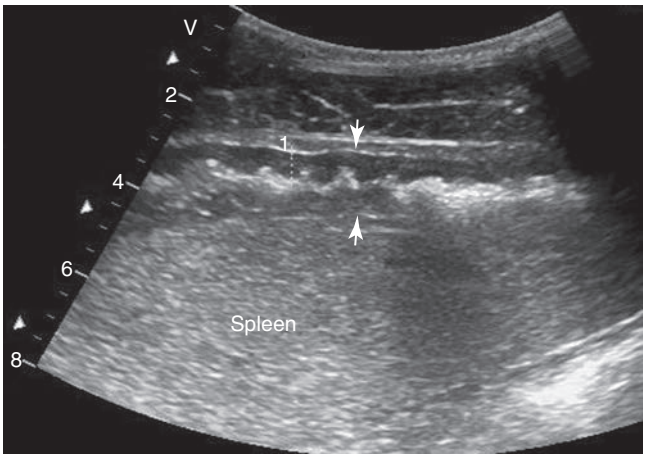

FIG. 32-17 This image was obtained from the left flank adjacent to the spleen, revealing the thickened and wavy wall of a longitudinally oriented segment of small intestine from a horse with chronic inflammatory bowel disease. The white arrows mark the serosal surfaces. The thickened walls are predominantly hypoechoic. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 8 cm.

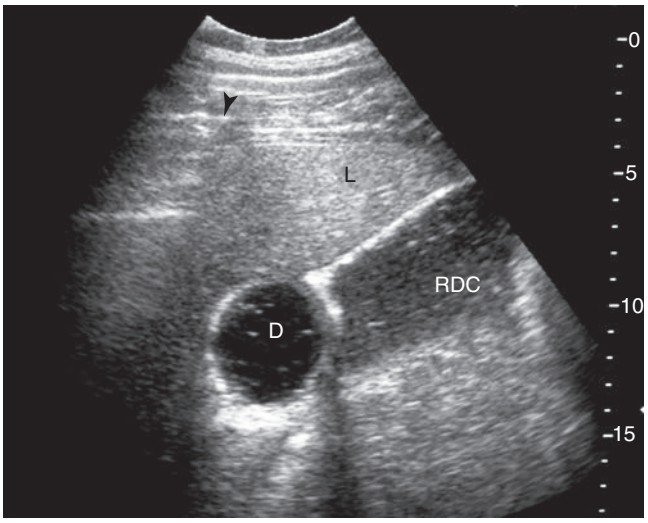

FIG. 32-16 This image was obtained from the right twelfth intercostal space using a 3.5-MHz curvilinear probe set to a depth of 18 cm. This patient has proximal enteritis. The duodenum *(D)* was distended to approximately 4 cm with reduced motility. The duodenal wall was mildly thickened at 4 mm. The black arrowhead marks the ventral tip of the lung. *L,* Liver; *RDC,* right dorsal colon.

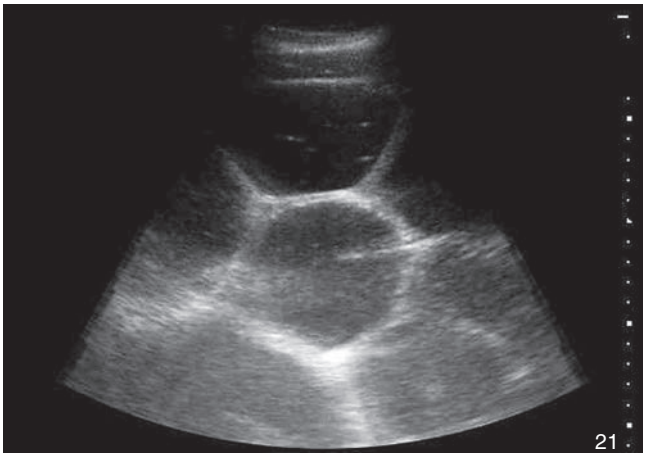

FIG. 32-18 This image was obtained from the left flank from a horse with a nonstrangulating obstruction that required an exploratory celiotomy for correction. Note the numerous turgidly round and distended loops of small intestine. In real time, these distended loops had no appreciable motility. This image was obtained with a 3.5-MHz curvilinear probe set to a depth of 21 cm.

diagnosis of inflammatory bowel disease or idiopathic hypertrophy requires histopathologic evaluation.

Nonstrangulating Obstructive Lesions of the Small Intestine. Mechanical obstruction of the small intestine in which the adjacent blood supply remains intact, such as an ileal impaction, adhesions, mural hematoma, or severe chronic infiltrative disease of the intestinal wall, would be expected to cause variable degrees of luminal distention proximal to the site of obstruction. In general, lack of significant changes in wall thickness or morphology would be helpful features for distinguishing simple nonstrangulating lesions of the small intestine from strangulating or severe inflammatory lesions. If serial ultrasonography reveals progressive severity of distention and lack of motility (see Fig. 32-17), surgical intervention should be considered.[23,24]

Strangulating Obstructive Lesions of the Small Intestine. Progressive pain with poor response to medical intervention, lack of fever, and serosanguineous peritoneal fluid with increased or increasing lactate concentrations are clinical features that might help distinguish strangulating lesions of the small intestine from simple obstructions and enteritis. As with nonstrangulating obstructive lesions of the small intestine, ultrasonographically, the intestine proximal to strangulating obstructions will be distended with either gas or fluid. The degree of distention and motility will vary with the duration of strangulation, although the presence of progressive distention of preobstruction segments to turgidly circular and completely amotile loops of small intestine is highly correlated with mechanically obstructive lesions that require surgical intervention (Fig. 32-18).[23,24] An important distinguishing feature of strangulated small intestine is the appearance of focally and usually uniformly thickened walls at the site of the strangulation (Fig. 32-19). Thus, when regional uniformly thickened small intestine is identified ultrasonographically, with other evidence of obstruction (hypomotile, hairpin turn stacks of turgidly round and distended loops of small intestine with dependent ingesta), a strangulating obstruction should be the top consideration. Frequently the strangulated loops are identified in the ventral portions of the abdomen. In one study, focally thickening and distended small intestine with no motility was 100% sensitive and 100% specific evidence for strangulating lesions of the small intestine.[23] If the affected segments are most readily visualized adjacent to the spleen and stomach on the left side of the abdomen (Fig. 32-20) or between the liver and right dorsal colon on the right side of the abdomen (Fig. 32-21), these respective locations are areas

VetBooks.ir

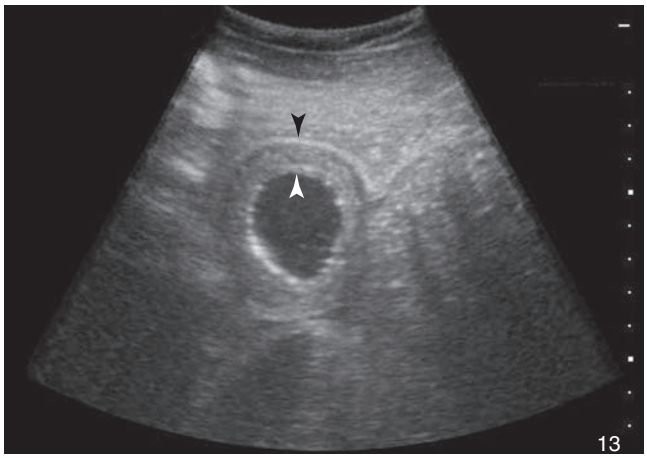

FIG. 32-19 This image was obtained from the left flank from a horse with a strangulating obstruction using a 3.5-MHz curvilinear probe set to a depth of 13 cm. Depicted is a single distended loop of small intestine with a uniformly thickened wall of approximately 8 mm (between *arrowheads*). In real time, this segment had no discernible motility.

FIG. 32-22 This image was obtained along the caudal ventral midline from a horse with a jejunojejunal intussusception. The arrowhead marks the inner loop telescoped into the outer loop of jejunum *(arrow),* creating the classic "bull's-eye" appearance. This image was obtained using a 3.5-MHz curvilinear probe set to a depth of 10 cm.

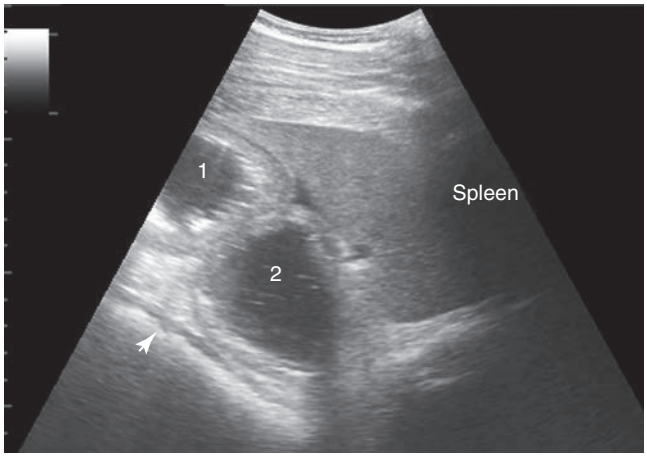

FIG. 32-20 This image was obtained from the gastric window from a horse with a strangulating gastrosplenic ligament entrapment, using a 3.5-MHz probe set to a depth of 17 cm. Two loops (labeled *1, 2*) of thickened, distended, and amotile loops of small intestine were found between the spleen and the stomach *(arrowhead).* Dorsal is to the left.

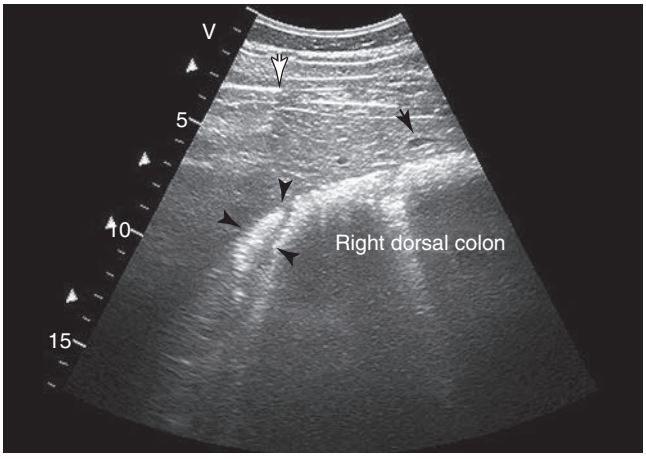

FIG. 32-23 This image was obtained at the eleventh right intercostal space at approximately the level of the shoulder, using a 3.5-MHz curvilinear probe set to a depth of 17 cm. Dorsal is to the left. The white arrow marks the ventral tip of the lung. The black arrowheads mark the serosal surface of the duodenum with a hyperechoic lumen, located between the liver and the right dorsal colon. Short hyperechoic parallel lines in the liver are the walls of portal veins *(black arrow).*

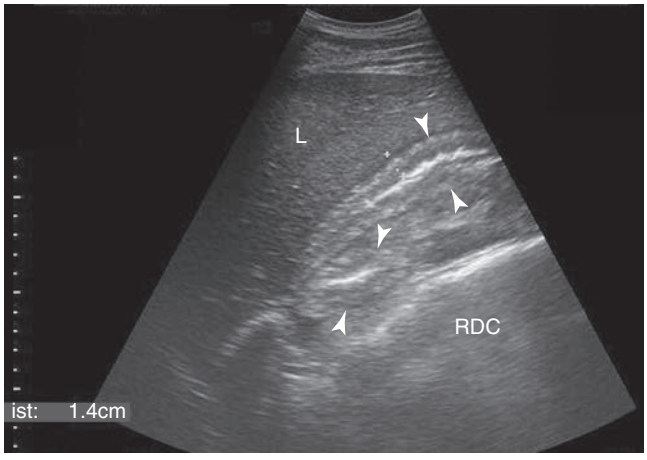

FIG. 32-21 This image was obtained from the right twelfth intercostal space from a horse with an epiploic foramen entrapment. Arrowheads mark the serosal surfaces of two thickened (14-mm wall) and compressed loops of amotile small intestine located between the liver *(L)* and the right dorsal colon *(RDC).* This image was obtained using a 3.5-MHz curvilinear probe set to a depth of 24 cm.

in which gastrosplenic and epiploic foramen incarcerations are readily found.

Intussusception. Finally, intussusceptions of the small intestine are most common in foals and young horses and have a characteristic "bull's-eye" or target lesion appearance of the affected segments when imaged across the short axis of the small intestine (Fig. 32-22).[26] The intussuscepted intestine tends to fall toward the dependent portion of the abdomen. Like other mechanical obstructive diseases, the proximal small intestine will have normal wall thickness but will be distended, with reduced motility and hairpin turns, depending on the degree of obstruction.

Ultrasonographic Anatomy of the Right Side of the Abdomen

LIVER AND PANCREAS. The liver, descending duodenum, and right dorsal colon have characteristic proximity of location and can be identified in the right rostral abdomen at the level of the shoulder (Fig. 32-23). The liver is located from the sixth to the fourteenth intercostal spaces between the diaphragm and the right dorsal colon (see Fig. 32-23). Gas in the lung or the right dorsal colon can obscure identification of the liver dorsally and ventrally, respectively; thus

VetBooks.ir

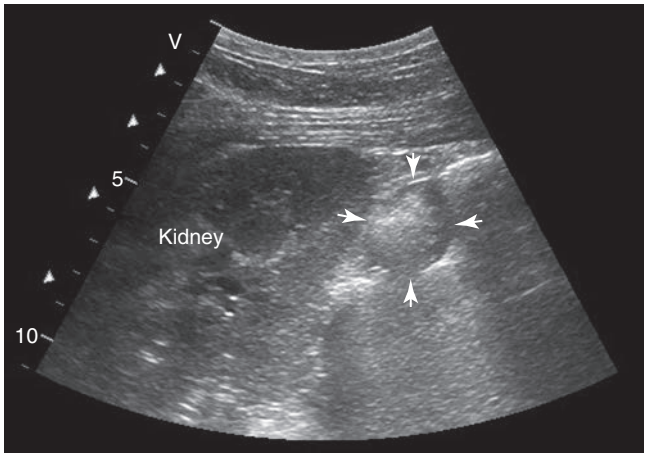

FIG. 32-24 This image was obtained from the right fifteenth intercostal space using a 3.5-MHz curvilinear probe set to a depth of 11 cm. Dorsal is to the left of the image. The duodenum *(arrows)* can be seen ventral to the right kidney. This still image was captured when a peristaltic wave distended the luminal diameter to approximately 2.5 cm.

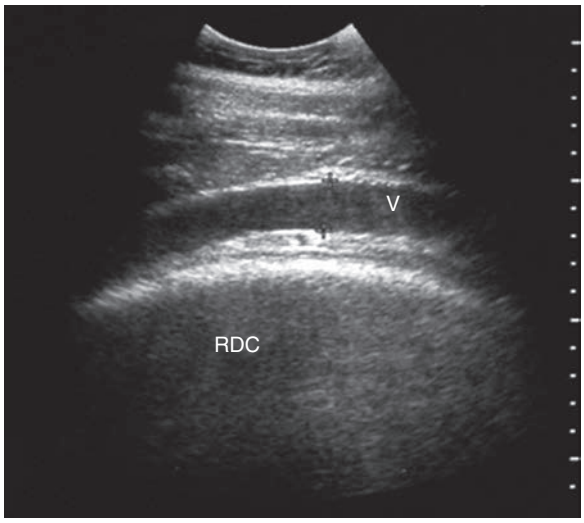

FIG. 32-25 This image was obtained from the right fifteenth intercostal space using a 3.5-MHz curvilinear probe set to a depth of 17 cm. A distended vein *(V)* is visible lateral to the wall of the right dorsal colon *(RDC)*. This horse had a colon volvulus. *(Courtesy Science In 3D, Inc. and © 2002—University of Georgia Research Foundation, Inc.)*

ultrasonographically, the liver may only be visible over a few intercostal spaces. Only a small portion of the right side of the liver can be imaged, so its size is estimated based on its expanse across the intercostal spaces.[9] It is unusual for the liver to be seen beyond the fifteenth intercostal space or in the same transverse plane as the right kidney, except at the most rostral aspect of the kidney. The ventral edges of a normal liver are distinctly sharp. As with the spleen, the architecture of the liver is relatively homogeneous, but more vessels are visible in the liver and the general echogenicity of the liver is less than that of the spleen.[14] Portal veins have more connective tissue in their walls and thus have more echogenic walls than the hepatic veins.[9] Short segments of smaller portal veins often appear as hyperechoic parallel lines (see Fig. 32-23). In some small horses, the portal vein can be seen entering the hilus deep on the medial side of the image. The common bile duct and its branches within the liver are not normally visible.[9] The pancreas is not usually identifiable via transabdominal ultrasonography.[9]

DUODENUM. The position of the duodenum is fixed by its suspending mesoduodenum; thus the duodenum can reliably be found descending the right middle abdomen at approximately the level of the shoulder and is located between the liver and the right dorsal colon (see Fig. 32-23), where it can be imaged transversely along its short axis. As with the jejunum, to locate the descending duodenum, the ultrasonographer must wait for a peristaltic contraction to deliver ingesta through the lumen, thereby expanding the lumen. Otherwise, the duodenum typically appears as a hyperechoic flattened or crescent-shaped line to flattened oval shape. It is unusual for the duodenal diameter to exceed approximately 3 cm in healthy horses during peristaltic propulsion of ingesta.[27] The duodenum contracts one to four times per minute in fed horses,[27] but contractions are less frequent in anorectic, fasted, or heavily sedated horses. The duodenum can be followed to the level of the ventral right kidney (Fig. 32-24), where it crosses medially into the abdomen and is no longer distinguishable. The wall of the duodenum is less than 3 mm thick.[14]

RIGHT COLONS. The right dorsal colon, which has no sacculations, is immediately ventral to the liver and duodenum and is usually found from the right tenth to twelfth intercostal space, although it can extend to the fourteenth intercostal space.[28] The wall of the right dorsal colon consistently appears as a hyperechoic curved line, adjacent to the liver (see Fig. 32-23), that measures less than 4 mm, although a range up to 5.9 mm has been reported in healthy horses.[28] If the ultrasonographer locates the right dorsal colon and slides the transducer ventrally, the interface between the right dorsal and right ventral colon is often identifiable as what appears to be an indentation in the wall between the nonsacculated right dorsal colon dorsally and the sacculated right ventral colon ventrally. The right ventral colon has sacculations, and its contractions and wall thickness are similar to those of the left colon, although a wall thickness up to 5.1 mm has been reported in healthy horses.[28] The contents of the right colons and their medial walls are normally obscured by luminal gas. The transverse colon is not usually identifiable via transabdominal ultrasonography.[9]

Right Dorsal Colitis. When diarrhea in a horse is accompanied by panhypoproteinemia and a history of nonsteroidal antiinflammatory drug (NSAID) use, transabdominal ultrasonography of the right dorsal colon can be a useful diagnostic aide.[28] In patients with NSAID-induced right dorsal colitis, the wall of the right dorsal colon will often appear thickened with mixed echogenicity and an irregular mucosal-luminal interface.

Right Dorsal Colon Displacement. Identification of a large gas-distended viscus in the right caudal abdomen by transrectal palpation with accompanying taut colonic bands is consistent with a diagnosis of right dorsal displacement of the colon. The only major blood vessels normally visible ultrasonographically in the right caudal abdomen are those associated with mesentery of the lateral cecal band.[12] Thus the ultrasonographic finding of distended vessels with reduced blood flow in colonic mesentery adjacent to the body wall implies that the colon is rotated along its long axis and would be consistent with a diagnosis of right dorsally displaced colon or a colon volvulus (Fig. 32-25).[21]

CECUM. The cecum has a sacculated wall that extends from the right paralumbar fossa to ventral midline and has motility that is similar to that of the colons.[7,12] A unique characteristic that can be useful to distinguish the cecum from the right ventral colon is that the lateral cecal band is oriented dorsoventrally and contains an associated artery and vein, whereas the lateroventral band of the right ventral colon is oriented caudocranially and does not have associated vasculature.[12] The cecal wall is less than 4 mm thick, and gas in the lumen precludes imaging the contents and far wall. Most diseases affecting the cecum can be sufficiently identified by transrectal palpation; however, transcutaneous ultrasonography can be helpful in confirmation of the diagnosis.

Typhlitis. With acute inflammatory disease of the cecum, the wall may be thickened, the mucosal surface may appear irregular or wavy, and motility will vary from hypomotile to hypermotile. Gas

VetBooks.ir

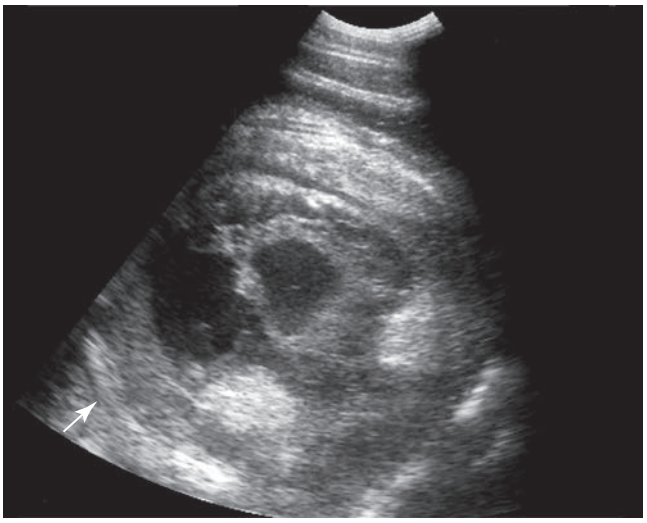

FIG. 32-26 This image was obtained from the right mid flank using a 3.5-MHz curvilinear probe set to a depth of 24 cm. This horse had a cecocolic intussusception that appears as a large mass. The appearance of a "wall within a wall" is most apparent in the near field.

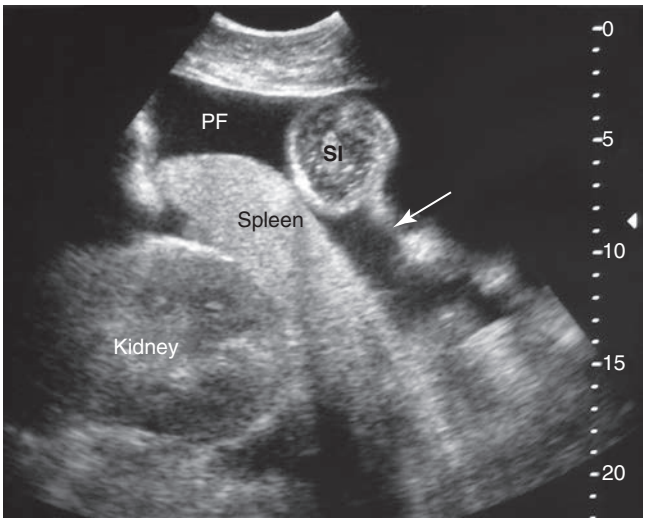

FIG. 32-27 This image was obtained from the left dorsal sixteenth intercostal space using a 3.5-MHz curvilinear probe. The left side of the image is dorsal. Excessive hypoechoic peritoneal fluid *(PF)* has displaced the spleen from the left body wall and enabled distinct visualization of a single loop of small intestine *(SI)* and its supporting mesentery *(arrow),* appearing as a "balloon on a string." This horse had metastatic mesothelioma.

normally present in the body or base of the cecum precludes visualization of its contents and distal wall; however, with typhlitis, the cecum is often distended with fluid that is readily seen swirling inside of the lumen and can enable visualization of the distal wall, especially toward the cecal apex.

Cecal Impaction. Transrectal palpation is a better method to diagnose cecal impactions, but transabdominal ultrasonography of cecal impactions may reveal loss of characteristic sacculations.

Cecocolic and Cecocecal Intussusception. Intussusceptions involving the cecum are often palpable on transrectal evaluation as indistinct large, firm masses in the right or mid caudal abdomen. Like small intestinal intussusceptions, the characteristic "target lesion" of the wall of the cecal apex or body within the lumen of the cecum or right ventral colon can be seen. In chronic intussusceptions, the walls are very thick and may appear abscessed or mass-like (Fig. 32-26).

RIGHT KIDNEY. Gas in the cecum, right dorsal colon, or lungs sometimes obscures visualization of the right kidney, which can normally be found in the rostral fifteenth to seventeenth intercostal space[17] (see Fig. 32-24). In Thoroughbred horses, the right kidney is 6.5 to 9.1 cm dorsoventrally (the slightly oblique transverse plane), 12.1 to 16.2 cm in length craniocaudally (the dorsal plane), and 6.5 to 8.4 cm lateromedially.[16] The ureters are usually difficult to identify, but the proximal right ureter sometimes appears as a hyperechoic circular structure at the hilus. The architecture of the right kidney is similar to that of the left kidney.

PERITONEAL CAVITY. In the healthy horse, only minute pockets of peritoneal fluid should be identifiable in the rostroventral area of the abdominal cavity or adjacent to sacculations of the ventral colons. The abnormal presence of excessive peritoneal fluid displaces organs and greatly facilitates visualization of structures not normally seen on ultrasonographic exam, such as the mesentery of the small intestine (Fig. 32-27).

PERITONITIS. Peritonitis should be suspected if there is increased volume or echogenicity of peritoneal fluid. In some cases, free-floating or adherent fibrin or fibrous tags may be visible (Fig. 32-28). An abdominocentesis would be an integral step to further characterize the etiology of peritonitis.

HEMOABDOMEN. Excessive blood in the peritoneal cavity will displace organs off the body wall. Blood in the peritoneal cavity

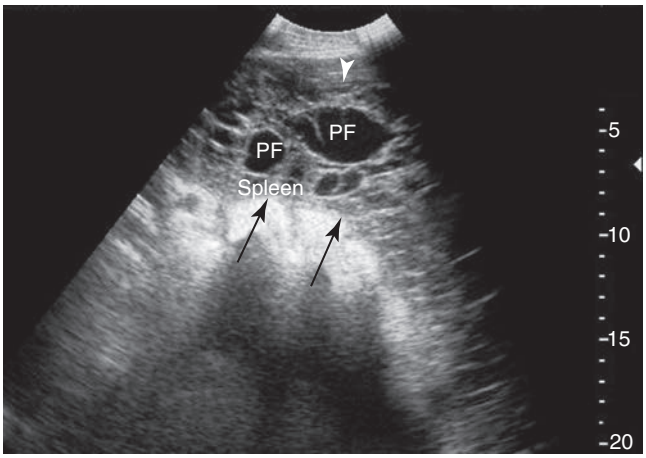

FIG. 32-28 This image was obtained from the lower right flank using a 3.5-MHz probe set to a depth of 21 cm. The left of the image is dorsal. Numerous hyperechoic fibrinous and fibrous adhesions trapping pockets of hypoechoic peritoneal fluid *(PF)* are present between the body wall *(white arrowhead)* and the serosal surface of the right ventral colon *(black arrows).* This horse had septic peritonitis.

appears as a mixed echogenic fluid that, in real time, often appears to "swirl" as it mixes with less echogenic peritoneal fluid (Fig. 32-29).[12] Abdominocentesis will confirm the presence of blood.

INTRAABDOMINAL MASSES. Abscessation, hematoma, and neoplasia are the top differential diagnoses for intraabdominal space-occupying lesions, each of which can be located just about anywhere in the peritoneal cavity, in or attached to bowel, other intraabdominal viscera (i.e., spleen, kidney, liver), or the peritoneum. Space-occupying lesions appear as soft tissue densities of variable shapes and acoustic properties that distort normal sonographic architecture (Fig. 32-30). Although the definitive cause of an intraabdominal mass is often not discernible ultrasonographically, both abscesses and hematomas appear as either uniform echogenic or loculated space-occupying masses of mixed echogenicity. Chronic abscesses may be characterized by the presence of a thick echogenic capsule. An abscess or hematoma more commonly is isolated to a single location, whereas metastatic neoplasia should be considered if variable sized space-occupying lesions that distort normal ultrasonographic

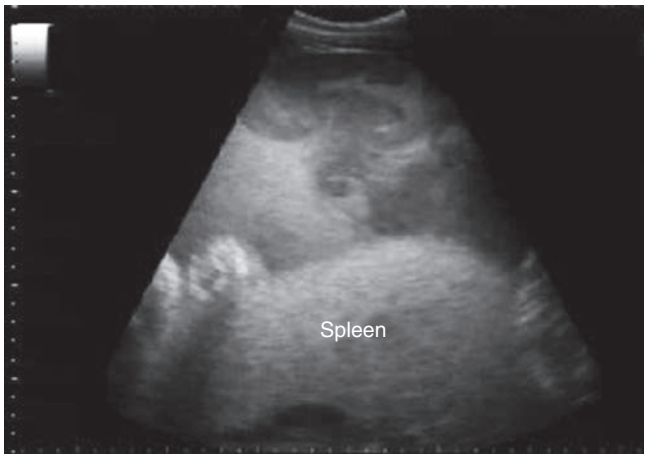

FIG. 32-29 This image was obtained from the lower left flank of a horse with hemoabdomen using a 3.5-MHz curvilinear transducer set to a depth of 24 cm. The left of the image is ventral. Blood displaces the spleen from the left body wall and appears as swirls of mixed echogenicity between the spleen and left body wall.

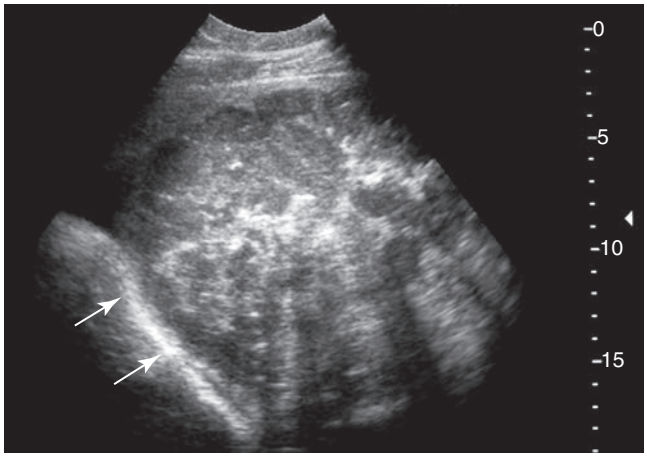

FIG. 32-30 This image was obtained from the gastrosplenic window using a 3.5-MHz curvilinear probe set to a depth of 19 cm. The left of the image is dorsal. A large mixed echogenicity mass occupies the space adjacent to the stomach wall *(arrows)* in the location normally occupied by the spleen. This horse had abdominal lymphosarcoma.

anatomy are present in multiple locations. Although the ultrasonographic appearance of a space-occupying lesion may not help determine the cause, ultrasonography can be a useful guide to biopsy or aspiration of the affected tissue.

Other Imaging of the Alimentary Tract

Radiography

In the horse the alimentary tract is a dynamic and complex environment to evaluate with any modality. Because of the size of the animal, as well as the distinct difference between air and soft tissue, radiographs are a useful diagnostic tool for evaluating the teeth, pharynx, esophagus, stomach, and intestinal tract. Portable x-ray units with maximal kilovolt peak (kVp) settings up to 100 and the upper limits of the milliampere-second (mAs) settings at 30 make it possible for ambulatory practitioners to obtain diagnostic images of the head and cranial esophagus. However, to obtain images of the thoracic esophagus and abdomen, a referral clinic with a more powerful x-ray generator is usually required.

For the average foal, abdominal radiographs have been described using exposures ranging from 80 to 88 kVp and 20 to 26 mAs for the

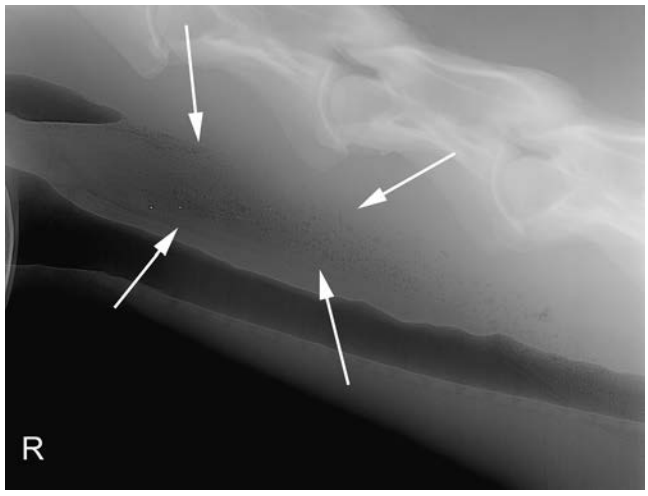

FIG. 32-31 Standing lateral radiograph of a 13-year-old Morgan gelding with an esophageal tear. Note the tubular region of small gas opacities caused by air trapped around the outer border of the esophagus *(arrows)*. An esophageal perforation secondary to an ingested foreign body was confirmed with endoscopy.

standard abdomen.[29] In adult horses, exposures range from 60 to 140 kVp and 20 to 70 mAs.[30,31] To do a complete evaluation of the abdomen, it is recommended that the abdomen be divided into four quadrants (cranioventral, midabdominal, caudodorsal, and caudoventral).[30] Large cassettes (35 cm × 43 cm) and fast screens are also needed to ensure a diagnostic image is obtained. Because of the large amount of scatter radiation produced from the high exposure and thickness of tissue penetrated, an 8:1 to 10:1 grid should be used.[29-33] Alternatively, an air gap technique can be used to prevent image degradation.

Availability of computed radiography (CR) and digital radiography (DR) has greatly increased the diagnostic capabilities of conventional radiographic examinations. Both of these systems, available to equine practitioners, are considered indirect imaging modalities in which the x-ray photon interacts with an intensifying screen to convert the x-ray photons to light. This light then interacts with an imaging plate: film, as with a conventional radiographic system; within a photostimulable phosphor, as with CR; or within a flat-panel detector, as with DR. Regardless of the method, these images are considered "indirect" because the x-ray photon is first changed to light and then detected by the imaging medium.[34] The main benefits of CR and DR are the increased latitude of the film. It is possible to change the contrast and grayscale levels after the exposure if an adequate number of photons is available to the detector. The DR systems also offer a rapid evaluation of the image because the cassette is directly connected to the computer. This allows the portable systems to show radiographic images within 10 seconds after the exposure is made. In contrast, the CR system requires the cassette to be placed into a reader in order to display the image. Finally, because both CR and DR are generally Digital Imaging and Communications in Medicine (DICOM) compliant, this allows any specialists with standard medical imaging software to view the images via a compact disk (CD) or via the Internet.

Survey radiography is generally helpful in evaluating the cervical esophagus for evidence of rupture as well as to evaluate the abdomen. Esophageal ruptures secondary to an obstruction or vigorous placement of a nasogastric tube result in a small volume of gas that tracks just dorsal to the trachea (Fig. 32-31). This can be confused with a tracheal laceration; however, with tracheal lacerations, generally the gas accumulation will surround the trachea and the volume of gas within the subcutaneous tissues and the cranial mediastinum will be severe. In addition, esophageal obstructions, also called *choke,* can sometimes be identified on survey radiographs depending on the material that is causing the obstruction and the amount of air or

VetBooks.ir

contrast medium that is able to surround the structure (Fig. 32-32). Although the nature of the obstruction cannot be determined, the extent of the abnormality can sometimes be identified.

Abdominal radiography is useful for evaluating the small and large intestines for sand accumulation, enterolithiasis, impactions, or small intestinal disorders in foals. When sand is ingested, it generally will accumulate within the large colon along the ventral abdomen[8] (Fig. 32-33). Radiography has been found to be a useful method for monitoring the resolution of sand impactions after medical management; however, sequential examinations are needed to verify that the

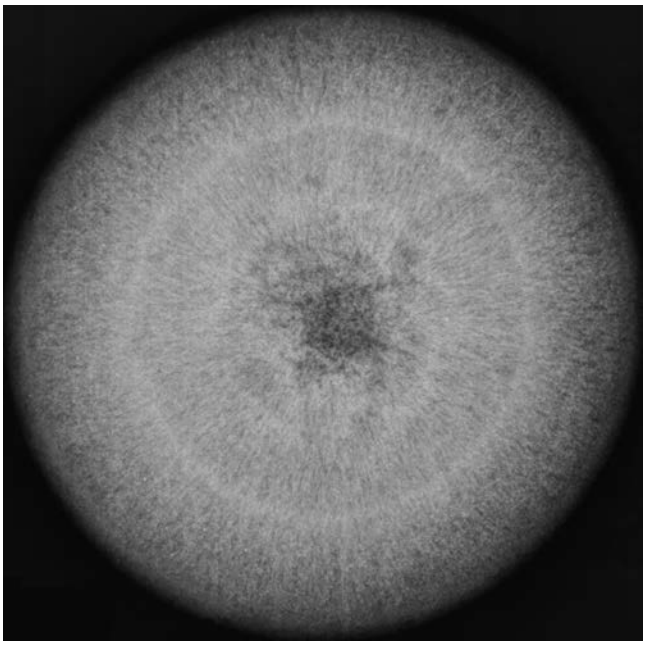

FIG. 32-34 Radiograph of enterolith obtained after surgical removal from the small colon. Note the variation in opacities caused by the various types of minerals that are contained within the enterolith.

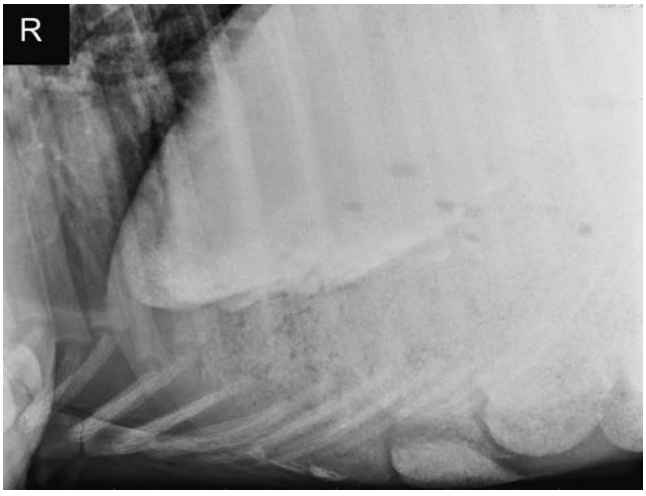

FIG. 32-35 Standing lateral radiograph of a 3-year-old Paint Horse gelding with a pelvic flexure impaction. The radiograph shows the sternal flexure with a large amount of granular material and a small amount of sand accumulation in the ventral colon.

volume of sand has reduced.[31] If the volume of sand is large enough, it is difficult to determine if an enterolith is present because of summation of the two lesions. Enteroliths are solid concretions of mineral that usually form around a nidus, such as a metallic foreign body (Fig. 32-34). The mineral composition is varied, as illustrated by the different opacities present within the enterolith. Radiographs have a 96.4% positive predictive value to detect enteroliths in high-prevalence areas. These enteroliths were generally found to be within the midabdominal radiograph, and 67% of small colon enteroliths caused large colon distention, which was also identified on radiographs.[30] Impactions are more difficult to diagnose because usually there is just increased feed accumulation within the abdomen. Although no enterolith or obstruction is identified, granular material can be seen, usually within the ventral colon near the sternal flexure. This is because pelvic flexure impactions will cause the feed material to accumulate orad, causing distention of the left ventral colon (Fig. 32-35). Intestinal disorders such as functional ileus secondary to

VetBooks.ir

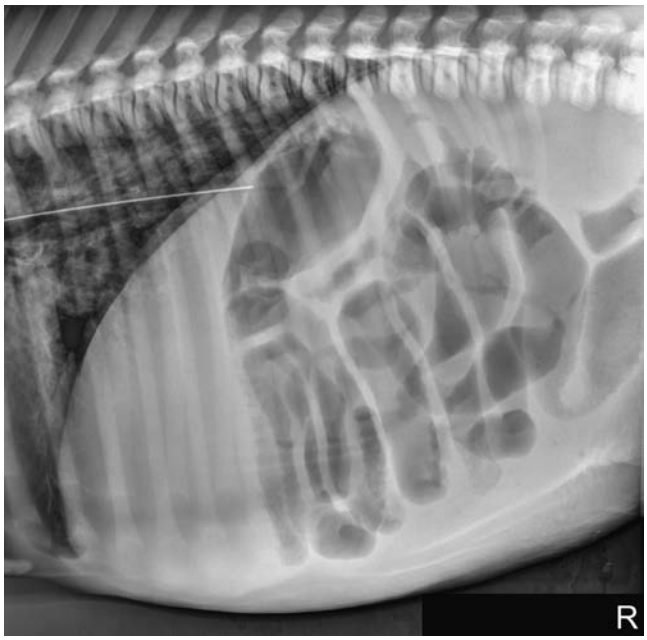

FIG. 32-36 Standing lateral radiograph of a 1-day-old, premature Quarter Horse filly. Note the large amount of gas-distended intestine. Because of the large amount of small intestinal distention, functional ileus is the primary differential diagnosis.

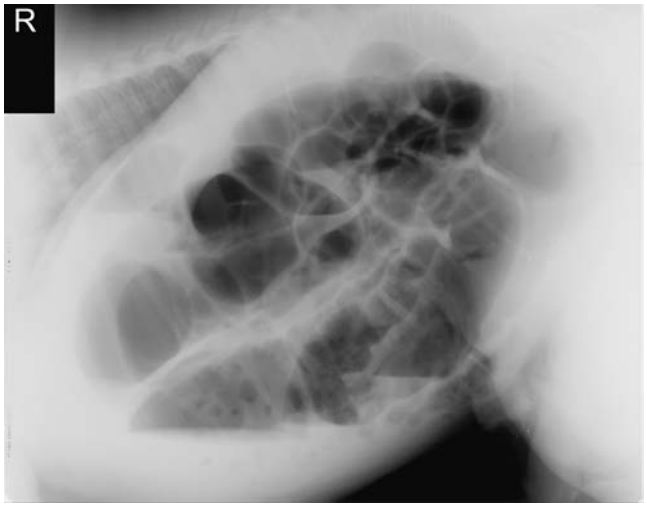

FIG. 32-37 Standing lateral radiograph of a 2-day-old Thoroughbred colt with a meconium impaction. Note the large amount of gas distention of the colon.

enteritis (Fig. 32-36) or obstruction secondary to intussusception or meconium impaction (Fig. 32-37) in foals can also be identified on abdominal radiographs. These images show large dilation of the small intestine, and differentiation between functional and mechanical ileus in foals is generally based on the size of the intestine and the volume of gas that is present.[32] Evaluation of the abdomen using ultrasound may aid in qualifying the small or large intestinal motility as well as identifying the source of an obstruction if the determination on radiographs cannot be made.

Radiography also allows for the use of contrast medium administration to further outline the alimentary tract as well as evaluate pharyngeal function and esophageal motility.[35-37] First administering approximately 60 mL of barium sulfate paste or liquid orally via a 60-mL dosing syringe and obtaining radiographs of the laryngeal region and esophagus provides useful information about swallowing as well as large obstructions. If the barium liquid is identified dorsal to the soft palate, within the larynx or trachea, abnormal pharyngeal

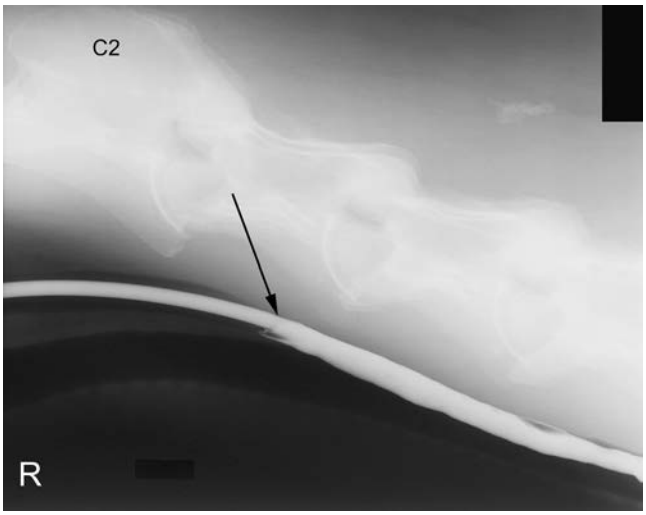

FIG. 32-38 Standing lateral radiograph showing a normal esophagram using barium liquid. The *arrow* marks the region where the nasogastric tube ends. This is approximately at the level of C3.

function is likely present.[35] The barium paste will coat the pharynx and esophagus and is useful in identifying any ulcerations or irregularities in the mucosal surface. After those procedures have been performed or if there is no evidence of an oropharyngeal dysphagia, then an esophagram is performed. This procedure is done using approximately 200 to 500 mL of barium sulfate liquid diluted 1:1 or 2:1 with water to bring the total volume to 500 to 1000 mL. This liquid is administered through a nasogastric tube or cuffed endotracheal tube placed within the cranial esophagus to the level of C2 to C3. If a cuff is available, the cuff can be inflated with approximately 10 mL of room air. A radiograph is then made to verify that the tube is not within the trachea, and when it has been confirmed that the tube is within the esophagus, the dose of barium is administered using a stomach pump. Toward the end of the dose, while still pumping the liquid, radiographs of the cranial, mid, and caudal esophagus are obtained (Fig. 32-38). The use of the pump provides distention of the esophagus to help identify strictures or irregularities in the esophageal wall.

Positive (barium sulfate) and negative (room air) contrast medium radiography have also been used to evaluate the stomach and intestinal tract through oral administration of contrast medium,[29,38,39] and the rectum and colon have been evaluated via retrograde administration of contrast medium.[39] These methods allow for the evaluation of the stomach, intestinal tract, and rectum for regions of obstruction as well as ulcerations, tumors, motility disorders, and/or malformations. Although these methods have been described, ultrasound has virtually eliminated the need to expose personnel and patients to the repetitive, high doses of radiation needed to obtain sequential radiographs of the abdomen.

Computed tomography (CT) and magnetic resonance imaging (MRI) are of little use for evaluation of the alimentary tract (except for the head). This is mainly because of the size of the patient compared with the size of the gantry and bore in CT and MR units, respectively. Dental disorders such as abscesses and fractures can be clearly seen on CT images, especially after three-dimensional reconstructions (Fig. 32-39), and CT is also useful to detect pharyngeal and esophageal masses that may not be fully identified with conventional radiographs. CT and MRI can be used in foals that can be placed within the gantry or bore of the magnet; however, because of the motion of the gastrointestinal tract and the long acquisition times used with respiratory gating sequences, MRI has not been used widely to evaluate the thorax or abdomen. A single case report has been published that described the use of contrast esophagography and CT to aid in the surgical planning of a persistent right fourth and left sixth aortic arch that caused a vascular ring anomaly in a foal.[40]

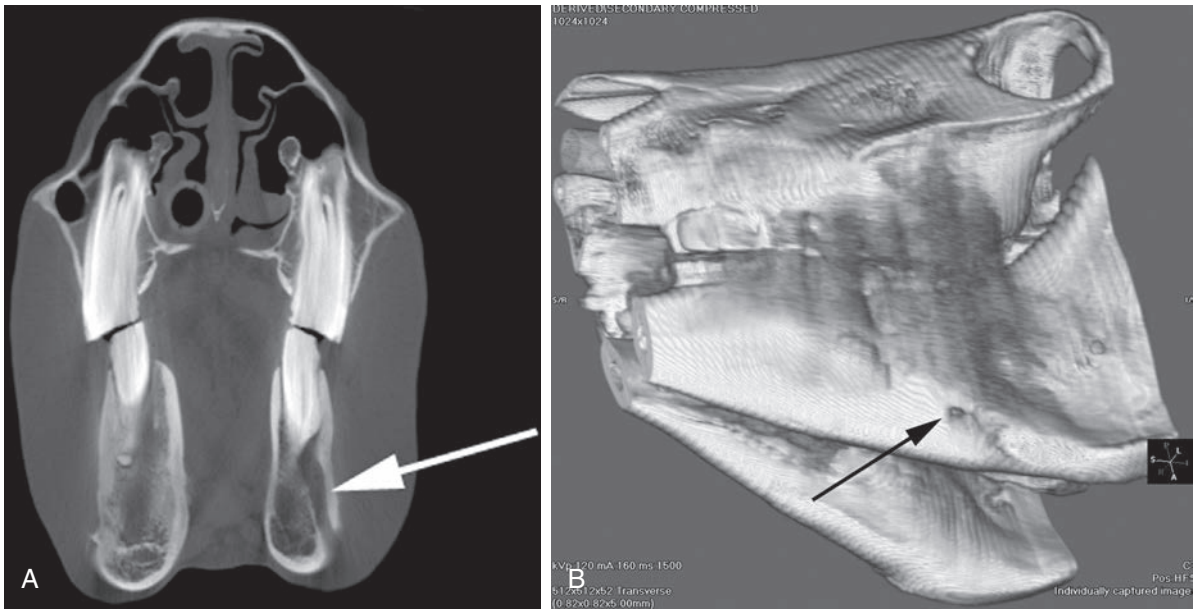

FIG. 32-39 These are transverse **(A)** and three-dimensional **(B)** reconstructed computed tomography images of the head of a 4-year-old pony mare with chronic draining tracts from the mandible. The *arrows* illustrate the tract through the mandible that communicates with the apical portion of the left mandibular first molar (tooth #309).

However, the applications for these technologies have yet to be realized.

Scintigraphy

Nuclear medicine is a widely used modality for imaging the gastrointestinal tract in humans and animals. Although physical obstruction can be assessed with endoscopy, ultrasound is unable to identify the pylorus in the normal horse because of the peripheral nature of the colon and colonic gas. Nuclear medicine provides a functional evaluation of the pylorus to determine if delayed gastric emptying compared with normal horses is present. This modality works better than gastric emptying with barium sulfate because of the minimal invasive nature and ease of acquisition of images. However, the need for a gamma camera to generate the images and the licensing requirements to handle radioactive material make this modality less universally available. The primary use for evaluating the gastrointestinal tract with scintigraphy is to evaluate gastric emptying time.[41-44] Two protocols have been outlined in the references provided. The first uses the readily available technetium-99m pertechnetate (^{99m}Tc) bound to disofenin or sulfur colloid.[42,45,46] This combination of radioisotope and radiopharmaceutical is fed in a pelleted ration alone or mixed with radiolabeled eggs. The normal range for the $t_{1/2}$ gastric emptying has been reported to be 1.49 ± 0.17 hours[23] and 1.56 ± 1.08 hours.[22] The other method is the carbon-13 (^{13}C) bound to octanoic acid breath test (^{13}C-OABT). This method was validated compared with the ^{99m}Tc sulfur colloid and found to have similar results compared with the solid phase gastric emptying $t_{1/2}$.[40] The main difference is that the ^{13}C-OABT is measured in the exhaled breath of the horse and with spectroscopy rather than with a gamma camera. The rationale for ^{13}C-OABT is that because a gamma camera is not needed, this test may be more portable and useful for field investigations.[45]

Another nuclear medicine procedure in the realm of alimentary tract evaluation involves the use of ^{99m}Tc hexamethyl propyleneamine oxime (^{99m}Tc-HMPAO). This procedure allows for radiolabeling WBCs in order to determine areas of inflammation.[47,48] The use of ^{99m}Tc is a matter of convenience because it is also used in equine bone imaging. Detection equipment, such as a low-energy, all-purpose collimator, is readily available in many practices. HMPAO is used because it binds to granulocytes and therefore should travel to areas of increased inflammation.[48] HMPAO also associates with the reticuloendothelial system, enabling localization within the lungs, liver, spleen, kidneys, and urinary bladder. The main drawback is that with the activity bound to WBCs there is a general lack of anatomic information, which can cause lesion localization to be difficult.[48] Although this technique is expensive and labor-intensive, the results from the limited studies available appear encouraging.

Biopsy

The decision about whether to obtain a biopsy is often based on the ease of obtaining a sample and the relative value of the evaluation that can be made. Very small samples, such as those obtained with an endoscope biopsy instrument, are relatively easy to obtain, but they provide limited information. Full-thickness bowel specimens, obtained by means of ventral midline or flank laparotomy, are more difficult to obtain, but they provide much more information. Laparoscopic techniques to safely obtain full-thickness intestinal biopsies are described and may be more practical than laparotomy.[49]

Taking a biopsy sample by endoscopy allows the practitioner to choose the biopsy site on the basis of the appearance of the mucosal surface, which most frequently reflects an inflammatory disorder. Conversely, when a biopsy sample is obtained through laparotomy, the serosal surface of the bowel may not reflect a disorder within the bowel wall. In such instances it may be useful to obtain several biopsy specimens. Rectal mucosal biopsies are easily performed. Many instruments can be used to obtain the biopsy specimen, and a uterine biopsy forceps works well. A fold of mucosa can be pinched readily between two fingers, and a sample of this tissue is obtained this way. The size of the sample is adequate for histologic or bacteriologic examination.

Fecal Examination

Cytologic, biochemical, bacteriologic, immunologic, and electron microscopic evaluations can be performed on fecal samples. In addition, observation of the consistency and color, the presence of foreign material such as sand or gravel, and the presence of parasites should be included in the examination of the alimentary system. In addition to fecal consistency, fecal particle size can be used to evaluate the efficiency of mastication or the colonic transit time. Increased particle size, with loose or watery stool, is suggestive of decreased colonic transit time.

VetBooks.ir

VetBooks.ir

Cytologic examinations are used primarily to evaluate the parasite burden of the animal. Ova of large and small strongyles, tapeworms, round worms, and *Strongyloides westeri* are most common. Coccidia are observed occasionally but are clinically unimportant. Examination of fecal WBCs has been advocated in the evaluation of horses and foals with enterocolitis. Because these cells are very labile, their presence in large numbers indicates that an inflammatory process is present and that the inflammation is in the distal colon or is associated with decreased transit time.

Determination of fecal occult blood has been recommended to diagnose gastric ulcers, duodenal ulcers, and other potentially hemorrhagic disorders of the alimentary tract. However, the usefulness of this test has been shown to be quite limited, because negative results can be obtained when blood is present in the proximal portion of the gastrointestinal tract.[50] The sensitivity of most commercially available tests is poor, giving negative results in the face of severe gastric bleeding.

Fecal culture is an essential component in the evaluation of many patients. In bacteriologic culture techniques for fecal samples, selective media that are designed to isolate *Salmonella* are routinely used. These media include selenite broth, tetrathionate broth, brilliant green agar, XLD agar, and *Salmonella-Shigella* agar. Less selective media, McConkey and eosin methylene blue agars are desirable to culture other potential gram-negative bacterial pathogens such as *Escherichia coli,* but the mere presence of *E. coli* in the feces does not determine its pathogenicity. Enterotoxigenic *E. coli* have been isolated from foals with diarrhea, but special tests, such as polymerase chain reaction (PCR) assays, must be performed to determine whether an isolate produces enterotoxin. Rapid enzyme-linked immunosorbent assays (ELISA) for detection of enterotoxins of *Clostridium difficile* (*C. difficile* Tox A/B Test, TechLab, Blacksburg, Va.) and *Clostridium perfringens* (*C. perfringens* enterotoxin test, TechLab, Blacksburg, Va.) in fecal specimens are available at diagnostic laboratories.

The presence of rotavirus in a fecal sample can be determined by use of an ELISA or an agglutination test. Both assays test for the presence of viral antigen in the feces. PCR assays are also available to detect rotaviral nucleic acids. The ELISA is reported to be more sensitive than the agglutination test but is less specific. Therefore the agglutination test is likely to give more false-negative results, and the ELISA test is likely to give more false-positive results. The ELISA test is more time-consuming and inconvenient to perform than the agglutination test. When rotavirus is a concern, particularly as a farm problem, a reasonable approach is to screen fecal samples with the agglutination test and repeat testing of samples that yield negative findings with the ELISA or PCR.

Some diagnostic laboratories have developed sensitive and specific multiplex PCR tests for panels of gastrointestinal pathogens (equine coronavirus and rotavirus, *Lawsonia intracellularis, Cryptosporidium, Rhodococcus equi, Neorickettsia risticii, Salmonella* spp., and *Clostridium difficile* toxins A and B), that provide relatively rapid diagnostic information that can be used alone or in combination with culture or antigen detection methods.

Absorption and Digestion Tests

Tests that evaluate the ability of the equine intestinal tract to digest and absorb nutrients have a more limited clinical application than in human or small animal medicine, but they can be useful in the evaluation of horses with chronic weight loss, suspected small intestinal inflammation or neoplasia, gastric and small intestinal partial obstruction, and postoperative small intestinal malabsorptive disorders. For absorption tests to be diagnostic, the intestinal disorder must either be diffuse or affect the delivery to and transit through the small intestine.

Maldigestion tests are performed to evaluate exocrine pancreatic function and small intestinal mucosal brush border disaccharidase activity. Pancreatic exocrine deficiencies have not been described in the horse, probably because equine pancreatic secretions consist primarily of water and bicarbonate and have less enzymatic activity than in monogastric omnivorous species. Mucosal brush border disaccharidase-related maldigestion is relevant in viral and bacterial enteritides of foals, particularly rotavirus and coronavirus enteritides. As a result of these viral infections, there is loss of the superficial villous epithelial cells of the small intestine, in which the disaccharidases lactase, cellobiase, maltase, sucrase, and trehalase are located.[51] Lactase levels are greatest in young suckling foals, and loss of this enzyme activity, secondary to loss of the mucosal villous cells, leads to lactose maldigestion. Lactose tolerance can be tested by administering a 20% solution of D-lactose at a dose of 0.5 to 1 g/kg. This dose should result in an approximate doubling of the serum glucose level within 60 minutes of administration.[52]

Clinically applicable absorption tests include the D-glucose and D-xylose absorption tests. The glucose absorption test has the advantage of being relatively easy and inexpensive to perform. However, cellular uptake and metabolism of glucose, as well as intestinal absorption, influence the results and thus are undesirable variables. The xylose absorption test is therefore advantageous because it more directly measures intestinal absorptive capacity. The results of both tests, however, are affected by gastric emptying rate and small intestinal transit time. In the United States, D-xylose is available only through chemical suppliers and only for research purposes; its availability for clinical diagnostic use is restricted.

The D-glucose and D-xylose tests are performed similarly. After an 18- to 24-hour fast, a 10% solution of D-glucose or D-xylose, 0.5 to 1 g/kg, is administered through a nasogastric tube. For the measurement of glucose, blood is collected in sodium fluoride tubes, and for the measurement of D-xylose, blood is collected in heparinized tubes. Samples are taken at 0, 30, 60, 90, 120, 150, 180, 210, and 240 minutes after administration. Peak levels, which normally range from 20 to 25 mg/dL, occur 60 to 120 minutes after administration, and levels thereafter should decrease. The normal curve resembles an inverted V. Variability in absorption curves occurs as a function of age and type of feed the horse is given.[53] Delay or flattening of the absorption curve may reflect delayed gastric emptying, increased intestinal transit time, or impaired intestinal absorption.[54] Accurate interpretation of the results of these tests depends on the results of other diagnostic evaluations. In addition, different types of diets have been shown to affect the height, although not the shape, of the absorption curves significantly. In general, diets that have higher digestible energy content result in a lower peak in the curve.

Breath Tests

In humans, dogs, and cats, breath tests are used to assess a variety of intestinal disorders. The urea breath test is used as part of an assessment of *Helicobacter* status of the patient,[55] but this is not an issue for horses. The hydrogen breath test is used in assessments of intestinal bacterial overgrowth and in determination of carbohydrate digestion and absorption in the intestine. In patients with an abnormal intestinal bacterial population or carbohydrate malabsorption, there will be excessive bacterial fermentation of carbohydrate, with one by-product being hydrogen. Because hydrogen is freely diffusible from the bowel into the blood, and from the blood into the alveoli, measurement of exhaled hydrogen gas can be used to assess the status of intestinal bacterial fermentation of carbohydrates. In horses, the hydrogen breath test is most applicable to conditions in which there is carbohydrate malabsorption and thus increased delivery of soluble carbohydrate to the large intestine for bacterial fermentation to occur. There are two reports of this technique in horses, one in which different carbohydrate substrates were evaluated in ponies[56] and another in which the hydrogen breath test was used in conjunction with D-xylose absorption in nine horses with a variety of clinical disorders.[57] In the study with ponies ($n = 7$), fasting resulted in negligible levels of breath hydrogen excretion. Sustained increases in breath hydrogen concentration greater than 10 parts per million (ppm) were observed for all ponies after the ingestion of oats or the administration of wheat flour, for three ponies after the

VetBooks.ir

administration of glucose and xylose, and for two ponies after the administration of lactulose and lactose. The pattern of breath hydrogen excretion was subject to variation among animals after the ingestion of identical test meals. In the clinical study the diseased horses showed higher fasting breath hydrogen (H_2) levels (range 7.5 to 61.5 ppm) than normal horses (range 0 to 5 ppm). After xylose administration, none of the healthy animals showed an increase in breath H_2 production, and five of diseased animals showed increases in breath hydrogen. In this group of patients, abnormalities in hydrogen breath measurement were more apparent than abnormalities in D-xylose absorption.

Dentistry and Oral Disease

Jack Easley

The equine species has evolved as a continuously grazing animal, developing its own dental form and function over millions of years. Its oral and dental structures provide the horse with the ability to detect, prehend, masticate, and begin the digestion of mixed grass forage. As humans have domesticated and confined the horse, we have altered its diet to consist of grazing improved pastures and more interval feedings of dry hay, grain, processed forages, and concentrates. Selective breeding and domestication practices have increased the incidence of equine dental and oral disease in modern equine populations.

Anatomy and Function

The structures the horse uses in eating include tactile and prehensile lips, hypsodont incisors, premolars and molars, the facial bones, muscles of mastication, tongue, hard palate, buccal mucosa, cheeks, olfactory organs, taste buds, salivary glands and ducts, and the blood vessels and nerves that support them. The equid oral cavity is long and cylindrical and is the entrance to the alimentary canal. The muscular lips form the entrance to the mouth, which is bound laterally by the cheeks, dorsally by the palate, and ventrally by the body of the mandible and the mylohyoid muscles. The caudal aspect of the mouth is composed of the soft palate, root of the tongue, and epiglottis and is continuous with the oropharynx.[1-2]

The blood supply to the mouth is derived from the maxillary, mandibular, labial, and sphenopalatine arteries. The venous drainage is chiefly through the linguofacial veins. Nerve sensation to the mouth, cheeks, and lateral aspect of the tongue is derived from the mandibular and maxillary branches of the trigeminal nerve (cranial nerve [CN] V). The sublingual and mandibular salivary glands, lacrimal glands, and facial and labial muscles receive motor function from the facial nerve (CN VII). The hard palate has a central raphe, dividing the surfaces into right and left halves. The portion of the palatal mucosa just caudal to the upper incisors may appear swollen in the young horse when permanent incisor teeth erupt. This normal mucosal enlargement seen in 2- to 5-year-old horses has historically been referred to as *lampas*. Further caudal, the hard palate becomes more concave and contains paired transverse ridges that traverse the cavity. These ridges are instrumental in moving a food bolus caudally in a spiral fashion as the horse masticates forage. The muscular tongue sits in the bottom of the mouth between the paired hemimandibular rami. The tongue is supported in a sling formed by the mylohyoideus muscles. The root of the tongue is attached to the lateral aspect of the soft palate, the pharynx, and the hyoid bone. The lingual muscles receive their motor innervation from the hypoglossal nerve (CN XII) and sensory innervation from the lingual and glossopharyngeal nerves (CN IX).

The mandible is the largest bone of the face and is formed by the paired hemimandibles, which fuse rostrally at the mandibular symphysis when the horse is approximately 2 to 3 months of age. Each hemimandible is composed of a horizontal and a vertical ramus. The horizontal ramus contains the alveoli of the teeth in the lower jaw. The vertical ramus terminates with the coronoid process rostrally and the mandibular condyle caudally. The temporalis muscle inserts on the coronoid process.

Between the incisors and the rostral aspect of the mandibular cheek teeth in the horizontal rami of the mandible, is a large diastema; the interdental space or "bars" of the mouth. Canine teeth, if present, are located in this area. In the young horse, the central border of the mandible is wide and round. Eruption swellings or bumps are often seen on the ventral border of the mandible of young horses as the permanent mandibular cheek teeth erupt. As the horse ages and eruption of the mandibular cheek teeth continues, the ventral border of the mandible takes on a sharper, angled appearance.

The paired incisive (premaxillary) bones form the rostral part of the upper jaw and contain the alveoli of the upper incisors. Caudally, the incisive bone becomes thinner and forms the rostral part of the hard palate. The suture line between the incisive bones and the maxillary bones is an anatomically weak area and a common site of facial fractures. The upper canines (if present) are situated just caudal to this suture line.

The paired, large maxillary bones extend from the incisive bone rostrally to the nasal bones dorsally and lacrimal bones caudally. The facial crest is a prominent ridge of bone on the lateral aspects of the maxillae. This crest continues caudally as the zygomatic process and joins the molar and temporal bones to form the zygomatic arch. The ventromedial aspects of the maxillary bones join to form a horizontal shelf that provides rigid support to the majority of the hard palate. The alveoli of the upper canines, premolars, and molars are embedded in the maxillae. The positions of the upper cheek teeth alveoli are somewhat variable, but usually the alveoli of the first two cheek teeth lie rostral to the maxillary sinuses. The third and fourth cheek teeth lie within the rostral maxillary sinus in the young to middle-aged horse. The caudal two cheek teeth lie within the caudal maxillary sinus. Each alveolus is separated by transverse interalveolar bony septa.

The horse has seven paired paranasal sinuses: ventral conchal, dorsal conchal, frontal, sphenopalatine, caudal maxillary, rostral maxillary, and ethmoidal sinuses. The rostral and caudal maxillary sinuses are contained within the maxillae and are usually separated by a thin bony septum, although this septum often breaks down with sinus disease. The long infraorbital canals (one on each side of the head) traverse longitudinally through the maxillary sinuses, encasing the large paired infraorbital nerves.

Sinusitis can occur secondary to disease of the third, fourth, fifth, and sixth upper cheek teeth and classically results in a unilateral, malodorous nasal discharge. In a young horse, virtually the entire maxillary sinuses are occupied by dental alveoli. Therefore, as the facial bones grow and reserve crowns of the upper cheek teeth erupt, the cheek teeth move forward and ventral in the sinus compartments. The maxillary sinuses drain into the back of the nasal cavity via a slit-like aperture, the nasomaxillary opening. The medial compartment of the rostral maxillary sinus is called the *ventral conchal sinus*. This compartment has poor drainage and is a common site for inspissated pus to accumulate. Its secretions must drain dorsally over the infraorbital canal into the lateral compartment of the rostral maxillary sinus. Drainage from both sinuses courses into the caudal middle meatus adjacent to the drainage angle of the caudal maxillary sinus.

The temporomandibular joint is a synovial joint formed by the articulation of the squamous temporal bone and the condylar process of the mandible. The joint lies approximately 15 cm above the level of the occlusal surface of the cheek teeth. The joint cavity is large and divided in two by a cartilaginous intraarticular disc. The joint is bound by a tight capsule and lateral and caudal ligaments. The equine temporomandibular joint has a wide range of lateromedial movements (allowing the medial directed power stroke of mastication) but limited vertical and rostrocaudal movements.

As a result of the wide lateromedial range of the temporomandibular joint, motion associated with the power stroke of chewing,

VetBooks.ir

the masseter and pterygoid muscles are the most highly developed muscles of mastication in the horse. The powerful masseter muscle originates along the full length of the facial crest and zygomatic arch and has wide insertions along the caudolateral aspect of the mandible. The superficial masseter muscle fibers run almost vertically while the deep fibers course in a ventrocaudal direction. The masseter pulls the jaw to the ipsilateral side and also contributes to closure of the jaw. The medial and lateral pterygoid muscles have origins and insertions similar to those of the masseter and these lie on the medial aspect of the mandible. The digastricus muscle originates on the occipital bone and attaches to the caudal aspect of the mandible and is small as a result of the minimal effort required to open the jaw with gravity assistance. The temporalis muscle, whose function is jaw closure, is also small and poorly developed in the horse due to limited vertical opening of the temporomandibular joint. The muscles of mastication are innervated by the motor branch of the mandibular nerve, which originates from the trigeminal nerve (CN V).

Teeth

At approximately 6 months of age, the foal has erupted 24 deciduous teeth. Development of the cranial and facial bones during the first 2 to 3 years of life allows room for the expansion of the dental formula from 24 deciduous to between 36 and 44 permanent teeth in the mature horse. The mature mouth of the horse contains six incisors each in both the upper and lower jaws and six permanent upper and lower cheek teeth on each side of the mouth (Fig. 32-40). The rostral three cheek teeth are premolars, and the caudal three cheek teeth are molars. Incisors and premolars have deciduous and permanent sets. Molars erupt at an older age and do not have deciduous counterparts. The cheek teeth of the upper jaw are broad and square, whereas the lower cheek teeth are narrower and rectangular shaped. The cheek teeth in each quadrant of the horse's mouth are commonly referred to by number, from rostral to caudal (1 to 6). The inconsistent and vestigial first premolar, often referred to as a "wolf tooth," is not included in the 1 to 6 nomenclature. To help avoid confusion, the American Veterinary Dental College Nomenclature and Classification Committee has endorsed use of the Modified Triadan Tooth Numbering System for the horse.[3] This three-digit tooth numbering system is based on a full phenotypic dentition composed of 44 total teeth. The first digit designates the quadrant and arcade location and whether the dentition is deciduous or permanent. The numbering sequence starts with 1 for the permanent upper right, 2 for the upper left, 3 for the lower left, and 4 for the lower right. As the permanent dentition is designated using numbers 1 to 4, the deciduous teeth quadrants are numbered 5 to 8. In each dental quadrant, the first central incisor is always 01 with incisors numbered 01 to 03. The canines, whether present or not, make up the 04 position in this formula. The premolars are numbered 05 to 08 and the molars 09 to 11.

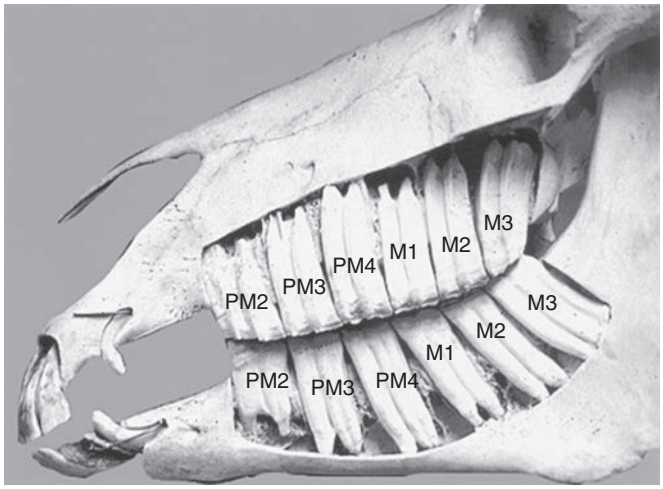

FIG. 32-40 Lateral view of equine cadaver skull. *M,* Molar; *PM,* premolar.

The equine incisor and molarized cheek teeth are hypsodont and have long anatomic crowns, which erupt throughout the life of the animal by a dynamic process of periodontal ligament and alveolar bond remodeling. The tooth crown is the enamel-containing portion of the tooth. When these hypsodont teeth first erupt, the occlusal surface is covered with cementum and enamel. As the teeth are subjected to masticatory forces and abrasive forage, the thin layers of occlusal cementum and enamel wear away, exposing the true or functional occlusal surface of the tooth. This process is termed *coming into wear.* The functional occlusal surface of hypsodont teeth is composed of thin, brittle sheets of hard enamel, sandwiched between softer but more stress-resistant layers of cementum and dentin. This three-textured occlusal surface is self-sharpening and very wear- and fracture-resistant. At the time of eruption, there are no true roots, and teeth are divided into apical and coronal regions, but most of the crown (reserve crown) lies within the alveolus. True roots are formed gradually over a period of 2 to 3 years after eruption.

The incisors and upper cheek teeth have enamel crown invaginations termed *infundibula.* These invaginations partially fill with cementum that receives its blood supply from the occlusal soft tissues covering the tooth prior to eruption. This shallow infundibulum presents on each incisor tooth and has a wide opening at the occlusal surface referred to as a "cup." As the tooth wears down over time, the small bottom portion of the infundibulum is exposed at the occlusal surface and is called the "spot." The upper cheek teeth have a rostral and caudal infundibulum. These extra enamel cones give the central area of these teeth a hard chewing surface. The center of the cement lake that fills the infundibulum contains a hole of variable diameter. This channel is a remnant (ghost) of the central blood vessel that supplied nutrition to the now dead infundibular cementum.

The interior of the tooth is composed primarily of dentine with primary dentine lining the common pulp chamber of the newly erupted hypsodont tooth. The pulp chambers of hypsodont teeth are active throughout the horse's life with primary and secondary dentine continually produced within the pulp cavity. This process of continuous secondary dentine production prevents pulp exposure at the occlusal surface as the tooth wears. The depth of secondary dentine at the occlusal surface of the pulp horns (seen as a brownish area on the occlusal surface of the tooth) varies in horses but is usually 5 to 7 mm thick. No age-related increased thickness of occlusal secondary dentine has been found in recent studies, which supports the theory that secondary dentine deposition is at least partially regulated by occlusal stimulation.[4-5] The pulp cavity in the young equine permanent cheek tooth is very large. With increasing age, it divides into smaller pulp chambers (or horns) as dentine deposition increases. From 2 to 4 years after eruption, mandibular cheek teeth have a distinct, apically located, common pulp chamber that communicates with the pulp horns. The number of pulp horns has been well described with five pulp horns present in the 07s to 10s, six pulp horns in the 06s, and six or seven pulp horns typically present in the 11s (Fig. 32-41). Two to four years after tooth eruption, the dentine divides the endodontic system of most of the mandibular cheek teeth into two distinct compartments or roots. Each compartment consists of a root canal, a pulp chamber, and two or three pulp horns. The maxillary cheek teeth, as well as the 311 and 411, have three roots: one palatal and two buccal. Because of the continuous production of cementum around the apical or root portion of the tooth and continuous crown wear, old equine teeth are primarily composed of dentine and cementum. When most of the crown enamel has worn away, the softer dentine and cementum are quickly worn flat, leading to the condition known as "smooth mouth."

Innervation of the dental structures is supplied by the trigeminal nerve (CN V), which exits the skull just below the ear. This nerve traverses rostrally and divides into the ophthalmic, maxillary, and mandibular branches. The maxillary nerve enters the caudal maxilla

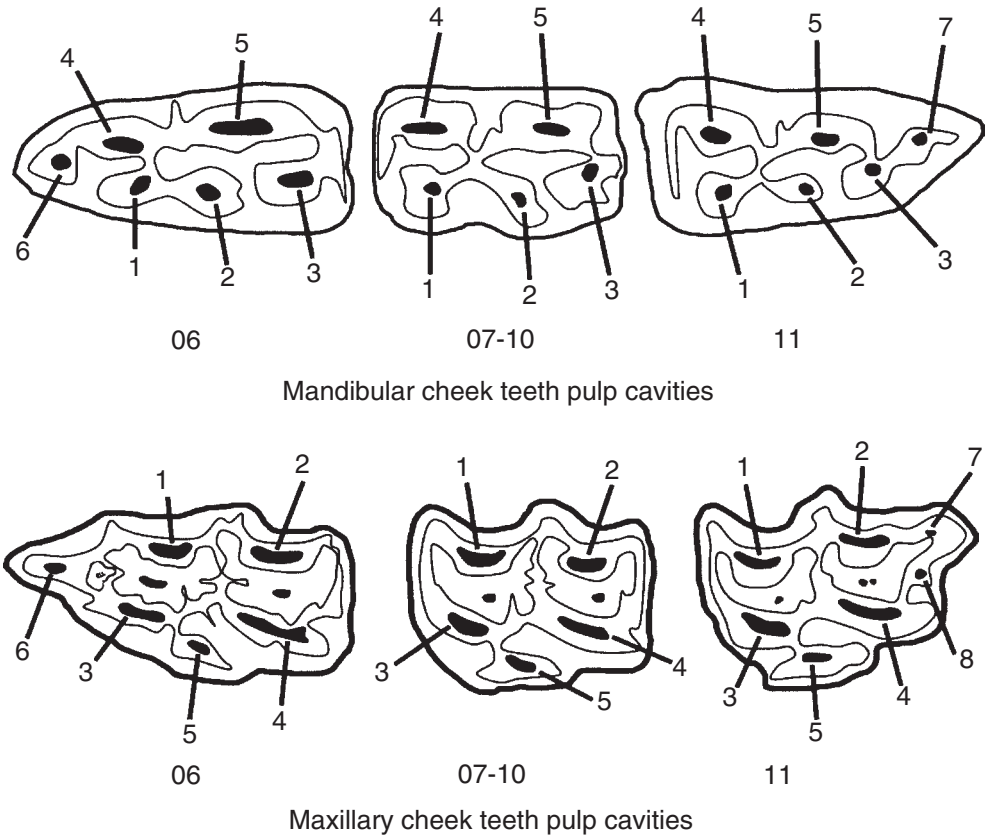

FIG. 32-41 Diagram of the premolar and molar pulp horns seen as areas of dark stained secondary dentine on the occlusal surface.

ventral to the orbit via the maxillary foramen and runs through the maxilla in the infraorbital canal, giving off branches to supply the maxillary cheek teeth. A branch of the infraorbital nerve exits the maxilla at the infraorbital foramen, just rostral and dorsal to the facial crest. The mandibular nerve runs medially along the mandible, with the lingual and inferior alveolar nerves arising as a common trunk and passing rostrally between the pterygoideus medialis and the ramus of the mandible. The inferior alveolar nerve enters the mandibular canal on the caudomedial aspect of the mandible, innervating the mandibular teeth. The mental nerve exits the mandibular canal via the mental foramen at the rostrolateral aspect of the mandible just rostral to the mandibular cheek teeth and supplies the ipsilateral soft tissues over the incisive portion of the mandible.

Rudimentary first premolars (wolf teeth) are constant in fetal life in both upper and lower jaws. Many never develop to the point of eruption but instead degenerate and become incorporated in the maxilla or mandible. The uppers erupt in 20% to 80% of horses; the lowers rarely erupt (1% to 5%).

Equine males normally have two upper and two lower canine (bridle) teeth. The upper canine erupts just caudal to the suture between the incisive and maxillary bones. Lower canines are forward, producing a long lower diastema or interdental space. Canines are absent or rudimentary in most mares.

The horse is anisognathic, meaning the bottom jaw is narrower (by about 25%) than the upper jaw. The lateral excursion of the jaw during mastication favors occlusal wear of the buccal aspect of the lower and the lingual aspects of the upper molar arcades. The horse's jaw anatomy and jaw motion have an effect on the angle of the molar tables.[7] As the horse chews, the jaw moves in rotational motion from side to side with limited rostral-caudal excursion. The construction of the molars with interdigitations of enamel, cementum, and dentine allows for uneven, continuous wear with a sharp, serrated surface when the horse is grazing. The extent of lateral excursion of the mandible during normal mastication is affected by the length of the stem or roughage in the horse's ration. A horse on pasture or hay has a full or wide area of mandibular excursion. However, horses eating pellets or concentrates have a limited range of lateral jaw excursion. Horses with limited lateral jaw excursion have incomplete wear of the molar surface, which predisposes the arcades to sharp enamel edges, a vaulted ceiling of occlusion, or the serious problem of shear mouth. Malocclusion of the incisor or molar arcades perpetuates abnormal wear patterns that will eventually predispose to diastema and secondary periodontal disease.

Rostral or caudal molar malocclusions or eruption problems (displaced, deformed, delayed eruption, missing or supernumerary teeth) lead to uneven dental wear. Horses with asymmetry between the upper and lower molar arcades (due to mandibular fracture, facial injury, congenital deformities such as brachygnathism [parrot mouth] and prognathism [sow mouth] or an abnormally narrow mandible in relation to the maxilla) often have abnormal tooth wear in the form of sharp enamel points, dental overgrowths (hooks or ramps), shear mouth, step mouth, or wave mouth.

The dynamic change that takes place in the mature horse's head continues at a slower rate throughout life, with continual eruption and crown wear of the hypsodont premolar, molar, and incisor teeth with their large reserve crowns and slowly forming short root structures. With continuous eruption and wear of the equine hypsodont teeth, all horses eventually wear their teeth smooth to the root.

Equine Dental Developmental Abnormalities

Equine dental developmental abnormalities can involve tooth number, morphology, or position in the dental arcades. Abnormalities of dental development and eruption occur quite commonly in the horse and result in a wide range of clinical conditions. A congenital/developmental problem that presents at the time of tooth eruption often leads to acquired dental problems as the teeth continue to erupt and wear. Some developmental abnormalities of the

VetBooks.ir

teeth of the very young horse may not cause it to exhibit clinical signs until middle age. Consequently, several different dental abnormalities, whose pathogenesis may be interrelated, are often present at the time of clinical presentation.[8-9]

Supernumerary Teeth

Supernumerary teeth are teeth in excess of the normal expected number in any of the dental arcades. This disorder has been referred to as *polydontia* or *hyperdentition*. Supernumerary teeth can be loosely categorized morphologically into two categories: (1) supplemental teeth that resemble teeth of the normal series in crown and root morphology but not always in size, and (2) rudimentary or dysmorphic teeth that are abnormally shaped and smaller in size than normal teeth.

In general, these extra teeth are encountered at the caudal aspects of the molar arcades, but supernumerary teeth can also occur lingual, buccal, or rostral to the normal arcades. Clinical signs most commonly associated with supernumerary cheek teeth are dental overgrowths and diastemata, which often cause secondary periodontal disease.

Supernumerary incisors are reported more often in horses than are supernumerary cheek teeth. The main differential diagnosis for supernumerary incisors or cheek teeth is retained deciduous teeth. In some cases, it may be clinically difficult to determine whether an extra tooth is a retained deciduous tooth or a supernumerary tooth. Examination with a radiograph that encompasses the entire affected dental arcade is often necessary to diagnose this condition. Radiographic examination of the affected jaw is often indicated to determine the identity of an extra tooth. A retained deciduous tooth has a more mature root and a shorter reserve crown than the adjacent permanent teeth. Such distinguishing characteristics are visualized with radiographs.

Management of horses with supernumerary teeth is generally limited to regular assessment of the dentition, coupled with aggressive dental floating to minimize the opportunity for soft tissue damage by unopposed elongations or sharp enamel points. If complications such as severe periodontal disease or maxillary sinusitis occur, the supernumerary tooth or displaced adjacent tooth should be extracted and appropriate therapy undertaken to manage associated pathology.

Oligodontia

Oligodontia is the congenital absence of a tooth germ or retention and inclusion of a tooth within the jaw. It is difficult to differentiate developmental oligodontia from acquired tooth loss caused by damage to, or displacement of, a dental bud from injury. It is possible for permanent tooth germs of a young horse to be damaged, displaced, or removed when deciduous teeth or jaw bones are injured. Absence of a tooth in the dental arcade leads to dental drift or tipping of adjacent teeth. Lack of wear of the antagonist to the missing tooth can lead to dental elongations and abnormal mastication. Radiographic examination is often necessary to confirm a diagnosis of true oligodontia. Oligodontia may be associated with other epidermal defects such as poor development of hair and hooves.

Dental Dysplasia or Hypoplasia

Dental dysplasia (i.e., abnormal growth and/or development of a tooth or teeth) may result in an irregularly shaped tooth that does not fit well into a dental row. The poor fit may lead to food entrapment and periodontal disease. Enamel hypoplasia has been associated with certain drugs or chemicals administered to the dam during gestation, or it may be idiopathic in origin. Dental dysplasia can involve the abnormal formation of the entire tooth structure or only a single tissue type. Abnormal enamel morphology, such as branched pulp horns or abnormally shaped teeth, has been observed. Enamel acts as the scaffolding and template for the deposition of dentine and cementum. These tissues follow the abnormal enamel pattern, and consequently all three calcified tissues are dysplastic. Cemental hypoplasia usually involves the infundibular portion of the tooth, but it can also be seen as a defect of the peripheral, coronal, or reserve crown or root cement.

Abnormal Dental Eruption

Abnormal dental eruption, or maleruption, is often seen following trauma to developing teeth or surrounding bones, but it has also been reported to be congenital or idiopathic in origin. Cheek teeth can become vertically impacted when dental buds are developing in abnormal or crowded areas in the dental arcades. Teeth may become rotated or otherwise displaced as a result of developmental malpositioning of tooth buds or overcrowding before, during, or after eruption.

Dixon reported that 70% of cheek tooth displacements were developmental in origin as a result of overcrowding of the cheek tooth row at the time of eruption.[6] This research team frequently found that if a cheek tooth was displaced in an arcade, the same tooth in the contralateral arcade was also displaced. The remaining 30% of tooth displacements were believed to be due to abnormal tooth positioning, which may result in non-eruption of the displaced teeth if they are sufficiently horizontal to the adjacent teeth. Developmental diastemata or abnormal spaces or gaps between cheek teeth are often due to insufficient angulation of teeth to achieve food compression between adjacent teeth. Another cause for diastemata is embryonic teeth developing too far apart.

A detailed oral examination includes checking teeth for proper number and position. Only the exposed crown of the equine tooth can be visualized in the oral cavity. Because many developmental defects may not be recognized simply by oral examination, the dentition should be examined radiographically to further delineate abnormalities.

Malocclusions of incisors are congenital, developmental, or acquired in origin. Mandibular brachygnathism (parrot mouth) is a congenital incisor malocclusion, the origin of which is usually genetic. Many horses have some degree of overjet of the premaxillary incisors, but the overjet rarely causes a problem with prehension, unless the premaxillary and mandibular incisors totally lack occlusion. If brachygnathism is discovered when the foal is young, treatment may correct, or at least improve, the functional outcome for the animal.

A main consideration with an incisor overjet in the adult horse is the cheek teeth malocclusions that accompany this condition. The maxillary cheek teeth arcades are usually positioned rostral to the mandibular cheek teeth, causing a rostral overgrowth of the 106 and 206 and a caudal overgrowth of the 311 and 411. Those check teeth malocclusions must also be reduced to allow for proper lateral jaw excursion and mastication.

Prognathism or undershot jaw occurs with less frequency in the horse and is seen most commonly in miniature or dwarf breeds. Early detection and correction of the malocclusion in the foal may prevent the condition from worsening with age. The cheek teeth should be evaluated for malocclusion caused by overgrowths of the 111, 211, 306, and 406.

Bony malformations of the head can result in malocclusion of the incisors and cheek teeth. These bony skull curvatures or asymmetries usually result in an offset or diagonal incisor bite. Some bony malformations, such as campylorrhinus lateralis (wry nose) are obvious, but subtle changes to the large bony plates in the head can be difficult to recognize. Care must be taken with correcting dental overgrowths associated with malocclusions. Overgrowths should be corrected gradually to prevent damage to pulp horns (which can lead to apical infection), dysphagia, and pain. Often, incisor malocclusion remains, but regular maintenance may prevent it from worsening.

Acquired Dental Disease

Dental disease is grouped into four basic categories or groups:

1. Type 1 dental malocclusions and abnormal occlusal wear patterns
2. Diastema and periodontal disease

VetBooks.ir

3. Infundibular or peripheral dental caries
4. Disease of the dental pulp

All of these basic dental disease types are interrelated, and in most clinical cases, the horse suffers from a combination of varying degrees of dental disease types.[8-11]

Alignment of the dental arcades is critical to the normal wear of equine dentition. Historically, abnormal dental wear patterns have been described as dental crown elongations, descriptive terms for which include *hooks, ramps, waves, steps,* and *transverse ridges.* These elongations usually involve a normal tooth that is out of occlusion with an abnormality in the opposite arcade. This opposite diseased, damaged, misplaced, or missing tooth and/or jaw should be evaluated when elongations are found. Most dental elongations are treated by reducing the crown height of the long tooth or portion of a tooth with a rasp or grinding instrument. Care should be exercised in dental reductions not to cause iatrogenic damage to the tooth, such as pulp horn exposure, thermal injury, or crown fracture. The viable pulp is usually 7 to 10 mm deep but may be as close as 2 to 4 mm below the occlusal secondary dentine. Therefore crown reductions should be carried out in stages, reducing no more than 3 to 4 mm of occlusal crown in a session.

Periodontal disease is often a painful dental condition and is described as the leading cause of "quidding" in horses. Gingivitis is the mildest form of periodontal disease and is often associated with local irritants such as plant awns or bristles, bot fly larvae, traumatic injury, or chemical exposure. Oral ulceration can be a reflection of systemic disease, such as vesicular stomatitis. Another mild form of periodontal disease affects primarily young horses 2.5 to 5 years of age when deciduous teeth (caps) are shed and permanent incisors and premolar teeth are erupting. A more progressive form of periodontal disease is seen in older horses as a result of the chronic effects of diastema or spaces that develop between teeth that are not aligned properly in the arcade. Diastema can form during tooth development when dental buds are spaced too far apart or abnormally angulated so that the teeth in a dental row are not properly compressed, allowing forage to become trapped between teeth. This is usually a progressive condition that, when left untreated, becomes worse over time. Spaces between teeth or teeth out of alignment in the dental row also predispose to abnormal wear patterns on the affected and opposing dental arcades.

Treatment of periodontal disease involves treating both the cause and the effect of the problem. Diastema with feed trapped in the gingival margin often responds to thorough cleaning with dental picks, irrigation, or both. Reduction of any associated abnormal wear patterns is also indicated. In more refractory cases, it may be necessary to open or widen the diastema with a special burr or a right angle grinder. This procedure may allow the horse's masticatory actions to more easily channel food in and out of the gap, thus preventing or reducing entrapment of feed or stagnations and decay. This procedure is not without risk of pulp exposure and should only be performed by a professional with the proper equipment and training.

Some practitioners have had positive results using high-pressure irrigation to clean out periodontal pockets, followed by packing the area with a perioceutic agent such as doxycycline gel or a powdered antibiotic. This technique packs a high concentration of antibiotic in contact with the infected and inflamed tissues and acts as a temporary barrier to recontamination. This form of therapy may need to be repeated on a regular basis (every 4 to 6 months) in order to achieve long-term positive results. Severe periodontal disease that has resulted in bone loss and tooth mobility will only respond positively to extraction of the involved teeth.

Dental caries usually involves the cemental layer of the tooth. Peripheral cemental caries is seen secondary to periodontal disease. The most common type of cemental caries involves the infundibular portion of the incisor and maxillary cheek teeth. All incisor infundibula show some evidence of cemental decay in the cup or open portion of the infundibula. The upper cheek teeth have two infundibula, each with a cup or open portion incompletely filled with cementum.[10] As the tooth wears, the infundibulum that is filled with cementum (except for the small central vascular channel) is exposed at the occlusal surface (referred to as the "spot" in the incisor teeth). Feed and other products of mastication can be compressed into a ghost of a vascular canal, and some degree of decay is always present. The infundibulum contains dead cementum and is lined with a layer of enamel. Therefore this decay does not usually lead to an inflammatory response or dental infection. True dental disease secondary to infundibular decay can occur only if this protective enamel layer is penetrated. Developmental malformations of the infundibulum may weaken this enamel and predispose to dentine exposure and pulp disease. In upper cheek teeth with very large vascular channels or deformed infundibula, decay may weaken the tooth and predispose the tooth to excessive crown attrition or midsagittal crown fracture. Infundibular caries lesions are innocuous in most cases, but the length of infundibulum and dental wear can predispose to dental elongations on the opposite occlusal arcades (wave mouth). The abnormal wear patterns need to be reduced on a regular basis. To help strengthen the tooth and delay the progression of infundibular decay, some practitioners advocate cleaning out abnormally enlarged infundibular vascular channels and partially packing and sealing them with a dental composite material. As advanced diagnostic methods such as CT become more readily available to equine practitioners, these abnormal appearing infundibula can be better evaluated and treated.

Disease of the dental pulp is seen primarily in younger horses between the ages of 4 and 10 years. The type of dental disease usually presents as an infection and associated inflammatory changes at the apical region of the tooth. The clinical presentation will be different depending on the structures adjacent to the apex of the affected tooth. Infections of the lower first four cheek teeth present as ventral mandibular swellings with a draining tract. The last two lower cheek teeth are embedded in the portion of the mandible surrounded by the large muscles of mastication. These muscles are often enlarged or swollen and, on ultrasound evaluation, exudate may be seen accumulating between the mandible and muscle. The upper rostral two or three cheek teeth apices are closely associated with the facial bones and nasal passages. The caudal three or four upper cheek teeth are in the maxillary sinuses and can be associated with secondary sinusitis. Unilateral nasal discharge is often seen when the upper cheek teeth are affected. Because pulp disease compromises the tissue responsible for the production of secondary dentine, the pulp horns and root canals on the affected teeth do not fill with secondary dentine as they should. In the later stages of pulp disease, the affected tooth usually shows some degree of pulp horn decay on the occlusal surface. This weakened, decayed area may predispose to crown fracture.[11-12] Medical therapy has been successful in the management of apical disease in the early stages of disease. Chronic apical infections are usually treated by surgically removing the tooth and treating any associated bone or sinus disease. Equine teeth have been removed surgically by three methods:

1. Extraction via oral approach
2. Repulsion via apical approach
3. Elevation via lateral buccotomy approach

More recently, minimally invasive procedures using small radiographic guided pins for repulsion or an oral trocar approach to teeth through the cheek have been developed.

Salivary Glands and Ducts

Saliva hydrates and lubricates the oral cavity, facilitates swallowing, prevents tooth demineralization, and regulates the oral flora.[13] Diseases of the salivary glands and ducts, including sialoadenitis, salivary calculi, salivary mucocele, trauma, and neoplasia are uncommon in the horse. During oral examination, the openings of the salivary ducts should be noted. The parotid salivary duct communicates with the oral cavity via a flap-like, dorsally directed papilla, opposite the upper third of fourth check tooth. The mandibular salivary duct opens into the mouth on the lateral aspect of the sublingual caruncle.

VetBooks.ir

The sublingual salivary ducts (approximately 30 in number) are seen as small pores in the sublingual recess.

Slobbering or drooling may indicate excessive accumulation of saliva in the mouth (sialism, ptyalism, or dysphagia). Heavy metal toxicity, parasympathomimetic poisoning, cholinesterase inhibiting insecticides (organophosphates or carbamates), neurologic disease, and stomatitis may cause ptyalism. A cholinergic agonist (slaframine) can cause "slobbers" in horses consuming forages, mostly commonly clover, contaminated with rhix. Dysphagia can be caused by esophageal obstruction (choke), oral foreign body, rabies, or other neurologic disease.

Sialoadenitis may be the result of salivary duct obstruction from accumulation of exudate or mucus or an ingested foreign body or sialolith. Sialoliths occur in the parotid duct and can cause duct obstruction and salivary retention, which can lead to glandular atrophy or acute sialoadenitis, swelling, and rupture. On palpation, sialoliths are usually hard, smooth, and painless enlargements over the course of the parotid duct on the lateral aspect of the jaw. The diagnosis of sialolith is straightforward and should differ from that of trauma, tooth abscess, or facial tumor. Surgical removal, usually orally, and primary closure often yield good results.

Salivary mucocele is an accumulation of salivary secretions in a single or multiloculated cavity adjacent to a ruptured salivary duct. A ranula is a type of mucocele that occurs secondary to obstruction of the sublingual salivary duct. Treatment consists of creating a salivary fistula into the oral cavity or excising the mucocele and associated salivary gland.

Laceration or iatrogenic injury to the salivary ducts can lead to salivary cutaneous fistula. These injuries can be surgically repaired by reapposing the severed duct and creating an oral opening for the duct or resecting the salivary gland. Oblation and sclerosis of the gland has been achieved by flushing 1% formalin solution into the duct. Wounds involving the salivary glands can usually be handled by cleansing, débridement, and primary skin closure.

Benign mixed tumors, adenocarcinomas, and acinar cell tumors of the salivary glands have been reported in horses. Local invasion of a salivary gland by tumor originating in adjacent tissues and metastasis of melanomas to the parotid salivary gland in older gray horses are more common.

Equine Oral Tumors

Equine oral tumors are rare, making up a very small percentage of the facial or mandibular swellings. These tumors can be divided into three basic types: odontogenic, osteogenic, and secondary.[14]

Odontogenic tumors are derived from remnants of dental epithelium. Five types have been recorded in the maxilla and mandibles of horses. They are ameloblastomas, ameloblastic odontomas, complex odontomas, compound odontomas, and cementomas. Because of their rarity, ill-defined biological behavior, and poorly defined radiographic features, diagnosis can be difficult. Histopathology can be confusing because of variation in appearance at different sampling sites and age-related changes in tumor appearance.

Primary bone tumors are rare in the horse and if present, they are usually benign. More than 80% of equine osteosarcomas occur in the head region. As is the case with odontogenic tumors, disagreement remains on histologic classification, terminology, and nature of tumor. In addition to gross and histologic examination, correlation of history clinical, radiologic, and some biochemical findings by clinicians and pathologists is often essential to establish a diagnosis.

Secondary tumors of the head include extensions of oropharyngeal squamous cell carcinoma, lymphosarcoma, papilloma, and melanoma. Squamous cell carcinoma is the most frequently reported oral tumor in the horse. Generally, these tumors are seen in older horses and there is no gender or breed predilection. There are many treatment options and methods of controlling the progression of oral tumors. Radiotherapy, hyperthermia, chemotherapy, cryosurgery, immunotherapy, autogenous vaccines, photodynamic therapy, laser therapy, and surgical resection have been used with variable success.

Dental Examination

Biannual dental examination of the horse should be performed as part of a routine health maintenance program. Improved eating efficiency and oral hygiene are the most important considerations from a medical standpoint. However, often owners are more enthusiastic about dental care because of its positive effects on the horse's sensitivity to the bit and athletic performance. Written documentation of dental examination findings is necessary to formulate a problem-oriented treatment plan and follow age-related dental changes and progress after maintenance, treatment, or both. A consistent routine on the part of the examiner increases the efficacy and quality of the examination (Box 32-1).

Several signs may be obtained from history or observed in a horse suffering from dental problems. A history of abnormal head carriage or head tossing when being ridden or eating, longer time taken to eat, halitosis, dysphagia, drooling or hypersalivation, dribbling feed (quidding), or eating hay before grain suggest that a dental problem exists. Indicators of dental problems in performance horses include tail wringing, headshaking, lunging in or out on the track, and fighting the bit (refusing to collect the head). Chronic colic or choke can result from improper mastication of feed. Reluctance to drink cold water may be a result of dental pain.[8,9,15]

Good dental health is extremely important to the equine digestive system. Proper mechanical digestion of feed allows better carbohydrate absorption in the small intestine and improved fiber fermentation in the cecum and large colon. Improperly masticated roughage and concentrate leads to poor digestibility in the small and large intestine because of large feed particles with decreased surface area per mass. This decreased surface area does not allow proper enzyme degradation or bacterial fermentation. Findings of whole grain or stem particles longer than 5 mm during manure examination indicate improper mastication.

As a routine aspect of the dental examination, a horse's overall condition should be evaluated in light of its use and dietary intake. A body score should be assigned, as this is a more accurate way to subjectively record body condition[16] (Table 32-1). Objective assessment of body condition using a scale, weight tape, or photographs is also beneficial and provides good data to assist in proper documentation and management.

The age of the horse should be considered during evaluation.[17] Different conditions need to be addressed for each stage of the horse's growth, development, and maturity. The use of the horse should be considered during evaluation, because horses that wear a bit might require dental care that differs from dental care required by horses that don't wear a bit. Stable surroundings should be carefully observed for evidence of vices (such as cribbing) or poor eating habits (such as quidding or dribbling grain).

The physical examination begins with observation of the horse's body condition, attitude, and temperament. The horse should be approached from the left side of the shoulder. Body and head conformation should be considered during evaluation of the masticatory system. Horses with small heads have more of an angle in the curve of the mandibular ramus (i.e., curvature of Spee) and are predisposed to dental crowding and ramps on the lower dental arcades. Observe the head from both sides and the front, noting any asymmetries, protuberances, or swellings. Check the tongue for proper movement, abnormal swellings, or signs of trauma or injury; also check the horse's ability to swallow. Lacrimation should be noted as well as any nasal discharge. Neurologic evaluation should be considered if any cranial nerve deficits are detected. Finally, examine the head by palpating the mandibular rami, masticatory muscles, temporomandibular joints, and submandibular lymph nodes to detect enlargements or asymmetry.

The frontal and maxillary sinuses should be percussed with the horse's mouth open. The width between the mandibular ramus should be noted as this correlates with the room in the mouth for the bit. The sides of the head lateral to the upper dental arcade should be compressed from the orbit, moving forward to the first cheek tooth

VetBooks.ir

BOX 32-1

Recommended Timetable for Routine Dental Examinations and Common Corrective Procedures

Birth

1. Examine for congenital defects of lips or palate.
2. Assess tongue motion and strength.
3. Identify dental malocclusions.
4. Evaluate all body systems.

Recommended Procedures

1. Provide genetic and orthodontic consultation and perform corrective surgery if necessary.
2. Look for other problem signs such as underdeveloped carpal or tarsal bones, ruptured extensor tendons, hernias, etc.

6 to 8 Months of Age

1. Check incisor and premolar occlusions.
2. Check to see that all incisors have erupted.
3. Check for sharp enamel points or hooks.
4. Check tongue and buccal mucosa for ulcers.

Recommended Procedures

1. Provide orthodontic consultation, and float teeth if necessary.

16 to 24 Months of Age

1. Check for expanded lower wolf teeth eruption.
2. Check points and hooks on premolars.
3. Look for bit lesions.

Recommended Procedures

1. Float teeth and round off rostral corner of premolar 2.
2. Extract wolf teeth.

2 to 3 Years of Age

1. Look for upper and lower wolf teeth.
2. Check corners of mouth and interdental space for bite injuries.
3. Evaluate incisors and molars for eruption and premolars for points and loose or retained deciduous teeth.

Recommended Procedures

1. Float outside of upper and inside of lower cheek teeth.
2. Remove caps if present and ready.
3. Extract wolf teeth.

3 to 4 Years of Age

1. Check corners of mouth and interdental space for bit injuries.
2. Evaluate incisors for retained deciduous teeth or supernumerary teeth.
3. Evaluate molars for eruption and premolars for points and retained or loose deciduous teeth.
4. Evaluate size and shape of lower jaw and percuss sinuses.
5. Check for blind wolf teeth.

Recommended Procedures

1. Remove caps if present and loose.
2. Float teeth.
3. Remove wolf teeth.

4 to 5 Years of Age

1. Check all incisors for eruption and wear occlusion.
2. Check canine teeth for sharp edges or eruption delays.
3. Evaluate entire molar arcade for proper eruption and alignment (third cheek tooth).
4. Visually check upper rostral and lower caudal cheek teeth for hooks from malocclusion.
5. Digitally check for points on sharp edges of cheek teeth.
6. Percuss sinuses.

Recommended Procedures

1. Remove deciduous teeth if loose and ready.
2. Reduce hooks if present.
3. Float teeth.
4. Remove mucosa over canines if gingival cysts are present.

5 Years and Older

1. Examine mouth visually and digitally, especially noting hooks and uneven wear.
2. Evaluate canines for sharp edges and tartar.
3. Percuss sinuses.
4. Use olfactory senses to detect evidence of oral decay or gingivitis.
5. Observe incisors for even wear.
6. Evaluate lateral jaw excursion.

Recommended Procedures

1. Float teeth.
2. Remove hooks.
3. Level or shorten incisors if indicated.

at the level of the nasal notch; note any protuberances, depressions, asymmetry, or evidence of pain.

The commissures of the lip should be observed and palpated for signs of trauma from sharp teeth or improperly fitting bits. A loose-fitting halter is necessary to properly evaluate the mouth and oral cavity. If the horse is fractious or resists examination, sedation should be administered before proceeding with the oral portion of the examination. Sedation should be given after a medical assessment of the animal (i.e., consideration of temperament, breed, age, body condition, mucous membranes appearance, CRT, heart rate and rhythm, and rectal temperature).

The mouth should be rinsed thoroughly with clean water. Impacted or trapped feed in the mouth should be removed manually or by using a dental pick and irrigation. Horses with sharp buccal points on the upper dental arcade often resist the full-mouth speculum. Floating the upper arcades before applying the speculum may decrease the horses' resistance. With a full-mouth speculum in place and the head properly restrained, a detailed visual and tactile oral examination can be carried out. A bright light source is necessary to illuminate the entire oral cavity for complete visual inspection. An examiner should manually inspect all hard and soft tissue in the oral cavity. A dental mirror and pick are often necessary to see and probe the occlusal surfaces and pickets between the cheek teeth. An oral endoscopic camera can aid in the completeness of the oral examination.

Dental Imaging

Diagnostic radiology is a valuable aid in the diagnosis and management of equine dental disease. The excellent contrast among air, bone, soft tissue, and tooth substance make the head an excellent area for radiologic evaluation. Good-quality films can be obtained with portable x-ray machines and rare-earth intensifying screens without a grid. Digital and computed radiology have improved radiograph image quality and allow for high-quality images to be shared electronically for consultation with colleagues.

Indications for radiographic examination of the head include a suspicion of dental infection, maleruption, diastema, or oral pain of unknown origin. Radiographs should be obtained before, during, and after dental extraction. Any facial swelling, deformity, neoplasm, trauma, or fracture may warrant a radiograph to aid in diagnosis and management.

Radiographs can be taken in the standing, sedated horse. The head and radiographic cassette can be placed on a stand to decrease motion distortion. A lateral view centered over the rostral edge of the facial crest will demonstrate fluid line in the sinuses. The lateral view

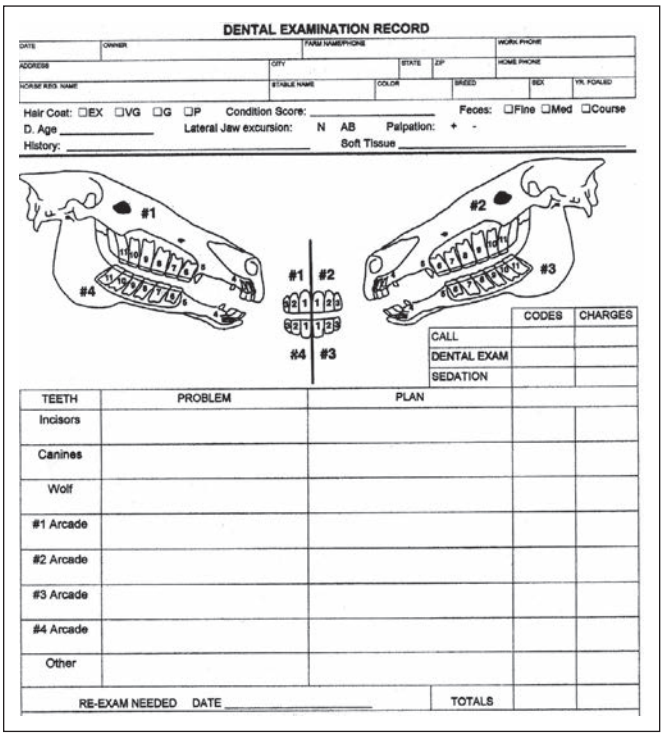
Henneke Body Condition Scoring System



Condition	Neck	Withers	Shoulder	Ribs	Loin	Tailhead
1 Poor	Bone structure easily noticeable	Bone structure easily noticeable	Bone structure easily noticeable	Ribs protruding prominently	Spinous processes projecting prominently	Tailhead, pinbones, and hook bones projecting prominently
2 Very thin	Bone structure faintly discernible	Bone structure faintly discernible	Bone structure faintly discernible	Ribs prominent	Slight fat covering over base of spinous processes Transverse processes of lumbar vertebrae feel rounded Spinous processes are prominent	Tailhead prominent
3 Thin	Neck accentuated	Withers accentuated	Shoulder accentuated	Slight fat cover over ribs Ribs easily discernible	Fat buildup halfway on spinous processes, but easily discernible Traverse processes cannot be felt	Tailhead prominent, but individual vertebrae cannot be visually identified Hook bones appear rounded, but are still easily discernible Pin bones not distinguishable
4 Moderately thin	Neck not obviously thin	Withers not obviously thin	Shoulder not obviously thin	Faint outline of ribs discernible	Negative-crease (peaked appearance) along back	Prominence depends on conformation Fat can be felt; hook bones not discernible
5 Moderate (ideal weight)	Neck blends smoothly into body	Withers rounded over spinous processes	Shoulder blends smoothly into body	Ribs cannot be visually distinguished but can be easily felt	Back is level	Fat around tailhead beginning to feel soft
6 Moderately fleshy	Fat beginning to be deposited	Fat beginning to be deposited	Fat beginning to be deposited	Fat over ribs feels spongy	May have a slight positive crease (a groove) down back	Fat around tailhead feels soft
7 Fleshy	Fat deposited along neck	Fat deposited along withers	Fat deposited behind shoulder	Individual ribs can be felt with pressure, but noticeable fat filling between ribs	May have a positive crease down the back	Fat around tailhead is soft
8 Fat	Noticeable thickening of neck	Area along withers filled with fat	Area behind shoulder filled in flush with body	Difficult to feel ribs	Positive crease down the back	Fat around tailhead very soft
9 Extremely fat	Bulging fat	Bulging fat	Bulging fat	Patchy fat appearing over ribs	Obvious crease down the back	Bulging fat around tailhead

superimposes the dental arcades and should not be relied on to diagnose diseases involving the dental reserve crown and roots. Lesion-oriented oblique films demonstrating the root or apical portion of the upper or lower cheek teeth are helpful in diagnosis of periapical disease. Open-mouth oblique films are beneficial in evaluating the exposed crown of the dental arcades. Special 4- by 8-inch flexible dental cassettes can be used to obtain intraoral radiographs of the maxillary dental arcades. Dorsoventral views centered over the tooth in question or area of concern can demonstrate periodontal disease on the buccal aspect of the upper cheek teeth, fractured teeth, or large area of infundibular decay. Intraoral occlusal films are useful in demonstrating incisor lesions or fractures rostral to the bars of the mouth. Other imaging techniques, such as ultrasonography, nuclear scintigraphy, computed tomography, and magnetic resonance imaging are useful in the diagnosis of many oral and dental-related diseases.[18]

Treatment

A plan for treatment based on the results of history, clinical findings, and oral examination should be outlined before proceeding with any dental work. This problem-oriented approach ensures that the owner and/or trainer is informed of any abnormalities and is given a plan for treatment, as well as an estimate of the cost, before any corrective procedure is taken.

Therapy must be planned to ensure all equipment is present to complete the prescribed task. The horse should be properly restrained and adequate help present to assist in performing and completing the

Routine Dental Maintenance

FLOATING (ODONTOPLASTY OF ENAMEL POINTS AND DENTAL CROWN ELONGATIONS). Dental floating is an age-old and routine method to correct the abnormal wear patterns associated with equine dental eruption and occlusal wear. Floating is also a procedure that allows the sculpting of the teeth to accommodate the bit. The main purpose of molar floating (leveling) is to remove points or sharp edges from the buccal aspect of the upper and lingual aspect of the lower molar arcades. Floating may also entail removing minor hooks or ramps from the rostral or caudal aspect of the arcades or leveling minor elevations on the occlusal surface of the arcades.

Proper equipment is required to reach all aspects of the cheek teeth molar surfaces completely, regardless of horse size. Smaller instruments are often needed to access the oral cavity of a miniature horse or pony. Longer, heavier instruments are often used to work in the mouths of large, warmblood, or draft horse breeds. Sharp float blades made of carbide chips or tungsten carbide planning blades make the work of floating more efficient and less strenuous than in the past. The outward curve of the upper arcade makes the central buccal area involving premolar 3 (PM3) through molar 2 (M2) the easiest to reach with the float. The area around PM2 and M3 requires an offset or angled head on the rasps to reach all extremities. In most cases the lower arcade can be floated to remove the lingual enamel points with a flat, long-handled rasp. To correct rostral and caudal hooks, specialized tools such as carbide planning blades or power burrs may be required. The use of all dental equipment requires special training and skill to prevent iatrogenic injury to the horse's mouth.

Use of a full-mouth speculum aids in the oral examination and floating procedures. Use of a speculum ensures the horse's mouth is kept in an open, safe (for the examiner as well as the animal) position for floating. In horses with slightly ramped back teeth caused by a greater curvature of Spee, a mouth speculum and a slightly curved or swivel-head float may be required to reach the table of the last molar.

In bitted horses, the rounding of the first upper and lower cheek teeth and lowering of the buccal cusps from upper PM2 and PM3 is referred to as a "bit seat" and usually requires an offset float or an S-shaped rasp. In theory, a bit seat is fashioned to prevent the soft tissue of the mouth from pressing against sharp points on the first premolars. To prevent pulp cavity exposure, care should be taken not to "overfloat" the occlusal surface of a tooth when forming bit seats or correcting overgrowths, as this could lead to a direct pulp horn exposure.[5] Routine floating and other corrective measures in the mouth may require the added physical restraint of a dental halter and mild chemical sedation.

WOLF TEETH. Wolf teeth are the first premolars to erupt and are present in 20% to 80% of horses. They are most often located in the upper arcade and seldom present in the lower arcade. Horses that are worked with a bit in their mouth benefit from having the wolf teeth extracted. Some wolf teeth are naturally exfoliated at about 3 years of age when the first cheek teeth (or 06 caps) are shed and the permanent tooth erupts. Although not all wolf teeth cause problems, a loose or sharp wolf tooth can be a distraction or even cause pain of such severity as to lead to bad bitting habits. In some instances, diagnosis of wolf tooth problems is difficult and confusing. Sometimes they do not erupt in a normal downward path, penetrating the gum but rather migrating rostrally under the gum and causing a subgingival enlargement, which in turn, is irritating to the horse. Such unerupted first premolars have been referred to as "blind" wolf teeth and should be removed. Most wolf teeth are easily elevated with the horse sedated and/or after infiltrating a small volume of local anesthetic around the tooth.

CANINE TEETH. Canine teeth are present in most male horses over 4 years old. Their unopposed position in the bars of the mouth make them unlikely to cause problems. Some mares have small or rudimentary canines that do not seem to cause a problem but can become loose or accumulate tartar and necessitate removal. Long or sharp canines in a stallion or gelding can interfere with bitting, be a nuisance or a danger to the groomer/handler, or become an area of tartar accumulation. Erupting canine teeth in the 4- to 6-year-old horse may cause an operculum to form and lead to subgingival pain and bit irritation, which may manifest as headshaking or other bad habits. The thin layer of tender mucosa should be removed over the canine if the gingival operculum is present. Severe calculus accumulation can be present on the lower canines, which predisposes to periodontal disease. Scaling calculus and frequent brushing of lower canines can control this problem in most horses.

The canine roots are long and curved, making this tooth extremely difficult to extract in the male. If the canine becomes injured, infected, or involved in painful odontoclastic tooth resorption, surgical removal through a bone flap is indicated.[19]

DENTAL CAPS. As the developing permanent tooth (incisor or premolar) pushes toward the surface, it presses on the roots of the worn down deciduous tooth, gradually cutting off that tooth's nutrition. The deciduous tooth becomes loose, its blood supply diminishes, dies, and the tooth is displaced occlusally. The osseous alveolar wall adjusts to these changes by bone production and resorption, thereby providing a new socket for the embedded portion of the newly formed permanent tooth. The remaining cap portion of the deciduous tooth has up to four "legs" (root slivers) that cover the crown of the permanent tooth. If these slivers are broken off and remain subgingivally after the cap has shed, gingivitis and periodontal disease often result.

The eruption pattern of permanent molarized dentition follows a sequence that predisposes to entrapment of deciduous PM3 and PM4.[20] Delayed shedding of deciduous premolars can predispose to gingivitis, periodontal irritation, or apical infection. Retained, split, or displaced deciduous premolars can be distracting to the training

VetBooks.ir

process of a young horse and may have been a factor in dorsal displacement of the soft palate.

Retained caps can cause displacement or delayed eruption of permanent teeth. Clinically, they present as bony enlargements on the ventral mandibular ramus or on the maxilla, rostral to the facial crest. Often, such swellings are benign. However, they can become diseased if eruption is severely inhibited or blood-borne bacteria inhabit the inflamed dental pulp, leading to anachoretic pulpitis and bony swelling with a draining tract. Caps should be evaluated visually as well as by manual palpation. A crease or indentation can be felt just above the gum line at the juncture of the separating deciduous and permanent tooth. Radiographs may be necessary to diagnose retained deciduous premolars.

Disorders of the Esophagus

Samuel L. Jones

Anatomic and Physiologic Considerations

The most cranial aspect of the esophagus is located on the median plane immediately dorsal to the trachea. However, at approximately the midcervical region (C4 to C5), the esophagus typically shifts to the left of the trachea and lies just deep to the external jugular vein.[1,2] It is here that intraluminal obstructions or the tip of a stomach tube may be visualized, and this is the region where trauma can readily result in esophageal perforation. When a stomach tube is passed, it is critical that the tube be palpated to ensure the tube is in the esophagus because jugular pulses can be confused with the appearance of the tip of the tube. In addition to its proximity to the external jugular vein, the esophagus is also located adjacent to the vagosympathetic trunk and the common carotid artery.[1] The esophagus is innervated by branches of the vagosympathetic trunk, and blood is supplied to the cervical esophagus by branches of the carotid arteries. The thoracic esophagus, which lies ventral to the trachea until it reaches the tracheal bifurcation, where it resumes a dorsal position, receives its blood supply from the bronchoesophageal artery. Venous drainage is via the external jugular veins in the cervical esophagus and the esophageal vein in the thoracic esophagus.

The muscular wall of the esophagus increases in thickness as the esophagus courses distally, while the lumen gets smaller.[1] The esophagus is not covered by a serosa except for a very short segment that traverses the abdominal cavity between the diaphragm and the stomach.[2] Instead, the outer wall of the esophagus is composed of adventitia that is loosely attached to surrounding tissues. This loose connection allows movement of the esophagus during swallowing and during movement of the neck. The cranial two thirds of the esophageal wall consists of skeletal muscle, whereas the distal third of the esophagus is composed of smooth muscle. Although the muscular layers are composed of an outer and an inner layer, similar to the remainder of the gastrointestinal tract, the skeletal muscle layers are oriented obliquely to one another.[1] This, and an abundant submucosa, enables extensive dilation of the esophagus as a bolus of food moves toward the stomach. In addition, the velocity of esophageal contraction is faster in the skeletal muscle segment of the esophagus compared with the distal smooth muscle segment.[3] The muscle layers become oriented in more of an outer longitudinal and inner circular configuration in the caudal esophagus.[1] In the resting collapsed state, redundant esophageal mucosa and submucosa become oriented in longitudinal folds. The mucosa is composed of stratified squamous epithelium that is continuous with the stratified epithelium of the cardiac portion of the stomach.[1]

The cranial esophageal sphincter is formed by the cricopharyngeus muscle and maintains a resting intraesophageal pressure of approximately 85 mm Hg and a postdeglutition pressure as high as 200 mm Hg. Although the caudal esophageal sphincter is anatomically indistinct, resting intraesophageal pressure in this region is maintained at approximately 13 mm Hg, and postdeglutition pressure in the caudal esophagus may be as high as 100 mm Hg. The pressure in the caudal esophagus is maintained at approximately 10 mm Hg higher than the intraluminal pressure of the stomach.[3,4] Although the higher pressure in the distal esophagus has been implicated as the cause for the inability of most horses to vomit and for gastric rupture, other factors such as a poorly developed vomiting reflex may be more important.[5]

Diagnostic Considerations

Esophageal disease should be a differential diagnosis in any horse that demonstrates excessive salivation. Such signs also indicate the need to assess hydration, electrolyte levels, and acid-base status. In a study in which horses had continual loss of saliva via an experimentally placed esophagotomy, abnormalities included hypochloremia, hyponatremia, and hypokalemia.[6] This results from the relatively high levels of these electrolytes in saliva. Furthermore, because horses depend on dietary intake of potassium, hypokalemia would be exacerbated in a horse that was also unable to eat because of esophageal obstruction. Loss of salivary fluid and bicarbonate also results in dehydration and metabolic acidosis. However, metabolic alkalosis subsequently occurs, presumably as a result of renal compensation for electrolyte loss, particularly chloride.[6]

Further examination of horses with esophageal disease may reveal evidence of swelling or emphysema in the region of the cranial or cervical esophagus that should prompt a thorough oral examination and further diagnostics such as radiography and endoscopy to define the nature of any esophageal abnormalities. If the esophagus has been perforated or ruptured, subcutaneous emphysema is usually evident. The lungs should be carefully auscultated for evidence of aspiration pneumonia. Radiographs of the chest are required for a full pulmonary assessment.

Radiographs of the esophagus should initially include plain films that may reveal evidence of an obstruction or areas of gas opacity within facial planes indicative of esophageal perforation.[7] However, facial and subcutaneous emphysema must be differentiated from other causes, including tracheal perforation.[5] The esophagus is often gas-distended cranial to an obstruction up to the cranial esophageal sphincter. Plain films may be diagnostic, but contrast radiographs are frequently required to fully define the nature of esophageal abnormalities.[7] Administration of barium paste or liquid will reveal linear opacifications as a result of the linear mucosal folds and may help outline intraluminal obstructions or strictures (Fig. 32-43).[7] A double-contrast study is a useful radiographic technique for defining esophageal wall abnormalities, particularly postobstruction mucosal ulceration. It is performed by placing a cuffed nasogastric tube in the cranial esophagus and injecting 300 to 500 mL of liquid barium

FIG. 32-43 Barium contrast esophagram outlining esophageal luminal structure. *(Courtesy Dr. K.E. Sullins.)*

VetBooks.ir

VetBooks.ir

followed by a similar volume of air. Care should be taken when evaluating such radiographs, because swallowing can create the false impression that there is a stricture.[8] The incidence of swallowing can be decreased by administration of xylazine. Liquid barium is preferable if swallowing function is compromised because it is less harmful to pulmonary tissues than paste, and water-soluble iodinated contrast material is particularly damaging to the lung because of its hypertonicity.[5] However, if an esophageal perforation is suspected, water-soluble contrast material is preferable.[5]

Ultrasonographic examination of the cervical esophagus is often helpful to identify the exact location of obstructions and to determine whether abnormalities of the esophagus are present. Perforations can be identified by periesophageal gas patterns. Whereas intraluminal contents cannot often be examined with ultrasonography because of the presence of air, abnormalities of the mucosal or muscularis layers can be identified. Intramural or extramural causes of esophageal problems (particularly obstructions) may be discovered using ultrasonography. The location and characteristics of masses (neoplasia, granulomas, abscesses, etc.) may be evaluated more readily with ultrasonography versus radiography or endoscopy. The thoracic esophagus cannot be evaluated using ultrasonography.

Endoscopic evaluation of the esophagus should be performed as part of a complete evaluation of esophageal injuries and abnormalities. After the patient is sedated, the endoscope should be passed all the way into the stomach before the esophagus is examined; the esophagus is viewed more easily as the endoscope is withdrawn.[7] Inflation of the esophagus must also be performed intermittently as the wall of the esophagus collapses around the end of the endoscope. The longitudinal folds of the esophageal mucosa will be readily appreciated and can be flattened out as the esophagus is distended to more clearly view the entire circumference of the esophagus. Swallowing may create artifacts such as the appearance of strictures, so the esophagus should be carefully reinflated after each swallow to carefully evaluate such findings.[8]

A recent study evaluated structures via thoracoscopy of the mediastinum, including the thoracic component of the esophagus. Although this procedure caused pneumothorax, a 15-minute period of evaluation allowed observation of numerous structures, including the esophagus.[9] Portals placed at the eighth, tenth, and twelfth intercostal spaces were useful for completion of this procedure and could provide additional information aside from radiographic and endoscopic evaluation of the thoracic esophagus.

Esophageal Obstruction

Esophageal obstruction, either primary (simple choke) or secondary to other disease processes, is the most common esophageal disorder seen in horses. Although primary obstructions may be caused by foreign bodies (including corncobs, potatoes, apples, carrots, medicinal boluses, stones, riding crops, or wood fragments), primary obstructions are most often caused by roughage, particularly leafy alfalfa hay, coarse grass hay, bedding, and even grass.[10-20] Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to esophageal impaction. Obstructions from roughage may be precipitated by wolfing or gulping food, particularly if the horse is exhausted or mildly dehydrated (such as after a long ride) or weakened from chronic debilitation. Secondary impactions are caused by intramural or extramural abnormalities that mechanically impede food passage. Examples of intramural obstructions include tumors (squamous cell carcinomas), strictures, diverticula, cysts, and vascular ring anomalies.[21-27] Mediastinal or cervical masses (tumors or abscesses) may cause extramural obstructions.

The clinical signs associated with esophageal obstructions are similar whether they are classified as primary or secondary and are rarely specific. Horses with esophageal obstruction are often anxious and stand with the neck extended. Gagging or retching may be noted, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva and food material, coughing, odynophagia, ptyalism, and dysphagia are usually the primary clinical signs, the severity of which varies with the degree and location of the obstruction. Distention of the cervical esophagus may be evident at the site of obstruction. Other clinical signs may be observed related to complications stemming from the obstruction, such as dehydration, weight loss, aspiration pneumonia, or esophageal rupture.

Thorough physical examination, including a complete oral examination, must be performed to rule out other causes of hypersalivation, dysphagia, and nasal discharge. Palpation of the jugular furrow may reveal a mass associated with the impaction. In most horses the esophagus is located in the left jugular furrow, but it may be found in the right furrow in some animals. Crepitus or cellulitis may be evident, suggesting rupture of the esophagus. Auscultation of the lungs can determine whether pneumonia or pleural fluid is present because of aspiration or intrathoracic esophageal rupture. Passage of a nasogastric tube is a good way to determine whether and where an obstruction is present, but it provides little information about the nature of the obstruction or the condition of the esophagus.

Ultrasonography of the cervical region is extremely useful not only to confirm the presence of a cervical esophageal impaction but also to provide critical information about the location and extent of the impaction and esophageal wall thickness and integrity. Ultrasonography may also provide information about the cause of the obstruction. Radiography, particularly air or barium contrast studies, may be useful to assess an esophageal impaction but may be more useful for evaluating the esophagus after, rather than before, relief of the impaction to demonstrate stricture, dilation, diverticula, esophageal rupture, or masses.[28,29] Care should be taken when interpreting radiographic studies in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.[30] Impacted food material can be detected in the esophagus by a typical granular pattern, and gas is often observed to accumulate proximal to the obstruction. Foreign bodies may be identified by contrast radiographic studies.

Definitive evaluation of esophageal obstructions often requires endoscopic examination. Most cases of esophageal obstruction occur at sites of natural narrowing of the esophageal lumen, such as the cervical esophagus, the thoracic inlet, the base of the heart, or the terminal esophagus; therefore an endoscope longer than 1 meter may be required. The endoscope can be used to localize and investigate the nature of the impaction if a foreign body is suspected. Foreign bodies may be retrievable via transendoscopic tethering.[18] Critical diagnostic and prognostic information is obtained after resolution of the impaction to determine whether mucosal ulceration, esophageal rupture, masses, or strictures are present.

The primary goal of treatment for esophageal impaction is to relieve the obstruction. Parenteral administration of acepromazine (0.05 mg/kg IV), xylazine (0.25 to 0.5 mg/kg IV) or detomidine (0.01 to 0.02 mg/kg IV), oxytocin (0.11 to 0.22 IU/kg IM), and/or esophageal instillation of lidocaine (30 to 60 mL of 1% lidocaine) may help reduce esophageal spasms resulting from pain or increased esophageal tone.[15,30-32] However, recent conclusive studies revealed that detomidine, acepromazine, or a combination of xylazine and butorphanol had the greatest effect on esophageal motility when evaluated by a monomer in conscious horses.[33] In vitro studies revealed a relaxant effect of oxytocin on esophageal muscle, suggesting it may be useful for relief of esophageal obstruction.[34]

Resolution of an impaction may require physical dispersal of the material. A nasogastric tube can be used to displace the impacted material in conjunction with external massage if the obstruction is in the cervical region. Often it is necessary to carefully lavage the esophagus with water via an uncuffed or a cuffed nasogastric tube while the head is lowered to aid in breaking up the impaction. Some clinicians advocate a dual tube method whereby a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water, food, or both, esophageal lavage is sometimes done under general anesthesia with a cuffed nasotracheal tube.

In refractory cases, intravenous administration of isotonic fluid containing 0.9% NaCl and KCl (10 to 20 mEq/L) for 24 hours at a

VetBooks.ir

rate of 50 to 100 mL/kg/day, in conjunction with an esophageal relaxant such as oxytocin, may promote hydration and softening of the impaction and will help prevent or alleviate any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium. Refractory cases may require esophagotomy to relieve the impaction. Restriction of access to food, water, and bedding material must be enforced until the obstruction is resolved and the esophagus has regained function.

Dilation proximal to the site of obstruction, mucosal injury from trauma, and esophagitis are sequelae to esophageal impaction that predispose patients to reobstruction (Color Plates 32-1 and 32-2). The rate of reobstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of reobstruction is high for 24 to 48 hours or longer; therefore food should be withheld for at least 24 to 48 hours after resolution of the obstruction. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, soft food (moistened pellets and bran mashes) can be fed. The patient can be returned to a high-quality roughage diet over a period of 7 to 21 days depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78%), but some horses may require permanent dietary modification if persistent chronic obstruction is a problem.[17]

Complications of esophageal impaction include metabolic alkalosis from prolonged loss of salivary chloride and sodium, esophageal ulceration, stricture, perforation, aspiration pneumonia, and megaesophagus. Esophageal endoscopy, ultrasonography, or both should be performed immediately after the impaction is relieved to determine whether any complications of the impaction have developed or if an inciting cause of the obstruction is present. Endoscopic evaluation is critical to determine the postobstruction treatment and follow-up. Reevaluation should be performed intermittently every 2 to 4 weeks after resolution of the impaction if esophageal dilation or mucosal injury is noted. Additional evaluation via radiography may be warranted to assess motility and transit times.

If the obstruction was present for 48 hours or longer, dehydration, hyponatremia, hypochloremia, and hypokalemia may occur and should be corrected via oral electrolyte solutions or intravenous administration of 0.9% NaCl and KCl (10 to 20 mEq/L). If aspiration is suspected, administration of broad-spectrum antibiotics that are effective against gram-positive and gram-negative organisms, including metronidazole for anaerobes, is advisable. Sucralfate (20 mg/kg orally [PO] q6h) may hasten healing if esophageal ulceration is evident, but this is controversial. Some clinicians suggest that administration of a nonsteroidal antiinflammatory drug such as flunixin meglumine (1 mg/kg PO or IV q12h) or phenylbutazone (1.1 mg/kg PO or IV q12h) for 2 to 4 weeks after resolution of the impaction may reduce the development of strictures.

Esophagitis

Inflammation occurs during many conditions of the esophagus. *Esophagitis* refers to a clinical syndrome of esophageal inflammation, which may or may not be ulcerative. Causes of esophagitis in horses include trauma (foreign bodies, nasogastric tube), infection (mural abscesses), and chemical injury (medicines, cantharidin).[35,36] An important category of esophagitis is reflux esophagitis, caused by reflux or delayed clearing of gastric contents into the distal esophagus and subsequent chemical injury to the mucosa (Fig. 32-44). Similar to ulceration of the squamous portion of the stomach in horses, a major cause of ulcerative esophagitis is epithelial damage resulting from exposure to acid, which is synergistically exacerbated by bile salts.[11,37] The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Thus esophagitis may be seen in conjunction with gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired lower esophageal sphincter function.

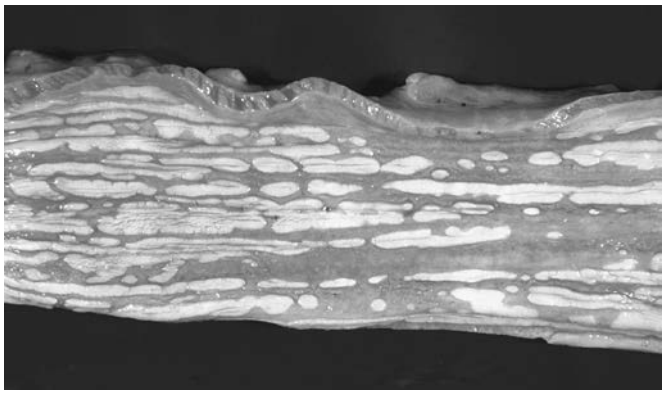

FIG. 32-44 Severe ulceration of the esophagus in a weanling foal that had severe duodenitis and gastric outflow obstruction. *(Courtesy Dr. M.J. Murray.)*

The clinical signs of esophagitis are nonspecific and similar to those of esophageal obstruction and gastric ulcer disease. In fact, esophagitis may occur concurrently with esophageal obstruction or gastric ulcer disease, so clinical signs may overlap extensively with these diseases. Gagging, or discomfort when swallowing, may be evident, and hypersalivation and bruxism are signs of esophageal pain. Partial or complete anorexia may be noted such that horses with chronic esophagitis may have significant weight loss. Motility dysfunction secondary to esophagitis may cause recurrent esophageal impaction. Clinical signs of underlying disease that predispose to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as anterior enteritis are at high risk for developing reflux esophagitis because of the presence of both gastric acid and bile salts in the fluid reflux. However, signs attributable to esophagitis secondary to ileus may not be noted because of the profound signs caused by the intestinal disorder. Foals with gastric outflow obstructions commonly have reflux esophagitis.

Diagnosis requires endoscopic examination of the esophagus. Diffuse, patchy, linear, or coalescing erosion or ulcerations may be noted. Significant edema or hyperemia may also be observed. It is important to determine whether underlying disease, such as infection, neoplasia, diverticula, or esophageal stricture is present. In addition, the stomach must be examined because reflux esophagitis is commonly accompanied by gastritis or gastric ulcer disease. Contrast radiography may be helpful if endoscopy is not available to detect esophageal ulceration and can be used to assess esophageal motility and transit time.

The principles of therapy for reflux esophagitis include control of gastric acidity and correction of any underlying disorder that is contributing to gastroesophageal reflux. Thus treatment with histamine-2 (H2)–receptor antagonists such as ranitidine or proton pump antagonists such as omeprazole is important for resolution of the disease. Some clinicians advocate sucralfate administration to aid healing of esophageal ulcers. However, the efficiency of sucralfate binding to ulcerated mucosa in the squamous epithelium of the gastrointestinal tract has recently been brought into question since low pH is optimal for the sucralfate polymers to bind ulcerated tissues. It is not clear whether reflux esophagitis provides the right pH environment for binding.

Foals with reflux esophagitis secondary to delayed gastric outflow caused by gastroduodenal ulcer disease or gastric paresis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract. Metoclopramide (0.02 to 0.1 mg/kg SC q4-12h) reduces gastroesophageal reflux by increasing lower esophageal sphincter tone, gastric emptying, and gastroduodenal coordination. Caution should be exercised when giving metoclopramide to horses because they are prone to extrapyramidal neurologic side effects. Continuous rate infusion of metoclopramide (0.04 mg/kg/h) is one way to administer the drug to reduce the risk or severity of neurologic side effects. The rate

VetBooks.ir

can be reduced if side effects appear. Cholinergic drugs such as bethanechol (0.025 to 0.035 mg/kg SC q4-24h or 0.035 to 0.045 mg/kg PO q6-8h) may improve gastric emptying and are effective for treating reflux esophagitis. For esophagitis from trauma or pressure injury after esophageal impaction, judicious use of nonsteroidal anti-inflammatory drugs may be warranted to reduce esophageal inflammation and pain.

Dietary modification may be necessary in patients with esophagitis, depending on the degree of ulceration or if motility is impaired. Horses with less severe esophagitis should be fed frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and complete esophageal rest for several days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture formation is high if severe circumferential or coalescing ulcerations are present. Animals with esophagitis from severe trauma or infection also may be prone to stricture formation.

Motility Disorders of the Esophagus

Esophageal hypomotility is the most common motility dysfunction of the equine esophagus and results in esophageal dilation or megaesophagus. Although megaesophagus in horses is most commonly acquired, there are reports of idiopathic megaesophagus in young horses that is likely congenital (Fig. 32-45 and Color Plate 32-3).[38-41] Acquired megaesophagus in adult horses is usually caused by either primary or secondary esophageal obstruction. Esophageal impactions of relatively short duration cause proximal dilation of the esophagus that is generally reversible. However, if the duration of the obstruction is long, the motility of the esophagus may be permanently impaired. Acquired megaesophagus in foals is often secondary esophagitis resulting from gastric outlet or duodenal obstruction. Other causes of acquired megaesophagus include extraesophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies. In addition, acquired megaesophagus may result from neurologic, neuromuscular, or muscular disorders. Neurologic diseases that cause vagal neuropathy, such as equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, and idiopathic vagal neuropathy, have been associated with megaesophagus in horses. Pleuropneumonia may be associated with vagal neuropathy, resulting in megaesophagus. Megaesophagus is also an early sign of equine dysautonomia[42] and may be noted in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in other species but has not been reported in horses. Also in other species, electrolyte disorders, cachexia, primary myopathies, myositis, and Addison disease may affect esophageal motility, but these have not been associated with megaesophagus in horses.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. However, because esophageal hypomotility may predispose to reflux esophagitis, it may be difficult to determine whether the esophagitis or the megaesophagus is the causative disorder (see Color Plate 32-3). Iatrogenic megaesophagus can be induced by the α_2-adrenergic agonist detomidine, but this is transient and reversible.[43] However, the use of this drug may complicate clinical evaluation of esophageal motility. Because esophageal hypomotility is a functional obstruction, the clinical signs of esophageal hypomotility or megaesophagus are similar to those of esophageal obstruction. These clinical signs include ptyalism, dysphagia, and nasal discharge of saliva and food material. The cervical esophagus may be sufficiently dilated to be evident externally. Weight loss is a common sign, and clinical signs attributable to an underlying disease may be evident.

Diagnosis of esophageal hypomotility requires transit studies. Transit time of a bolus from the cervical esophagus to the stomach can be measured by fluoroscopy or contrast radiography.[7,42] Other signs of esophageal hypomotility and megaesophagus include pooling of contrast material and an absence of peristaltic constrictions. Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves. Evidence of underlying disease causing obstruction or esophageal dilation may be observed. The esophagus should be evaluated for evidence of esophagitis that is either causing esophageal motility dysfunction or is a result of impaired esophageal clearance of gastric fluid. Esophageal manometry may be useful to document abnormal postdeglutition contraction pressures, contraction time, and propagation times.[4,38] Other diagnostic tests such as a CBC and chemistry to help identify an underlying cause should be performed. A careful neurologic evaluation should be performed. Signs of neurologic disease and abnormal cerebrospinal fluid analysis suggest an underlying neurologic disorder. Myopathy may be detected by electromyography.

Treatment of esophageal hypomotility or megaesophagus should be aimed at the underlying cause. Dietary modification should be aimed at improving esophageal transit of food. Slurries of pellets should be fed. In addition, it may be beneficial to feed from an elevated position to promote transit. In patients with reflux esophagitis associated with megaesophagus, metoclopramide or bethanechol may be beneficial to increase lower esophageal tone, promote gastric emptying, and reduce gastroesophageal reflux. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus, including congenital megaesophagus, have a poor prognosis.

Congenital Disorders

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,[44] persistent right aortic arch, congenital strictures, esophageal duplication cysts,[45,46] and idiopathic megaesophagus.[47] In the one report on congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground after each feeding.

Persistent right aortic arch is a congenital anomaly in which the right fourth aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery.[24] Clinical signs may include dysphagia, drooling of saliva, and distention of the cervical esophagus as a result of partial obstruction of the thoracic esophagus.[48] Endoscopic examination typically reveals dilation of the esophagus cranial to the obstruction with evidence of diffuse esophagitis. In addition, evaluation of the thorax usually reveals the presence of aspiration pneumonia. Successful surgical treatment of persistent right aortic arch has been reported in one foal.

Esophageal duplication cysts cause typical signs of esophageal obstruction, including salivation, dysphagia, and swelling of the cervical esophagus as they enlarge. Such signs can make them difficult to differentiate from simple obstruction (choke). However, an

VetBooks.ir

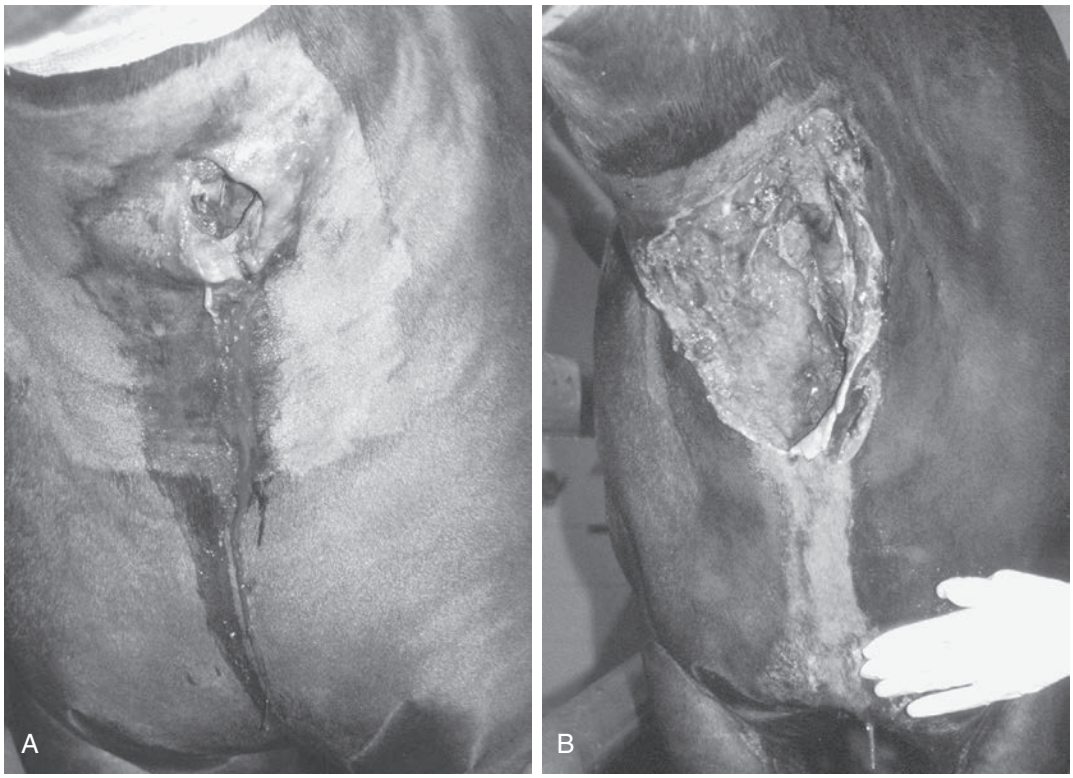

FIG. 32-46 Esophageal perforation in a horse. **A,** An open esophageal laceration was detected on presentation in the midcervical region. The wound was treated by lavage and débridement, and the horse was fed via a tube inserted into the esophagus through the wound. **B,** Approximately 14 days later, dissection of esophageal contents within surrounding fascial planes resulted in extensive sloughing of tissue.

aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.[49] Cysts may communicate with the lumen of the esophagus. Surgical treatments have included complete surgical resection and surgical marsupialization. The latter appears to be more successful and to result in fewer complications. Complications of surgical resection have included (1) laryngeal hemiplegia secondary to surgical trauma to the recurrent laryngeal nerve in the region of the esophagus and (2) esophageal fistula formation.

Esophageal Perforation

Perforation typically occurs in the cervical region in response to external trauma or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because it is covered by only a thin layer of muscle at this location.[50] Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus. Esophageal perforations may be open or closed and tend to cause extensive necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes (Fig. 32-46). This may lead to extensive cellulitis and endotoxemia. Closed perforations of the esophagus are particularly troublesome, as wound discharge may migrate all the way to the mediastinum and pleural space via fascial planes and may cause abscessation (Fig. 32-47). In addition, extensive subcutaneous and fascial emphysema frequently develops and is usually evident on cervical radiographs.

Treatment should include conversion of closed perforations to open perforations if possible,[51] extensive débridement and lavage of affected tissues, broad-spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The latter may be achieved by placing a feeding tube into the esophagus via the wound. Alternatively, a nasogastric tube should be placed using a small tube (12-French diameter). For open perforations, once the wound has granulated and contracted to a small size, oral feeding may be attempted. Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. In addition, transient metabolic acidosis occurs because of salivary bicarbonate loss, followed by progressive metabolic alkalosis. Although there are reports of esophageal wounds healing well by second intention, it takes a prolonged period of time.[52] In addition, some perforations never completely heal and form permanent esophagocutaneous fistulas that may require surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other complications of esophageal wounds include Horner syndrome and left laryngeal hemiplegia.

VetBooks.ir

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived long term,[17] and in a report on esophageal trauma secondary to nasogastric intubation, 4 of 5 horses were euthanized.[35] The prognosis is therefore poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

Esophageal Stricture

Strictures most commonly occur as sequelae to esophageal obstructions that result in circumferential erosion or ulceration of the esophageal mucosa, although strictures may result from oral administration of corrosive medicinal agents and trauma to the neck.[53] Congenital strictures have also been reported. Strictures that result from mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).[54] Horses with these lesions have a presentation similar to that of horses with simple obstructions because strictures result in partial obstruction and accumulation of feed material in the lumen. Esophageal webs or rings can be observed endoscopically, whereas mural strictures or annular stenosis may require double-contrast esophagrams to confirm their presence.

In one study on esophageal stricture after simple obstruction, maximal reduction in esophageal lumen occurred within 30 days of esophageal obstruction. Although surgery has been employed to reduce such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days after ulceration. In one report, seven horses with esophageal obstruction-induced stricture were treated conservatively by feeding a slurry diet and administering antiinflammatory and antimicrobial medications, and five of seven were clinically normal within 60 days. One of the five successfully treated horses had a 10-cm area of circumferential ulceration, suggesting extensive mucosal injury may resolve without permanent stricture formation. If there is insufficient resolution of strictures within 60 days, other methods to increase esophageal diameter should be investigated. Bougienage has been used successfully in small animal patients and human beings. The technique involves passage of a tubular dilatable instrument down the esophagus and stretching of the stricture. Some authors have suggested that this may be accomplished by passing a nasogastric tube with an inflatable cuff (Fig. 32-48).[55] However, the procedure has to be performed frequently to have any success and is often not well tolerated by horses. Alternatively, several surgical techniques have been used to resolve strictures, including resection and anastomosis,[56,57] temporary esophagostomy with fenestration of the stricture, esophagomyotomy for strictures of the muscularis and adventitia,[58,59] and patch grafting with local musculature.[60] However, such surgeries are fraught with complications, largely because of the propensity of the traumatized esophagus to restricture. The esophagus lacks a serosal layer and does not rapidly form a fibrin seal, as does the remainder of the intestinal tract, so anastomoses tend to leak. In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.

Esophageal Diverticula

There are two types of diverticula: traction (true) diverticula and pulsion (false) diverticula. Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal pressure (Fig. 32-49). Traction diverticula appear as a dilation with a broad neck on contrast esophagography, whereas pulsion diverticula typically have a flask shape with a small neck on an esophagram.[61] Whereas traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction.[62] However, a movable mass in the midcervical region may be noticed before onset of complete obstruction.[5] Pulsion diverticula may be surgically corrected by inverting or resecting prolapsed mucosa and closing the defect in the wall of the esophagus.[26,61,62] Inversion of excessive mucosa may predispose horses to esophageal obstruction and should therefore be reserved for small diverticula.

Neoplasia

Neoplasia of the esophagus is rare, but squamous cell carcinoma[63,64] and leiomyosarcoma[65] have reportedly affected the esophagus either as the primary site or in association with a lesion in the squamous portion of the stomach. The predominant clinical signs are weight loss, colic, and recurrent esophageal obstruction. The tumor is typically detected antemortem on esophagoscopy and radiography, but a definitive diagnosis may require a biopsy during laparotomy.[21,65] When neoplasia affects the lower esophageal sphincter, gastroesophageal reflux may contribute to ulceration of esophageal mucosa. The prognosis for malignant neoplasia of the esophagus is grave.

Disorders of the Stomach

Ben Sykes

Equine Gastric Ulcer Syndrome

Gastric ulceration is the most common disease condition of the equine stomach. The term *equine gastric ulcer syndrome* (EGUS) was first adopted in 1999 to describe the gastric ulceration in the horse.[1] By definition the term EGUS refers to a syndrome, within which numerous disease entities exist. Recently an attempt has been made to clarify the terminology to recognize this distinction.[2] The distinction is important, as the proposed pathophysiologies of the diseases are different, different risk factors have been described for squamous[3-7] and glandular[8] disease, the presence of squamous and glandular ulcerations within an individual are unrelated,[9-11] and the response of glandular ulceration to treatment with omeprazole is inferior to that of squamous ulceration.[12-14] As such, the direct extrapolation of findings from the squamous mucosa, which is by far the more thoroughly studied of the two, to the glandular mucosa is inappropriate. Instead, disease of the squamous mucosa should be considered as a distinct entity to disease of the glandular mucosa.

For the purposes of this discussion, diseases of the squamous and glandular mucosa will be discussed separately. The term *equine squamous gastric ulcer syndrome* (ESGUS) will be used to discuss diseases of the squamous mucosa, while the term *equine glandular gastric ulcer syndrome* (EGGUS) will be used to discuss diseases of the glandular mucosa.

Diagnosis

Gastroscopy remains the only reliable method of diagnosis for gastric ulceration; however, the advent of smaller portable units and a dramatic reduction in price has meant that gastroscopy is no longer the domain of referral centers only. Adequate patient preparation, plus some operator skill and patience, is required for a complete diagnostic evaluation of the entire stomach. A fasting period of at least 16 hours is required in most horses, and even small amounts of residual food make accessing the pyloric antrum difficult. In horses on low-roughage diets (e.g., racehorses), shorter durations of starvation may be acceptable. Removal of water 1 hour prior to examination is advantageous but not mandatory. A complete examination of the stomach is important and the presence or absence of squamous ulceration cannot be used as a predictor for the presence or absence of glandular ulceration.[9-11] Observation of the squamous mucosa is relatively easy, whereas passage through to the pyloric antrum is more technically demanding. However, observation of the pyloric antrum is critical as the majority of glandular ulceration occurs in this region.[8,11-14] Observation of the most ventral portion of the fundus is typically not possible because of the presence of fluid; however, ulceration in this region is rare.[15] The squamous and glandular mucosa should be scored separately and, although a variety of scoring systems have been described, the author prefers the system first described by the EGUS council[1] shown in Table 32-2. Examples of the normal appearance of the gastric and duodenal mucosa and lesions encountered in horses and foals undergoing gastroscopy are shown in Color Plates 32-4 through 32-12.

In the absence of gastroscopy, various other methods have been proposed for diagnosis. The presence of clinical signs, including recurrent colic, poor appetite, weight loss, hair coat and behavioral changes, pain on tightening of the girth, and diarrhea,[15-17] can be useful with a significantly greater prevalence of ESGUS in symptomatic horses compared with asymptomatic controls.[16] The link between colic and EGUS is controversial, but the author believes that EGUS should be considered as a differential in all cases of idiopathic colic and that investigation is warranted, especially in recurrent cases. Further, clinical experience tells us that many horses will have relatively severe gastric ulceration with no apparent clinical signs. However, treatment of the ulceration in these horses often results in a change in behavior or appetite of the horse, suggesting that the symptoms displayed by many animals are mild and readily overlooked.

TABLE 32-2

Scoring System for Equine Gastric Ulcer Syndrome

Grade	Squamous Mucosa	Glandular Mucosa
0	The epithelium is intact and there is no appearance of hyperkeratosis (yellow appearance to the mucosa)	The epithelium is intact and there is no hyperemia (reddening) of the mucosa
I	The mucosa is intact, but there are areas of hyperkeratosis	The mucosa is intact, but there are areas of hyperemia
II	Small single, or multifocal lesions	Small single, or multifocal lesions
III	Large single, or multifocal lesions, or extensive superficial lesions	Large single, or multifocal lesions, or extensive superficial lesions
IV	Extensive lesions with areas of apparent deep ulceration	Extensive lesions with areas of apparent deep ulceration

The presence of overt clinical signs increases the clinical index of suspicion, while their apparent absence does not discount EGUS as a differential. If gastroscopy is not readily available, then a therapeutic trial with omeprazole can be useful. A positive response to treatment with omeprazole confirms the diagnosis of EGUS but does not differentiate between ESGUS and EGGUS. Such a distinction is important because the treatment recommendations for ESGUS and EGGUS vary and as such, in the author's opinion, a positive response to treatment should be viewed as a clear indication to conduct a gastroscopic exam to obtain a definitive diagnosis. A negative response to trial therapy with omeprazole reduces the likelihood of EGUS but does not completely discount it, as some animals are slow to respond clinically and symptoms may not completely resolve until healing has occurred, especially with EGGUS. As such, in light of a negative response to omeprazole, other more likely differentials should be discounted first, but gastroscopic examination is indicated if no specific diagnosis is made.

Fecal occult blood testing is appealing in terms of ease of use and cost, and kits specifically designed for the equine market are available. However, its accuracy has not been validated in the peer-reviewed literature, and several theoretical reasons exist as to why fecal occult blood is likely to be of limited use in the horse. As such, the use of fecal occult blood cannot be recommended as a diagnostic test until further validated. The use of sucrose as a marker of gastrointestinal permeability has been reported and a blood test developed for the purpose[18,19]; however, the test has not found favor and gastroscopy remains the diagnostic of choice because of its accuracy and ability to distinguish ESGUS from EGGUS.

Equine Squamous Gastric Ulcer Syndrome

Squamous ulceration can be a primary problem or, occasionally, a secondary problem that results from obstruction of gastric outflow with subsequent backflow of acid gastric juices. For the purposes of this discussion, the focus will be on primary squamous disease with the understanding that management of secondary squamous disease is largely dictated by treatment of the primary disease causing delayed gastric outflow.

Pathophysiology

Squamous ulceration occurs, fundamentally, as a result of increased exposure of a tissue with limited defense mechanisms to highly acidic gastric contents. Horses are constant secretors of gastric acid[20,21] with HCl primarily responsible for the damage to the squamous mucosa. Damage occurs rapidly with evidence of acid injury within 30 minutes of exposure in vitro.[22] The

VetBooks.ir

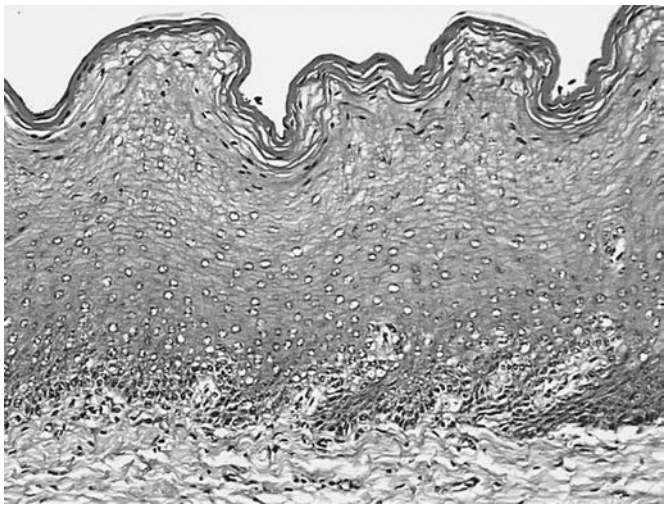

FIG. 32-50 Photomicrograph of equine gastric squamous epithelial mucosa. There are multiple layers of epithelium arranged in parallel with the luminal surface. The most superficial layers of cells are cornified, and superficial to these cells are layers of keratin. (Hematoxylin and eosin stain.)

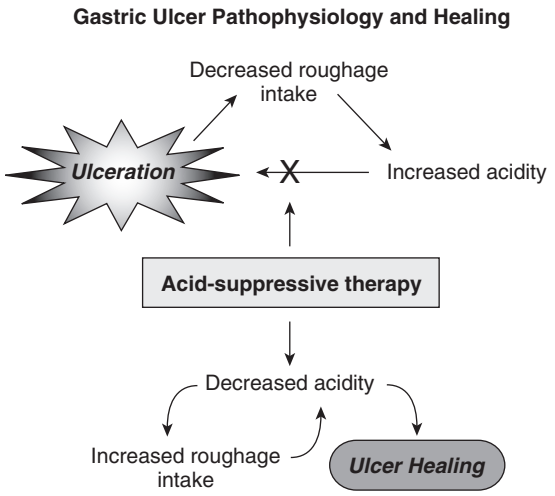

FIG. 32-51 Diagram representing the pathophysiology of ulceration of the equine gastric squamous mucosal epithelium and the permissive effect of acid suppression on ulcer healing.

horse has evolved as a constant grazer, and under pasture conditions the consumption of roughage creates a basketball-sized bolus of feed in the stomach that acts as a buffer to absorb gastric acidity and physically prevents the splashing of highly acidic gastric contents into the dorsal region of the stomach that is lined by squamous mucosa (Fig. 32-50). Any disruption in normal feeding or behavior results in breakdown of this protective mechanism and a resultant increase in the risk of ESGUS. Short-chain fatty acids released during fermentation of soluble carbohydrates consumed in the diet are likely also to directly contribute to squamous mucosal injury[23] and disrupt the physical protective effect of a predominantly roughage-based diet. As such, ESGUS is largely a disease that results from the management changes imposed on horses for a variety of purposes.

Prevalence and Risk Factors

The prevalence of ESGUS mirrors exercise intensity with the risk of disease increasing as the intensity of work increases. The highest prevalences have been reported in Thoroughbred racehorses with more than 70% of animals affected across a wide range of studies.[9,24-26] However, it is the author's opinion that these studies overstate the prevalence of clinically significant ulceration because many of the "affected" animals are likely to have had only small focal lesions that are unlikely to be of clinical significance but by definition meet the criteria of ulceration. This overrepresentation of the rate of the ESGUS has led many clinicians to dismiss ESGUS as a "normal" finding in the performance horse. Along these lines the author proposes that mild (grade II/IV) ESGUS maybe an incidental finding and that, although it may be associated with clinical signs, typically horses with grade III-IV/IV ESGUS are more likely to be clinically affected. As such, discussions on the prevalence and significance of ESGUS should be conducted in context with the relative severity of lesions observed.

The Thoroughbred racehorse is the best studied of horse breeds and the focus on this group in both developing an understanding of the disease and validating various treatments has led to a misconception that ESGUS is solely a disease of racehorses. On the contrary, ESGUS is seen across a wide range of other horse types. In a recent Danish study, ESGUS was observed in 69% of horses ranging from horses at pasture to horses in hard work, and there was no apparent association between presence of ESGUS and horse use.[10] Similar prevalences of ESGUS have been reported in Standardbred (63% to 87%[3,27]), endurance (67% to 93% during competition[28,29]), show (58%[30]), and western performance (40%[31]) horses. The prevalence of ESGUS in horses at rest is variable but typically lower and, when observed, tends to be less severe. However, in selected cases, severe (grade III-IV/IV) ESGUS can be observed in horses at pasture, and ESGUS should not be discounted as a differential simply because a horse does not meet the "typical" risk profile.

The commencement of training, with the multitude of management changes imposed, including exercise[32] and high-concentrate/low-roughage diets,[33] can result in the development of ESGUS within 7 days.[7,34] In addition to the overall risk associated with the induction of training, specific risk factors that have been identified for ESGUS include fasting,[21] transport,[7] stabling,[21] and time in work.[8] Although nonsteroidal antiinflammatory drugs (NSAIDs) may induce ESGUS experimentally, epidemiologic study results[25] and the lack of a direct link to the pathophysiology of squamous ulceration make it unlikely that they contribute to ESGUS in the clinical setting.

Treatment

Treatment of ESGUS focuses on suppression of acid production and, where possible, changing management practices that may have contributed to the disease (Fig. 32-51). Acid suppression therapy does not directly contribute to healing, but the squamous mucosa has an enormous proliferative capacity and the removal of ongoing insult is sufficient for the tissues to heal. Theoretically, removal of the horse from the risk factors that caused disease in the first place and reestablishment of a normal pH gradient in the stomach should result in healing. However, a reduction in workload is not possible in many cases, and treatment is required in the face of ongoing exposure to risk factors. Further, even when removal from the risk factors is possible (i.e., resting of the horse), acid suppression therapy is often required to restore a normal appetite so that enough roughage is consumed to reestablish the pH gradient in the stomach allowing healing to occur. If removal from work is used to manage ESGUS, then follow-up gastroscopy 4 to 6 weeks later is indicated to ensure that healing has occurred.

Because the ability to remove risk factors, such as exercise and concentrate diets, is often limited, the use of acid suppression therapy remains a cornerstone in the management of ESGUS. Various drugs have been used for this purpose, but omeprazole remains the most effective and best studied. Omeprazole impairs the H^+, K^+-ATPase (proton) pump that secretes HCl. It is most commonly registered at a dose of 4 mg/kg PO q24h for 28 days, and its efficacy at this dose for treatment of squamous ulcer disease is well documented by several clinical trials.[35-39] Recently, the use of lower doses has been evaluated and, under certain conditions, doses as low as 1 mg/kg have been shown to be as efficacious as 4 mg/kg in the treatment of ESGUS.[13] Based on experimental studies,[40-46] it is widely believed that once-daily administration of omeprazole results in 24 hours of acid suppression; however, a recent study has suggested that the duration of acid suppression following dosing at 4 mg/kg may be as short as

VetBooks.ir

12 hours.[47] Considering this, the timing of administration may be important, with exercise considered to be the peak risk period for ESGUS development[32]; however, a recent study found no advantage of administration of omeprazole 1 to 4 hours prior to exercise compared with administration after exercise.[12] Reported healing rates at 28 days for horses that stay in work are typically around 70% to 80%.[12,35,36,39] As such, although the majority of animals will have improved by 28 days,[12-14,35] control gastroscopy is recommended before therapy is terminated to ensure that healing has occurred.

Other drugs have been used in the treatment of ESGUS, most commonly the H2 receptor antagonists ranitidine and cimetidine. Both drugs work by competitively blocking the H2 receptor on the parietal cell, and their efficacy is dependent on maintaining plasma concentrations. Ranitidine, most commonly used at 6.6 mg/kg PO q8h, has been shown to effectively suppress gastric acidity in experimental studies[20,48-50] and provides an option for acid suppressor therapy where omeprazole is not available or is cost prohibitive. However, in a study directly comparing the efficacy of ranitidine versus omeprazole, ranitidine was shown to be inferior[37]; thus omeprazole remains the treatment of choice. Cimetidine is relatively poorly studied and its use is not justified.

Nonpharmaceutical methods, such as feed supplements and antacids, of treating ESGUS are popular among owners, typically because of low cost and availability. Although antacids can effectively reduce gastric acidity, their effect is short lived (2 hours)[48,51] and, as such, their use beyond short-term symptomatic control cannot be recommended. Mucosal protectants, such as pectin-lecithin complexes, may play a role in providing a physical barrier between the mucosa and acid, and symptomatic relief as a result of their use is often reported. Their use in selected cases may be sufficient for control of ESGUS, but the author's opinion is that they are more likely to be effective as preventive, and alongside omeprazole in the treatment of EGGUS, than as a primary treatment for ESGUS.

Prevention The approach to prevention of ESGUS is similar to treatment. The instigation, where possible, of management changes such as increased roughage and decreased concentrate in the diet and increased turnout are likely to decrease the risk of disease. However, in most cases, ongoing use of the horse results in ongoing exposure to risk factors, and the risk of recurrence is typically moderate to high. Prevention should be approached on a case-by-case basis, wherein the greater the ability is to affect risk factors, the lower the need will be for additional therapy. When additional therapy is required, the use of mucosal protectants such as the pectin-lecithin complexes may be adequate in low- to moderate-risk environments, whereas omeprazole is indicated in cases where the risk of recurrence is deemed to be high. Omeprazole is typically used at 1.0 mg/kg PO q24h for prevention,[52] but 0.5 mg/kg PO q24h has been shown, under specific conditions, to be as effective.[53]

Equine Glandular Gastric Ulcer Syndrome

The advent of gastroscopy as a diagnostic tool in the 1990s created an enormous wave of publications on EGUS but, despite awareness of gastric ulceration as a disease for more than 20 years, it is only recently that a real emphasis has begun to be placed on distinguishing ESGUS from equine glandular gastric ulcer syndrome (EGGUS). A key reason for this is that when the original endoscopes were developed for use in the horse, they were only 2.5 meters in length and, as such, the pyloric antrum, where the majority of glandular ulceration occurs,[8,10,12-14,54] was rarely observed in clinical cases.

However, interest in distinguishing EGGUS as a separate entity from ESGUS has increased,[2] and a series of recent studies have clearly demonstrated that the risk factors for,[8] and response to treatment of,[12-14,54] EGGUS differ dramatically from those of ESGUS. This is not surprising given the differences in the anatomy of the glandular mucosa (Fig. 32-52) and pathophysiology of the conditions.

Pathophysiology The glandular mucosa differs fundamentally from the squamous mucosa in that under normal physiologic conditions it is exposed to highly acidic gastric contents with the pH in the ventral portion of the stomach relatively stable at between 1 and 3.[47] As such, whereas ESGUS results from exposure of mucosa unaccustomed to acidity, EGGUS is believed to result from a breakdown of the normal defense mechanisms that protect the mucosa from acidic gastric contents. Under normal conditions the glandular mucosa of the stomach is lined by a continuous layer of gastric mucus

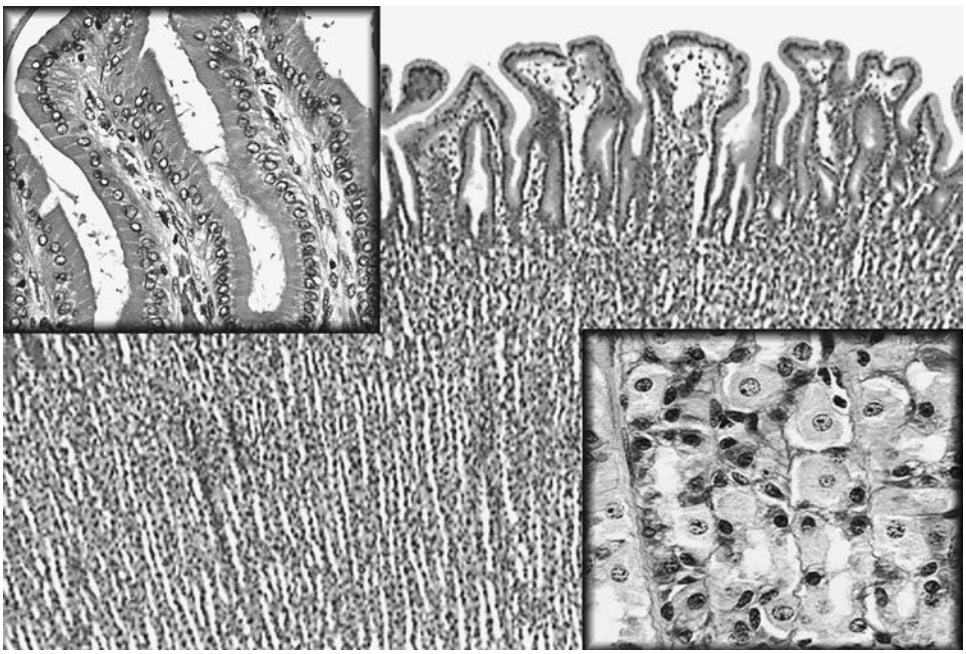

FIG. 32-52 Photomicrograph of equine gastric glandular mucosa. In contrast to the squamous mucosa, the glands are parallel to one another and perpendicular to the luminal surface. There are multiple cell types within the mucosa, with surface epithelial cells and mucus-secreting cells toward the lumen, and parietal cells, chief cells, enterochromaffin-like cells, G cells, and D cells deeper in the mucosa. The insert at the top left shows a high-power magnification of cells lining gastric pits on the surface of the epithelium. The insert at the lower right shows a high-power magnification of cells lining the gastric glands deeper in the mucosa. (Hematoxylin and eosin stain.)

VetBooks.ir

that is a complex mixture of glycoproteins, water, electrolytes, lipids, and antibodies.[15] The factors that contribute to breakdown of this protective layer are yet to be elucidated in the horse, but in humans bacterial agents and NSAIDs are the predominant causes of gastric ulceration with *Helicobacter pylori*–negative NSAID-negative gastric ulceration rare.[55] As such, current research in the horse is focused primarily on these two mechanisms.

To date there remains significant conflict in the literature as to the role of bacteria in EGGUS. A recent study demonstrated that both gastric-adapted bacteria and opportunistic pathogens may play a role in squamous ulceration,[56] but whether the situation is similar in the glandular mucosa is unknown. *Helicobacter*-like organisms have been identified in horses affected with EGGUS in some studies,[57-59] whereas other studies have failed to identify such organisms.[60,61] Pending further investigation of the subject, the author believes that the potential exists in the individual patient for bacteria to be significant, and it is likely that, in some patients, bacterial infection, either primary or secondary, plays a role in the establishment or perpetuation of disease.

The potential for NSAIDs to cause EGGUS under clinical conditions is controversial. An ulcerogenic capacity has been demonstrated for flunixin, phenylbutazone, and ketoprofen at doses only 50% higher than typically recommended,[62] whereas at clinical doses phenylbutazone and suxibuzone did not induce gastric ulceration when administered for 15 days.[63] Further, the administration of NSAIDs was not identified as a risk factor in a recent study.[8] The author believes that, at clinically used doses in otherwise healthy animals, the risk of EGGUS associated with short-duration NSAID therapy is negligible, but in animals receiving NSAIDs for long durations (>2 weeks), or in animals that are systemically compromised, EGGUS should be considered as a potential side effect.

Prevalence and Risk Factors

Prevalences of 47%[9] and 62.5%[8] have been reported in Thoroughbred racehorses in Australia, whereas the prevalence in Thoroughbred racehorses in the United Kingdom is significantly lower (8%).[8] However, the low prevalence reported among UK horses should be interpreted with caution as only a small number of horses (n = 25) were examined. A mixed population of horses in Denmark had an overall EGGUS prevalence of 57%,[10] endurance horses have reported prevalences of 27%[28] and 33%,[29] whereas abattoir studies have reported rates of 57%[60] and 67%[61] in a variety of horse types.

In a study of Thoroughbred racehorses,[8] the risk factors identified for EGGUS were gender (colts are at reduced risk), trainer, no grass turnout, horses in direct contact with each other, horses not fed haylage, horses fed unprocessed grain, horses that were infrequently fed a complete diet, horses that underwent fast exercise on fewer days of the week, and horses that went swimming. In contrast to ESGUS, where the risk of ulceration increases with time in work,[8] time in work was not a significant risk factor; similarly, a Danish study found that horses in work were no more likely to have EGGUS than were young horses, breeding mares, or mature horses at pasture.[4] The results of these studies suggest that whereas diet may influence the risk of EGGUS in a manner similar to that of ESGUS, with high-concentrate/low-roughage diets increasing the risk of disease, the relatively direct relationship between intensity of, and duration in, work and the prevalence of ESGUS is not observed in horses with EGGUS. As such, while the clinical index of suspicion for ESGUS is relatively low for horses at rest and increases with the intensity of work, EGGUS should be a differential in horses demonstrating clinical signs of the disease regardless of the intensity of work.

Treatment

Until recently, treatment recommendations for EGUS have not differentiated between squamous and glandular disease. However, in three recent studies only 25% of glandular ulcers healed with 28 to 35 days of omeprazole therapy at 4.0 mg/kg PO q24h in direct contrast to an ESGUS healing rate of 78%[12-14]; these findings suggest that specific treatment recommendations for EGGUS are needed. In humans, the duration of therapy for glandular ulceration is dependent on the primary cause of the lesion and, although acid suppression remains a cornerstone of treatment, its duration and the use of adjunctive agents depend on the primary cause.[55] In the horse it is widely believed that once-daily dosing of omeprazole results in 24 hours of acid suppression[64]; however, a recent study has suggested that the duration of acid suppression may be less than 12 hours.[47] As such, it is possible in the horse that the duration of acid suppression required, either within each 24-hour period or over the total course of treatment, for squamous healing may be less than that required for glandular healing and that the primary reason for failure of omeprazole to work on glandular ulcers might be that the duration of acid suppression, although adequate for squamous healing to occur, is inadequate for glandular healing to occur. Given the slow rate of healing the author typically recommends a minimum of 6 weeks of therapy prior to control gastroscopy for EGGUS.

An alternative explanation, as discussed earlier, is that bacteria may play a role in the development or perpetuation of glandular ulceration and that acid suppression therapy alone may be inadequate. Antimicrobial therapy is commonly recommended as an adjunct to acid suppression therapy in refractory EGGUS[64,65]; however, in a recent study the addition of trimethoprim-sulfadimidine at 30 mg/kg PO q24h to omeprazole at 4.0 mg/kg PO q24h failed to improve the treatment response compared with omeprazole therapy alone.[54] Based on these results, and in line with the principles of responsible use of antimicrobials, the author does not believe that antimicrobial therapy is justified as a first-line treatment for EGGUS. However, as a potential role for bacteria cannot be ruled out, antimicrobials may be considered in refractory cases. Consistent with this, the author does not use antimicrobials until at least 6 weeks of omeprazole and mucosal barrier therapy have failed to resolve the condition at which point doxycycline at 10 mg/kg PO q12h administered concurrently with sucralfate at 20 mg/kg PO q12h may be beneficial. Doxycycline is chosen for its relatively broad spectrum, and the concurrent administration of sucralfate prolongs contact of the antimicrobial at the site of the ulcer bed.[66]

Give the proposed role of failed mucosal defenses in the pathogenesis of EGGUS, the use of mucosal protectants as a component of therapy is logical. It is unlikely that mucosal protectants alone will result in significant healing, but they may serve as an important adjunct to omeprazole therapy. The two most commonly used agents are sucralfate and pectin-lecithin complexes. The mechanism of action of sucralfate is likely a combination of adherence to ulcerated mucosa, stimulation of mucous secretion, prostaglandin E synthesis, and enhanced blood flow, all of which are likely to be beneficial in horses with EGGUS.[17] Anecdotally superior healing has been reported with the addition of sucralfate over omeprazole therapy alone[66] and its use at 20 mg/kg PO q12h in addition to omeprazole therapy as a front-line treatment is logical. Alternatively, pectin-lecithin complexes may be of benefit. Apolectol (Boehringer Ingelheim, Ingelheim en Rhein, Germany), a unique pectin-lecithin complex, has been shown to increase the total mucus concentration in gastric juice,[67] and another study suggested that it may have a role in the treatment of EGUS in clinical patients.[68] Its use has been suggested in cases where reduced mucosal barrier integrity is suspected,[66] and the author believes that its use as a adjunctive front-line treatment at 150 g q12h is warranted.

Prevention

Prevention of EGGUS, either as primary disease or recurrence, is problematic. In a series of recent studies, worsening of EGGUS grade was observed in 23% of horses despite omeprazole therapy at doses ranging from 1 to 4 mg/kg PO q24h.[12-14] Further, it has been suggested that gastric hyperplasia may be present in a percentage of EGGUS cases and that in such cases omeprazole therapy is contraindicated.[66] At the time of writing, the exact role of omeprazole for prevention is unclear; however, use as per the recommendations for ESGUS is logical until further defined. Gastric mucosal biopsy is indicated in patients that develop EGGUS in the face of omeprazole therapy in order to individually tailor treatment.

VetBooks.ir

Given the risk factors associated with the feeding of low-roughage and high-concentrate diets that have been identified for horses with EGGUS,[8] the use of dietary modification similar to that for treating ESGUS is logical. However, such changes are often difficult to achieve and the author has observed numerous cases of EGGUS in horses with "good" management strategies (i.e., free choice hay, pasture turnout, and reduced concentrate feeding). In one study, the addition of corn oil at 0.3 to 0.45 mL/kg/day (150 to 225 mL/day for a 500-kg horse) decreased gastric acid output and increased prostaglandin E_2,[69] both of which are, in theory, beneficial for the treatment and prevention of EGGUS. As such, the addition of corn oil at 0.5 mL/kg/day may be beneficial. Last, given the fundamental role of failed mucosal defenses in the pathogenesis of EGGUS, the use of mucosal barrier protectants is logical and the use of Apolectol at 150 g q12h as a follow-up in clinical cases of EGGUS has been suggested[66] and is logical.

Gastric Impaction

Gastric impaction is a relatively common presentation. Clinical signs are diverse, with inappetence the most common presentation and representing 50% of cases in one study.[70] Affected horses typically eat small amounts but have a significantly decreased total daily intake. Acute and recurrent colic are also common presentations.[70,71] The causes of gastric impaction are unclear and although poor dental care has been proposed as a predisposing factor,[17] cases commonly occur in horses with no dental abnormalities. The author has recognized three types of gastric impaction: type I is impaction of feed material where the stomach size is not increased; type II is impaction of feed material where the stomach size is significantly increased and, although difficult to prove, there is commonly a suspicion of an underlying motility disorder in these cases that is reflected in the poor response to treatment and prognosis; type III impactions occur following the formation of a phytobezoar secondary to persimmon seed ingestion.[71,72] Classification of the type of gastric impaction is important because treatment and prognosis vary depending on the type. Distinguishing between types I and II can be difficult.

Diagnosis of gastric impaction in the field is difficult, but it should be considered as a differential in any horse that presents with mild colic symptoms that dramatically worsen following the administration of fluids via a nasogastric tube, horses with unexplained inappetence, and horses with colic that appears to resolve with fasting only to relapse with the reintroduction of feed and recurrent colic cases. The presentation of type I impactions is typically mild with a normal heart rate.[70] Symptoms may be slightly more pronounced in type II impactions, and displacement of the spleen may be palpable on rectal examination. Type III impactions more commonly present with mild to severe colic and/or weight loss.[71,72] Definitive diagnosis is made when, after an appropriate period of starvation, entry to the stomach with a gastroscope is obstructed by feed material. Alternatively, in type I cases the stomach can often be entered and distended with air, but a clearly defined ball of feed material extending above the level of the margo plicatus is visible. In type III impactions a phytobezoar is typically visible once the stomach has otherwise emptied of feed material. Ultrasonography can be useful to distinguish between type I impactions, where visualization of the stomach is difficult or limited, and type II impactions where the distended stomach will often extend for several rib spaces.

Treatment and prognosis are dependent on the type of impaction present. In all cases, correction on any concurrent systemic abnormalities such as dehydration and/or electrolyte imbalances is indicated, and resolution of the impaction should be confirmed by gastroscopic examination before reintroducing food.

- Type I. The use of enteral fluids is highly effective in this population with 1 L/100 kg of isotonic electrolyte solution given q2h via an indwelling large-bore nasogastric tube. Depending on the response, the rate and volume can be increased or decreased. The author routinely uses flunixin at 1.1. mg/kg IV/PO q12h until resolution of the impaction, as mild symptoms of abdominal discomfort are not uncommon. The use of indwelling, small-bore nasogastric tubes for the administration of enteral fluids has been described[73]; however, theoretically the bolus administration of fluids should result in a more pronounced stimulation of the gastro-colic reflex. Other treatments such as dioctyl sodium succinate (DSS) and gastric lavage have been proposed[17] but given the good prognosis reported for enteral fluid therapy alone (90% survival to discharge),[70] alternative therapies appear to offer little advantage.
- Type II. Treatment of type II impactions is similar to that of type I impactions, but caution should be exercised in the volume of fluids administered as the stomach wall is often friable and gastric rupture can occur. Concurrent intravenous fluid therapy should be considered if fluid requirements cannot be met with enteral therapy alone. The response of type II cases to treatment is often poor and the addition of prokinetics may be beneficial in some cases; however, the response to prokinetic therapy is often disappointing. Bethanechol at a dose of 0.025 mg/kg SC q4-6h is the prokinetic of choice,[17] although it is often difficult to obtain, and erythromycin at 1 mg/kg IV q6-8h is a reasonable alternative. Surgery should be considered in impaction types I and II if the animal is showing signs of systemic deterioration or if medical therapy has not resolved the impaction within 5 to 7 days with successful treatment by gastrotomy reported.[74] The prognosis for type II impactions has not been reported but in the author's opinion is guarded as gastric rupture is a relatively common occurrence (even without enteral fluid therapy) and reoccurrence is common. The use of low-bulk diets during the refeeding stage is logical.
- Type III. Persimmon seed phytobezoars are generally refractory to standard enteral and intravenous fluid therapy. The use of carbonated cola drinks has been reported with a variety of techniques ranging from constant infusion of 1 L/h for 1 to 3 days to bolus administration via nasogastric tube at 700 mL q12h with the mechanism believed to be a combination of the mucolytic effects of sodium bicarbonate, the acidifying effects of the cola, and mechanical disruption of the fibers of the phytobezoar by the carbon dioxide bubbles.[71] Constant infusion via a small-bore nasogastric tube appears to be the treatment of choice and the use of caffeine-free, diet cola is recommended to reduce the risks of caffeine toxicoses or laminitis secondary to carbohydrate overload. The prognosis for type III impactions appears good with five of eight horses responding to medical therapy in one report.[71] In the same report two additional horses were successfully treated surgically via laparotomy with manual manipulation of the phytobezoar without gastrotomy while the horse in which a gastrotomy was attempted was euthanized at surgery because of extensive contamination of the abdominal cavity.[71]

Miscellaneous Diseases of the Stomach

A variety of miscellaneous disease conditions also affect the stomach of the horse, including, but not limited to, gastric rupture, tumors, abscesses and pyloric stenosis. Gastric rupture most commonly occurs secondary to obstruction of the small intestine or chronic gastric impaction. Idiopathic rupture accounted for 17% of cases in one report,[75] suggesting that a variety of other causes can result in rupture. Squamous cell carcinoma (Fig. 32-53) is the most commonly reported of the tumors that affect the stomach, representing nearly 80% of cases in a recent report,[76] although a variety of other neoplastic conditions occur. No breed or sex predilection exists, and a wide range of ages are affected. Clinical signs of abdominal neoplasia and abscesses are typically nonspecific, although weight loss, inappetence, and lethargy are common, and the diagnosis is typically made based on gastroscopic examination.

Pyloric stenosis is an uncommon condition that typically affects foals and young horses,[77] although horses of any age can be affected. The presentation is thought to most commonly result from chronic gastric ulceration, although other space-occupying lesions may be

VetBooks.ir

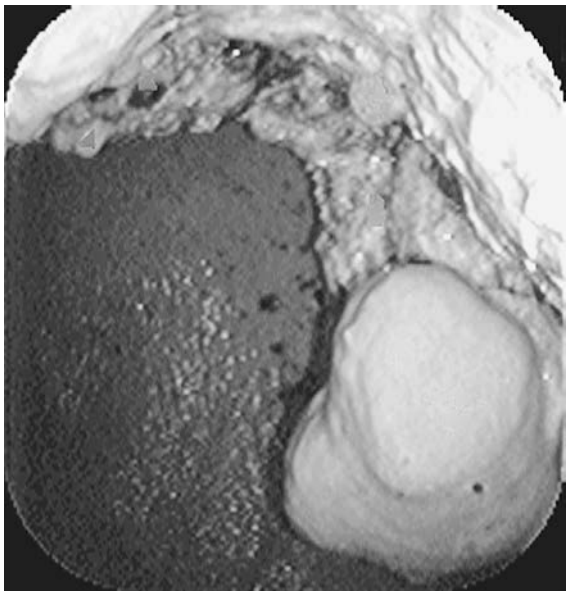

FIG. 32-53 Endoscopic view of a gastric squamous cell carcinoma.

the cause. Affected animals typically have a history of weight loss, poor appetite, and postprandial colic or recumbency.[77] Excessive ptyalism or spontaneous reflux of gastric contents from the nasal passages is common. Diagnosis is typically made on gastroscopy, although ultrasonography and contrast radiography are useful adjunctive tests. Conservative management involves acid suppression therapy, with omeprazole at 4 mg/kg PO q24h effective in less severe cases. Intravenous therapy is indicated in patients with spontaneous reflux of gastric contents or where gastric emptying is significantly delayed. Omeprazole at 0.5 mg/kg IV q24h is highly effective at acid suppression, but the availability of intravenous preparations of omeprazole is limited and the instability of the solution limits shelf life to a few hours. Ranitidine at 2 mg/kg IV q6h is a reasonable alternative. The response to medical therapy is often disappointing and early surgical intervention is indicated in such cases. Long-term survival rates of 50% to 69% have recently been reported for gastrojejunostomy,[78,79] further supporting early surgical intervention in nonresponsive cases.

Intestinal Injury and Healing in the Horse

Nathaniel A. White, II

There are numerous causes of intestinal injury in animals with equine acute abdomen. Classic pathophysiologic explanations use ischemia, ulceration, and inflammation from infection, parasites, trauma, toxins, or immune complexes to categorize and explain intestinal injury. For the clinician, understanding the underlying pathophysiology of injury is important for recognition and treatment of horses with colic. For many of these intestinal disorders, the signs can be similar, making clinical differentiation difficult.

Cellular injury was once characterized by the morphologic change it caused. However, dysfunction caused by cellular injury is more important when considering the resultant clinical signs and morbidity. The response to a stimulus is mediated by numerous autocrine and paracrine messengers, which include cytokines, chemokines, prostaglandins, neuropeptides, and proinflammatory substances such as interleukins (ILs), tumor necrosis factor alpha (TNF-α) complement, histamine, bradykinin, serotonin, and interferon (IFN).[1-3] In the intestine, inflammatory responses to these messengers can be orchestrated by mucosal cells, fibrocytes, macrophages, mast cells, endothelial cells, neurons, muscle cells, and polymorphonuclear cells.[1] The chain of events is complex, and the relationship of the different cell responses is not yet fully understood. It is clear that the inflammatory response from any insult initiates a multitude of chemical and immune reactions, which, depending on the severity of the insult, can cause both local and systemic effects.

Several mechanisms can stimulate an inflammatory response, including ischemia, reperfusion after ischemia, inflammation from bacterial or viral infection, and inflammation from parasites, trauma (surgical), or toxins. The resulting tissue injuries vary and may be differentiated by their effect on the different layers of the intestine and by the vascular and nervous response. Although the mucosa and serosa are often affected first, the inflammatory response frequently involves the remaining layers of the intestine, the submucosa, and smooth muscle.[4,5] The inflammatory response may also vary depending on the specific cause. For example, ischemia can be caused by strangulation of the blood supply, distention of the intestinal wall, or poor perfusion resulting from systemic shock. Although the response of individual intestinal cells may be similar for each, each stimulus appears to evoke different sequences of cell response, thereby causing different clinical signs and varying responses to treatment. In some instances injury to the intestine may be secondary to another disease process, but the damage to the intestine can still initiate a systemic response resulting in systemic inflammatory response syndrome (SIRS) with multiple organ failure.[6]

Intestinal Inflammation: General Concepts

The cascade of events initiated by infection or ischemia has been studied extensively. Inflammatory mediators increased during bowel inflammation are released from numerous cell types, including mucosal cells, endothelial cells, fibrocytes, myocytes, mesothelial cells, and neurons.[1] There is also evidence that the compounds making up the tissue ground substance and cytoskeleton can also initiate an inflammatory response and help transmit signals or cells between immunocytes and afferent neurons.[7] Theoretically all cells in the intestine can act as effector cells, both producing cytokines to send messages to other cells and being activated to respond to the insult by chemokines.[1,3,8] Cytokines, growth factors, and adhesion molecules can all initiate an inflammatory response.[1,3] This response also alters cell apoptosis, resulting in delayed removal of mucosal cells and neutrophils or turnover of immunocytes or specific cells in organs.[6,9] Cytokines such as IL-1β and TNF-α, platelet-activating factor (PAF), complement (C5a), IFN-γ, and histamine are all reported to be involved in inciting intestinal inflammation.[10] Describing all the effects and interactions of the inflammatory cytokines and eicosanoids is beyond the scope of this chapter, but it is apparent these substances can stimulate and inhibit the inflammatory reaction by directing cell communication and cell response to injury. As a result the disease process should be viewed as a sequence of altered cell functions, which are integrated and designed to protect the intestine from permanent injury.

Most intestinal cells—including mucosal cells, endothelial cells, neurons, fibroblasts, mast cells, eosinophils, neutrophils, and macrophages—initiate a response associated with inflammation. Rather than responding independently, these cells appear to respond to the initial insult, each with its inherent cytokine production or cell activation, which stimulates or suppresses other cell responses. Envisioned as a group acting simultaneously, the sequence can proceed from an initial stimulus to mucosal or serosal cells or, in the case of ischemia, the vascular endothelium or enteric neurons.

Mucosal cells react by releasing cytokines to activate macrophages and lymphocytes in the lamina propria.[8] These cells release cytokines and adhesion molecules, which in turn activate other cells while initiating local defenses. Simultaneously, endothelial cells respond to the cytokine message by releasing chemokines to attract neutrophils and eosinophils and subsequently enable them to migrate through the endothelium into the interstitium.[3,7] Afferent neurons detect

VetBooks.ir

cytokine increases and initiate neuropeptide, cytokine, or eicosanoid release from the efferent neurons, resulting in activation of numerous cells, including those already activated by the initial cell messengers.[11-13] Fibrocytes, responding to the initial cytokine messages and growth factors, subsequently release cytokines and growth factors such as IL-1α, IL-1β, TNF-α, transforming growth factor, and platelet-derived growth factor. All can be proinflammatory or can help to repair the mucosa.[14,15] Metalloproteinases released in response to inflammatory cytokines alter the basement membranes and collagen in the different layers, allowing migration of cells to the extracellular space and stimulating other cells to release chemoattractants.[1,16] Muscle cells, once thought to be neutral in the inflammatory cycle, appear to be able to release cytokines, thereby participating in the inflammatory reaction.[17] Increased adhesion molecule production in the muscle after surgical manipulation has been linked to neutrophil infiltration and subsequent bowel dysfunction.[4,18-20]

Although all the cells in the intestine participate in the inflammatory response as effector cells, they can also act as suppressors. Each appears to communicate with other cells locally to cause or suppress the inflammatory response. Production of nitric oxide by endothelial cells can reduce neutrophil adhesion, whereas increased release of growth factor by fibroblasts and the vascular endothelium speeds healing of the mucosa.[14] The response to receptor activation can take only seconds to minutes to upregulate cytokine production. Lack of suppression, perhaps because of chronic or overwhelming stimulation or severe damage to cells, which release the inhibitor messengers, allows amplification of inflammation and permanent cell damage.

The role of each cell type as effectors and messengers is slowly being unraveled. The role of some cells is better understood than that of others. Reperfusion, cytokines, and complement initiate endothelial cell changes. Subsequent production of cytokines and prostanoids by endothelial cells attracts neutrophils and macrophages.[21] Endothelial cells also stimulate the inflammatory response by altering capillary permeability, promoting neutrophil adhesion, and altering blood flow.[22] The interaction between the endothelial cells and neutrophils or eosinophils is a pivotal response in causing intestinal injury. This response is made possible by PAF, leukotrienes (LTB_4), and adhesion molecules produced by endothelial cells and neutrophils.[3,21] Neutrophil migration into affected tissues subsequently causes severe damage, including damage to cells and tissue ground substance, which further promotes the inflammatory response.[6]

Although all intestinal cells can be involved in the inflammatory process, the nervous system is now known to be integral in the inflammatory response. Release of potassium, adenosine triphosphate (ATP), bradykinin, and prostaglandin E_2 all stimulate afferent neurons.[11,23] Neuropeptides are released from neurons in response to afferent signals caused by products of cell injury, including cytokines, eicosanoids, and histamine.[11,23] Substance P, neurokinin, calcitonin gene-related protein (CGRP), and vasoactive peptide (VIP) have all been found in increased levels in inflamed tissues, suggesting that they act as messengers to histiocytes or immunocytes, which subsequently release cytokines.[11,12] The paracrine response differs in different tissues, but inflammatory responses by mast cells, neutrophils, T cells (cytokine release), B cells, macrophages, fibroblasts, and muscle cells are in part caused by neuropeptide stimulation. The coordination of this response is not totally understood, but it is known that neuropeptides serve as proinflammatory mediators or suppressors.[24,25] This system allows for immediate response of cells to a stimulus without humoral involvement and likely can cause persistent inflammatory reactions in response to inflamed tissue.

Local inflammation of the intestine is known to cause changes in other organs distant to the intestinal damage, specifically the lung. Circulating cytokines and activated neutrophils rapidly initiate an inflammatory response in the lung after intestinal inflammation.[26] This response is well known in experimental models and humans but has not been reported during intestinal disease in the horse. Other organs are likely affected, creating signs of multiple organ involvement as part of SIRS.

Ischemia and Reperfusion

Ischemia is a deficiency of blood flow in tissue or an organ. The lack of energy production in the cell starts a degenerative process. Within 5 minutes there are alterations in mitochondria, characterized by swelling and disorganization of cristae. Mitochondrial changes precede cytoplasmic and membrane changes, which occur in the first 30 minutes by activation of phospholipases, cytokine production, and accumulation of arachidonic acid. If ischemia persists, the cell degradation continues with failure of the membrane ion pumps, allowing calcium to move into the cytoplasm.[27] This calcium accumulation within the cell activates proteases, which cause cell membrane damage and nuclear clumping. Calcium uptake in the mitochondria is increased, which inhibits oxidative phosphorylation, thereby decreasing the cell's source of energy.

During ischemia, microscopic changes become evident at 30 minutes when the mucosal epithelial cells and serosal mesothelial cells separate from their basement membranes.[28] This appears to be a mechanical separation caused by water movement from the vasculature into the subepithelial space. Metalloproteinases may also be involved in altering the basement membrane. The space, created by the initial separation, named *Gruenhagen space,* occurs at the tip of the villus in the small intestine (Fig. 32-54).[28] If ischemia continues, the cell damage progresses as the mucosal cells progressively slough off the lamina propria toward the intestinal crypts (see Fig. 32-54). The change is similar in the colon, with epithelial cells sloughing off the surface of the mucosa (Fig. 32-55). However, the slough is somewhat slower in the colon as it proceeds into the crypts. The serosa reacts in a similar fashion, with mesothelial cells lifting off the basement membrane before there is visible cell membrane or cytoplasmic change. Other than vascular congestion, there is minimal change in the architecture of the supporting tissues in the mucosa or the serosa for the first 60 minutes of total ischemia. After 180 minutes of ischemia the lamina propria and mucosal vascular tuft have lost their architecture. The tissue is necrotic and becoming homogeneous, with lack of nuclear definition and cell structure.

Estimating the time required to create ischemic lesions depends on the experimental methods used. Different types of anesthesia in the horse and other animals have resulted in different rates of mucosal degeneration during ischemia. For example, experiments using animals anesthetized with inhalant anesthetics are different from those that require animals breathing air, most likely from higher tissue oxygen concentrations.[28-30] Also, some cell types, such as muscle, appear more resistant to ischemia, which probably depends on the intracellular energy reserves of the cells. There are also differences in the response to low-flow ischemia versus total arteriovenous obstruction. Nevertheless, lesions caused by ischemia progress with reperfusion.

If reperfusion—either resumption of blood flow or increased flow after low-flow conditions—occurs while cells are still viable, a cascade of events is set in motion by the delivery of oxygen to the previously ischemic tissue.[21,31] The resultant injury is called *reperfusion injury* and relies on renewed oxygen in the tissue, with participation of endothelial cells and afferent receptors to create the subsequent inflammatory response. Although it makes sense that oxygen is needed to resuscitate the previously ischemic cells, the innate defense system in many cell types is to respond to the ischemic change with an inflammatory response. This response appears to help initiate a defense against bacterial invasion and is aimed at removing the damaged cells from the system. If enough cells have been damaged, the reperfusion effect can cause enough inflammation to prevent cells from surviving, thereby delaying healing.

Reperfusion injury starts as a change in intracellular metabolism in previously ischemic tissue. It does not require exposure to a microbe or toxin, but it does rely on cell production of complement, cytokines, and leukotrienes as signals to numerous blood and tissue cells required to complete the process.[32] One primary initiator of reperfusion injury in the intestine is the production of oxygen (O_2) radicals. Oxygen has the ability to take on an extra electron during

enzymatic processes in the cell. Most cells, including endothelial cells and the small intestinal mucosal cells, contain xanthine dehydrogenase, which, when converted to xanthine oxidase, catalyzes hypoxanthine to xanthine.[31] Hypoxanthine is increased in the cytoplasm of cells during ischemia. Calcium and proteases initiate xanthine dehydrogenase conversion to xanthine oxidase, a process that can be stimulated in endothelial cells by IL-1, TNF-α, and C5a, as well as neutrophil adherence. Oxygen is used in the reaction and ends up with an extra electron, making an O_2 radical or superoxide.

Once released, O_2 radicals can initiate a number of chemical reactions that cause cell membrane damage directly and by stimulating phospholipase activity. During O_2 radical production, nitric oxide (NO) production is decreased, thereby allowing neutrophil adhesion and migration. Superoxide interaction with iron or catalase causes production of hydroxyl (OH) radicals or hydrogen peroxide (H_2O_2) respectively. Both are cytotoxic. The OH radicals alter or destroy cell membranes. Affected cells rapidly express cytokines and leukotrienes, which act as chemoattractants for neutrophils. After the initial free radical production, cell injury progresses as two main events. Calcium, already increased in the cell, increases further, effectively blocking further energy production in the mitochondria and activating proteases, causing further degradation of the cell nucleus and cytoplasm.[27] Second, radicals formed from molecular oxygen can cause cell membrane damage, thereby initiating a similar cellular response. The formation of chemical mediators takes only seconds to minutes after reperfusion and rapidly sets the inflammatory cascade in motion.

Although the mucosal cells and serosal mesothelial cells are damaged early in ischemia and are able to release cytokines to alert other cells locally, endothelial cells appear to be the primary initiators of reperfusion injury.[2] They participate in cytokine production and are involved with neutrophil adhesion and migration from blood into tissues. Endothelial cells are also involved with the changes in blood flow after reperfusion.[22,24,33] The platelets and neutrophils accumulate in and obstruct capillaries, altering blood flow (Fig. 32-56). Endothelial cell swelling or contraction causes constriction of blood vessel lumens. Changes in endothelial cells in response to histamine, complement, leukotrienes, and PAF increase capillary permeability, allowing fluid and protein to move into the interstitium.[24] Even though the metabolic state of the tissue during initial reperfusion initially results in overall increased blood flow, the increased vascular permeability increases interstitial pressure, causing capillary collapse. Combined with endothelial cell change, plugging of capillaries with neutrophils, vascular constriction, and capillary collapse result in a "no-reflow phenomenon," promoting further tissue ischemia.

Endothelial cell membrane changes allow expression of adhesion molecules and receptors, which are necessary for neutrophil adhesion and migration through the capillary and venule endothelium (Fig. 32-57). This migration of neutrophils causes the most prominent inflammation in the tissue, because activated neutrophils release elastase, oxygen radicals, and other serine proteases, which attack collagen, ground substance, and cell membranes.[34] The respiratory burst, a buildup of oxygen free radicals in neutrophils during activation, is responsible for most of the inflammation and tissue damage seen during reperfusion. It is also apparent that reperfusion injury can expand the initial injury into the surrounding viable tissue and that it can cause irreversible tissue damage.[4,35] Reperfusion injury can also cause injury distant from the local damage and has been observed in the lung because of cytokine and activated neutrophil circulation.[36] Although not reported in the literature, the resulting lesion can be seen in the lungs of horses that succumbed to severe intestinal strangulation, obstruction, and shock.

Cell necrosis is recognized as a pathologic feature during ischemia and reperfusion. Recently, however, alterations in apoptosis (programmed cell death) have been found to increase during ischemia and reperfusion in experimental studies of the heart, brain, liver, adrenal glands, kidney, and intestine.[37-39] Alternatively, epithelial cells undergoing hypoxia and reoxygenation modulate neutrophils to delay apoptosis, suggesting a role in initiating SIRS.[6] A significant

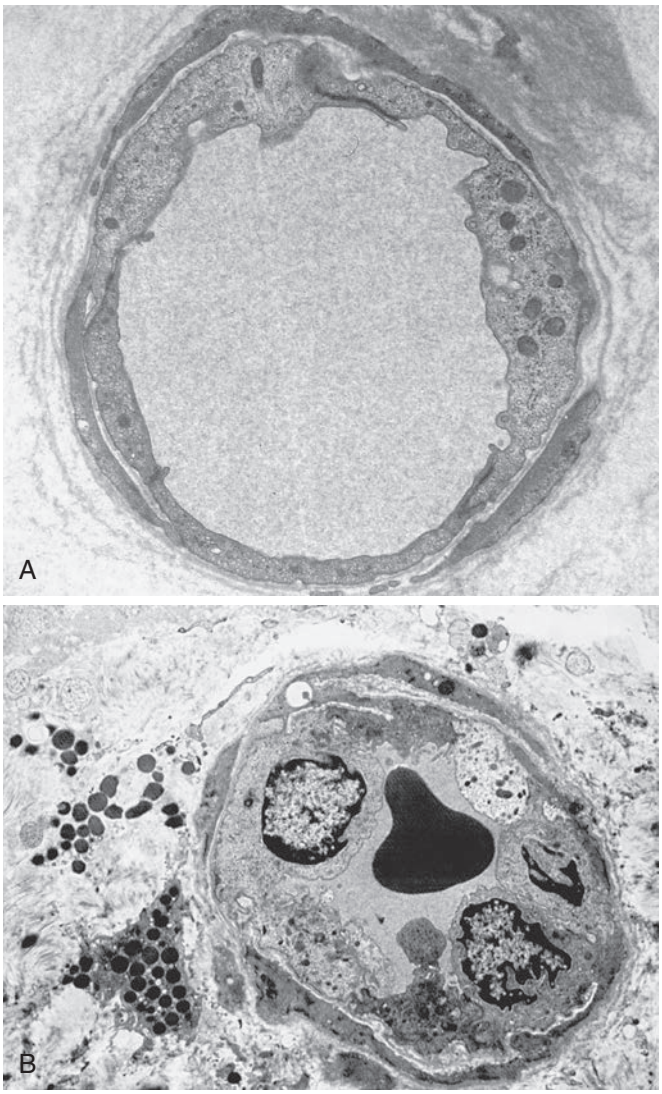

FIG. 32-56 Transmission electron photomicrographs of small vessels in the serosa, with normal endothelial cells prior to ischemia **(A)** and with plugging of the vessel with adherent neutrophils during reperfusion **(B).**

increase in the number of apoptotic cells in muscle, mucosa, neurons, and glia in naturally obstructed or strangulated equine intestine suggests apoptosis is stimulated by, and may promote, the inflammatory response (Fig. 32-58).[40,41]

Apoptosis is also increased in intestine distant to the primary lesion, supporting systemic stimulation by cytokines.[40] The amount of apoptosis observed in experimental animals and in horses with intestinal obstruction suggests this process is excessive during reperfusion and may result in both morphologic and functional changes.

The importance of oxygen radical generation as a mechanism of injury in strangulating lesions has been questioned in the horse.[42] However, both clinical signs and lesions from clinical cases suggest that intestinal damage progresses after reperfusion. In a low-flow to no-flow model of ischemia with subsequent reperfusion, treatment to counteract injury from superoxide production and neutrophil accumulation decreased intestinal injury.[43] This suggests that free radical production is part of the cascade of events causing an inflammatory response in the small intestine after bowel strangulation. Lack of malondialdehyde and conjugated diene production in the large intestine suggests less of a role for tissue-generated oxygen radicals and that reperfusion injury is caused primarily by the oxygen radical release from migrating neutrophils as seen in xanthine oxidase–deficient rats.[34,44]

Recent research suggests that endothelial cells are not the only cells that act as "local effectors" of inflammation during reperfusion. Signs of inflammation are present in all parts of the intestine, including the muscle and myenteric plexus.[17,45-47] Alterations in muscle mitochondrial morphology have been identified in equine jejunum after low-flow ischemia.[22] Similarly, during large colon volvulus, the neurons in the myenteric plexus undergo degeneration and decrease in number compared with normal conditions.[46] Evidence of ischemic injury and inflammation occurs in both muscle and myenteric plexuses. This is relevant in horses with colon volvulus, in which survivors had significantly more neurons than nonsurvivors.[46] Perhaps of greater importance is the long-term effect of the inflammation in the myenteric plexus after ischemia and reperfusion. One can speculate that the high rates of repeat colic episodes in horses after colon torsion or large colon obstruction are related to damage to the enteric nervous system.[48]

Reperfusion injury occurs after low-flow and no-flow ischemia. These models appear to emulate the clinical event, although the onset of ischemia in strangulation obstruction most likely starts as low-flow progressing to no-flow ischemia. Although the time frame of reperfusion injury is somewhat understood from the experimental models, the functional effects of dynamic events set in motion by reperfusion such as "no reflow," as well as persistent inflammation in the serosa and around the intestinal nerve ganglia, are not well understood.

Functional effects of reperfusion are elucidated in intestine undergoing experimental ischemia and reperfusion. Lidocaine treatment for ischemia and reperfusion injury inhibited cyclooxygenase type 2 (COX-2) expression, and when combined with flunixin meglumine neutrophil migration was decreased.[49] Ischemic muscle treated with lidocaine in vitro improved contractility compared with untreated muscle.[50] Treatment of experimentally created intestinal ischemia with Carolina rinse solution significantly decreased neutrophil migration and subsequently resulted in less serosal fibrosis.[51] These responses suggest that ischemia-reperfusion injury stimulates intestinal inflammation and decreases motility and that the effects can be decreased with treatment.

Low-Flow Ischemia

The effect of ischemia-reperfusion differs with the type of ischemia. Low-flow ischemia is defined as flow less than 25% of normal blood flow. At this flow rate, vascular and cell damage is minimal, and degeneration occurs over a long time period. When normal flow is returned by increasing vascular volume or by release of the arterial obstruction, there is a hyperemic response doubling the normal blood flow to the affected intestine.[22] Cell damage accelerates during reperfusion, with marked changes in vascular permeability, mucosal damage, serosal damage, and signs of fluid accumulation in the submucosa, muscle, and serosa.[22,52,53] Edema in the submucosa and serosa causes vascular collapse, leading to decreased blood flow and eventually a "no-reflow" phenomenon in the serosa and mucosa, resulting in decreased flow to the affected segment.[33,54,55] The decreased flow is partially caused by endothelial cell swelling and neutrophil margination in the vasculature. Neutrophils migrate into all intestinal layers but predominantly the mucosa and serosa. As neutrophils migrate through the capillary or venule, they accumulate around the vessels. As reperfusion progresses, the greatest injury is observed in the serosa, with marked accumulation of neutrophils beneath the serosal basement membrane. This type of low-flow ischemia is rarely documented in equine abdominal disease, but it likely exists in distended intestine in which there is low flow to the affected bowel wall. The flow is directly related to the intraluminal pressure, with pressures causing greater than 50% reduction in blood flow common in severe small intestinal distention.[55]

When examined in experimental models or when observed in clinical cases, most of these changes from acute low-flow ischemia are reversible and the affected intestine survives and heals. The effect varies greatly and is dependent on the length of ischemia. It is suspected that function is compromised temporarily, resulting in ileus,

VetBooks.ir

endotoxin absorption, or enteritis with excess secretion. In the small intestine, serosal scarring and adhesions are the most common long-term result and may increase the risk of colic episodes in the future. Even if lesions are not grossly evident and appear minor on microscopic examination, horses with colic, particularly those requiring surgery, likely have intestinal injury, which can ultimately result in temporary or permanent intestinal dysfunction. Hypothetically this is one possible reason for increased risk of colic after previous colic episodes or previous surgery for colic.[48,56]

Nonstrangulating infarction is the classic example of low-flow ischemia. In the horse, thromboembolic colic is reported to be caused by thrombosis of the mesenteric artery and its branches in horses infected with fourth-stage larvae of *Strongylus vulgaris*.[57] The mechanism of infarction is most likely reduction of blood flow from a thrombus in the artery or thromboembolism obstructing the peripheral vasculature. In nonstrangulating infarction the intestinal injury most likely results from long-term low-flow ischemia or low-flow ischemia with episodes of reperfusion injury. In clinical cases the injury is severe, often resulting in necrosis in all layers of the bowel, with obvious infarction.

Low-flow ischemia may also occur during shock.[58] In horses with obstructing or strangulating lesions, biopsies from nonaffected, grossly normal intestine have evidence of some degree of bowel injury, including neutrophil infiltration.[4,59,60] This injury can also be caused by endotoxemia with loss of mucosa and neutrophil infiltration in the mucosa. This may be relevant to assessing horses in shock.

Total Arteriovenous Occlusion

Total ischemia caused by arteriovenous occlusion causes total vascular stasis. The most common cause of this form of ischemia is incarceration of bowel in hernias or constricted spaces. Early in the occlusion, capillary congestion is observed in all layers of the intestine. The intestine undergoes degeneration as previously described for ischemia. When total ischemia exceeds 2 hours in the small intestine and 3 hours in the large colon, the tissue changes during blood flow occlusion are extensive, and cell necrosis may preclude a response to reperfusion.[28,61,62] If the capillary damage is not too extensive during total ischemia, reperfusion causes further degeneration, including mucosal cell loss, increased edema, and neutrophil migration.[59] However, oxygen radical production seen with low-flow ischemia and reperfusion may not be responsible for the continued damage during total arteriovenous occlusion.[63] Furthermore, these events cannot be separated from systemic shock or circulation of cytokines, which can cause secondary lesions seen in intestine distant to the lesion.[26] Despite the questions about the validity of reperfusion in the total ischemic event, continued intestinal injury during reperfusion is seen in both the small intestine and the large colon after total ischemia.[35,60,64] The epithelial cell loss after reperfusion is progressive and is likely caused by either countercurrent exchange creating a decreased oxygen concentration in the distant mucosa or by inflammation resulting from oxygen radical–induced inflammation from neutrophil activation.[45,65] The response in the serosa includes marked edema with initiation of neutrophil migration. Eventually a massive collection of neutrophils fills the outer border of the serosa.[54,64] During this type of ischemia and reperfusion, the damage from the inflammatory reaction can continue for days and, if severe enough, can prevent healing of the mucosa and serosa and is consistent with persistent ileus and shock.

Venous Occlusion

Venous obstruction without arterial obstruction causes increased pressure at the capillary, resulting in decreased blood flow with red blood cell (RBC) and fluid extravasation into the interstitium. The result is separation of the tissues with an increased diffusion distance for oxygen and nutrients. The RBC accumulation causes tissue damage, and if it is severe enough a continuation of cell hypoxia becomes irreversible even with reperfusion. Injury during venous obstruction appears more severe than observed during subsequent reperfusion.[66] Small intestine can survive 2 hours of venous obstruction, although the resultant degeneration is severe and the intestine is permanently scarred after healing.[29] The gross lesion is marked with obvious thickening of the bowel, which at first is red and eventually turns purple. With time and subsequent necrosis the color turns black or green as a result of alterations in hemoglobin.

For the surgeon, venous occlusion is the most difficult type of lesion to assess, as intestinal thickness or amount of hemorrhage may not correlate with viability.[67] Recent reports of survival of horses with hemorrhagic lesion at surgery suggest that this injury can be reversed more readily than a lesion caused by total arteriovenous occlusion. The sequence of mucosal degeneration remains the same in this type of ischemia, making the biopsy the most reliable method for determining if the intestine can survive and heal.[67]

Distention

Although distended intestine may appear to have normal color and motility after decompression, alterations in blood flow in the intestinal wall create low-flow ischemia. During intestinal distention, intraluminal pressure causes collapse of the veins and capillaries, thereby decreasing the vascular capacity. This occurs even when blood pressure is normal. When small intestinal pressure is increased to 18 cm of water, as previously measured in clinical disease,[68] mesenteric blood flow to the intestine is decreased by at least 50%.[55,69] Increasing capillary back pressure while maintaining arterial pressure alters Starling forces in the intestinal wall. The result is secretion of fluid from the vasculature even with an increase in wall tension. Water and some protein escape into the interstitium, causing submucosal and serosal edema. At higher intraluminal pressures there is more secretion than absorption of water, creating a cyclic increase in intraluminal pressure after bowel compliance has reached its limit.[69a] Fluid and eventually protein leak through the serosa into the intestinal lumen and peritoneal cavity.

If the pressure is maintained, intestinal compliance allows blood flow to gradually increase, acting as a form of reperfusion.[55] Serosal and submucosal edema progresses during the period of distention. The mucosal and serosal lymphatics dilate, and RBCs and white blood cells (WBCs) migrate into the mucosa, submucosa, and serosa (Fig. 32-59). There is minimal injury to the mucosal epithelium at pressures seen in clinical cases during simple obstruction of the small intestine or colon.

Subsequent decompression of the bowel causes reperfusion with a hyperemic response similar to that seen after low-flow or total ischemia. Blood flow to the affected bowel can initially double, but this effect is temporary, with subsequent blood flow decreasing below normal.[55] The mucosa appears relatively resistant to short-term distention, whereas the edema in the serosa causes capillary closure and increased vascular permeability. Serosal edema increases and more neutrophils migrate into the serosa, causing destruction of collagen and ground substance.[54] Intestinal smooth muscle is also affected with edema, and neutrophil migration is evident in the fascial planes around the myenteric plexuses (Fig. 32-60). Although bowel can frequently heal after this type of ischemic insult, the serosa is often thickened by fibrous tissue with the possibility of adhesion formation and mesenteric constriction.[51,70] The mucosa appears relatively resistant to the low-flow ischemia created by bowel distention, but the response is time dependent. Rarely does prolonged distention cause bowel necrosis. Bowel wall necrosis is more common when foreign bodies or impactions cause focal distention. Because the response to distention is both time and pressure dependent, the time frame for permanent damage is difficult to determine. The small intestine is more susceptible to distention injury compared with the large colon. Clinical measurement of intraluminal pressure during obstruction indicates that the large colon can tolerate at least twice the distention pressure with no adverse effects.[71,72]

Intestinal dysfunction occurs after decompression of previously obstructed bowel. Ileus with gastric reflux is common in horses with previously distended small intestine, and the bowel pressure measured at surgery can predict the severity.[71,72] Abnormal motility with lack of response to prokinetic drugs is also observed after small

VetBooks.ir

intestine distention in vitro.[73] Although the injury from distention cannot be separated from conditions in the peritoneal cavity or failure of the cardiovascular system, the correlation of increased intraluminal pressures and survival indicates the importance of intestinal distention in causing injury.

The enteric nervous system also appears to respond to intestinal distention. Chronic obstruction caused by impaction of the colon or cecum or colon displacement has been associated with a significant decrease in the number of neurons in the myenteric plexuses of the large colon, whereas the number of myenteric plexuses was similar to that in normal horses.[46] This change in neuron number was also associated with increased thickness of the longitudinal muscle in the pelvic flexure or both circular and longitudinal muscle hypertrophy in the cecum.[74] This appears similar to pseudoobstruction in humans and to experimental denervation of intestinal segments in rats. The lack of nervous inhibition is hypothesized to allow constant and uncoordinated muscular contractions with resulting hypertrophy and eventually poor transit of ingesta.

Myenteric plexuses from distended or obstructed large colons also had an increase in the number of glial cells (Fig. 32-61).[46] This appears to be an inflammatory response by the enteric nervous system to the conditions involved with bowel distention.[47] Alternatively the inflammation and neuron dropout may have been responsible for colon dysfunction in these horses examined because of colon obstruction.

Infection

Enteritis caused by infection is frequently a result of *Salmonella* spp., *Clostridia* spp., *Neorickettsia risticii, Lawsonia intracellularis,* or virulent *E. coli.* Viruses such as rotavirus can also cause infection in foals with subsequent clinical signs. These agents adhere to and attack mucosal cells. When bacteria bind to the mucosal cells, the release of endotoxins or exotoxins causes the mucosal cells to release cytokines, which signal immunocytes and neutrophils of impending invasion. The gut has a large number of lymphocytes and

VetBooks.ir

macrophages in the lamina propria, suggesting constant stimulus by agents or substances.[10,75] Although the mucosal cell has an innate ability to resist infection, the communication between the immunocytes and the mucosa is likely the chief defense. The infection can change mucosal function without destroying the mucosal barrier; increased TNF-α concentration has been shown to impair barrier function at the tight junctions.[76] The change can cause lack of absorption and/or massive secretion of fluid into the bowel, causing diarrhea.

Interaction of neutrophils with the apical membrane of epithelial membrane after paracellular migration stimulates adenosine receptors by production of 5′ adenosine monophosphate (5′-AMP).[77] Subsequent functional secretion is caused by stimulation of adenyl cyclase and guanyl cyclase, which catalyze formation of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), respectively. These cyclic nucleotides subsequently activate protein kinases, which block the sodium chloride (NaCl) absorptive process in the absorptive mucosal cell and stimulate chloride (Cl) secretion in the crypt cell.[78] Inflammation with release of eicosanoids and bradykinin can also initiate the secretory process. The enteric nervous system can also induce inflammation and secretion in the bowel, which can be inhibited by nerve-blocking agents or indomethacin.[79] Neuropeptides from efferent nerves are hypothesized to initiate this response by affecting mucosal cells, fibroblasts, and endothelial cells.[1]

When bacteria cause injury by adhering to the mucosal surface and invading the mucosa, the response of the mucosal cells stimulates both the afferent nervous system and an immediate local immune reaction. Cytokines from local macrophages or injured epithelial cells serve as the messengers of recognition, which stimulate macrophages, neutrophils, and eosinophils to migrate to the region of invasion. Lymphocytes are also activated, releasing cytokines, including IFN-γ. After an initial delay in mucosal cell apoptosis during bacterial adhesion and invasion, apoptosis is increased, theoretically to increase cell turnover and healing. TNF-α and nitric oxide appear to control mucosal cell apoptosis.[6]

The inflammatory response to invasion often causes massive mucosal necrosis, with loss of mucosal cells and a massive infiltrate of neutrophils and lymphoid cells. Fibrin exudate creates a "cast" on the mucosal surface of the bowel. The vasculature is exposed to the bowel lumen, allowing subsequent invasion of the bacteria, both pathogens and others, as well as bacterial toxins. The remaining mucosal cells are stimulated to secrete water via the stimulation of cAMP within the crypt cells. Water is also retained in the bowel because of the lack of absorptive cells; the result is diarrhea.

The infection can involve the other layers of the intestine, although it rarely involves the serosa. Still, some diseases such as hemorrhagic fibrinonecrotic duodenitis–proximal jejunitis (DPJ) affect all layers of the intestine. The cause of DPJ is unknown, but the lesion is similar to that seen with clostridial disease in young swine.[80] Similar to reperfusion injury, the inflammatory process creates dysfunction that can last for days. Although long-term complications from DPJ have not been reported, animals with severe cases have not survived because of the lack of healing and severe residual inflammation in the bowel wall.

Peritoneal Inflammation

The serosal layer is made of a single-cell mesothelial layer mounted on a layer of connective tissue. This layer is important for maintenance of a lubricated barrier at the bowel surface, necessary for normal intestinal motility and peritoneal cavity fluid exchange. The mesothelial layer attaches to a basement membrane, which is adjacent to an elastic layer. The mesothelial cells vary in type. Some are short and have channels linking the peritoneal surface to the serosa. Others have long microvilli, which appear to help trap fluid on the surface of the peritoneum, providing the chief mechanism of lubrication on the bowel surface. Mesothelial cells react to circulating or intraperitoneal lipopolysaccharide (LPS), infection, and surgery by releasing TNF-α, IL-1β, IL-6, and macrophage inflammatory protein (MIP).[81] The response in the serosa is attraction and migration of neutrophils into the serosal connective tissue.

The initial response to serosal injury has been studied in laboratory animals using predominantly scarification of organs or fecal contamination of the peritoneal surface. The response to ischemia or distention of the equine small intestine is similar, although often more severe. During ischemia the mesothelium is rapidly lost, with subsequent serosal swelling with edema. During reperfusion the serosal vasculature becomes more permeable, and polymorphonuclear cells and mononuclear cells migrate through capillaries or venules and infiltrate into the serosal connective tissue layer. Neutrophils accumulate at the basement membrane around vessels and within lymphatics. Fibrin accumulates within the serosa layer and on the surface. WBCs release oxygen radicals and proteolytic enzymes, resulting in disruption of collagen, the primary ground substance of the serosa. The denuded serosal response includes increased vascular permeability, which allows the surface to be covered with a fibrin clot. After 24 to 48 hours there is massive accumulation of cells, which are predominantly neutrophils, within the serosa and at its new surface.

Cytokines are involved in the response to serosal injury and the subsequent healing. [82,83] After intestinal anastomosis in rabbits, macrophages increased in number until about day 4. Superoxide levels in these cells are high in the first 24 hours. Prostaglandins, cytokine secretion, and plasminogen activator inhibitor activity are known to increase during the first 3 days after peritoneal injury.[82] IL-1 and TNF-α are secreted by peritoneal macrophages after injury and appear to modulate peritoneal healing.[84] Peritoneal macrophages also secrete plasminogen activator. The secretion of both plasminogen activator and plasminogen activator inhibitor is stimulated by IL-1. After intestinal anastomosis there is a decrease in fibrinolytic activity for the first 5 days. Thereafter, plasminogen activator returns to the normal preoperative level. Normally fibrin will be dissolved by plasmin after plasminogen is activated by tissue plasminogen activator (TPA). The severity of the serosal injury is also related to the reduction of TPA and to the suppression of plasminogen activator normally produced by macrophages. If plasminogen is not activated or is absent, adhesions have a greater likelihood of becoming fibrous and permanent.

As healing progresses, fibroblasts migrate into the fibrin and a layer of granulation tissue forms both beneath and on top of the original basement membrane (Fig. 32-62). Mesothelial cells produce connective tissue growth factor in response to IL-1β, which simulates fibroblast proliferation.[15] During this stage IL-1β stimulates and prostaglandin E_2 inhibits fibroblast activity in the injured serosa.

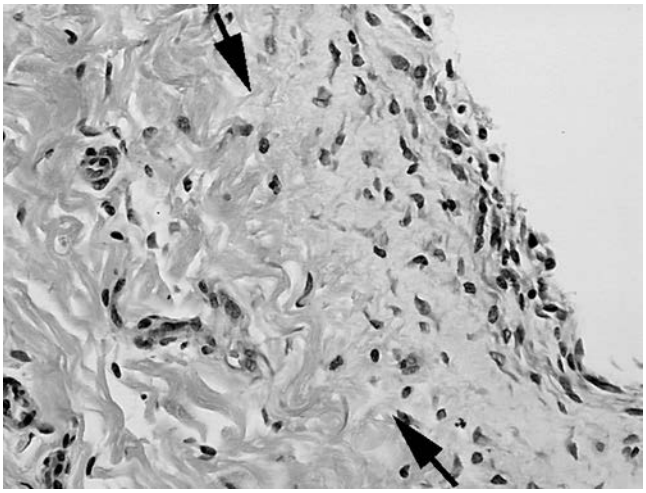

FIG. 32-62 Photomicrograph of the serosa with addition of a fibrous layer extending beyond the original level of the basement membrane *(arrows)* 10 days after bowel ischemia and reperfusion (hematoxylin and eosin stain). The new serosal surface has yet to heal with a new mesothelial layer.

VetBooks.ir

Primordial stem cells migrate to the surface and change to form a new mesothelium, a metaplasia likely under the control of growth factor from fibroblasts. The greater the inflammatory reaction is within the serosa and on the surface, the more fibroplasia occurs, thereby delaying mesothelium resurfacing and increasing the chance for adhesion formation or bowel scarring. Under experimental conditions the severity of adhesions is correlated with increasing concentrations of TNF-α in peritoneal fluid, and antibodies against TNF-α can decrease adhesion formation.[85] Healing of the serosa may not result in bowel-to-bowel adhesions but can still cause bowel and mesenteric scarring, which can cause luminal narrowing or kinking. The serosa also becomes thickened, which may result in bowel dysfunction or may interrupt the vascular supply, resulting in chronic obstruction.

In the horse the serosal injury is frequently caused by bowel distention. The cellular injury is similar to an inflammatory model except for the vascular sequelae. After small intestinal ischemia there is an initial vascular hyperemia in most of the bowel but a reduction of perfusion to the serosa.[33] This same effect occurs during bowel distention and is even greater after alleviation of distention. The edema formation in distended bowel takes place immediately and increases serosal tissue pressure, which exerts extravascular pressure and closes capillaries and venules.[33] This continues after bowel decompression, resulting in ischemic injury during reperfusion of the serosa. Reperfusion after decreasing bowel distention also causes serosal endothelial cell swelling and capillary plugging. This helps to explain the adhesions seen in bowel that was distended only proximal to an obstruction or strangulating lesion but was otherwise not involved in an ischemic lesion.

Decreasing the inflammatory response, including neutrophil migration in bowel after experimental ischemia and reperfusion, is associated with a marked decrease in subsequent fibroplasia and gross adhesion formation. Use of flunixin combined with antibiotics or depressing the initial inflammatory response to reperfusion using rinse solutions suggests that controlling septic serositis is required to decrease scarring of the serosa.[51,86]

Adhesions resulting from septic peritonitis occur in response to a massive inflammatory response in the serosa. Similar to the response to ischemia, neutrophil migration and fibrin deposition occur in and on the serosa.[83] The inflammatory response may be so great that the proteolytic enzymes may prevent adhesion between bowel loops by breaking down fibrin. However, in most cases there is massive fibrin production, and bowel-to-bowel adhesions occur frequently.

Bowel Healing

After ischemic damage, the mucosa heals rapidly.[87] Enterocytes migrate along the lamina propria, covering the surface within 24 to 38 hours. In the mucosa the crypt cells are responsible for rapid multiplication and physically forcing the older cells to the mucosal surface. Delayed healing is associated with a massive inflammatory response, which can stimulate delayed epithelial apoptosis and lack of cell replacement.[9,88] Connective tissue growth factor stimulates mucosal growth and may be responsible for excessive fibrosis in chronic inflammatory disease.[89]

Common use of nonsteroidal antiinflammatory drugs (NSAIDs), in particular flunixin meglumine, delays mucosal cell function during reperfusion.[87] Although replacement of the mucosal cell lining after ischemia is rapid, in vitro application of flunixin meglumine delays normal return of mucosal barrier function. Increased permeability to endotoxin in flunixin-treated bowel compared with the control intestine may lead to shock or delayed healing of intestine.[90]

Lidocaine administration has been shown to decrease the bowel injury in response to experimental ischemia and reperfusion.[91] When lidocaine was added to horses treated with flunixin meglumine mucosal barrier function was preserved. COX-2 inhibitors such as meloxicam administered to bowel did not increase bowel permeability; this suggests that total COX inhibition affects mucosa healing after ischemia and reperfusion.[92] In a similar manner, firocoxib inhibited lipopolysaccharide permeability across ischemic-injured mucosa.[93]

The serosal mesothelium also heals rapidly after loss from abrasion, although it takes longer than the mucosa to heal with a functional cell boundary. The mesothelial cells come from multipotent stem cells in the serosal connective tissues. These migrate to the serosal surface and form an initial layer of cuboidal cells before transforming to the more characteristic flattened mesothelial cells. The healing time appears to be dependent on the amount of inflammation and subsequent production of fibrous tissue on the serosal surface.

Although healing is thought to be successful when clinical signs of colic, obstruction, or peritonitis are no longer observed, the latent effect of serosal fibrosis, residual mucosal inflammation, and ganglionitis with loss of neurons may increase the risk of future colic episodes. Horses that have had a colic episode or previous abdominal surgery are three to four times more likely to have a second colic episode than horses that have never had colic.[56] Whether chronic inflammation or intestinal scarring is responsible for recurrent colic has not been determined.

Endotoxemia and Sepsis

Kelsey A. Hart • Robert J. MacKay

Definitions

The term *endotoxin* was originally coined to describe toxic bacterial components that were contained within or on the bacterial cell rather than "exotoxins" that were secreted from bacterial cells. The heat-stable endotoxic activity of *Vibrio cholerae* identified by Pfeiffer more than 100 years ago resides in lipopolysaccharide (LPS), the principal component of the outer leaflet of the outer membrane of all gram-negative bacteria[1] (Fig. 32-63). Today, the terms *endotoxin* (the activity) and *LPS* (the molecule) are used synonymously to refer to this specific gram-negative bacterial membrane component, except when purified LPS is being referenced.[2] Each LPS molecule has three structural domains: a polar polysaccharide O-region, which projects into the aqueous extracellular environment; a hydrophobic lipid A-region, which is largely buried in the bacterial outer membrane; and a core acidic oligosaccharide region connecting the two. The O-region is highly variable, consisting of repeating units each of one to eight glycosyl residues, and contains antigens specific for each bacterial strain; the core glycolipid region is relatively constant among bacteria and mediates most of the toxic effects of endotoxin. On bacterial death or during bacterial proliferation, large (>10^6-dalton molecular mass) aggregates of LPS and membrane protein are released. It is these protein-lipid micelles that constitute native endotoxin.

Endotoxemia literally is the presence of endotoxin in the blood. However, when the term is used clinically, it implies only the presence of clinical signs typically caused by the inflammatory response to circulating endotoxin. Endotoxemia—actual circulating endotoxin or related clinical signs—can occur with gram-negative bacterial infection in any tissue or through exposure to gram-negative enteric bacteria any time the intestinal mucosal barrier is compromised.

The ability to respond to minute local concentrations of endotoxin by mounting vigorous inflammatory responses is well conserved across species.[3] Endotoxemia as a clinical syndrome in equine patients was first recognized more than 45 years ago.[4] The potential clinical importance of equine endotoxemia is clear from reports that intravenous infusion of LPS into horses reproduced many of the adverse clinical signs of diseases such as colitis, metritis, and strangulating intestinal obstruction.[5-10] Further evidence for the importance of endotoxemia is the detection of circulating endotoxin in some horses with experimentally induced laminitis[11] or intestinal strangulation obstruction[12] and in horses with naturally occurring

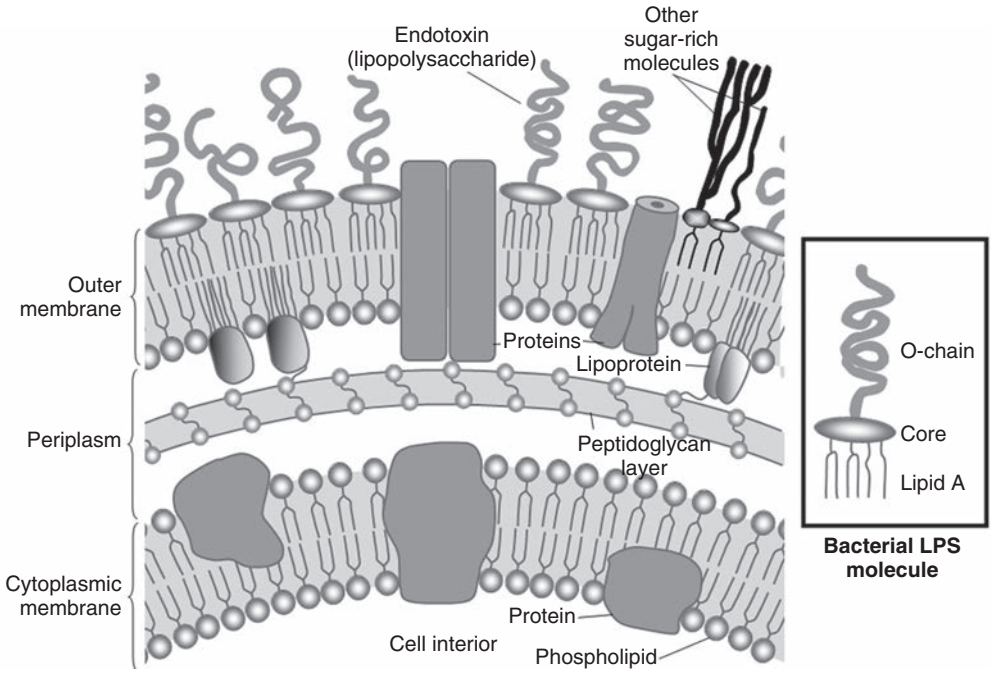

FIG. 32-63 Cross-section of the double lipid bilayer that forms the cell membrane of gram-negative bacteria. As is shown in this figure, lipopolysaccharide *(LPS)* is the principal component of the outer leaflet of the outer membrane. The insert shows a single LPS molecule with an O-polysaccharide chain, a two-part core oligosaccharide, and a hydrophobic lipid A phospholipid. R-mutant bacteria lack the O-chain ± varying amounts of the core oligosaccharide.

gastrointestinal diseases or septicemia,[13-17] hemostatic disorders,[16] and exhaustion associated with endurance[18] or racing[19] events. Since these original descriptions were published, a large body of review literature has documented the efforts that have been made to understand and, more important, treat equine endotoxemia.[20-23]

Endotoxemia should not be confused with either *bacteremia,* which refers only to the presence of viable circulating bacteria and can occur without clinical signs, or *septicemia,* which refers to systemic disease caused by any circulating microorganisms and/or their products. *Sepsis* is a related term that is best defined as clinical evidence of an infection (documented or suspected) coupled with the presence of a *systemic inflammatory response syndrome* (SIRS) that is characterized by alterations in body temperature, heart rate, respiratory rate, and leukogram parameters.[24,25] A scheme showing increasingly severe stages of SIRS and sepsis, from local infection to death, and adapted definitions for SIRS and organ dysfunction adapted for horses is shown in Fig. 32-64 and Table 32-3. In general, *severe sepsis* includes sepsis (infection + SIRS) and evidence of organ dysfunction, and *septic shock* includes severe sepsis plus acute circulatory failure (usually manifested by persistent hypotension after appropriate volume resuscitation).[25] Dysfunction of two or more organs in severe sepsis/septic shock is termed *multiple organ dysfunction syndrome* (MODS) and is associated with increased mortality in human beings.[25a] The lethality of each grade increases from the base to the apex (see Fig. 32-64), with reported mortality rates among humans of 10% to 20% for sepsis, 20% to 50% for severe sepsis,[25b] and 40% to 80% for septic shock.[26] Comparable mortality data are not currently available for horses.

It is important to note that endotoxemia—as the clinical manifestation of a systemic inflammatory response to circulating endotoxin—is a subset of sepsis and can manifest at all stages of disease. Note also that sepsis is defined as *suspected* infection plus SIRS; therefore a horse with a strangulating intestinal obstruction and clinical evidence of SIRS (tachycardia, tachypnea, leukopenia) but no easily identifiable infection is still classified as septic or endotoxemic. Horses with signs of mild endotoxemia (e.g., leukopenia and fever) also fit the definition for sepsis.

The fundamental difference between serious sepsis in humans and the syndromes seen in equids is the propensity for the latter to be associated with laminitis. In the context of sepsis, laminitis is often life-threatening. Because an organ is defined here as "a dispersed or solid tissue that performs a specialized function," it is probably inappropriate to classify the hoof as an organ as part of an equine MODS definition. It is clear from recent data, however, that the same types of global inflammatory and coagulation disorders that lead to MODS in patients with sepsis also are involved in the pathogenesis of both carbohydrate- and black walnut–induced laminitis.[27-31] In light of their likely common pathogenesis, MODS and laminitis (MODS/L) are presented together in Fig. 32-64. With the exception of laminitis, the definitions listed in Table 32-3 are not validated for horses, but they are reasonable extrapolations from accepted human criteria. Several recent studies have used these or similar criteria for SIRS, MODS, or septic shock in horses or foals.[32-37]

The extraordinary ferocity of SIRS as triggered by endotoxin was nicely captured by Thomas[38]:

The gram-negative bacteria … display lipopolysaccharide … in their walls and these macromolecules are read by our tissues as the very worst of bad news. When we sense lipopolysaccharides we are likely to turn on every defense at our disposal; we will bomb, defoliate, blockade, seal off, and destroy all tissues in the area …. Cells believe that it signifies the presence of gram-negative bacteria, and they will stop at nothing to avoid this threat.

Although this picture still accurately describes modern concepts of the early immune response to endotoxin, it has become clear that a variety of other pathogen-derived molecules set off similar or identical host responses. For example, toxic shock syndrome resulting from *Staphylococcus aureus* infection[39] and streptococcal toxic shock[40] are examples of hyperinflammatory septic syndromes in horses that resemble diseases characterized by true endotoxemia (circulating LPS). Thus, in sepsis, including putative endotoxemia in horses, it is likely that the clinical presentation is an aggregate of responses to multiple or varied microbial signals as well as to certain "danger" signals generated by the host itself. Circulating endotoxin is not always detectable in horses described as "endotoxic"; in fact, it is typically found in less than 30%[41,42] of these horses; this suggests that other microbial components and host inflammatory molecules

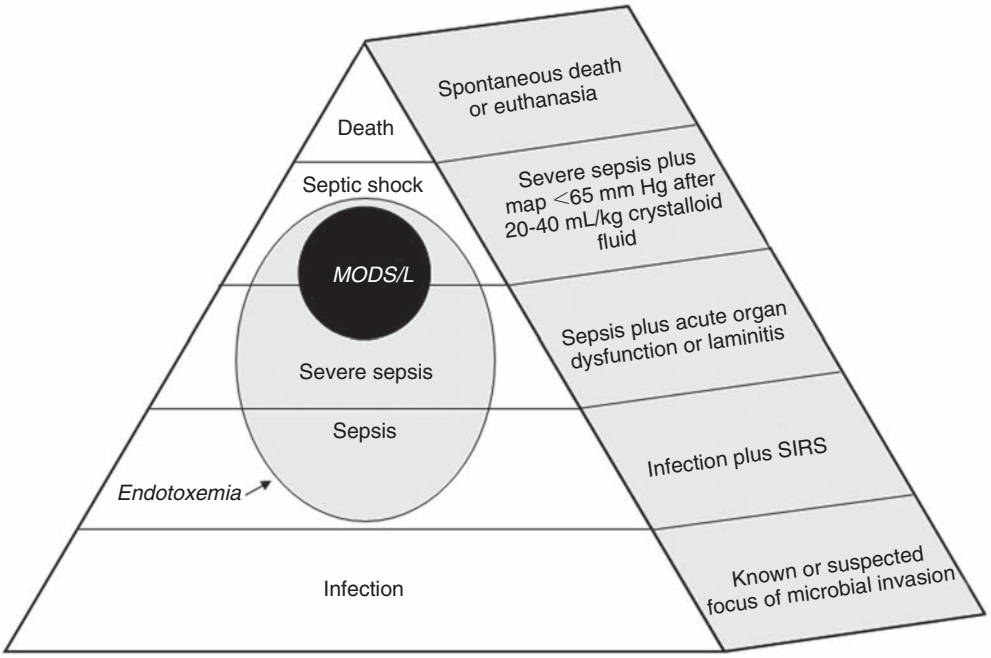

FIG. 32-64 Scheme for sepsis classification. Definitions for systemic inflammatory response syndrome, organ dysfunction, and laminitis are given in Table 32-3. *MODS/L,* Multiple organ dysfunction syndrome/laminitis; *SIRS,* systemic inflammatory response syndrome.

TABLE 32-3

Criteria for Systemic Inflammatory Response Syndrome, Organ Dysfunction, and Laminitis

SIRS Criteria (Two or More of the Following)	
Hypothermia	<98° F or hyperthermia >101.5° F
Leukopenia	<5000/μL or leukocytosis >14,500/μL
Tachycardia	>50 beats/min
Tachypnea	>25 breaths/min or Pa_{CO_2} < 32 mm Hg
Organ Dysfunction and Laminitis Criteria	
Neurologic	Severe obtundation (stupor, semicoma, coma)
Renal	Creatinine >2 mg/dL after ≥20 mL/kg IV crystalloid fluids, or increase of ≥0.5 mm Hg since last measurement
Hemostatic	Platelet count < 100,000/μL or aPTT > 70 seconds
Respiratory	Pa_{O_2} < 65 mm Hg, or <75 mm Hg with oxygen supplementation or mechanical ventilation
Intestinal	Absent gut sounds, or absent motility on ultrasound examination
Hemodynamic	Mean arterial pressure <65 mm Hg after ≥20 mL/kg IV crystalloid fluids
Hepatic	Bilirubin concentration > 6 mg/dL; GGT > 60 U/L with no other explanation
Laminitis	Bounding digital pulses, sensitivity to digital pressure over the coronary band, sensitivity to hoof tester pressure over the sole, Obel grade >1

aPTT, Activated partial thromboplastin time; *GGT,* γ-glutamyltransferase; *IV,* intravenous; *SIRS,* systemic inflammatory response syndrome.

likely trigger similar clinical signs. Thus, the terms *sepsis* and *SIRS* might be more appropriate than *endotoxemia* to accurately describe the clinical signs usually attributed to endotoxin in horses (e.g., hyperemic or toxic mucous membranes, fever, tachycardia, tachypnea, leukopenia). In this section, sepsis will be used to imply SIRS in response to any microbial infection, and endotoxemia will be used to refer specifically to the presence of endotoxin in the blood or to the specific clinical signs related to documented circulating endotoxin. However, our understanding of the molecular basis of sepsis in the horse via mechanisms other than endotoxemia is limited at best, so the majority of the following discussion will center on endotoxemia as an important component of equine sepsis.

Pathophysiology

Endotoxin or Other Microbial Products Enter the Circulation

Although endotoxin and other microbial components are ubiquitous in the environment (both free and as a component of intact bacteria), these components normally are excluded from the body by the skin and mucous membranes. If the protective integument or mucosae are subjected to bacterial infection or otherwise damaged, bacteria or bacterial components such as endotoxin may reach the blood in a sufficient amount (<1 μg of purified LPS in experimental situations) to cause clinical signs. Gram-negative bacterial enterocolitis (e.g., salmonellosis), metritis, pleuropneumonia, wound infection, and neonatal septicemia are common pathways to endotoxemia in horses. Because gram amounts of free endotoxin normally are safely sequestered within the intestine of the adult horse, damage to the gut wall—as a result of local (e.g., intestinal volvulus, infarction, incarceration) or systemic (e.g., hypovolemic shock) causes of tissue hypoxia; inflammation (e.g., duodenitis–proximal jejunitis [DPJ] or clostridial enteritis); mechanical trauma (e.g., rectal perforation, prolonged exercise); or intraluminal acidification (e.g., grain overload)—is particularly likely to result in endotoxemia. In highly contaminated environments, potentially harmful amounts of endotoxin can be introduced into the lungs via inhalation.[43] Endotoxin may even be delivered directly into the blood via contaminated parenteral solutions (e.g., homemade intravenous fluids). Other microbes and microbial components (e.g., flagellin) or secreted toxins (e.g., staphylococcal exotoxins) can enter the circulation in similar ways, although our understanding of these pathways in horses is less well understood.

Interaction with Pattern Recognition Receptors

Animals have the ability to recognize many distinctive patterns on molecules that signal potential danger. As a group, these molecules that express danger motifs are aptly termed *damage-associated molecular patterns* (DAMPs). Included among DAMPs are microbial signals like endotoxin, collectively termed *pathogen-associated molecular patterns* (PAMPs), and *alarmins,* endogenously produced molecules that originate from damaged or inflamed tissues[44,45] (Table 32-4). A limited number of germ-encoded receptor types, both soluble and cell-associated, are dispersed throughout the body to detect potential threats (both septic and nonseptic). These are pattern-recognition receptors (PRRs) and are exemplified by Toll-like receptors (TLRs) on (and in) cells and complement receptor proteins and Hageman factor in plasma.[44-46] A partial list of these and other PRRs is given in Table 32-5. The interaction between DAMPs and PRRs is the initial event in the innate immune responses that result in the clinical presentation of endotoxemia or other forms of sepsis.

In 1985 almost nothing was known about the way in which LPS molecules interacted with cells of the immune system. In fact, endotoxin was widely believed to enter cells not via engagement of cell-surface receptors but by hydrophobic insertion into the membrane (Fig. 32-65). Since then, sequential discoveries of a plasma LPS-binding protein (LBP; 1989 for humans,[47] 2005 for horses[48]), CD14 (1990 for humans,[49] 2003 for horses[50]), and TLRs (1998 for humans,[51] 2005 for horses[52]) have elucidated the molecular processes of endotoxin binding and signaling (see Fig. 32-65). LPS first interacts with LBP, a normal plasma acute-phase protein; this interaction facilitates binding to the soluble or cell-associated co-receptor CD14. The LPS/LBP/CD14 complex recruits and activates TLR4 dimer and an accessory component MD-2 in preparation for LPS signaling. On ligation of the receptor, the conserved intracellular domain of TLR4 (Toll-IL-1 receptor [TIR]) initiates multiple downstream pathways that culminate in translocation to the nucleus of inducible transcription factors including nuclear factor κB (NF-κB) and activator protein 1 (AP-1).[53] NF-κB binds to consensus sequences on the promoter or enhancer regions of an array of genes whose products are involved in the inflammatory response.[53] It has been argued that the global activation of TLR4 typical of sepsis also requires the actions of endogenous agonists (e.g., proteases).[54] Endotoxin also may activate NF-κB via TLR4-independent interactions with β_2-integrins, heat-shock proteins, and the intracellular Nod-1 receptor.[55]

Endotoxin engages TLR4 on cells of the innate and adaptive immune systems, especially mononuclear phagocytes (monocytes and macrophages), neutrophils, endothelial cells, and dendritic cells. Pulmonary intravascular macrophages and Kupffer cells likely are the most important mononuclear phagocytes in this regard. Although endotoxin binds predominantly to TLR4, a still-growing family of TLRs (13 in rodents, 10 in humans, unknown in horses) is available

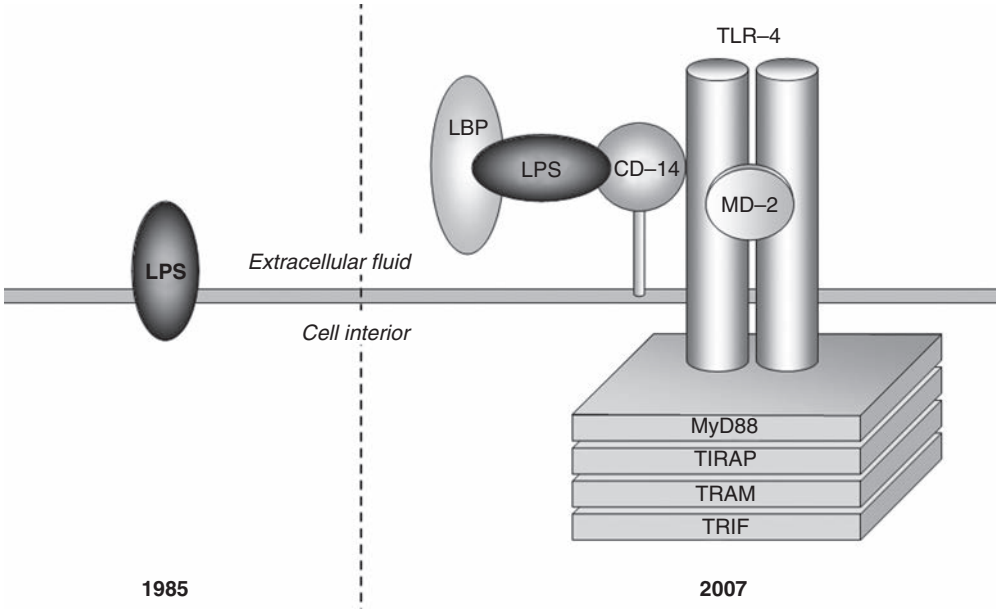

FIG. 32-65 Binding of lipopolysaccharide *(LPS)* to mammalian cell membranes. In 1985 it was widely believed that LPS initiated cellular signaling by hydrophobic interactions with the plasma membrane. By 2007 the components of the signaling complex were more fully understood. In addition to the extracellular receptor components (discussed in the text), the intracellular Toll-IL-1 receptor *(TIR)* domain is shown interacting with four adaptor molecules (MyD88, TIRAP, TRAM, TRIF) to initiate a molecular signaling cascade that ultimately leads to gene activation.

to bind to other DAMPs (Table 32-6).[56] During sepsis, this diversity of TLRs allows redundant signaling of inflammatory cells. For example, non-LPS components of gram-negative bacteria may bind other TLRs (e.g., flagellin binds to TLR5, lipoprotein and peptidoglycan to TLR2), whereas PAMPs from gram-positive bacteria, viruses, or fungi bind different TLRs in the course of polymicrobial sepsis.[56] Equine TLR signaling has been characterized in many cells and tissues.[57-59] It is interesting to note that whereas LPS is a potent stimulator of equine monocytes via TLR4, flagellin (via TLR5) preferentially stimulates neutrophils and induces little response from monocytes,[60] suggesting differential expression of these TLRs between cell types in the horse that could play a role in clinical sepsis. Thus, while TLR ligand-specificity appears to be well conserved across species, specific TLR expression varies among cells, tissues, and species and can result in varied responses to the same DAMP. Tissues subject to attack by mediators produced after the initial round of TLR binding can also feed back and amplify the inflammatory response by releasing alarmins (e.g., high-mobility group box 1 [HMGB1]),[61] which in turn can bind to TLR or other PRRs.

Simultaneous with cellular activation, endotoxin and other microbial products interact with soluble PRRs normally present in plasma. Of particular importance, endotoxin binds to complement proteins to initiate the lectin-dependent and alternative pathways of complement activation and activates coagulation factor XII (Hageman factor) to set off the "contact" system of coagulation.

Mediators Are Released

Endotoxin-induced NF-κB activation in peripheral blood and tissue leukocytes (and many other cell types) acts via multiple signaling pathways to induce the expression of more than 200 genes, many of which are involved in the pathogenesis of sepsis.[45,53,62] These include genes for proinflammatory cytokines (e.g., TNF, IL-1β, IL-6, IL-8, IL-12, IL-18), chemokines (e.g., IL-8, MIP), type 1 IFNs, procoagulants, adhesion molecules, immunoreceptors (e.g., TNF receptors), enzymes (e.g., elastase), and acute-phase proteins (e.g., fibrinogen). NF-κB activity is further amplified by the paracrine actions of these proinflammatory cytokines and by other DAMPs, cellular hypoxia, cellular necrosis, and chemical stress (including oxidant stress). Two of the cytokines secreted by macrophages, IL-12 and IL-18, stimulate IFN-γ synthesis and secretion from natural killer (NK) and other cells.[63] Because IFN-γ is a potent stimulator of both innate and acquired immune responses, it is considered to be a principal link between the two systems.

Endotoxin activates coagulation factor XII (Hageman factor), leading both to liberation of bradykinin and to initiation of intravascular coagulation. Even more important, complement is activated by alternative, lectin-mediated, and classical pathways to yield numerous active peptide products that are important for opsonization, inflammatory cell trafficking, and microbial cell lysis. Other microbial structural components and products similarly stimulate inflammation, complement activation, and coagulation, although specific pathways and molecular mechanisms are not well characterized for horses.

SIRS in Early Sepsis

The initial, early phase of sepsis is often referred to as the "hot" phase and is characterized by inflammation, coagulation, and necrosis. The principal NF-κB–mediated events during early sepsis are summarized in Fig. 32-66. This phase has been described as a "cytokine storm," during which there is flooding of inflammatory, procoagulant, and vasoactive mediators throughout the body. The net effects of these mediators promote microvascular injury and hypotension. The singular contributions of many mediators to sepsis is demonstrated by experiments using sepsis models in which blocking or deleting a single mediator has had a positive effect on outcome.

In early sepsis, large numbers of neutrophils accumulate on the endothelial surfaces of organs undergoing failure, and insult to one organ can trigger the widespread recruitment and sequestration of neutrophils in others. Such a scenario may contribute to the association of laminitis with severe intestinal disease,[64-67] although altered insulin and glucose dynamics,[68,69] vascular derangements,[65] or contributions of multiple inflammatory mediators[70] may also play a role in the development of laminitis in septic horses.

In response to PAMPs (including LPS), inflammatory cytokines produced by macrophages and other cells, and complement peptides, endothelial cells, and neutrophils express selectins.[45] Selectins on endothelial cells (E and P) and neutrophils (L) reciprocally engage glycoprotein ligands to "tether" the neutrophil to the endothelial surface. A series of these transient interactions between ligands and receptors allows neutrophils to roll along the endothelial surface (Fig. 32-67). Neutrophil capture is most efficient in areas of low shear force, such as the walls of postcapillary venules and in pulmonary capillaries. During rolling, neutrophils are activated or "triggered" by selectins, chemokines, and PAF expressed on endothelial cells. The firm attachment or arrest step of the cascade is mediated by the avid interaction of neutrophil integrins with adhesion molecules of the immunoglobulin superfamily expressed on endothelial cells. During firm attachment the activated neutrophil spreads out and, in the healthy animal, squeezes between the intercellular junctions of adjacent endothelial cells and migrates into tissues up a gradient of chemotactic factors such as microbial chemotaxins, LTB_4, IL-8, or C5a. By contrast, when compared with normal neutrophils, those found in septic animals have defective chemotactic responses but bind with greater avidity to the endothelium and to other neutrophils. When cultured, macrophages and neutrophils from patients with gram-negative sepsis are hyporesponsive to LPS, suggesting a functional switch to LPS tolerance during the early stages of endotoxemia[71] (see Fig. 32-67). Sequestration of neutrophils on activated endothelium and in neutrophil aggregates accounts for the neutropenia found in most horses with endotoxemia. It is interesting to note that the lifespan of these sequestered neutrophils is prolonged during sepsis because normal apoptosis is prevented,[72] which might potentiate the inflammatory response during early sepsis.

Tightly adherent neutrophil-endothelial conjugates formed during sepsis seal off microscopic pockets between the juxtaposed cells into which cellular products can be concentrated. Of particular significance are the reactive oxygen species (ROS) produced as a result of the activation of NAD(P)H-oxidase in neutrophils (respiratory burst) and xanthine oxidase in endothelial cells.[44,62] Digital laminae of horses may be particularly vulnerable to the effects of ROSs because of low content of the endogenous oxidant scavenger superoxide dismutase.[73] In the presence of neutrophil granule myeloperoxidase and H_2O_2, highly toxic hypochlorous acid is formed on the endothelial surface. Superoxide anion generated as part of the

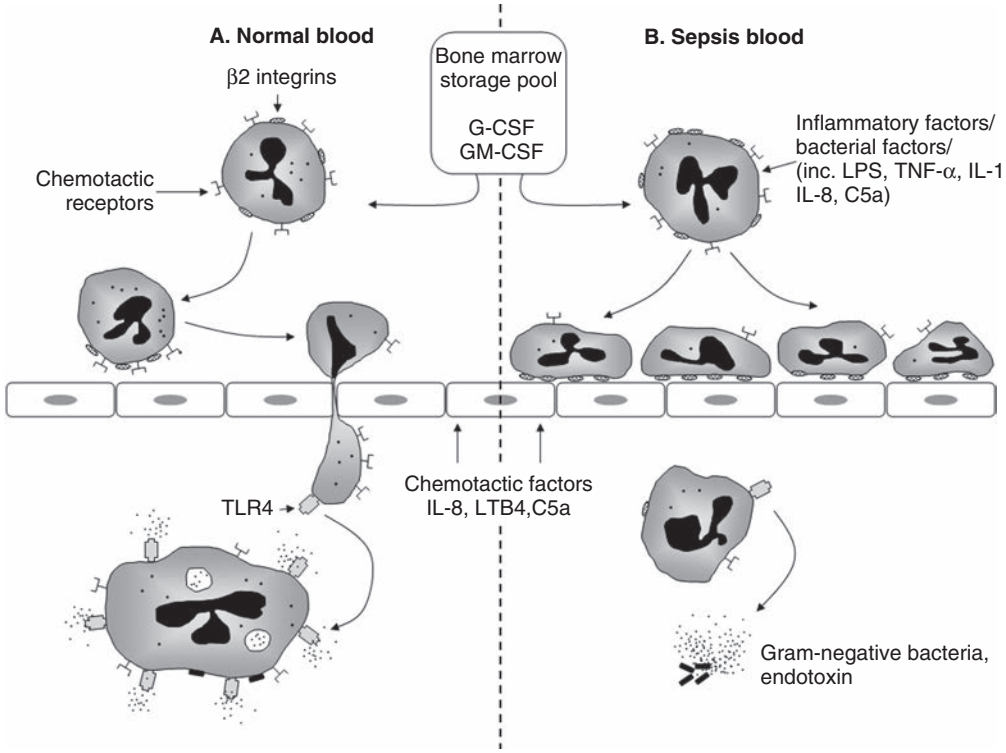

FIG. 32-67 Recruitment and activation of neutrophils to bacterial infection in healthy horses and septic or endotoxemic horses. In response to bacterial infection, cytokines are generated that induce the release of neutrophils from the bone marrow. In the normal state, large numbers of blood neutrophils enter sites of bacterial infection by first adhering to the activated endothelium of local postcapillary venules before migrating up a concentration gradient of chemotactic factors. Endotoxin is bound to Toll-like receptor 4 (TLR4), and bacteria are eliminated by phagocytosis. In patients with endotoxemia or sepsis, high levels of circulating inflammatory factors promote upregulation of surface integrins to promote firm endothelial adhesion to postcapillary venules. However, some of these factors also downregulate the expression of chemotactic receptors. Consequently, neutrophils are strongly bound but less responsive to underlying chemotactic factors. *G-CSF,* Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor. *(Modified from Fig. 2 in Braun U, Linggi T, Pospischil A. 1999. VetBooks.ir

neutrophil respiratory burst also reacts with nitric oxide (NO) from endothelial cells to yield reactive peroxynitrite radicals (both reactive nitrogen species, RNS). Other potentially corrosive substances are contributed by neutrophil granules and include elastase, serine proteases, matrix metalloproteinases (MMPs), and defensins. In addition to direct damage caused by membrane lipid peroxidation, ROSs and RNSs indirectly stimulate the expression of multiple inflammatory, procoagulant, and vasoactive mediators via activation of NF-κB in both neutrophils and endothelial cells.[44] Mediators such as bradykinin, PAF, C3a, C5a, and leukotriene B_4 (LTB_4) directly increase vascular permeability by promoting active retraction of endothelial cells via phosphorylation of the light chain of nonmuscle myosin.[44] Vascular leak then facilitates the movement of these potentially harmful substances into tissues.

In healthy animals, the antithrombotic phenotype of endothelial cells is maintained by the presence of low amounts of prostacyclin (prostaglandin I_2 [PGI_2]) and NO, and surface expression of thrombomodulin, protein S, and protein C complex and TPA.[74] During endotoxemia, endothelium supports extrinsic pathway activation because of leukocyte-induced physical damage, expression of the procoagulant tissue factor, downregulation of antithrombin-III and protein C, and inhibition of fibrinolysis through expression of plasminogen activator inhibitor 1 (PAI-1).[75-77] Additional procoagulant effect may be provided by deposition on the endothelial surface of all of the components of the intravascular coagulation system. Microvascular perfusion is further compromised by sepsis-associated increase in "stiffness" of both red blood cells (RBCs) and white blood cells (WBCs),[78] rendering such cells less able to deform and squeeze through narrow capillaries.

The effect of endotoxemia and sepsis on vascular tone depends on the stage and severity of disease and the particular organ (vascular bed) considered. Neuroendocrine responses to sepsis lead to the upregulation of predominantly pressor mediators, including arginine vasopressin, angiotensin II, serotonin, epinephrine, and norepinephrine. Inflammatory mediators are a mix of vasoconstrictors (thromboxane A_2 [TXA_2], endothelin, C3a, C4a, C5a) and vasodilators (PGE_2, PGI_2, adenosine, bradykinin, NO). In animals with serious sepsis, balances of constricting and dilating influences unique to each vascular bed, loss of vasoregulatory tone, and refractoriness of damaged endothelium to vasoactive substances cause maldistribution of blood flow among organs and systemic hypotension.

Because of poor perfusion pressure, direct microvascular injury, thrombosis, and loss of endothelial integrity (capillary leak), ischemia and hypoxia of organs and tissues occur.[27] Indeed, the fundamental event in serious sepsis is the development of global tissue hypoxia, perhaps also complicated by *dysoxia*.[45] Global tissue hypoxia results when systemic oxygen delivery fails to meet the oxygen requirements of tissues, and dysoxia results when tissues are unable to effectively use delivered oxygen. During serious sepsis, widespread microvascular and mitochondrial injury decrease oxygen delivery and consumption at the cell, tissue, and organ levels.[44,79,80] Oxygen delivery to tissues is a product of cardiac output and oxygen content (which itself is a product of hemoglobin oxygen saturation and hemoglobin concentration). The product of systemic oxygen delivery and the percentage of oxygen extracted (normally <25%) by the tissues is the systemic oxygen consumption. The balance between systemic oxygen delivery and consumption is reflected by the mixed venous hemoglobin oxygen saturation (SVO_2). SVO_2 has been shown in other species to be a useful surrogate for cardiac index as a target for goal-directed therapy.[81] Central venous oxygen saturation ($ScVO_2$), obtained through a central venous line, is a reasonable and easily measurable substitute for SVO_2 (which must be measured via a Swan-Ganz catheter).

Various hemodynamic combinations may create a systemic imbalance between tissue oxygen supply and demand[45,82]:

- *Hypovolemia.* Because of decreased preload caused by hypovolemia, concomitant left ventricular dysfunction, and reflex systemic arterial vasoconstriction, early endotoxemia is often characterized by low cardiac output (i.e., hypodynamic circulatory insufficiency).
- *Compensated but maldistributed perfusion.* After fluid-electrolyte resuscitation, compensatory mechanisms and low afterload drive transition to a hyperdynamic state. Even with normal or increased cardiac output, perfusion abnormalities may persist owing to regional hypoperfusion associated with derangements in blood flow distribution and loss of vasoregulatory control to vascular beds. This state is often described as *distributive shock.*
- *Myocardial depression.* Myocardial depression secondary to effects of inflammatory mediators and apoptosis of cardiomyocytes is the predominant cause of death in severe sepsis and septic shock.[83] Myocardial injury, as indicated by increased cardiac troponin concentrations, was recently reported in horses undergoing emergency abdominal surgery,[84] suggesting similar pathology likely develops in horses with sepsis and SIRS.
- *Increased metabolic demands.* SIRS increases metabolic demands, as evidenced by increased splanchnic and total body oxygen consumption.
- *Impaired oxygen use.* The bioenergetics of cellular extraction and use or respiration may be abnormal partially because of mitochondrial dysfunction.[44,79,80]

These derangements may occur independently of measured hemodynamic parameters. The theoretic components of each of these hemodynamic states are shown in Table 32-7.

In sum, current thoughts on early sepsis pathophysiology support development of a self-perpetuating imbalance in the systemic redox state resulting in oxidative stress that is believed to be at the root of SIRS and resultant organ dysfunction in sepsis.[44,79,80] Activation of local and systemic inflammatory responses results in production of ROS and RNS, which can directly and irreversibly damage cells and inhibit normal cellular activity, as described earlier. In healthy animals, ROS and RNS production is tightly regulated by inducible antioxidant enzymes, production of which is regulated by the nuclear transcription factor Nrf2.[44] However, Nrf2 activity is impaired by excessive ROS and RNS production, resulting in less activation of these antioxidant pathways and generating an overall oxidant environment.[44] Mitochondria are a key source of ROS and RNS, but they are also very sensitive to oxidative injury. Mitochondrial dysfunction and oxidative stress can result in tissue dysoxia and organ failure, as well as further stimulate inflammatory responses and NF-κB activation, creating the vicious cycle characteristic of SIRS and MODS.

Immunosuppression in Late Sepsis

It recently has become apparent that many patients with sepsis are profoundly immunosuppressed, as shown by lymphopenia, anergy, and susceptibility to opportunistic infections[44,45,85] (e.g., pulmonary aspergillosis in horses with enteric salmonellosis).[86,87] This immunosuppression has been explained by the reactive production of antiinflammatory mediators in response to the cytokine storm and is termed *compensatory antiinflammatory response syndrome* (CARS).[88] Although many such mediators are produced and can have favorable antiinflammatory effects when used as therapy in models of sepsis, it is now clear that three additional and primary mechanisms involving both innate and adaptive immune responses contribute to sepsis-associated immunosuppression: (1) widespread apoptotic death of lymphocytes (particularly B cells and CD4-positive T-helper cells) secondary to activation of intracellular caspases; (2) dendritic cell loss and dysfunction, leading to inefficient or impaired antigen presentation; and (3) impaired phagocyte chemotaxis and killing responses.[44,85,89] It is interesting to note that macrophages and neutrophils are spared premature apoptotic death; neutrophils are prevented from physiologic apoptosis during sepsis and remain viable in sequestered sites.[72] In people with sepsis, aspects of this immunosuppression are characterized by loss of cutaneous delayed-type hypersensitivity responses,[44] although this has not been investigated in horses to date. The relationship and interplay between SIRS and immunosuppression in sepsis are still unclear, and it cannot necessarily be inferred that hot and cold phases always occur sequentially in the same patient.

Signs of Endotoxemia and Sepsis

Clinical Signs

The clinical signs of horses given intravenous endotoxin experimentally may range from fever without obvious malaise to multiple organ failure and death. Signs of the primary disease resulting in endotoxemia (e.g., severe pain caused by intestinal strangulation or diarrhea in horses with *Salmonella* colitis) may greatly influence the overall clinical presentation of horses with naturally acquired endotoxemia. The clinical signs of polymicrobial or gram-positive sepsis are generally indistinguishable from the signs associated with endotoxemia/gram-negative sepsis (described later).[39,40,90,91]

Typically in an adult horse given a moderate sublethal dose of endotoxin intravenously (e.g., 0.1 to 1 μg of LPS per kilogram of body weight), an early period of mild tachypnea peaks within 30 minutes and resolves within 2 hours. During this period, mucous membranes are pale. Beginning within 90 minutes of LPS injection, depression, restlessness, and inappetence are present and rectal temperature begins to rise. Auscultable intestinal sounds usually cease during this period and remain depressed for several hours. Intermittent signs of colic usually are seen, including recumbency (usually without rolling). Small amounts of loose feces usually are passed. Heart rate peaks during the stage of maximal abdominal discomfort (approximately 2 hours after administration of endotoxin), then temporarily declines. During this time, mucous membranes become congested, the capillary refill time is prolonged, and a dark "toxic" line may become apparent around the gingival margins of the teeth. Beginning at 4 to 6 hours after endotoxin administration, there is a secondary phase of tachycardia and tachypnea that likely is related to development of systemic hypotension and fever. This secondary phase persists for several hours. Horses presented clinically with mild to moderate endotoxemia or sepsis usually resemble experimental animals during the period 2 to 6 hours after intravenous endotoxin administration.

At higher LPS doses (e.g., 100 μg/kg) in experimental animals or in patients with severe endotoxemia or sepsis, signs of circulatory failure and disordered hemostasis dominate the clinical picture. Usually these horses are stuporous and totally anorectic. Signs of dehydration such as reduced skin turgor, dry mucous membranes, and sunken eyes are obvious. As systemic blood flow becomes more compromised, rectal temperature may drop into or below the normal range. Urine output is reduced or nonexistent. There are dark, congested mucous membranes, rapid and weak peripheral pulses, cold extremities, and sweating, and the horse may have muscle tremors or become recumbent.

Vascular damage may be seen as petechial and ecchymotic hemorrhages on mucous membranes. A poor prognostic sign is the development of a hypercoagulation syndrome, during which routine venipuncture or catheter placement initiates thrombosis along the entire visible length of the jugular veins (or other superficial veins). If both jugular veins are thus occluded, there usually is massive swelling of the soft tissues of the head, and associated laryngeal edema may cause signs of upper respiratory tract obstruction. In some horses, thrombosed superficial vessels can easily be palpated through the skin of the legs and abdomen. Infarction of bowel segments or lungs may cause severe clinical signs that are unresponsive to treatment. A rare syndrome of thrombosis of major limb arteries found in young foals is likely a result of sepsis syndrome.[92,93] At the time that hypercoagulation syndrome is recognized clinically, there is often also evidence of a secondary bleeding tendency (a consequence of platelet and clotting factor depletion and uncontrolled activation of fibrinolysis in disseminated intravascular coagulation [DIC]), seen as prolonged hemorrhage from venipuncture sites and widespread mucosal petechiation. In cases with a severe pulmonary component, there may be hemorrhage into the respiratory tract with progressive tachypnea and dyspnea. Alterations in coagulation (both hyper- and hypocoagulable states) were recently shown to be associated with incidence of SIRS and mortality in horses with acute gastrointestinal disease[34,94,95] and with mortality in septic foals.[96]

If moderately to severely affected animals survive for more than 24 hours, there usually is visible edema of the ventral abdomen and limbs. Signs of MODS/L may first become apparent at this stage (see Table 32-3). Laminitis may present or progress in severity as a result of mechanical failure of the lamina even after improvement or resolution of other systemic signs of SIRS and sepsis. It is important to note that experimental endotoxin infusion does not reliably reproduce laminitis in horses, so other DAMPs or cellular responses in the sepsis syndrome likely play a role in laminar failure in equine sepsis.

Clinicopathologic Signs

Early and profound leukopenia is principally caused by neutropenia (usually accompanied by left shift and a toxic appearance of stained cells). Lymphopenia (<1000/μL) is found in the most severe cases and likely reflects sepsis-induced apoptosis and immunosuppression. Adult horses with sepsis often are hyperglycemic, whereas neonates with sepsis are usually hypoglycemic. Other abnormalities are nonspecific and reflect altered tissue perfusion and organ dysfunction (see Table 32-3).

In horses with moderate and severe cases of endotoxemia, there also may be clinicopathologic evidence of disordered hemostasis, including any to all of the following: reduction in the circulating platelet count (<100,000/μL), reduction in plasma fibrinogen concentration; prolongation of the activated partial thromboplastin, prothrombin, or thrombin time; increased activity of PAI-1; and increased concentration of fibrin degradation products. Recent studies have used viscoelastic coagulation testing to provide a more global assessment of coagulation function in horses with SIRS and foals with sepsis, and have provided further documentation of hyper- and hypocoagulable states and the association between coagulation derangements and increased disease severity and mortality in equine sepsis.[34,96] In horses with acute gastrointestinal diseases, there also is increased activity in peritoneal fluid of many of the elements of the fibrinolytic system, including tissue plasminogen activator (TPA). Depletion of key clotting factors can most simply be detected as prolongation of plasma recalcification time.[97]

Although the measured concentration of endotoxin in blood does not correlate well with incidence or severity of clinical signs, demonstration of circulating endotoxin is definitive proof of endotoxemia.

VetBooks.ir

Among horses with acute gastrointestinal disease, 12% to 29% have detectable plasma endotoxin.[41,42] Experimentally, plasma endotoxin usually is assayed by some variant of the *Limulus* amebocyte lysate bioassay, which requires anticoagulation of samples with LPS-free heparin. A simple horse-side test for endotoxin that was marketed for use in clinical practice is no longer commercially available, although measurement of endotoxin activity in equine blood via neutrophil chemiluminescence has recently been described.[98] Tests for other microbial PAMPs that could play a role in equine sepsis (e.g., staphylococcal toxins, flagellin, etc.) are currently unavailable or limited to research settings.

Assessment of the Stage of Sepsis

Horses with signs of sepsis or endotoxemia should be staged according to the criteria found in Fig. 32-64 and Table 32-3. It is especially important to recognize that horses with serious sepsis need aggressive intervention in order to survive.

Treatment of Sepsis

There is no "silver bullet" for treatment of sepsis or endotoxemia. It has to be admitted that, almost without exception, potentially novel treatments for gram-negative sepsis that have been promising at the experimental level have failed when applied in clinical settings in human beings (and to the limited number of equine studies). A short list of such trials includes anti–TNF-α, IL-1–receptor antagonist, ibuprofen, PAF antagonist, elastase inhibitor, nitric oxide synthase (NOS) inhibitor, antithrombin III (AT-III), and tissue factor pathway inhibitor. It is clear that most experimental sepsis models do not replicate naturally occurring sepsis, at least as it occurs in humans and probably in horses. Several of many likely explanations for the disparity between the results of experimental models and large clinical studies are (1) heterogeneity of presentations among enrollees in clinical studies; (2) diversity in genetic susceptibility to sepsis among outbred populations; (3) differences between experimental and clinical study species; (4) differences in timing of potential treatments relative to the onset of sepsis between the two study populations; (5) preponderance of "cold sepsis" and immunosuppression states in naturally occurring sepsis compared with the "cytokine storm" of early sepsis usually re-created in experimental models.

Even among sepsis models, results for the same candidate treatment are often inconsistent. For example, neutralization and inhibition of inflammatory cytokines such as TNF-α usually have salutary effects in LPS-infusion experiments; however, equivalent studies involving the cecal ligation and puncture model in mice (widely considered to be one of the best sepsis models) usually have shown either neutral or negative effects on mortality.[99] Evidence-based medicine so far acknowledges only one agent, drotrecogin alfa (activated protein C),[100] as able to reduce mortality in some patients with sepsis, although there has been some recent controversy regarding the side effects of the drug and subsequent studies showing less convincing benefit in a clinical setting.[62,101-103] Despite this theoretic potential in some patients with endotoxemia and severe sepsis, drotrecogin alfa is cost-prohibitive in horses.

Fortunately, there is powerful evidence to support the value of early aggressive cardiovascular resuscitation. Use of oxygen, fluids, pressors, inotropes, and packed RBCs during the first 6 hours after admission to achieve a sequence of physiologic goals reduced in-hospital mortality of human patients with serious sepsis from 46.5% in the group that received standard therapy to 30.5% in patients given early goal-directed therapy (EGDT).[104] Similar protocols now are widely used in emergency rooms throughout the United States and in many other countries.[82,105] Many of the underlying principles of EGDT can be applied to resuscitation of septic horses, especially neonates (Fig. 32-68). It is reasonable to conclude that improvements in cardiovascular support of horses with sepsis will continue to be of much more value than any single therapeutic agent available now or in the future. In fact, because clinical sepsis is likely almost always caused by multiple pathogen and host-derived DAMPs stimulating multiple, complementary and redundant inflammatory pathways, successful management of sepsis is much more likely when therapy focuses on combating the clinical sequelae of severe SIRS and subsequent immunosuppression rather than targeting a specific inflammatory mediator or PAMP.

A prioritized strategy for management of horses with sepsis or endotoxemia is as follows: (1) cardiovascular resuscitation; (2) laminitis prevention; (3) removal of the cause(s) of sepsis; (4) neutralization of circulating endotoxin or other PAMPs; and (5) inhibition of PAMP-induced inflammation. These approaches are most applicable to horses with serious endotoxemia or sepsis, as based on the stages outlined in Fig. 32-68.

Cardiovascular Resuscitation

Expansion of blood volume remains the cornerstone of treatment for horses with serious sepsis or endotoxemia. Most cases (e.g., adults with blood lactate of 2 to 4 mmol/L) can be treated successfully with intravenous balanced polyionic solution according to guidelines for estimating water deficits provided in the fluid therapy section of this chapter. Urination should begin during the rapid replacement of estimated losses. Ideally the fine control of fluid replacement should be based on clinical evidence of blood volume and perfusion (e.g., mucous membrane color, heart rate, capillary refill time, pulse quality, jugular refill time, extremity temperature), as well as serial measurements of packed cell volume (PCV) or plasma protein concentration and blood lactate concentration. Some clinicians prefer the early use of compatible plasma (5 L for a 450-kg horse, 1 to 2 L for a neonate) or other colloid solutions such as 6% hydroxyethyl starch solution to replace the extravasated colloid lost as a result of vascular leak. Plasma has the advantage of providing immunoglobulin, acute-phase proteins, and anticoagulants, and can provide anti-endotoxin antibodies (see Hyperimmune Plasma and Serum section).

In horses with the most life-threatening forms of endotoxemia and sepsis (lactate >4 mmol/L [>5 mmol/L in neonates <24 hours old], MODS/L, septic shock), aggressive hemodynamic monitoring and EGDT are indicated. Owners should be informed that such treatment still carries at best a guarded prognosis for survival, financial commitment often in the range or $5000 to $20,000 or more if complications develop, and transfer to a referral center. However, early and aggressive intervention is essential in sepsis therapy; in critical care parlance, terms such as the *golden 6 hours* and the *silver 24 hours* exemplify this concept.[82]

Relatively simple equipment and supplies but time-intensive monitoring and treatment are needed for effective EGDT in septic horses and foals. A central venous catheter (e.g., for ~50-kg neonates, two-lumen indwelling catheter, 7-French × 30 cm; for ~500-kg adults, two-lumen indwelling catheter, 9-French × 90 cm), a blood gas and lactate analyzer, an indirect arterial blood pressure monitor, and a central venous blood pressure monitor (transducer and data display and recorder, or water monometer) are required for the full EGDT bundle; however, much can be achieved with a jugular catheter, water manometer, and lactate analyzer. The details of an intensive approach to EGDT for the first 6 hours after admission are shown in Fig. 32-68. $ScVO_2$ has been shown to correlate well in this context with cardiac index. It is important to remember that jugular blood SO_2 correlates poorly with central measurements in endotoxemic pigs[106] and probably should not be used for that purpose, so a central venous catheter really is critical for equine EGDT. Although labor-intensive, none of these monitoring techniques is technically difficult. One advantage of being able to measure both lactate and $ScVO_2$ is that inferences can be made as to the particular hemodynamic derangement responsible for signs of global tissue hypoxia (see Table 32-5).

When the goals of EGDT have been met, fluid management should continue according to standard protocols (see Fluid Therapy for Horses with Gastrointestinal Diseases section) with adjustments made according to the results of continued monitoring of clinical signs of blood volume status and perfusion as described earlier, blood acid-base status, PaO_2, $ScVO_2$, lactate, CVP, and mean arterial

VetBooks.ir

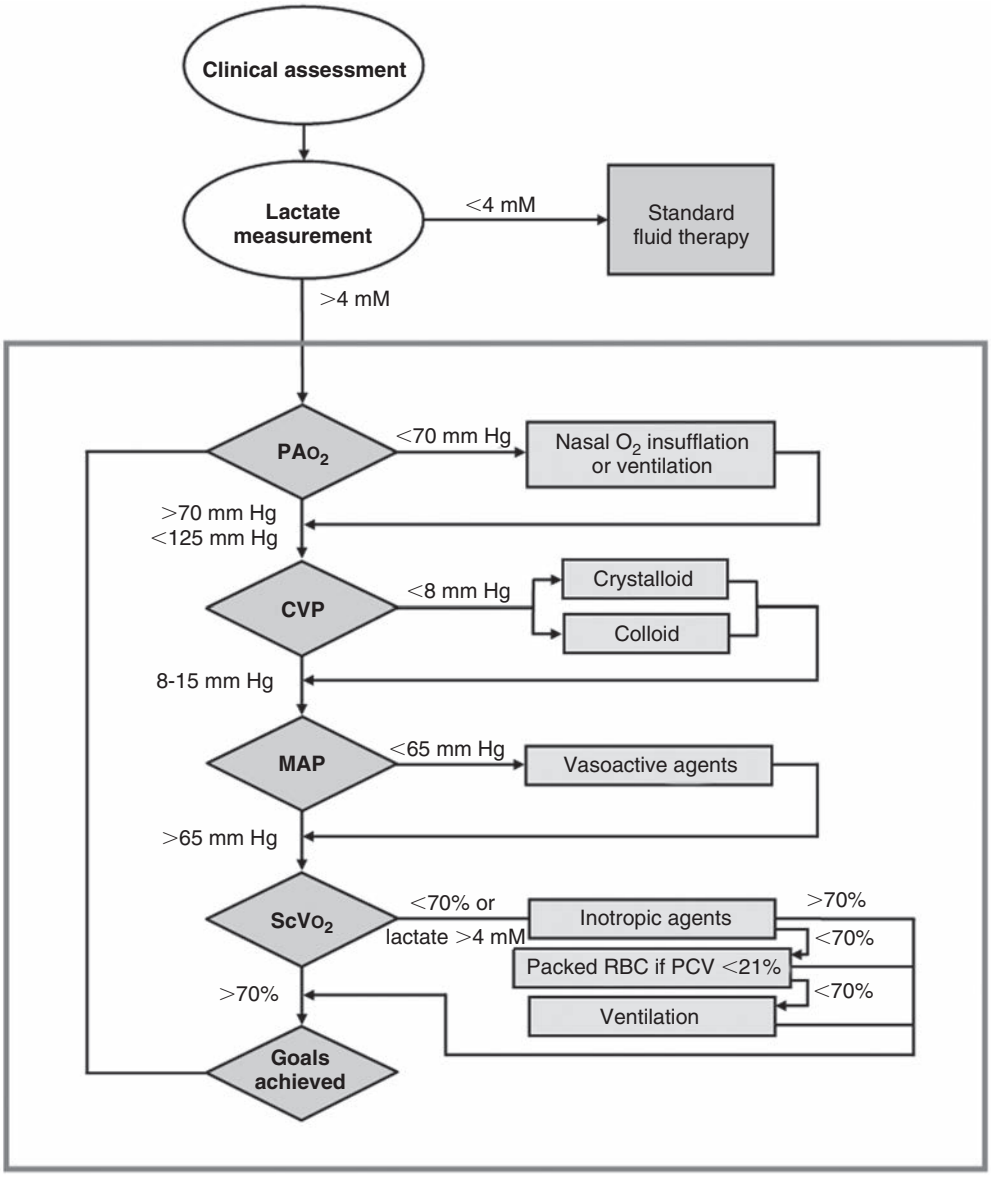

FIG. 32-68 Protocol for early goal-directed therapy. An initial 20-mL/kg bolus of isotonic crystalloid (or equivalent colloid) is given, followed by boluses of 10 mL/kg every 30 minutes until CVP reaches 8 to 15 mm Hg. If the heart-base adjusted MAP is still less than 65 mm Hg, vasopressors are given to effect. Norepinephrine, dopamine, or vasopressin can be used according to the clinician's preference. If the $ScVO_2$ is still less than 70%, dobutamine continuous rate infusion can be increased in increments up to 15 µg/kg/min. If the PCV is less than 21% after the preceding steps and $ScVO_2$ is less than 70%, packed cells should be given to increase oxygen-carrying capacity. *CVP,* Central venous pressure; *MAP,* mean arterial pressure; *PCV,* packed cell volume; *$ScVO_2$,* central venous oxygen saturation.

pressure (MAP). If the blood bicarbonate concentration is lower than 16 mmol/L after EGDT goals have been met (or plasma total CO_2 concentration is lower than 17 mmol/L), sodium bicarbonate should be given intravenously to replace calculated deficits. During correction of acidemia, intravenous fluids should be supplemented with potassium (10 to 20 mmol/L) to prevent correction-induced hypokalemia. A maintenance-rate infusion of glucose should be given to neonates with sepsis (4 mL of 5% dextrose-containing fluids per kilogram per hour) and hypoglycemic adults (2 mL of 5% or 0.2 mL of 50% dextrose per kilogram per hour). Glucose concentration should be regularly monitored, and the use of concurrent insulin therapy should be considered in persistently hyperglycemic animals.

Laminitis Prevention

Adult horses with serious sepsis are at high risk for the development of laminitis. Among the clinical risk factors likely operative in the setting of sepsis are body condition score higher than 5, being a pony, 24 hours or more since onset of signs of endotoxemia or sepsis, rectal temperature above 101.5° F, CRT >2 seconds, or cold extremities. The digital laminae are likely injured early in sepsis, potentially irreversibly, by processes associated with the cytokine storm and resultant global tissue hypoxia. Insulin resistance, hyperglycemia, microvascular injury and thrombosis, and protease activation may also be involved in the pathogenesis of sepsis-associated laminitis. The laminitis prevention bundle provided in Box 32-2 provides a reasonable preventive strategy based on current understanding of laminitis pathophysiology, but it must be implemented very early (preferably before increased digital pulses are detected) and is not universally protective. Global tissue hypoxia is addressed with standard or EGDT fluid resuscitation, and small vessel plugging addressed with flunixin (reduced TXA_2), pentoxifylline (vasodilation with PGI_2, suppression of inflammatory cytokines, increased RBC deformability), cryotherapy (suppression of lamellar inflammation), and plasma and heparin (increased active AT-III). The use of insulin (with or without glucose) infusions in horses with sepsis may also be indicated to combat persistent hyperglycemia associated with sepsis-mediated insulin resistance. However, because insulin infusions at very high rates have been associated with laminitis development in normal horses and

Plasma (10 mL/kg)/heparin (4 U/mL plasma)

ponies[107,108] and hyperinsulinemia is associated with endocrinopathic laminitis,[109] glucose and/or insulin infusions could possibly potentiate the development of laminitis in susceptible animals. The use of insulin-sensitizing drugs such as metformin or pioglitazone could have potential in treating sepsis-mediated insulin resistance in horses, but to date these drugs have not been examined in clinical equine sepsis and recent evidence suggests that their effects on insulin sensitivity in horses may be variable at best.[110-112] If laminitis is already present, or if it develops during the course of treatment, it should be treated as described in Chapter 38.

Removal of the Cause(s) of Endotoxemia and Sepsis

Removal of the cause of sepsis usually involves both removal of the source of endotoxin or other microbial PAMPs, as well as correction of the abnormality that allows access of endotoxin or other PAMPs into the blood. In some cases, the source can be mechanically removed; for example, bacteria and associated inflammatory effusion can be drained from pleural or peritoneal cavities or carefully siphoned from the postpartum uterus. Antimicrobial therapy also is essential. In general, broad-spectrum bactericidal drugs should be selected because septic horses may be immunosuppressed. In horses in which endotoxemia or sepsis is associated with diarrhea or other signs of colitis or typhlitis, the use of antimicrobial drugs is controversial because of their causal association with severe colitis. Antimicrobials probably should be given to equids with colitis only in the following situations: (1) the horse is younger than 6 months; (2) there is suspicion of clostridial or antimicrobial-associated enteritis (consider use of metronidazole); (3) there is degenerative left shift or severe leukopenia with total neutrophil or lymphocyte count of less than 1000 μg/mL; (4) there is concurrent peritonitis; or (5) there is clinical evidence of dyshemostasis (e.g., jugular thrombosis or abnormal coagulogram). However, these recommendations and outcomes following treatment of equine colitis with and without antimicrobials have not been critically evaluated to date. It should also be noted that effective antimicrobial therapy could temporarily worsen clinical signs by causing the release of endotoxin from killed bacteria. This possibility should be anticipated and minimized by the timely use of nonsteroidal antiinflammatory drug (NSAID) or other antiendotoxic therapy (see Nonsteroidal Antiinflammatory Drugs section).

When intestinal strangulation is the cause of sepsis, surgical correction is of paramount importance. For the purposes of perioperative management, however, it should be noted that resumption of intestinal blood flow could worsen endotoxemia and sepsis: sequestered endotoxin and other microbial components may be flushed into the circulation through compromised intestinal walls. At least in the case of small intestinal ischemia, the mucosal barrier to endotoxin may be further compromised by ischemia-reperfusion injury when full blood flow is restored by luminal decompression or other manipulation. Again, prophylactic or intraoperative use of NSAIDs, ROS scavengers, polymixin B, and/or hyperimmune plasma or serum (as described in the following subsection) prior to or immediately after correction of a strangulating intestinal lesion may be warranted.

Neutralization of Circulating Endotoxin

HYPERIMMUNE PLASMA AND SERUM. An antiserum (Endoserum [Immvac Inc., Columbia, Mo.]) and several hyperimmune plasmas (e.g., Equiplas-J [Plasvacc, Templeton, Calif.]) produced by immunization of horses against R-mutant endotoxins are used in horses with suspected endotoxemia (in some cases, this is an off-label use). As is the case with studies in human beings and small experimental animals, use of cross-reactive endotoxin antibodies in horses with either experimentally or naturally acquired endotoxemia has yielded conflicting results. In several studies there was impressive reduction of mortality rate or improvement in clinical signs when antiendotoxin serum or plasma was given to horses[113-115]; however, in other studies no improvement was demonstrated.[116,117] Pretreatment of foals with antiserum was associated in one report with significant worsening of clinical response to endotoxin administered intravenously compared with foals that received no pretreatment.[118] These disparate results probably reflect, at least in part, variation in the quality of antisera and experimental conditions; therefore, no blanket recommendation can be made as to the clinical use of such products. As evidence of the potential general value of hyperimmune plasmas, it is worth noting the reduction in mortality achieved when antiendotoxin plasma raised against the *E. coli* mutant J5 was given to bacteremic humans (39% for controls versus 22% for those give antiendotoxin plasma) in a masked, well-controlled study at a single hospital.[119] In contrast, subsequent large multicenter studies of two different antiendotoxin monoclonals failed to show beneficial effects.[120,121] A recent equine study demonstrated no effect of hyperimmune plasma on clinical parameters or peak plasma TNF-α concentrations in horses undergoing an experimental low-dose endotoxin challenge, although peak plasma TNF-α bioactivity was reduced in horses receiving plasma as compared with controls.[122] This suggests that hyperimmune plasma may contain factors such as soluble TNF-α receptor that could limit the activity of endotoxin-induced inflammatory cytokines. Hyperimmune plasmas (raised against any antigen[s]) also contain colloid, anticoagulant, and increased amounts of substances such as acute-phase proteins, which might have a nonspecific beneficial effect in the setting of endotoxemia and sepsis. Therefore the use of 10 to 40 mL of hyperimmune plasma (of any specificity) per kilogram can be justified in treatment of serious endotoxemia or sepsis in horses.

POLYMYXIN B. Polymyxin B is a broad-spectrum cyclic peptide antibiotic with potent endotoxin-binding activity. Potentially lethal side effects of respiratory paralysis and nephrotoxicity have precluded use of this agent as a systemic antimicrobial drug; however, polymyxin B retains endotoxin-neutralizing capacity at nontoxic dosages. Pretreatment of foals with polymyxin B at a dosage rate of 6000 U (1 mg)/kg significantly suppressed clinical and cytokine responses to intravenous endotoxin without causing toxic side effects.[118] Repeated administration to ponies of 15,000 U/kg also produced no sign of toxicity.[123] At a dose of 5000 U/kg, polymyxin B protected horses even when given 30 minutes after the start of LPS infusion.[124] The results of a pharmacokinetic and pharmacodynamic study of polymyxin B in horses suggested that the drug could safely be given at 6000 U/kg every 8 hours to maintain continuous endotoxin neutralization.[125] Lower doses also appear to have anti-TNF-α effects, but for shorter time periods.[124,126] Thus, in horses with moderate or severe endotoxemia, consideration should be given to the cautious use of polymyxin B (Polymyxin B sulfate [Bedford Laboratories, Bedford, Ohio]) given intravenously two or three times daily at a dosage rate of 5000 to 6000 U/kg. Each treatment should be diluted in saline and given over at least 15 minutes. However, it is important to note that although polymyxin B and the nontoxic polymyxin B-dextran 70 conjugate PMX622 safely prevented signs of endotoxemia when given before LPS to otherwise healthy horses,[124,126,127] the drug has not advanced beyond phase 1 trials in human patients because experimental studies showed that it did not protect mice when given after intraperitoneal endotoxin.[128]

Inhibition of Endotoxin-Induced Inflammation and Related Sequelae

NONSTEROIDAL ANTIINFLAMMATORY DRUGS. Through inhibition of cyclooxygenase (COX), NSAIDs reduce the formation of prostanoid metabolites (e.g., thromboxanes and prostaglandins)

VetBooks.ir

from arachidonic acid and thereby attenuate much of the adverse effect of endotoxin. Flunixin meglumine, phenylbutazone, ketoprofen, carprofen, meloxicam, firocoxib, and aspirin are examples of this class of drugs used in horses. When flunixin is administered at 0.25 mg/kg IV or PO every 6 to 8 hours in horses, endotoxin-induced prostanoid production is prevented, and maximal antiendotoxic effects are produced in experimental situations without obscuring the signs of colic or risking toxic side effects of the drug.[129] It should be noted that flunixin treatment does not affect endotoxin-induced leukopenia. Because there is evidence that aspirin does not prevent endotoxin-induced aggregation of equine platelets,[130] there appears to be no rationale for the practice of adding aspirin to the NSAID regimen. Most NSAIDs inhibit constitutive COX-1 activity (in addition to endotoxin-induced COX-2 activity), so there is some morbidity associated with their use. There may be gastric ulceration, right dorsal colitis, renal papillary necrosis, and possibly impairment of intestinal motility.[131,132] Further, flunixin meglumine has been shown to slow mucosal healing and increase mucosal permeability to LPS in ischemic-injured equine jejunum,[133,134] although similar inhibition of mucosal barrier function does not appear to occur in the equine colon.[135] However, concurrent administration of misoprostol (a PGE-1 analog)[136] or a lidocaine constant rate infusion[137] ameliorated these effects in an equine model, suggesting these drug combinations might be more appropriate than flunixin alone for horses with endotoxemia caused by intestinal ischemia.

In light of this toxic potential of equine NSAID use, it has also been suggested that use of COX-2–selective drugs may minimize side effects while maintaining efficacy. Three NSAIDs with documented analgesic effect in horses—firocoxib, carprofen, and meloxicam—have been shown to be COX-2 selective.[138,139] Etodolac, a COX-2–specific drug in dogs and humans, is not COX-2 selective in horses when used at analgesic doses (23 mg/kg PO once or twice daily).[140] Firocoxib and meloxicam do not appear to retard small intestinal mucosal healing or increase LPS permeability in ischemic-injured equine jejunum as flunixin can,[133,141] suggesting these agents might be better suited for provision of analgesic, antiinflammatory, and antiendotoxic effects in horses after intestinal ischemia. It is important to remember, though, that COX-2 activity may also have potentially beneficial effects in horses with sepsis; for instance, COX-2 products (e.g., PGE_2, PGI_2) mediate epithelial restitution in damaged equine colon[131] and are thought to be important in maintaining the antithrombotic phenotype of normal endothelium. NSAIDs in the coxib class, which are potently COX-2 specific, have also been shown to increase the risk of atherosclerotic cardiovascular disease in humans.[142] Similar risks for coxibs in horses have not been described, but at present firocoxib is the only drug in this class labeled for equine use and it has been in use clinically only for a short period.

Finally, although various NSAIDs have been shown to effectively prevent the clinical and molecular sequelae of equine endotoxemia in experimental models,[76,129,143-150] there is no convincing study that shows NSAIDs save lives in human or equine patients with naturally occurring sepsis. A large multicenter, controlled, masked, prospective study of ibuprofen in humans with sepsis syndrome showed no effect of this drug on the development of shock or acute respiratory distress syndrome, and no improvement in survival.[151] Similar studies have not been conducted in horses to date.

METHYLXANTHINE DERIVATIVES. Inflammatory cytokine production by macrophages is suppressed in dose-dependent fashion by methylxanthine derivatives. This effect appears to be caused by phosphodiesterase inhibition and consequent elevation of intracellular cyclic adenosine monophosphate (cAMP). Pentoxifylline, a drug that is in widespread use in human beings as a hemorheologic agent, has also been shown to increase RBC deformability in horses.[152] Pentoxifylline also inhibits TNF production in horse blood and in cultured equine macrophages while increasing secretion of prostacyclin.[153,154] Studies in other species suggest that pentoxifylline stimulates production of the antiinflammatory cytokine IL-10, suppresses neutrophil activation, and inhibits activation of NF-κB.[155] A pharmacokinetic study in horses has indicated that administration at 10 mg/kg PO two times daily provides serum concentrations equivalent to those used therapeutically in humans.[156] Finally, intravenous pentoxifylline significantly, albeit only partially, reduced adverse signs in horses given LPS.[157] The usefulness of this finding is called into question, though, by the observation that the lethality-sparing effect of pentoxifylline in endotoxemic mice was removed if the drug was given in combination with indomethacin, a potent NSAID.[158,159] In this study, it was concluded that upregulation of prostacyclin production by pentoxifylline, which was prevented by concurrent indomethacin, reduced mortality in subject mice by preventing endotoxin-induced leukopenia. It is interesting to note that pentoxifylline alone increased WBC counts in horses, although this effect is prevented by flunixin.[154,157] Thus, there may be a conceptual and potential beneficial effect of pentoxifylline therapy (10 mg/kg PO bid) in endotoxic horses, although any effect could be partially or wholly neutralized by concurrent NSAID administration (as is commonly done in equine practice).

CORTICOSTEROIDS. The corticosteroid class of drugs theoretically has many useful actions in combating inflammation in endotoxemia and sepsis. These include reduced production of cytokines, inhibition of TNF production by macrophages, stabilization of cell membranes, and prevention of neutrophil activation. It is surprising, however, that neutral or negative effects of moderate or high-dose steroid use were found in large, multicenter studies of humans with gram-negative sepsis,[160] most likely related to immunosuppressive effects at these doses. Corticosteroids also are widely believed to increase susceptibility to laminitis in endotoxemic horses, perhaps by increasing the sensitivity of digital vessels to the constrictive actions of circulating catecholamines or by inducing insulin resistance and hyperglycemia.[161] Use of high-dose corticosteroids is currently contraindicated in the treatment of endotoxemia or sepsis in people and horses.

Some human patients with sepsis appear to respond to low, "physiologic" doses of hydrocortisone.[161-165] Most of these patients have high baseline cortisol concentrations but are thought to be in a state of adrenal insufficiency termed *critical illness-related corticosteroid insufficiency* (CIRCI), a syndrome that also appears to occur in some septic neonatal foals and some horses with systemic illness and SIRS.[35,166-168] Low-dose hydrocortisone is associated with reduced vasopressor use and lower mortality rates in people with septic shock in a number of reports,[162,163,169-171] although other studies have not demonstrated a beneficial effect.[172] At present, low-dose hydrocortisone therapy is recommended for septic patients meeting criteria for CIRCI but not universally for all septic patients.[170] The use of low-dose hydrocortisone therapy has not yet been reported in septic equine patients, but a 3.5-day tapering low-dose hydrocortisone regimen (1.3 mg/kg/day divided q4h IV) administered to healthy neonatal foals was recently shown to ameliorate LPS-induced inflammatory cytokine production from peripheral blood leukocytes without impairment of neutrophil function in an ex vivo model.[173]

HEPARIN. The use of heparin in horses with endotoxemia is somewhat controversial. It prevents microvascular thrombosis principally by promoting the anticoagulant activity of AT-III. Unfortunately, heparin cannot reverse existing thrombosis, and because AT-III is consumed during severe coagulopathy, it may not prevent additional intravascular coagulation in such cases. Fresh and fresh-frozen plasma are good sources of AT-III, but they also provide clotting factors that could potentiate intravascular coagulation. When given at the recommended intravenous or subcutaneous dose of 40 U/kg tid or 150 U/kg bid, respectively, unfractionated heparin causes intravascular agglutination of equine RBCs.[174] Therefore it could be argued that the use of heparin might actually exacerbate intravascular cellular plugging, which is theorized to play a role in some cases of laminitis in equine sepsis. This side effect can be avoided by using *low-molecular-weight* heparin (LMWH), which is nonagglutinating but retains anticoagulant activity, principally via

VetBooks.ir

inhibition of factor Xa.[175] Two clinical studies have suggested that LMWH may have benefits over unfractionated heparin for the prevention of jugular thrombosis or laminitis in some equine colic patients,[176,177] although this is not universally accepted. The use of heparin should be considered in horses with sepsis that are at high risk for laminitis (e.g., DPJ, colitis, or grain overload) or that have evidence of hypercoagulation syndrome (early evidence of dyshemostasis such as abnormal coagulogram or spontaneous venous thrombosis). In the latter setting, heparin should be given with plasma (10 to 40 mL/kg) at a dose of either 200 to 300 IU/kg/day for unfractionated heparin (either divided bid-tid IV or SC or as a continuous intravenous infusion) or 50 IU/kg for LMWH (SC q24h). Foals at risk for thrombosis may require a higher dose of LMWH, in the range of 100 IU/kg.[178]

SCAVENGERS OF REACTIVE OXYGEN SPECIES. ROSs are thought to cause corrosive tissue damage during endotoxemia and potentiate the production of inflammatory cytokines via activation of NF-κB. Surgical deflation of distended small intestine is thought to lead to ischemia-reperfusion injury, a process that generates ROSs from epithelial xanthine oxidase. The life-saving process of fluid resuscitation in horses with hypovolemic shock may even lead to whole body ischemia-reperfusion and systemic release of ROSs. Despite these key associations between oxidant stress and sepsis, little effort has been made to intervene therapeutically at this level. There is some evidence that allopurinol, a hydroxyl radical scavenger and inhibitor of xanthine oxidase activity, has positive clinical effect during sublethal endotoxin infusion in horses.[179] A recommended dose for allopurinol is 5 mg/kg IV. Because dimethyl sulfoxide (DMSO) has been shown to be a potent scavenger of hydroxyl radicals with efficacy in rodent sepsis models,[180] it has been considered for use in the treatment of equine endotoxemia although effects in experimental models have been variable. DMSO is typically administered via rapid intravenous infusion (or by nasogastric tube) as a 10% to 20% solution in saline at a dose of 0.02 to 1 g/kg every 6 to 12 hours. However, intravenous infusion of DMSO at the low and high ends of this dose range was recently shown to have little to no effect on clinical signs (with the exception of fever at the high dose), clinicopathologic abnormalities, and TNF-α production following endotoxin infusion in horses.[181] DMSO may also reduce intestinal mucosal injury after ischemia-reperfusion, although to date, evidence for efficacy in this setting in horses is also mixed.

Ethyl pyruvate, a stable analog of pyruvate, has been shown to have remarkable protective efficacy in a variety of models of septic and nonseptic shock in rodents and other species, with these beneficial actions ascribed to its antioxidant effects.[182] Because this agent is inexpensive and can be given in intravenous crystalloid fluids, it could have potential for the treatment of endotoxemia and sepsis in horses. Recent reports in equine experimental endotoxemia support this theory, demonstrating beneficial effects on clinical manifestations of endotoxemia (except fever) and suppression of proinflammatory gene expression.[183-185] Use of ethyl pyruvate in clinical cases of equine sepsis or endotoxemia is not described to date, and other antioxidants that have shown benefit in rodent sepsis models (e.g., vitamin C, vitamin E, and *N*-acetylcysteine) have not been evaluated in horses.

Miscellaneous Treatments

A number of other treatments for endotoxemia and sepsis have been described in horses and other species, although on the whole, currently available data are less supportive of their use in clinical cases. Naloxone, a narcotic antagonist, at a dose of 0.2 mg/kg, blunted some of the cardiovascular effects of high-dose endotoxin in one study,[186] but a dose of 1 mg/kg had no effect in another.[187] Of importance, 0.75 mg/kg naloxone caused signs of colic in conscious horses,[188] probably by blocking the actions of endogenous β-endorphins at the high affinity μ-receptor. The detergent tyloxapol was remarkably effective in preventing the effects of endotoxin in anesthetized horses.[189] The mechanism of antiendotoxic action of tyloxapol is unknown, but the detergent has been shown to have wide-ranging effects on cells and proteins, some of which may preclude its use in clinical cases. For example, the detergent has been shown to inhibit cellular phagocytosis, clearly an important event in innate immunity and sepsis. Also, this agent induces marked hyperlipidemia (up to 100-fold higher than controls) in horses because of interference with lipoprotein metabolism. Similarly, a phospholipid emulsion effectively prevented adverse effects of subsequent endotoxemia; however, the treatment induced hemolysis sufficient to preclude its use in clinical cases.[190] A published report[191] on the use of the sulfonyl analog of the alpha-phenyl-*N*-tert-butyl-nitrone spin trap molecule suggests that this agent was effective in reducing clinical signs in horses given endotoxin. However, a cautionary note was the observation that some rodents given the same agent at high doses suffered enhanced endotoxin-induced mortality.

Platelet activating factor inhibitors have been effective antiendotoxic agents in some species but have not yet shown much positive clinical effect in horses or humans.[192] In dogs and other experimental animals, inhibitors of NO production such as N^G-monomethyl arginine reverse endotoxin–induced (or more likely TNF-induced) hypotension[193]; however, NOS inhibitors generally have no protective effect in sepsis models. Furthermore, NO production may not be increased in horses with endotoxemia.[194] The antifibrotic pyridine compound pirfenidone (5 methyl-1-phenyl-2-[1H]-pyridone) had no effect on endotoxin-induced clinical signs, leukopenia, or TNF-α production in horses.[195] Hyperbaric oxygen therapy also did not appear to have any protective effect on clinical or cytokine changes in experimental endotoxemia in horses.[196]

Ketamine administered at a constant rate infusion (CRI) has been theorized to have beneficial effects in equine endotoxemia after it was shown in vitro to suppress the production of inflammatory mediators by LPS-stimulated equine peritoneal macrophages.[197] Ketamine CRI at 1.5 mg/kg/h for 320 minutes achieves blood concentrations compatible with this inflammatory effect and has been shown to be safe and nonsedating in horses. However, pretreatment with ketamine had no effect on clinical signs, leukopenia, or inflammatory cytokines in horses after endotoxin infusion.[198] The putative antiinflammatory actions of ketamine appear to be mediated by the actions of adenosine on the adenosine A2A receptor[199]; as the equine adenosine A2A receptor was recently cloned and characterized pharmacologically, it may prove to be a potential direct target for antiinflammatory drugs in the future.

Future Treatment Considerations

In sum, current research in horses, people, and experimental animals suggests that a single therapeutic agent with universal benefit in endotoxemia and sepsis will be very hard (or impossible) to find. Most antiinflammatory approaches that show promise in experimental endotoxemia, even if they are aimed at the "root and trunk" of the inflammatory cascade (e.g., NF-κB activation), do not work consistently in severe sepsis models (e.g., cecal-ligation puncture) or in phase 3 clinical trials of human patients. It is becoming increasingly clear that a substantial portion of the morbidity and mortality associated with sepsis may result as much from "cold" sepsis, the state characterized by profound immunosuppression, as from the cytokine storm in "hot" sepsis. Immunosuppressed patients could be injured further by antiinflammatory therapy, which might explain some of the discrepancy between specific therapeutic efficacy in experimental versus clinical sepsis. This raises the issue of the need for accurate recognition of the stages of sepsis. Plasma biomarkers such as procalcitonin, C-reactive protein, or HMGB1 levels have been used to diagnose sepsis, define sepsis categories, and provide prognostic information in humans,[200,201] although a universally reliable biomarker or combination of markers has yet to be identified. These or equivalent markers need to be introduced into equine sepsis diagnosis.

On the treatment horizon are some different approaches that have the potential to be both effective and affordable. There is some indication that IFN-γ, a cytokine that is pivotal in both innate and acquired

VetBooks.ir

immunity, may be beneficial for combating immunosuppression in bacterial sepsis.[202] IL-7 and IL-15 may also prevent or modulate immunosuppression in sepsis by preventing leukocyte apoptosis and supporting both innate and adaptive immune function.[44] There also remains enthusiasm in human critical care for antioxidant strategies aimed at effective means to suppress or scavenge ROSs.[44,79,80] In this regard, the remarkable effects of ethyl pyruvate in multiple models of inflammation, which likely mediates via its antioxidant effects, offer considerable promise. Antioxidant vitamins also may be both beneficial and cost-effective in equine endotoxemia and sepsis. Inhibition of complement activation with anti-C5a antibody shows promise in some sepsis models and is currently in clinical trials in people.[44] Finally, one of the most exciting possibilities in the distant future is the use of gene therapy to transiently transfect host cells in a targeted way with genes supporting immune and bactericidal function.[203]

Medical Disorders of the Small Intestine

Jennifer L. Davis • Nicola Pusterla

Ulcerative Duodenitis

Pathophysiology Ulcerative duodenitis is a rare condition that most often affects foals and, to a lesser degree, yearling horses. One retrospective study cited 32 of 691 (4.6%) nonsurviving foals that had ulceration of the duodenum and of those foals, only 1 of 691 (0.14%) had duodenal involvement alone.[1] Lesions occur primarily in the proximal duodenum and may include erosions, focal ulceration, and diffuse inflammation with or without ulceration. The terms *duodenal ulceration* and *ulcerative duodenitis* may refer to differing clinical manifestations of the same problem, and the terms are used interchangeably in this section.

The pathophysiology of duodenal ulcer disease in foals is less well understood than gastric ulcer disease. The disorder is classically considered to be a peptic disease, one in which damage to the duodenal mucosa results from excessive exposure to hydrochloric acid and pepsin. This concept may require revision. Equine duodenal ulcer disease has been presumed to be similar to the disorder in humans, but most cases of duodenal ulcer disease in people are associated with *H. pylori* infection.[2] *H. pylori* bacteria have not been reported in equine gastrointestinal tissues; however, *H. pylori* colonize only gastric (glandular) mucosa, and infection of the duodenum must be preceded by metaplasia of areas of duodenal mucosa to gastric mucosa. This is thought to occur from chronic peptic injury. In humans the incidence of duodenal ulcer disease increases with age,[3] which contrasts with horses, in which duodenal ulcer occurs primarily in animals less than 1 year old.[4]

Duodenal ulceration and inflammation have been recognized to occur in cases that were clustered geographically (same farm) and temporally. All of these foals had moderate to severe gastric ulceration, and they had extensive inflammation with varying degrees of erosion or ulceration in the proximal duodenum (see Color Plates 32-10 and 32-11). A similar temporal and geographic association was reported in two cases of ulcerative duodenitis in yearlings.[5] These findings seem inconsistent with a purely peptic insult as the cause for the ulcerative duodenitis. In one report of seven foals with ulcerative duodenitis,[6] lesions typically extended into a large area of the proximal duodenum, were characterized by mucosal necrosis, and often had a sharp line of demarcation between affected and more normal-appearing mucosa. In the foals of that report, no common microbial organism other than *E. coli* was identified, and a cause for the ulcerative duodenitis was not determined. In most foals with duodenal disease the lesions were not focal ulcers but rather appeared as more generalized inflammation. An infectious cause seems likely but has not been identified. In the 1980s rotavirus infection was thought to be associated with gastroduodenal ulcer disease in foals, but most foals with duodenal ulcer disease do not have rotavirus infection.

Duodenal ulcer disease in foals may have a component of peptic injury. The duodenal mucosa possesses some intrinsic properties that are protective against peptic injury, although these are not as elaborate as in the gastric glandular mucosa. The most important factor that protects the duodenal mucosa from acidic gastric secretions may be the sodium- and bicarbonate-rich secretions that probably originate from the pancreas and that will neutralize acid entering the duodenum from the stomach.[7]

Clinical Signs The signs of duodenal ulceration or ulcerative duodenitis have been classically described as being the severe forms of gastric ulcer signs,[8] and in many cases duodenal and gastric ulcers occur simultaneously. However, many foals with ulcerative duodenitis will not have signs similar to those of gastric ulceration until severe gastric ulceration has occurred. Thus the primary signs of duodenitis can be nonspecific; they include fever, mild to moderate abdominal discomfort, mild obtundation, and diarrhea. A complete blood count (CBC) will often reveal peripheral blood leukocytosis and hyperfibrinogenemia.

Gastric ulceration frequently occurs along with duodenal ulceration and may be secondary to physiologic or anatomic obstruction to gastric emptying. The gastric ulceration tends to be severe (see Color Plate 32-12), often leading to gastroesophageal reflux and esophagitis. Foals with esophagitis often exhibit ptyalism. In general the sequelae of duodenal ulceration are more severe than those of primary gastric ulceration. Complications of duodenal ulceration include duodenal perforation with peritonitis or adhesions, duodenal stricture with complete or partial obstruction (Figs. 32-69 and Fig. 32-70), ascending cholangitis and hepatitis, and ascending pancreatitis.

Diagnosis Duodenoscopy is the most specific means of diagnosis. It requires an endoscope with at least a 200-cm working length in foals up to 6 months of age, and in older foals a longer endoscope is required to examine the duodenal mucosa. Because of the size of the stomach and the anatomic configuration of the duodenum in foals, it is usually not possible to advance the endoscope past the duodenal ampulla. Occasionally the endoscope can be advanced into the descending duodenum.

A diagnosis is most readily made in cases in which lesions are diffuse or located within the ampulla. Excessive enterogastric reflux of bile through the pylorus is consistent with duodenal dysfunction. Ulceration at the pylorus or pyloric antrum may accompany duodenal ulceration and thus provide an indication of potential duodenal involvement. Severe gastric ulceration in foals should alert the

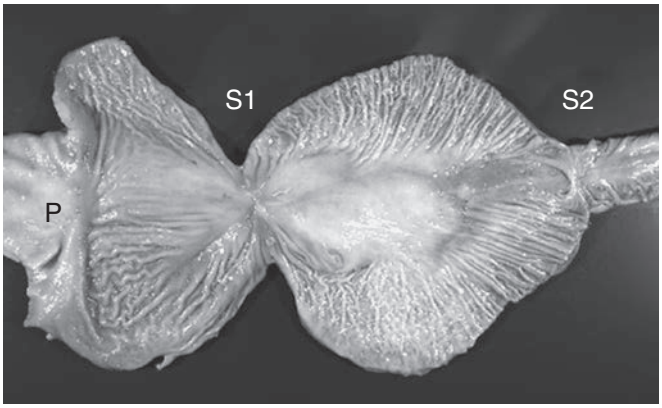

FIG. 32-69 Proximal duodenum of a 10-month-old horse with a history of chronic poor appetite and condition. The pylorus *(P)* is at the left. There are two strictures in the duodenum: S1 is orad from the major duodenal papilla, and S2 is aborad from the duodenal papilla. The segment of the duodenum between the strictures is dilated. *(Courtesy Dr. M.J. Murray.)*

VetBooks.ir

endoscopist to the potential for duodenal involvement. In such cases, oral histamine-2 (H_2)–receptor antagonist therapy may be less effective in resolving gastric lesions than in cases of primary gastric ulceration, because of delayed gastric emptying secondary to duodenal ulceration. Therefore, if a foal has received such treatment before endoscopy and if gastric ulceration is severe, suspicion of duodenal ulceration should increase.

Other diagnostic procedures that may be helpful include evaluation of peritoneal fluid; serum liver enzymes, particularly biliary-associated enzymes (γ-glutamyltransferase [GGT], alkaline phosphatase [ALP]); serum bile acids; and radiography. With severe duodenal ulceration, survey radiographs of the cranial abdomen may reveal accumulation of fluid within the stomach and gas ascending the biliary ducts.[9] If barium contrast medium is placed into the stomach, complete emptying is usually delayed (>2 hours) and an irregular mucosal border may be noted in the descending duodenum. It should be recognized that in most cases radiography would not contribute to a diagnosis of duodenal ulcer per se, although duodenal stricture may be noted. If the descending duodenum is to be imaged, the volume of contrast medium placed in the stomach should not exceed 0.5 to 1 L in a foal and 1 to 2 L in a weanling or yearling, or the proximal descending duodenum will be obscured by contrast medium within the stomach.

Treatment The effectiveness of treatment of duodenal ulceration or ulcerative duodenitis depends on the extent and severity of ulceration and the absence of complications, particularly perforation and stricture of the duodenum. Treatment objectives are to decrease duodenal inflammation, treat secondary gastric and esophageal ulceration, promote gastric emptying, and treat related problems such as peritonitis. If duodenal ulceration is confirmed or even suspected on the basis of clinical signs, treatment should be aggressive.

In acute cases of ulcerative duodenitis there usually is a pronounced lymphocytic infiltration of the mucosa. In more chronic cases there is a mixture of neutrophils, macrophages, fibroblasts, and fibrinonecrotic exudate. Definitive antiinflammatory therapy has not been described for these cases, and the use of corticosteroids or nonsteroidal antiinflammatory drugs (NSAIDs) is controversial because they may worsen gastric ulcer disease through inhibition of protective prostaglandin synthesis.

Suppression of gastric acid secretion is still an important objective in the treatment of ulcerative duodenitis in foals, because most affected foals have gastric ulcers. Initially, acid suppression should be accomplished via parenteral administration of H_2 antagonist (cimetidine, 7 mg/kg IV q6h, or ranitidine, 1.5 mg/kg IV q8h) or proton pump inhibitors (pantoprazole 1.5 mg/kg IV q24h). Oral medications are unlikely to be adequately delivered to and absorbed from the small intestine in the first days of treatment. Gastric emptying can be enhanced with bethanechol (0.02 mg/kg SC q6-8h or 0.35 mg/kg PO q8h when the foal can consume orally). In foals that have severe duodenal disease or that have required surgery, bethanechol has been given for up to 3 months. Once the foal can accept oral medication, it should be treated with the proton pump inhibitor omeprazole at a dose of 4 mg/kg once daily for the paste formulation. It should be noted that in the 24 hours after the first dose, acid suppression is incomplete, and maximal suppression of acid secretion is achieved between days 1 and 5.[10] Therefore a common practice is to administer an H_2 antagonist IV for the initial 2 days of treatment with omeprazole in foals with duodenitis.

Misoprostol is a synthetic prostaglandin E_1 analog that has been successfully used in treating duodenal ulcerations in humans. Doses of 2 to 5 μg/kg q8-12h can be used in horses, although side effects may include abdominal pain and diarrhea. Sucralfate promotes duodenal mucosal healing in humans.[11] The dose of sucralfate that is effective in humans with duodenal ulceration ranges from 1 to 2 g two to four times daily. Foals treated for duodenal ulceration that do not have impaired gastric emptying should be administered 2 to 4 g of sucralfate three times daily. *Sucralfate should not be used as the sole therapeutic agent for duodenal ulceration.*

Foals with duodenitis must usually be prevented from nursing or eating for 1 to 3 days. During this time, parenteral feeding should be considered. Depending on the age of the foal, administration of parenteral nutrition should provide 40 to 60 kcal/kg/day.

If medical therapy is ineffective or if sequelae of duodenal ulceration cause complications, surgical intervention may be required. Gastroenterostomy has been reported to be effective in some cases through bypassing the affected portion of duodenum and allowing for an alternative route for gastric emptying.[9] However, short-term survival and long-term quality of life and use are often unsatisfactory. Patients that have a successful surgical outcome require long-term aftercare and usually require long-term maintenance acid suppression and treatment with a prokinetic drug until gastric emptying is normalized. Therefore an owner should be prepared to make a significant time and financial commitment before surgery is considered.

Duodenitis-Proximal Jejunitis

Duodenitis–proximal jejunitis (DPJ), also known as *anterior enteritis* or *proximal enteritis,* describes a clinical syndrome that is characterized by inflammation and edema of the duodenum and proximal jejunum, excessive fluid and electrolyte secretion into the small intestine, and, consequently, large volumes of enterogastric reflux. The syndrome of DPJ was first described in 1982[12] and was more fully characterized in 1987.[13] A subsequent report[14] described clinical and clinicopathologic parameters in horses with DPJ that differed somewhat from cases in the 1982 report, suggesting that either the cases were of similar etiopathogenesis but of different severity, or that the cases were of different etiopathogenesis with the only similarity being the segment of bowel affected. A diagnosis of DPJ is often applied to cases in which there is abdominal discomfort, small intestinal distention, and excessive enterogastric reflux without obstruction, yet it is unclear whether all of these cases lie along a spectrum of severity of DPJ or whether there are several disease entities that affect the proximal small intestine and that share clinical features. The latter seems more likely.

Pathophysiology In horses with DPJ, lesions are consistently found in the duodenum, but the severity and frequency of lesions in the jejunum are variable. Serositis is a consistent finding, characterized by bright red to dark red petechial and ecchymotic hemorrhages

VetBooks.ir

on the serosal surface.[13] Histologic lesions include hyperemia and edema of the mucosa and submucosa, villous epithelial degeneration, epithelial cell sloughing, neutrophilic pleocytosis, hemorrhages in the muscular layers, and fibrinopurulent exudation on the serosa.

With DPJ there is an increased volume of duodenogastric reflux, typically 50 to 100 mL/min. This reflux has been considered to result from increased intestinal fluid secretion and decreased motility. Mechanisms of intestinal fluid secretion include passive transmucosal exudation, secondary to mucosal and submucosal inflammation and characterized by a protein-rich fluid secretion, and active fluid secretion, caused by increased cyclic nucleotides and characterized by fluid with a high electrolyte and low protein content. The components of fluid in the intestines of horses with DPJ have not been characterized, but they are likely to result from a combination of passive and active secretion. In some horses the hemorrhagic nature of the gastric reflux implies increased capillary permeability of the duodenal mucosa, whereas in other horses the watery nature of the reflux, the presence of serum electrolyte disturbances,[15] and the absence of peripheral hypoproteinemia are most consistent with an active secretory process.

Another potential source of the large volume of fluid secreted into the proximal small intestine and refluxed into the stomach is the pancreas. Normally there is periodic orad movement of duodenal contents into the stomach, which has been observed endoscopically and has been documented by collecting gastric contents with and without pyloric obstruction.[7] The duodenal contents have a large component of water, sodium, and bicarbonate, as well as bile salts from the liver. These secretions are presumed to originate from the pancreas, as well as the liver, and pathology of either of those organs may contribute to the pathophysiology in cases of DPJ.

Suppurative cholangiohepatitis has been reported in cases of small intestinal inflammation secondary to DPJ.[16,17] The pathophysiology behind this observation may be related to an increased luminal pressure in horses with DPJ, increasing the likelihood of intestinal content regurgitation into the bile ducts. It is also possible that horses with DPJ absorb inflammatory mediators or bacterial products from the small intestine via the portal blood flow or systemic circulation.

Although the exact cause of DPJ is not known, several bacteria and toxins have been implicated. *Clostridium difficile* has been frequently implicated in causing the disease. One prospective study cultured toxigenic species of *C. difficile* from the reflux of 10 of 10 horses diagnosed with DPJ, and only 1 of 16 horses diagnosed with other causes of nasogastric reflux. Of the strains cultured from these horses, 8 of 10 produced both A and B toxins, whereas the remaining two produced only toxin B.[18] This is significant in that toxin B has been shown to cause inhibitory electromechanical disturbances to smooth muscle in the small intestine, which may be a possible cause of ileus in these horses.[19] Toxin A has also been shown to promote inflammatory cell infiltration into the smooth muscle layers.[20] Influx of neutrophils and release of inflammatory mediators in the intestinal wall have been shown to activate nitric oxide pathways, which results in inhibition of the enteric nervous system, increases in sympathetic tone, and a subsequent reduction of contractile activity in the gut.[21] *C. difficile* can also be cultured from the proximal intestinal tract in horses without evidence of gastrointestinal disease, however, and these strains can produce both toxin A and B.[22] *Clostridium perfringens* and *Salmonella* spp. have also infrequently been associated with DPJ, but the significance of these pathogens remains unknown.

Feeding practices may be associated with the development of DPJ. In one study, horses with DPJ were fed significantly more concentrate and were significantly more likely to have grazed pasture than horses with other types of colic or horses with lameness.[23] This may indicate that these horses are exposed to some type of toxin or infectious agent through different types of feed. *Fusarium moniliforme* has been cultured from the feed of horses with naturally occurring DPJ. Under experimental conditions, *F. moniliforme* producing fumonisin B1 mycotoxins also caused lesions consistent with DPJ.[24] Neurologic lesions were present in those horses, however, and both of those horses died with lesions consistent with equine leukoencephalomalacia. Cantharidin toxins can also cause reddening of the mucosa in the small intestine, as well as excessive gastric reflux,[25] and may be a cause in some cases. It is possible that this one syndrome has multiple initiating causes and that no one causative agent will ever be definitively identified.

Clinical Signs and Differential Diagnosis

The major differential diagnoses for DPJ include simple or strangulating small intestinal obstructions. Differentiation can be extremely difficult in some cases and may delay surgical intervention in cases of small intestinal obstruction, to the detriment of the patient. The criteria used to discriminate between DPJ and obstructive lesions include degree of pain, presence of fever, and changes in hematologic parameters and abdominal fluid.

Horses with DPJ have a history of an acute onset of moderate to severe abdominal pain that often is followed by varying degrees of depression. Nasogastric intubation yields a large volume of enterogastric reflux, which is frequently orange-brown in color, with a fetid odor. Rectal palpation reveals multiple loops of mild to moderately distended small intestine. The initial volume of reflux may range from as little as 4 to 5 L to up to 32 L. The duration of the reflux may be as short as 24 to 48 hours, but it usually lasts 3 to 7 days. Horses are often febrile (rectal temperature higher than 38° C [101° F]) and dehydrated and have injected mucous membranes, prolonged capillary refill time, diminished intestinal sounds, tachycardia (>60 beats/min), and tachypnea.[12-15,26,27] Horses with DPJ also tend to have a higher incidence of gastric ulceration than horses with abdominal pain secondary to other causes.[28] Although abdominal pain usually abates after gastric decompression, most horses remain depressed, which perhaps is the most consistent and characteristic clinical sign of the disease. If the fluid that accumulates in the proximal intestinal tract is not removed periodically, signs of abdominal pain recur.

Assessments of the degree of small intestinal distention and the thickness of the intestinal wall can be useful indicators. Often, horses with DPJ have generalized distention of small intestine, but when palpated per rectum the intestine does not feel taut. In many cases of small intestinal obstruction the bowel will feel tightly distended, but this is not universally true. Ultrasonography can be used, both transrectal and transabdominal, to determine the diameter of the small intestine, evaluate contractions, and measure the thickness of the wall of the intestine. With acute obstruction one can see several segments of small intestine that are 6 to 10 cm in diameter, have no contraction, and have a wall diameter of 3 to 5 mm. With DPJ, small intestinal diameter may be less, and the thickness of the intestinal wall may exceed 6 mm.

Culture of the reflux for *Clostridium* and *Salmonella* spp. can be attempted. This can be difficult, however, given the special conditions required for anaerobic cultures, as well as the intermittent shedding of *Salmonella* spp. into the gastrointestinal tract of normal horses. Also, the large volume of reflux in these cases may dilute the bacterial population to the point where isolating low numbers of bacteria is difficult.

Clinicopathologic Findings

Clinical laboratory findings include increased packed cell volume (PCV) and total plasma proteins (hemoconcentration). Abdominocentesis often reveals an elevated peritoneal fluid total protein concentration and a mild to moderate increase in the peritoneal white blood cell (WBC) count (>5000 cells/μL).[26] The peritoneal fluid is usually yellow and turbid, but in severe cases diapedesis occurs, resulting in a serosanguineous color. An abdominal fluid total protein concentration above 3.5 g/dL is associated with a poorer prognosis.[26] The WBC count in the peripheral blood may be normal, increased, or decreased.[13,14] In addition, hypocalcemia, hyponatremia, hypochloremia, hypokalemia, and acid-base alterations have been reported in horses with DPJ.[15] An elevated anion gap may be present, secondary to decreased calcium and magnesium or increased lactate or albumin concentrations.[26] Increases in the anion gap to 15 mEq/L or above have also been associated with a poor prognosis. Horses with enteritis

VetBooks.ir

have been found to have higher plasma D-dimer concentrations and more severe coagulopathies on admission than horses with other types of colic.[29]

Elevations in liver enzymes, particularly GGT, may be seen in horses with DPJ and may be a useful way to help differentiate between DPJ and strangulating lesions of the small intestine.[16,17] A study examining a large series of DPJ cases retrospectively to determine the prevalence of hepatic damage in horses with small intestinal inflammation showed that horses with DPJ had significantly higher hepatic enzyme activities than the control group of horses with small intestinal strangulating obstruction (SISO).[17] Over 50% of horses with proliferative enteropathy (PE) had biochemical evidence of hepatic disease (high GGT, aspartate aminotransferase [AST], or ALP activity). Horses with DPJ had a 12.1-fold higher risk of having a high GGT activity and a 1.8-fold risk of having a high AST activity than horses with SISO. AST activity in horses with PE ranged from 133 to 2994 IU/L (reference range 215.8 to 365 IU/L), GGT ranged from 7 to 117 IU/L (reference range 6.2 to 19.1 IU/L), and ALP ranged from 86 to 1103 IU/L (reference range 69.4 to 293.7 IU/L). Bile acid concentrations were rarely abnormal, indicating that hepatic failure was uncommon. Histopathologic evidence of liver pathology was a common feature in the horses with PE that had either biopsies or necropsies performed. Centrilobular necrosis and inflammation were noted in some cases.

Treatment Because the causative agent(s) of DPJ are unknown, treatment remains empiric and consists of aggressive supportive therapy. The continuous production of enterogastric reflux requires gastric decompression every 1 to 2 hours to relieve pain and to prevent gastric rupture. The stomach should be decompressed frequently, regardless of whether or not the horse is showing signs of abdominal pain, as these signs may be masked by severe depression or the administration of analgesic or antiinflammatory medications. Horses should receive nothing by mouth until small intestinal function has returned, recognized clinically by cessation or reduction of the nasogastric reflux to 1 to 2 L over a 4-hour period and increased frequency of borborygmi. The time necessary for gastric decompression varies with each patient. Repeated rectal examinations after the first day of therapy will inconsistently reveal distended loops of small intestine, depending on the frequency of removal of the reflux and the severity of the initial lesion. Ultrasonography may reveal fluid-filled small intestine when such bowel is not discernible by rectal palpation. Loops of small intestine are most frequently visualized in the ventral flank area, near the udder or prepuce; therefore this area should be examined in all cases of suspected small intestinal distention.

Intravenous administration of a balanced electrolyte solution is necessary to maintain intravascular fluid volume and cardiovascular performance. In some horses even rapid administration of fluid fails to adequately restore and maintain intravascular volume because of enteric fluid losses that can be as great as 8 L per hour. In addition, the very large volume of isotonic crystalloid fluid that must be given intravenously to keep pace with enteric fluid losses in horses with DPJ may accelerate the flux of fluid from the vasculature into the intestinal lumen because of reduced intravascular oncotic pressure, increased capillary perfusion pressure, and increased capillary permeability in the inflamed intestine. Consequently, the balance between adequate hydration and the volume of enterogastric reflux obtained requires careful and frequent monitoring.

Administration of colloid solutions may be of benefit in preserving intravascular volume without promoting enterogastric reflux. The most frequently used colloids in the horse include hyperimmune plasma and hydroxyethyl starch solutions. Plasma products require a large volume of administration to exert a colloidal effect, which is cost prohibitive in many cases. Smaller doses, however, may have a beneficial effect in horses with DPJ, particularly in animals showing signs of sepsis or endotoxemia. Hydroxyethyl starch solutions have been shown to significantly increase plasma oncotic pressure in ponies administered 10 mL/kg[30] and represent a reasonably priced alternative to plasma. These solutions have been associated with changes in the hemostatic profile in normal ponies at higher doses of 20 mL/kg[31] and should be used only with caution in horses already at risk for coagulopathies.

During the initial hours of therapy, even aggressive intravenous fluid administration may result in only moderate clinical improvement. A positive clinical response—as evidenced by improved hydration status, decreased heart rate, decreased enterogastric reflux, improved attitude, and improvement in parameters reflecting kidney function (decreased blood urea nitrogen [BUN] and serum creatinine)—correlates with resolving intestinal inflammation.

NSAIDs should be used judiciously to avoid masking the clinical signs of a potential surgical lesion. Flunixin meglumine can be used at a dose of 0.25 to 0.5 mg/kg PO every 6 hours to reduce the untoward effects of arachidonic acid metabolites.

Antimicrobial agents are typically administered to horses with DPJ, although the necessity for antimicrobial treatment in horses with DPJ is uncertain. Given the association of DPJ with *C. difficile,* administration of intravenous penicillin G sodium or potassium (22,000 to 44,000 IU/kg IV q6h) is warranted. Metronidazole also has excellent activity against *C. difficile;* however, administration is difficult because nothing can be administered per os. Rectal administration of metronidazole has been studied[32] and can be used in these cases. The dose and frequency of administration should be increased because bioavailability after rectal administration is much less than after oral administration (30% vs. 74%, respectively). Broad-spectrum antimicrobial treatment may be indicated in horses with low WBC counts, but care must be taken in selecting an antimicrobial to avoid potential adverse effects, particularly nephrotoxicosis with aminoglycosides in a dehydrated patient with compromised renal function.

Horses with DPJ may have to be kept from eating for several days and are often in a hypermetabolic state; therefore they rapidly develop a negative energy and nitrogen balance. In these horses parenteral nutritional support should be considered. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with a variety of intestinal disorders, including DPJ. Providing for part of the horse's nutritional requirements (8000 to 12,000 kcal/day) is possible with glucose–amino acid solutions that are of moderate cost. The rationale for this treatment is that through provision of nutritional support to an anorectic, severely ill horse, the healing process will be facilitated, complications will be reduced, and the duration of hospitalization may be shortened. Thus the overall cost of providing nutritional supplementation, enteral or parenteral, to horses with DPJ may well be offset by quicker recoveries and diminished requirements for other costly treatments.

Prokinetic agents may also be useful in cases of DPJ. Of the available prokinetics, lidocaine is used most frequently.[33] A loading dose of 1.3 mg/kg slow intravenous bolus followed by a continuous infusion of 0.05 mg/kg/h has been shown to shorten the time of reflux and decrease the hospital stay in horses with DPJ.[34] It may do this by decreasing sympathetic tone, acting as an analgesic agent, or decreasing granulocyte infiltration in the intestinal wall. Its use should be reserved for horses in which a surgical lesion has been ruled out, as it can very effectively mask intestinal pain. Horses should be refluxed frequently during the infusion and checked for other signs of complications, such as laminitis, routinely. Metoclopramide, erythromycin lactobionate, and cisapride are also used in cases of DPJ.[33] The efficacy of prokinetics in this disease is debated, mainly because they require a healthy intestine in order to exert an effect. A more in-depth discussion of prokinetic agents can be found in the section on gastrointestinal ileus in this chapter.

Medical therapy is sufficient in most cases of DPJ; however, surgical exploration is sometimes necessary for definitive diagnosis, or if horses show uncontrolled pain, have prolonged nasogastric reflux (>7 days), excessive fluid losses that cannot be corrected with conventional fluid therapy, or clinical and laboratory findings strongly suggestive of an intestinal obstruction. Retrospective analysis

VetBooks.ir

comparing medical and surgical therapy of DPJ showed that surgical cases had a significantly decreased survival and a longer duration and larger total volume of nasogastric reflux. They were also more likely to develop complications such as diarrhea, and showed an increased rate of incisional infection compared with other horses operated on for other types of colic.[35]

Complications Complications of DPJ include septic peritonitis, myocardial and renal infarction, aspiration pneumonia, adhesions of the proximal small intestine, and laminitis. Animals with severe cases of DPJ may develop infarction of a segment of the small intestine that requires surgical removal. The prognosis for surviving the initial intestinal insult is good in cases of DPJ. The death and function losses from this disease are more commonly related to the secondary complications such as laminitis and intraabdominal adhesions. In one report, laminitis occurred in 28% of horses with DPJ, and associated factors were high body weight and hemorrhagic gastric reflux.[36] Laminitis prophylaxis is routinely incorporated into the medical therapy and can include cryotherapy, NSAIDs, topical glyceryl trinitrate, and DMSO (200 mg/kg given as a 10% solution in normal saline). In one study horses that received heparin as a prophylactic treatment for laminitis were less likely to develop clinical laminitis than horses that did not receive heparin.[36]

Equine Proliferative Enteropathy

Nicola Pusterla

Equine proliferative enteropathy (EPE) is a disease of foals caused by the obligate intracellular organism *Lawsonia intracellularis*. This disease affects mainly weanling foals and occasionally young adults and is characterized by fever, lethargy, peripheral edema, diarrhea, colic, and weight loss. The diagnosis of EPE may be challenging and relies on the presence of hypoproteinemia due to hypoalbuminemia, thickening of segments of the small intestinal wall observed on abdominal ultrasonography, positive serology, and molecular detection of *Lawsonia intracellularis* in feces. The disease has almost reached a worldwide occurrence and has been reported in the United States, Canada, Europe, South Africa, Australia, Brazil, and Japan.[37-41]

Epidemiology In pig populations, the chronic form of the disease is maintained by subclinically affected pigs or is established environmentally in some sites, allowing transmission of *L. intracellularis* to serial flows of pigs.[42] Mice and rats have been shown to be important reservoirs of *L. intracellularis* on pig farms with prevalences of animals testing positive on polymerase chain reaction (PCR) assays varying substantially between farms (4% to 83%).[43,44] Rodents appear to be suitable reservoir hosts because of their susceptibility to *L. intracellularis,* their close contact to domestic animals, and their high reproductive rate, and they maintain *L. intracellularis* across generations. The source of infection has not been determined for horses. Exposure to pig feces has been speculated as a potential source of infection for horses since the first reported cases of EPE. However, in most cases of EPE, no history or evidence of direct or indirect exposure to pigs or pig feces has been reported. Further, multilocus variable number tandem repeat (VNTR) profiles of pig and equine isolates differ greatly. A recent experimental study has shown host specificity for *L. intracellularis* isolates cultured from pig or horse intestines.[45] The study showed that clinical signs, longer periods of shedding, and stronger serologic immune responses were observed in animals infected with species-specific isolates. Previous studies have shown that a variety of wild and domestic animals (including dogs, cats, rabbits, opossums, skunks, mice, and coyotes) can shed *L. intracellularis* on farms with diagnosed EPE cases.[46,47]

Fecal-oral transmission of *L. intracellularis* has been documented in naive foals housed with clinically infected foals experimentally challenged with an equine isolate of *L. intracellularis*.[48] A recent study has shown that feces from experimentally infected rabbits with an equine isolate of *L. intracellularis* served as infectious material for weanling foals.[49] Although infected rabbits and foals remained asymptomatic, infection was supported by fecal shedding of *L. intracellularis* and detection of specific antibodies to *L. intracellularis*. Although the natural infectious dose for foals has not been determined, pigs receiving as low as 10^5 *L. intracellularis* organisms have been shown to develop infection.[50]

In piglets, large group size, weaning, transportation, diet change, and mixing have been associated with clinical disease. Predisposing factors such as the stress of weaning, overcrowding, decline in *L. intracellularis*–specific colostral antibodies, endoparasitism, and introduction of new animals have been suggested as factors in the development of EPE in foals.[37] In pigs, infection and fecal shedding of *L. intracellularis* may persist for as long as 12 weeks.[50] This is in sharp contrast to experimentally infected foals showing onset and duration of fecal shedding ranging from 10 to 14 days and 17 to 27 days, respectively.[48] Previous work has shown that *L. intracellularis* is likely to survive in environmental conditions for 1 to 2 weeks at 5° C to 15° C.[51]

Pathophysiology The mechanism of enteritis after infection with *L. intracellularis* involves invasion of the proliferating crypt cells in the ileum, causing excessive mitotic division and severe hyperplasia.[52,53] The hyperplastic mucosa becomes grossly thickened and develops a corrugated appearance. As would be expected, this thickening of the mucosa, along with the proliferation of immature crypt cells rather than mature villous cells, leads to a limited brush border development and a decreased absorptive capacity, which results in the weight loss and hypoproteinemia present in these cases. The organism can divide within the infected cells and migrate up to the mucosal layers as the cells proliferate and advance. The main differential diagnosis in these cases is *Rhodococcus equi* enteritis, which can also cause ulceration in the areas of Peyer patches throughout the small intestine, cecum, and colon.

Clinical and Laboratory Findings EPE manifests in characteristic signalment, seasonality, clinical signs, and blood work abnormalities. The disease is generally manifested in foals less than 1 year of age and in North America is often seen between August and February.[38] Although the disease is commonly seen in weanling foals 4 to 7 months of age, cases of EPE have been seen in young adults.[41] Lethargy, anorexia, fever (>38.5° C), peripheral edema (ventrum, sheath, throatlatch, and distal limbs), weight loss colic, and diarrhea are among the most common clinical findings in affected foals. Early clinical signs are generally unspecific and include mild depression, partial anorexia, and fever. Although diarrhea is commonly seen in affected foals and can vary from cow pie to watery, some affected foals may have normal fecal character. Fatal necrotizing enteritis associated with *L. intracellularis* has recently been reported with foals developing acute onset of clinical signs followed by rapid clinical deterioration and death caused by endotoxemia, bacteremia, or disseminated intravascular coagulation.[54]

Foals with EPE may also have concurrent disorders such as respiratory tract infections, gastric ulcerations, and intestinal parasitism. It must be kept in mind that signs of EPE may resemble those of more common gastrointestinal disorders such as parasitism, bacterial infections *(Clostridium* spp., *Salmonella* spp., *Rhodococcus equi*, *Neorickettsia risticii),* rotavirus, coronavirus, ulcerations, sand accumulation, intestinal obstruction, and intoxication with plants, chemicals, and pharmacologic agents such as NSAIDs or antimicrobials. Similar to pigs, the disease can be subclinical in foals and be manifested by a self-limiting and transient decrease of total serum protein concentration coupled with decreased daily weight gain when compared with unaffected foals.[48] It will remain to be determined if growth retardation or unthriftiness are associated with subclinical infection.

The most consistent laboratory finding of clinical EPE is hypoproteinemia due to hypoalbuminemia. Total protein is generally less than 5.0 g/dL and albumin is usually less than 2.0 g/dL. In a

VetBooks.ir

recent case report, hypoalbuminemia was the only consistent clinicopathologic abnormality of 57 affected foals with albumin concentrations ranging from 0.9 to 3.3 g/dL (normal reference range 2.7 to 4.2 g/dL).[38] The exact mechanisms by which hypoalbuminemia develops in affected foals have not been investigated. It appears that decreased feed intake, coupled with malabsorption and protein-losing enteropathy due to the proliferative nature of the disease, may explain why low albumin occurs.[55] Affected foals may also demonstrate nonspecific blood abnormalities such as anemia or hemoconcentration, leukocytosis or neutropenia, hyperfibrinogenemia, increased activity of muscle enzymes, and electrolyte abnormalities (hypocalcemia, hypochloremia, and hyponatremia). Urine analysis to rule out protein-losing nephropathy and cytologic evaluation of abdominal fluid to rule out protein lost to a third space are generally unremarkable.

Diagnostic Workup A presumptive diagnosis of EPE is generally made based on age of the affected animal, clinical signs, hypoproteinemia/hypoalbuminemia, presence of thickened small intestinal loops on ultrasonographic evaluation, and ruling out other causes of enteropathy and protein losses. Abdominal ultrasonography, although not very sensitive, may show segments of thickened small intestine and excessive abdominal fluid. In these cases, abdominocentesis will yield a noninflammatory transudate. An antemortem diagnosis is generally confirmed via PCR detection of *L. intracellularis* in feces or rectal swab and/or serologic findings.

It is essential to combine both molecular and serologic diagnostic testing, as these modalities have high analytical specificity but variable sensitivity depending on the situation. Negative PCR results can be expected if the fecal samples are collected from foals with prior antimicrobial treatment or during advanced disease stage, when *L. intracellularis* organisms are no longer expected in the feces. Negative serologic results can be expected in the early stage of the disease, when humoral immune responses are not yet strong enough to be detectable by serology. Further, differences in sensitivity among different PCR and serologic assays can lead to divergent results. Among PCR assays, the use of a real-time platform has been shown to yield the best sensitivity and to reduce the likelihood of crossover or carryover contamination (i.e., false-positive results).[56-58] Several serologic assays, including indirect fluorescent antibody test (IFAT), enzyme-linked immunosorbent assay (ELISA) and immunoperoxidase monolayer assay (IPMA), have been validated and established for pigs.[59-61] A comparative study using equine serum samples has shown that various serology assays are accurate; however, the IPMA is the most specific when determining the presence of anti–*L. intracellularis* antibodies in adult horses with EPE.[62]

Pathologic Findings Lesions are most frequently found in the distal jejunum and ileum, although diffuse thickening of the small intestine may occur.[52] Classically there is pronounced mucosal thickening with varying severity of ulceration and transmural edema. The affected bowel appears to be stiff, and the mucosal surface has a corrugated appearance. Mucosal pleocytosis is a common feature, but in different cases the predominating inflammatory cell type will differ. A lymphocytic or plasmacytic cellular infiltration may be present. There is crypt proliferation, accompanied by crypt elongation and epithelial hyperplasia. The villi are blunted and may become fused. Silver staining with Warthin-Starry stain reveals elongated, curved bacilli in the apical zone of the crypt epithelial cells.

Treatment It is important to treat affected animals early, before lesions become advanced and result in marked weight loss and critically low serum protein values. Treatment of EPE in horses involves the use of antimicrobials such as macrolides, alone or in combination with rifampin, chloramphenicol, oxytetracycline, doxycycline, or minocycline, administered for 2 to 3 weeks. The choice of antimicrobial in the treatment of EPE should take into account the risk of inducing disturbance of the gastrointestinal flora and renal toxicity. This is especially a concern when treating older foals with severe hypoalbuminemia. Supportive therapy with crystalloid fluids to correct dehydration, electrolyte imbalances, and azotemia secondary to fluid losses from profuse diarrhea is warranted. Colloidal support with plasma or hydroxyethyl starch solutions can help correct the edema and decreased colloid oncotic pressure. NSAIDs should be used with caution in foals showing signs of dehydration.

Prognosis in these cases is generally good with early and correct diagnosis of the problem. Therapy can be prolonged and should be continued until the diarrhea and hypoproteinemia have resolved and there is no longer evidence of thickened small intestine on ultrasound.

Concurrent medical conditions should also be addressed. Rapid clinical improvement following treatment is to be expected; however, it may take weeks for the hypoproteinemia to resolve. Spontaneous recovery of clinically infected foals has not been documented, and up to 93% of treated foals usually survive the disease.[38] Generally nonsurvivors develop complications associated with gastrointestinal translocation, gastrointestinal perforation, or kidney failure.[54] Frazer reported that clinically affected and successfully treated foals sold for an average of 68% of the average price of unaffected foals by the same stallion.[38] However, their monetary earnings from racing were not significantly different from those of other horses.[63]

Monitoring and Prevention Early recognition of clinical cases and separating them from the rest of the susceptible foals until full recovery or cessation of fecal shedding appears to be a logical biosecurity measure to prevent spread and environmental contamination. The monitoring of a herd with endemic EPE status includes the regular physical evaluation of resident foals and the monthly or bimonthly assessment of total protein concentration and monthly serologic status. Monitoring for exposure to *L. intracellularis* and hypoproteinemia/hypoalbuminemia should begin at least 4 weeks prior to the historical first detection of clinical cases.

The lack of epidemiologic data regarding potential natural reservoir hosts as well as the lack of information pertaining to the biology of *L. intracellularis* precludes the institution of any management changes on endemic farms. Further, maintaining good pest control and preventing non-equine domestic and wild animals from gaining access to feed and feeding areas may potentially minimize the risk of disease spread.

Prevention strategies have been best described in pigs using in-feed antimicrobials and a commercially available *L. intracellularis* vaccine.[64-66] Recent work has shown that detectable humoral and cellular responses can be measured in foals administered an avirulent live *L. intracellularis* vaccine.[67,68] The *L. intracellularis* vaccine has been shown to be safe and the administration well tolerated by the foals. A field efficacy trial performed on EPE endemic farms in central Kentucky in 2008 showed that vaccinated foals maintained higher daily weight gains and higher total protein concentrations when compared with a nonvaccinated, naturally seroconverted group.[69] Under experimental conditions, weanling foals vaccinated intrarectally with an avirulent live vaccine against *L. intracellularis* were protected against clinical and subclinical EPE following challenge exposure with a virulent *L. intracellularis* isolate of equine origin.[70] This was determined by lack of clinical disease, absence of hypoproteinemia and ultrasonographic abnormalities compatible with EPE, and a significant reduction in *L. intracellularis* fecal shedding in vaccinated foals compared with nonvaccinated foals. Further, average daily weight gains from the vaccinated foals over the entire study period were similar to those of the control foals and significantly higher when compared with those of the nonvaccinated foals, highlighting the benefit of the vaccine in the prevention of subclinical disease. The extralabel use of the *L. intracellularis* vaccine should be considered on naive and endemic farms in an attempt to reduce or prevent EPE. Timing of vaccine administration should again be synchronized with historical disease occurrence. Further, routine monitoring for clinical signs and hypoproteinemia/hypoalbuminemia is still recommended even when vaccine prophylaxis is used.

Rhodococcus equi Enteritis

Rhodococcus equi most frequently causes a severe pyogranulomatous pneumonia in foals 2 to 3 months of age. Extrapulmonary disorders (EPDs) have been associated with *R. equi* infection in foals, and the presence of EPDs is associated with an increase in mortality. Gastrointestinal EPDs may occur in as much as 50% of cases. Diarrhea is reported to occur in up to 33% of *R. equi* cases. Enterocolitis and typhlitis have been reported in 31 of 150 foals from one study. Intraabdominal abscesses (25 of 150) and abdominal lymphadenitis (25 of 150) were also reported in that same study. Septic peritonitis was present in 11 of 150 foals.[71]

Pathophysiology Intestinal infection with *R. equi* can occur through either fecal-oral transmission or swallowing of infected sputum. The organism invades and reproduces within the macrophages, causing a pyogranulomatous disease. In a survey of normal foals on two different farms, *R. equi* was shed in the feces of 16 of 17 and 19 of 26 foals, respectively.[72] Only two foals developed clinical signs of intestinal disease, and the shedding of bacteria in the feces increased threefold to fourfold during those times. Such foals, as well as adults, are likely the source of repeated contamination on endemic farms. Whether or not the organism causes disease is based on the presence of virulence factors, particularly VapA, which has been most commonly associated with disease in pneumonic foals.

Clinical and Laboratory Findings Foals diagnosed with *R. equi* enteritis typically manifest the signs of pneumonia first, although foals in which the enteric form is the major pathology have been reported.[73] With the enteric form of the disease, diarrhea, weight loss, and colic are present. Foals are often febrile, anorectic, and depressed. Typical clinicopathologic findings include leukocytosis with neutrophilia and severe hyperfibrinogenemia. Ultrasound of the abdomen may reveal pyogranulomatous abscesses in the lymph nodes.

A diagnosis of *R. equi* enteritis can be presumed in pneumonic foals showing signs of gastrointestinal disease that culture positive for *R. equi* in transtracheal wash fluid. *R. equi* can also be cultured from the feces, small intestinal luminal contents, or, occasionally, the peritoneal fluid of affected animals. A PCR based on the *vapA* gene has been developed and can be used as an adjunct diagnostic in these cases.[74]

Pathologic Findings The most common small intestinal lesion is multifocal ulcerative enteritis in the area of the Peyer patches of the ileum. Other parts of the small intestine may be affected, with lesions present throughout the entire small intestine.[74] These lesions frequently extend into the cecum and colon as well. A suppurative exudate is also present, along with pyogranulomatous inflammation of the mesenteric lymph nodes. Co-infection with *L. intracellularis* has also been reported to occur.[75]

Treatment Treatment of *R. equi* enteritis is similar to treatment of *R. equi* pneumonia. Erythromycin estolate (25 mg/kg PO q6-8h) or erythromycin phosphate (37.5 mg/kg PO q12h) combined with rifampin (5 to 7.5 mg/kg PO q12h) has been the traditional treatment for these foals, and it is still effective but requires a long duration of treatment and is difficult for owners to administer because of the frequency of the treatments. Alternative treatments include azithromycin (10 mg/kg PO q24h for 5 days, followed by q48h) and clarithromycin (7.5 mg/kg PO q12h). To prevent relapses it is very important to continue treatment until the hematologic abnormalities and radiographic or ultrasonographic examinations have returned to normal.

Complications Complications associated with *R. equi* enteritis include septic peritonitis and the development of intestinal adhesions. These may lead to death of the animal or chronic abdominal problems in those that survive. Therapy is often prolonged in these cases, and owners should be warned that foals with extrapulmonary disorders associated with *R. equi* pneumonia have a more guarded prognosis.[71]

Enteric Pythiosis

Pythium spp. are protistal organisms that belong to a group of phycomycotic organisms that also includes *Conidiobolus* and *Basidiobolus* spp. They are a frequent cause of severely pruritic cutaneous granulomas in horses along the Gulf Coast and southern United States. Much less frequently, the disease can cause granulomatous lesions in the small intestine.

Pathophysiology *Pythium* spp. are presumed to be transmitted via contact with contaminated water. Once ingested, the organisms are thought to penetrate the intestinal mucosa through an existing lesion, because necrotic tissue is considered chemotactic.[76] *Pythium* spp. may be able to penetrate healthy tissue, however, because some cases in dogs have been reported to have mesenteric lymph node involvement without any mucosal lesions.[77]

Clinical and Laboratory Findings Four reports of enteric pythiosis can be found in the literature.[78-81] In all cases, masses occurred in the mid to distal jejunum. One horse died suddenly, one was euthanized during surgery, and two were successfully treated with a jejunal resection. Organic iodide therapy was instituted in one horse postoperatively for 30 days. In three cases clinical signs of intestinal disease had been present for several months before diagnosis. Chronic colic, weight loss, inappetence, and ill thrift have all been reported and could be related to the intestinal lesion. None of the reported animals had skin lesions. Hematologic evaluation was nondiagnostic in the three cases in which it was performed.

Grossly, lesions are caseous with discrete yellow foci ("kunkers"), and the intestinal wall is thickened because of a pyogranulomatous inflammation. Microscopically, a diffuse, mixed inflammatory infiltrate, along with granulation tissue, is found in the submucosa, tunica muscularis, and mesenteric attachments. Culture of the organism is difficult in these lesions; however, an indirect immunoperoxidase technique to stain for *Pythium*-positive hyphae is available in some laboratories.[80]

Treatment Treatment of phycomycetes is often difficult. They are not true fungi; therefore they are resistant to many antifungal drugs. Systemic amphotericin B is only rarely effective in treating the cutaneous disorder. Organic iodides are inexpensive and safe when administered orally, but the mechanism of action as an antimicrobial drug is not understood, and the efficacy of this compound to treat this disease has not been proven. A vaccine can be formulated against the organism, and this has been shown to shrink the lesions in horses with cutaneous disease. Whether or not it would work in enteric disease is unknown at this time. In addition, premortem or presurgical diagnosis of the disease is extremely difficult, making surgical resection and biopsy the most effective treatment.

Inflammatory Bowel Disease

Several intestinal disorders characterized by inflammatory cell infiltration have been placed under the umbrella of inflammatory bowel disease (IBD), including granulomatous enteritis, multisystemic eosinophilic epitheliotropic enterocolitis, eosinophilic enterocolitis, lymphocytic-plasmacytic enteritis, and basophilic enterocolitis.[82-88] IBD in humans is typically characterized by a neutrophilic inflammation, but neutrophils are just the effector cell in a highly complex disease process.[89] The syndromes described for equine inflammatory intestinal disorders therefore appear to differ from those of human IBD; given the different types of cellular infiltrates found in affected horses, these disorders presumably reflect different pathophysiologic mechanisms. Thus use of the term *inflammatory bowel disease* is not intended to imply either a similarity to the condition described in

human beings or similarity among the various syndromes described in horses.

Clinical and Laboratory Findings Horses with IBD typically have progressive weight loss despite a good appetite and have intermittent abdominal discomfort. If the disease predominates in the small intestine, diarrhea may not be a feature. In some cases there will be associated dermatitis.[90] Horses often present with peripheral edema secondary to hypoproteinemia from enteric protein losses. Ultrasonographic examination may reveal thickened small intestine (>5 mm wall diameter).

Clinicopathologic abnormalities may include anemia, hypoalbuminemia, hypoproteinemia, and malabsorption of glucose and D-xylose. Hypoalbuminemia in the absence of proteinuria or severe liver dysfunction is consistent with protein-losing enteropathy. Some horses may have a relative gammopathy. Serum electrolyte concentrations and total CO_2 are usually normal. Subclinical disseminated intravascular coagulation with thrombocytopenia and increased fibrinogen degradation products have been identified in horses with chronic enteritis.[85,91] Serum antibodies to gluten have been detected in horses with IBD, as well as those on a gluten-rich diet.[92] This suggests a potential pathogenic role of gluten in at least some cases of equine IBD, and dietary changes may play an important role in treatment.

In many horses inflammatory cells infiltrate throughout the intestinal tract. Therefore rectal mucosal biopsy may be useful to identify cases of IBD in horses.[93] If the proximal duodenum is involved, endoscopic biopsies can be used for diagnosis (Fig. 32-71). A definitive diagnosis often requires biopsy of the small intestine, large intestine, or both. With appropriate instruments this can be done by laparoscopy, although an exploration via a ventral midline approach permits a more thorough evaluation of the abdomen. In most horses cellular infiltration can be found to varying degrees throughout the intestinal tract.

Histopathologic evaluation of biopsy specimens can be used to differentiate among the various IBDs reported in horses, based on the following criteria.[86] A diagnosis of granulomatous enteritis is made when aggregates of macrophages and epithelioid cells are found in the mucosa, submucosa, or both, along with villous atrophy. In lymphocytic-plasmacytic enterocolitis, lymphocytes and plasmacytes are present in the lamina propria, and villous atrophy usually occurs. For multisystemic eosinophilic epitheliotropic disease, eosinophils, lymphocytes, and macrophages are found in the mucosa and submucosa. In rare cases, basophils have also been reported.

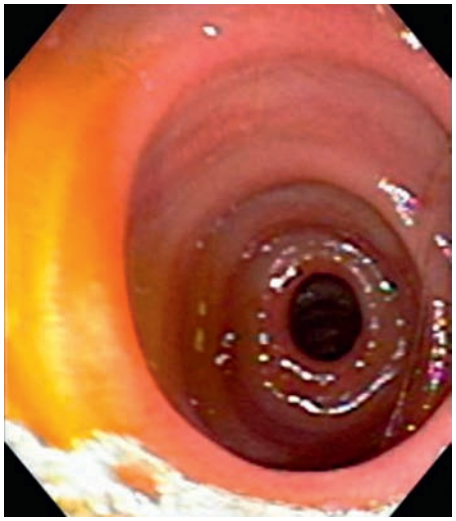

FIG. 32-71 Endoscopic view of the duodenum in a horse with lymphocytic-plasmacytic enteritis. Note the heterogeneous appearance of the duodenal mucosa.

IBD syndrome, termed *idiopathic focal eosinophilic enteritis* (IFEE), involves focal areas of eosinophilic inflammatory infiltrates within the small intestine.[88,94-98] Affected horses typically are examined not because of chronic weight loss or diarrhea, but rather as acute colic cases. Hypoproteinemia and malabsorption are not present. The lesions are intramural masses or circumferential mural bands. Eosinophils with or without lymphocytes are seen infiltrating all layers of the intestine, with varying degrees of fibrosis.[98] Further characterization of the inflammatory lesions indicate that IFEE most likely represents a focally exacerbated inflammatory reaction in horses with diffuse eosinophilic enteritis.[97] No underlying cause of the disease has been found, although food allergy, parasitism, and *Pythium* spp. have all been suggested.[98] The incidence, or at least the diagnosis, of this disease appears to be increasing.

Treatment and Prognosis Because the specific diseases included under the general category of IBD are quite different, a generalized treatment recommendation cannot be made. Most reported cases of IBD in horses have been fatal, even with aggressive treatment with corticosteroids. Classically reported cases of eosinophilic, lymphocytic, and basophilic enteritis have failed to respond to treatment. If treatment is attempted, immunosuppressive doses of dexamethasone, up to 0.2 mg/kg, once daily are recommended. Successful remission of granulomatous enteritis was reported in one patient that was treated with dexamethasone[99]; however, in the vast majority of cases treatment is unsuccessful. Cases of IFEE should be differentiated from other types of IBD with regard to treatment and prognosis. These cases frequently respond to surgical decompression without resection if circumferential mural bands are the only lesion present.[98] In cases of intramural masses, surgical resection of the lesions usually resolves the problem.[96] Other treatments attempted include anthelmintic drugs with larvicidal activity, hydroxyurea, metronidazole, clioquinol (iodochlorhydroxyquin), and sulfasalazine.[100]

Neoplasia

Primary and secondary neoplasia involving the alimentary tract of horses is relatively uncommon, although several cases have been reported.[101] Typical signs associated with, but not diagnostic for, small intestinal neoplasia include colic and weight loss. In most horses with focal intestinal neoplasia the problem becomes apparent when only lumen obstruction develops. Lymphosarcoma can be disseminated throughout a large portion of intestine, eventually resulting in a malabsorption and weight loss syndrome. Lymphosarcoma affects horses of all ages and can be manifested as an enteric disorder, as well as affecting other systems.[102] The diagnosis of enteric lymphosarcoma can occasionally be made on the basis of cytologic examination of fluid obtained by abdominocentesis. In other cases intestinal biopsy is required to diagnose the neoplastic disorder. The prognosis is best if the tumor is discrete and can be removed surgically. A combination chemotherapy protocol of cytarabine (170 mg/m^2 IM), cyclophosphamide (142 mg/m^2 IV), and prednisolone (86 mg/m^2 PO q48h) has been reported to be effective in the treatment of mixed-cell thoracic lymphoma.[103] In other cases, corticosteroid therapy may induce clinical remission for several months, although it is not curative.

Other neoplasms affecting the small intestine are unusual, typically arising from the wall of the bowel, and include adenocarcinoma,[104] leiomyosarcoma,[105] and neurofibroma.[106] These tumors often result in intestinal obstruction and signs of abdominal discomfort. Discrete tumors may be surgically removed.

Paraneoplastic syndromes may be the first sign of neoplastic processes in the horse. Pemphigus, hypoglycemia, hypercalcemia, erythrocytosis, and neuropathies have all been associated with tumors in horses.[107] Paraneoplastic processes may also lead to intestinal tract dysfunction in horses with extraintestinal tumors. Amyloid deposition secondary to multiple myeloma in a horse has been described.[108]

VetBooks.ir

VetBooks.ir

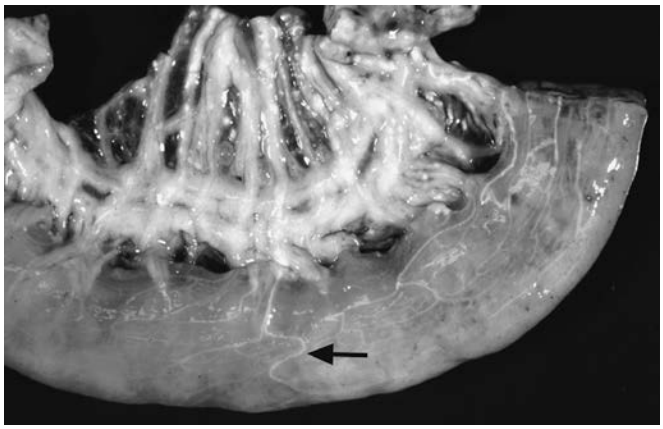

FIG. 32-72 Section of small intestine from a foal with chyloabdomen and a *Rhodococcus equi* abdominal abscess. Mesenteric lymphatics are distended with white chyle, as are serosal lymphatics. *(Courtesy Dr. M.J. Murray.)*

Small Intestinal Fibrosis

Small intestinal fibrosis is a rare syndrome that causes weight loss, chronic colic, and progressive debility in horses and ponies. Clusters of affected animals are reported in Colorado[109,110]; however, newer reports have been published in horses from Missouri.[111] The pathophysiology behind the fibrosis is not known, although ingestion of toxins (*Convolvulus arvensis* or common bindweed), inhibitors of 11β-hydroxysteroid dehydrogenase, or compounds with mineralocorticoid activity has been suggested.

Rectal palpation typically reveals thickening of the small intestinal wall, which may be confirmed by ultrasound.[110] Grossly, the overall length of the intestine may be shortened by as much as 50%.[109,110] The histologic lesions include arteriosclerosis, capillary endothelial hypertrophy, extensive fibrosis of the submucosa, and hypertrophy of the muscularis mucosae and tunica muscularis.[109] The prognosis for the disease is determined by the length of the intestine that is involved. Surgical resection may be attempted.

Lymphangiectasia and Chyloabdomen

There are few reports of lymphangiectasia and chyloabdomen in the literature. Lymphangiectasia is dilation of the lymphatics of the small or large intestine (Fig. 32-72), usually caused by an abscess[112] or neoplasia. There are reports of chyloabdomen resulting from congenital lymphatic defects in a neonatal foal, intraabdominal abscesses in a foal, and abdominal adhesions in a miniature horse.[112-114] Typically, thickening of the intestinal wall and leakage of chyle into the peritoneal cavity results from obstruction or rupture of the lymphatics. Animals can have signs that include abdominal discomfort, diarrhea, and chronic weight loss. Diagnosis is made on the basis of abdominal fluid analysis and ultrasonography. Chylous abdominal fluid appears milky and may contain a high percentage of lymphocytes. Ultrasonograms may reveal segments of thickened small intestine. Diagnosis is confirmed at surgery or postmortem examination, and treatment, if possible, is usually surgical, although in my experience medical resolution of the effusion has been achieved.

Surgical Disorders of the Small Intestine

Anthony T. Blikslager • John F. Marshall

Simple Obstruction

Simple intestinal obstruction is a physical obstruction of the lumen without obstruction of vascular flow. The most common causes are intraluminal masses composed of feed material (e.g., ileal impaction) or accumulation of parasites (e.g., ascarid impactions). There are other instances in which the bowel is obstructed without associated compromise of blood supply, most commonly by extraluminal compression by a mass or band of tissue in horses with intraabdominal adhesions. The large volume of fluid entering the small intestinal lumen on a daily basis[1,2] causes the obstructed intestine to become distended. Therefore, although the blood supply is not directly involved in simple obstructions, progressive and marked distention can result in decreased mural blood flow[3,4] and eventual necrosis of tissues.[5]

Ascarid Impactions

Impactions caused by *Parascaris equorum* typically occur in weanling foals (median age, 5 months; range, 4 to 24 months) that have been on a poor deworming program and that are administered an anthelmintic when they have a heavy parasite burden.[6] Products that cause sudden ascarid paralysis or death, including piperazine, organophosphates, and pyrantel pamoate, have been incriminated.[7] However, it is likely that any effective broad-spectrum anthelmintic, such as the avermectins, will have the same effect. Clinical signs include variable onset of colic after administration of an anthelmintic (usually within 1 to 5 days) and signs compatible with small intestinal obstruction, including nasogastric reflux.[6] The onset of the disease varies according to the degree of obstruction.[7] Diagnosis may be tentatively based on the history in a foal that appears unthrifty, has been recently dewormed, and has signs referable to small intestinal obstruction. The presence of dead ascarids in nasogastric reflux would raise the index of suspicion of this particular form of obstruction.[6] Abdominal radiographs or ultrasound will likely indicate the presence of multiple loops of distended small intestine but neither is needed if clinical signs indicate the need for immediate surgery. Surgical treatment typically involves an enterotomy made over the intraluminal impaction and removal of ascarids.

Although simple intestinal obstruction tends to carry a favorable prognosis for survival, ascarid impaction is a notable exception. The mortality rate in these cases is high (up to 92% in one study) as a result of severe intestinal compromise, peritonitis, and development of adhesions. The severe intestinal compromise is almost entirely attributable to the duration of impaction, which, for unknown reasons, is not as readily recognized in foals as it is in adults. Reasons for this could include failure of the owner or farm manager to recognize colic in foals or failure on the part of the owner or veterinarian to recognize the implications of colic in foals. Although foals readily display signs of colic, other medical causes of colic such as gastric ulcer disease or enteritis might be higher on the list of differential diagnoses than for adults. Second, the size of a foal may make episodes of colic appear more manageable than in adults, in which colic-induced trauma, especially to the head, may force the issue of referral and surgery at an earlier stage. This is speculative, but early intervention in foals with ascarid impaction would likely result in dramatic reductions in the reported mortality rate.[6] However, more recent reports indicate an increasing survival rate. For example, one report indicated that 80% of horses (12 of 15 horses studied) survived to discharge and 60% (6 of 10 for which follow-up data were available) survived for at least 1 year.[8] This improvement was related to changing the surgical technique to manually evacuating ascarids into the cecum rather than performing an enterotomy.[8] However, many cases have multifocal and marked impaction by ascarids that are large and difficult to manipulate. Whether or not an enterotomy is needed may therefore relate to the initial severity of disease.

Ileal Impaction

Ileal impactions occur most commonly in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in the regional distribution of this disease, it has been difficult to separate geographic location from regional hay sources as risk factors.[9] However, a study from the southeastern United States showed that feeding coastal Bermuda hay and failing

VetBooks.ir

to deworm with an anthelmintic with efficacy against tapeworms are significant risk factors for ileal impaction.[10] Furthermore, in a study performed in the United Kingdom, horses with evidence of tapeworm infection were at risk for developing ileal impaction.[11] Signs are typical for an adult horse with small intestinal obstruction, including onset of moderate to severe colic and palpable loops of distended small intestine per rectum as the condition progresses. As the ileum is the most distal aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in only approximately 50% of horses requiring surgical correction of ileal impaction.[12,13] The diagnosis is usually made at surgery, although an impacted ileum may be palpated per rectum.[14] However, multiple loops of distended small intestine frequently make the impaction difficult to palpate. Nonetheless, clinicians working in the southeastern United States who evaluate horses with cases of mild or moderate colic that have a history of eating coastal Bermuda hay, and in which distended loops of small intestine can be detected adjacent to the cecum, should have ileal impaction high on the list of differential diagnoses. Ileal impactions may resolve with medical treatment. In particular, horses with clinical signs compatible with obstruction of the small intestine and normal abdominal fluid should be treated medically unless pain is unmanageable or subsequent abdominal fluid samples indicate intestinal compromise. In those cases in which surgery becomes necessary, fluids (2 to 3 L) can be directly infused into the mass, allowing the surgeon to break down the impaction. However, extensive small intestinal distention and intraoperative manipulation of the ileum frequently leads to postoperative ileus (POI).[15] Therefore some surgeons now elect to perform an enterotomy and to flush the contents from the intestinal lumen with minimal manipulation. Although early studies indicated a guarded prognosis,[13] a more recent study indicates that the prognosis is excellent for both medically and surgically managed ileal impactions.[16]

Ileal Hypertrophy

Ileal hypertrophy is a disorder in which the muscular layers (both circular and longitudinal) of the ileum hypertrophy for unknown reasons. Parasitism has been implicated, particularly for those parasites that tend to localize to the ileum (such as tapeworms),[17] but this has never been proven. In some cases the jejunum may also be hypertrophied, either alone or in combination with the ileum.[18] It is clear from these findings that initial functional obstruction initiates this syndrome, causing the musculature of the intestine to hypertrophy in order to push intestinal contents aborally, but there is no evidence as to the mechanisms of this disease. Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually occludes the lumen. In one study partial anorexia and chronic weight loss (1 to 6 months) were documented in 45% of the horses.[19] The diagnosis is usually made at surgery, although in some cases the hypertrophied ileum may be palpated per rectum or seen on ultrasonographic evaluation of the abdomen.[19] For treatment, an ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum is performed. Without surgical bypass, intermittent colic persists, and the thickened ileum may ultimately rupture. According to one recent report of 11 horses with hypertrophy of the ileum, only 1 horse survived, indicating a poor prognosis. The most common reason for euthanasia was spontaneous ileal rupture.[18]

Meckel Diverticulum

A Meckel diverticulum is an embryonic remnant that may become impacted. The diverticulum arises from the vitelloumbilical duct, which fails to completely atrophy, and becomes a blind pouch projecting from the antimesenteric border of the ileum.[20,21] Occasionally an associated mesodiverticular band may extend from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands may also originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, thereby forming a potential space within which intestine may become entrapped (Fig. 32-73).[22] Clinical signs range from chronic colic for an impacted Meckel diverticulum to acute severe colic if a mesodiverticular band strangulates intestine. The diagnosis is made at surgery, and treatment requires resection of the diverticulum and any associated bands.[23]

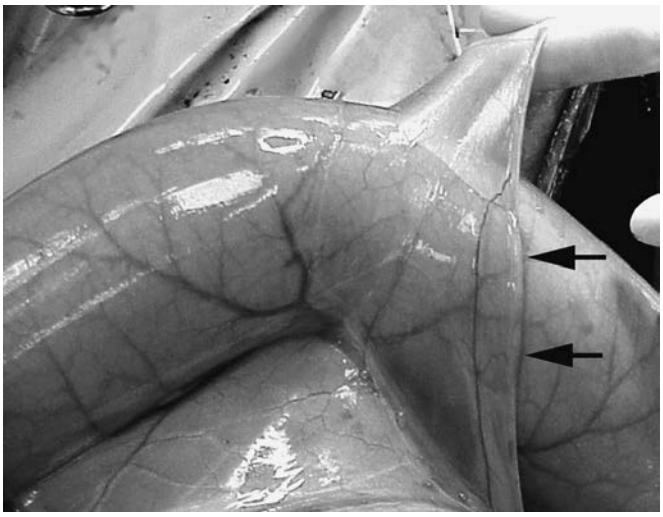

FIG. 32-73 Jejunal mesodiverticular band. This anomaly was discovered in this horse as an incidental finding during exploration of the abdomen. Intestine may become entrapped within the mesenteric pocket formed by the attachment of the ventral to the dorsal mesentery *(arrows)*.

Strangulating Obstruction

Strangulation obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of endotoxemia. Therefore clinical signs (including pain, heart rate, mucous membrane color, and capillary refill time) are typically more severe, and the prognosis is less favorable.

A great deal of work has been done to characterize mucosal injury that occurs during strangulation[24,25] and reperfusion.[26] In general, the lesion that develops during strangulation is severe, leaving little viable bowel for further injury during reperfusion.[27] The severity of the ischemic lesion is partly attributable to the fact that in most cases initial occlusion of veins and partial occlusion of arterial blood supply during strangulation induces a hemorrhagic lesion. This results in extensive congestion and mucosal degeneration (Fig. 32-74).[24] Bowel peripheral to the strangulating lesion may also become injured as a result of distention.[28] In addition, distended small intestine that remains viable after surgical correction of strangulation may be subject to reperfusion injury through the generation of reactive oxygen metabolites after surgical correction of the lesion.[29] While attempts at reducing mucosal injury in the horse with antioxidants have met with some success,[30] their clinical use is limited.

The prognosis for survival in horses with small intestinal strangulating obstruction (SISO) is generally lower than with most other types of colic. A number of studies have reported short-term survival rates for horses with SISO of between 55% and 84%. A large single-center study that included 147 horses with small intestinal disease found that short-term survival rate was significantly lower for horses with SISO (54.8%) than for those with a simple obstruction (79.6%).[31] In contrast, a review of 74 horses found no significant difference in short-term survival rate between horses with SISO (84%) and those with a simple obstruction (91%).[32] When communicating with owners, it is important to discuss potential postoperative complications and long-term survival rates. Studies following horses after discharge from the hospital have found significantly lower survival

rates after 12 months ranging from 47% to 68%.[32-35] Episodes of colic are the most frequently reported complication following discharge[34,36] and are significantly more common in horses with small intestinal obstruction than those with large colon disease.[34] A significant reason for repeated episodes of colic and reduced long-term survival in patients that have had small intestinal surgery is intraabdominal adhesions (Fig. 32-75). For example, in one study 22% of horses undergoing small intestinal surgery required further surgery or were euthanized because of adhesions, and only 25% of horses that had a clinical problem with adhesions survived.[37] A more recent study of 99 horses requiring repeat celiotomy found that intraabdominal adhesions were the most common pathologic finding.[38] However, in this study horses with small intestinal lesions were not more likely to develop adhesions than those with large colon lesions and horses with adhesions were no less likely to survive than those without.[38]

Epiploic Foramen Entrapment

The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. It is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, the hepatoduodenal ligament, and the portal vein.[39,40] Clinical signs include acute onset of severe colic with examination findings compatible with small intestinal obstruction. Although the condition was reportedly more prevalent in older horses, recent studies have not detected an age predilection.[41] However, studies have detected a seasonal pattern for this disease. Specifically, more horses appear to suffer from epiploic foramen entrapment during the fall and winter months, which may reflect management practices.[42] An additional factor associated with epiploic foramen entrapment is crib-biting. One possible reason for this association is the development of negative intrathoracic pressure during cribbing, which might then result in cranial movement of intestine into the vicinity of the epiploic foramen. The association between crib-biting and epiploic foramen entrapment has been shown in separate studies performed in the United Kingdom and the United States.[43]

The diagnosis is definitively made at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall are suggestive of epiploic foramen entrapment.[39] Entrapped small intestine may enter the foramen from the visceral surface of the liver toward the right body wall or in the opposite direction. However, in the vast majority of cases the intestine enters the foramen in a left-to-right direction.[39,44] Entrapped small intestine may be limited to a portion of the intestinal wall (parietal hernia).[45] In addition, the large colon may become entrapped within the epiploic foramen.[46] In treating epiploic foramen entrapment, the epiploic foramen must not be enlarged either by blunt force or with a sharp instrument, because rupture of the vena cava or portal vein and fatal hemorrhage may occur. In addition, excessive force used to extract entrapped bowel during surgery may also result in rupture of a mesenteric branch of the cranial mesenteric

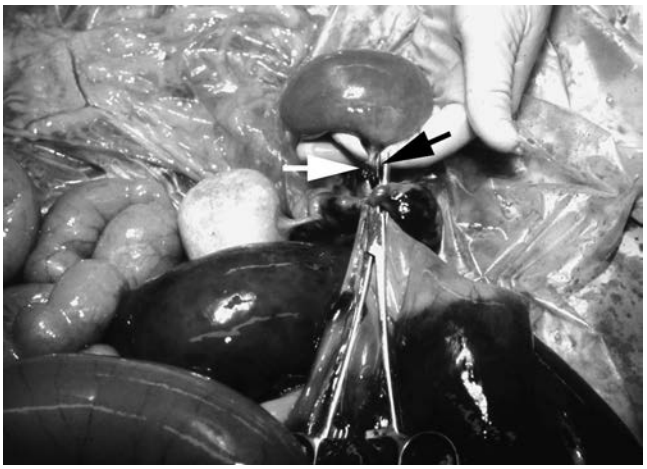

FIG. 32-76 Strangulating lipoma of the ileum. A lipoma, together with its mesenteric stalk *(arrows)*, has become intertwined with a loop of the ileum, resulting in a hemorrhagic strangulating obstruction.

artery. The finding of intraabdominal hemorrhage in some cases of epiploic foramen entrapment before surgery may result from compromise of the mesenteric blood supply rather than the major blood vessels that border the epiploic foramen. Prognosis has substantially improved over the past 25 years, with short-term survival rates (discharge from the hospital) ranging from 74% to 95% in the most recent studies.[39,47,48]

Strangulation by Mesenteric Pedunculated Lipoma

Lipomas form between the leaves of the mesentery as horses age, and mesenteric stalks develop as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma and a loop of small intestine or small colon may become intertwined, causing strangulation (Fig. 32-76). Strangulating lipomas should be suspected in mature horses (>10 years old) with acute colic referable to the small intestinal tract.[49] In addition, geldings and ponies appear to be at risk for developing strangulating lipomas,[50] possibly because of differences in fat metabolism. One study documented a case of strangulating lipoma in a much younger patient, indicating that although the aging process is associated with development of lipomas, this disease cannot be ruled out preoperatively purely on the basis of age.[51,52] The diagnosis is usually made at surgery.

Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is, on occasion, viable. Studies indicate that approximately 60% to 78% of horses are discharged from the hospital after surgical treatment.[49,53,54]

Small Intestinal Volvulus

A volvulus occurs when a segment of small intestine is twisted greater than 180 degrees along the axis of the mesentery. Small intestinal volvulus is theoretically initiated by a change in local peristalsis, but the mechanisms of this disease are unclear.[55] It is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.[56] It has been theorized that young foals may be at risk for small intestinal volvulus because of changing feed habits as they adapt to a forage-based adult diet. However, a report of 115 cases of small intestinal volvulus found that 74% of the cases were aged 3 years or older.[57] Onset of acute, severe colic, a distended abdomen, and radiographic or ultrasonographic evidence of multiple loops of distended small intestine in a young foal would be suggestive of small intestinal volvulus. However, volvulus is not possible to differentiate from other causes of small intestinal obstruction preoperatively.

In adult horses, volvulus frequently occurs in association with another disease process, during which small intestinal obstruction results in distention and subsequent rotation of the small intestine around the root of the mesentery (e.g., in horses that have strangulation caused initially by a pedunculated lipoma). Although any segment of the small intestine may be involved, the distal jejunum and ileum are most frequently affected, most likely because the mesentery is longer in the more distal bowel. The diagnosis is made by palpating a twist at the origin of the cranial mesenteric artery during surgical exploration. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement. For example, if complete volvulus of the small intestinal tract occurs, the only option would be to untwist the intestine and hope that the bowel was sufficiently viable to survive the disease process. This would in turn depend on the duration of disease and the extent of intestinal ischemia (i.e., how tightly the intestine twisted as the volvulus developed). Prognosis is based on the extent of small intestine involved and its appearance after surgical correction of the lesion.[58] For example, the degree of sepsis may relate to the surface area of devitalized tissue. In addition, the length of the time it takes to complete the surgery can become problematic, particularly in patients with sepsis, in which it is difficult to maintain adequate arterial blood pressure. Nonetheless, survival in patients with extensive small intestinal resection may not relate to the absolute length of intestine resected.[59] The prognosis for short-term survival is good; one study suggested that 80% of horses are discharged following surgery.[31]

Inguinal Hernia

Inguinal hernias are more common in Standardbred and Tennessee Walking horses, which tend to have congenitally large inguinal canals. Inguinal hernias may also occur in neonatal foals, but they differ from hernias in mature horses in that they are typically nonstrangulating. Typical historical findings in mature horses with inguinal hernias include acute onset of colic in a stallion that has recently been used for breeding. A cardinal sign of inguinal herniation is a cool, enlarged testicle on one side of the scrotum.[60,61] This is attributable to occlusion of the testicular blood supply in most cases rather than strangulated intestine within the scrotum itself. Inguinal hernias can also be detected on rectal palpation, and ultrasound of the testicle is very helpful in determining the diagnosis, particularly considering the differential diagnosis of testicular torsion. The nature of the hernia (direct versus indirect) is determined by the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is said to be indirect, because the bowel remains within the peritoneal cavity. Direct hernias are those in which bowel ruptures through the parietal vaginal tunic and occupies a subcutaneous location, followed by strangulation. Direct hernias most commonly occur in foals and should be suspected when a congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region of the prepuce, and intestine that may be palpated subcutaneously.[62,63] Although most congenital indirect inguinal hernias resolve with repeated manual reduction and/or application of a diaper, surgical intervention is recommended in foals with congenital direct hernias in order to reduce the hernia as well as repair the parietal vaginal tunic.

In stallions with indirect inguinal hernias, herniated bowel can be manipulated through the rectum to reduce the hernia, but this procedure is not generally recommended because of the risk of a rectal tear. In addition, the inability to visually assess the integrity of the bowel may be problematic. However, in many cases taken to surgery the short segment of herniated intestine will markedly improve in appearance once it has been manually or surgically reduced, and in some cases the affected intestine can be left unresected. In these cases, subsequent laparoscopic closure of the internal vaginal ring is recommended to prevent recurrence.[64] In nonreducible hernias, the affected testicle will be congested because of vascular compromise within the spermatic cord, and although it may remain viable, it is recommended that it be resected. Furthermore, the inguinal canal should be partially closed at surgery to prevent recurrence, and the risk that this procedure will reduce spermatic cord vasculature is another problem. The prognosis in adult horses is good, with 76% of horses

VetBooks.ir

alive 6 months after discharge.[61] Horses that have been unilaterally castrated during surgical treatment of inguinal hernias may be used for breeding. In these horses, the remaining testicle will have increased sperm production, although an increased number of sperm abnormalities will be noticed after surgery because of edema and increased temperature of the scrotum.

Strangulating Umbilical Hernias

Although umbilical hernias are common in foals, strangulation of herniated bowel is rare. In one study, 6 of 147 horses with umbilical hernias (4%) had incarcerated intestine.[65] Clinical signs include a warm, swollen, firm, and painful hernia sac associated with signs of colic. The affected segment of bowel is usually the small intestine, but herniation of the cecum or large colon has also been reported.[66] In rare cases a hernia that involves only part of the intestinal wall may be found and is referred to as *Richter hernia.* In foals that have Richter hernia, an enterocutaneous fistula may develop. In one study, 13 of 13 foals with strangulating umbilical hernias survived to discharge, although at least 3 horses died because of long-term complications.[66]

Diaphragmatic Hernias

Herniation of intestine through a rent in the diaphragm is uncommon in the horse, accounting for 0.3% of all cases of colic in a large multicenter study.[31] Any segment of bowel may be involved, although small intestine is most frequently herniated.[67] Diaphragmatic rents may be congenital or acquired, but acquired hernias are more common. Congenital rents may result from incomplete fusion of any of the embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, and esophageal mesentery. In addition, abdominal compression of the foal at parturition may result in a congenital hernia. Acquired hernias are presumed to result from trauma to the chest or a sudden increase in intraabdominal pressure such as might occur during parturition, distention of the abdomen, a sudden fall, or strenuous exercise.[68] In one study, 19 of 40 horses diagnosed with diaphragmatic hernia (48%) had a history of recent trauma.[68] Hernias have been located in several locations, although large congenital hernias are typically present at the most ventral aspect of the diaphragm and most acquired hernias are located at the junction of the muscular and tendinous portions of the diaphragm. In addition, a peritoneal-pericardial hernia has been documented in at least one horse.[69]

The clinical signs are usually associated with intestinal obstruction rather than respiratory embarrassment. However, careful auscultation may reveal an area of decreased lung sounds associated with obstructed intestine and increased fluid within the chest cavity. Such signs may prompt thoracic radiography or ultrasound, both of which can be used to make a diagnosis. In one review, 7 of 40 horses reported in the literature with diaphragmatic hernia (18%) had dyspnea.[68] Auscultation may also reveal thoracic intestinal sounds, but it is typically not possible to differentiate these from sounds referred from the abdomen. In one report, two of three horses diagnosed with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia, attributable to decreased ventilation.[70] Given the difficulties in correcting diaphragmatic hernias and the associated complicating factors such as pneumothorax, these cases are generally considered to have a poorer prognosis than other causes of colic. A recent report of 31 cases found that 46% of cases undergoing surgical treatment survived to discharge while the overall success rate was only 23%.[71]

Intussusceptions

An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussuscipiens). The reason for such invagination is not clear, but it may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms *(Anoplocephala perfoliata)* have been implicated.[72] Ileocecal intussusceptions are the most common intestinal intussusceptions in the horse and typically affect young animals. For example, in one study evaluating 26 cases of ileocecal intussusception, the median age of the horses was 1 year old.[73] Acute ileocecal intussusceptions are those in which the horse has a duration of colic of less than 24 hours and involve variable lengths of intestine that ranged in one study from 6 cm to 457 cm long. In acute cases the involved segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm long), and the ileal blood supply is frequently intact. Abdominocentesis results are variable because strangulated bowel is contained within the adjacent bowel. There is often evidence of obstruction of the small intestine, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. A mass may be palpated in the region of the cecal base in approximately 50% of cases. Transabdominal ultrasound may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross-section.[74]

Other segments of the small intestine may also be intussuscepted, including the jejunum. In one study on 11 jejunojejunal intussusceptions, the length of bowel involved ranged from 0.4 to 9.1 m.[75] Attempts at reducing intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. Jejunojejunal intussusceptions should be resected. For acute ileocecal intussusceptions the small intestine should be transected as far distally as possible, and a jejunocecal anastomosis performed. In cases with particularly long intussusceptions (length up to 10 m has been reported), an intracecal resection may be attempted. For horses with chronic ileocecal intussusceptions, a jejunocecal bypass without small intestinal transection should be performed.

In one study that evaluated the survival of horses with ileocecal intussusceptions, 7 of 7 horses with chronic intussusceptions survived long term (>4 months), whereas only 5 of 12 horses with acute intussusceptions (42%) survived long term.[73] In a separate study that evaluated survival in horses with jejunojejunal intussusceptions, 6 of 11 horses (54%) were discharged from the hospital after surgery, and 4 of 11 horses (36%) survived long term (>16 months).[75]

Other Small Intestinal Strangulations

Entrapment of the small intestine may occur through rents in the mesentery, internal ligaments such as the gastrosplenic ligament,[76] the broad ligament, and the proximal aspect of the cecocolic ligament.[77] Entrapments may also occur through trauma-induced body wall hernias. For all of these conditions it is often necessary to enlarge the rent or hernia to allow reduction of entrapped small intestine. In the case of body wall hernias, the defect should be closed with suture or patched using mesh. Entrapment of small intestine within mesenteric rents appears to be particularly problematic because it is difficult to reduce and has an unfavorable prognosis. The latter may be a result of the fact that large lengths of intestine may become strangulated, and because the mesenteric vasculature is frequently compromised to the extent that intraabdominal hemorrhage has been noted in some cases.[78]

Nonstrangulating Infarction

Nonstrangulating infarction occurs secondary to cranial mesenteric arteritis caused by migration of *Strongylus vulgaris*[79] and has become a rare surgical disorder since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases. These findings suggest that vasospasm plays an important role in this disease.[79] Clinical signs are highly variable, depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are

VetBooks.ir

more commonly involved. There are no clinical variables that can be used to reliably predict or differentiate this disease from strangulating obstruction. In some cases massive infarction results in acute, severe colic. Other cases may have intermittent colic as smaller emboli are released into the colonic blood supply. Occasionally an abnormal mass and fremitus may be detected on palpation of the root of the cranial mesenteric artery per rectum. This disease should be considered a differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although fecal parasite egg counts should be performed, they are neither indicative of the degree nor specific for the type of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg q24h) to decrease thrombosis. Definitive diagnosis requires surgical exploration. Surgical treatment depends on the distribution of infarction. Unfortunately, these cases are difficult to treat because of the patchy distribution of the lesions and the possibility of lesions extending beyond the limits of surgical resection. In addition, further infarction may occur after surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy, but horses that require surgical intervention have a poor prognosis.[79]

Medical Disorders of the Large Intestine

Samuel L. Jones

Acute Diarrhea

Diarrhea in the horse can be defined as the passage of fecal material that has increased water content. It can vary from soft, formed stools with a mild to moderate increase in water content to projectile fecal passages that contain little solid matter. The passage of excessive water in the feces reflects disruption of the normal balance of fluid and electrolyte secretion and absorption in the intestinal tract. In adult horses diarrhea results almost exclusively from disorders of the large intestine, although diarrhea may be a feature of some descending small colon disorders. Diarrhea can result in significant losses of water, electrolytes, and plasma protein and is often accompanied by local and systemic inflammatory responses.

Diarrhea disorders in adult horses can be divided into those characterized by inflammation of the cecum and large intestine (typhlitis, colitis) and those in which there typically is not an inflammatory response. Inflammatory disorders can be those characterized by an acute inflammatory response (salmonellosis, Potomac horse fever [PHF], and clostridiosis, described later), disorders associated with endoparasitism (small and large strongyle larval migration or encystation), disorders arising from toxicity (cantharidin toxicity, described later, and nonsteroidal antiinflammatory toxicity), and disorders included under the umbrella term *inflammatory bowel disease* (IBD). Disorders that can manifest with diarrhea but that typically do not have colonic inflammation include those in which there is increased intestinal hydrostatic pressure (congestive heart failure, cirrhotic liver disease), intraluminal osmolarity, and poorly defined disorders in which fluid secretion may be stimulated by the enteric nervous system.

Colitis is active inflammation within the colon that is usually associated with myriad local and systemic pathophysiologic events. Diarrhea is an important problem in horses with colitis, but impaired cardiopulmonary function, coagulopathies, and other sequelae of activation of inflammatory mediator cascades and septicemia can be most life-threatening. Complications that occur in patients with colitis, regardless of cause, include overwhelming sepsis triggered by endotoxemia, septicemia and hematogenous organ colonization by bacteria, immune suppression and susceptibility to superinfection with bacteria or fungi, cecum or colon infarction, jugular vein thrombosis, and laminitis.

A variety of inflammatory cells and mediators affect the equine colon. With acute colitis the neutrophil is the effector cell, and the cascade of activation of inflammatory mediators associated with acute colitis is designed to bring neutrophils to where chemical signals indicative of bacterial infection have been detected. Signs of sepsis associated with endotoxemia frequently accompany, or even precede, diarrhea in horses. Severe tissue inflammation can result in ulceration of the mucosal epithelium, resulting in chronic malabsorption and protein-losing enteropathy. Malabsorption of volatile fatty acids (VFAs) and metabolic alterations that result from excessive production and release of inflammatory mediators can lead to an energy deficit and catabolism of body tissues.

Specific diseases affecting the equine large colon (e.g., salmonellosis, PHF, clostridial colitis, and cantharidin toxicity) may have different activators of local and systemic inflammatory responses, and they can produce unique toxins that further contribute to tissue injury. Regardless of the cause, the clinical problems of affected horses are often similar, and the clinician must consider treatments that modify inflammatory changes and replace losses of fluid, electrolytes, and plasma protein. In many cases the cause of the diarrhea is not determined. Descriptions of important causes of diarrhea in horses follow.

Salmonellosis

Salmonella bacteria possess an array of virulence factors that confer attributes of mucosal adhesion and invasion, produce enterotoxins that stimulate intestinal fluid secretion, activate local inflammation (including recruitment of inflammatory cells and the release of their mediators), cause local cytotoxic effects, and initiate systemic responses attributable to lipopolysaccharide (LPS).

Epidemiology Numerous *Salmonella* serotypes have been associated with equine colitis, and overall more than 2500 serotypes of *Salmonella* have been described. *Salmonella enterica* serovar Typhimurium is the most frequently isolated serotype in horses, with dozens of other serotypes isolated sporadically. There are many reports describing clusters of cases of equine salmonellosis in which specific *Salmonella* serovars predominate. Nosocomial infections associated with *Salmonella* Krefeld,[1-3] *Salmonella* Typhimurium,[2] *Salmonella* Anatum,[4] *Salmonella* Infantis,[5] and *Salmonella* Newport[6] have been reported. Pertinent features of these bacteria are the ability to withstand a wide range of environmental conditions, the ability to rapidly invade and spread within the host (and thus be shed into the environment through the feces), and the range of severity of illness that results from infection.

Other key elements that influence whether clusters of cases will occur given the presence of a *Salmonella* serovar in the environment are availability and population density of susceptible hosts and the size of the infective dose of the pathogen. It is for these reasons that veterinary hospitals, breeding farms, and other facilities that may have a high density of horses are most vulnerable to the development of *Salmonella* outbreaks. In several studies at veterinary teaching hospitals, horses that were at greatest risk for developing salmonellosis or shedding *Salmonella* in their feces were those treated with antimicrobial drugs or admitted for treatment of colic.[7-9] Such horses are the majority of patients in any equine referral hospital and account for a significant biosecurity concern in equine hospitals and potentially in the home stables of shedding patients after discharge if susceptible animals have contact with discharged horses that are shedding.[10] Breeding farms are susceptible to *Salmonella* outbreaks (or other enteric infections) because of the concentration of large numbers of immunologically immature newborn animals. In either case the particular *Salmonella* organism involved in disease outbreaks may not have to be especially virulent, because the inherent susceptibility of the host provides the microbe the opportunity to colonize and invade the host. Also of importance is the ability of the organism (inherent or acquired) to persist in the environment, lying

VetBooks.ir

in wait for both susceptible hosts and environmental conditions that favor its propagation and dissemination.

Serovars or strains of *Salmonella* that have newly acquired virulence plasmids can rapidly become established and spread among farms, sales areas, veterinary clinics, and veterinary teaching hospitals. Often the origin of these "new" bacteria is undetermined, but in some cases the organism can be traced to contaminated feed,[11] a specific shedder or index case introduced into the environment,[6] or domestic, feral, or wild animals.

Salmonellae are ubiquitous in the environment, and the prevalence of fecal shedding varies by the group of horses sampled and the method of detection. Prevalence of fecal shedding, based on fecal culture, in asymptomatic horses admitted to teaching hospitals varied from 1% to 5%.[12,13] In a nationwide survey of prevalence of *Salmonella* in fecal samples from horses on farms and ranches, *Salmonella* bacteria were cultured from less than 1% of horses.[14] The incidence of *Salmonella* shedding in feces has been reported to be 17% in horses admitted to a teaching hospital for lameness examination and 35% to 60% or higher in hospitalized horses with gastrointestinal disease.[9,15] In these reports the polymerase chain reaction (PCR) technique was determined to be specific for *Salmonella* DNA, but the test cannot differentiate between shedding of live bacteria and DNA from dead organisms.

Horses are not considered to be carriers per se of *Salmonella,* because no host-adapted *Salmonella* spp. have been identified in horses. *Salmonella abortus equi* has now disappeared in the United States. Horses that shed *Salmonella* spp. in the feces usually do so transiently for several days to weeks; infrequently horses may shed salmonella bacteria for several months.

In acutely affected horses, large numbers of highly infective salmonellae can be shed in the diarrheic feces. Susceptible animals such as young foals, hospitalized horses receiving antimicrobial drugs, and horses under stress can become ill after becoming infected by numbers of salmonellae 100 to 1000 times less than those required to infect immunocompetent normal horses. Thus particular care should be taken in the management of horses and foals with diarrhea in environments in which there are other animals at risk (e.g., hospitals, breeding farms, show stables, racetracks). Asymptomatic shedders generally pass relatively small numbers of salmonella organisms in the feces and do not appear to pose an important threat to healthy horses not being treated with antibiotics,[10] although asymptomatic shedders have been responsible for outbreaks of salmonellosis in hospitals and on breeding farms.

Clinical Findings

Salmonellosis typically is characterized by an acute colitis that results in profuse diarrhea and occasionally abdominal pain. Horses with salmonellosis often have signs of sepsis associated with endotoxemia and suffer from cardiovascular shock, vascular leak syndrome, and coagulopathies. Horses are usually febrile, tachycardic, moderately to severely obtunded, and dehydrated. With other clinical syndromes of *Salmonella* infection, diarrhea is not a feature. These syndromes include fever and leukopenia, colic, and proximal enteritis with gastric reflux.

Diagnosis

Confirmation of salmonellosis requires bacteriologic culture and/or PCR detection of *Salmonella* bacteria. Multiple fecal cultures and/or quantitative PCR for *Salmonella* spp. should be performed on all horses with diarrhea, particularly if they have signs of systemic inflammation (fever, neutropenia or leukopenia, tachycardia, or tachypnea). It is recommended that at least three to five fecal samples collected 12 to 24 hours apart be submitted to increase the sensitivity of culture.[16] Samples with little solid matter often yield negative culture results, even when the horse is infected with *Salmonella.* Formed fecal samples are more likely to result in a positive culture result from infected horses. A 5- to 10-g amount of feces should be submitted for culture in selective media such as tetrathionate broth or selenite broth and brilliant green agar or XLD agar. Culture of a rectal mucosa biopsy may be a useful adjunctive test used to diagnose salmonellosis. PCR is a sensitive screening tool for detection of fecal *Salmonella* DNA and is important for environmental monitoring and biocontrol measures in hospitals. Quantitative PCR is very sensitive and specific when compared with conventional culture and has a high positive predictive value for individual patients with clinical signs consistent with salmonellosis.[17]

Treatment and Prevention

In most cases of salmonellosis, aggressive treatment facilitates resolution of the severe diarrhea and associated metabolic disorders within 7 to 10 days of the onset of illness. Intravenous administration of polyionic fluids is required to replace fluid and electrolyte losses and to augment preload in horses with poor venous return (see the Fluid Therapy for Horses with Gastrointestinal Diseases section in this chapter and Chapter 44 for more comprehensive information about fluid therapy in horses with diarrhea). Plasma may be required to replace lost plasma proteins and increase plasma colloidal pressure. Alternative colloidal fluids, such as hetastarch, may be useful and more cost-effective than plasma in horses with vascular leak syndrome and hypoproteinemia. Flunixin meglumine is often used to treat inflammation in horses with signs of sepsis. Flunixin and other nonsteroidal antiinflammatory drugs (NSAIDs) should be used with caution and at the lowest dose possible to prevent worsening of colonic mucosal damage or inhibition of mucosal repair. Other antiinflammatory strategies may be used to treat sepsis associated with salmonellosis. Total or partial parenteral nutritional support is often indicated to provide adequate calories and amino acids during the most debilitating period of the illness. Antimicrobial administration to horses with suspected or known salmonellosis is not universally practiced. Antimicrobial administration may decrease the spread of *Salmonella* bacteria to other organs and may have some direct effect on *Salmonella* bacteria in the colon. Traditionally, use of antimicrobial drugs such as chloramphenicol, trimethoprim-sulfonamide (TMS), gentamicin, and cephalosporins has not appeared to accelerate resolution of signs of colitis. Fluoroquinolones, such as enrofloxacin, although potentially arthropathic in young horses, may be more effective because of high lipid solubility and bactericidal activity against *Salmonella* bacteria. The prevalence of infection and shedding of multidrug-resistant *Salmonella* strains appears to be increasing in high-risk facilities such as equine veterinary hospitals.[6]

Horses that have severe diarrhea and sepsis for 10 days or longer are unlikely to survive, even with intensive therapy, because they often have extensive ulceration of colonic mucosa and chronic, severe inflammation within the wall of the colon. Ulceration may be exacerbated by administration of NSAIDs. Complications such as catheter-associated thrombophlebitis, colonic infarction (Fig. 32-77), colonization of other organs by salmonellae or other enteric bacteria, and laminitis can occur.

FIG. 32-77 Colonic infarction in a horse with salmonellosis. Tenesmus and rectal prolapse were early clinical signs of colonic infarction. *(Courtesy of Dr. M.J. Murray.)*

VetBooks.ir

Measures designed to prevent the spread of *Salmonella* in an environment with potentially susceptible hosts need not be excessively laborious or expensive. The goal is to minimize the size of the infective dose of an enteric pathogen to which a susceptible host may be exposed. Thorough cleaning of areas where fecal contamination is likely and prevention of mechanical distribution of contaminated material are the most important measures that should be taken. Extensive use of disinfectants may not be necessary if cleaning measures are adequate. Cleaning must include removal of organic debris, which can be accomplished with several products designed for that task. Areas that require particular attention are stalls, including water buckets or automatic watering systems, drains, and cracks in the floors and wall; stall implements; surgical areas, including drains; and nasogastric tubes and pumps.

If a diarrheic horse is in the environment, it should be isolated to the greatest degree possible, and biosecurity measures should be instituted to prevent transmission and to detect and monitor any potential outbreak.[6] Bedding material should be removed frequently to minimize accumulation of potential enteropathogens. Personnel entering the stall should be restricted to the professional staff, and they should wear gloves, disposable coveralls, and disposable plastic boots. Footbaths with disinfectant are only effective if they are kept clean and fresh because they quickly accumulate organic material that interferes with the disinfectant activity of the footbath. Vacated stalls should be thoroughly cleaned, allowed to dry, and disinfected, and selected sites in the stall (floor, drain, waterer) must be determined to be negative for *Salmonella* by culture and/or PCR. Biosecurity protocol compliance is critical to prevent an outbreak.

Potomac Horse Fever

PHF is an infectious enterocolonic disorder caused by *Neorickettsia risticii* (formerly *Ehrlichia risticii*).[18-20] The organism is an obligate intracellular parasite, infecting peripheral monocytes and macrophages, colonic and small intestinal epithelial cells, and colon mast cells.[21] The pathophysiology of the disease is incompletely understood, although horses infected with *N. risticii* often have clinical signs and complications similar to those in horses with salmonellosis. After experimental inoculation with *N. risticii,* horses had a mild, transient fever 2 to 4 days after infection.[22] By 10 to 14 days after experimental infection, horses became febrile, had a poor appetite, and exhibited mild to severe gastrointestinal signs ranging from mild colic and soft stool to profuse diarrhea.

In clinical cases of PHF, there are signs of sepsis, including fever, leukopenia, congested mucous membranes, and hypercoagulability. The early fever observed in experimental cases is usually not detected by owners, and when clinical signs are seen it is presumed that the horse was infected 10 to 14 days previously. Hypoproteinemia is a frequent finding in horses with clinical cases of PHF, which reflects loss of serum protein through inflamed intestinal mucosa. It is interesting to note, however, that the magnitude of intestinal inflammation is typically much less than with salmonellosis, yet the magnitude of hypoproteinemia (total protein < 3 g/dL) can be as severe.

Laminitis is a frequent sequela and may occur in 30% in horses with PHF. *N. risticii* has also been associated with abortion in mares, although this is an unusual occurrence.[23] In some horses that show significant seroconversion to *N. risticii,* laminitis is the only clinical sign.

Mode of Transmission

Although originally described as a disease of horses living near the Potomac River in Maryland and Virginia, horses with serologic evidence of exposure to *N. risticii* have been reported in most U.S. states. Because early research on PHF demonstrated that infection was readily transmitted through blood,[32] it was presumed that the natural mode of transmission involved an insect or arthropod vector. However, several studies have failed to demonstrate any such vectors.[24,25]

The association between an affected horse and proximity to a river (within 5 miles) remains strong. Investigators have found a possible link between this association and how the disease may be transmitted. *N. risticii* and *Neorickettsia helminthoeca* were found to share a high degree of DNA homology.[26] *N. helminthoeca* is transmitted to mammals via a trematode that parasitizes fish and aquatic snails.[26] This prompted investigators to search for evidence that *N. risticii* might reside in trematodes and their hosts found in riverine inhabitants. *N. risticii* DNA was detected in operculate snails (Pleuroceridae: *Juga* spp.) collected from stream water in a northern California pasture in which PHF is enzootic.[27] Moreover, *N. risticii* was detected in trematode stages found in the secretions of freshwater snails and in aquatic insects.[28,29] The sequences of these genes were virtually identical to those of the genes of an equine *N. risticii* strain isolated from horses located on a property near the snail collection site. Further work demonstrated *N. risticii* DNA in two trematodes, *Acanthatrium* spp. and *Lecithodendrium* spp., found in bats and swallows, suggesting that these animals may serve as a reservoir and that trematodes are a vector for the organism.[30] Oral transmission of *N. risticii* with infected cell cultures has been produced experimentally,[31] supporting a role for ingestion of *N. risticii,* rather than blood transmission, as the route of natural infection. Oral transmission and clinical signs of PHF were demonstrated in horses fed *N. risticii*–infected aquatic insects (caddis flies), suggesting that ingestion of infected aquatic insects may be the natural route of infection.[32,33] Ingestion of water containing infected trematode stages released from aquatic snails may also be a route of infection.

Diagnosis

Accurate confirmation of PHF can be difficult, because clinical signs of disease are nonspecific and available diagnostic tests are not entirely reliable. Conventional recommendation is that paired acute and convalescent blood samples should be submitted for indirect fluorescent antibody (IFA) or ELISA testing for antibodies to *N. risticii.* However, serologic evaluation to confirm the disease is not as straightforward as in many other infectious diseases. A fourfold increase in titer between acute and convalescent sera is considered to confirm infection with *N. risticii,* but failure to seroconvert does not rule out infection. Because the onset of clinical signs can be delayed as long as 14 days after infection, horses may seroconvert by the time an acute sample is obtained.[31] The magnitude of titer does not always correlate with active infection, because many horses in endemic areas have high titers but no disease. Vaccination also can affect the titer. There is significant interlaboratory variability in results of IFA tests, and false-positive results occur frequently.[34] Therefore it has been suggested that IFA testing for antibodies to *N. risticii* not be performed in areas that are not endemic for *N. risticii.*[34]

The current standard for diagnosis of PHF used by most clinicians is quantitative PCR testing of whole blood samples to detect *N. risticii* DNA in leukocytes.[35] PCR testing appears to be sensitive and specific in horses with compatible clinical signs, but a thorough evaluation of the test has not yet been completed.

Treatment and Prevention

Treatment with oxytetracycline (7 to 11 mg/kg IV twice daily for 4 days) effectively eliminates *N. risticii* from the horse in experimental infections. Fever should resolve within 48 hours of beginning treatment with oxytetracycline, and diarrhea typically resolves within 24 to 72 hours of beginning treatment. In one horse we treated, clinical signs persisted until the dose of oxytetracycline was increased to 15 mg/kg twice daily. Orally administered doxycycline (10 mg/kg q12-24h) may be effective, although in horses with severe gastrointestinal signs, absorption of doxycycline may be adversely affected. Doxycycline must not be given intravenously because it will cause the horse to collapse. Some horses have had clinical relapses 2 to 3 weeks after initial resolution of clinical signs that were responsive to tetracycline. Horses do not remain chronic carriers of *N. risticii.*

In most cases of PHF, intravenous administration of polyionic fluids is required to replace fluid and electrolyte losses and to augment preload in horses with poor venous return. Plasma may be required to replace lost plasma proteins. Other colloidal fluids may also be used in patients with hypoproteinemia or sepsis. Because horses

VetBooks.ir

improve rather quickly once treatment with oxytetracycline has begun, parenteral nutritional support is usually unnecessary.

Vaccination has appeared to diminish the incidence and severity of disease, but PHF may still develop in vaccinated animals. Experimental results with vaccine were mixed, and the duration of immunoprophylaxis was very limited.[36] Disease severity has appeared to be less in vaccinated animals, although in the summer of 1994 many vaccinated horses developed severe cases of PHF. All of these horses were located in the area where PHF was originally described, and a new strain of *N. risticii* was identified.[37] PCR analysis has revealed multiple strains of *N. risticii,* which may account for the unreliable efficacy of the vaccine.[38] Horses in endemic areas should be vaccinated in the early spring and early to mid-summer on an annual basis.

Clostridial Diarrhea

Enteric clostridiosis was reported as a clinical problem in the 1970s, and clostridial bacteria were implicated as the causative agents of colitis X.[39] Difficulty in substantiating clostridial bacteria as the cause of enterocolitis in horses led to a de-emphasis of this potential cause for diarrhea in adult horses. In the 1990s, improved laboratory techniques for identification of clostridial toxins resulted in increased confirmation of clostridial bacteria as common causative agents of colitis in foals and adult horses.

The two most important clostridial species affecting the equine intestinal tract are *Clostridium difficile* and *Clostridium perfringens.* Most reported cases in adult horses have involved *C. difficile,* although in one report the prevalences of *C. difficile* toxin A and *C. perfringens* enterotoxin in fecal samples from horses with diarrhea were similar, and in some horses toxins from both clostridial species were identified.[40] (Also see p. 824 for more on *Clostridium perfringens* types and toxins.)

Pathogenesis

C. difficile is a gram-positive sporulated obligate anaerobe responsible for most cases of antibiotic-associated diarrhea in many species, including horses, and for a substantial proportion of nosocomial infections in humans and horses.[41,42] *C. difficile* produces two important toxins, named toxin A and toxin B. Most isolates of *C. difficile* produce both toxins, but some isolates produce only one of these. Toxin A can elicit both fluid secretion and a pronounced inflammatory response in the bowel. Toxin A has intestinal secretory and cytotoxic effects,[43,44] increases intestinal permeability,[45] and can activate epithelial cells, neutrophils, mast cells, monocytes, and macrophages to release a multitude of proinflammatory cytokines and vasoactive mediators.[46-48] An interesting feature of toxin A is its induction of the neurotransmitter substance P in both the intestine and dorsal root ganglia, and the apparent dependence on substance P for expression of the full pathologic effects of toxin A in the intestine of rodents.[49] Thus, the effects of toxin A appear to be mediated both through direct effects on intestinal cells and via the enteric nervous system.

Toxin B exhibits enterotoxigenic (secretory) activity and has also been shown to have potent cytotoxic effects on human colonic epithelium.[50] Toxin B has little relevance to the pathogenicity of *C. difficile* in animal models, however, and the roles of toxins A and B in the pathogenesis of equine clostridial enterocolitis are not known.

Strains of *C. perfringens* are classified on the basis of the toxins that are produced, with at least a dozen identified to date.[51] *C. perfringens* type A and type C have been recovered from equine specimens,[52] and several *C. perfringens* toxins have been identified in equine specimens.[53,54] *C. perfringens* type A is the most frequently isolated type, and its enterotoxin is released on sporulation of *C. perfringens* within the intestine. Other exotoxins of *C. perfringens* have phospholipase activity (alpha-toxin), necrotizing cytotoxic effects (beta-, epsilon-, and iota-toxins), and hemolytic effects (theta-toxin).

Clinical Features

Clostridial enterocolitis affects foals and adult horses. In some reports, toxigenic *C. perfringens* organisms were isolated from more than 50% of foals with diarrhea.[54,55] The clinical presentation in foals with *C. perfringens* is predominantly hemorrhagic diarrhea with sepsis. *C. perfringens* can cause septicemia and can often be cultured from the blood of foals with hemorrhagic diarrhea. In some foals, classic necrotizing enterocolitis will be manifested by gas- or fluid-distended intestines and thickened intestinal mucosa. These changes can be appreciated radiographically and ultrasonographically, and intramural gas produced by clostridial bacteria may be detected with ultrasonography as hyperechoic areas within the bowel wall. *C. difficile* infection is also a cause of acute enterocolitis in foals.[56]

Adult horses with clostridial enterocolitis frequently have diarrhea but may have abdominal discomfort or fever as the primary presenting problem. There are no clinical features that consistently distinguish clostridiosis from salmonellosis, and a spectrum of clinical signs exists, from moderate illness to severe toxemic colitis. Most horses with clostridial enterocolitis develop diarrhea, but in some cases enteritis manifested by ileus and gas distention of the small intestine may be the primary problem. Although both *C. perfringens* and *C. difficile* and their toxins have been detected in a significant number of adult horses with colitis, *C. difficile* appears to be more common.[57-59] Indeed, *C. difficile* appears to be the most common cause of antibiotic-associated diarrhea and is a very significant cause of nosocomial diarrhea in horses.[42,60] The most common antibiotics associated with *C. difficile* colitis in horses are erythromycin, trimethoprim/sulfonamides, β-lactam antimicrobials, clindamycin, rifampicin, and gentamicin. Strain differences among isolates of *C. difficile* cultured from the diarrheic feces of horses in intensive care units are associated with toxigenicity, severity of disease, and metronidazole resistance.[42,61] *C. perfringens* and *C. difficile* have been implicated in duodenitis–proximal jejunitis, but a cause-and-effect association has not been proven.

Similar to salmonellosis, clostridial enterocolitis can develop into a widespread problem affecting several animals in a hospital or equine facility.[62] Risk factors for developing nosocomial clostridial enterocolitis are similar to those for nosocomial salmonellosis: antimicrobial administration, concurrent gastrointestinal disease, and age susceptibility (foals). In addition, *Clostridium* spp. are well suited to persist in the environment because of the production of spores that are resistant to environmental extremes and many disinfectants.

Diagnosis

Diagnosis of clostridial enterocolitis requires identification of toxigenic clostridia from intestinal contents or tissue. Several direct and indirect methods are used to detect toxigenic clostridia; these methods include culture, identification of toxins, and identification of toxin genes. Culture of *C. difficile* or *C. perfringens* requires anaerobic conditions, and the ability to culture these organisms from ingesta or fecal specimens rapidly diminishes with increased time from collection to arrival at a laboratory. It is recommended to transport samples, chilled (not frozen) on ice, immediately or by overnight delivery for best recovery of clostridial organisms. Tissue specimens submitted for culture, toxin identification, or toxin gene identification should be handled similarly. Because nonpathogenic clostridia are common,[59,63] isolates should be tested for toxin production either by PCR or bioassay before a definitive diagnosis is made in horses with clinical signs consistent with clostridial enterocolitis. Commercially available tests for clostridial toxins include an ELISA for *C. difficile* toxin A/B, a latex-agglutination test for *C. perfringens* enterotoxin, and an ELISA for *C. perfringens* enterotoxin. *C. difficile* A/B toxin tests have the advantages of being rapid, sensitive, and specific. Tests for *C. perfringens* enterotoxin are not as reliable for definitive diagnosis in most species. Also available is quantitative PCR for *C. difficile* toxin A/B genes that can be applied directly to intestinal content or fecal samples without prior culture and isolation of the bacteria.[64]

Treatment

Supportive care may be required, as with other cases of acute diarrhea in horses. Treatment with metronidazole (15

VetBooks.ir

to 20 mg/kg PO q6-8h) appears to be effective in eliminating enteric clostridial infection in most cases. In one veterinary teaching hospital, isolates of *C. difficile* were resistant to metronidazole,[65] and vancomycin was used with reported success. Large-scale resistance to metronidazole has not been reported elsewhere, and it should be the first choice in the treatment of suspected clostridial enterocolitis. *Saccharomyces boulardii* is a nonpathogenic yeast used in the treatment of *C. difficile* diarrhea and colitis in humans. The yeast releases a protease that specifically degrades *C. difficile* toxins A and B, and this has been shown to be protective in experimental *C. difficile* colitis in rats and to prevent damage to human colonic epithelium by *C. difficile* toxins A and B in vitro.[66] Although *S. boulardii* (25 g PO q12h) has been shown to colonize the intestinal tract in horses,[67] the efficacy for prevention or treatment of enterocolitis in horses is not clear. *S. boulardii* decreases the severity and duration of enterocolitis in one small study[68] but not in a larger study of antibiotic-associated diarrhea in horses.[67] Di-tri-octahedral (DTO) smectite powder (Bio-Sponge [Platinum Performance, Buellton, Calif.]) has been shown to bind clostridial toxins[70] and may be useful for treating clostridiosis in horses. DTO smectite is available as a powder or paste and should be administered according to the manufacturer's instructions for 3 to 5 days.

Cantharidin (Blister Beetle) Toxicity

Pathogenesis Cantharidin is the toxic principal found in beetles of the genus *Epicauta,* commonly known as blister beetles.[71-73] Ingestion of the beetles in contaminated alfalfa hay results in absorption of cantharidin through the gastrointestinal tract. Blister beetles feed on the flowers of alfalfa and are incorporated into baled alfalfa hay if the hay is cut and processed simultaneously.[71-73] Large swarms of beetles may be found in relatively small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies from species to species of blister beetles.[71,72] Therefore as many as 100 to as few as 6 to 8 beetles may be lethal. Often more than one horse will be affected. The fatality rate may be 50% or greater.[71,74]

Cantharidin is a potent irritant, causing cell damage and necrosis on contact.[71,73,74] The mucosa of the gastrointestinal tract is most commonly affected in horses because they ingest the toxin. Ulceration throughout the alimentary tract has been observed in natural and experimental cantharidin toxicity. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein. Large volumes of fluid and protein are lost in the gastrointestinal tract, causing hemoconcentration and profound hypoalbuminemia in some cases.[71,72,74] Cystitis, nephrosis, and myocarditis occur in natural and experimentally produced cases of cantharidin toxicity.[71,73,74] Cystitis and nephrosis occur from the high concentration of cantharidin in the urine. The cause of the myocarditis and myocardial necrosis is unknown, but they may also be direct effects of the toxin on the myocardium. Elevated plasma CK activity is often observed and has been postulated to arise from the damaged myocardium.[71,72] Horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma CK activity has not been observed.[72] Hypocalcemia and hypomagnesemia are characteristic features of cantharidin toxicity in horses that have not been explained.[71,72,74] Hypocalcemia may occur from hypoalbuminemia, but the ionized calcium concentration is often decreased, along with the total calcium concentration, indicating that hypoalbuminemia is not responsible for the hypocalcemia.[72]

Clinical Features Cantharidin toxicity can cause a range of clinical signs, from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin.[71,72,74] Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydipsia, and profuse diarrhea.[71,72,74] Blood is rarely seen in the feces. Affected horses frequently posture to urinate; indeed, stranguria and pollakiuria are characteristic of cantharidin toxicity.[71] Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. A stiff and stilted gait may be evident. Neurologic signs such as head pressing, swaying, and disorientation may be noted.[74] Signs of systemic inflammation from endotoxemia may be seen in severe cases. Some horses develop severe depression and toxemia and may die within hours after ingestion of cantharidin without developing diarrhea.[71,74] Hematologic abnormalities are similar to those of other causes of acute diarrhea, reflecting dehydration and sepsis. Hypocalcemia (both ionized and total calcium concentrations) and hypomagnesemia are characteristic biochemical features of cantharidin toxicity and may be profound. Azotemia with a urine specific gravity in the hyposthenuric range is common.[71,72,74] Microscopic hematuria and mild proteinuria may be evident.

Diagnosis Tentative diagnosis can be made based on clinical signs and the finding of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.[71,75]

Treatment Fluid therapy and maintenance of electrolyte balance are important, as in all cases of acute diarrhea. Particular attention should be paid to the degree of hypocalcemia and renal function as a fluid therapy plan is developed. Specific therapy is limited. Administration of absorbent powders via nasogastric tube is important early to prevent further systemic absorption of cantharidin and local toxicity. Mineral oil administration may also help reduce absorption of the toxin. Pain control may be needed for colic or urinary pain. Nonsteroidal antiinflammatory therapy should be used judiciously to avoid further injury to the intestinal mucosa and renal toxicity. Alternative analgesics, such as butorphanol or a lidocaine controlled-rate infusion, may be better choices.

ANTIMICROCIAL-ASSOCIATED DIARRHEA. The onset of acute diarrhea in horses has been associated with the use of several antimicrobial drugs. Lincomycin administered orally and tetracycline administered parenterally have been demonstrated to induce severe diarrhea in horses.[76,77] The oral administration of trimethoprim-sulfonamide, kanamycin, erythromycin, metronidazole, and penicillin and parenteral administration of ceftiofur and gentamicin have been implicated with onset of diarrhea, including fatal colitis, in horses. In one report there was no association between trimethoprim-sulfonamide and diarrhea.[78] However, in other reports, prior administration of antimicrobial drugs was positively associated with onset of colitis and negatively associated with prognosis for survival in horses with colitis.[79]

Antimicrobial-associated diarrhea is presumed to be secondary to disruption of normal colonic microflora and the proliferation of an enteropathogen, such as *Salmonella* spp., *C. perfringens,* and *C. difficile.* Of these, *C. difficile* is the most common cause of antimicrobial-associated diarrhea in horses.[42] Of interest, it was reported that mares whose foals were treated with erythromycin for *Rhodococcus equi* infection developed severe, acute colitis, from which *C. difficile* and its toxins were isolated.[80] The mares had erythromycin detected in their feces, and exposure to the erythromycin was presumed to have occurred by the mares licking erythromycin from the foals' faces.

OTHER CAUSES OF ACUTE DIARRHEA. NSAID toxicity has been associated with diarrhea secondary to damage to the colonic mucosa. Grain (carbohydrate) overload may cause acute diarrhea resulting from overproduction of lactate in the colon. A combination of hyperosmolarity of the luminal contents and damage to the colonic mucosa account for the pathophysiology of grain overload. The clinical signs are similar to those of other acute diarrheal diseases in

VetBooks.ir

horses and depend on the severity of the overload. Hyperlactemia, metabolic acidosis, and sepsis are key features of grain overload, and laminitis is a common sequela. Acute diarrhea in adult horses has also been associated with conditions such as lymphosarcoma enterocolitis and other IBDs, intestinal lymphosarcoma, peritonitis, heavy metal intoxication, anaphylaxis, and stress.

CLINICAL ASSESSMENTS OF PATIENTS WITH ACUTE DIARRHEA. The diagnostic evaluations performed on horses with acute diarrhea are intended to provide the clinician with information to accurately assess the horse's condition and thus direct therapy toward specific requirements. The first part of the evaluation is a thorough physical examination, with particular attention paid to the horse's hydration status (skin turgor, gum moisture, capillary refill time), evidence of sepsis (fever or hypothermia, hyperemic mucous membranes, prolonged capillary refill time), cardiovascular system (heart rate and rhythm, character of peripheral pulse, capillary refill time), and signs of laminitis (lameness, digital pulse, palpable temperature of hoof walls). Horses with colitis are often moderately to severely dehydrated, with either purplish or brick-red mucous membranes. Purple mucous membrane color reflects venous congestion and poor venous return, whereas brick-red membrane color reflects venous congestion and poor venous return plus arteriole and venule shunting and poor tissue oxygen exchange.

Blood pressure should be monitored, and whereas direct measurements via an arterial catheter are the most accurate, indirect pressure measurements obtained using a Doppler transducer placed over the coccygeal artery are satisfactory. Hypotension and hypertension occur in horses with colitis, and the blood pressure status of a patient often is unpredictable. Blood pressure can be monitored as frequently as labor permits and should be done hourly if vasoactive pharmaceutical agents are used.

Laboratory tests that should be performed include complete blood count (CBC) and plasma protein and total solids. Total hemoglobin and packed cell volume (PCV) are used to assess hydration status. Total protein is used to assess hydration status and degree of protein loss through inflamed intestinal mucosa, and in more chronic cases through protein catabolism. Comparison of clinical hydration, PCV, and total protein is useful in determining the extent of protein loss, and daily evaluations can be used to determine the rate of protein loss. Colloid oncotic pressure measurements are useful, particularly if colloidal fluids other than plasma are given.

Total white blood cell (WBC) count, WBC differential, and WBC morphology are used to assess severity of sepsis; plasma fibrinogen is used to assess the severity of inflammation. Typically the total WBC and neutrophil counts decrease initially. This is primarily attributable to bacterial endotoxins and the host's mediators of systemic inflammation and it occurs in most cases of acute colitis, not just in those caused by *Salmonella* spp. The morphology of the WBCs reflects the severity of the inflammatory response. "Toxic" changes such as basophilia, granulation, vacuolation of the cytoplasm, and scalloped borders of the cell membrane or adherence of neutrophils to red blood cells (RBCs) do not reflect injury to the neutrophils by toxins but reflect the cells' responses to stimulation by proinflammatory agents (tumor necrosis factor [TNF], interleukin 1 [IL-1]) and the production of inflammatory mediators by the neutrophils that are toxic to bacteria. The degree of these changes in circulating neutrophils can be used to assess the severity of disease and also to assess the progress the horse is making. Often the initial sign that the horse is improving is a decrease in the "toxic" appearance to the neutrophils and a regenerative neutrophil response. A horse that continues to have severe neutropenia with a degenerating left shift or neutrophils, with cytoplasmic vacuolation, granulation, and basophilia, for more than 10 days has severe colitis that is unlikely to resolve.

Serum chemistry tests that should be performed include electrolytes (sodium, chloride, potassium, and calcium), blood urea nitrogen (BUN) and creatinine, blood lactate concentration, and assessment of acid-base status (blood pH and bicarbonate, or total CO_2). Horses with diarrhea often are hyponatremic, hypochloremic, and hypokalemic. With decreased feed intake, hypocalcemia occurs. A high gap metabolic acidosis with hyperlactemia may be noted, particularly in horses with sepsis. The severity of these electrolyte disturbances should be monitored, often daily, to allow for appropriate therapy. Parameters that assess renal function, BUN and creatinine, are frequently increased in horses with diarrhea for several reasons. Prerenal azotemia resulting from dehydration and decreased filtration across the glomerulus accounts for some of the increase in these parameters. Hyponatremia and hypochloremia can cause a decrease in glomerular filtration and an increase in BUN and creatinine secondary to tubuloglomerular feedback. Horses that are adequately hydrated yet moderately hyponatremic (serum sodium 120 to 128 mEq/L) often remain azotemic until sodium levels increase above 130 mEq/L. In addition, horses with toxemic colitis often have damage to renal parenchyma, presumably the result of the effects of inflammatory mediators and alterations in renal blood flow.

The acid-base status can be evaluated by estimating serum bicarbonate on the basis of the total CO_2 or directly from a venous or arterial blood gas analysis. Evaluation of a venous blood gas sample is useful in assessing perfusion and oxygen extraction. An increased venous oxygen partial pressure (>60 mm Hg) is indicative of poor capillary perfusion and oxygen delivery to the tissues. Affected horses usually have brick-red mucous membranes.

PRINCIPLES OF THERAPY FOR ACUTE DIARRHEA. Because the pathophysiology of equine colitis is complex, treatment is often multifaceted. Many of these treatments provide well-documented benefit, whereas with others the efficacy is based on empiric judgment only. Outcome is determined not only by the severity of the primary disease causing colitis but also by complications that may arise from the disease.

In cases of acute colitis, fluid administration remains the treatment of primary importance. Most patients require intravenous administration in the early stages. The fluids used must replace fluid, sodium, chloride, and potassium losses. Often, large volumes are required for several days. (More specific guidelines for fluid therapy in colitis patients are covered in the Fluid Therapy for Horses with Gastrointestinal Diseases section and in Chapter 44.)

Most horses with colitis become hypoproteinemic secondary to protein leakage through the inflamed colon and catabolism of albumin secondary to negative energy balance. Hypoproteinemia frequently leads to edema formation in several areas of the body, including the intestinal tract, and can compromise the clinician's ability to keep the patient properly hydrated through fluid administration. Intravenous plasma therapy is often beneficial. Plasma, 4 to 10 L, should be given intravenously. Other colloidal fluids may be more cost-effective for increasing colloidal oncotic pressures in hypoproteinemic horses but do not have the additional properties of plasma that may be beneficial.

Plasma contains proteins besides albumin and therefore can be of benefit beyond improvement of plasma oncotic pressure. The immunoglobulin present in plasma is of recognized benefit in the treatment of failure of passive transfer in foals. The role of nonspecific immunoglobulin in the treatment of colitis is not known. Fibronectin is essential to the normal function of the monocyte-macrophage system in the processing of a variety of antigens. Other plasma proteins such as elastase and proteinase inhibitors, complement inhibitors, antithrombin III (AT-III), and other inhibitors of hypercoagulability may be beneficial to patients with colitis.

The nutritional requirements of patients with colitis need to be considered, particularly in a case that may be protracted. Horses with colitis are typically anorectic, and the disruption of normal physiologic processes in the inflamed cecum and colon limits the effectiveness of these organs to digest and absorb nutrients. In addition, several mediators of inflammation and septicemia alter protein and calorie metabolism, resulting in a catabolic state. Therefore, even if the horse eats, it is likely to be in a severe caloric deficit for some time. Normally an average horse requires approximately

VetBooks.ir

15 Mcal/day. An endotoxemic horse may require 25 Mcal/day. In a catabolic patient, muscle and fat tissue are mobilized and used in lieu of ingested nutrients. The plasma protein pool, including albumin and immunoglobulins, also is catabolized. In many cases of colitis the decrease in plasma protein may be as much a result of catabolism as of leakage through the inflamed colon. A variety of products can be used for enteral feeding (see Chapter 50).

Colitis is an inflammatory disease, and limiting inflammation is desirable when treating patients, particularly those with severe disease. Moreover, horses with acute colitis, regardless of the cause, have signs compatible with systemic inflammation associated with sepsis. Flunixin (0.25 to 0.5 mg/kg IV q6-8h) is the most commonly used antiinflammatory therapy in horses with colitis. However, the use of flunixin should be judicious and must be carefully monitored to avoid unwanted side effects on the gut mucosa and kidneys. Other antiinflammatory therapies, such as lidocaine controlled rate infusions, may also be beneficial.

Sepsis is a common clinical feature in horses with acute colitis. Most of the clinical signs of sepsis are likely attributable to the effects of endotoxin. Therefore specific therapy for endotoxemia may be warranted.

The use of antimicrobial drugs in the treatment of colitis is controversial. In cases of colitis caused by *N. risticii,* the efficacy of tetracycline, 6.6 to 11 mg/kg IV once or twice daily, is documented.[81,82] In other cases of colitis, including *Salmonella* colitis, in which specific antimicrobial sensitivities to the *Salmonella* spp. have been established, the efficacy of antimicrobial administration is less well documented. Many clinicians believe that the use of an antimicrobial for which the *Salmonella* spp. have demonstrated sensitivity, such as chloramphenicol, enrofloxacin, gentamicin, amikacin, or a third-generation cephalosporin, does not significantly alter the course of the disease or hasten the elimination of the organism from the body. However, there is no published evidence either supporting or not supporting the efficacy of antimicrobial treatment for salmonellosis, and the use of antibiotic therapy remains a judgment of the clinician. In patients with sepsis, the use of broad-spectrum antibiotics is justified to prevent bacteremia or organ colonization by *Salmonella* spp. or other enteric organisms. Antibiotics such as chloramphenicol and enrofloxacin that are lipid permeable and/or are concentrated in cells are a benefit because *Salmonella* reside, proliferate, and persist intracellularly in macrophages and other cells.

Medications that minimize or abolish colonic fluid secretion would be of tremendous benefit in the treatment of equine colitis. Medications such as kaolin, bismuth subsalicylate, and activated charcoal are frequently used in cases of colitis in adult horses, but their efficacy as antisecretory agents in this context has not been established. These medications are more effective in foals with diarrhea, probably as a result of an effect on the small intestine rather than the colon. Absorbent powders such as activated charcoal or DTO smectite (Bio-Sponge) may be useful to absorb bacterial toxins, particularly in horses with clostridiosis.

Chronic Diarrhea

Chronic diarrhea is one of the most frustrating disorders encountered by equine practitioners, with regard to both determining the cause and therapeutically managing the diarrhea.[83] Chronic diarrhea may be defined as persistent diarrhea of at least a month's duration. Although there are many causes of chronic diarrhea, these cases can generally be divided into two groups: diarrhea resulting from a chronic inflammatory condition and diarrhea resulting from a disruption in normal physiologic processes. With inflammatory conditions there will be histologic changes in the colon mucosa, including pleocytosis (neutrophils, eosinophils, and lymphocytes), mucosal congestion, and mucosal erosion and ulceration. Submucosal edema, capillary congestion, and lymphatic congestion may be present. With physiologic disorders there are no morphologic changes in the colon, and diarrhea is presumed to result from abnormal VFA synthesis or absorption. A small percentage of horses with chronic diarrhea have a primary disorder of a system other than the intestinal tract, such as congestive heart failure or hepatic disease. A thorough physical examination and evaluation of a minimum database (CBC, serum chemistry profile, urinalysis) should differentiate horses with primarily nonenteric disorders.

Causes

Inflammatory disorders that can cause chronic diarrhea include disorders caused by infectious agents such as chronic salmonellosis; chronic parasitism with *Strongylus vulgaris, Strongylus edentatus,* and larval cyathostomiasis; abdominal abscessation; and, in weanling foals, equine proliferative enteritis caused by *Lawsonia intracellularis,* gastrointestinal *R. equi* infection, and rotavirus infection.

Noninfectious inflammatory causes include cellular infiltrative disorders such as granulomatous enteritis and lymphosarcoma, as well as sand enteropathy. Sand causes diarrhea through continued irritation of the mucosal lining of the colon. In weanling foals, gastric ulceration and gastric emptying disorders have been associated with chronic diarrhea that resolved when H_2 antagonist therapy was started. NSAIDs can cause chronic diarrhea, which is accompanied by varying degrees of pathologic change in the large intestine.

Noninflammatory chronic diarrhea of colonic origin is thought to be a result of abnormal fermentation of cellulose by the resident bacteria in the large intestine. In vitro fermentation of feces from normal horses and horses with chronic diarrhea revealed that feces from the diarrheic horses produced more gas, acetate, and propionate than feces from normal horses.[84] Whether this reflects fermentative activity within the colon is not known, but an abnormal increase in acetate could lead to fluid retention within the colonic lumen, because acetate inhibits colonic absorption of sodium and water.

Diagnosis

The diagnostic approach to cases of chronic diarrhea should be based on an attempt to differentiate inflammatory from physiologic causes. The evaluation can be extensive and expensive, and the owner should be prepared for the cause of the diarrhea to remain undetermined. Horses with chronic diarrhea may be adequately hydrated if water consumption has matched water losses. Often, however, such horses are brought to the veterinarian in a condition of mild to moderate dehydration. Moderate weight loss also has often occurred. On physical examination, signs of toxemia (injected mucous membranes, congested or hyperemic mucous membranes) should be noted.

A CBC should be evaluated for signs of chronic inflammation. Such changes include a decrease in the RBC count and PCV as a result of decreased erythrogenesis secondary to sequestration of iron by bone marrow macrophages (anemia of chronic inflammation). The WBC count may be normal or moderately increased. The fibrinogen levels can be normal or increased. Changes in WBC count and fibrinogen levels are influenced by the degree of inflammation and whether the inflammatory response is localized. Therefore a normal CBC does not rule out an inflammatory cause of the chronic diarrhea.

Peritoneal fluid analysis may reveal an increase in protein or WBCs, which is indicative of an inflammatory process within the peritoneal cavity. Often, however, colon inflammation is not reflected by alterations in the peritoneal fluid.

Serum chemistry values vary in horses with chronic diarrhea. Many affected horses have evidence of hyponatremia, hypokalemia, hypochloremia, azotemia, and metabolic acidemia. Other horses with less severe chronic diarrhea may have no serum chemistry abnormalities.

The total serum protein is usually decreased with a chronic inflammatory disorder of the colon, reflecting protein leakage from the capillaries and disruption of the colonic mucosal integrity. This is usually reflected by hypoalbuminemia. In some cases, hyperglobulinemia occurs and total protein concentration may be normal.

Increases in hepatic-associated enzymes, including sorbitol dehydrogenase, γ-glutamyltransferase (GGT), and aspartate aminotransferase (AST), and serum bile acids indicate that hepatic disease is present. Hepatic changes and dysfunction such as inflammation,

VetBooks.ir

fibrosis or fatty infiltration, or biliary inflammation can be associated with diarrhea.

Feces should be examined for parasite ova; cultured for *Salmonella* spp., *C. difficile,* and *C. perfringens;* and tested for clostridial toxins. Weanling age foals should be tested for *L. intracellularis* and *R. equi*. In cases of acute diarrhea, it has been recommended that five consecutive fecal samples be cultured for *Salmonella* spp., but in cases of chronic diarrhea, many more are often necessary. As many as 15 fecal cultures may be needed to get a positive *Salmonella* spp. culture. In addition, a rectal mucosal biopsy should be cultured. In weanlings the feces should be examined for rotavirus by transmission electron microscopy or ELISA. Although it is an unusual cause of diarrhea in weanlings, rotavirus should be considered when dealing with a problem of chronic diarrhea in several foals on the same farm.

An oral glucose absorption test can be done to determine if there is small intestinal malabsorption, which would indicate a widespread small and large intestinal disorder if both diarrhea and glucose malabsorption are present.

A rectal mucosal biopsy may provide evidence of a widespread inflammatory disorder, such as one of the IBDs.[85] Biopsies should be evaluated by a pathologist experienced in examining equine tissue specimens, and some caution should be taken to avoid overinterpretation of the presence of few lymphocytes, plasma cells, and eosinophils.

Frequently the results of the previously mentioned diagnostic procedures do not determine the cause of the chronic diarrhea. In such cases an exploratory laparotomy may be warranted. This is particularly true if episodes of abdominal discomfort accompany the chronic diarrhea. In addition to exploration of the abdomen for the presence of masses or abscesses, the colon and cecum should be thoroughly examined. Biopsies from several sites of the colon, cecum, and mesenteric lymph nodes should be submitted for histopathology and culture for *Salmonella* spp.

Treatment Treatment of horses with chronic diarrhea is often empiric, because either a cause has not been determined or the cause is not amenable to treatment. With inflammatory causes such as lymphosarcoma and granulomatous enteritis, the disease is usually untreatable. Some cases of eosinophilic colitis have been treated successfully with corticosteroids.

Chronic parasitism may be resolved with appropriate anthelmintic therapy, although damage to the mucosa may have become too extensive to allow normal absorption to occur. Administration of larvicidal doses of fenbendazole (15 mg/kg PO daily for 5 days) is usually effective. Concurrent administration of prednisolone (1 mg/kg PO once daily for 5 to 7 days) may minimize inflammation secondary to killing migrating larvae within the vasculature and mucosa of the colon.

Chronic salmonellosis does not lend itself to specific treatment, because antimicrobial therapy is generally unrewarding in resolving *Salmonella* infection in horses.

Administration of products containing bismuth subsalicylate is effective in some cases of chronic diarrhea. The action of bismuth subsalicylate is mediated through inhibition of prostaglandin synthesis and possibly by other undefined mechanisms. In full-size horses a large volume, 1 to 4 L/day, must be administered to be effective.

Iodochlorhydroxyquin administered orally is effective in managing some cases of chronic diarrhea caused by maldigestion of cellulose by colonic microorganisms.[86] The actual mechanism of action of iodochlorhydroxyquin in resolving the diarrhea is not known. The drug was originally administered to horses with chronic diarrhea because an increase in fecal trichomonads was observed. However, this observation likely reflected that trichomonads were washed out of the cecum and colon rather than that they were the cause of the diarrhea. Iodochlorhydroxyquin has minimal effect on colonic protozoal populations. It is not uniformly effective, and in many cases its effectiveness is only transient. Stools may initially become formed, but the diarrhea often recurs within several days. An initial dose of 20 mg/kg/day is recommended. If diarrhea recurs, decreasing the dose to 10 mg/kg/day is sometimes effective. If the medication is effective, it must be continued, because if it is discontinued, the diarrhea resumes.

Changes in diet occasionally are helpful in horses with noninflammatory chronic diarrhea. Feeding a complete pelleted feed may positively affect the constituent VFAs produced in the colon and thus facilitate water absorption. Alternatively, trying different types of roughage may result in selecting one that creates a more favorable metabolic environment in the large intestine.

The removal of sand from the colon by nonsurgical means is difficult, and in one report the administration of psyllium to remove experimentally introduced sand was not effective.[87] Other treatments used with anecdotal, but undocumented, success include fecal transfaunations, probiotics, cultured yogurt, and brewer's yeast.

Surgical Disorders of the Large Intestine

John F. Marshall • Anthony T. Blikslager

Simple Obstruction

Simple obstructions of the large intestine tend to have a more gradual onset than those of the small intestine and, in the case of large colon impactions, are frequently amenable to medical therapy.[1] Cecal impactions present much more of a dilemma because of the greater propensity of this organ to rupture[2] and the relative difficulty of surgically manipulating the cecum.[3]

Cecal Impaction

Cecal impaction may develop as a primary condition or may arise as a complication in hospitalized horses, particularly those that have undergone surgery.[4] Reasons for development of cecal impaction in hospitalized horses are unclear, although motility disturbances arising from postoperative pain may play a role. Cecal impactions may occur as one of two types: impaction of the cecum with firm ingesta or gross distention of the cecum with fluid ingesta. The latter has been termed *cecal dysfunction* and may be initiated by abnormalities in cecal motility. Evidence in favor of this supposition includes the fact that the right ventral colon is typically empty in horses with cecal dysfunction, suggesting a lack of aborad movement of digesta through the cecocolic orifice. However, clinical differentiation of cecal impaction and cecal dysfunction may be very difficult.[5] Horses with dry-ingesta–filled cecal impactions tend to be presented with the condition as the primary complaint, and there is often a gradual onset of abdominal pain over a number of days. Such impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be closely monitored. In horses with cecal dysfunction, there is frequently an association with surgery, particularly orthopedic surgery. For horses that develop this condition in the postoperative period, it is often very difficult to detect because there is an expectation for horses to show some degree of depression after surgery and because horses are often already on analgesics such as nonsteroidal antiinflammatory drugs (NSAIDs) or opiates. The simplest method to detect these cases is to closely monitor fecal output in the postoperative period.[6] A normal horse should produce six to eight piles of manure per day, whereas an abnormal horse may have no evidence of defecation or a marked reduction in fecal production (less than three piles of manure per day). These horses should be carefully evaluated for both pain and intraabdominal evidence of an impaction and treated accordingly.

The diagnosis of primary cecal impaction is based on palpation of a firm, impacted cecum or a grossly distended fluid-filled cecum per rectum. According to one study such findings were detected in 89% of horses with cecal impaction that underwent per rectum

VetBooks.ir

palpation of the abdomen.[5] In some cases, cecal impactions may be difficult to differentiate from large colon impactions. However, careful palpation will reveal the inability to move the hand completely dorsal to the impacted viscus because of the cecum's attachment to the dorsal body wall.

Treatment for horses with dry-ingesta–filled cecal impactions may include initial medical therapy, including aggressive administration of intravenous fluids, judicious use of analgesics, and administration of oral laxatives (e.g., 2 to 4 L of mineral oil per 500 kg).[7] Other oral laxatives have also been recommended, including magnesium sulfate (1 g/kg in 4 L of water PO up to twice daily for up to 3 days) and psyllium (1 kg q6-8h). However, if the cecum is grossly distended or if medical therapy has had no effect within a reasonable period of time, surgical evacuation of the cecum via a typhlotomy is indicated. In addition, it is advisable to perform an ileocolostomy in order to bypass the cecum, as postoperative cecal motility dysfunction with recurrence of the disease is common.[8] However, this aspect of surgical treatment remains controversial and there are cases of cecal impaction, particularly those secondary to feed impaction, which, if identified early, can be treated via typhlotomy alone.[9]

In horses with cecal dysfunction, immediate surgery is indicated. In addition, cecal bypass is often warranted because it is suspected that motility disturbances initiate the disease, and therefore recurrence in the absence of cecal bypass may occur. However, this decision can be made based on the appearance of the cecum at surgery.

The prognosis depends on the type of cecal impaction encountered. In a report in which dry-ingesta–filled cecal impactions were treated by typhlotomy and ileocolostomy or jejunocolostomy, seven of nine horses (78%) lived long term.[3] The cecum of horses in which cecal dysfunction develops has a great propensity to rupture, which is universally fatal. The prognosis for this condition tends to be less favorable because of postoperative complications. A recent long-term study of horses undergoing typhlotomy alone (3 horses) or typhlotomy and ileocolostomy (17 horses) found that 55% of horses were alive after 1 year.[10]

Large Colon Impaction

Impactions of the large colon with ingesta occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal colon.[11] Although there are a number of reported risk factors, most have not been proven. However, a sudden restriction in exercise associated with musculoskeletal injury appears to be frequently associated with onset of impaction. A further consideration is equine feeding regimens, which usually entail twice-daily feeding of concentrate. Such regimens are associated with secretion of large volumes of fluid into the small intestine, resulting in transient hypovolemia (15% loss of plasma volume).[12] This leads to activation of the renin-angiotensin-aldosterone system, and because aldosterone stimulates absorption of fluid from the large colon, this may dehydrate colonic contents.[12,13] Large concentrate meals may decrease small intestinal transit time, resulting in increased presentation of soluble carbohydrate to the cecum and large colon. Large shifts of fluid into the colon occur as concentrates are readily fermented in the large intestine, which would be expected to activate the renin-angiotensin-aldosterone system. This in turn triggers net fluid absorption from the large colon. The effects of these large fluid fluxes on development of large intestinal disorders remains to be fully characterized, but undoubtedly they play some role in the syndrome of colic. From a practical standpoint, intestinal fluid fluxes may be reduced with frequent small feedings in those horses requiring concentrate to maintain condition.[12]

Clinical signs of large colon impaction include slow onset of mild colic that is typically well controlled with administration of analgesics but becomes increasingly more severe and refractory if the impaction does not resolve. The diagnosis is based on rectal palpation of a firm mass in the large colon. However, the extent of the impaction may be underestimated by rectal palpation alone because much of the colon will be out of reach. Adjacent colon may be distended if the impaction has resulted in complete obstruction. Initial medical treatment should be attempted. Intermittent abdominal pain is controlled with administration of analgesics (flunixin meglumine 0.25 mg/kg IV q6h to 1.1 mg/kg IV q12h; butorphanol 0.05 mg/kg IV as needed [prn]; xylazine 0.3 to 0.5 mg/kg IV prn). Detomidine (4 to 10 mg IV prn) can be administered but with great caution, as this agent readily masks severe pain. In addition to analgesics, an oral laxative should be administered via nasogastric tube. Although mineral oil (2 to 4 L/500 kg PO) is commonly used as a laxative, hydration of the colonic contents can be better achieved by administration of magnesium sulfate (1 g/kg in 4 L of water PO) or sodium sulfate (1 g/kg in 3 L of water PO) by stomach tube.[14] Although sodium sulfate has been shown to result in greater colonic content hydration than magnesium sulfate, it also results in significant thirst and hypocalcemia; thus magnesium sulfate is preferred.[14] Access to feed should not be permitted but water should be freely available. For impactions that persist, aggressive oral and/or intravenous fluid therapy should be instituted. One study demonstrated the increased efficacy of a continuously administered oral rehydration solution in softening feces as compared with intravenous fluids, which are probably best suited to restoring the systemic extracellular fluid compartment.[15] If the impaction remains unresolved, the horse becomes uncontrollably pained, or extensive gas distention of the colon occurs, surgery is indicated. At surgery the contents of the colon are evacuated via a pelvic flexure enterotomy. The prognosis is good for those horses in which impactions resolve medically (95% long-term survival in one study) and fair for horses that require surgical intervention (58% long-term survival in the same study).[1]

Enteroliths

These mineralized masses are typically composed of ammonium magnesium phosphate (struvite).[16] One study has suggested that an increase in magnesium in the diet may predispose to the formation of enteroliths.[17] Enteroliths almost always form around a nucleus such as a silicon dioxide stone, a nail (Fig. 32-78), or piece of rope that has been ingested and are most commonly found in the right dorsal and transverse colons. Although enterolithiasis has a wide geographic distribution, horses in California have a high incidence. In one California-based study, horses with enterolithiasis represented 28% of the surgical colic population. In addition, Arabians, Morgans,

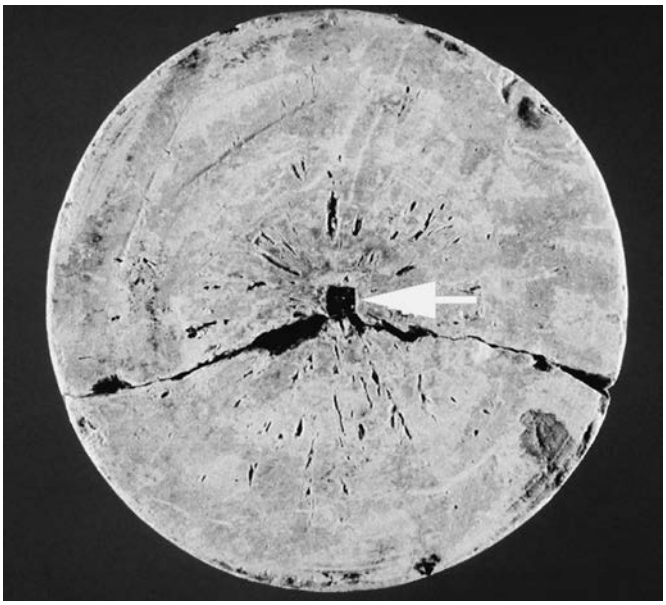

FIG. 32-78 Cut section of an enterolith. Note the presence of a nail head *(arrow)* that served as a nucleus for the formation of a struvite enterolith. *(Courtesy Dr. David G. Bristol.)*

VetBooks.ir

American Saddlebreds, and donkeys are at risk of this disease.[18] A prospective, unmatched case-control study performed in California indicated that horses fed a diet composed predominantly of alfalfa hay are at risk for development of enterolithiasis, and allowing horses to graze on pasture was protective against this disease.[19]

Initially, clinical signs include intermittent abdominal pain in mature horses (almost always older than 4 years of age),[20] with few abnormalities on rectal examination. As enteroliths become larger, they may occlude the lumen of the colon and cause acute pain and large colon distention that necessitate surgical exploration. In some cases an enterolith is forced into the small colon, where it causes acute small colon obstruction. Enteroliths may be diagnosed by abdominal radiography or at surgery. On rare occasions, an enterolith may be palpated per rectum, particularly if it is present in the distal small colon.

In general, surgery is required for these cases, although there are reports of enteroliths being retrieved per rectum. In fact, in one study 14% of horses presented for treatment of enterolithiasis had a history of passing an enterolith in the feces.[18] However, enteroliths are typically located in the right dorsal colon, transverse colon, or small colon. At surgery the enterolith is gently pushed toward a pelvic flexure enterotomy, but removal frequently requires a separate right dorsal colon enterotomy to prevent rupture of the colon. After removal of an enterolith, further exploration must be conducted to determine if other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (92% 1-year survival of horses recovered from surgery in one study of 900 cases) unless the colon is ruptured during removal of an enterolith[18]; colon rupture occurred in 15% of these cases.[18]

Sand Impactions of the Large Colon

Sand impaction of the large colon is common in horses with access to sandy soils, particularly horses whose feed is placed on the ground. Sand accumulates in the large colon, particularly the right dorsal colon and pelvic flexure, but it may be present in multiple locations.[21,22] In addition, sand may trigger diarrhea, presumably as a result of irritation of the colonic mucosa.[23] In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions. In addition, sand may be found in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.[24] Radiography of the cranioventral abdomen may be useful for the detection of sand within the large colon and can serve to monitor resolution of sand accumulation.[25] The diagnosis is definitively made at surgery but may be tentatively based on clinical signs compatible with a large colon impaction together with evidence of sand in the feces. To determine the presence of sand, several fecal balls are placed in a rectal palpation sleeve or other container, which is subsequently filled with water. If sand is present, it will accumulate at the bottom of the container.

Initially, medical therapy using a laxative such as mineral oil, magnesium sulfate, or psyllium combined with enteral or intravenous fluid therapy is warranted and is usually successful in the management of uncomplicated sand enteropathy.[25] Administration of psyllium hydrophilic mucilloid in water by stomach tube may facilitate passage of sand, although an experimental study failed to show a benefit of this treatment.[26] If colic becomes intractable, surgical evacuation of the large colon should be performed. Care must be taken to prevent tearing of the colon due to the weight of sand during exteriorization.[27] The prognosis is good.

Nonstrangulating Obstruction of the Colon

Several configurations of displacements, including nephrosplenic entrapment of the colon, obstruct the colonic lumen but do not compromise the colonic blood supply. Therefore technically these are simple obstructions. However, the lumen may not be completely obstructed, and some degree of venous congestion is common.[28] In some cases nonstrangulating obstructions are difficult to differentiate from large colon volvulus, because a volvulus of less than 270 degrees will not result in strangulation of blood supply but can cause considerable abdominal pain and gas distention of the abdomen. In this regard, nonstrangulating obstructions represent early stages of strangulating obstructions. Clinical signs include mild to moderate colic with evidence of large colon distention on palpation of the abdomen per rectum. The diagnosis is confirmed at surgery.[29] If pain is recurrent, particularly if it is of increasing intensity and frequency, or if there is evidence of intestinal compromise (particularly progressive changes in abdominal fluid and cardiovascular parameters indicating systemic deterioration), the horse should be taken immediately to surgery. The prognosis for nonstrangulating obstructions of the large colon is good, with more than 80% of horses surviving to hospital discharge.[30]

Right Dorsal Displacement of the Large Colon

With right dorsal displacement of the colon, the colon displaces to the right of the cecum. Findings on rectal palpation typically include colonic bands coursing horizontally across the abdomen, with evidence of colon lateral to the cecum. In the most common configuration of right dorsal displacement, the large colon wraps around the cecum (pivoting counterclockwise around the cecum, looking from above the horse) with the pelvic flexure lying in the left dorsal quadrant. Alternatively, the colon may wrap around the cecum in the opposite direction, with the pelvic flexure lying in the right dorsal quadrant.[31] A recent study suggested that although the prognosis for recovery following surgical correction of right dorsal displacement is good, this condition is associated with an increased risk of colic episodes in the postoperative period.[32] The reason for this has not been elucidated but may reflect a possible different etiology between right dorsal displacement and other simple obstructions of the large colon.

Nephrosplenic Entrapment (Left Dorsal Displacement) of the Large Colon

On the left side, colon displacements most commonly involve entrapment of the colon over the nephrosplenic ligament, although left dorsal displacements may be detected before the colon is fully entrapped. Clinical signs include gradual onset of mild to moderate colic as the entrapped colon fills with gas. Palpation per rectum will reveal a gas-distended ventral colon and displacement of the spleen toward the center of the abdomen. Careful palpation following colonic bands up to the left dorsal quadrant often reveals the presence of colon between the left kidney and the spleen. Diagnosis may be based on palpation per rectum of the colon traversing the nephrosplenic ligament. Alternatively, a tentative diagnosis can be reached using abdominal ultrasonography.[33] The spleen can be visualized on the left side of the abdomen, but the dorsal spleen and left kidney will be obscured by gas-distended bowel, which may be followed cranially from the paralumbar fossa. As with other examination techniques, ultrasonography is not uniformly reliable and false-positive results and false-negative results may occasionally occur. A definitive diagnosis may require surgery. Treatment has traditionally been surgical intervention, during which the colon is gently rocked free of the nephrosplenic space. However, good success rates for nonsurgical intervention have been reported using either light exercise (trotting) or physical manipulation (rolling) to return the colon to a normal location.[34,35] If such manipulations are to be attempted, the clinician must be certain of a diagnosis. Phenylephrine (3 to 6 µg/kg/min over 15 minutes) may be administered prior to exercise or rolling to decrease the size of the spleen.[36] In cases exhibiting mild pain and normal abdominocentesis findings, light trotting exercise for a period of 30 to 45 minutes might correct the displacement.[34,37] Alternatively, the horse is anesthetized and placed in right lateral recumbency in preparation for rolling. The horse is rotated up to dorsal recumbency, rocked back and forth for 5 to 10 minutes, and then rolled down into left lateral recumbency.[38] Regardless of the nonsurgical technique adopted, the resolution of displacement should be monitored by repeat palpation of the nephrosplenic space per rectum and

VetBooks.ir

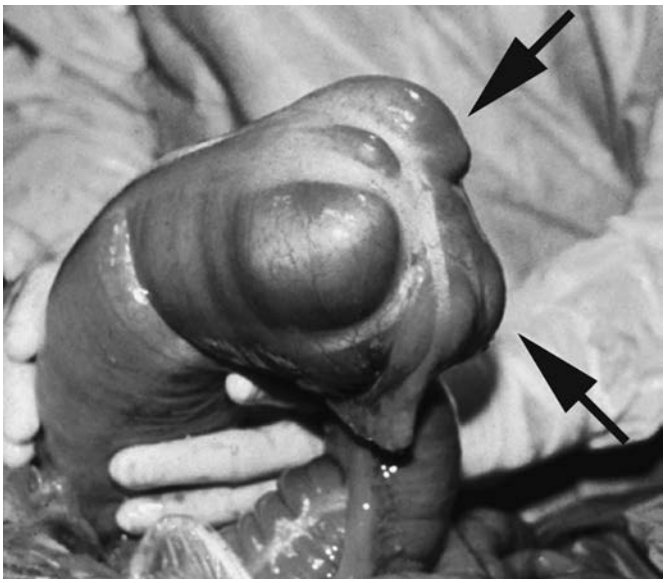

FIG. 32-79 Operative view of a foal with atresia coli. Complete atresia of the pelvic flexure has resulted in a blind-ended ventral colon *(arrows)* resulting in gas distention of the colon. The ventral colon was subsequently anastomosed to the dorsal colon in this foal.

ultrasonography to determine whether or not the entrapment has been relieved. If the entrapment remains or there is any deterioration in clinical signs, the horse should be taken to surgery.

Regardless of technique, the prognosis is good. Several studies have reported survival rates in excess of 90%.[34,39] Recurrence of left dorsal displacement has been described and may affect up to 8.1% of horses.[34] To prevent recurrence, laparoscopic closure of the nephrosplenic space may be performed following correction of the displacement.[40]

Atresia Coli

Atresia of any segment of the colon is a rare congenital abnormality in horses (Fig. 32-79).[41] The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which secondarily results in necrosis of a segment of intestine. Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal gas-distended colon. The diagnosis is made at surgery. Any portion of the colon may be absent, but the distal segment of the large colon and/or the proximal small colon is usually most severely affected. If sufficient tissue is present, anastomosis to the proximal blind end of the colon may be attempted. The prognosis depends on which segment of the colon is absent but is usually poor because of an absence of distal colon.

Strangulating Obstruction

Although simple obstruction of the large colon carries a very favorable prognosis, strangulating obstruction of the large colon is associated with high fatality rates. Two forms of strangulating obstruction are recognized: hemorrhagic strangulating obstruction, in which the arterial blood flow remains patent while veins are collapsed, and ischemic strangulating obstruction, in which both the arteries and the veins are collapsed. The differentiating factor between the two is likely how tightly twisted the volvulus is. It has been suggested that ingesta-filled intestine is more likely to develop a hemorrhagic lesion during volvulus because the intestinal contents prevent the intestine from twisting tightly.[42]

Large Colon Volvulus

Clinical signs of large colon volvulus include rapid onset of severe, unrelenting abdominal pain.[43] Although postparturient broodmares appear to be at risk, this association has not been conclusively determined. Once the large colon is strangulated (>270 degrees volvulus), gas distention is marked, leading to gross distention of the abdomen, compromised respiration as the distended bowel presses against the diaphragm, and visceral pooling of blood as the caudal vena cava is compressed. Horses with this condition are frequently refractory to even the most potent of analgesics. These horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases, because the time elapsed from the onset of strangulation to surgical correction is critical. Experimentally the colon is irreversibly damaged with 3 to 4 hours of 360-degree volvulus of the entire colon.[44] Despite severe pain and hypovolemia, horses may have a paradoxically low heart rate, possibly related to increased vagal tone. However, in those cases with a high heart rate this can be associated with a poor prognosis.[45] More accurate prognostic information can be obtained from plasma lactate. A plasma lactate concentration of 6 mmol/L is 84% sensitive and 83% specific for predicting nonsurvival.[46] Results of abdominocentesis are often not indicative of the degree of colon compromise,[47] and in many cases abdominocentesis should not be performed because of extreme colonic distention. Palpation per rectum will reveal severe gas distention of the large colon, often restricting access to the abdomen beyond the pelvic brim. The diagnosis may be tentatively based on signalment, severity of pain, and degree of distention.

At surgery the volvulus is typically located at the mesenteric attachment of the colon to the dorsal body wall, and the most common direction of the twist is dorsomedial using the right ventral colon as a reference point. However, the colon may twist in the opposite direction, twist more than 360 degrees (up to 720 degrees has been reported), or twist at the level of the diaphragmatic and sternal flexures. In all cases the colon should be decompressed as much as possible, and in many cases evacuation of colon contents via a pelvic flexure enterotomy will facilitate correction of the volvulus. A determination must be made after correction of the volvulus as to whether the colon has been irreversibly injured. This is frequently based on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of muscular motility. However, determination of viability based on these parameters is unreliable. Currently, one of the most reliable techniques for determining viability is histologic evaluation of frozen sections of colonic mucosa. Biopsies may be obtained at the pelvic flexure because it has been determined that mucosal changes are uniform throughout strangulated colon.[48] A prediction of viability is based on the degree of luminal and crypt epithelial loss and the interstitium-to-crypt (I:C) ratio (based on measurements of the crypt width and the width of interstitial space between crypts). In one study, morphologic changes consisting of an I:C ratio less than 3 and 60% loss of glandular epithelium predicted survival with a sensitivity and specificity of 95% and 92%, respectively, in a population of 52 horses.[49] In addition, it has been suggested that accuracy of viability determination can be increased by combining histologic evaluation with surface oximetry or laser Doppler determination of blood flow.[50] Unfortunately, frozen histologic sections are not available at most referral centers on an emergency basis. A recent retrospective study of formalin-fixed pelvic flexure biopsies from 28 horses found that morphologic scoring could not accurately predict short-term survival.[51] One study assessed intraoperative colonic intraluminal pressure as a more practical potential indicator of outcome in horses with large colon volvulus but found this measurement to be of little benefit in accurately making this determination.[52]

If the colon is judged to be irreversibly damaged, the feasibility of a large colon resection can be considered. Although 95% of the colon can be resected (that part of the colon distal to the level of the

VetBooks.ir

cecocolic fold), damage from the volvulus usually exceeds what can be resected. In these cases surgeons may elect to resect as much damaged bowel as possible or may advise euthanasia.

Postoperative complications include hypovolemic and endotoxemic shock, extensive loss of circulating protein, disseminated intravascular coagulation, and laminitis. In addition, large colon volvulus has a propensity to recur. Recent reports have described the prognosis for survival to hospital discharge for cases of large colon volvulus as between 58% and 74%.[53-56] Studies that have completed long-term follow-up have found that survival rates decline to between 34% and 66% after 2 years.[52,53] Although one study documented a recurrence rate of less than 5%,[47] some authors believe recurrence may be as high as 50%. Methods to prevent recurrence can be considered in patients considered at risk for recurrence.[57,58]

Intussusception

The most common intussusception of the large intestine is cecocolic intussusception, although when this is compared with all forms of colic, it is a relatively rare condition of the horse, accounting for 11 of 842 horses (1.3%) taken to surgery because of colic at one hospital.[59] The condition tends to occur in young horses (2 to 3 years of age) and may be associated with intestinal parasites, particularly tapeworms[60] and heavy larval cyathostome burden.[61] Clinical signs include acute onset of colic that varies in severity according to the degree of intussusception. Initially, the cecal tip inverts, creating a cecocecal intussusception, which does not obstruct flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral colon (cecocolic intussusception), which obstructs flow of ingesta and often causes severe colic. In one report on cecocecal and cecocolic intussusception, 26 of 30 horses had acute colic signs.[60] However, the condition may also present as a chronic disease.[60] The cause of abdominal pain is often difficult to differentiate in these cases, although it is sometimes possible to detect a mass on the right side of the abdomen and the concurrent absence of a palpable cecum. Treatment involves manual surgical reduction by retracting the intussusceptum directly or via an enterotomy in the right ventral colon with or without a partial typhlotomy.[60] The prognosis is usually regarded as poor because of severe compromise to the cecum and the risk of cecal rupture or severe contamination during surgery. However, a report of 18 horses without peritonitis and recovered from surgery found that 15 survived long term.[60]

Colocolic intussusceptions are rare but have reportedly affected the pelvic flexure and the left colon.[62-65] Although the condition is reportedly more common in young horses, older horses may be affected. Clinical findings may include a palpable mass on the left side of the abdomen. Ultrasonography may also be useful. Treatment requires manual reduction of the intussusception at surgery, or resection of the affected bowel.

Disorders of the Descending (Small) Colon

Vanessa L. Cook

Colic resulting from a problem with the small colon is comparatively rare—it has been identified in only 4.2% of surgical colics.[1] However, American Miniature Horses (AMHs) seem to be at increased risk for obstruction of the small colon,[2] with small colon lesions comprising 60% of surgical colics in that breed.[3] The Arabian breed may also be overrepresented compared with the hospital population.[1,2] It is interesting to note that horses over 15 years of age also seem to be at an increased risk for small colon conditions,[2] especially strangulating lipoma, injury from foaling, and submucosal hematoma.[1] Mares may also be at increased risk for small colon lesions, possibly because of hormonal fluctuations affecting gastrointestinal motility,[2] because of the small colon's predisposition to injury during foaling, or because of the possibility that the small colon could become entrapped by an ovary.

One of the biggest challenges with small colon lesions is that the associated clinical signs and rate of physiologic deterioration are less severe than with a more oral obstruction, often resulting in later referral.[1,2] A complete examination including rectal examination and abdominocentesis provides useful information in determining the diagnosis and indicating surgical intervention.[1] However, because the small colon lies caudally in the abdomen, transabdominal ultrasonography may be less useful than it is for lesions in other sections of the intestinal tract. Transrectal ultrasonography, performed with care, may be a more sensitive method to detect a compromised small colon and may aid in earlier diagnosis.[4]

Conditions affecting the small colon can be divided into congenital diseases, simple obstructions, vascular lesions, and strangulating lesions.

Congenital Diseases

Atresia Coli and Aganglionosis

Atresia coli is much more rare in foals than it is in calves, with a reported incidence of 0.44%.[5] There are several theories on the pathogenesis of this disease, but an ischemic vascular accident that results in atrophy of the affected segment is the most widely accepted one.[6] There are four types of atresia.[7] Type 3, blind-end atresia, with no connection of the atretic segments, is the most common type found in foals.[5,8] Atresia coli may be confused with overo lethal white syndrome, in which affected foals have myenteric aganglionosis of the distal intestinal tract resulting from a mutation in the endothelin receptor type B gene.[9,10] However, in this condition the intestinal tract is patent but nonfunctional. Loss of neurons in the myenteric plexus of the small colon can also be found in equine dysautonomia (grass sickness), although it is usually less severely affected than the ileum.[11]

Foals with atresia are usually normal at birth but develop progressive abdominal distention and colic within 24 hours of birth. Atresia can be differentiated from other causes of colic in foals by the complete absence of feces with no meconium staining on digital rectal examination or even after an enema.[6] It may be possible to confirm a blind-ending rectum or distal small colon by digital palpation or passage of a soft catheter or endoscope. However, the defect is usually too proximal to visualize this way, and perforation of the friable colonic mucosa can easily occur; therefore this method is not recommended for diagnosis. Plain radiographs do not usually identify the atresia but can help to differentiate it from a meconium impaction. Retrograde contrast radiography, as described later in this section for meconium impaction, may give a more definitive answer.[12] A large volume of barium sulfate, up to 20 mL/kg, may be needed if the atresia is proximal to the transverse colon. If atresia is present, the contrast agent will be seen to end abruptly at the atretic segment.

The only chance for survival in cases of atresia is early exploratory celiotomy to assess the affected segment and determine if surgical correction is possible. In calves with atresia, the prognosis is vastly improved if the diagnosis is made early and the animal is alert and is stabilized medically before surgery.[13,14] However, in foals, despite attempting surgical resection of the atretic segment and anastomosis, the prognosis is grave, with a 100% mortality rate reported in several studies.[5,8]

Simple Obstructions

Simple Impaction

Small colon impaction is the most common abnormal condition of the small colon in adult horses, affecting 1.9% to 2.5% of all horses seen for colic at referral institutes.[15,16] Several studies report a strong association between small colon impaction and diarrhea. The most

VetBooks.ir

recent study documents that horses with diarrhea are 10 times more likely to develop a small colon impaction than horses without diarrhea.[17] In other studies, diarrhea developed during hospitalization in 70% of all horses with small colon impaction, and 43% of those treated surgically cultured positive for *Salmonella* spp.[15] These studies suggest that impaction of the small colon may be a sequela to colonic inflammation, such as *Salmonella* infection. Therefore some hospitals use isolation protocols for all horses with a small colon impaction. Previous reports have documented a dramatic increase in the incidence of small colon impaction in the fall and winter, possibly because of decreased water intake or close housing that increases the incidence of infectious colitis, but a definitive reason is unknown. It is interesting to note that this seasonal incidence was not significant in the most recent study, possibly because of the milder winters in the southern United States.[17]

Diagnosis of a small colon impaction is most easily made by rectal palpation, with an accuracy of 79% to 87%.[15,17] A solid tube of ingesta with loss of the normal sacculations is found. However, great care should be taken when performing a rectal examination because the rectal mucosa may be edematous, and frequently the horse will strain.[18] It now appears that the best parameter for determining when surgical treatment of these cases is required is the presence of abdominal distention. It has been reported that horses with a small colon impaction and abdominal distention are five times more likely to require surgical correction than horses without abdominal distention.[17] Unlike other types of colic, this single factor has been found to be more significant than heart rate, temperature, or duration of colic when determining the need for surgical intervention.[17] However, transabdominal trocharization in the right paralumbar fossa is an extremely effective and safe method to relieve gas accumulating orad to the impaction. This can be performed to relieve abdominal distention and improve the chance of success with medical therapy rather than proceeding directly to surgery.

Medical therapy should consist of intravenous fluid therapy to correct electrolyte abnormalities, combined with enteral fluid therapy with a balanced electrolyte solution, and analgesics as necessary.[15,16] Typically 4 to 6 L of warm water with 1 oz of sodium chloride alternating with 1 oz of potassium chloride is administered by gravity flow every 2 hours. Administration of *N*-butyl scopolammonium bromide may relax the smooth muscle spasm around the impaction and allow it to pass more easily. The length of time for the impaction to resolve with medical treatment is often longer than for large colon impactions, with a mean time to resolution of over 2 days.[17] Surgical correction of the impaction via exploratory celiotomy is usually performed via a high enema combined with extraluminal massage by the surgeon. The impacted small colon is extremely friable, and great care should be taken by the surgeon when manipulating the bowel in order to avoid serosal tears. Application of sterile carboxymethylcellulose to the serosal surface may help lubricate the intestine and reduce the trauma of manipulation. In severe cases, infusion of the impacted contents with isotonic fluids or an enterotomy in the small colon may be necessary to facilitate evacuation of the impaction.[18] An additional concern is the risk of reimpaction of the small colon as ingesta from the large colon move aborally after surgery. Therefore, if there are ingesta in the large colon at the time of surgery, a pelvic flexure enterotomy is also recommended to empty the large colon and reduce the risk of recurrence.[15] Surgical correction of the impaction can be time-consuming; to reduce anesthesia time it is advisable to assemble the items needed for a high enema, such as a stomach tube with a rounded atraumatic end, stomach pump, and buckets of warm water, in the operating room before induction.

The prognosis for medical and surgical treatment appears to be similar in most studies.[15,17] It is interesting to note, however, that overall prognosis appears to have improved in recent years, increasing from approximately 75% in cases from 1986 to 1996[15] to approximately 95% in cases from 1999 to 2004.[17] Therefore, overall, the prognosis for small colon impaction is excellent, even if surgical intervention is necessary. However, because of the underlying inflammatory cause of this condition, length of hospitalization and associated costs tend to be higher than those incurred with a simple large colon impaction.[17]

Fecaliths, Enteroliths, and Foreign Bodies

Simple obstruction of the small colon also occurs from inspissated feces (fecaliths), enteroliths, foreign bodies, or, less frequently, concretions of plant material (phytobezoars) or masses of matted hair (trichobezoars).

Fecaliths are improperly formed fecal balls that are larger than normal at 4- to 6-cm diameter in miniature horses.[19] They are a common cause of colic in young miniature horses,[19] with an occurrence rate of 63% in a study of surgical colic in miniature horses.[20] Causes of fecaliths are probably similar to those of other impactions and include poor-quality roughage, dental disease causing problems with mastication, and reduced water intake.[19,20] Fecaliths that become lodged in the small colon usually cause complete intestinal obstruction and require surgical removal as described later. When managing colic in miniature horses, regardless of the cause, the patient should have serum triglyceride concentration monitored to allow early detection and treatment of hyperlipemia.[21]

Enteroliths are mainly composed of magnesium ammonium phosphate deposited in concentric layers around a nidus such as a small rock.[22] The incidence is very high in certain regions, such as California, where enterolithiasis constitutes 15.1% of all colic seen at the University of California, Davis,[23] compared with less than 2% of colic cases at Texas A&M University.[24] Several studies report an increased incidence in Arabians, although the reason for this is unknown. Enteroliths can lodge in the large colon, transverse colon, or small colon, but the last is a relatively common site, with over 41% to 45% of enterolithiasis cases involving an obstructive enterolith in the small colon.[23,25] Horses with enteroliths were found to have certain changes in the composition of their colonic contents, compared with other surgical colic cases, which may predispose them to enterolith formation. These differences include a more alkaline pH, more colonic fluid, and higher mineral concentrations.[26] Certain management practices may also predispose to enterolith formation, including a high proportion of alfalfa in feed and less access to pasture.[24,26] Clinical signs of enterolithiasis are similar to those seen with other nonstrangulating obstructions of the large or small colon. However, many horses with enterolithiasis have a history of intermittent colic, and some may even have passed enteroliths in the feces.[23] Horses with an enterolith in the small colon are more likely to be tachycardic and leukopenic than horses with an ascending colon enterolith.[25] Abdominal radiographs may be a useful aid in diagnosis, although the sensitivity is reduced when the enterolith is in the small colon.[27] Medical management aimed at reducing colonic pH has been suggested to try to prevent recurrence after surgery. However, when an enterolith lodges in the small colon, it usually causes complete obstruction and acute colic that require surgical intervention as described later. Rupture of the gastrointestinal tract is particularly common if the enterolith is lodged in the small colon and surgery is delayed.[23] Such cases should therefore be prioritized as requiring emergency surgery, even when there is a history of chronic colic. The vast majority of enteroliths that obstruct the small colon lodge in the proximal third,[25] presumably because of the change in lumen diameter between the transverse colon and descending colon.

Obstruction of the small colon can also occur from ingestion of foreign material such as rope, twine, rubber fencing, cloth, or tires.[28,29] This is usually a problem in younger horses, possibly because they are more inquisitive and will eat nonfood items found in their environment. It is possible for the foreign body to cause signs of small intestinal obstruction first, followed by a period of quiescence while it passes through the large colon before it finally causes complete obstruction of the small colon and acute onset of severe colic[30] and abdominal distention.[28] The fibers become covered in crystalline material during their transit through the intestinal tract, and the resulting irregular sharp projections cause pressure necrosis and mucosal ulceration,[1] which can be seen during exploratory celiotomy

VetBooks.ir

oral to the site where the foreign body has finally become lodged. These sharp projections make it virtually impossible to manipulate the foreign body orally or aborally within the lumen, making removal more complicated.

The majority of these obstructions requires exploratory laparotomy and an enterotomy to allow the obstruction to be removed.[19,23,28] Regardless of the cause of the obstruction, the overlying intestine is friable and can easily rupture either during induction of anesthesia[28] or during surgical manipulation.[23,29] If possible, the mass should be gently manipulated more proximal or distal to the original site at which it lodged, so that the enterotomy can be performed in uninjured intestine.[1] However, foreign bodies in particular may be difficult to manipulate, and the enterotomy may have to be performed directly over the top of the obstruction. The site selected for the enterotomy should be isolated from the abdomen with sterile towels before the enterotomy incision is made. The incision should be made longitudinally through the antimesenteric taenia in order to preserve luminal diameter, reduce hemorrhage, and maximize speed and ease of the procedure.[31,32] The enterotomy can be closed in one layer using an inverting suture pattern.[32] Small areas of necrosis caused by transmural pressure from the obstruction can be managed by oversewing the affected segment. Problems arise when intraluminal obstructions occur at the proximal portion of the descending colon, where the lumen narrows between the transverse and descending colon. Here, manipulation of the obstruction aborally into a section of small colon that can be exteriorized may be impossible. In such cases an antimesenteric teniotomy, through the seromuscular layer alone, can be performed. This will allow the obstruction to be advanced aborally into a section that can be exteriorized, while the intact mucosa prevents abdominal contamination.[33] The enterotomy and seromuscular incision are then closed as described earlier. An alternative approach is to perform a high enema to repulse the obstruction orally into the ascending colon where it can be removed via a pelvic flexure enterotomy. The overall prognosis for enteroliths of the descending colon is excellent. A recent study reports a 94% short-term survival rate, if horses euthanized at surgery are excluded.[25] Common postoperative complications include fever, anorexia, and diarrhea, which do not seem to worsen the prognosis but may prolong hospitalization.

Meconium Retention

Meconium is composed of substances that are present in the intestinal tract at birth, such as glandular secretions, sloughed cells, and swallowed amniotic fluid, and is therefore sterile. It is thick and tarry and is usually passed within 48 hours of birth. Several studies indicate a higher incidence of meconium retention in colts than fillies, presumably because of the longer, narrower pelvis in males.[34,35] Any factors that reduce intestinal motility (such as failure to ingest colostrum) and dysmaturity can result in difficulty passing meconium, which is described as *meconium retention*. This results in progressive clinical signs of colic such as tail flagging, straining, and reduced suckling. This can progress to more severe signs of colic over time, such as rolling and abdominal distention. These signs are similar to those seen with ruptured bladder, and the two conditions can occur together; therefore a complete examination of the foal is important.

It may be possible to palpate meconium retained at the pelvic inlet by careful digital rectal examination. If the meconium is retained more proximally, it may be identified on a plain lateral radiograph. Confirmation of the obstruction may be provided by retrograde contrast radiography, which provides excellent sensitivity and specificity for evaluation of the transverse and descending colon.[12] After plain radiographs are obtained, a Foley catheter is placed into the rectum and inflated. Up to 20 mL/kg (approximately 1 L) of 30% barium sulfate is carefully allowed to flow in by gravity until it squirts around the catheter or discomfort is observed.[12] Lateral and, more important, ventrodorsal radiographs are then obtained. If a meconium impaction is present, the contrast agent stops before it reaches the transverse colon. A high meconium impaction may be visualized on transabdominal ultrasonography.

Supportive medical management of all foals should be performed first, including correction of fluid and electrolyte imbalances, provision of nutritional support, and correction of failure of passive transfer if indicated.[36] Judicious use of analgesics such as flunixin meglumine or butorphanol and oral fluids may aid resolution of the impaction. However, the most effective treatment is administration of an enema. The enema can be a commercial phosphate enema or simply soap and water administered through a Foley catheter using gravity flow as described previously. In cases that are refractory to simple enemas, an acetylcysteine enema may be effective. Acetylcysteine is a mucolytic, which acts by breaking disulfide bonds to make meconium less viscous. These enemas are available commercially (E-Z Pass Foal Enema Kit [Animal Reproduction Systems, Chino, Calif.]) or can be formulated by adding 20 g of baking soda to 200 mL of water, and then adding 8 g of acetylcysteine powder to make a 4% solution.[34] The solution is infused slowly through a Foley catheter, which is then clamped to allow the solution to be retained for up to 45 minutes to allow maximum activity of the acetylcysteine. Successful resolution of the meconium retention occurred in all acetylcysteine-treated foals in one study, although 5% of foals required three enemas before resolution was obtained.[34]

Previous reports have indicated that approximately one third of foals with meconium retention require exploratory celiotomy for resolution.[35] However, this study was carried out prior to the increased use of acetylcysteine retention enemas, and it is likely that the current rate of surgical intervention is much lower. Considering the high rate of adhesions in neonatal foals undergoing exploratory laparotomy,[35,37] this should result in an improved prognosis for this condition.

Other Causes of Simple Obstruction

Because of the proximity of the descending colon to the urogenital tract, it is possible for the descending colon to be obstructed by intraabdominal structures such as an ovary or retained testicle. Although such conditions occur infrequently, the most common is for the small colon to become entwined around an ovary.[1] The intestine can be freed and is not usually compromised, but the ovary itself is usually nonviable and requires resection.[38] A similar problem has been reported from the spermatic cord of a retained teratoma occluding the small colon.[39]

Vascular Lesions

Intramural Hematoma

Intramural hematoma of the small colon is relatively rare, although some cases may not be diagnosed if they do not cause complete obstruction and if they resolve without intervention.[40] Hemorrhage occurs between the mucosa and muscularis layers, which expand to occlude the lumen and cause complete obstruction. The length affected has been reported to range from 24 to 65 cm. The cause is unknown, although in people, blunt abdominal trauma has been associated with the condition.[41] In one equine case series, iatrogenic rectal trauma was implicated as the cause.[42] There is an increased incidence in older horses, with those affected having an average age of 11 years in one study.[1] Affected cases frequently have blood in the rectum and may show signs of vascular compromise from blood loss.[1,42]

Exploratory celiotomy with complete resection of the affected segment and end-to-end anastomosis (as described later) is necessary. Because of the long length of the affected segment, it may be difficult to exteriorize and resect all damaged intestine. However, if the entire affected segment can be removed, the prognosis is good; one study reported a 75% survival rate.[40]

Mesocolic Tears and Rectal Prolapse

Tears in the mesentery of the small colon can occur as a complication of parturition, especially in multiparous mares,[43,44] and result in segmental ischemic necrosis of the small colon. Trauma and straining during parturition can result in tearing of the mesocolon and

VetBooks.ir

devitalization of the associated descending colon, which may progress to an intussusception of the small colon, which manifests as a type III or IV rectal prolapse. In a type III rectal prolapse the rectal ampulla prolapses, as with a type II prolapse, but in addition, a portion of the small colon intussuscepts into the rectum. In type IV rectal prolapse part of the small colon and the rectum intussuscepts through the anus.[43,45] Gentle palpation around the prolapse can help determine the type of prolapse. Although a rectal prolapse is readily identifiable, tears of the mesocolon resulting in devitalization of the small colon result in a more insidious onset of clinical signs, including depression and lack of feces.[43,44]

The mesocolic tear is frequently located caudally, resulting in the affected area being inaccessible via a midline celiotomy. Therefore it may be more prudent to first perform standing flank laparoscopy to determine the location and extent of the lesion.[46] This allows assessment of the lesion to determine if resection and anastomosis of the affected segment via celiotomy are feasible, or if a permanent colostomy is required.[47]

Strangulating Obstructions

Strangulating Lipoma

Pedunculated lipomas can cause a strangulating or nonstrangulating obstruction of the small colon, but this occurs much less frequently than in the small intestine. In a large retrospective study, lipomas were found to involve the descending colon in less than 10% of cases.[48] The overall incidence of lipomas affecting any portion of the gastrointestinal tract is increased in older geldings[48,49] and in Saddlebreds and Arabians.[48] It is therefore likely that lipomas specifically affecting the descending colon have a similar distribution. Fig. 32-80 illustrates a pedunculated lipoma that had strangulated a short section of the small colon. Clinical signs typical of a strangulating obstruction are seen, with a significantly elevated heart rate, abnormal abdominocentesis, and distended large colon on rectal examination.[1] In addition, on rectal examination a constriction of the lumen of the small colon caused by the lipoma may be palpated and feels like a blind end or narrowing of the lumen. Surgery is necessary to free the constricting lipoma, followed by resection and anastomosis if the intestine is nonviable (Fig. 32-81). Strangulating lipomas of the small colon are the most common reason for a resection and anastomosis.[50] The prognosis is worse if resection is required, with a 50% survival rate in one study, compared with 100% survival for nonstrangulating lipomas.[1] However, a recent multicenter study has documented a substantially better survival rate after resection and anastomosis of the small colon, the majority of which were horses with a strangulating lipoma.[50] In this study 84% of cases were discharged from the hospital with a median duration of hospitalization of 8.5 days. The end-to-end anastomosis is usually sutured in two layers, with a simple continuous pattern in the mucosa followed by closure of the serosa with an inverting suture pattern interrupted at 180 degrees. It is possible that failure of the anastomosis occurs more commonly in the small colon than the small intestine, but numbers are too low to definitively state this.[50] Many surgeons perform a concurrent pelvic flexure enterotomy to reduce the risk of impaction at the anastomosis after surgery, but this does not appear to improve postoperative survival.[50] Diarrhea, fever, and delayed passage of feces are common postoperative complications, but long-term survival is good with 93% of horses discharged alive at 6 months.[50]

Other Causes of Strangulating Obstruction

Several other causes of strangulating obstruction can occur, but each condition is relatively rare. These include volvulus of the small colon[30] and strangulation through internal hernias such as a vaginal tear[2] or tears in the gastrosplenic ligament.[51]

Prognosis A good survival rate was found in two large studies reviewing small colon disorders, with 71% and 91% of patients being discharged from the hospital.[1,2] The main reason for euthanasia at the time of surgery was an inability to completely exteriorize the affected segment to allow adequate resection and anastomosis.[1] Previous reports have suggested that resection and anastomosis in the small colon may carry a poor prognosis because of a relatively poor blood supply, higher bacterial counts, solid fecal material, and increased collagenase activity compared with the small intestine.[30] However, if the patients euthanized at surgery are excluded, short-term survival after surgery for a small colon lesion is excellent, with a report of 100% survival in one study.[52] In addition, horses that required resection and anastomosis did not have a worse prognosis for survival[2] and are less likely to develop the complications associated with small intestinal resection, such as postoperative ileus (POI).[53]

FIG. 32-80 A short section of small colon that had been strangulated by a pedunculated lipoma.

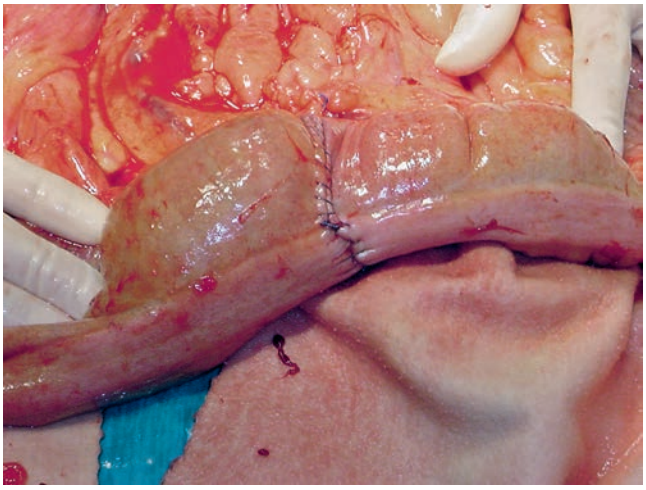

FIG. 32-81 The same case as in the previous figure after resection of the ischemic segment and end-to-end anastomosis.

Disorders of the Peritoneum in Horses

Tiffany L. Hall

Peritonitis

Anatomy and Physiology The peritoneum consists of a single layer of mesothelial squamous cells covering the peritoneal cavity and abdominal organs. These cells rest on a thin basal lamina attached to a layer of loose connective tissue, allowing a variable degree of motion. The peritoneum is coated with a thin serous film that serves to minimize friction and facilitate free movement between abdominal viscera. In males the peritoneum forms a closed sac, whereas in females it communicates with the external environment via the fallopian tubes.

The peritoneum is divided into the visceral peritoneum and the parietal peritoneum. The visceral peritoneum, which encloses the intraperitoneal organs and forms the omentum and mesenteries, is supplied by the splanchnic vasculature and is innervated by the visceral autonomic nervous system. The parietal peritoneum lines the abdominal walls, pelvis, and diaphragm and receives its blood supply via branches of the lower intercostal, lumbar, and iliac arteries, which drain via veins into the caudal vena cava. Irritation of the parietal peritoneum gives rise to afferent stimuli that are perceived as somatic pain, which is transmitted by the intercostal and phrenic nerves, and may manifest as splinting of the abdomen and a reluctance to move. In contrast, there are no pain receptors in the visceral peritoneum.

Peritoneal fluid is constantly being produced and absorbed through the passive diffusion of fluid and solutes across the semipermeable peritoneum. Transperitoneal fluid movement is increased during peritoneal inflammation and may cause a rapid, massive transudation of fluid into the peritoneal cavity that can lead to hypotension and shock.[1]

The peritoneal lymphatics, particularly the diaphragmatic lymphatics, play a major role in the removal of fluid and solutes from the peritoneal cavity, emptying primarily into the thoracic duct and providing the first line of defense against peritoneal contamination. Cellular defenses are provided by peritoneal macrophages, mast cells, mesothelial cells, and activated peritoneal T cells. Peritoneal macrophages have antimicrobial activity resulting from their complement receptors, phagocytic ability, cellular recruitment, and T cell–mediated immune responses. Peritoneal mesothelial cells are an abundant source of plasminogen activator, which is responsible for normal fibrinolytic activity on peritoneal surfaces.[1]

Pathogenesis Peritonitis is inflammation of the peritoneum resulting from a number of infectious and noninfectious causes. It is classified as primary or secondary, acute or chronic, and localized or diffuse. Common causes of peritonitis in horses are listed in Box 32-3. Primary peritonitis is uncommon in adult horses but may be diagnosed in foals with sepsis or young horses infected with *Streptococcus equi*. More commonly, peritonitis occurs secondary to translocation of bacteria from the gastrointestinal tract, following urogenital trauma, or from other inflammatory conditions. A subset of infectious peritonitis with a unique presentation and associated with *Actinobacillus equuli* has been described and is discussed at the end of this section.

Recent retrospective studies concluded that a cause of peritonitis is often not identified (50 of 65 and 19 of 55 of cases).[2,3] In both groups, cases of confirmed gastrointestinal rupture were excluded from analysis and horses having undergone abdominal surgery were excluded from one study. The conditions most commonly associated with peritonitis in these studies included recent abdominal surgery (18 of 55), postpartum complications (22 of 120), suspected cyathostomiasis (4 of 65), infiltrative bowel diseases (3 of 65), and internal abscesses (3 of 65).[2,3]

The local response of the peritoneum to insult is similar regardless of the cause. Initially, peritoneal mast cells and macrophages release histamine and serotonin, resulting in vasodilation and increased vascular permeability with transudation of fibrinogen-rich plasma into the peritoneal cavity. The release of tumor necrosis factor (TNF) and interleukin 1 (IL-1) stimulates neutrophil chemotaxis and degranulation, and the inflammatory response is promoted by the release of platelet-activating factor (PAF), prostaglandins, and leukotrienes. Damage to mesothelial cells results in release of tissue thromboplastin and decreased levels of plasminogen activator, which favors fibrin formation and deposition.[4] Fibrin functions to confine bacteria and seal the peritoneal defect; however, if the immune system fails to clear the bacteria and foreign debris, the inflammation will continue and fibrin production results in abscess and adhesion formation.

Clinical Features Clinical signs of peritonitis vary and depend on the cause and duration of the peritonitis. Localized infections often have limited systemic symptoms, whereas diffuse peritonitis can elicit generalized signs of endotoxemia and sepsis. Horses with peracute peritonitis caused by intestinal rupture show signs of acute, severe sepsis and cardiovascular collapse with tachycardia, tachypnea, sweating, varying degrees of abdominal discomfort, and death within hours.

BOX 32-3

Causes of Peritonitis in Horses

Gastrointestinal

- Intestinal perforation
- Rectal tear
- Intestinal ischemia
- Proximal enteritis
- Colitis
- Intestinal parasites
- Intestinal neoplasia
- *Actinobacillus equuli*

Iatrogenic

- Celiotomy
- Enterocentesis
- Chemical irritation (lavage solutions)
- Colpotomy/castration

Foals

- Bladder rupture/uroabdomen
- Umbilical/urachal Infection
- Septicemia
- Necrotizing enterocolitis
- *Rhodococcus equi*

Extragastrointestinal

- Neoplasia of abdominal organs
- Hemorrhage of abdominal organs
- Abscessation of abdominal organs
  - *Streptococcus equi*
  - *Streptococcus zooepidemicus*
  - *Corynebacterium pseudotuberculosis*
- Hepatitis
- Nephritis
- Pancreatitis
- Cystitis
- Urolithiasis
- Endometritis
- Uterine/vaginal tears
- Scirrhous cord
- Systemic amyloidosis
- Viral infection
  - Influenza
  - Equine viral arteritis
  - Equine infectious anemia

VetBooks.ir

Based on two retrospective studies of 65 and 55 horses, the most common presenting clinical signs for peritonitis include colic, depression/lethargy, tachycardia, tachypnea, pyrexia, and altered mucous membrane character.[2,3] Much of the clinical presentation reflects the degree of systemic inflammation and is associated with endotoxemia and hypovolemia. Colic symptoms may be related to inflammation of the parietal peritoneum and are characterized by a "guarded" or splinted abdomen and a reluctance to move or defecate.[5] Sympathetic stimulation, hemoconcentration, and/or serosal surface trauma may decrease gastrointestinal motility, and subsequent ileus can lead to gastric fluid accumulation and small intestinal distention, which intensify the abdominal pain. In addition, gastrointestinal impactions commonly develop as fluid is reabsorbed from the cecum and large colon in an attempt to replace intravascular fluid deficits resulting from extravasation of fluid into the peritoneal cavity.

Rectal examination may identify either roughened peritoneal surfaces or an abnormally empty abdomen in cases of intestinal rupture. Distended bowel associated with the presence of adhesions or ileus may occur. Occasionally, abdominal masses, abscesses, or enlarged mesenteric lymph nodes may be palpable; however, in many cases, no abnormalities are identified on rectal palpation. Animals with a recent history of foaling or castration should have a urogenital examination performed to rule out vaginal, cervical, and uterine tears in mares or infected castration sites in males.

Diagnosis

ULTRASONOGRAPHY. Ancillary diagnostics such as transabdominal and transrectal ultrasonography aid in diagnosis and identification of the source of peritonitis. The clinical utility of ultrasound greatly depends on the quality of equipment and the experience of the practitioner; identification of abnormalities in cases of peritonitis ranges from 50% to 90%.[2,3] The most common finding on transabdominal ultrasound is an increase in volume or altered echogenicity of peritoneal fluid. Other findings can include intraabdominal abscesses, lymphadenopathy, or the presence of dilated small intestine with or without increased intestinal wall thickness. Fibrinous strands or fibrin adhesions may also be identified by ultrasound (Fig. 32-82) and a site for abdominocentesis selected. Perirectal masses may be observed on transrectal ultrasound, particularly in cases associated with vaginal tears.

HEMATOLOGY AND BIOCHEMISTRY. Alterations in laboratory values are widely variable depending on the cause and duration of peritonitis. Hematologic abnormalities seen in acute, severe peritonitis include elevated packed cell volume (PCV) secondary to transudation of fluid into the peritoneal cavity and severe neutropenia associated with endotoxemia and systemic inflammation. Initially an increase in plasma protein levels occurs, reflecting the degree of hypovolemia; however, in chronic cases hypoproteinemia may be present. Peripheral cell counts will vary from leukopenia to leukocytosis and a left shift with greater than 5% immature neutrophils is observed in approximately 40% of patients.[3] Hyperfibrinogenemia is a common finding with levels ranging from 490 to 1120 mg/dL in a review of 65 cases.[2] Peritonitis of longer duration and internal abscesses may present with a normal or increased systemic neutrophil count, monocytosis, and elevated plasma protein and/or fibrinogen levels.[6]

Alterations in serum chemistry and blood gas reflect the patient's cardiovascular status at the time of presentation, associated with the degree of systemic inflammation. Prerenal azotemia, hypokalemia, hyponatremia, and hypochloremia may be seen, as well as acidosis and an increase in unmeasured anions, such as lactate, as the patient's condition declines. Other changes on serum chemistry could indicate an underlying condition in a specific organ system.

ABDOMINOCENTESIS. Peritoneal fluid analysis confirms the diagnosis of peritonitis, although the cause may remain unknown. Expected values for peritoneal fluid in normal horses, as well as in horses having undergone abdominal exploratory and castration and in postpartum mares, are listed in Table 32-8.[7-10] The cytologic appearance of the leukocytes and mesothelial cells should be normal, although activated mesothelial cells are not an unusual observation in normal horses.

Evaluation of fluid character and quantity can aid in developing and prioritizing a differential list. Turbid, cloudy fluid indicates an increased cell count. Serosanguineous fluid indicates an increase in erythrocytes or free hemoglobin that may be caused by intestinal degeneration with transmural erythrocyte leakage, splenic puncture during abdominocentesis, abdominal viscera laceration, or skin contamination. Green fluid results from enterocentesis or intestinal rupture, and brown fluid is associated with late-stage tissue necrosis. The quantity of fluid varies among horses and can be increased in acute, diffuse peritonitis or absent in low-grade and localized peritonitis. The presence of large quantities of dilute, colorless fluid should alert the clinician to the possibility of ascites or uroperitoneum.

Cytologic examination of the peritoneal fluid should include a Wright-Giemsa and a Gram stain. Peritoneal fluid cell morphology is an important diagnostic aid and can be evaluated from the Wright-Giemsa stain. Neutrophils are evaluated for degenerative changes such as nuclear swelling and cytoplasmic vacuolation, indicating activation associated with the presence of bacterial toxins. Identification of exfoliative cells from neoplasms, such as melanoma, is rare but diagnostic and will aid in directing therapy and prognosis.[11] The Gram stain is used to identify bacteria and guide initial antimicrobial therapy until culture and sensitivity results become available.

Peritoneal fluid parameters consistent with peritonitis vary widely, depending on the disease process. Cytologic findings show increases in total nucleated cell counts and protein with the predominance of degenerative neutrophils and intracellular bacteria. Nucleated cell counts ranged from 5800 to 350,000 cells/μL and protein levels up to 8 g/dL in one study,[2] but cell counts as high as 800,000 cells/μL have been reported in horses with peritonitis. Cytologic evidence of extracellular bacteria can result from skin contamination and should be interpreted in light of the clinical signs and remainder of the fluid analysis.

Distinguishing between early, mild septic peritonitis and nonseptic peritoneal inflammation using clinical findings and routine fluid analysis alone may be difficult; however, peritoneal fluid pH and glucose concentrations have been found to be significantly lower in horse with septic peritonitis compared with those with nonseptic peritonitis and with healthy horses. In a prospective study in 46 horses, serum-to-peritoneal fluid glucose concentration differences greater than 50 mg/dL were diagnostic for septic peritonitis. Peritoneal fluid pH less than 7.3, glucose concentration below 30 mg/dL, and fibrinogen concentration above 200 mg/dL were highly indicative of septic peritonitis.[12] A more recent study found that peritoneal concentrations of L- and D-lactate were highest in horses with peritonitis compared with other causes of colic; however, determination of bacterial originating D-lactate is not available in the clinical setting.[13] In addition to these findings, other markers of inflammation and coagulopathy are altered in cases of septic peritonitis, including significant elevations in peritoneal transforming growth factor beta 3 (TGF-β3) compared with other causes of colic and significantly higher peritoneal D-dimer concentrations compared with healthy horses or those with obstructive colic.[14,15]

BACTERIAL CULTURE AND SENSITIVITY. Microbiological culture and sensitivity testing is recommended to help identify bacterial agents and direct antimicrobial therapy. Serial cultures of the peritoneal fluid may be necessary to identify emerging or resistant bacterial strains. Optimal bacteria isolation from peritoneal fluid requires the use of an enriching broth, blood culture medium, and/or antimicrobial removal device.

Bacteria were cultured or identified on cytology in 48 of 67 horses (71.6%) and 28 of 36 cases (77.8%) with peritonitis. *E. coli, Staphylococcus epidermidis,* and *Staphylococcus aureus* were the most common bacteria isolated from peritoneal fluid samples.[3,5] Anaerobes are frequently cultured from peritoneal fluid of equine peritonitis cases, with *Bacteroides fragilis* most commonly identified.[16] Failure to identify or culture bacteria from peritoneal fluid does not rule out septic peritonitis.

Treatment

Horses with peritonitis often require early, aggressive therapy to address hypovolemia and dehydration, correct metabolic and electrolyte abnormalities, and reduce the effects of endotoxemia. The goals of therapy are to (1) stabilize the patient, (2) treat the inciting cause of peritonitis, (3) manage pain and inflammation, and (4) minimize complications.

FLUID THERAPY. Horses with peritonitis present with varying degrees of dehydration; thus fluid resuscitation with balanced, polyionic crystalloids should be the first step in treatment. Hypertonic solutions may be indicated in cases presenting with signs of hypovolemic shock, which may develop secondary to massive fluid shifts into the peritoneal cavity as a result of severe, acute inflammation. Because third spacing of albumin can lead to hypoproteinemia, administration of colloid solutions may be beneficial. Hydroxyethyl starch solutions (6%) are effective in fluid resuscitation and can increase colloid oncotic pressure at doses of 8 to 10 mL/kg.[17] Large volumes of hyperimmune plasma may be used to raise plasma protein levels; however, lower doses of 4.4 mL/kg may help in cases demonstrating signs of endotoxemia.[18]

Acid-base disorders, as well as shifts in calcium, potassium, sodium, and chloride concentrations may be observed in cases of peritonitis. Monitoring of acid-base status and electrolyte concentrations is recommended during the course of therapy with intravenous or oral supplementation as needed. See the Fluid Therapy for Horses with Gastrointestinal Diseases section for a more in-depth discussion of fluid resuscitation and selection.

ANTIMICROBIAL THERAPY. Antimicrobial therapy should be initiated in all cases of peritonitis as soon as fluid has been collected for culture, even when the inciting cause cannot be immediately identified. The site of infection, pathophysiology, likely pathogens involved, and concurrent patient conditions should be taken into consideration when selecting an antimicrobial regimen. Lipophilic antibiotics (fluoroquinolones, potentiated sulfonamides) will reach higher concentrations within the peritoneal cavity and in abscesses compared with hydrophilic antibiotics (aminoglycosides, β-lactams); however, in the acute stages of the disease, inflammation of the peritoneal surfaces often results in therapeutic levels of hydrophilic antibiotics.[18] Further, intravenous administration is recommended as drug concentrations achieved are more reliable compared with oral administration in cases suffering from dehydration or ileus.

Based on the predominance of mixed bacterial infection and concurrent gastrointestinal disease, a broad-spectrum antimicrobial regimen is recommended until culture and sensitivity results are available. Administration of a combination of β-lactam (potassium penicillin G 20,000 IU/kg IV qid or ceftiofur sodium 2.2 mg/kg IV bid) and aminoglycoside (gentamicin 6.6 mg/kg IV q24h) is appropriate. Enrofloxacin (7.5 mg/kg IV q24h) may be substituted for gentamicin based on its increased lipophilicity, activity against *Staphylococcus,* or in cases of renal compromise. Metronidazole (20 mg/kg PO or per rectum q6-8h) is often added to this regimen based on the frequency of *B. fragilis* isolated in horses with peritonitis.

Oral antibiotic administration may be initiated after patients are stabilized and should be based on culture and sensitivity. Commonly administered antibiotics would include trimethoprim-sulfa (20 to 30 mg/kg PO bid), chloramphenicol (50 mg/kg PO qid), or doxycycline (20 mg/kg PO q24h) depending on the underlying condition, client finances, and concurrent conditions. Resistance to trimethoprim-sulfa is not uncommon[18] and thus it should be used cautiously; however, it is a good option for long-term treatment or in combination with rifampin (5 mg/kg PO bid) when intraabdominal abscesses are suspected. Chloramphenicol is bacteriostatic and should not be used as a first line in compromised patients; however, it has a broad spectrum of activity against aerobes and anaerobes with few reports of resistance. Doxycycline should be used only when indicated (based on culture results), but it does have the added benefit of antiinflammatory properties.

Neonatal foals with peritonitis should be maintained on broad-spectrum intravenous antibiotics, as for septicemia, including a combination of β-lactam (ampicillin 20 mg/kg IV qid or ceftiofur sodium 5 mg/kg IV bid) and aminoglycoside. Amikacin (20 to 25 mg/kg IV q24h) is often used in place of gentamicin as it has increased activity against organisms commonly isolated from neonates and decreased potential for nephrotoxicity in these patients. However, therapeutic drug monitoring is recommended.

Older foals and weanlings have a higher incidence of *Rhodococcus equi* and *S. equi* infection; thus antimicrobial regimens in these patients include either penicillin (procaine penicillin G 20,000 IU/kg IM bid) or a macrolide/rifampin combination in the absence of

VetBooks.ir

other inciting causes. Azithromycin (10 mg/kg PO q24-48h) and clarithromycin (7.5 mg/kg PO bid) have a broader spectrum of activity and fewer side effects compared with erythromycin (37.5 mg/kg PO bid).[19,20]

The duration of antimicrobial therapy is dependent on the inciting cause and the patient's response to treatment. Most peritonitis cases will require a minimum antimicrobial course of 7 to 10 days and cases with intraabdominal abscesses may require a 6- to 8-week course of antimicrobials. Antibiotics should be continued for several days after clinical signs resolve and peritoneal fluid counts return to normal in cases of idiopathic peritonitis. Other methods for monitoring progress and determining termination of therapy include serial ultrasound evaluation, complete blood counts, and fibrinogen levels in cases of internal abscesses.

ANTIINFLAMMATORY THERAPY. All horses with peritonitis will have varying degrees of local and systemic inflammation, and some may present with endotoxemia or endotoxic shock. Administration of medications with antiinflammatory properties, as well as those that bind and inactivate endotoxin, may be beneficial.

Nonsteroidal antiinflammatory drugs (NSAIDs) should be administered in all cases of peritonitis for both analgesia effects and ability to reduce the production of inflammatory mediators via cyclooxygenase (COX) inhibition. Flunixin meglumine is most often used and may be administered at higher doses (1.1 mg/kg IV or PO bid) in horses showing signs of discomfort or at lower doses to minimize side effects while taking advantage of antiinflammatory properties (0.25 mg/kg IV or PO q6-8h). Other NSAIDs such as phenylbutazone (2.2 mg/kg IV or PO bid) or COX-2 selective firocoxib (0.1 mg/kg IV or PO q24h) may be used in place of flunixin meglumine.

Lidocaine has gained considerable use as an antiinflammatory in recent years. Research demonstrated that horses administered lipopolysaccharide (LPS) intraperitoneally and treated with lidocaine (1.3 mg/kg IV bolus followed by CRI 0.05 mg/kg/min) had significantly lower clinical scores of endotoxemia and lower concentrations of plasma and peritoneal TNF-α compared with those receiving saline.[21]

Therapy targeted at binding and inactivating endotoxin includes the administration of hyperimmune plasma, endoserum, and polymyxin B. Polymyxin B (3000 to 6000 IU/kg IV bid) has been demonstrated to effectively bind circulating endotoxin; however, there is a risk of nephrotoxicity and its use is cautioned in cases with azotemia or preexisting renal insufficiency. The pathophysiology and therapy for endotoxemia is discussed in depth elsewhere in this chapter.

ANTHELMINTICS. Peritonitis may develop in association with intestinal cyathostomiasis or verminous arteritis secondary to *Strongylus vulgaris* migration; therefore, anthelmintic administration is recommended in cases with a high suspicion or poor deworming history. Traditionally, fenbendazole (15 mg/kg PO for 5 days) or ivermectin (0.2 mg/kg PO) is recommended following stabilization of the peritonitis patient; however, resistance has been reported. Alternative deworming protocols may include administration of moxidectin (0.4 mg/kg PO) or oxibendazole (10 mg/kg PO for 3 days).

SURGICAL MANAGEMENT. Surgical intervention in peritonitis may be indicated to identify and correct the underlying cause, particularly when leakage or compromise of the intestinal or urogenital tracts is suspected. Occasionally, intraabdominal abscesses may be identified on ultrasound which could be drained via catheter or marsupialization. Peritoneal lavage and drainage should also be considered based on peritoneal fluid analysis and is recommended when total nucleated cell counts exceed 100,000 cells/μL. The benefits of lavage and drainage include (1) reduction of bacterial numbers and concentrations of inflammatory mediators, (2) removal of foreign debris from the peritoneal/serosal surfaces, and (3) dilution of adhesion-promoting substances. Horses treated with peritoneal lavage must be monitored for dehydration, protein loss, and electrolyte imbalances. Complications associated with peritoneal drains include visceral puncture during insertion, ascending infection, subcutaneous leakage and edema, and herniation of intestine or omentum through the drain.[22]

Several techniques for peritoneal lavage and drainage have been described elsewhere, including the placement of ventral midline catheters in the standing horse, the use of active intraabdominal systems, and open peritoneal drainage.[18,23,24] Briefly, standing intraabdominal catheters may be placed aseptically under ultrasound guidance by insertion through the skin, subcutaneous tissues, and external muscle layers at ventral midline, then secured in place using a purse-string and several half-hitches. Foley, mushroom, or thoracic catheters may be used and should have numerous fenestrations, which are maintained within the body wall at all times to minimize leakage of fluid into the surrounding tissues. Catheters are then either allowed passive drainage and connected to a Heimlich valve, or connected to an active-drain system, to prevent ascending contamination.

Balanced, polyionic solutions with a neutral pH are used to lavage the abdomen. Antibiotics, antiseptics (povidone-iodine), and heparin have been suggested as additives to the lavage solution; however, no controlled studies have been performed to demonstrate any benefit. Severe inflammation of the peritoneal surfaces has been reported following the use of 3% or greater povidone-iodine lavage solutions. Peritoneal lavage is performed by allowing 10 to 20 L of solution to enter the abdomen via gravity flow through the ventral catheter. The catheter is then clamped and the patient walked for 10 to 20 minutes to encourage distribution of the lavage fluid after which the clamp is removed and fluid drained. This is repeated 1 or 2 times daily for 3 to 5 days or until fluid analysis normalizes.

A retrospective evaluation of 67 horses receiving active intraabdominal drainage following celiotomy found a high incidence of minor complications (49%), including obstruction of the drainage system, leakage of fluid around the system, and subcutaneous fluid accumulation. Further, the incidence of incisional infection in this group was higher (32%) compared with the control group (23.5%); however, this was attributed to the severity of the primary condition for which the patients had undergone surgery.[24]

Although open peritoneal drainage is preferred in humans and is reported to be successful in management of dogs and cats with peritonitis, this method has not been promoted in horses. In an experimental study, horses with induced peritonitis receiving open drainage therapy using a plastic mesh sutured at the ventral abdominal wall had a significantly increased inflammatory reaction at the linea alba compared with those that were closed routinely. Further, all horses in the open drainage group developed incisional infections following removal of the mesh.[23]

ADHESION PREVENTION. Development of intraabdominal adhesions has a significant impact on long-term outcomes for horses with septic peritonitis. Systemic administration of antimicrobials, dimethyl sulfoxide, and flunixin meglumine has been promoted to reduce adhesion formation by decreasing peritoneal inflammation.[25] In addition, the systemic administration of heparin (20 to 40 IU/kg SC q8h) has been advocated for up to 72 hours in horses at risk of adhesion development or coagulopathy.[25] Heparin acts to decrease fibrin formation through its inhibition of thrombin.

Various intraperitoneal therapies have been evaluated in horses for the prevention of adhesions. Abdominal lavage, both intra- and postoperatively, has demonstrated benefit in reducing the incidence of adhesion formation in horses undergoing exploratory celiotomy and those with peritonitis.[22,24] Introduction of heparin directly into the peritoneum during abdominal lavage may be beneficial, with dosages of 20,000 IU recommended[26]; however, studies evaluating the effects of concurrent systemic and local administration on systemic coagulation have not been reported in the horse. Intraperitoneal administration of recombinant tPA and 0.4% sodium hyaluronate has been shown to decrease adhesion formation; however, these are

VetBooks.ir

currently cost prohibitive in clinical cases.[25] The use of 1% sodium carboxymethylcellulose (2 L throughout the abdomen and applied to intestinal surfaces intraoperatively) has the most dramatic impact on adhesion formation, significantly decreasing the incidence of adhesions in experimental horses and associated with a decreased risk of death compared with untreated horses.[27,28] In a study of 203 clinical cases, 75% of horses receiving sodium carboxymethylcellulose during surgery survived to 180 days compared with 75% of untreated horses surviving to 8 days postoperatively.[28]

Prognosis Prognosis depends on the cause, severity, duration, and complications associated with peritonitis. Prognosis is poorest for those horses suffering from gastrointestinal perforation or rupture and best for horses with peritonitis associated with *A. equuli*. In two recent retrospectives, short-term survival was 86% (56 of 65) and 78% (43 of 55); however, both of these studies excluded horses diagnosed with gastrointestinal rupture.[2,3] Another retrospective evaluation of 67 cases, including those with gastrointestinal rupture, demonstrated a higher mortality rate (40%).[5] In that study, serum creatinine levels, anion gap, and pH at the time of presentation were significantly different between survivors and nonsurvivors; however, more recent research has not confirmed these findings. Celiotomy was found to have a negative impact on survival, with an odds ratio of 9.87 for nonsurvival in cases undergoing exploratory within 2 weeks of diagnosis or as a part of the treatment for peritonitis.[3]

Complications are not uncommon, occurring in 40% (22 of 55) of cases, and can have a negative impact on long-term survival.[2,3] Reported complications include thrombophlebitis, ileus, diarrhea, drain site complications, intraabdominal adhesions, and laminitis. Monitoring and prophylactic therapy for these conditions may help reduce their impact on outcome. With early diagnosis, correction of the inciting cause, aggressive medical therapy, and peritoneal lavage, a fair-to-good prognosis can be given in acute cases of septic peritonitis in the horse.

Actinobacillus Peritonitis

A subset of peritonitis attributed to *A. equuli* infection has been reported among horses in Australia, New Zealand, and North America. Infection is generally thought to be secondary to translocation of the bacteria from the gastrointestinal tract or associated with *Strongylus* migration; however, the exact origin is unknown.[29-31] Horses present with symptoms of mild to moderate colic (60%), tachycardia (94%), tachypnea (90%), decreased to absent borborygmi (88%), and elevated rectal temperature (77%). A chronic form of the disease with a history of progressive weight loss is also reported. A poor deworming history was noted in 9 of 18 horses tested having elevated numbers of strongyle ova on fecal examination.[29,30]

As with other causes of peritonitis, hemoconcentration, an absolute left shift, and hyperfibrinogenemia are common. In addition, peritoneal fluid cell counts are markedly increased—100,000 cells/μL in 88% of samples (46,000 to 810,000/μL)—and protein is elevated in 98%. In contrast to other cases of peritonitis, cytologic findings are characterized by a predominance of nondegenerate neutrophils, and pleomorphic gram-negative rods are identified in 53% of slides. In that report, a pure growth of *A. equuli* was obtained in 72% of cases.[30] These cases responded rapidly to antibiotic administration (100% short-term survival) and most isolates were sensitive to penicillin; however, it is recommended that therapy include penicillin/gentamicin or oral therapy with trimethoprim-sulfa until sensitivity results are available. Therapy should be continued for 7 days beyond return of peritoneal fluid analysis to normal values.

Presentation of horses with mild to moderate signs of colic, lethargy, elevated heart and respiratory rates, and marked elevations in peritoneal fluid protein and cell counts, which does not progress to endotoxemia or shock, and characterized by a rapid response to antimicrobial therapy sets peritonitis associated with *A. equuli* apart from other causes of peritonitis.

Hemoperitoneum

Hemoperitoneum is defined as the abnormal accumulation of blood within the abdominal cavity. Several recent retrospective case series have evaluated the causes, clinical presentation, and outcomes associated with the diagnosis of hemoperitoneum.[32-34] The various conditions diagnosed in horses presented with hemoperitoneum are summarized in Box 32-4. Clinical signs and prognosis depend on the cause and severity of the hemorrhage; however, most cases present with symptoms referable to abdominal discomfort/colic (78% to 79%) and hemorrhagic shock (60% to 85%), including tachycardia, tachypnea, pale mucous membranes, depression, weakness, and cool extremities.[33,34]

Antemortem diagnosis of hemoperitoneum is made based on the identification of hemorrhagic effusion within the abdominal cavity either by ultrasound or abdominocentesis. Characteristic swirling of echogenic fluid is noted on ultrasound in cases of intracavitary hemorrhage, and a specific origin of hemorrhage may be identified by ultrasound in 25% to 44% of cases.[33,34] Peritoneal fluid analysis confirms hemorrhage based on findings of packed cell volumes greater than 5%, elevated protein levels, and gross appearance. Hematology and biochemistry are often unremarkable; however, alterations in acid-base status, blood gas analysis, and plasma lactate concentrations reflect the severity of hemorrhagic shock.

Therapy for hemoperitoneum includes emergency stabilization of hemorrhagic shock, promotion of clot retention, and addressing the primary cause. Treatment of hemorrhagic shock includes conservative volume resuscitation with intravenous crystalloids, colloids, and blood transfusion (see the Fluid Therapy for Hemorrhagic Shock section in Chapter 44). Additional medications to support perfusion (inotropes, vasopressors) may also be indicated. Antifibrinolytics (aminocaproic acid at 3.5 mg/kg IV, conjugated estrogens at 25 to 50 mg/500 kg) are often administered to prevent breakdown of clots and help suppress continued hemorrhage.[35] Exploratory laparotomy

may have both diagnostic and therapeutic indications as the source of bleeding may be identified and corrected.[34] Abdominal drainage and lavage is often not performed in these cases, unless severe abdominal distention precludes allowing autotransfusion. Antimicrobial administration is indicated if bacterial contamination is likely in order to guard against development of septic peritonitis.

Prognosis for horses presenting with hemoperitoneum is guarded, with overall survival rates ranging from 39% to 74%, and depends greatly on the severity of hemorrhage, ability to control hemorrhage, and underlying cause.[32-34] Nonsurvival is associated with respiratory rates higher than 30 bpm, diagnosis of neoplasia (odds ratio 35.08), mesenteric vessel injury (OR 243.5), and uterine artery rupture (OR 13.72).[33] Idiopathic hemoperitoneum is associated with the best long-term survival outcomes.[34]

Gastrointestinal Ileus

L. Chris Sanchez • Guy D. Lester

A number of factors are responsible for movement of feed through the gastrointestinal tract, and disturbance to any of these can result in ineffective transit and signs of abdominal pain. Gastrointestinal motility involves an extremely complex interaction among the enteric nervous system, intestinal wall, and luminal contents. Other factors potentially influencing the transit of digesta include gravity, the volume and viscosity of intestinal contents, and pressure gradients created by simultaneous contraction and relaxation of adjacent bowel segments. The inhibition of propulsive bowel activity is usually referred to as *ileus*.

Several equine diseases and syndromes that likely involve altered gastrointestinal motility include postoperative ileus (POI), cecal emptying defect, gastroduodenal ulcer disease, simple bowel distention, intra- and extraluminal obstructions, peritonitis, and inflammatory bowel diseases (IBDs). Ineffective intestinal motility can also be a feature of several neonatal diseases, including prematurity, systemic sepsis, and neonatal encephalopathy, and can be found in postparturient mares. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify intestinal transit in horses of all ages. Intestinal motility is also disturbed by general anesthesia and sedation, especially with the α_2 receptor agonists.

Physiology of Intestinal Motility

The control of intestinal motility is complex and involves a combination of central innervation, autonomic innervation, and the enteric nervous system. Intestinal contractions are primarily controlled by the enteric nervous system and do not require extrinsic neural input. The inherent rhythmicity of electrical activity in the intestine is controlled by the interstitial cells of Cajal (ICCs). These are highly specialized cells that are electrically coupled to the smooth muscle syncytium via gap junctions.[1] ICCs are responsible not only for generation of slow waves (cyclical electrical activity) but also for coordination of pacemaker activity and propagation of slow waves along the intestine. ICCs appear to be critically involved in a range of motility disorders in human beings, including gastroparesis, pseudoobstruction, and chronic constipation.[1] In horses a reduction in ICC density has been demonstrated with equine grass sickness and other large intestinal diseases.[2,3] The inherent "excitability" of smooth muscle cells in response to stimuli varies among regions of the gastrointestinal tract and among species. This variability in cell excitability is dependent on the magnitude of the membrane potential, which in turn is regulated by the number and subtype of potassium channels.[4]

The enteric nervous system plays an important role in control and coordination of intestinal contraction. Contractile events are influenced by central and autonomic innervation, but external neural input is not required for contraction. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurons within each plexus integrates and amplifies neural input, and the intensity and frequency of resultant smooth muscle contractions are proportional to sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin, can be found within the enteric nervous system and on smooth muscle cells.[5] It is important to appreciate that mechanisms to slow progressive intestinal motility are also critical in order to retain feed for adequate digestion and absorption of nutrients. The terms *jejunal* and *ileal brake* have been used to describe the slowing of transit caused by mediators such as peptide YY, noradrenergic nerves, and opioid, serotonergic, and chemosensitive afferent neurons.[6]

Acetylcholine (ACh) is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscarinic type 2 (M_2) and M_3 receptors. Sympathetic fibers innervating the gastrointestinal tract are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of α_2-adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of ACh and therefore reduces intestinal contraction. The β_1, β_2, and β-atypical receptors are directly inhibitory to the intestinal smooth muscle.[7] Inhibitory nonadrenergic, noncholinergic (NANC) neurotransmitters include adenosine triphosphate (ATP), vasoactive intestinal peptide (VIP), and nitric oxide (NO).[8,9] These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a NANC neurotransmitter that may be involved in contraction of the small intestine and large colon.[10-12] The rate and force of intestinal contractions along the small intestine and large colon of the horse are key determinants of intestinal motility. Of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the small intestinal and colonic migrating motility complexes (MMC).[13] The colonic complex usually originates in the right ventral colon and variably traverses the ascending and descending colons. Many of these complexes are temporally related to a specialized motility event of the ileum known as the migrating action potential complex.

Mediators of Gastrointestinal Ileus and Major Disease Categories

Inflammation within the intestinal muscularis and inhibitory neural events are important initiators of intestinal ileus.[14,15] Intestinal inflammation is not only important in primary inflammatory intestinal diseases in horses, such as duodenitis–proximal jejunitis (DPJ) and colitis, but also induced after simple intestinal handling during laparotomy. Experimental data from other species suggest that handling of the small or large intestine at the time of surgery induces an intense inflammatory response within the muscularis and a reduction in the intensity of smooth muscle contraction.[15-17] Furthermore, the inflamed intestine fails to contract normally in response to putative prokinetic agents. Additional studies have identified that this inflammatory response was not restricted to segments that were manipulated at the time of surgery but also involved other regions throughout the gastrointestinal tract.[14] Intestinal handling in experimental animals causes local overproduction of NO because of the upregulation of inducible nitric oxide synthase (iNOS) by resident macrophages.[18] NO is a key inhibitory neurotransmitter of the NANC system.[9] Consequently, NOS inhibition could be an important target for prevention of ileus.

The inhibition of motility associated with peritoneal inflammation may also be mediated through neural reflexes. The afferent segment is partly composed of capsaicin-sensitive visceral afferent C-fibers that terminate in the dorsal horn of the spinal cord, where they can activate inhibitory sympathetic fibers or, alternatively, synapse directly on the sympathetic ganglia. Consequently, the efferent limb of the reflex expresses increased sympathetic outflow,

VetBooks.ir

primarily mediated through stimulation of α_2-adrenoreceptors, with subsequent inhibition of ACh release. This provides the rationale for α_2 blockade in the treatment of ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats.[19] This finding highlights the importance of visceral afferent fibers in the development of POI.

Ileus can also occur with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.[20,21] Excessive distention results in inhibition of motility within the distended segment of bowel. Intestinal stasis is not always detrimental and, under certain conditions, may be protective.

Endotoxemia is a feature of many diseases of the equine gastrointestinal tract, and endotoxins can independently exert a negative effect on intestinal motility and transit.[22] Various mediators are likely involved, but activation of α_2-adrenoreceptors and production of prostanoids appear to be important, as the inhibitory effects of experimental endotoxin infusion are ameliorated by pretreatment with yohimbine or NSAIDs (phenylbutazone or flunixin), respectively.[23,24] Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked that induced by handling during laparotomy.[25]

Cecal Emptying Defect (Cecal Impaction)

An important and specific motility problem involving the cecum occurs sporadically in adult horses and foals.[26-30] The pathophysiology of cecal emptying defect is not known. This syndrome may best mimic POI in humans, which is generally considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extraabdominal surgical procedures. General anesthesia is a potent inhibitor of gastrointestinal motility in horses, but the effects are short-lived and reversible within hours of anesthetic withdrawal.[31] The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.[32]

Retrospective data regarding cecal impactions suggest that two subtypes exist, and recent retrospective studies highlight those differences. In a United Kingdom report of 20 horses undergoing surgery because of cecal impaction, the condition appeared secondary to previous orthopedic (10 of 20) or colic (5 of 20) surgery in the majority of horses.[33] Short-term survival in that report was 65%, and all but 3 underwent cecal bypass. Alternatively, in a Texas report of 114 horses with cecal impaction, approximately half were treated medically and half surgically.[34] Of the horses allowed to recover from surgery, 95% survived to discharge, and typhlotomy alone was performed in 34 of 37 horses. Eighty-one percent of horses treated medically survived to discharge.[34] These reports appear to describe the two types of cecal impactions nicely, and the secondary (also called type II) impactions appear associated with cecal emptying defect and are therefore often categorized as a form of POI. In postoperative horses, cecal impaction was evident at a mean of 3.6 and 7.5 days following orthopedic and colic surgery, respectively.[33] The earliest detectable signs include lethargy and a reduction in appetite, fecal output, or both. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifest by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture, resulting in fatal peritonitis.

Postoperative Ileus

The most frequently reported form of ileus occurs after laparotomy and is termed *simple* or *uncomplicated postoperative ileus.* When intestinal motility is disturbed for longer periods after surgery, typically for more than 72 hours, the term *complicated* or *paralytic ileus* is used.[35] POI in horses is most commonly associated with surgery of the small intestine, particularly after resection and anastomosis. As stated previously, inflammation is likely a key mediator of POI. The true incidence of POI in horses undergoing laparotomy for gastrointestinal disease is difficult to determine because of variation in definition, surgical skill, and anesthetic technique. POI was reported as a complication in only 10% of horses that underwent laparotomy for a small intestinal lesion at one referral practice[36] but 27% in another.[37] In the latter study, horses with DPJ were included, but 30% of horses developed POI after small intestinal resection. In a multicenter study 47 of 251 (19%) horses undergoing laparotomy for acute colic including small and large intestinal disease developed POI.[38] As stated previously, the retrospectively collected POI data are extremely hard to interpret, and many mechanical obstructions and surgical complications can mimic POI[39]; thus, authors are encouraged to adopt uniform definitions of POI and make every attempt possible to distinguish POI from intestinal obstruction.[40]

POI can have a significant negative impact on short-term postoperative survival.[41-43] Motility dysfunction is likely present in all horses after laparotomy, but most cases are subclinical and require minimal intervention. In symptomatic animals, clinical signs are typically observed within 24 hours of recovery; these signs include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasound may reveal small intestinal distention with rare or absent wall movement. The severity and duration of intestinal stasis is variable, lasting from minutes to days.

The development of small intestinal POI, but not cecal emptying dysfunction, is influenced by the duration of surgery.[27,38] Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than in those that had a hand-sewn end-to-end procedure.[41] The duration of ileus after stapled end-to-end anastomosis was no different from that after either procedure.

Reported risk factors for the development of POI in horses include age (>10 years), small intestinal resection and anastomosis, breed, heart rate at admission, large volume (>8 L) reflux at admission, and duration of anesthesia and surgery.[37,38,43,44] Jejunocecostomy and side-to-side jejunojejunostomy have been associated with an increased risk of POI.[36,45] Pelvic flexure enterotomy and intraoperative and postoperative lidocaine infusion have been associated with a decreased incidence of POI.[38,43-45]

Miscellaneous Motility Disruptions

Other disruption of normal intestinal motility can occur in the horse. Many, but not all, are associated with analgesic or sedative drug administration. The inhibitory effects of α_2-adrenergic agonists, such as xylazine and detomidine, on intestinal motility in horses are well described.[46-54] The activation of postganglionic cholinergic nerves in the myenteric plexus by this class of drugs results in reduced ACh release from autonomic and enteric nerves. Intravenous xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. The α_2-antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, suggesting that normal motility is under constant α_2-adrenergic tone.[48]

Other analgesic medications can also decrease gastrointestinal motility. Opioids such as morphine have long been associated with decreased motility in humans.[55] Morphine has been shown to delay gastrointestinal transit and decrease gastrointestinal moisture content in the horse.[56,57] Butorphanol administered alone appears to reset the antroduodenal MMC without substantial negative effects on motility, but it will decrease duodenal motility when combined with xylazine above the effects of xylazine alone.[50,58] The role of selective or preferential μ- and κ-receptor agonists can vary in different regions of the equine gastrointestinal tract, in that κ-receptor agonists appear to have a more inhibitory effect in the jejunum whereas μ-receptor

VetBooks.ir

agonists appear to inhibit the large colon more significantly.[59,60] Ketamine has also been shown to increase total gastrointestinal transit in healthy horses.[61]

Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, individual small intestinal, cecal, and colonic contractions are inhibited for about 120 minutes, but small intestinal and colonic migrating complexes are suppressed for up to 8 hours.[62] The negative effect of atropine on gastrointestinal motility in the horse can also be evident with topical ophthalmic administration of atropine.[63] This effect, in combination with pain and other management factors, likely relates to the high reported risk of colic in horses hospitalized for ocular disease.[64]

Gastric and small intestinal ileus, with no identifiable mechanical or physical disruption to motility, has also been identified as a cause of acute colic in postparturient mares.[65] An apparent etiology for this condition has not been identified, but most mares responded well to decompression.

Diagnosis

The diagnosis of ileus is based on history and physical examination findings. Important tests include determination of pulse rate and rhythm, auscultation and percussion of the abdomen, rectal palpation, and passage of a nasogastric tube. A complete blood count (CBC) with fibrinogen estimation and cytologic analysis of peritoneal fluid may improve the accuracy of diagnosis. Affected animals may be colicky because of accumulation of fluid in the upper gastrointestinal tract (classical POI) or cecal contents (cecal emptying defect). Decompression of the stomach is important diagnostically and therapeutically in horses with POI after small intestinal surgery. Failure to relieve pain with gastric decompression could point toward mechanical obstruction, severe inflammation of the intestine, or peritonitis. Most animals with ileus are depressed and have reduced fecal output and intestinal borborygmi. Intestinal sounds should, however, be interpreted with caution, because the presence of borborygmi does not always equate to progressive intestinal motility and may merely reflect local, nonpropagated contractions. Rectal palpation findings in cases of persistent POI or DPJ are usually nonspecific but may reveal dilated, fluid-filled loops of small intestine. Roughened peritoneal surfaces can occasionally be palpated with peritonitis. Cecal distention with either firm or fluidy contents can be palpated in horses with cecal dysfunction.

It is important to distinguish functional ileus from mechanical obstruction. This can be extremely difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time. Distinguishing mechanical obstruction from POI is especially important, as horses with mechanical obstruction in the postoperative period may benefit from early repeat laparotomy.[39]

Treatment

Supportive care

The management of gastrointestinal ileus is dependent on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract typically involves a combination of gastric decompression, fluid and electrolyte therapy, and antiinflammatory drugs. Nasogastric decompression is the mainstay of management to prevent excessive distention of the stomach and small intestine. This often necessitates placement of an indwelling nasogastric tube, a procedure that some have speculated may in itself delay gastric emptying. The placement of an indwelling tube for 18 hours did not adversely affect the emptying of liquids, but in a recent study a delay was noted when the tube was left in place for 72 hours.[66,67] Both studies used apparently healthy animals.

Electrolyte balance is important, particularly with respect to maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of appropriate fluid replacement volume should include maintenance requirements (40 to 60 mL/kg/day) plus an estimate of losses, especially those lost through gastric decompression. Overhydration should be avoided. Whereas medical therapy with fluid replacement and antiinflammatory drugs may be helpful for horses with primary cecal impaction, surgical therapy is likely required for horses with secondary cecal emptying defect.[33,34,68] Surgical management may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[33,68] If affected horses survive postoperatively to discharge from the hospital, long-term survival appears good.[33]

A significant clinical or economic benefit of parenteral nutrition in adult horses with gastrointestinal disease has also yet to be demonstrated.[69-71] Parenteral nutrition should be considered when feed has been withheld for more than 96 hours, particularly in the horse with a surgical wound, increased metabolic demands, or risk of hyperlipidemia. Limited exercise, in the form of hand-walking, may provide some benefit to these animals, although there is no evidence that exercise has a direct impact on intestinal motility in either horses or humans with POI.[72]

The pivotal role of intestinal inflammation provides a strong rationale for the use of antiinflammatory drugs in affected animals. Flunixin meglumine is widely used in equine practice as an analgesic and antiinflammatory agent, and it also ameliorates many of the adverse systemic effects of endotoxin. A potential negative effect of NSAIDs on large intestinal contractility has been suggested on the basis of in vitro studies[73]; however, a similar response has not been reported in whole animal studies.[46,48,74] Novel antiinflammatory agents may play a role in the future, but they are not yet available for widespread use. For example, carbon monoxide (CO) has prevented POI in experimental animals, a benefit not only when CO was inhaled but also when CO was dissolved in a peritoneal lavage solution, making potential administration considerably easier and safer.[75] CO has potent intestinal antiinflammatory properties and is derived from the degradation of heme by the enzyme heme oxygenase. Expression of a heme oxygenase isoform (HO-1) can be induced by a variety of stimuli. The use of lidocaine will be discussed along with potential prokinetic drugs, but its primary benefits are likely associated with antiinflammatory effects.

Broad-spectrum antimicrobial drugs are indicated when sepsis is suspected or if the immune system is compromised, as in cases with moderate to severe endotoxemia. Theoretic concerns have been raised regarding the use of aminoglycoside antibiotics in animals with ileus. Inhibition of intestinal contractions occurred when sections of intestine were exposed to high concentrations of aminoglycoside antimicrobial drugs, but this inhibitory effect is unlikely to occur at clinically relevant doses.[76] The administration of benzyl penicillin and/or ceftiofur was associated with an increased risk of colic in the week after anesthesia for diagnostic imaging or nonabdominal surgical procedures.[77] Potassium penicillin appears to have a modest, positive effect on large intestinal motility and frequency of defecation in the horse.[78]

Motility Modification

Motility-modifying drugs could play an important role in the prevention and treatment of gastrointestinal ileus. An effective prokinetic agent could shorten the length of hospitalization, thereby reducing the cost of treatment and the number of potential complications such as weight loss, thrombophlebitis, and laminitis. There is also evidence that the development of abdominal adhesions could be minimized with the use of an effective prokinetic drug.[79,80] A potential negative impact of prokinetic use in the postoperative period after anastomosis is increased predisposition to dehiscence.[81]

Most motility-modifying drugs require a healthy intestinal wall in order to enhance intestinal contraction. There are several examples in horses in which the expected contractile response to certain drugs is blunted in the face of disease. It is reasonable to assume that many putative prokinetic drugs would be partially or

VetBooks.ir

totally ineffective in horses with abdominal disease. This would include intestine that has undergone prolonged or excessive distention or that is in any inflammatory condition, such as after intestinal manipulation or associated with primary inflammatory diseases such as DPJ or *Salmonella* enteritis. Numerous drugs have been investigated in humans with POI, but currently there is no prokinetic agent that has been found to be safe and effective.[82] The financial pressures associated with equine patient management often compel attending veterinarians to experiment with a range of putative prokinetic drugs.

Lidocaine, an aminoamide local anesthetic, appears to be the most commonly used putative prokinetic agent in the management and prevention of POI.[83] Intravenous infusion of lidocaine may suppress primary afferent neurons, thereby limiting reflex efferent inhibition of motility. It is also possible that lidocaine may block the inhibitory effect of NANC neurotransmitters on smooth muscle.[84] Lidocaine also has significant antiinflammatory properties, including amelioration of the cytokine response to endotoxemia, reduced neutrophil free-radical production, impaired leukocyte phagocytic function, and inhibition of leukocyte migration through suppression of chemokines.[85,86] In addition, lidocaine has been shown to decrease, relative to untreated controls, clinical scores following experimental endotoxin administration in healthy horses.[86] Lidocaine administration can also ameliorate the inhibitory effects of flunixin meglumine on jejunal mucosal barrier recovery following ischemia.[87,88] Because systemic administration of lidocaine was shown to increase somatic thermal antinociceptive, but not visceral distention, threshold, the beneficial effect of lidocaine in horses with gastrointestinal disease may not be associated with analgesia.[89]

A combination of intraoperative and postoperative lidocaine infusion is commonly used as a preventive strategy against POI. Postanesthetic treatment typically involves a slow intravenous bolus of 2% lidocaine (1.3 mg/kg) followed by a constant infusion at 0.05 mg/kg/min for 24 hours, with a target serum concentration between 1 and 2 mg/dL. In a prospective study of horses undergoing laparotomy for colic, the authors failed to demonstrate any difference between lidocaine and saline infusion with respect to return of borborygmi, time to first feces, or gastric reflux.[90] The study was limited by a low incidence of small intestinal strangulating lesions and POI. Lidocaine infusion was associated with a reduction in reflux duration, time to fecal passage, and hospital stay for survivors in a study of 32 horses with POI or DPJ.[84] In a larger retrospective study of 126 horses undergoing surgery for small intestinal colic, lidocaine administration was associated with a reduced incidence of POI and increased short-term survival.[43]

The rate of lidocaine infusion requires close monitoring, because infusion can be associated with reversible side effects that include muscle fasciculations, ataxia, and seizure. The drug is highly protein-bound, so hypoproteinemic horses may be more susceptible to signs of toxicity.

Bethanechol is a methyl derivative of carbachol and is an ACh receptor agonist. The drug acts both at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. The actions are primarily mediated through activation of M_3 receptors, although M_2 receptors are also involved to a lesser extent.[91] There is evidence in other species that activation of M_2 receptors not only facilitates intestinal contraction but also may lead to antinociception.[92] Bethanechol is not degraded by the enzyme anticholinesterase. As anticipated, the drug has a range of cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered subcutaneously at 0.025 to 0.05 mg/kg of body weight. Bethanechol is one of the most useful prokinetic agents in equine practice, as it exerts effects throughout the gastrointestinal tract; however, it does not appear to be commonly used.[83] It is most commonly used in the management of delayed gastric emptying and slowed small intestinal transit. Experimentally the drug has been shown to significantly increase gastric contractility and hasten the emptying of liquid and solid phase markers from the stomach of normal horses.[93] The drug has potent effects in the hindgut as well. Bethanechol increases both the relative strength and duration of wall contractions in the cecum and right ventral colon and consequently speeds up cecal emptying.[48] When given to ponies at a dose of 0.05 mg/kg SC, the drug increased electrical activity in the large colon for approximately 80 minutes.[74] There are wide ranges in reported dose rates of bethanechol, with the most commonly recommended dose range from 0.025 to 0.05 mg/kg SC.

Neostigmine increases receptor levels of ACh by inhibiting cholinesterase. The drug (0.022 to 0.025 mg/kg IV) promotes cecal and colonic contractile activity and enhances cecal emptying in normal ponies.[48] Neostigmine has been used in the management of small intestinal ileus but significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.[57] A survey of prokinetic use indicated that neostigmine was more commonly used in the management of large intestinal disease.[83]

Metoclopramide is a moderate partial 5-hydroxytryptamine 4 (5HT-4)–receptor agonist, a moderate 5HT-3-receptor antagonist, and an antagonist of both dopamine 1 (DA_1) and 2 (DA_2) receptors. It has been suggested that the 5HT-4 agonist properties are primarily responsible for the prokinetic effects of metoclopramide. Antagonism of prejunctional DA_2 receptors facilitates ACh release and smooth muscle contraction. The effect on dopamine receptor antagonism is absent in newer benzamides. Metoclopramide crosses the blood-brain barrier, where its antagonist properties on central DA_2 receptors can result in extrapyramidal signs, including seizure. These have been observed when the original reported dose of 0.25 mg/kg, given by intravenous infusion over 30 minutes, was used in practice.[94] These signs were responsible for poor acceptance of the drug in equine practice. An experimental bolus of endotoxin caused a delay in gastric emptying, as assessed using the acetaminophen absorption test; this delay was partially ameliorated through pretreatment with metoclopramide (0.125 mg/kg in 1 L infused over 15 minutes), but again the investigators reported adverse side effects.[95] Most investigators have failed to demonstrate significant effects of metoclopramide in experimental animals, but constant intravenous infusion (0.04 mg/kg/h) in a population of postoperative horses significantly decreased the volume and duration of gastric reflux over control and intermittent drug infusion groups.[96] Infusion was well tolerated and was superior to intermittent infusion or no treatment at all.

Cisapride is a second-generation benzamide that is commonly reported to act as a primary 5HT-4 agonist and 5HT-3–receptor antagonist. Furthermore, stimulation of 5HT-4 receptors within the enteric nervous system enhances release of ACh from the myenteric plexus, thereby promoting intestinal contraction. In vitro studies of equine jejunum concluded that the contractile actions of cisapride in the species were primarily mediated through 5HT-2 and not 5HT-4 receptors and that the response was noncholinergic.[97] Several reports suggest efficacy of cisapride in the management of intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and prevention of POI in horses after small intestinal surgery.[98-101] Cisapride has the potential to cause adverse cardiac side effects mediated through blockage of the rapid component of the delayed rectifier potassium current that include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia. These adverse effects have resulted in drug withdrawal in the United States and in many other countries.

Another benzamide, mosapride, resulted in increased myoelectric activity of the small intestine and cecum of horses after oral administration. The authors reported that mosapride is a selective 5HT-4 agonist; consequently, the reported effects are surprising given that the actions of 5-HT on the equine jejunum were reported to be primarily mediated through activation of 5HT-2 and 5HT-3 receptors.[97] Further work has demonstrated increased gastric emptying, jejunal and cecal motility following mosapride administration (2 mg/kg PO) to healthy horses.[102] Mosapride (1.5 mg/kg PO) was also shown to increase electrointestinography maximum amplitude within the

VetBooks.ir

small intestine, relative to untreated controls, following jejunocecostomy in normal horses.[103]

Tegaserod, a selective 5-HT4–receptor agonist, is used in humans for the treatment of irritable bowel syndrome.[104] In horses, tegaserod has been shown to decrease total gastrointestinal transit time[105] and increase pelvic flexure contractile activity in vitro.[106,107] Tegaserod appears safe when administered orally to horses, and therapeutic plasma concentrations, based on in vitro work, were obtained after administration of a single dose orally at 0.27 mg/kg.[106]

Domperidone acts as a competitive antagonist at peripheral DA_2 receptors; these receptors are inhibitory. The drug has been used to manage gastroparesis in humans for many years.[108] The primary use in equine practice is in the management of mares grazing endophyte-infected tall fescue (1.1 mg/kg/day PO), principally because of drug-enhanced prolactin release from the anterior pituitary. The potential prokinetic effects of domperidone have not been extensively studied in horses, but a modest efficacy of domperidone (0.2 mg/kg IV) was demonstrated in a model of experimental ileus in two ponies.[109]

Erythromycin is a direct motilin receptor agonist acting directly on smooth muscle cells as well as within the enteric nervous system to facilitate the release of ACh and motilin. Erythromycin enhances gastric emptying in normal horses but, in contrast to most other species, has a more pronounced effect on the hindgut.[93,110] This is somewhat surprising given that a higher density of motilin receptors was reported in the duodenum than in either the cecum or pelvic flexure of the adult horse.[111] Erythromycin lactobionate (1 mg/kg IV) hastens cecal emptying in normal animals and induces propagating colonic MMC-like activity across the colon. Administration is often associated with defecation and abdominal discomfort. Several problems limit the use of erythromycin as a prokinetic agent in equine practice. The principal use in human medicine has been restricted to management of acute exacerbations of diabetic gastroparesis, facilitation of feeding tube placement, and upper gastrointestinal endoscopy.[112] Although it has been shown to enhance emptying in normal horses, it was not as effective as bethanechol.[93] Given its potent prokinetic effects in the cecum, erythromycin may be helpful at preventing cecal impaction in horses after anesthesia. However, its effectiveness on cecal motility appears to be markedly reduced in the immediate postoperative period.[32] High doses, constant infusion, or prolonged use of erythromycin also induces receptor tachyphylaxis and therefore reduced efficacy. There is also evidence that as little as 2 hours of intraluminal distention leads to a reduction in the total number of motilin receptors and in the amount of motilin receptor mRNA, although erythromycin binding to remaining motilin receptors is not affected.[113] Erythromycin can induce diarrhea in adults; therefore administration over many days should be avoided. The diarrhea induced by erythromycin is most likely mediated by *Clostridium difficile* overgrowth and toxin elaboration.[114]

Given that opiates have an inhibitory effect on normal intestinal motility, it is not unreasonable to assume that antagonists may have the potential for prokinetic activity. Naloxone (0.05 mg/kg IV) has been shown to induce contractile activity in the cecum and left colon.[115] The administration of naloxone was often followed by defecation within 15 to 20 minutes. Naloxone has not been beneficial in preventing POI in human beings.[116] Peripherally acting opioid antagonists, such as *N*-methylnaltrexone (MNTX), can improve gastrointestinal tract function in humans requiring opioids for pain management. An in vitro study reported a direct contractile effect of MNTX on the circular muscle layer of the jejunum and large colon.[117] In healthy horses, MNTX administration increased daily fecal weight and, when administered concurrently with morphine, partially prevented morphine-associated increases in intestinal transit time and decreases in fecal production.[118]

α_2-Adrenoreceptor antagonists, such as yohimbine and tolazoline, counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine (75 µg/kg by slow intravenous infusion) hastens cecal motility and emptying in normal ponies and also attenuates the negative effects of endotoxin on motility.[23,48]

Prevention and Early Identification

Close monitoring is essential when horses have multiple risk factors for either POI or other forms of ileus, such as administration of opioid agonists, α_2-adrenergic agonists, and atropine, either alone or in combination. Monitoring fecal output closely can often help owners and practitioners identify horses developing impaction, thus allowing for early medical therapy. Similarly, close postoperative monitoring and gastric decompression is important for early detection of POI.

For horses at risk of cecal impaction or other miscellaneous motility disorders, limiting the number of drugs likely to inhibit motility and altering the diet to include increased water consumption and decreased bulk may be beneficial.

Nonsteroidal Antiinflammatory Drug Toxicity

Samuel L. Jones

Use of nonsteroidal antiinflammatory drugs (NSAIDs) is common in equine practice because of their antipyretic, analgesic, and antiinflammatory properties. These drugs are used to treat horses with colic, endotoxemia, musculoskeletal disorders, and other medical problems. In addition to these therapeutic properties, NSAIDs also exhibit unwanted toxic side effects. NSAIDs have a relatively narrow therapeutic range, and when they are administered at excessive doses, toxicosis can occur within a few days. Although generally safe when administered at recommended doses,[1] some horses may exhibit signs of toxicosis at these doses within days or weeks.[2,3] The risk of toxicity is exacerbated in animals that are dehydrated or septic (e.g., endotoxemic patients). Recommended doses for NSAIDs commonly administered to horses include the following:

- Phenylbutazone, 2.2 to 4.4 mg/kg IV, PO q12h
- Flunixin meglumine, 1.1 mg/kg q12h or 0.25 mg/kg IV, PO q8h
- Ketoprofen, 2.2 mg/kg IV q24h
- Naproxen, 5 to 10 mg/kg IV, PO q12-24h
- Aspirin, 12 to 25 mg/kg PO q12-48h
- Meloxicam, 0.6 mg/kg IV q24h
- Firocoxib, 0.1 mg/kg PO q24h, 0.09 mg/kg IV q24h

Pathophysiology and Predisposing Factors The principal mechanism of the therapeutic and toxic effects of NSAIDs is related to their inhibition of prostaglandin synthesis by inhibition of the cyclooxygenase (COX) enzyme. Two isoforms of the COX enzyme have been identified: COX-1 and COX-2.[4] COX-1 is generally constitutively expressed and is thought to play an important role in maintaining physiologic homeostasis; it is found in such tissues as the gastrointestinal mucosa and kidney and in the endothelium and platelets. In contrast, COX-2 is primarily an inducible enzyme that has a critical role in inflammation and is produced by a variety of cells, including monocytes, neutrophils, epithelial cells, fibroblasts, synoviocytes, and chondrocytes.

It has been postulated that drugs that nonselectively inhibit both COX-1 and COX-2 have greater toxic potential because they inhibit prostaglandins necessary for physiologic homeostasis as well as prostaglandins that mediate inflammation and pain.[4] Both COX-1– and COX-2–dependent prostaglandins play an important role not only in maintaining the epithelial barrier in the gut but also in healing the epithelium when the mucosa is damaged (e.g., because of ischemic injury or infection). Most of the commonly used NSAIDs in horses are considered to be nonselective. Exceptions include meloxicam (3.8 to 10 times more selective for equine COX-2 versus COX-1[5,6]) and firocoxib (268 to 643 times more selective for COX-2 than for COX-1[7]). NSAIDs that are COX-2 selective are less ulcerogenic in other species and may be so in horses. For example, COX-2 selectivity

VetBooks.ir

decreases the adverse effects of NSAIDs in a model of epithelial repair in horses.[8]

Although the COX-1 versus COX-2 scheme is currently considered valid, evidence exists that it may be overly simplistic. For example, COX-1 may play an important role in inflammation and is at least partly inducible.[9] In contrast, COX-2 can be induced physiologically in various organs and tissues and by stimuli other than inflammation.[4,10] In horses, gastric ulcerogenicity of even the nonselective NSAIDs varies (phenylbutazone > flunixin meglumine > ketoprofen).[11] This difference in toxicity among drugs may relate not only to the COX selectivity but also to other factors such as tissue distribution.

The gastrointestinal tract and the kidneys are the most common targets for NSAID toxicity. NSAID-induced injury can develop anywhere in the gastrointestinal tract (from the mouth to the rectum). Two well-recognized syndromes may be attributed, at least in part, to NSAID toxicity. The first is gastric ulceration. In the stomach, inhibition of COX can increase acid secretion, decrease output of mucus and bicarbonate, impair vasodilation, and diminish epithelial restitution, cell division, and angiogenesis.[12] Inhibition of COX also impairs the healing of existing ulcers. A second syndrome attributed to NSAID toxicity is right dorsal ulcerative colitis (RDUC). Although the right dorsal segment of the large intestine is most commonly affected, other segments may also be involved. Ulcerative lesions in the large intestine can be particularly troublesome because they can cause chronic debilitation, are difficult to diagnose, and can be refractory to treatment. In the kidney, prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2) produce vasodilation in the autoregulatory response of renal blood flow to hypoperfusion; consequently, hypovolemia, hemorrhage, or renal disease will increase the risk of renal NSAID toxicosis. Damage is greatest at the renal crest (papilla), and papillary crest necrosis may be associated with subsequent nephrolithiasis or ureterolithiasis and chronic renal failure.[13] In humans the most common side effect of NSAIDs is bleeding, caused in part by reduced function of platelets and in part by gastrointestinal hemorrhage.

Not all of the adverse effects of NSAIDs are attributable to COX inhibition. The NSAIDs also cause injury from a variety of mechanisms, including microvascular damage, increased intracellular concentration of reactive oxygen and other free radicals, direct local injury (particularly with ion trapping in the stomach), inhibition of cell division, and reduced hydrophobicity of the gastric mucous coat.[10,12] Inhibiting COX may shunt arachidonic acid metabolism toward the lipoxygenase pathway, thereby producing other biologically active eicosanoids. The clinical significance of this shunting is unclear, but the potential for deleterious effects exists.

Although the toxicity of NSAIDs is related to the dose and duration of administration, some horses develop toxicosis at recommended doses. Predisposing factors such as dehydration, renal disease, hepatic disease, or sepsis may contribute to the development of NSAID toxicity. Dehydration, renal disease, and hepatic disease predispose to NSAID toxicosis because of reduced tissue perfusion and reduced drug elimination. Sepsis may predispose to NSAID toxicosis because of secondary hypovolemia, decreased tissue perfusion, and direct and indirect effects of various mediators produced in response to sepsis (e.g., platelet aggregating factor). In humans, risk of NSAID-induced ulceration is increased among those with various gastrointestinal disorders (e.g., inflammatory bowel diseases [IBDs]). NSAIDs inhibit the ability of injured equine intestinal mucosa to repair, which may increase the risk of ulceration in horses with ischemic damage or intestinal infections. Body weight may be a predisposing factor in that NSAIDs are often administered to ponies, miniature horses, and small horses at doses higher than those recommended for their body weight. Inadvertent overdosing can occur regardless of body weight or size (e.g., administration of a 12-g tube of phenylbutazone paste when administration of an anthelmintic paste was intended).

Some horses may have an idiosyncratic predisposition, particularly for ulceration of the right dorsal colon. Experimentally, arthritic laboratory animals were more susceptible to NSAID-induced gastropathy than were healthy animals.[14] This finding may have relevance to horses because NSAIDs are often administered to chronically lame horses. Two or more NSAIDs are used concurrently in some situations. It is important to recognize that the effects of combining NSAIDs are additive, such that administering two NSAIDs at each of their recommended doses is similar to giving twice the recommended dose of one NSAID. Combination of two NSAIDs will prolong their pharmacologic effect and increase the risk of toxicity.[15]

Clinical Signs

Clinical signs of NSAID toxicity are usually referable to the alimentary system and vary depending on the segment involved. Oral or lingual ulceration may lead to difficulty in prehension and mastication. Esophageal ulceration may result in excessive salivation and apparent signs of pain (stretching of the neck, groaning) during swallowing. Gastric ulceration may result in slow consumption of feed, inappetence (particularly for grain in some horses), or anorexia. Horses that have gastric outflow obstruction associated with gastroduodenal ulceration may exhibit ptyalism, reflux esophagitis, and, in severe cases, spontaneous nasogastric reflux. Horses with ulceration anywhere in the gastrointestinal tract may exhibit signs of colic, which may be intermittent and may vary in severity. Horses with colonic ulceration may have soft stool or diarrhea and ventral edema secondary to enteric protein loss. Diarrhea can be severe, even fatal. Endotoxemia may result from intestinal mucosal damage caused by NSAIDs. Clinical signs of endotoxemia (e.g., tachycardia, altered appearance of mucous membranes, fever, and dehydration) may be seen in some horses with NSAID enteropathy. In some horses, hematuria may be seen.

Horses may have clinical signs days to weeks after having been administered NSAIDs. Such horses typically are presented because of recurring colic, weight loss, or loose manure. It is particularly important in these horses to determine whether there is any history of NSAID administration, even if it was several weeks previous to the time of presentation.

Diagnosis

Diagnosis is usually made on the basis of history of NSAID use, clinical signs, and clinicopathologic findings. The most consistent clinicopathologic abnormalities in horses with NSAID toxicosis are hypoproteinemia and hypoalbuminemia, presumably from loss of protein through inflamed and/or ulcerated intestinal mucosa. These findings are more commonly observed with damage to the distal intestinal tract and are not reliable for diagnosis of NSAID gastropathy. Some horses have decreased serum concentration of calcium, presumably attributable to intestinal loss of protein-bound calcium. In horses with NSAID-induced diarrhea, hyponatremia, hypochloremia, hypokalemia, acidemia, and hypovolemia may be observed if the diarrhea is severe. In such cases, hypovolemia may make the serum protein concentration appear to be higher than its actual value would be were the horse adequately hydrated.

In chronic cases, horses may be anemic from inflammation, intestinal loss of blood through ulceration, or reduced function of platelets. Occult blood may be found in the feces of horses with lesions in the more distal portions of the intestinal tract. Tests for occult blood often lack sensitivity, and false-positive results may be expected for up to 24 hours after rectal palpation.

The concentration of leukocytes is usually within the reference range, although leukocytosis and hyperfibrinogenemia, associated with inflammation, and leukopenia and neutropenia, presumably caused by endotoxemia, can be seen in some horses with acute NSAID toxicosis affecting the distal intestine. Generally, results of peritoneal fluid analysis are within reference ranges, but increased concentration of nucleated white blood cells (WBCs), total protein, and fibrinogen may be seen when there is advanced intestinal damage or intestinal vascular infarction. When findings of cytologic examination of peritoneal fluid are abnormal, results are more consistent with nonseptic than septic inflammation; however, septic

VetBooks.ir

inflammation may be observed when severe intestinal ulceration leads to transmural lesions and septic peritonitis.

Several clinicopathologic changes may accompany NSAID-induced renal damage. The most consistent finding is decreased urine specific gravity, from 1.008 to 1.020. Inability to properly dilute urine can be found with acute NSAID toxicosis for years after the original insult. This results from preferential damage to areas of the kidney that contribute most to concentrating urine (medulla, papilla). In chronic cases urine specific gravity typically ranges from 1.013 to 1.020. Some horses with NSAID toxicosis are azotemic. In acute cases azotemia can result from dehydration, NSAID-induced alterations in renal blood flow, and tubuloglomerular feedback mechanisms. Chronic azotemia, with serum creatinine ranging from 2.1 to 3.5 mg/dL, results from tubuloglomerular feedback mechanisms that reduce glomerular filtration to compensate for reduced reclamation of solutes in the medullary collecting ducts. In acute NSAID toxicosis, there may be overt hematuria. In other cases, urinalysis may reveal occult blood, increased renal cells, and increased WBCs. In chronic cases other than decreased urine specific gravity, urinalysis results are typically normal.

Endoscopy can be useful to visualize the location and extent of esophageal and gastric lesions. NSAID-induced gastric lesions are more common in the glandular epithelium, although nonglandular lesions can be observed. Contrast radiography or scintigraphy may be useful to document delayed gastric emptying in some horses. Lesions of the jejunum, ileum, cecum, and colon can be difficult to identify without celiotomy and enterotomy. Isotope-labeled WBC scintigraphic scans may identify colonic ulceration[16]; the sensitivity and availability of the procedure is limited, however. Ultrasonography may reveal thickening of the right dorsal colon or other colonic segments, but the technique appears to lack sensitivity.[17] Horses with renal crest necrosis may have increased ultrasonographic echogenicity of the renal crest and echogenic debris in the renal pelvis.

Management Administration of NSAIDs should be discontinued if NSAID toxicosis is suspected. Gastric lavage and administration of 1 gallon of mineral oil per 450 kg of body weight via nasogastric tube may be of benefit in horses with acute NSAID overdose to reduce the absorption of the administered NSAID. Treatment for gastric ulceration with a proton-pump inhibitor (e.g., omeprazole [GastroGuard, Merial Ltd., Iselin, N.J.]), an H_2-receptor blocker (e.g., ranitidine), and/or sucralfate should be implemented for horses with gastric ulceration. Sucralfate (10 to 20 mg/kg PO q8-12h) may also have a benefit in more distal segments of the equine intestine affected by NSAID toxicity. Sucralfate reduced ulceration in the stomach, small intestine, and colon and reduced protein loss in weanling age horses treated with an overdose of phenylbutazone.[18]

Regardless of the site of NSAID toxicity, administration of PGE analogs or mimics may be of benefit because administration of a synthetic analog of PGE_2 has been demonstrated to prevent phenylbutazone-induced gastrointestinal lesions in horses.[19] Misoprostol, a synthetic analog of prostaglandin E_1, ameliorated the effect of flunixin and promoted repair in vitro of equine intestinal mucosa damaged by ischemia.[20] Misoprostol can be administered orally starting at doses of 5 µg/kg q12h or 2 µg/kg q6h. Some horses will develop signs of abdominal discomfort or diarrhea at these doses; another protocol is starting at 1.5 µg/kg q8h for 2 to 4 days and increasing at increments of 0.5 µg/kg q8h every 2 to 4 days until a maintenance dose of 2.5 to 3 µg/kg q8h is achieved. Because of the paucity of experimental and clinical data for this drug, dosage schedules should be individually tailored for the horse's illness and tolerance to the drug.

For horses with hypovolemia secondary to colitis, administration of crystalloid fluids is indicated. Infusion of plasma may benefit horses with NSAID-induced enteropathies and signs of endotoxemia. The aim of plasma transfusion in a hypoproteinemic horse with colitis need not be to increase the plasma concentration into the reference range, because this may be cost-prohibitive and infused protein may be rapidly lost via the intestinal tract. Smaller volumes of plasma (1 to 3 L in an average-size horse) may exert beneficial effects by increasing colloid oncotic pressure and perhaps by modulating the effects of endotoxemia. Alternative colloidal fluids may be beneficial as well. Hetastarch (5 to 10 mL/kg IV q48-72h) may maintain plasma colloid oncotic pressure in the acute stages of the NSAID toxicity. Administration of broad-spectrum antimicrobial drugs may be indicated when signs of endotoxemia are observed. Parenteral administration of antimicrobial drugs is preferable to oral administration in horses with colitis because of the presumed increased risk of antimicrobial-associated diarrhea with the oral route. Oral administration of metronidazole (10 to 15 mg/kg PO q8-12h) might be an exception to this guideline, because evidence exists that metronidazole may exert an antiinflammatory effect and enhance healing in NSAID-induced intestinal ulceration.[21]

For horses with RDUC, dietary management directed toward providing a low-bulk diet in the form of a pelleted concentrate and restricting or eliminating ingestion of roughage is recommended. The aims of this approach are to decrease the mechanical and physiologic load of the colon. A complete pelleted diet (i.e., a diet that contains both concentrate and adequate but relatively low dietary roughage) will decrease intestinal fill in the colon. A diet lower in fiber should decrease the physiologic load of the colon because the cecum and large colon are the primary sites in horses of fiber digestion and exchange of fluid and electrolytes. Concentrate should be fed in smaller amounts and frequently (four to six feedings per day). Addition of corn oil may provide additional calories and may also aid in healing of the damaged intestinal mucosa by promoting PGE_2 production. Some horses will not eat complete pellets, and some horses that have roughage withheld will eat bedding or wood as a consequence. These horses should be allowed to eat fresh grass in small amounts on a frequent basis (four to six times daily). The importance of, and optimal duration for, restriction of roughage is unknown, but it likely requires months for the colon to heal. Horses should be changed from, and returned to, their usual diet over a period of several days to decrease the risk of inducing other digestive disorders.

Feeding psyllium mucilloid may promote colonic healing in horses with RDUC. In other animal species, psyllium mucilloid has been demonstrated to increase the concentration of short-chain fatty acids of the large bowel, and increased short-chain fatty acids can promote colonic mucosal repair.[22] The amount and duration of psyllium mucilloid administered orally that is required to alter the colonic concentration of short-chain fatty acids and the role of short-chain fatty acids in repair of RDUC in horses is unknown. Continuous feeding according to manufacturer's recommendations for 3 to 6 months is suggested, or feeding 1 to 2 oz of psyllium mucilloid once or twice daily for the same duration may be considered.

Horses with strictures of the pylorus, duodenum, jejunum, or colon may require surgical management. Bypass or resection of affected intestinal segments may be necessary.

Limiting the extent of predisposing factors, such as dehydration, should decrease the risk of NSAID toxicosis. Avoiding use of NSAIDs or limiting the dose and duration of treatment to the minimum that is required to control the primary problem is recommended to decrease the risk of NSAID toxicosis. Other approaches to analgesia, such as regional (epidural or perineural nerve blocks of distal limbs) anesthesia or administration of butorphanol or lidocaine via constant rate infusion should be considered.

Fluid Therapy for Horses with Gastrointestinal Diseases

Tiffany L. Hall

Most horses presenting with acute gastrointestinal disturbances will require fluid therapy to address decreased intake or excessive loss

VetBooks.ir

of fluids and correct alterations in acid-base and/or electrolyte balance. Conditions such as high-volume diarrhea and gastric reflux necessitate aggressive fluid therapy to correct hypovolemia, whereas other conditions (including intraluminal impactions) may require a more conservative approach to maintain appropriate hydration. Assessment of hydration status and acid-base balance in horses presenting with gastrointestinal disease, as well as an understanding of the primary gastrointestinal condition, is critical to developing a plan for fluid therapy. This section focuses on fluid therapy in horses with gastrointestinal disease. (For a more in-depth discussion of critical care and fluid therapy for horses, including selection of fluid types, monitoring and assessing fluid resuscitation, and complications associated with fluid therapy, please see Chapter 44.)

Identifying Patients Requiring Fluid Therapy

Clinical assessment begins with distinguishing hypovolemia from dehydration (Fig. 32-83). Hypovolemia is an emergency due to an acute decrease in circulating blood volume resulting in decreased tissue perfusion, anaerobic metabolism, organic acidosis, and ultimately shock. Clinical diagnosis of hypovolemia is based on altered perfusion parameters, including increased jugular refill time, prolonged capillary refill, tachycardia, poor peripheral pulse quality, decreased extremity temperature, decreased urine production, and/or altered mentation. Dehydration, on the other hand, is associated with a more insidious decrease in total body water and clinical signs reflect this, including decreased skin turgor, decreased tear film, sunken eyes, and tacky mucous membranes.

Laboratory parameters are beneficial in evaluating hydration status, developing a fluid plan, and monitoring response to therapy. Packed cell volume (PCV) and plasma total solids (TS) are commonly used to assess hypovolemia; however, these are neither sensitive nor specific. Splenic contraction and protein loss are two conditions commonly seen in horses presenting with acute abdomen which affect the clinical utility of PCV/TS alone in assessing hydration. PCV/TS values are most useful when greatly increased or when used serially to monitor the response to fluid therapy.

Increased concentrations of blood lactate serve as an indicator of decreased tissue perfusion. The most common causes of increased lactate in the horse with gastrointestinal disease are hypovolemia, endotoxemia, and intestinal ischemia secondary to strangulation. Lactate can be measured in the field on whole blood using handheld analyzers. Increased blood lactate concentrations were associated with worse outcomes in equine colic[1] and should be suspected in metabolic acidosis (decreased pH, negative base excess) in the absence of hyperchloremia or hyponatremia.[2]

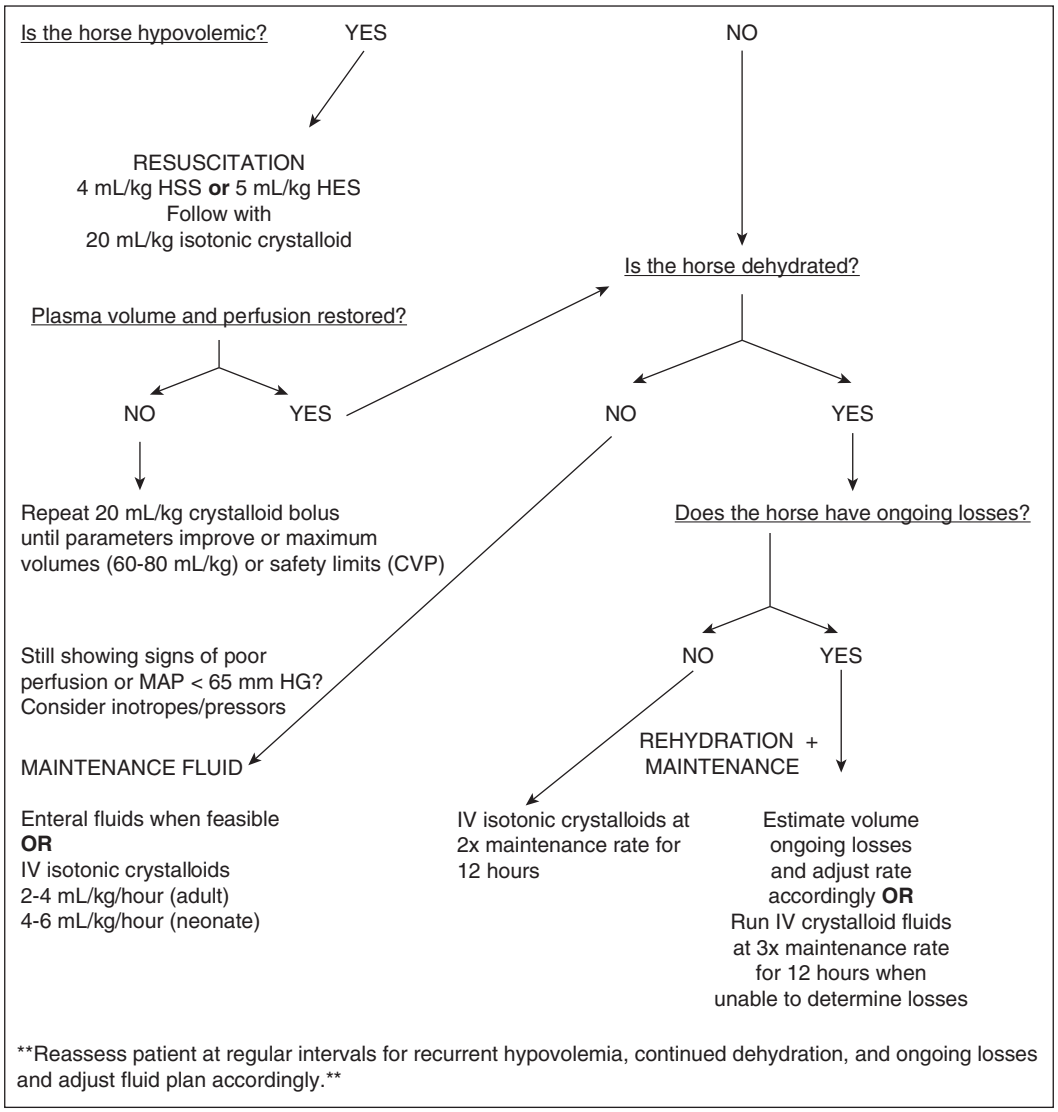

FIG. 32-83 Clinical assessment of perfusion parameters and hydration status.

VetBooks.ir

Plasma or serum creatinine concentrations are useful to assess hydration status in the absence of renal dysfunction. Creatinine concentrations up to 3.5 mg/dL (310 µmol/L) are common with moderate to severe hypovolemia, and concentrations as high as 5 mg/dL (450 µmol/L) are possible with prolonged or marked hypovolemia. Even in severe hypovolemia, the creatinine concentration will not increase by much more than 2.3 mg/dL (200 µmol/L) per day.[3]

Urine specific gravity provides valuable information regarding renal function and hydration status. High urine specific gravity (>1.040) indicates probable dehydration and normal renal function. Isosthenuria (1.010 to 1.015) indicates possible renal damage or a recent high fluid load. Urine specific gravity is especially useful in monitoring hydration status of neonates, as these patients are normally hyposthenuric (<1.010) when well hydrated, although this can be affected by the types of fluids administered (colloids vs. replacement fluids vs. maintenance), medications, inappropriate antidiuretic hormone (ADH) secretion, and glucosuria.

Central venous pressure (CVP) is an indirect measure of the quantity of blood returning to the heart, or preload, and is often used in the hospital setting to assess restoration of circulating volume, assuming normal cardiac function. The normal CVP of the adult horse is 7 to 12 mm Hg. Assessment of CVP is one of the more accurate, readily available methods of evaluating response to fluid therapy; however, measurement is affected by a number of factors, including catheter placement, head position, and presence of distributive shock.[4]

Measurement of blood pressure, particularly mean arterial pressure (MAP), is also important in determining efficacy of fluid resuscitation for improving tissue perfusion. Blood pressure in the horse may be determined directly or indirectly using oscillometric devices. When CVP is normalized, indicating restoration of blood volume, but MAP is decreased (<60 to 65 mm Hg), inotropes and pressors are often used to improve vascular tone and restore normal tissue perfusion.[4]

Formulating a Fluid Therapy Plan

The goals of fluid therapy are to increase cardiac output, by increasing and then maintaining cardiac preload; improve oxygen delivery; and correct electrolyte and acid-base disturbances. The plan for fluid therapy consists of four overlapping phases: (1) resuscitation, (2) rehydration, (3) maintenance, and (4) ongoing loss provision. Frequent monitoring of the patient and adjustment of the fluid plan are also important to a successful outcome. The fluid plan should be based on the clinical status of the horse, an understanding of the primary disease process, and any laboratory information available.

Resuscitation

Rapid fluid resuscitation is indicated in horses with clinical signs of hypovolemia. Reversal of hypovolemia is associated with improved outcome in human medicine and is shown to improve cardiovascular parameters in horses.[5-7] Balanced polyionic, isotonic crystalloid solutions are frequently used to restore circulating volume in hypovolemic equine patients; however, the use of colloids and/or hypertonic crystalloid solutions may provide more rapid results when available and indicated.

The use of small volume resuscitation with hypertonic crystalloid and/or colloid solutions has been promoted to rapidly restore plasma volume in horses presenting with signs of hypovolemia.[8] The administration of hypertonic saline solution (HSS) was found to restore plasma volume and induce urination more rapidly than administration of an equal volume of isotonic crystalloids.[9] Hetastarch (hydroxyethyl starch solution [HES]) has been shown to increase circulating blood volume and improve tissue perfusion based on decreases in heart rate and urine concentration following administration of 10 mL/kg HES with concurrent 10 mL/kg isotonic saline to horses with colic.[10] Further, in horses undergoing exploratory laparotomy, cardiovascular indices were significantly improved following preoperative administration of 4 mL/kg 10% pentastarch compared with 4 mL/kg 7.2% saline.[11] The administration of HSS is associated with development of an inorganic acidosis and hypokalemia, and the plasma expansion effects of small volume resuscitation are short-lived; thus fluid therapy should include concurrent or immediate follow-up with polyionic, isotonic crystalloid solutions when hypertonic or colloid solutions are used.[8,9]

During resuscitation, isotonic crystalloid solutions are administered at doses of 20 to 40 mL/kg in adults (10 to 20 mL/kg in neonates) as rapid bolus. Following each 20-mL/kg bolus, clinical evaluation of the patient, including evaluation of perfusion parameters, is performed in order to assess the need for repeat boluses. If perfusion parameters and blood pressure have not normalized on obtaining a normal CVP or at the completion of a total maximum "shock dose" of 60 to 80 mL/kg crystalloids, then inotropes and pressors are often incorporated and the fluid rate adjusted to maintenance rates. In horses and foals presenting for gastrointestinal disorders, alterations in vascular permeability and decreases in protein concentrations must be considered in determining the volume of crystalloid to be administered.

Rehydration

In horses that do not present with signs of hypovolemia or whose hypovolemia has been reversed, dehydration is corrected over the first 12 to 24 hours of hospitalization. To rehydrate the patient, isotonic crystalloids are administered at rates in excess of ongoing losses plus maintenance requirements. Clinically, this is accomplished in most patients with gastrointestinal disease by administering isotonic crystalloid fluids at two to three times the maintenance rate. Once dehydration is corrected, based on clinical parameters such as PCV/TS and urine specific gravity, these rates are slowed to that needed to maintain hydration. Horses with urine specific gravities below 1.020, and foals with urine specific gravities below 1.010, are unlikely to be dehydrated.

Maintenance

Depending on the gastrointestinal disease, horses presenting for acute abdomen may have free-choice food and water withheld for a period of time during which fluid requirements must be supplemented to maintain hydration. The mean daily water intake (including the water content of feed) of normal resting adult horses is 57 to 64 mL/kg/day at ambient temperatures of 5°C to 25°C (41°F to 77°F). Mares restricted to 40 mL/kg/day demonstrated significant dehydration.[12] Maintenance fluid rates for adult horses (2 to 4 mL/kg/h) and neonatal foals (4 to 6 mL/kg/h) can be met through enteral administration when appropriate for the diagnosis and when gastrointestinal function is normal. When enteral administration is contraindicated, polyionic, isotonic crystalloids are most frequently used for the parenteral administration of fluids.

Frequent monitoring of electrolyte concentrations, as well as monitoring hydration status, should be part of the maintenance fluid plan. Replacement crystalloid solutions higher in electrolyte concentrations are usually administered over maintenance crystalloid solutions given the size of equine patients, the volume of fluids required, and availability. (See Chapter 44 for a comparison of commercially available fluid solutions.) Some patients, particularly neonates or those losing large volumes of fluid, are at risk of developing a free water deficit and subsequent inorganic acidosis when maintained on isotonic, replacement, crystalloid solutions. Monitoring of electrolytes, particularly sodium and chloride, will help identify these patients. In adults, physical examination and monitoring of body weight, PCV/TS, creatinine concentrations, and urine specific gravity are useful in evaluating the efficacy of a fluid treatment plan. Overhydration in adults with normal renal function may be indicated by frequent urination, urine specific gravity below 1.013, and development of dependent edema. In neonatal foals, body weight, urine production, urine specific gravity, and evaluation of perfusion parameters are used to monitor hydration status, and detection of excessive fluid supplementation can be difficult as nursing, neonatal

VetBooks.ir

foals normally produce hyposthenuric urine. Development of preputial or stifle edema is an indication of overhydration in neonates. As such, it is important that the volume of all intravenous solutions and enteral feedings be accounted for when calculating fluid rates in neonates to prevent volume overload.

Ongoing Losses

Horses that present with gastrointestinal conditions resulting in excessive fluid losses such as gastric reflux and diarrhea will require supplementation in excess of maintenance fluid rates. Calculating the volume of fluid lost is the most accurate method of determining how much fluid will need to be replaced. Whereas the volume of nasogastric reflux can be tracked, determining the volume of fluid lost in adults and ambulatory foals with diarrhea is not possible; therefore, frequent assessment of the patient by clinical examination and determination of relevant laboratory parameters are useful in evaluating the fluid plan to prevent continued dehydration or recurrence of hypovolemia.

Special Considerations in the Fluid Therapy Plan

The selection of fluids to be administered, rate and route of administration, parameters to be monitored, and frequency of monitoring are based on thorough individual case assessment. In addition to the various phases of fluid therapy, special circumstances encountered in horses with gastrointestinal disease must also be considered in the fluid therapy plan. These include commonly observed electrolyte disturbances, acidemia, hypoproteinemia, and endotoxemia. Table 32-9 lists common fluid choices and additives for conditions observed in horses with gastrointestinal disease.

Enteral Fluid Administration

Enteral fluid therapy may be sufficient to correct and maintain hydration in horses with gastrointestinal disease that have mild dehydration and normal small intestinal function.[13] In horses with gastrointestinal disease but no apparent dehydration, administration of an electrolyte paste and provision of fresh drinking water may be sufficient to supplement water and electrolytes.[14] However, enteral fluid therapy is contraindicated in horses with small intestinal obstruction or ileus and is not sufficient to treat hypovolemia.

Enteral fluids are often included in the treatment of impaction colics. Nasogastric administration of a balanced electrolyte solution (5.27 g NaCl + 0.37 g KCl + 3.78 g $NaHCO_3$ per L water) at 5 L/h is superior to enteral magnesium sulfate, enteral sodium sulfate, or enteral magnesium sulfate with IV crystalloids at promoting hydration of colonic contents and does not alter plasma electrolyte concentrations.[15,16] An isotonic solution for enteral administration can be made without the use of weight scales by measuring salt crystals in the barrel of a syringe (15 mL of Lite salt and 15 mL of table salt added to 4 L of water).[17] In a prospective clinical trial, enteral fluids administered at 8 to 10 L every 2 hours were successful in the treatment of 99% of colonic impactions and 83% of left-sided colon displacements.[18] As enteral fluids are significantly less costly than commercially available intravenous fluids, this is an ideal treatment in some gastrointestinal conditions.

Electrolyte Disturbances

Horses with gastrointestinal disturbances will often have changes in plasma electrolyte concentrations, which may need to be addressed during fluid therapy. Portable blood gas and electrolyte measuring equipment allows the field veterinarian to easily obtain

TABLE 32-9

Fluids and Additives for Electrolyte Disturbances in the Horse

Metabolic Disturbance	Recommended Fluid	Dose
Lactic acidosis	Polyionic crystalloids with or without small volume resuscitation (HSS/HES)	Up to 60 mL/kg/h
Hyponatremia	Isotonic crystalloids	Sodium should be corrected no faster than 1 mEq/L/h
With hypochloremia	Polyionic crystalloids or sodium chloride	
Without hypochloremia	Sodium bicarbonate	
Hypernatremia	5% Dextrose or 2.5% dextrose/0.45% sodium chloride	Sodium should be corrected no faster than 0.5 mEq/L/h
Hypochloremia	Polyionic crystalloids or sodium chloride	0.9% or 7.5%, to effect
Hyperchloremia	Increase free water intake or administration	
With hypernatremia	Polyionic maintenance crystalloid or 5% dextrose	To lower sodium no faster than 0.5 mEq/L/h
Without hypernatremia	Sodium bicarbonate	5%, slowly, to effect
Hypokalemia	Potassium chloride	10-40 mEq/L 0.5 mEq/kg/h Maximum 1 mEq/kg/h
Hyperkalemia		
With clinical signs	Calcium gluconate	1 mL/kg IV over 10 min 250 mL/1 L sodium chloride
Or >7 mEq/L	Sodium bicarbonate	1-2 mEq/L IV over 15 min
Without clinical signs	5% Dextrose in polyionic crystalloids	2 mL/kg IV over 5 min
Hypocalcemia	Calcium gluconate	250-500 mL 23% solution/5 L
Hypercalcemia	Polyionic crystalloids (without calcium)	4-16 mg/kg as an initial dose
	Magnesium sulfate	10 mL/5 L (max 50 mg/kg)
Hypomagnesemia	Magnesium sulfate IV	4-16 mg/kg as an initial dose
Hypermagnesemia	Calcium gluconate	250-500 mL of 23% solution
Hypoalbuminemia	Fresh or fresh frozen equine plasma	To effect, not to exceed 10 mL/kg
	Hetastarch	5-10 mL/kg to increase COP

COP, Colloid oncotic pressure; *HSS/HES,* hypertonic saline solution/hydroxyethyl starch solution (hetastarch); *IV,* intravenous; *PO,* by mouth.

Always take into account all disturbances present before commencing treatment.

VetBooks.ir

information necessary to guide electrolyte supplementation and selection of appropriate fluids. Without case-specific determination of electrolyte concentrations, maintenance phase fluids in gastrointestinal disease should be limited to administration of isotonic, polyionic crystalloid fluids supplemented with 10 to 20 mEq/L of potassium chloride.

Generalized changes in electrolytes among horses with gastrointestinal disease are related to decreased feed intake, increased loss, and sequestration. Decreased sodium and chloride concentrations may be observed in cases of acute colitis, peritonitis, or intestinal torsion.[19] Hypochloremia without hyponatremia is also observed in proximal enteritis and grass sickness associated with loss of hydrochloric acid in gastric reflux.[20] Hypokalemia is commonly seen in horses following colic surgery because of decreased feed intake, enhanced mineralocorticoid release, and kaliuresis associated with administration of sodium-containing fluids. Hypokalemia is also seen with colitis and metabolic alkalosis. Potassium is primarily an intracellular ion and decreases in whole body potassium may not be detected by plasma measurements; therefore, it is common to supplement potassium in maintenance fluids. Hypocalcemia is commonly observed in horses presenting with gastrointestinal disorders, including those with surgical colic, colitis, functional disorders of the small intestine, organic acidosis, and endotoxemia.[21] Plasma ionized calcium provides a better indicator of physiologic calcium status, as hypoalbuminemia occurs in many gastrointestinal conditions. In one report, 44% of horses with gastrointestinal disease had low plasma magnesium concentrations.[22] Hypomagnesemia may be associated with refractory hypocalcemia and hypokalemia; thus supplementing magnesium may be beneficial in those situations. Hypophosphatemia has been reported in horses with strangulating intestinal lesions or intestinal ileus.

Acidosis

Inorganic and organic metabolic acidoses occur frequently in horses presenting with gastrointestinal disorders. Inorganic acidosis occurs with hyponatremia (colitis, peritonitis, intestinal torsion) and relative or absolute hyperchloremia (colitis, free water deficit). These patients often have a normal anion gap. Organic acidosis in horses with gastrointestinal disease is common, secondary to elevated lactate concentrations and associated with an increased anion gap. Increased blood or plasma lactate concentrations in these cases are usually a result of poor tissue perfusion or inappropriate anaerobic metabolism in endotoxemia.

Metabolic acidosis in horses with gastrointestinal disease will usually resolve with correction of hypovolemia and restoration of tissue perfusion. Occasionally, in the case of inorganic acidosis, electrolyte abnormalities may be severe enough to require selection of a particular commercially available fluid. Administration of sodium bicarbonate to correct acidemia is reserved for cases in which the blood pH falls below 7.2 or where there is a severe hyponatremia with relative hyperchloremia, and only in patients with normal respiratory function.

Other, less frequently observed acid-base disorders in horses with gastrointestinal disorders include inorganic metabolic alkalosis (hypochloremia or hypoalbuminemia), respiratory alkalosis (hyperventilation associated with pain), and respiratory acidosis (hypoventilation caused by extreme abdominal distention or respiratory center depression).[2]

Hypoproteinemia

Hypoalbuminemia is seen in horses with moderate to severe compromise of the colon, parasitism, intestinal malabsorption, or third spacing (peritonitis). Endotoxin exposure and ischemia-reperfusion injury induce capillary damage that allows plasma albumin to leak out into the interstitium. Clinical signs of hypoalbuminemia are peripheral, tissue, and organ edema leading to reduced oxygen uptake by cells and, in severe cases, organ failure. Albumin is a weak acid; thus severe hypoalbuminemia may contribute to metabolic alkalosis or mask concurrent metabolic acidosis.[2] Determination of the colloid oncotic pressure (COP) of the plasma is most useful in guiding colloidal fluid therapy, particularly when synthetic colloids have previously been administered.[23] COP and total protein concentrations were found to decrease over the course of anesthesia in horses undergoing colic surgery.[24]

Hypoalbuminemia and decreased COP should be treated when acute or if there are clinical signs. Options for colloidal support in horses include plasma transfusion and synthetic colloid solutions, such as HES. Approximately 6 to 8 L of fresh-frozen plasma are required to effectively treat significant hypoproteinemia in the adult horse, making plasma cost prohibitive in the treatment of decreased COP.[25] However, plasma has a role in treatment of systemic inflammatory response syndrome (SIRS) by providing antithrombin III (AT-III) and other cofactors. The administration of 6% HES at 8 to 10 mL/kg to conscious hypoproteinemic horses significantly improved COP for 6 hours after infusion and maintained an oncotic effect for 24 hours; however, administration of 2.5 mL/kg 6% HES did not alleviate the decrease in COP observed in healthy horses receiving crystalloid during general anesthesia.[26,27]

Endotoxemia

Horses presenting with gastrointestinal disorders, particularly ischemic lesions and conditions involving inflammation of the bowel, are at risk of exposure to endotoxin as damage to the intestinal mucosa allows intraluminal bacteria to gain systemic access. During endotoxemia, capillary damage leads to increased vascular permeability, altering fluid dynamics and contributing to tissue edema. HSS has been shown to reduce the capillary endothelial swelling that may occur as part of SIRS and improve tissue microcirculation and oxygen delivery.[28]

Studies of the effects of HSS in horses with experimentally induced endotoxemia have yielded mixed results. Whereas one study found that administration of 5 mL/kg HSS following administration of a low dose of endotoxin (1.64 ± 0.22 μg/kg) to conscious horses improved cardiac output and decreased peripheral vascular resistance compared with isotonic saline, a study in horses under general anesthesia did not support these findings.[29] Administration of combined 5 mL/kg HSS and 10 mL/kg HES to horses with hyperdynamic shock induced by administration of 50 μg/kg endotoxin did not improve cardiopulmonary parameters while horses were under general anesthesia.[30] The combination of HSS and HES may protect against hypocalcemia associated with endotoxemia without negatively affecting coagulation beyond that seen in control horses.[31]

Nutritional Support

Horses presenting with gastrointestinal disease will often be inappetant or will be held off feed as part of their treatment for a variable amount of time. An enteral diet based on the horse's normal diet is the first choice for nutritional support; however, in adult horses held off enteral feeding for over 3 days because they have gastric reflux, ileus, esophageal obstruction, or anorexia should be supplemented parenterally.[32] In addition, horses with moderate obesity which are not eating may be at increased risk of developing hyperlipemia and should be supplemented earlier. Parenteral nutrition can range from the administration of 1% dextrose in intravenous fluids to the administration of a combination of dextrose, amino acids, and lipids based on the maintenance energy requirements for the individual patient. (See Chapter 50 for a complete discussion of nutritional support in the horse.)

Eruption of Teeth

Determining an animal's age by examining the teeth is not an exact science, because the appearance of the teeth can be affected by inherited factors, nutrition, and geographic location.[1,2] At birth or within 2 weeks, four deciduous incisors usually are present. All eight deciduous incisors erupt within the first month.[3] The fourth incisor (corner) is a modified canine tooth. The incisors meet with the dental pad of the upper jaw for the purpose of gripping and cutting herbage. Usually, all three pairs of deciduous premolars have erupted at birth or shortly afterward.[1,2] In cattle, the formula for the deciduous teeth is as follows:

$$2\,(\text{incisors } 0/4, \text{premolars } 3/3) = 20$$

The age at which permanent teeth erupt often is the best criterion for determining the animal's age if a registration certification is not available. However, systemic illnesses and malnutrition can retard dental development and cause retention of the deciduous teeth.[4] The first molars erupt at 8 months of age and are fully developed at 12 months. At 18 months, the second molar is fully developed. The third molar erupts at 24 months and is fully developed at 30 months. The permanent premolar teeth start to replace the deciduous at 24 months and the 3 permanents are usually present at 3 years.[1,2] The first pair (centrals) of permanent incisors erupt at 18 to 24 months of age. The second pair (medials) of incisors appears at 24 to 30 months. At 3 years of age, the third pair (laterals) of incisors erupt. Between 3½ and 4 years of age, the fourth pair (corners) of incisors erupt.[3,4] Consequently, cattle have a complete set of permanent teeth at age 4½ years. Cattle have a shallow depth of the alveolar socket and associated tooth root. This may lead to dental attrition in cattle more readily than in horses. However, this also makes dental extraction easier in cattle compared with horses. The formula for the permanent teeth in cattle is as follows:

$$2\,(\text{incisors } 0/4, \text{premolars } 3/3 \text{ molars } 3/3) = 32$$

The deciduous and permanent dental formulas of the sheep and goat are identical to those of cattle.[3] In sheep and goats, the periods of eruption are as follows: The incisors are present at birth or within the first 4 weeks. The premolars erupt 2 to 6 weeks after birth. The first pair of permanent central incisors (centrals) replaces the deciduous teeth at 12 to 18 months. The third pair (laterals) erupts between 30 and 36 months; and the fourth pair (corners) appears at 3½ to 4 years. The three permanent premolars have erupted between 18 and 24 months of age; the first molar at 3 months, second molar between 9 to 12 months, and the last molar between 18 to 24 months.[3]

Examination of Teeth

Dental disease in ruminants should be considered first on a flock or herd basis.[5,6] Determining dental health is particularly useful when unconventional feeds are incorporated into the herd nutritional program.[7,8] The clinical manifestations of dental diseases include inadequate food intake, inadequate calf development, weight loss, unthriftiness, low body condition score, quidding, low pregnancy rate in replacement heifers, and mandibular or maxillary swellings, or draining tracts.[3,6-9] Dental examination is especially of concern when animals are grazing on short grass. Examination of the herd should then be followed by dental examination of individual animals. For examination of the premolars and molars, the tongue should be withdrawn from the mouth and held at the commissure of the mouth opposite the teeth being examined. Use of a headlight or flashlight is useful to perform a good oral examination. A small dose of xylazine (0.03 to 0.04 mg/kg IV) and the use of a mouth speculum allows for much more thorough dental examination, including manual palpation in cattle. Radiographic examination can also be important in certain cases.

The incisors have a sharp edge in front and are used for gripping and cutting herbage.[3,6] The incisors should be aligned closely with little space between them.[3,6] In sheep, the periodontium of the incisor allows a movement of up to 2 mm anterioposteriorly to accommodate rotating or turning forces during grazing.[9] This makes the sheep incisor very prone to loss following periodontal damage. The length of the premolar and molar teeth and their firm placement in the alveolar bone means that they are lost less often than the incisors.[1,2,6]

Dental Attrition and Erosion

Rapid wearing of teeth is seen most commonly in grazing sheep 5 years of age and older. Sheep and cattle grazing forage-deficient or sandy pastures and arid ranges in Africa, Australia, New Zealand, and the southwestern United States often display accelerated rate of tooth wear.[6,10] In Rhodesia, the incisors of Hereford cattle had an increased rate of wear because of softer enamel, compared with those of indigenous cattle.[11]

Examination of an animal with dental attrition reveals worn incisor and/or molar teeth (or both); often only short stumps are seen. The teeth also may be loose, fractured, or missing. Dental attrition from excessive wear needs to be differentiated from periodontal disease that causes tooth loss.[6,12,13] The pathogenesis of excessive tooth wear relates to tooth hardness and diet quality. Ingestion and mastication of soil and sand with forage abrades and wears the incisor and molar teeth. In New Zealand, dental attrition in sheep was attributed to acids and enzymes in the herbage consumed, acting on the tooth dentine.[10] A calcium deficiency or calcium/phosphorus imbalance, creating softness of the tooth enamel and dentine, may accelerate the rate of wear.

In the United States feeding fermented sweet potato cannery waste to cattle resulted in substantial increases in incisor erosion.[7,8] Cattle producers feeding sweet potato cannery waste noticed poor growth rate, inadequate calf development, low pregnancy rates in heifers, and worn, mottled, discolored incisors.[7,8] Sweet potato cannery waste is highly acidic (pH 3.2) and causes calcium loss and tooth erosion. Deciduous teeth are etched more rapidly, placing young cattle at higher risk for severe tooth wear and dental infection. In addition, the distance between the original enamel surface and the pulp chamber is less in deciduous teeth than in permanent teeth, which is again more significant in younger cattle.[7,8] Mixing 10% broiler litter with sweet potato cannery waste raised the pH to 4, thus providing a palatable high-quality feed and preventing the severe dental problems associated with sweet potato cannery waste alone.[7]

A syndrome involving excessive wear of deciduous incisor teeth, maleruption of permanent incisors, and an increased prevalence of dentigerous cysts in sheep has been reported from New Zealand.[14] Excessive wear of the incisor teeth of cattle also was recorded on the same farms. Ingestion of soil during winter because of the inclement weather, overgrazing of pastures, and the presence of low copper levels in the blood of affected animals were the main causes for the

VetBooks.ir

syndrome.[14] Dental attrition is prevented by providing supplemental feed to avoid overgrazing of pastures. The addition of 1% ground limestone to the feed in calcium-deficient areas is recommended.[15]

Periodontal Disease

Periodontal disease refers to a disease involving the supporting tissue that surrounds the teeth.[16,17] Periodontal disease of sheep is endemic in parts of New Zealand. A periodontal disease known as *cara inchada,* or "swollen face," has caused losses of cattle in Brazil.[18,19] Periodontal disease is characterized by protruding and loose incisors.[6,12] With time, incisors, premolars, and molars may be missing. Why periodontal disease is prevalent in sheep, but less common in cattle, is unknown. Periodontal disease results in pain on mastication, leading to poor maceration of food and reduction in food digestibility.

Periodontal disease has been associated with bacterial plaque-induced gingivitis.[16,19-21] The acute gingivitis is replaced progressively by a chronic inflammation in the gingival sulcus. The periodontal ligament is destroyed by plaque-forming oral microorganisms and host enzymes. At this stage, periodontal pockets are formed, which lead to loosening of teeth. This process may take months or years. With time, extension of the infection progresses to the apical area. The gum margin begins to recede over the lesion, food accumulates within the pocket, and the entire alveolus becomes infected. At that point, the tooth becomes a sequestrum. The alveolar pyorrhea causes a periostitis of the external surface of the alveolar process, and swelling is observed. Once a tooth is lost from an affected alveolus, granulation tissue fills the alveolus. Deep to granulation tissue, alveolar bone is redeposited.

Bacteria such as *Bacteroides* spp., *Actinomyces* spp., and spirochetes; metabolic or immune disorders in the host; and mechanical or chemical agents have been implicated in the pathogenesis of periodontal diseases in sheep.[6,20,22,23] Bacterial invasion in the gingival pockets has been associated with a defect of host immune competence.[24] Hypomagnesemia has been a common finding in sheep with periodontal disease, but this may be secondary.[23] Gingival trauma may be important in the etiology.[25] Dissolution of the enamel at the attachment of the gingival epithelium by organic acids from microorganisms of the soil may be a predisposing factor.[26] The serum values for calcium, albumin, alkaline phosphatase, and citrate were lower for sheep with periodontal disease compared with sheep not affected by dental disease.[27]

A postmortem examination of Scottish-Hill sheep revealed that 60% of 478 aged sheep had either loose or missing teeth. Gingival pockets were present in 87% of the population and were correlated with tooth looseness.[28] In the United States a 25% mortality caused by dental disease in a herd of 300 ewes has been reported.[29] The clinical signs were depression, anorexia, ataxia, and emaciation.[29] Necropsy revealed dental disease of the mandibular teeth with plaque, plant fibers in periodontal pockets, and osteomyelitis of the mandibular bone. An initial trauma to the gingiva from cheatgrass awns in the hay field was implicated.[29]

A particular type of periodontal disease in cattle has been reported from Brazil.[18,19] This condition involves an inflammatory process of the periodontium of calves and older Zebu cattle that results in alveolar periostitis of the maxilla or, less often, the mandible.[18,19] Examination reveals deep periodontal pockets and loss of or loosened teeth. Affected animals suffer from malnutrition, diarrhea, and loss of condition and often die. *Bacteroides* and *Actinomyces* organisms often are found in the lesion and are suspected of causing the disease.[18] This disorder is seen only in certain areas of Brazil, and the cattle improve if moved to unaffected areas. In one trial the development of periodontal disease in calves was avoided by administration of the antimicrobial drug spiramycin.[19]

The assumption that incisor condition is a good indicator of future productivity is not well founded. Little scientific evidence exists on which to base the practice of culling sheep with periodontal disease. Three farms with a high prevalence of periodontal disease were selected, and the body condition and weight of the sheep were compared with those of sheep with no signs of periodontal disease. On only one farm was a significant association noted between periodontal disease and body condition or weight. It was concluded that periodontal disease in sheep may impair productivity on some farms, but not others.[30,31]
